When liver injury was induced by carbon tetrachloride administration, a significant reduction in the rate of excretion of I in bile occurred (Table II). The excretion of I in bile in carbon tetrachloride-treated rats decreased to the extent that it is doubtful that a linear model would apply. The extent of parameter changes that would be calculated from the data may be a reflection of both the liver damage produced by the carbon tetrachloride treatment and the nonlinear behavior of I.

In summary, the disposition of I in the rat was characterized. The apparent first-order elimination kinetics of I in plasma were nonlinear because the liver uptake process was saturable. This was evident from the increase in elimination half-life and disproportionate increase in area under the plasma concentration–time curve with increase in dose. The nature of the saturation was not determined in this study, but it does appear that it is not a Michaelis–Menten effect because I is neither metabolized (2) nor does it demonstrate the appropriate plasma concentration–time profiles with ascending doses (*i.e.*, parallel slopes at concentrations below K_m). It is also not a facilitated transport effect because metabolic inhibitors do not influence the uptake of I by liver cells (4). The amount of I excreted in bile was dependent on the amount present in the liver reflecting the uptake saturability.

These findings could be applied to other nonmetabolizing organic anions and, with adaptations, to compounds that are metabolized. Further work regarding the nature of the saturation and regarding the disposition in higher animals is suggested in order to completely evaluate the use of I as a general index for hepatobiliary function.

Picrotoxin-Like Lactones

JAMES D. McCHESNEY *x and ALAN F. WYCPALEK

Received April 26, 1982, from the *Department of Medicinal Chemistry, School of Pharmacy, The University of Kansas, Lawrence, KS 66045.* Accepted for publication July 23, 1982.

*Present address: Department of Pharmacognosy, School of Pharmacy, University of Mississippi, University, MS 38677.

Abstract □ Preparation of some simple lactone analogues of picrotoxin and their biological evaluation is reported. Certain analogues possessed activity, but at potencies insufficient to warrant further work.

Keyphrases □ Picrotoxin—lactone analogue synthesis, CNS activity □ Analogues—of picrotoxin, synthesis, CNS activity □ CNS activity—of picrotoxin lactone analogues, synthesis

Although picrotoxin [an equimolar mixture of picrotin (I) and picrotoxinin (II)] was used as early as the 18th century as a fish toxin and clinically in humans during the 1930s and 1940s, only in the last decade has an understanding of its mode of action as a CNS stimulant begun to emerge. It was first recognized as a γ-aminobutyric acid antagonist (1), but more recently its mechanism of antagonism has been shown to be inhibition of chloride ion permeability in neuronal preparations (2). Jarboe and coworkers (3) have examined aspects of the structure–activity relationship (SAR) of these materials and concluded that in order to possess activity, certain features were required: (*a*) a free bridgehead hydroxyl group, (*b*) a lactone ring connecting carbons 3 and 5, and (*c*) an isopropenyl group (which appears to govern potency).

0022-3549/83/1000-1131$01.00/0

mg/kg in rats, indicating that saturation occurred and caused a decrease in the distribution from plasma. There was no change in the bile-to-liver concentration ratio over the same dose range, suggesting that nonlinear plasma elimination was due to saturable liver uptake only.

The data from the liver studies support the data of Takada (4) because a partial saturation of the transfer process (uptake) from the plasma to the liver occurred at the higher dose (Fig. 4). It has been previously hypothesized that the saturability of the uptake process is due to the limited binding capacity on the hepatic intracellular macromolecules (Y and Z), which have been shown to be instrumental in the hepatobiliary transport of I (4, 5). Nagashima *et al.* (15) suggested that saturable tissue binding can be responsible for the type of nonlinearity observed with this data. If the macromolecular binding sites for I become saturated at higher doses, the fraction of free drug in the liver should increase. Classically, only free drug can transfer across membranes. Therefore, I could then transfer back into plasma resulting in an increase in the apparent elimination (β-phase) half-life. The same result would occur if a very tight binding site for I was saturated and more dye was bound to a protein for which it normally has less affinity. The data from this study and from previous studies (3–6) support the hypothesis that the plasma nonlinearity is due to the saturation of the hepatic protein binding sites for I.

The saturation of the liver at higher doses of I was reflected in the bile as well (Fig. 5). Takada *et al.* (4) reported that the excretion of I in bile was not saturable over the dose range of 11.2–66.7 mg/kg because the bile-to-liver concentration ratio remained unchanged. Therefore, the observed differences in the cumulative amount excreted and in the excretion rate of I in the bile after 5.6- and 11.2-mg/kg doses must be a direct result of the saturation of the uptake process in the liver (Fig. 5). The same result occurred with the infusion data; *i.e.*, the amount of I excreted per hour in the bile plateaued at 8.5 mg/hr at the two highest infusion rates, indicating a dependence on the amount of I present in the liver (Fig. 6). Overall, the excretion of I in bile was linear.

When liver injury was induced by carbon tetrachloride administration, a significant reduction in the rate of excretion of I in bile occurred (Table II). The excretion of I in bile in carbon tetrachloride-treated rats decreased to the extent that it is doubtful that a linear model would apply. The extent of parameter changes that would be calculated from the data may be a reflection of both the liver damage produced by the carbon tetrachloride treatment and the nonlinear behavior of I.

In summary, the disposition of I in the rat was characterized. The apparent first-order elimination kinetics of I in plasma were nonlinear because the liver uptake process was saturable. This was evident from the increase in elimination half-life and disproportionate increase in area under the plasma concentration–time curve with increase in dose. The nature of the saturation was not determined in this study, but it does appear that it is not a Michaelis–Menten effect because I is neither metabolized (2) nor does it demonstrate the appropriate plasma concentration–time profiles with ascending doses (*i.e.*, parallel slopes at concentrations below K_m). It is also not a facilitated transport effect because metabolic inhibitors do not influence the uptake of I by liver cells (4). The amount of I excreted in bile was dependent on the amount present in the liver reflecting the uptake saturability.

These findings could be applied to other nonmetabolizing organic anions and, with adaptations, to compounds that are metabolized. Further work regarding the nature of the saturation and regarding the disposition in higher animals is suggested in order to completely evaluate the use of I as a general index for hepatobiliary function.

Picrotoxin-Like Lactones

JAMES D. McCHESNEY *x and ALAN F. WYCPALEK

Received April 26, 1982, from the *Department of Medicinal Chemistry, School of Pharmacy, The University of Kansas, Lawrence, KS 66045.* Accepted for publication July 23, 1982.

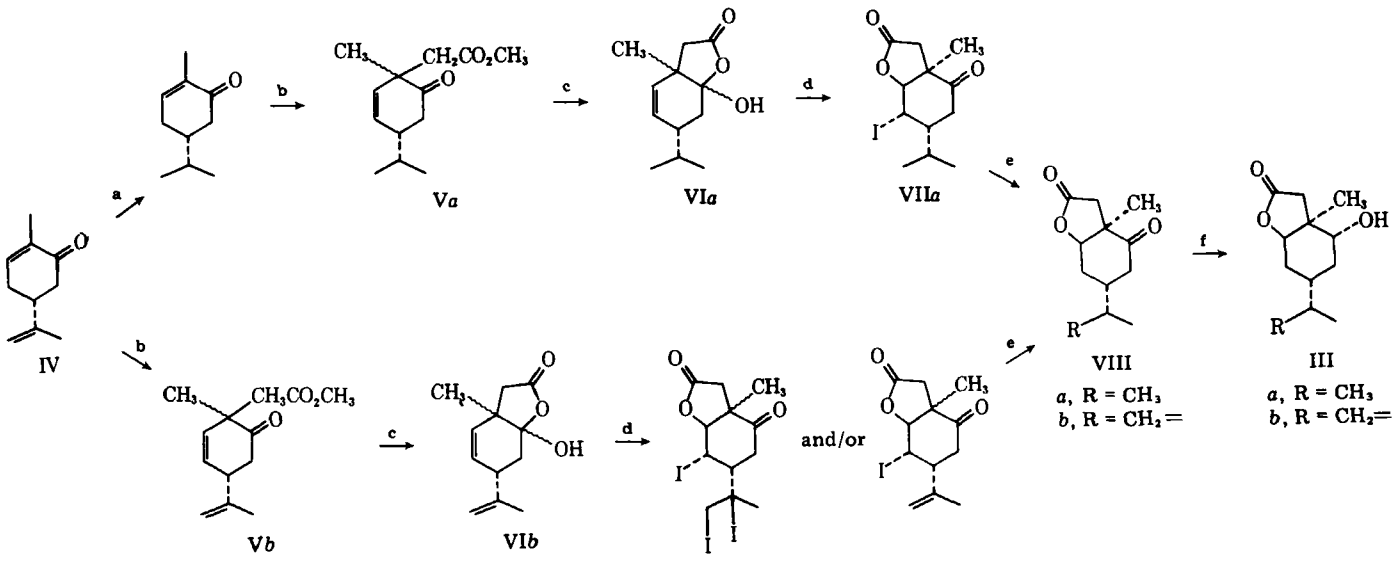
*Present address: Department of Pharmacognosy, School of Pharmacy, University of Mississippi, University, MS 38677.

Abstract □ Preparation of some simple lactone analogues of picrotoxin and their biological evaluation is reported. Certain analogues possessed activity, but at potencies insufficient to warrant further work.

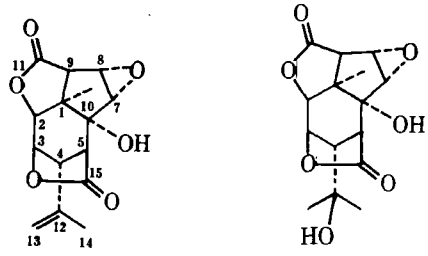
Keyphrases □ Picrotoxin—lactone analogue synthesis, CNS activity □ Analogues—of picrotoxin, synthesis, CNS activity □ CNS activity—of picrotoxin lactone analogues, synthesis

Although picrotoxin [an equimolar mixture of picrotin (I) and picrotoxinin (II)] was used as early as the 18th century as a fish toxin and clinically in humans during the 1930s and 1940s, only in the last decade has an understanding of its mode of action as a CNS stimulant begun to emerge. It was first recognized as a γ-aminobutyric acid antagonist (1), but more recently its mechanism of antagonism has been shown to be inhibition of chloride ion permeability in neuronal preparations (2). Jarboe and coworkers (3) have examined aspects of the structure–activity relationship (SAR) of these materials and concluded that in order to possess activity, certain features were required: (*a*) a free bridgehead hydroxyl group, (*b*) a lactone ring connecting carbons 3 and 5, and (*c*) an isopropenyl group (which appears to govern potency).

0022-3549/83/1000-1131$01.00/0

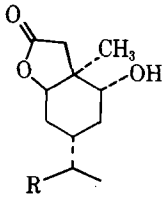


Scheme I—Synthesis of lactones III. Key: (a) *tris*-triphenylphosphine rhodium chloride–hydrogen; (b) potassium-*tert*-amylate–methyl bromoacetate; (c) potassium hydroxide; (d) iodine–potassium iodide, sodium bicarbonate; (e) triphenyltin hydride; (f) sodium borohydride.



I II

To ascertain if a simpler agent might possess picrotoxin-like activity, *i.e.*, if the lactone ring connecting carbons 3 and 5 is essential while the lactone connecting carbons 2 and 11 plays no role (as previously suggested), we set about to prepare analogous lactones (III) and determine if they showed CNS stimulatory activity similar to picrotoxin in rodents.

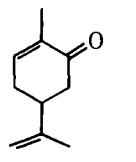


III

a R = CH_3
b R = CH_2=

RESULTS AND DISCUSSION

The most convenient preparation of the target compounds with asymmetric centers of the same configuration as picrotoxin seemed to reside in choosing a starting material with at least some of these centers already established. Then one may rely on the particular features of the molecule, such as steric factors and conformation, to control the course of reactions which would be, thereby, regio- and stereoselective. With these factors in mind, it can be seen that the most suitable starting material is the known natural product (−)-carvone (IV).



IV

The desired lactones (III) should be available from carvone *via* introduction of a suitable two-carbon side chain α to the ketone, lactonization, and subsequent reduction of the ketone function. A convenient approach for the introduction of the two-carbon side chain was expected to be the alkylation of the enolate generated by base abstraction of a γ proton of an α,β-unsaturated ketone. There is ample precedent for this expected alkylation in polycyclic systems (4). However, Theobald (5) reported dimerization of carvone under the projected reaction conditions. Initial attempts in our laboratory at direct base-catalyzed alkylation of carvone afforded only over-alkylated products. Finally, careful investigation of the effects of the nature of the alkoxide anion, metal cation, solvent, and temperature conditions[1] of the base-catalyzed alkylation afforded a convenient direct procedure. It was found that alkylation of carvone with potassium *tert*-amylate–methyl bromoacetate in a mixture of dimethoxyethane and dimethylformamide afforded acceptable yields of the desired product, methyl-2-[1(*R*,*S*)-methyl-2-oxo-4(*S*)-isopropenyl-5-cyclohexenyl]acetate (V*b*). Alternatively, prior reduction of the isopropenyl group of carvone followed by alkylation under the same conditions afforded V*a*. The keto esters were then hydrolyzed in base producing lactols VI, which were lactonized under iodolactonization conditions to a mixture of iodo lactones VII. Iodo lactone VII*b* was not characterized fully because it darkened rapidly on isolation, apparently due to the presence of triiodo lactone formed by iodination of the isopropenyl group during the lactonization sequence. The iodo lactones were deiodinated by reduction with triphenyltin hydride and the resultant keto lactones VIII were reduced to the hydroxy lactones III with sodium borohydride (Scheme I).

The structural assignments were based on the following:

1. The sequence was initiated with a starting material of known absolute configuration. Selective reduction of the isopropenyl group should not modify any centers of stereochemistry.
2. The base-catalyzed alkylation would be expected to produce a mixture with β-alkylation (*trans* to the isopropyl and isopropenyl group) predominating (6).
3. Hydrolysis of the acetate ester mixture and iodolactonization produced a mixture (3:1 ratio) of γ-lactones, showing carbonyl absorption at 1780 cm^{-1} in the IR spectrum.
4. The major iodo lactone isomer was assigned structure VII based on its carbonyl absorption and by an examination of the coupling pattern of the methine hydrogen α to the lactone ether linkage, showing one proton doublet, δ 5.1 ppm (J = 4 Hz). This proton is clearly diequatorially coupled to the adjacent methine α to the iodine function. This is consistent with the usual transdiaxial iodolactonization mechanism.

[1] H. N. Edwards; unpublished work.

5. Deiodination does not alter stereochemistry at any centers, so structure VIII represents the keto lactones.

6. Sodium borohydride reductions of cyclohexanones proceed with introduction of hydrogen from the less hindered face, in this case from the β face, to produce hydroxy lactones III.

Biological evaluation was made with a screening procedure which attempts to selectively utilize available techniques to identify major types of central nervous system (CNS) activity. It is not definitive, but rather a qualitative evaluation. Generally, it is a comparison of activity between an unknown and a control vehicle. The detection screen employs direct visual observation of behavior plus measures of simple reflex activities. In this particular case attention was given to muscle tonus. The animals were placed in an observation arena, which is a large metal tray lined with bedding[2]. The animals were provoked to walk and were gently handled to judge body tonus. Compounds III*a*, III*b*, VIII*a*, and VIII*b* were evaluated at doses of 1, 10, 100 (and higher, if quantities permitted) mg/kg in female Wistar rats. Compound III*a* produced no effect at doses of ≤200 mg/kg (the highest dose tested). Compound III*b* produced no effect at doses of ≤100 mg/kg, but caused death within 24 hr at 150 mg/kg, the highest dose evaluated. It is unknown if picrotoxin-like convulsions were produced. At doses of <100 mg/kg, ketolactone VIII*a* caused no observable effect, but caused the animal to die within 4 days after a 100-mg/kg dose. At a dose of 200 mg/kg this ketolactone produced onset of tonic convulsions within 3 min followed by clonic convulsions by 10 min, with pilorection and salivation. The animals died within a 20-min period. Keto lactone VIII*b* produced no effects at doses <100 mg/kg, but at a dose of 125 mg/kg (the highest dose tested) the animals died within 12–15 hr. It is unknown if convulsions were produced. Because doses >100 mg/kg were required to produce biological effects, the potency of this series was not sufficient to develop further.

EXPERIMENTAL[3]

Preparation of Potassium-*tert*-amyloxide—To 60 ml of *tert*-amyl alcohol (44.5 g, 0.55 mole) contained in 500 ml of dimethoxyethane under argon was added potassium (23.45 g, 0.6 g-atom), and the mixture was heated to reflux for 2 days. The contents were allowed to cool to room temperature, and the reflux condenser was replaced with a rubber septum. The resulting stock solution was standardized by titration with 2.42 × 10^{-2} *N* potassium acid phthalate solution (phenophthalein as indicator) before each base reaction was carried out.

Alkylation Reactions Using Potassium-*tert*-amyloxide—To 0.1 mole of enone in 250 ml of dimethylformamide stirring in an ice bath under argon was added 0.086–0.14 mole of freshly prepared base solution over a period of 10 min. To the resultant mixture was added 0.2 mole of alkylating agent, and the contents were allowed to stir an additional 45 min at room temperature. The reaction was quenched with ice water and extracted with ether. The ether layer was washed 5 times with equal volumes of water and dried over sodium sulfate. The ether was removed, and the resulting oil was chromatographed or distilled.

Methyl 2-[1(*R,S*)-Methyl-2-oxo-4(*S*)-isopropenyl-5-cyclohexenyl]acetate, (V*b*)—*l*-Carvone (30.04 g, 0.20 mole) in 500 ml of dimethylformamide was alkylated with 62 ml of potassium-*tert*-amylate base solution (0.20 eq) and methyl bromoacetate (61.2 g, 0.40 mole). The resulting oil was distilled to give (V*b*) (8.6 g, 20%): bp 86–88° (0.05 mm); IR (neat) 1745, 1720, and 890; NMR ($CDCl_3$) 1.22 (3, s, CH_3), 1.78 (3, s, vinyl CH_3), 3.62 (3, s, OCH_3), 4.81 (2, m, $=CH_2$), and 5.73 ppm (2, m, H—C=C—H); $M^{\oplus}$ *m/z* 222; n_D^{22} 1.4955.

***l*-Carvotanacetone, 5(*R*)-Isopropyl-2-methyl-2-cyclohexanone**—The procedure used was that of Birch and Walker (7). Modifications were made in the percent of catalyst and the hydrogenation apparatus used. To *l*-carvone (80 g, 0.53 mole) in 150 ml of absolute ethanol contained in a Parr bottle was added *tris*-triphenylphosphine rhodium chloride. The hydrogenation was carried out at room temperature and 30 psi over a period of 6 hr. The bottle was refilled with hydrogen twice during this period. The ethanol was removed, and the crude oil was distilled to produce *l*-carvotanacetone (77.4 g, 95%): bp 54–60° (0.4–0.6 mm); IR (neat) 1680, 1380, and 1365; NMR (CCl_4) 0.72 (6, d, *J* = 6 Hz, 2 CH_3), 1.72 (3, s, CH_3), and 6.6 ppm (1, br s, =CH); n_D^{28} 1.4760 [lit (8) bp 227–228°; n_D^{19} 1.4822].

Methyl 2-[1(*R,S*)-Methyl-2-oxo-4(*R*)-isopropyl-5-cyclohexenyl]acetate, (V*a*)—*l*-Carvotanacetone (15.2 g, 0.10 mole) in 250 ml of dimethylformamide was alkylated with 100 ml of potassium-*tert*-amylate solution (0.11 eq) and methyl bromoacetate (30.6 g, 0.20 mole). Chromatography (alumina; 10% ethyl acetate in cyclohexane) produced V*a* (6.75 g, 35%): bp 86–88° (0.075 mm); IR (neat) 1745, 1720, 1387, 1368, and 735; NMR ($CDCl_3$) 0.99 (6, d, *J* = 6 Hz, 2 CH_3), 1.2 (3, s, CH_3), 3.68 (3, s, OCH_3), and 5.84 ppm (2, m, HC=CH); $M^{\oplus}$, *m/z* 224; n_D^{24} 1.4744.

Ester Hydrolyses—The procedure used was that of Allen and Kalm (9) modified by shortening the reaction time to 2 hr. To 1 mmole of the keto ester in 2 ml of 95% ethanol was added 1.5 mmoles solid 85% KOH, and the mixture was heated to reflux for 2 hr. The ethanol was removed by evaporation, and the resulting oil was diluted with 5 volumes of ice water and acidified (pH 1) with 5 *N* sulfuric acid. The organic portion was extracted with ether, and the ether extract was dried over sodium sulfate.

2-[1(*R,S*)-Methyl-2-oxo-4(*S*)-isopropenyl-5-cyclohexenyl]-acetic acid-γ-lactol, (VI*b*)—The keto ester (V*b*) (6.3 g, 28 mmoles) in 55 ml of 95% ethanol was hydrolyzed with 85% KOH (3.0 g, 45 mmoles). The ether was removed to give 5.8 g of (VI*b*): IR (neat) 3400, 1780–1720 (br), 1650, and 890; NMR (CCl_4) 1.21 (3, s, CH_3), 2.75 (3, s, CH_3), 4.79 (2, m, $=CH_2$), and 6.6 ppm (2, m, HC=CH); $M^{\oplus}$, *m/z* 208; n_D^{26} 1.5088.

2-[1(*R,S*)-Methyl-2-oxo-4(*R*)-isopropyl-5-cyclohexenyl]-acetic acid-γ-lactol, (VI*a*)—The keto ester V*a* (4.92 g, 22 mmoles) in 40 ml of 95% ethanol was hydrolyzed with 85% KOH (2.2 g, 33 mmoles). The ether was removed affording 4.2 g of (VI*a*): IR (neat) 3440, 1775, and 1720; NMR (CCl_4) 0.95 (6, d, *J* = 6 Hz, 2 CH_3, 1.23 (3, s, CH_3), 5.6 (2, m, HC=CH), and 6.9 ppm (1, s, lactol H); $M^{\oplus}$, *m/z* 210; n_D^{24} 1.4990.

Procedure for Iodolactonization—The procedure used was that of Van Tamelen and Shamma (10). The only modification made was a one-fold increase of iodine and potassium iodide in the doubly unsaturated lactol. To a solution of 5 mmoles of the lactol in 30 ml of 0.5 *N* $NaHCO_3$ was added 30 mmoles of potassium iodide in 15 ml of water and 10 mmoles of iodine. The mixture was allowed to stand in the dark for 24 hr. The contents of the reaction was transferred to a separatory funnel and diluted with ether. The mixture was shaken with a saturated solution of sodium thiosulfate until two almost colorless phases were obtained. The ether layer was concentrated and the iodo lactones were allowed to crystallize.

2-[1 (*R*)-Methyl-2-oxo-4 (*S*)-(1′,2′-diiodo)-isopropyl-5 (*S*)-iodo-6(*S*)-hydroxycyclohexyl-acetic acid-γ-lactone or 2-[1 (*R*)-Methyl-2-oxo-4 (*R*)-isopropenyl-5 (*S*)-iodo-6 (*S*)-hydroxycyclohexyl]-acetic acid-γ-lactone (VII*b*)—The lactol (VI*b*) (4.25 g, 20 mmoles) in 60 ml of 0.5 *N* $NaHCO_3$ was lactonized with iodine (20.0 g, 79 mmoles) and potassium iodide (2.0 g, 12 mmoles). The ether extract was concentrated, and the mixture was treated with triphenyltin hydride without purification.

2-[1 (*R*)-Methyl-2-oxo-4 (*R*)-isopropyl-5 (*S*)-iodo-6 (*S*)-hydroxycyclohexyl]-acetic acid-γ-lactone, (VII*a*)—The lactol VI*a* (4.8 g, 23 mmoles) in 130 ml of 0.5 *N* $NaHCO_3$ was lactonized with iodine (10.44 g, 41 mmoles) and potassium iodide (2.16 g, 13 mmoles). Fractional crystallization afforded the major isomer, VII*a* (2.16 g, 36.5%): mp 113–114°; IR ($CHCl_3$) 1780 and 1712; NMR ($CDCl_3$) 0.98 (3, d, *J* = 6 Hz, CH_3), 1.05 (3, d *J* = 6 Hz, CH_3), 1.55 (3, s CH_3), 4.79 (1, m, I—C—H), and 5.15 ppm (1, d *J* = 2 Hz, O—C—H); $M^{\oplus}$, *m/z* 336; $[\alpha]_D^{25}$($CHCl_3$) −13.5°.

Anal.—Calc. for $C_{12}H_{17}IO_3$: C, 42.86; H, 5.06. Found: C, 43.04; H, 5.21.

Preparation of Triphenyltin Hydride—The preparation used was that of Kuivila (11) without modification. To 150 ml of dry ether containing lithium aluminum hydride (1.56 g, 41 mmoles) was added slowly triphenyltin chloride (32.5 g, 100 mmoles). The mixture was stirred at room temperature under argon for 3 hr and then hydrolyzed with 100 ml of ice water while cooling in an ice bath. The ether layer was washed twice with ice water then dried over magnesium sulfate. The ether was removed, and the hydride was distilled rapidly with a bath preheated to 200°; yield 19.5 g (69%); bp 144–152° (0.2–0.3 mm) [lit. (11) 162–168° (0.5 mm)].

Triphenyltin Hydride Reduction of Iodolactones—The procedure used was that of Kuivila (11). The only modification which was made was a onefold increase of the hydride in the iodo lactones of the doubly unsaturated γ-lactol. To 1 mmole of the iodo lactone contained in 10 ml of dry benzene stirring under argon was added 1 mmole of triphenyltin hydride. The mixture was stirred at room temperature overnight, and then the benzene was removed. The resulting product was either fractionally sublimed or fractionally distilled.

[3] All melting points were taken on a Thomas-Hoover Unimelt and are corrected. Analyses were performed by either Midwest Microlab, Inc., Indianapolis, Ind., or on an F and M Model 185, C, H, N, Analyzer, University of Kansas. IR data were recorded on Beckman IR-8, IR-10, and IR-33 spectrophotometers and are reported in cm^{-1}. ^1H-NMR data were recorded on Varian A-60, A-60A, and T-60 analytical spectrometers with tetramethylsilane as the internal standard. ^1H-NMR data are reported as δ-values (ppm). Mass spectra were recorded on a Varian-Atlas CH-5 at 70 eV at a resolution of ~4000.

2-[1(*R*)-Methyl-2-oxo-4(*R*)-isopropenyl-6(*R*)-hydroxycyclohexyl]-acetic acid-γ-lactone, (VIII*b*)—The iodo lactone(s) VII*b* (3.8 g) in 100 ml of dry benzene was reduced with triphenyltin hydride (6.72 g, 0.02 mole). Distillation (150–154° and 0.1 mm) provided VIII*b* (975 mg, 72% based on monoiodo starting material, 91% based on triiodo starting material): IR ($CHCl_3$) 1795 and 1720; NMR ($CDCl_3$) 1.35 (3, s, CH_3), 1.75 (3, s, CH_3), 4.68 (1, t, J = 2 Hz, O—C—H), and 4.82 ppm (2, m, $=CH_2$); $M^{\oplus}$, m/z 208; $[\alpha]_D^{26}$ ($CHCl_3$) +114.2°.

Anal.—Calc. for $C_{12}H_{16}O_3$: C, 69.20; H, 7.68. Found: C, 68.95; H, 7.79.

2-[1(*R*)-Methyl -2- oxo-4(*R*)-isopropyl-6(*R*)-hydroxycyclohexyl]-acetic acid-γ-lactone, (VIII*a*)—The iodo lactone VII*a* (1.0 g, 3 mmoles) in 30 ml of dry benzene was reduced with triphenyltin hydride (0.98 g, 2.8 mmoles). The benzene was removed, and the resulting gum was fractionally sublimed [67° (0.05 mm)] to yield VIII*a* (200 mg, 32%): IR ($CHCl_3$) 1785 and 1715; NMR ($CDCl_3$) 0.95 (6, d, J = 6 Hz, 2 CH_3), 1.35 (3, s, CH_3), and 4.67 ppm (1, t, J = 2 Hz, O—C—H); $M^{\oplus}$, m/z 210; $[\alpha]_D^{26}$ ($CHCl_3$) +127°; mp 84–85°.

Anal.—Calc. for $C_{12}H_{18}O_3$: C, 68.55; H, 8.57. Found: C, 68.33; H, 8.52.

Sodium Borohydride Reductions—The procedure used was that of Elisberg *et al.* (12) modified by length of reaction time and solvent. To 0.5 mmole of the keto lactone in 30 ml of 95% ethanol stirring in an ice bath was added 1 mmole of sodium borohydride. Ice water was added to the mixture, the solution was extracted with ether three times, and the organic layer was dried over sodium sulfate.

2-[1(*S*)-Methyl-2(*R*)-hydroxy -4(*S*)- isopropenyl-6(*R*)-hydroxycyclohexyl]-acetic acid-γ-lactone, (III*b*)—The keto lactone (VIII*b*) (560 mg, 2.69 mmoles) in 40 ml of 95% ethanol was reduced with sodium borohydride (200 mg, 5.38 mmoles). Workup after a 6-hr reaction time and distillation produced III*b* (270 mg, 48%): IR (neat) 3500 and 1770; NMR ($CDCl_3$) 1.1 (3, s, CH_3), 1.74 (3, s, CH_3), 4.35 (1, t, J = 3 Hz, O—C—H), and 4.73 ppm (2, s, $=CH_2$); $M^{\oplus}$, m/z 210.

Anal.—Calc. for $C_{12}H_{18}O_3$: C, 68.59; H, 8.57. Found: C, 68.34; H, 8.63.

2-[1(*S*)-Methyl-2(*R*)-hydroxy-4(*S*)-isopropyl-6(*R*)-hydroxycyclohexyl]-acetic acid-γ-lactone, (III*a*)—The keto lactone, VIII*a* (315 mg, 1.5 mmoles) in 30 ml of 95% ethanol was reduced with sodium borohydride (113 mg, 3.0 mmoles). Workup after a period of 7 hr and distillation gave III*a* (130 mg, 41%): IR (neat) 3500 and 1775; NMR ($CDCl_3$) 0.85 (3, d, J = 5 Hz, CH_3), 1.1 (3, d, J = 4 Hz, CH_3), 1.22 (3, s, CH_3), and 4.3 ppm (1, s, O—C—H); $M^{\oplus}$, m/z 212.

Anal.—Calc. for $C_{12}H_{20}O_3$: C, 67.94; H, 9.43. Found: C, 67.85; H, 9.49.

Received November 20, 1981, from *INTERx Research Corporation*, a subsidiary of *Merck Sharp & Dohme Research Laboratories, Lawrence, KS 66044.* Accepted for publication August 16, 1982.

Abstract □ The rectal absorption of gentamicin sulfate in rats, both in the presence and absence of sodium salicylate, was facilitated by the use of high ionic strength aqueous formulations. The relative order of effectiveness in promoting gentamicin absorption was sodium dihydrogen phosphate ≃ sodium chloride ≫ potassium chloride, indicating a preferential effect of sodium ions. The increased gentamicin bioavailability in response to sodium salicylate adjuvant activity appeared to be independent of and additive to the increased gentamicin absorption due to high ionic strength conditions. The inability of sorbitol to increase gentamicin bioavailability above control levels indicated that elevated osmotic pressure was not a major determinant of rectal gentamicin absorption.

Keyphrases □ Gentamicin—rectal absorption, effect of ionic strength and specificity, sodium salicylate adjuvant □ Sodium salicylate—as adjuvant, rectal absorption of gentamicin, effect of ionic strength and specificity □ Absorption, rectal—gentamicin, sodium salicylate adjuvant, effect of ionic strength and specificity

Sodium salicylate has been reported to enhance the rectal absorption of water-soluble compounds (1, 2). Two types of formulations were used in the salicylate studies, an aqueous microenema and a fatty-base suppository. The influence of variations in ionic strength and ionic specificity on salicylate-enhanced rectal absorption has not been thoroughly examined in either formulation.

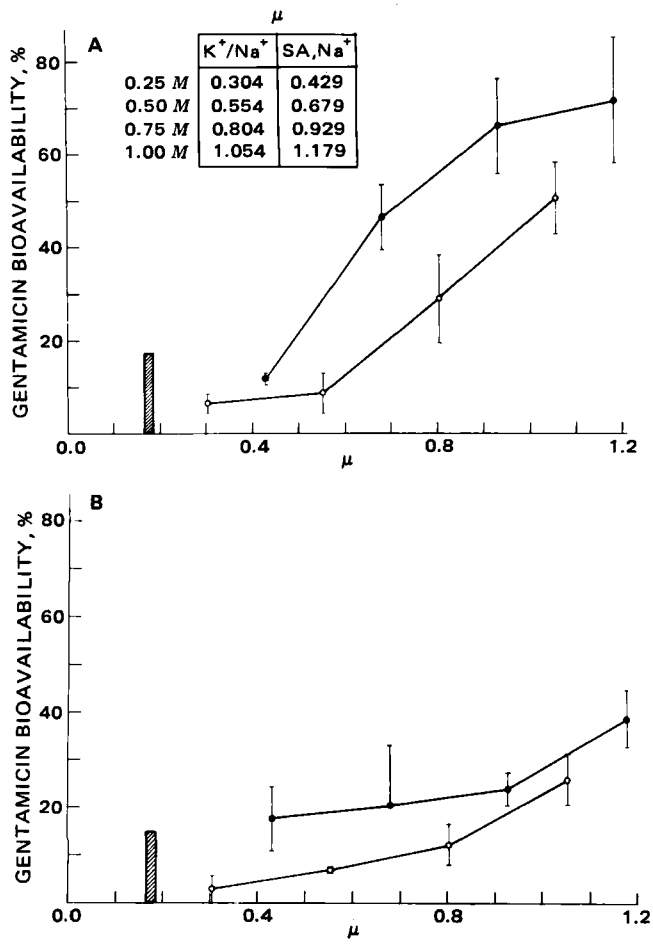

Figure 1—*Gentamicin bioavailability in the presence (●) or absence (○) of sodium salicylate following administration of aqueous microenemas of varying ionic strength (μ) to the unligated rectal compartment. Sodium chloride (A) or potassium chloride (B) at 0.25, 0.50, 0.75, and 1.00* M *was the major determinant of ionic strength, with minor contributions from sodium salicylate (SA) and gentamicin sulfate. Bars (▨) represent ionic strength of standard physiological solutions. Error bars represent standard deviations for* n = 3–6.

absorption, is well documented (3, 4). Recent studies have demonstrated a direct link between the transport of sodium ions and macromolecules in the rat small intestine (5, 6). Sodium ions have also been shown to influence calcium transport in the small intestine (7). However, the influence of ionic strength on adjuvant-assisted rectal absorption of water-soluble compounds has not been reported.

In the present study, the effect of various ionic species on the rectal absorption of gentamicin, a model water-soluble compound, in the presence and absence of sodium salicylate are examined. The purpose of the study is threefold: (*a*) to determine the effect, if any, of ionic strength on rectal absorption of a water-soluble compound; (*b*) to examine possible ionic specificity with regard to promoting rectal absorption; and (*c*) to determine if the absorption-promoting activity of sodium salicylate is influenced by alterations in ionic species or total ionic strength.

EXPERIMENTAL

Adult male Sprague-Dawley rats (200–250 g) were fasted, with free access to water, for 18–24 hr prior to the experiments. Animals were anesthetized by intramuscular injections of urethane (0.1 ml of 43% ethylcarbamate[1] in distilled water/100 g of body weight).

Experimental formulations were administered as aqueous microenemas, given with a 1-ml syringe at an intrarectal depth of 2.5 cm. Each animal received a 250-μl microenema, pH 5.0, containing 2.5 mg of gentamicin sulfate[1] with or without 5 mg of sodium salicylate. Ionic strength was controlled by the addition of various salts, as indicated in each individual set of experiments. Total ionic strength included contributions from the drug and adjuvant, as well as from the added salts, and was determined by the following formula:

$$I = \tfrac{1}{2}\sum m_i z_i^2 \qquad \text{(Eq. 1)}$$

where I is the ionic strength, m_i is the molality of i, and z_i is the charge of i.

In some experiments, designed to minimize effects due to possible movement of the microenema solution away from the site of administration, the rectum was ligated 4 cm from the anal opening. With care taken not to restrict the vasculature, this procedure ensured retention of the microenema in the distal 4 cm of the rectal compartment.

Blood samples (0.5 ml) were taken from the external jugular vein at 15, 30, 60, and 90 min following rectal administration of the microenema. Serum was isolated and frozen until assayed within 1–2 weeks. For determination of intravenous serum profiles, each animal received 2.5 mg of gentamicin sulfate in 250 μl of 0.1 *M* Tris-HCl buffer, pH 7.5. Blood samples (0.5 ml) were collected at 5, 10, 20, 30, 60, and 90 min and processed as described for rectal administration. Serum gentamicin was determined by microbiological assay using *Bacillus subtilis* (ATCC #6633) as the target organism (8). Results are expressed as percent bioavailability, calculated as:

$$\%\ \text{Bioavailability} = \frac{(\text{AUC})_{\text{rectal}}(\text{Dose})_{\text{iv}}}{(\text{Dose})_{\text{rectal}}(\text{AUC})_{\text{iv}}} \times 100 \qquad \text{(Eq. 2)}$$

The area under the serum concentration–time curve from 0 to 90 min, AUC_0^{90}, was calculated by a summation of trapezoidal areas. For the calculation of the intravenous AUC_0^{90}, the linear portion of the log serum concentration *versus* time profile was extrapolated to $t = 0$ min to correct for the drug distribution phase. Three to six animals were used for determining mean AUC_0^{90} values for both rectal and intravenous serum profiles. Following rectal administration, the absorption of gentamicin sulfate was virtually complete by 30–60 min, and the serum $t_{1/2}$ value (220–240 min) was the same as that observed after intravenous administration.

RESULTS

The effect of sodium chloride on unligated rectal delivery of gentamicin, with and without sodium salicylate as the adjuvant, is shown in Fig. 1A. Without adjuvant, no apparent sodium chloride effect is observed until the ionic strength (μ) in the microenema exceeds 0.55. A linear increase in percent bioavailability occurred from $\mu = 0.544$ to $\mu = 1.054$ ($r = 0.9998$ by regression analysis). At 1.0 *M* NaCl ($\mu = 1.054$), gentamicin bioavailability was 51 ± 7.9%. Solutions of greater sodium chloride ionic strength were not examined, so it is not known whether the sodium chloride effect on bioavailability would plateau prior to reaching 100% gentamicin delivery. At all ionic strengths examined, gentamicin bioavailability was greater in the presence of sodium salicylate. At higher ionic strengths with sodium salicylate, the effect of sodium chloride was no longer linear and appeared to plateau around 70–80% bioavailability.

Figure 1B shows the results of a similar set of experiments using unligated rectum in which potassium chloride was substituted for sodium chloride as the major contributor to total ionic strength. The effect of potassium chloride alone (26 ± 5.6% at $\mu = 1.054$) on gentamicin delivery was significantly less than the corresponding response observed with sodium chloride (51 ± 7.9% at $\mu = 1.054$). In the presence of sodium salicylate, the gentamicin bioavailability using potassium chloride was 39 ± 5.9% at $\mu = 1.179$, whereas with sodium chloride the bioavailability was 72 ± 13.4%.

In the absence of adjuvant and added salts, gentamicin sulfate bioavailability was 12 ± 4.5%. The inclusion of 2–10% sorbitol in the formulation caused a slight decrease in gentamicin sulfate absorption (Table I). Including 30% sorbitol in microenemas containing gentamicin sulfate and adjuvant did not significantly increase bioavailability (36 ± 14.8%) above that seen with sorbitol-free microenemas containing adjuvant and drug along (29 ± 7.4%).

Table I—Effect of Sorbitol on Rectal Gentamicin Sulfate Absorption from Aqueous Formulations

Formulation[a]		Gentamicin Sulfate
Adjuvant, %	Sorbitol, %	Bioavailability, %[b]
0	0	12 ± 4.5
0	2	5 ± 3.4
0	5	3 ± 0.3
0	10	4 ± 2.3
2	0	29 ± 7.4
2	30	36 ± 14.8

[a] All formulations contained 1% gentamicin sulfate. [b]Based on $n = 3$ animals.

The use of potassium chloride or potassium dihydrogen phosphate with ligated tissue produced somewhat equivocal results (Fig. 2A). There was no apparent difference between the gentamicin bioavailability after the administration of potassium chloride alone compared with that of potassium chloride administered with sodium salicylate, except at very high ionic strengths ($\mu > 1.0$). Potassium dihydrogen phosphate, in conjunction with sodium salicylate, yielded the highest gentamicin bioavailability in the potassium series (63 ± 9.4% at $\mu = 1.179$), although this value was significantly less than the bioavailability observed with sodium dihydrogen phosphate and sodium salicylate (88 ± 13.2% at $\mu = 0.929$) (Fig. 2B). As seen in the experiments with unligated rectal tissue, bioavailabilities attained with sodium chloride and sodium salicylate were greater than those observed with sodium chloride alone.

DISCUSSION

The ability of salicylate-type adjuvants to enhance the GI absorption of water-soluble compounds has been previously established (1, 2). In this study, the ionic contributions of sodium and potassium salts to rectal absorption of a model water-soluble compound, gentamicin, were examined. Ionic strength and specificity were found to significantly affect the rectal absorption of gentamicin.

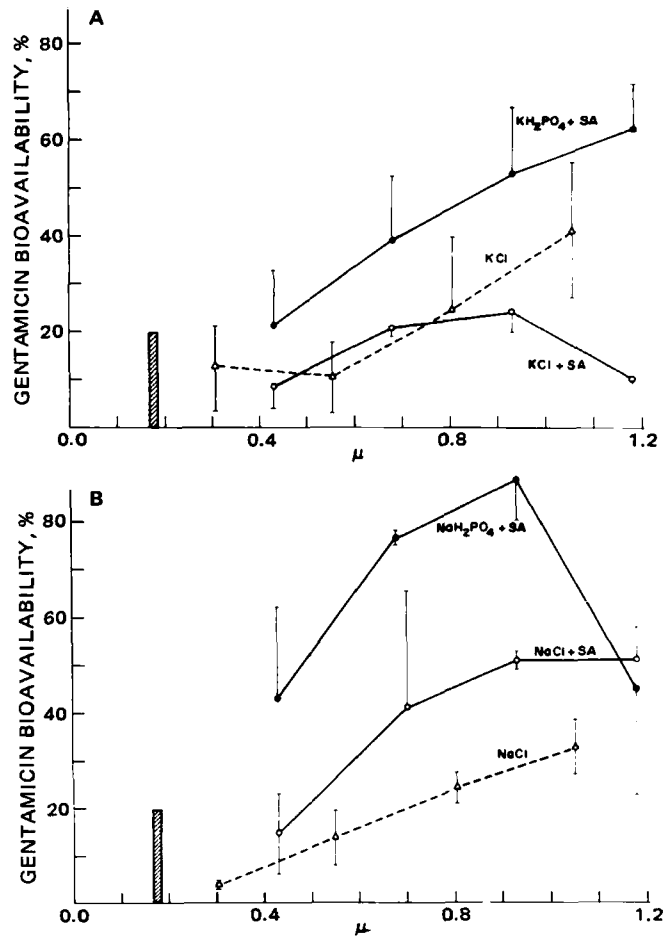

Figure 2—*Gentamicin bioavailability in the presence (—) or absence (- - -) of sodium salicylate (SA) following administration of aqueous microenemas of varying ionic strength (μ) to the ligated rectal compartment. The potassium (A) or sodium (B) salts were the major determinants of ionic strength, with minor contributions from sodium salicylate and gentamicin sulfate. Bars (▨) represent ionic strength of standard physiological solutions. Error bars represent standard deviations for* n = *3–6.*

Sodium chloride significantly increased gentamicin absorption, even in the absence of sodium salicylate. It is not possible to determine, from the present data, the precise mechanism involved in the sodium chloride enhancement of drug permeability across the rectal mucosa. However, several possibilities exist: (*a*) high sodium or chloride concentrations may activate some undefined transport mechanism for gentamicin; (*b*) active transport of sodium out of the rectal lumen, with concomitant water movement, may establish mass transfer conditions favoring absorption of gentamicin; or (*c*) high ionic strength solutions may damage or disrupt the normal epithelial barrier and allow concentration-dependent movement of gentamicin through the disrupted barrier.

The mucosal layer in the rectum and lower portion of the large intestine is not classically viewed as an absorptive area except for the absorption of water and small ions (*e.g.*, sodium). This does not preclude the possible existence of specific transport mechanisms for water-soluble compounds (*e.g.*, gentamicin), although it is unlikely that such a system exists. The apparent inability of the rectal tissue to absorb gentamicin in the absence of the salicylate adjuvant further refutes the existence of a specific transport system which could be affected by the sodium or chloride ion.

Possible tissue damage at very high concentrations of sodium chloride may account for part of the observed increase in gentamicin absorption, although comparable gentamicin serum levels were not observed at higher concentrations of potassium chloride or sorbitol. The inability of sorbitol to increase gentamicin bioavailability indicates that the osmotic pressures generated by high sodium chloride or potassium chloride solutions are unlikely causes of the increased delivery. The fact that sodium chloride was twice as effective as potassium chloride in both the presence and absence of sodium salicylate (at comparable ionic strengths) suggests certain ionic specificities, possibly implicating the involvement of the membrane sodium–potassium pump.

Sodium dihydrogen phosphate and potassium dihydrogen phosphate were tested in the ligated rectum to determine if the absorption promoting potential of the salts was influenced by the anionic species. Maximal effects in the ligated rectum were observed at lower ionic strengths than in the unligated rectum. This is probably due to the increased effective concentration of drug and salt in the limited exposed surface area of the ligated rectum. With both sodium and potassium, the dihydrogen phosphate salts appeared to be more effective than the chloride salts in promoting gentamicin delivery. While this increased absorption using dihydrogen phosphate salts may be a real effect, it is also possible that alterations in rectal pH may have caused ionic strengh changes that were responsible for promoting absorption. All microenemas were administered as buffered solutions (pH 5) with sodium dihydrogen phosphate predominately existing in solution as sodium and dihydrogen phosphate. The rectal compartment in the rat is capable of some buffering activity and tends to adjust the pH of aqueous solutions to a range of pH 7–8 (unpublished observations). If the pH of the microenema is buffered *in vivo* to the pH 7–8 range, a significant portion of the dihydrogen phosphate may be ionized to monohydrogen phosphate. Since the ionic strength is a function of charge squared, this would significantly increase the total ionic strength of the solution and could account for the greater effect of sodium dihydrogen phosphate as compared with sodium chloride. Sodium chloride ionic strength is unaffected by pH. Since the buffering effect of the rectal compartment is not instantaneous, the relative concentrations of the two ionized species of the phosphate salts will be continually changing. To determine if the buffering capacity of the rectum changes the ionic strength of the formulation, and therefore the absorption of gentamicin sulfate, controlled pH perfusion studies will be required. At this point, the possibility that phosphate has a greater effect on gentamicin sulfate absorption than chloride cannot be precluded.

An important deduction that can be made from this study is that the absorption-promoting activity of sodium salicylate is not solely attributed to ionic strength. In the data presented in the figures, ionic contributions from sodium salicylate were included in the calculations of total ionic strength in the microenemas. The increase in gentamicin bioavailability due to the adjuvant activity of sodium salicylate is significantly greater than the bioavailability achieved with adjuvant-free microenemas at the same total ionic strength (adjusted by sodium chloride). Sodium salicylate, therefore, possesses an absorption-enhancing potential above that which can be attributed to sodium ionic strength alone.

Ionic strength and ionic specificity were found to have a significant influence on the rectal absorption of gentamicin. Sodium was more effective than potassium in promoting rectal absorption, but the enhancing effect of sodium salicylate could not be totally explained on the basis of ionic strength. These data, while helping to elucidate some parameters that affect rectal drug absorption, may offer potential insights into new formulation designs for systemic delivery of water-soluble drugs from the rectal compartment.

Effect of Quinidine on Digoxin Distribution and Elimination in Guinea Pigs

JUN SATO, YASUFUMI SAWADA, TATSUJI IGA ˣ, and MANABU HANANO

Received June 4, 1982, from the *Faculty of Pharmaceutical Sciences, Department of Pharmaceutics, University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113, Japan.* Accepted for publication August 20, 1982.

Abstract □ The effect of quinidine on the distribution and elimination of digoxin was examined by comparing the change in the steady-state volume of distribution (Vd_{ss}), determined both from *in vivo* plasma elimination and tissue distribution and *in vitro* serum binding studies, with that in the total body clearance (CL_{tot}) determined from biliary, renal, and metabolic clearances in guinea pigs. The plasma disappearance of digoxin after a 250-μg/kg iv dose followed a triexponential decline in both the control and quinidine-treated guinea pigs. In the quinidine-treated guinea pigs, the pharmacokinetic parameters Vd_{ss} and CL_{tot} significantly decreased to approximately half of that for the control guinea pigs. The tissue-to-plasma partition coefficients (K_p) of all tissues studied, *i.e.* liver, heart, muscle, and brain, at 6 hr after bolus injection of digoxin decreased in the presence of quinidine. The serum free fraction and the plasma-to-blood concentration ratio of digoxin in the therapeutic range did not show a significant alteration in the presence of quinidine. This suggested that the decrease of K_p is due mainly to the inhibition of tissue distribution of digoxin by quinidine. The biliary clearance (CL_B) and renal clearance (CL_R) also significantly decreased in the presence of quinidine. It was concluded that quinidine caused a inhibition of digoxin in the tissue binding or uptake, which significantly decreased the K_p values of digoxin; this result may explain the significant decrease of Vd_{ss}. Moreover quinidine may be the cause of a reduction of biliary, renal, and metabolic clearances, which significantly decrease the CL_{tot} of digoxin.

Keyphrases □ Quinidine—effect on the distribution and elimination of digoxin, guinea pigs □ Digoxin—pharmacokinetics, effect of quinidine coadministration, guinea pigs □ Pharmacokinetics—digoxin in the guinea pig, effect of quinidine coadministration

When quinidine is given to patients (1–5), dogs (6), or guinea pigs (7) receiving digoxin, the serum digoxin concentration increases. Reduction in the total body clearance (CL_{tot}) (5, 6) and the volume of distribution (Vd) (5, 6, 8) of digoxin has been observed and accounts for the elevated digoxin concentration. Quinidine has been reported to diminish the renal clearance (CL_R) of digoxin in humans (2, 4, 5, 8, 9) and dogs (10, 11) without significantly altering the glomerular filtration rate as measured by the creatinine clearance. Doherty *et al.* (12) reported that quinidine reduced the canine skeletal and heart muscle concentrations of digoxin, while increasing concentrations in the plasma and brain. Straub *et al.* (13) showed that quinidine reduced the number of digitalis-binding sites, as determined by *in vitro* binding studies with Na^+,K^+-ATPase from bovine heart membrane. Evidence has been reported that quinidine was capable of decreasing the affinity for digoxin of cardiac glycoside receptor sites on purified Na^+,K^+-ATPase in guinea pigs and on intact human erythrocyte membranes (14).

The present study examined the effect of quinidine on the distribution and elimination of digoxin by comparing the changes in Vd and CL_{tot} *in vivo*, which were determined from the tissue distribution, metabolism, excretion, serum protein binding, and plasma-to-blood distribution ratio. As a model animal for digoxin–quinidine interaction in the human, the guinea pig, a species in which digoxin distribution appears similar to that observed in the human, was selected.

EXPERIMENTAL

Digoxin[1] and quinidine sulfate[2] were used. Tritiated digoxin, labeled at the 12α-position (14.0 Ci/mmole)[3], which was found to be at least 99% pure by TLC, was used as the radioactive compound. All other reagents were commercially available and analytical grade.

Animal Experiments—Adult male Hartley guinea pigs[4], weighing 280–300 g, were used. Under light ether anesthesia, the jugular vein and carotid artery were cannulated with polyethylene tubing[5]. For the biliary and urinary excretion studies, bile fistula and urinary bladder cannulation were used to collect samples of bile and urine, respectively. Cannulated animals were kept in restraining cages with access to water under normal housing conditions prior to the experiments.

The guinea pigs were simultaneously given 250 μg/kg of digoxin (containing 100 μCi/kg of 12α-[^{3}H]digoxin) in 40% ethanol solution and 25 mg/kg of quinidine sulfate in physiological saline through the jugular vein cannula. The digoxin solution containing 40% ethanol was administered alone to the control guinea pigs. Blood samples (0.25 ml) were obtained for the determination of digoxin at 1, 5, 30, 60, 120, 180, 240, 300, and 360 min, and for the determination of quinidine (in different animals) at 5, 10, 15, 20, 30, 45, 60, 90, 120, 180, and 240 min in heparinized poly-

ethylene centrifuge tubes[6]. Bile samples were obtained at 15, 30, or 60 min, while the urine sample was collected for 360 min. The body temperature was kept at 37° using a heat lamp. Plasma was separated by centrifugation for 20 sec[7].

For the tissue distribution study the animals were sacrificed at 1 and 6 hr after digoxin administration by an injection of air into the carotid artery. After removal of blood samples, the brain, heart, liver, and muscle were quickly excised, rinsed with cold saline, blotted, and weighed. All tissues and plasma were stored at −40° until assayed. Tissue samples were homogenized with a three-fold excess of physiological saline[8]. The separation of the metabolites from digoxin was carried out using the method of Harrison and Gibaldi (15). A 100-μl quantity of the plasma sample and 1 ml of the tissue homogenate were shaken for 10 min and then extracted twice with 2 ml of chloroform–methanol (1:1, v/v). The pooled extracts were then streaked on silica gel plates and chromatographed. Glass sheets precoated with silica gel 60[9] of 0.25 mm thickness were developed twice in ethyl acetate–chloroform–acetic acid (90:5:5, v/v/v). Digoxin was visualized by spraying the plate with 3,5-dinitrobenzoic acid and 2 *N* KOH in methanol to develop a violet color. The spots attributable to digoxin from chromatograms of biological samples were scraped into scintillation vials containing 10 ml of scintillation fluid[10]. The extraction coefficients of digoxin from plasma, brain, heart, liver, and muscle were 0.85, 0.45, 0.68, 0.55, and 0.86, respectively. The concentration of ^{3}H-labeled digoxin was determined[11]. Quinidine concentration was determined by the double-extraction method according to Crámer and Isaksson (16).

Serum Protein Binding—Serum was separated from the blood, obtained through the carotid artery, by centrifugation for 10 min at 3000 rpm after standing for 60 min at room temperature. The serum free fraction of digoxin was determined by equilibrium dialysis at 37° for 16 hr using *semimicrocells*[12] and a semipermeable membrane[13] against

A, μg/ml	68.6 ± 23.6	134.9 ± 5.9
α, min^{-1}	0.022 ± 0.005	0.0308 ± 0.0041
B, μg/ml	11.5 ± 2.5	33.2 ± 11.8
β, min^{-1}	0.00313 ± 0.00067	0.00388 ± 0.00035
Vd_{ss}, liter/kg[b]	5.25 ± 0.78	2.76 ± 0.31[f]
CL^p_{tot}, ml/(min kg)[c]	31.5 ± 2.6	17.3 ± 3.6[f]
CL_R, ml/(min kg)[d]	3.4 ± 0.8	0.9 ± 0.5[f]
CL_B, ml/(min kg)[d]	4.9 ± 0.5	0.9 ± 0.1[f]
CL_M, ml/(min kg)[e]	23.2	15.5

[a] Results are given as the mean ± *SE* of three or four animals. [b] The volume of distribution at steady state (Vd_{ss}) was calculated by a conventional equation (18) using triexponential equation constants from plasma disappearance curves. [c] The total plasma clearance (CL^p_{tot}) was calculated using CL^p_{tot} = dose/AUC. [d] The biliary clearance (CL_B) and the renal clearance (CL_R) were calculated using the equation in the text. [e] The mean metabolic clearance (CL_M) was calculated by $CL_M = CL_{tot} - CL_B - CL_R$ (see text). [f] Significantly different ($p < 0.05$) from the control guinea pigs.

Krebs–Ringers buffer (pH 7.4), containing 0.6–46.8 ng/ml of [^{3}H]digoxin and 1 and 10 μg/ml of quinidine. The protein binding of digoxin to serum was unchanged between 16 and 20 hr of dialysis at 37°. The quinidine concentration in the protein chamber after dialysis was in the same range as that of the *in vivo* concentration of quinidine (0.5–5 μg/ml) in plasma.

Plasma-to-Blood Concentration Ratio of Digoxin—All procedures were carried out immediately after the blood collection. The blood was incubated with 1 μCi/ml of [^{3}H]digoxin and various amounts of nonlabeled digoxin (1–300 ng/ml as blood concentration) at 37° for 20 min in the presence of quinidine (1 and 10 μg/ml). Preliminary experiments indicated that equilibration was attained within 30 sec between plasma and red blood cells (unpublished data). After centrifugation, an aliquot of the plasma was removed and the concentration of [^{3}H]digoxin was determined as described above. An analytical blank without substrate was determined in the same manner. The hemolysis during the incubation was negligible.

Data Analysis—The digoxin concentration data for individual animals were fitted to the equation $C_t = Pe^{-\pi t} + Ae^{-\alpha t} + Be^{-\beta t}$ for the plasma concentration C_t at time t by nonlinear least-squares regression (17). Pharmacokinetic constants (Table I) were determined from the three-exponential equation constants, *i.e.*, P, π, A, α, B, and β, using conventional equations (18). All means are presented with their standard error (the mean ± *SE*). The Student's t test was utilized to determine significant differences between the control and the quinidine-treated groups.

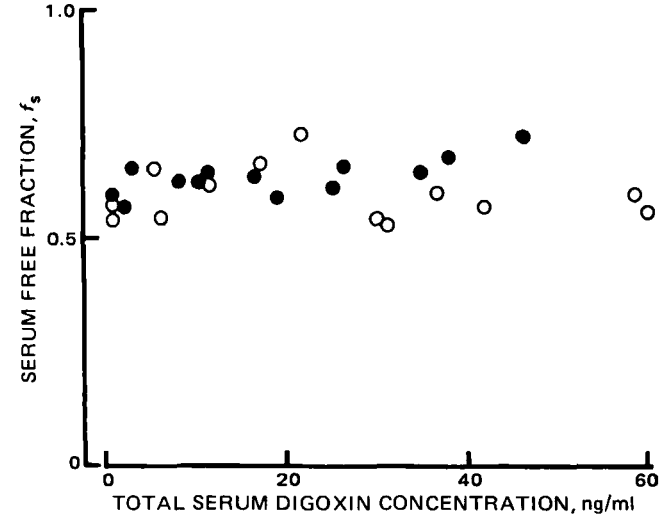

Figure 2—*Serum free fraction as a function of total blood concentration of digoxin with (○) and without (●) quinidine. Equilibrium dialysis was performed at 37° for 16 hr against Krebs–Ringer buffer (pH 7.4) containing 0.61–46.8 ng/ml of [^{3}H]digoxin. The concentration of quinidine was 1 and 10 μg/ml.*

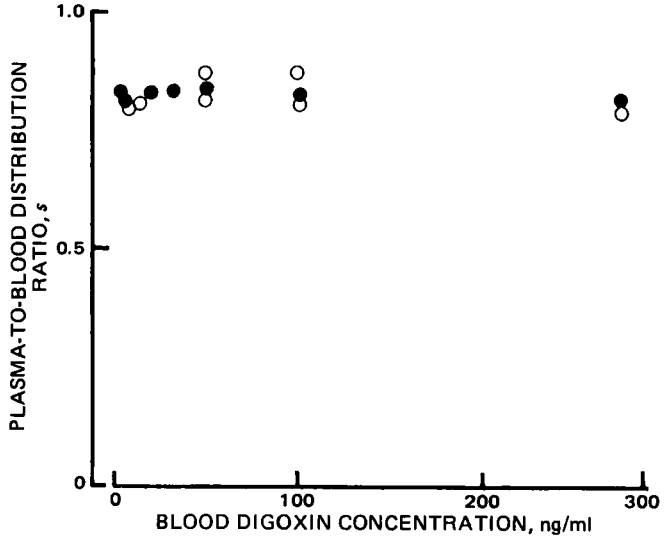

Figure 3—*Plasma-to-blood concentration ratio of digoxin as a function of total plasma concentration with (○) and without (●) quinidine. The blood was incubated with 1–300 ng/ml of [^{3}H]digoxin (as the blood concentration) at 37° for 20 min. The concentration of quinidine was 1 and 10 μg/ml.*

RESULTS

Effect of Quinidine on Digoxin Elimination from Plasma—The plasma disappearance of digoxin after intravenous administration of 250 μg/kg in the presence and absence of quinidine is shown in Fig. 1. The disappearance of digoxin followed three-exponential curves in both the control and quinidine-treated guinea pigs. The range of the plasma quinidine concentration was 0.5–5 μg/ml during the sampling period of 4 hr. The pharmacokinetic constants were computed by a nonlinear iterative least-squares method (17) and are listed in Table I. In the quinidine-treated guinea pigs, a significant decrease was observed in the total body plasma clearance (CL^p_{tot}). The Vd_{ss} was decreased significantly by quinidine.

Effect of Quinidine on Serum Protein Binding of Digoxin—The results from serum protein binding experiments are shown in Fig. 2. In both the experiments, *i.e.*, with and without quinidine, the serum binding of digoxin exhibited apparent linear relationships. The serum free fraction (f_s) did not show a significant alteration in the presence of quinidine.

Plasma-to-Blood Concentration Ratio of Digoxin—The plasma-to-blood concentration ratio of digoxin in the dose range from 1 to 300 ng/ml were determined in the presence and absence of quinidine (Fig. 3). The ratio seems to be constant over the dose range studied and did not show a significant alteration in the presence of quinidine.

Effect of Quinidine on Tissue Distribution of Digoxin—Table II demonstrates the changes in the tissue concentrations of digoxin at 1 and 6 hr after intravenous bolus administration of 250 μg/kg. It is apparent that the tissue concentration of digoxin did not show a significant alteration in the quinidine-treated guinea pigs. There are two exceptions: the liver, with a 50% decrease (significantly different from the control group, $p < 0.05$) in the quinidine-treated group and the brain, where a 370% increase (significantly different from the control, $p < 0.05$) occurred in the same group at 1 hr after intravenous bolus administration of digoxin. The apparent tissue-to-plasma partition coefficients (K_p) at 1 and 6 hr after intravenous bolus administration of digoxin in the presence and absence of quinidine are shown in Table II. The K_p values of most tissues studied significantly decreased in the quinidine-treated group, while the apparent brain-to-plasma concentration ratio at 1 hr significantly ($p < 0.05$) increased in the same group.

Effect of Quinidine on Biliary and Renal Excretion of Digoxin—In the quinidine-treated guinea pigs, no significant difference was observed in the mean bile flow rate for 6 hr when compared with that in the control animals (138.3 ± 16.1 μl/min/kg for the quinidine-treated group, $n = 3$, and 133.8 ± 17.4 for the control, $n = 3$). The biliary excretion rates of digoxin are shown in Fig. 4A; significant decreases ($p < 0.05$) were observed, except at 3 and 4 hr. Cumulative biliary excretion curves of digoxin are shown in Fig. 4B. The amount of digoxin excreted during 6 hr in the control guinea pigs was 13.8 ± 1.1% of the dose ($n = 3$), while that of the quinidine-treated group was 5.6 ± 1.1% ($n = 3$). The cumulative amount of digoxin excreted in urine during 6 hr after intravenous bolus administration in the control guinea pigs was 9.9 ± 2.3% of the dose ($n = 3$), while that of the quinidine-treated group was 5.2 ± 2.9% ($n = 3$). The mean biliary (CL_B) and renal clearances (CL_R) were calculated by:

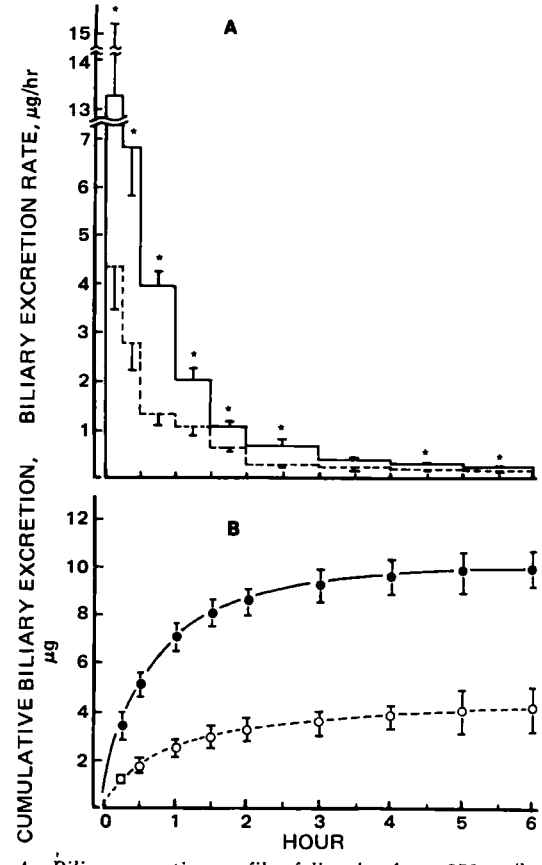

Figure 4—*Biliary excretion profile of digoxin after a 250-μg/kg iv dose. (A) Biliary excretion rate. Each datum and bar represents the mean and standard error of three control (—) quinidine-treated (---) guinea pigs; (*) statistically significant at p = 0.05 when compared with the biliary excretion rate of the control guinea pigs. (B) Cumulative biliary excretion curves. Each point and bar represents the mean and standard error of three control (●) or quinidine-treated (○) guinea pigs.*

$$CL_B \text{ or } CL_R = \frac{\text{Cumulative amount of digoxin excreted for 360 min}}{AUC_{0\text{–}360\ min}}$$

where AUC is the area under the plasma concentration *versus* time curve calculated from pharmacokinetic parameters listed in Table I. The CL_B and CL_R calculated by this equation in the presence and absence of quinidine are also listed in Table I. Both clearances significantly decreased in the presence of quinidine.

From the digoxin content in plasma, liver, and bile, the liver-to-plasma and the bile-to-liver concentration ratios were calculated (Table III). These ratios indicated that the transport of digoxin from plasma to liver and from liver to bile were against a large concentration gradient in the control guinea pigs. But after quinidine treatment, the liver-to-plasma concentration ratio significantly decreased, while the bile-to-liver concentration ratio did not show a significant alteration.

DISCUSSION

The results of this study in guinea pigs are in agreement with previous studies, in which the increases in the serum (plasma) concentrations of digoxin were observed in the presence of quinidine in humans (1–5), dogs (6), and guinea pigs (7). Many investigators have reported that quinidine decreased Vd and CL_{tot} of digoxin in humans (5) and dogs (6). In this study the decreases of both parameters were also observed in guinea pigs (Table I). The lack of a substantial change in the elimination half-life ($t_{1/2}$) of digoxin suggested that the parallel changes in Vd and CL_{tot} tend to counterbalance each other. In plasma protein binding, no significant difference was observed in the serum free fraction of digoxin with or without quinidine (Fig. 2). This finding suggests that quinidine does not

Table II—Tissue Distribution of Digoxin in Guinea Pigs [a]

alter the binding of digoxin to serum (plasma) proteins. A possible reason for this effect might be that digoxin binds mainly to albumin in serum (plasma), but the basic drug quinidine binds not only to albumin but also to lipoprotein or α_1-acid glycoprotein (19).

The plasma-to-blood concentration ratio (s) of digoxin did not show a significant change when coadministered with quinidine in guinea pigs (Fig. 3). Using ^{86}Rb-labeled human erythrocytes, Doering *et al.* (20) recently showed that quinidine did not interfere with the glycoside receptor. Thus, changes in s in the presence of quinidine cannot be explained by this mechanism. The decrease in Vd at steady state may be compatible with the hypothesis that quinidine displaces digoxin from the tissue binding sites (14). As shown in Table II, digoxin extensively binds to tissues such as skeletal muscle, liver, and heart, and the K_p values significantly decreased in the presence of quinidine. Straub *et al.* (13) recently reported that high concentrations of quinidine displace digoxin from bovine heart ATPase preparations. However, similar studies by Doering (2) failed to demonstrate the displacement of ouabain by quinidine from the sarcolemma fraction of lamb ventricular myocardium. Recent *in vitro* studies by Ball *et al.* (14) showed that quinidine competes for the binding site on Na^+,K^+-ATPase with digoxin. The effect of quinidine on Na^+,K^+-ATPase, however, occurred at considerably higher concentrations of quinidine than those in the therapeutic range found in humans. Thus, it is uncertain whether quinidine displaces digoxin from Na^+,K^+-ATPase in therapeutic serum concentrations. It has also been reported that another cinchona alkaloid, quinine, decreases the initial uptake rate of ouabain, a cardiac glycoside, by isolated rat hepatocytes (21). In a similar way, digoxin uptake may be inhibited by quinidine.

The renal clearance (CL_R) significantly decreased in the presence of quinidine (Table I). This suggested that quinidine may reduce digoxin secretion or increase digoxin reabsorption as shown in dogs (11), but it is difficult to determine which is the predominant factor from the restricted findings to date.

Koup *et al.* (22) reported the mean value of CL_{tot} for digoxin, which was significantly higher than that of the CL_R of digoxin in the human, and Fenster *et al.* (23) also reported a similar result. Furthermore, considerable biliary excretion of digoxin was evident in guinea pigs (24) and rats (25). It has been suggested that the CL_{tot} of digoxin in rats essentially reflected the sum of CL_R and the hepatic clearance (CL_H) which involves the biliary and metabolic clearance (25). Therefore, the mean metabolic clearance (CL_M) was estimated by the difference calculated by $CL_M = CL_{tot} - CL_B - CL_R$ (Table I). The decrease of CL_M in the quinidine-treated guinea pigs was not so remarkable when compared with the decreases in CL_B or CL_R.

The hepatic transport of digoxin may occur in at least two discernible steps: the uptake from plasma into liver and the transport from liver into bile. As shown in Table III, quinidine may suppress the carrier-mediated transport of digoxin from plasma to liver or the tissue binding, but the transport from liver to bile may not be affected by quinidine.

Table III—Liver-to-Plasma and Bile-to-Liver Concentration Ratios for Digoxin in Control and Quinidine-Treated Guinea Pigs [a]

	Control (Digoxin)	Digoxin plus Quinidine
Liver-to-Plasma	9.88 ± 0.40	1.95 ± 0.61[b]
Bile-to-Liver	4.25 ± 0.53	5.49 ± 3.10

[a] Results are given as the mean ± *SE* of three guinea pigs. The mean digoxin concentrations in the liver and plasma at 6 hr, and in the bile from 5 to 6 hr after bolus intravenous administration of 250 μg/kg of digoxin were used for the calculation of the ratios. [b] Significantly different ($p < 0.05$) from the control guinea pigs.

The distribution of digoxin to the CNS is of interest in view of the suggestion that some of the effects of cardiac glycosides may occur as a result of the effect on the CNS (26). As shown in Table II, the concentration of digoxin measured in the brain was low in guinea pigs (this study), and in humans (27) digoxin seems to gradually enter the spinal fluid. But the concentration of digoxin in the choroid plexus of the human has been found to be at least as high as that in the ventricular myocardium (27). The slow entry of digoxin into the brain may be due to an efflux mechanism through the choroid plexus. Thus, the increase of digoxin distribution to the brain at 1 hr after bolus intravenous administration in the presence of quinidine might be due to the inhibition of the transport system from the cerebrospinal fluid to blood through the choroid plexus for digoxin. On the contrary, the decrease of the apparent brain-to-plasma concentration ratio (K_p) at 6 hr after bolus intravenous administration of digoxin might be due mainly to the displacement of the glycosides from the binding sites (Na^+,K^+-ATPase) in the brain cells.

In conclusion, the quinidine–digoxin interaction was demonstrated in guinea pigs. Quinidine caused an inhibition in the tissue distribution of digoxin, which was shown in the significant decrease of the K_p values of digoxin, and this result may explain the significant decrease of Vd_{ss}. Furthermore, quinidine may cause a reduction of biliary, renal, and metabolic clearances, which significantly decrease the CL_{tot} of digoxin.

Pharmacokinetics of Heparin V: *In Vivo* and *In Vitro* Factors Affecting the Relationship Between Concentration and Anticoagulant Effect of Heparin in Rat Plasma

LLOYD R. WHITFIELD and GERHARD LEVY ˣ

Received June 21, 1982, from the *Department of Pharmaceutics, School of Pharmacy, State University of New York at Buffalo, Amherst, NY 14260.* Accepted for publication August 25, 1982.

Abstract □ There are appreciable interindividual variations in rats of baseline activated partial thromboplastin time (APTT) and of the anticoagulant effect of heparin added to plasma (as reflected by the slope of the regression line describing the essentially linear relationship between ln APTT and heparin concentration). Determination of baseline APTT and slope value on two occasions, 7 days apart, in the same rats revealed that (unlike in humans) these characteristics were subject also to considerable intraindividual variation. To explore the possible reasons for the observed variability, the effect of citrate concentration (acid citrate solution is used as a blood anticoagulant in the collection of plasma), calcium concentration (in the recalcifying solution used to initiate coagulation), and plasma incubation time (for activating the coagulation system) was determined. All three variables had pronounced effects on the anticoagulant response to heparin. Since rat erythrocytes are almost totally impermeable to citrate, hematocrit is a determinant of plasma citrate concentration when acid citrate solution is added in constant proportion to rat blood. Accordingly, inter- and intraindividual differences in baseline APTT and slope values were measured in another experiment in which the citrate solution to plasma (rather than blood) volume ratio was held constant and blood samples were obtained 30 days apart to permit the return of hematocrit values to normal. Intraindividual variation of the coagulation characteristics was appreciably decreased under these conditions. There are important differences between rats and humans with respect to the effect of citrate concentration and plasma incubation time on baseline APTT and on the anticoagulant action of heparin, as well as with respect to the relationship between these two characteristics.

Keyphrases □ Heparin—pharmacokinetics, concentration and anticoagulant effect, *in vivo* and *in vitro* factors □ Pharmacokinetics—heparin, concentration and anticoagulant effect, *in vivo* and *in vitro* factors □ Anticoagulants—heparin, effect of concentration, *in vivo* and *in vitro* factors, pharmacokinetics

Safe and effective anticoagulant therapy with heparin is complicated by the chemical and pharmacological heterogeneity of this natural product (1–3), by inter- and intraindividual differences in anticoagulant response (4–8) that necessitate individualization and frequent changes of the dosing rate of this drug, and by questions concerning the suitability of the various *in vitro* clotting tests used as intermediate therapeutic end points to serve as indices of therapeutic efficacy (prevention of thrombosis) and safety (absence of hemorrhagic episodes due to excessive anticoagulation) (9, 10). An individual's anticoagulant response to a given dose or dosing rate of heparin is subject to two sources of considerable variation, one pharmacokinetic and the other pharmacodynamic: the disposition (systemic clearance and biological half-life) of the drug and the relationship between heparin concentration in plasma (the site of anticoagulant action) and the magnitude of anticoagulant effect (6). Practical and ethical considerations impose limitations on exploration of these problems in humans and make it desirable to use animal models for certain pharmacokinetic and pharmacodynamic studies of heparin. The rat appears to be promising for this purpose. Like humans, rats exhibit dose-dependent elimination kinetics of heparin (11). The anticoagulant response to this drug as reflected by the activated partial thromboplastin time (APTT) is log-linearly related to the concentration of added heparin in plasma over a wide concentration range in both humans and rats (4, 11).

Studies in normal human adults (4) have shown a significant correlation between hematocrit and an index of the anticoagulant response of plasma to added heparin (the slope of the essentially linear relationship between ln APTT and the concentration of heparin added to plasma, to be referred to in this article as the slope or slope value). It has also been observed that there are pronounced interindividual differences in both baseline APTT (*i.e.*, APTT of plasma without added heparin) and slope value, but that intraindividual differences are relatively small in humans (4).

Contrary to these findings, it was found in the initial phase of the present study that baseline APTT and slope values in individual rats, while exhibiting similar interindividual differences as in humans, were poorly reproducible when measured again 7 days later. To explore the reasons for these intraindividual differences in rats, the relationship of hematocrit, citrate concentration (acid citrate solution is added to blood to prevent coagulation),

Pharmacokinetics of Heparin V: *In Vivo* and *In Vitro* Factors Affecting the Relationship Between Concentration and Anticoagulant Effect of Heparin in Rat Plasma

LLOYD R. WHITFIELD and GERHARD LEVY ˣ

Received June 21, 1982, from the *Department of Pharmaceutics, School of Pharmacy, State University of New York at Buffalo, Amherst, NY 14260.* Accepted for publication August 25, 1982.

Abstract □ There are appreciable interindividual variations in rats of baseline activated partial thromboplastin time (APTT) and of the anticoagulant effect of heparin added to plasma (as reflected by the slope of the regression line describing the essentially linear relationship between ln APTT and heparin concentration). Determination of baseline APTT and slope value on two occasions, 7 days apart, in the same rats revealed that (unlike in humans) these characteristics were subject also to considerable intraindividual variation. To explore the possible reasons for the observed variability, the effect of citrate concentration (acid citrate solution is used as a blood anticoagulant in the collection of plasma), calcium concentration (in the recalcifying solution used to initiate coagulation), and plasma incubation time (for activating the coagulation system) was determined. All three variables had pronounced effects on the anticoagulant response to heparin. Since rat erythrocytes are almost totally impermeable to citrate, hematocrit is a determinant of plasma citrate concentration when acid citrate solution is added in constant proportion to rat blood. Accordingly, inter- and intraindividual differences in baseline APTT and slope values were measured in another experiment in which the citrate solution to plasma (rather than blood) volume ratio was held constant and blood samples were obtained 30 days apart to permit the return of hematocrit values to normal. Intraindividual variation of the coagulation characteristics was appreciably decreased under these conditions. There are important differences between rats and humans with respect to the effect of citrate concentration and plasma incubation time on baseline APTT and on the anticoagulant action of heparin, as well as with respect to the relationship between these two characteristics.

Keyphrases □ Heparin—pharmacokinetics, concentration and anticoagulant effect, *in vivo* and *in vitro* factors □ Pharmacokinetics—heparin, concentration and anticoagulant effect, *in vivo* and *in vitro* factors □ Anticoagulants—heparin, effect of concentration, *in vivo* and *in vitro* factors, pharmacokinetics

Safe and effective anticoagulant therapy with heparin is complicated by the chemical and pharmacological heterogeneity of this natural product (1–3), by inter- and intraindividual differences in anticoagulant response (4–8) that necessitate individualization and frequent changes of the dosing rate of this drug, and by questions concerning the suitability of the various *in vitro* clotting tests used as intermediate therapeutic end points to serve as indices of therapeutic efficacy (prevention of thrombosis) and safety (absence of hemorrhagic episodes due to excessive anticoagulation) (9, 10). An individual's anticoagulant response to a given dose or dosing rate of heparin is subject to two sources of considerable variation, one pharmacokinetic and the other pharmacodynamic: the disposition (systemic clearance and biological half-life) of the drug and the relationship between heparin concentration in plasma (the site of anticoagulant action) and the magnitude of anticoagulant effect (6). Practical and ethical considerations impose limitations on exploration of these problems in humans and make it desirable to use animal models for certain pharmacokinetic and pharmacodynamic studies of heparin. The rat appears to be promising for this purpose. Like humans, rats exhibit dose-dependent elimination kinetics of heparin (11). The anticoagulant response to this drug as reflected by the activated partial thromboplastin time (APTT) is log-linearly related to the concentration of added heparin in plasma over a wide concentration range in both humans and rats (4, 11).

Studies in normal human adults (4) have shown a significant correlation between hematocrit and an index of the anticoagulant response of plasma to added heparin (the slope of the essentially linear relationship between ln APTT and the concentration of heparin added to plasma, to be referred to in this article as the slope or slope value). It has also been observed that there are pronounced interindividual differences in both baseline APTT (*i.e.*, APTT of plasma without added heparin) and slope value, but that intraindividual differences are relatively small in humans (4).

Contrary to these findings, it was found in the initial phase of the present study that baseline APTT and slope values in individual rats, while exhibiting similar interindividual differences as in humans, were poorly reproducible when measured again 7 days later. To explore the reasons for these intraindividual differences in rats, the relationship of hematocrit, citrate concentration (acid citrate solution is added to blood to prevent coagulation),

0022-3549/83/1000-1141$01.00/0

and calcium concentration (calcium chloride is added to the citrated plasma to initiate the clotting process) to baseline APTT and slope value were determined. Based on the results of these experiments, the assessment of inter- and intraindividual differences in baseline APTT and slope value was repeated under conditions in which the volume ratio of citrate solution to *plasma* (rather than blood, as is the usual practice) was kept constant. Since citrate is almost totally excluded from erythrocytes (12), this prevents any variation of plasma citrate concentration due to differences in hematocrit. Another variable studied in this investigation was the effect of the incubation time of citrated plasma with APTT reagent (before recalcification) on baseline APTT and on slope. The results of these studies (*a*) serve to identify those variables which have to be carefully controlled in pharmacodynamic and pharmacokinetic (based on bioassay) experiments on rats, (*b*) provide an indication of the magnitude of inter- and intraindividual differences of baseline APTT and anticoagulant effect of heparin in rats, and (*c*) permit a comparison of differences between humans and rats with respect to inter- and intraindividual variations of baseline APTT and slope, and the relationship of these two indices to one another and to certain other physiological and methodological variables.

EXPERIMENTAL

Adult, male Sprague–Dawley rats[1] were used in this investigation. They had free access to food[2] and water at all times. The APTT was determined as described previously (11): Samples of frozen citrated plasma were thawed at 37° and the tubes were then transferred to an ice-water bath. Within 1 hr, 0.25 ml of the plasma was transferred to a 0.75-ml polypropylene tube containing 10 μl of normal saline solution. One-tenth milliliter of this plasma was mixed with 0.1 ml of APTT reagent[3], and this mixture was incubated at 37° for exactly 15 min (except when incubation time was studied as a variable). One-tenth milliliter of calcium chloride solution (0.025 *M* except when calcium concentration was studied as a variable) was then added to initiate clotting. The incubation and subsequent determination of APTT were done with a coagulation timer[4]. All samples were prepared and APTT was measured in duplicate. The duplicate values, which usually varied by <4%, were averaged.

To determine the effect of added heparin on APTT, the 10 μl of normal saline solution added to a plasma sample for determination of baseline APTT was replaced by 10 μl of sodium heparin (bovine lung origin)[5] in normal saline solution. The heparin concentration in this solution was varied such as to yield plasma heparin concentrations of 0.05–1.0 U/ml, usually in nine increments. The slope of the relationship between ln APTT and heparin concentration was determined by least-squares linear regression analysis of APTT values obtained from plasma samples in the 0.1 to 1.0-U/ml heparin concentration range. The statistical significance of differences between slope values of plasma obtained on different days from the same animal was determined by analysis of covariance (13).

To determine the effect of plasma citrate concentration on baseline APTT and on the anticoagulant activity of heparin, 10-ml blood samples were collected from each of seven rats, weighing 470–567 g. The blood was drawn from the abdominal aorta, during ether anesthesia, into a plastic syringe containing 0.6 ml of 0.1 *M* acid citrate solution (14). The blood samples were pooled in a plastic beaker immersed in an ice-water bath and kept well mixed by magnetic stirring. Aliquots (9.6 ml) of the pooled, citrated blood were transferred by polypropylene pipet to screw-capped polycarbonate centrifuge tubes containing 0.45 ml of either isotonic saline solution or acid citrate solution of six different (66–330 m*M*) concentrations. Since citrate is almost totally excluded from rat erythrocytes (12), the plasma citrate concentration was calculated from the known whole blood citrate concentration and the hematocrit. Plasma was obtained by centrifuging the blood samples at 14,000×*g* for 5 min in a temperature-controlled centrifuge at 15°, and baseline APTT and slope value were determined as described in the preceding paragraphs.

The effect of calcium chloride concentration in the recalcifying solution used to initiate plasma clotting was determined at a constant citrate concentration (*i.e.*, changing calcium–citrate concentration ratio) and at a constant calcium–citrate concentration ratio[6]. Pooled citrated plasma was obtained from eight rats, weighing 442–530 g, using the aforementioned procedure except that the final citrate concentration in half of the plasma samples was kept constant. The calcium chloride concentration in the recalcifying solution ranged from 12.5 to 46.6 m*M*, in six increments. Baseline APTT and slope values were determined.

To determine the effect of incubation time on baseline APTT and slope, 10-ml blood samples were obtained from each of 15 rats weighing 344–382 g. A 30-μl sample of blood was first drawn from the tail artery into a heparinized microhematocrit tube; the tube was centrifuged (4) and the hematocrit determined. A sufficient volume of acid citrate solution was then drawn into a plastic syringe such that on collection of 10 ml of blood from an animal, the volume ratio of citrate solution to plasma was 1:6. Individual plasma samples from five of the rats were divided into three equal volumes, and plasma samples from the other 10 rats were divided into two equal volumes. One of the plasma aliquots from each of the initial five rats was used to determine the time required for maximum activation of the intrinsic coagulation pathway. This was done by incubating the citrated plasma–APTT reagent mixture at 37° in covered tubes for 1–20 min before recalcification. Except for the variation of incubation time, the APTT measurements were performed by the standard procedure. Based on the results of the five-animal study, baseline APTT and slope value determinations on plasma from the other 10 rats were made after 3 and 15 min of incubation. (It should be noted that these experiments were not done with pooled plasma, but with individual plasma samples from a total of 15 animals.)

Inter- and intraindividual differences of baseline APTT and slope values were determined in two experiments. All rats had a silicone rubber cannula implanted in the right jugular vein under ether anesthesia 3 days before the start of the experiment (15). Their body weight and hematocrit were determined on each study day. Thirteen animals were used in the first experiment. On day 1, 4 ml of blood was collected through the cannula in a plastic syringe containing 0.44 ml of 0.1 *M* acid citrate solution using the technique previously described (11). On day 7, 9 ml of blood was obtained from the abdominal aorta, under ether anesthesia, in a plastic syringe containing 1 ml of the acid citrate solution. The second experiment, with 12 rats, consisted of blood withdrawals on days 1 and 30. In this experiment, hematocrit was determined first from a microsample of blood taken from the tail artery, and the volume of acid citrate solution was individualized to yield a constant acid citrate solution–plasma volume ratio of 1:6. In all cases, the blood and citrate anticoagulant solution were mixed gently and platelet-poor plasma was separated by centrifugation at 14,000×*g* for 5 min at 15° in polycarbonate tubes. These plasma samples were transferred to stoppered polypropylene tubes, frozen in a dry ice–methanol bath, and stored at −80° until assayed.

RESULTS

The baseline APTT in a group of 13 rats ranged from 11.1 to 27.1 sec, averaging 19.5 sec. Identical average APTT and a similar range of individual values were found in the same animals 7 days later, but there was no significant correlation between the day 1 and day 7 baseline APTT values in individual rats (Table I). An essentially linear correlation between ln APTT and the concentration of heparin added to plasma was consistently found over a heparin concentration range from 0.1 to 1.0 U/ml. However, the APTT at a heparin concentration <0.1 U/ml and the baseline APTT were usually above the linear regression line (Fig. 1). Slope values ranged from 1.14 to 2.31 ml/U on day 1 and from 1.36 to 2.49 ml/U on day 7; 7 of the 13 animals had significantly different slope values on these 2 days and there was no apparent correlation between day 1 and day 7 slope values for individual rats (Table I). On day 1, baseline APTT showed a positive correlation with hematocrit; on days 1 and 7, the slope correlated negatively with hematocrit (Table II).

Slope *versus* hematocrit, day 7	−0.75	<0.01

[a] N.S. = not significant.

The baseline APTT and slope values were found to be extensively affected by the concentration of citrate added as an anticoagulant to the blood to permit separation of plasma. The baseline APTT increased with increasing citrate concentration while the slope decreased (Table III). The opposite relationships were observed with respect to the concentration of calcium used to initiate the clotting process: baseline APTT decreased and slope increased with increasing calcium concentration (Table IV). When citrate and calcium concentrations were increased simultaneously, at a constant ratio, the citrate effect predominated with respect to the baseline APTT (which increased with increasing concentration), while the calcium effect predominated with respect to slope (which also increased with increasing concentration) (Table V).

Incubation time of citrated plasma with APTT reagent (before addition of calcium to initiate clotting), intended to activate the intrinsic coagulation pathway, had a pronounced effect on APTT. As reflected by the decreasing APTT, the activation process predominated during the first 3 min (Fig. 2). At longer incubation times, APTT gradually increased, suggesting degradation of one or more components of the coagulation system. Comparing the results obtained after 3 and 15 min of incubation, the change in slope values was relatively more pronounced than the change in baseline APTT (Table VI). However, the 3- and 15-min values for the same animals correlated strongly, and the ratio of the 15- to 3-min values varied little between animals (Table VI). The intercept of the ln APTT *versus* heparin concentration regression lines at zero heparin concentration determined in this experiment is lower, on the average, than baseline APTT (Fig. 1).

Based on the preceding results, the reproducibility of individual baseline APTT and slope values was reexamined in another experiment (Table VII). Compared with the first experiment (Table I), the citrate solution–plasma volume ratio rather than the citrate solution–blood volume ratio was held constant, and the time interval between repeated measurements was lengthened from 7 to 30 days. The mean baseline APTT values and standard deviations obtained in the two studies are similar. The slope values in the second experiment are slightly higher than those in the first experiment, but the coefficients of variation are similar.

Table III—Effect of Added Citrate on the Baseline APTT of Pooled Rat Plasma and on the Anticoagulant Response to Added Heparin[a]

Citrate Concentration in Plasma, m*M*	Baseline APTT[b], sec	Slope[c], ml/U
8.75	11.6	2.31
13.5	17.8	2.42
17.5	24.6	1.87
20.9	27.1	1.59
24.3	31.4	1.55
32.7	38.6	1.33

[a] Calcium concentration in recalcifying solution was constant at 25 m*M*. [b] Significantly correlated with citrate concentration ($r = 0.991$, $p < 0.001$). [c] Significantly correlated with citrate concentration ($r = -0.923$, $p < 0.01$).

Table IV—Effect of Added Calcium Concentration on the Baseline APTT of Pooled Rat Plasma and on the Anticoagulant Response to Added Heparin[a]

Calcium Chloride Concentration[b], m*M*	Baseline APTT[c], sec	Slope[d], ml/U
12.5	37.6	0.85
19.0	24.8	1.09
25.0	28.6	1.38
29.8	22.6	2.57
34.6	21.8	2.14
46.6	21.8	2.46

[a] Citrate concentration in plasma was constant at 18.75 m*M*. [b] Refers to concentration in the recalcifying solution added to plasma. [c] Not significantly correlated with calcium concentration ($r = -0.78$). [d] Significantly correlated with calcium concentration ($r = 0.864$, $p < 0.05$).

Based on the preceding results, the reproducibility of individual baseline APTT and slope values was reexamined in another experiment (Table VII). Compared with the first experiment (Table I), the citrate solution–plasma volume ratio rather than the citrate solution–blood volume ratio was held constant, and the time interval between repeated measurements was lengthened from 7 to 30 days. The mean baseline APTT values and standard deviations obtained in the two studies are similar. The slope values in the second experiment are slightly higher than those in the first experiment, but the coefficients of variation are similar.

Table V—Effect of Added Citrate and Calcium Concentrations[a] on the Baseline APTT of Pooled Rat Plasma and on the Anticoagulant Response to Added Heparin

Concentration, m*M*		Baseline APTT[b], sec	Slope[c], ml/U
Citrate in Plasma	Calcium Chloride in Recalcifying Solution		
8.74	12.5	9.7	1.47
13.5	19.0	15.8	1.83
17.5	25.0	19.0	1.92
20.9	29.8	25.6	1.92
24.3	34.6	27.0	2.59
32.7	46.6	39.0	2.75

[a] At a constant concentration ratio. [b] Significantly correlated with citrate and calcium concentrations ($r = 0.994$, $p < 0.001$). [c] Significantly correlated with citrate and calcium concentrations ($r = 0.943$, $p < 0.01$).

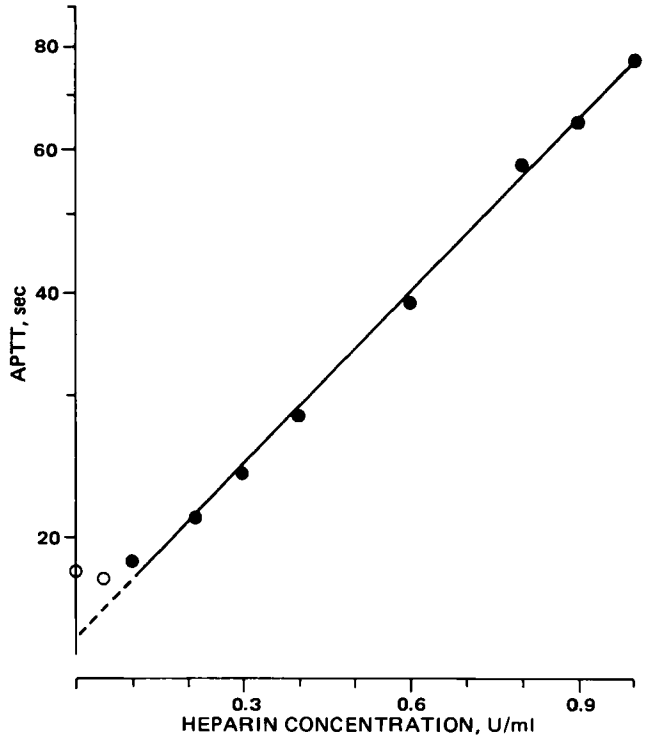

Figure 1—*Relationship between APTT and concentration of added heparin in plasma of a rat. The ordinate scale is logarithmic. The open circles at zero and very low heparin concentrations are usually above the regression line, which was calculated without these two data points. The incubation time was 15 min.*

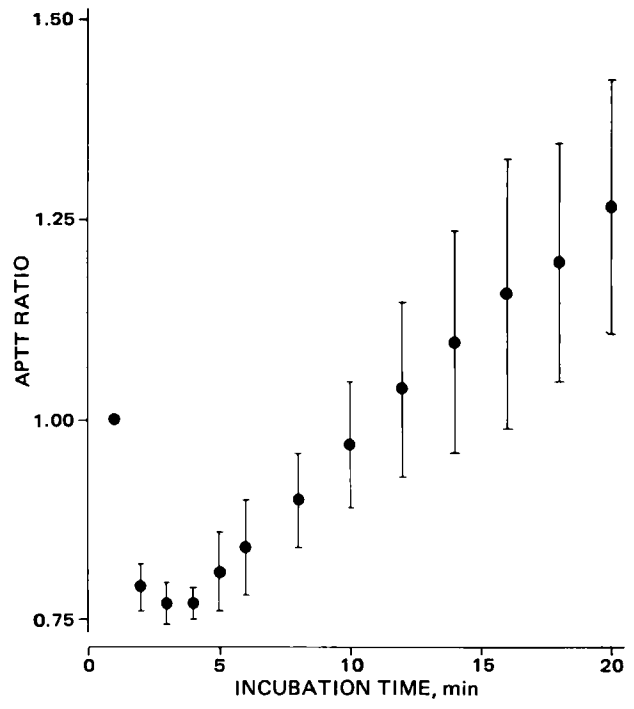

Figure 2—*Effect of incubation time on the baseline APTT of plasma from five rats. Plotted are the APTT ratios (APTT at a given time/APTT at 1 min), as mean ±SD, against incubation time. The APTT at 1 min ranged from 15.4 to 23.9 sec.*

The correlation coefficients for the baseline APTT and slope values, respectively, of the first and last day of each study were higher in the second study. Only the second study showed a statistically significant correlation between slope values obtained on different days from the same animals. During the 30-day interval of the second study, hematocrit values returned to normal, and body weight of the animals increased significantly (Table VII).

DISCUSSION

The magnitude of interindividual variation of baseline APTT and slope values observed in this investigation is similar to that found previously in another investigation on rats (11)[7] and is similar also to the magnitude of interindividual variation of these characteristics in humans (4, 5). All of the cited studies were carried out, at various times, in this laboratory with reagents from the same sources and with the same coagulation timer and are therefore readily comparable. However, unlike the situation in humans (4), the reproducibility of baseline APTT and slope values determined twice, on different days, in the rats was poor (Table I). An examination of the results of the first crossover experiment in rats (Tables I and II) suggested that one reason for the relatively poor reproducibility of individual results may be related to the inter- and intraindividual variation of hematocrit values.

Baseline APTT and slope values were significantly correlated with hematocrit (Table II). Since the permeability of rat erythrocytes to citrate is almost negligible (13) and the standard method of blood collection for plasma APTT determinations involves the addition of acid citrate anticoagulant solution to *blood* in a constant volume ratio, increasing hematocrit values are associated with increasing citrate concentration in *plasma*. As citrate concentrations are increased (all else being constant by use of pooled blood), baseline APTT increases and slope values decrease (Table III). The positive correlation between hematocrit and baseline APTT and the negative correlation between slope and hematocrit, obtained by statistical analysis of individual results from 13 rats (Table II), are consistent with these observations. Thus, a modification of the experimental methodology whereby the citrate solution–blood volume ratio is individualized on the basis of the animal's hematocrit such as to assure a constant citrate solution–plasma volume ratio was indicated. Moreover, a 7-day interval between blood withdrawals was apparently not sufficient for the animals to regenerate the considerable volume of blood that was taken on the first day of the experiment, as reflected by the significantly lower hematocrit values on the seventh day (Table I). It is possible also that the levels of certain clotting factors, which are likely to have been lowered by the first blood withdrawal, may not have returned to normal within 7 days. It was therefore deemed advisable to increase the time interval between blood withdrawals considerably.

In the second experiment to determine inter- and intraindividual differences in baseline APTT and slope value, the citrate solution–plasma volume ratio was held constant, and the interval between the two blood withdrawals was 30 days. The results of this experiment (Table VII) yielded higher correlation coefficients for the individual pairs of baseline APTT and slope values, respectively, than in the first experiment. The hematocrit values had returned to normal within the 30-day period. However, while intraindividual variation was decreased relative to the first experiment, interindividual variation was not appreciably different. The correlation between slope values and hematocrit was no longer statistically significant (Table VIII). On the other hand, there remains a significant correlation between hematocrit and baseline APTT, but this correlation is now negative rather than positive. The reason for this is

Table VI—Effect of Incubation Time on the Baseline APTT of Plasma from Rats and on the Anticoagulant Response to Added Heparin [a]

	Incubation Time, min		Ratio	Correlation Coefficient	
	3	15	15:3 min		
Baseline APTT, sec	18.6 ± 2.8	24.5 ± 3.0	1.32 ± 0.08	0.933	$p < 0.001$
Ordinate Intercept, sec	17.3 ± 2.4	20.5 ± 2.5[b]	1.19 ± 0.09	0.855	$p < 0.001$
Slope, ml/U	0.98 ± 0.13	1.74 ± 0.26	1.78 ± 0.13	0.872	$p < 0.001$

[a] Data and ratio values are expressed as mean ± *SD*, $n = 15$. [b] Significantly different from baseline APTT, $p < 0.001$.

[7] The slope values reported by Bjornsson and Levy (11) are based on heparin concentrations in plasma before it was diluted 10-fold for APTT determination. The slope values in the present study are based on heparin concentration in plasma that was used undiluted for APTT determination. For comparison with the results of this investigation, the slope values reported by Bjornsson and Levy (11) must be multiplied by 10.

Table VII—Baseline APTT, Slope, Hematocrit, and Body Weight of Rats Determined Twice, 30 Days Apart When the Citrate Solution–Plasma Volume Ratio was Constant at 1:6

[a] Significantly different ($p < 0.05$) from slope value on day 1. [b] N.S. = not significant.

unknown; it could reflect differences in dilution (by the addition of acid citrate solution to blood in variable proportions) of one or more endogenous substances that distribute readily between plasma and erythrocytes and whose concentration is relevant to the clotting of plasma.

One potential alternative to individualization of the citrate solution–blood volume ratio (to achieve a constant citrate solution–plasma volume ratio) is to adjust the concentration of calcium chloride in the recalcifying solution such as to achieve a constant molar ratio of citrate to calcium. Increasing the concentration of calcium while citrate concentration was held constant did in fact cause an increase in slope and may also have decreased baseline APTT, although the latter effect was not statistically significant (Table IV). However, maintaining a constant molar ratio of citrate to calcium did not abolish the citrate concentration dependency of baseline APTT and indicated a predominance of the calcium effect over the citrate effect on the slope (Table V).

It has been the practice in this laboratory to incubate the plasma–APTT reagent mixture 15 min, rather than the customary 3 or 5 min, for activation of the intrinsic coagulation pathway. This change was made to increase the sensitivity of the APTT to changes of heparin concentration. A detailed study of the relationship between APTT and incubation time revealed considerable complexity (Fig. 2), with the activation process predominating initially and degradation of component(s) of the clotting process predominating at later times (after ~3 min). Increased incubation time had a more pronounced effect on slope than on baseline APTT (Table VI) and contributed to a more pronounced difference between the actual and apparent baseline APTT, determined by back-extrapolation of the ln APTT–heparin concentration regression line to a heparin concentration of zero (Fig. 1, Table VI). Since there is a relatively constant relationship between baseline APTT and slope values, respectively, obtained after 3 and 15 min of incubation, the time variable should have little or no effect on the analysis and interpretation of the results of heparin studies such as the one described here. The 15-min procedure is more sensitive to heparin concentration (due to the increased slope value) and is more convenient.

The results of this investigation, assessed in conjunction with the results of corresponding clinical studies also performed in this laboratory (4, 5) provide interesting information concerning species differences between rats and humans (Table IX). These differences should be appreciated in the context of the two major similarities between these species: the pharmacokinetics of heparin are dose dependent and there is an essentially linear relationship between ln APTT and heparin concentration in both humans and rats (11). On the other hand, citrate concentration in plasma has a pronounced effect on baseline APTT and slope in rats, but not in humans. Both human and rat erythrocytes are essentially impermeable to citrate (12). In view of the pronounced citrate concentration effect in rats, the human experiments were repeated recently and the previously observed lack of a citrate concentration effect was reconfirmed (unpublished data).

Another striking difference between rats and humans is the effect of plasma incubation time on APTT. The APTT of human plasma decreased and eventually reached a constant value during incubation for up to 21 min (5), indicative of activation of the clotting system without noticeable degradation of clotting factors. On the other hand, the APTT of rat plasma first decreases (indicative of activation) and then increases,

Table VIII—Correlations of Data in Table VII

Data Pair	Correlation Coefficient	Significance, p
Baseline APTT *versus* slope, day 1	−0.70	<0.05
Baseline APTT *versus* slope, day 30	−0.67	<0.05
Baseline APTT *versus* hematocrit, day 1	−0.10	N.S.[a]
Baseline APTT *versus* hematocrit, day 30	−0.66	<0.05
Slope *versus* hematocrit, day 1	0.01	N.S.
Slope *versus* hematocrit, day 30	0.48	N.S.

[a] N.S. = not significant.

Table IX—Comparison of Healthy Humans and Rats with Respect to the Coagulation of Plasma and the Anticoagulant Effect of Heparin [a]

Characteristics	Humans	Rats[b]
Relationship between ln APTT and added heparin concentration	Linear	Linear
Effect of incubation time on APTT	Decreases asymptotically	First decreases, then increases
Effect of citrate concentration	No effect on baseline APTT or slope	Significant positive correlation with baseline APTT and significant negative correlation with slope
Slope–hematocrit correlation	Significant, negative	(*a*) Often significant, negative (*b*) no correlation
Slope–baseline APTT correlation	Significant, positive	(*b*) Significant, negative
Baseline APTT–hematocrit correlation	Not significant[c]	Variable
Citrate uptake by erythrocytes	Negligible	Negligible
Reproducibility of baseline APTT values on repeated testing at different times	Excellent	Very poor
Reproducibility of slope values on repeated testing at different times	Excellent	Poor

[a] Based on our previous studies (4, 5, 13) and on the results of the present study. [b] Different results were observed in some cases depending on whether plasma was obtained from animals with (*a*) citrate solution–blood volume ratio held constant or (*b*) citrate solution–plasma volume ratio held constant. [c] Significant negative correlation in patients (5, 7).

apparently due to the opposing effects of activation and subsequent degradation of coagulation factors. In a search for factors that may be useful for predicting an individual patient's response to heparin, baseline APTT has emerged as the variable which consistently correlates positively with slope value (4, 5, 8). Unlike humans, rats exhibit a negative correlation between baseline APTT and slope value. The reason for this species difference is not known.

In summary, coagulation studies in rats require considerably more attention to the control of the variables examined in this investigation than do similar studies in humans. The volume of blood required to determine baseline APTT and slope represents a significant fraction of a rat's total blood volume, but is negligible compared with the human blood volume. This is an additional complicating factor in studies on rats. The observed species variation may, however, be useful for exploring various aspects of the blood coagulation process. Parallel and coordinated studies on humans and rats, and perhaps also on other species, may facilitate the elucidation of important pharmacokinetic and pharmacodynamic aspects of the anticoagulant action of heparin.

Distribution and Elimination of Poly(methyl methacrylate) Nanoparticles After Subcutaneous Administration to Rats

JÖRG KREUTER *x, **M. NEFZGER** ‡, **E. LIEHL** ‡, **R. CZOK** ‡, and **R. VOGES** §

Received June 14, 1982, from the *School of Pharmacy, Federal Institute of Technology, CH 8092 Zurich, Switzerland, ‡SANDOZ Forschungsinstitut, A 1235 Vienna, Austria, and §SANDOZ LTD., CH 4002 Basle, Switzerland. Accepted for publication August 25, 1982.

Abstract □ Poly(methyl [1-^{14}C]methacrylate) nanoparticles were injected subcutaneously into rats. Almost all of the radioactivity stayed at the injection site. After an initial urinary and fecal excretion of ~1% of the administered dose per day, the rate of elimination dropped to a low level (~0.005%/day *via* the feces and ~0.0005%/day *via* the urine) within 70 days. After 200 days, the fecal elimination increased exponentially until a >100-fold increase was observed after 287 days in one rat. After this time, a tendency for an increase in fecal elimination was also observed in the other animals, and the radioactivity in all organs and tissue increased by ~100 times in all animals in comparison with the organ radioactivity determinations at earlier times.

Keyphrases □ Poly(methyl methacrylate)—^{14}C-labeled nanoparticles, distribution and elimination in rats, subcutaneous administration □ Distribution—^{14}C-labeled poly(methyl methacrylate) nanoparticles, subcutaneous administration in rats □ Elimination—^{14}C-labeled poly(methyl methacrylate) nanoparticles, subcutaneous administration in rats

Poly(methyl [1-^{14}C]methacrylate) nanoparticles were shown to be promising adjuvants for vaccines (1–4). In contrast to the rapidly biodegradable cyanoacrylates, they achieve a good adjuvant effect. The reproducibility of the adjuvant effect was much better than that of the presently widely used aluminum hydroxide (5). Moreover, in preliminary experiments (2), poly(methyl [1-^{14}C]methacrylate) nanoparticles seem to cause much milder tissue reactions than aluminum hydroxide.

However, the distribution and elimination of these nanoparticles after subcutaneous administration so far has not been studied. In a previous study (6) concerning the fate of poly(methyl [1-^{14}C]methacrylate) nanoparticles after intravenous administration, a strong affinity of the nanoparticles to the reticuloendothelial system, especially to the liver, was observed.

The elimination of radioactivity after implantation of poly(methyl [1-^{14}C]methacrylate) films was investigated in two studies (7, 8). In one study (7), an elevated elimination rate of radioactivity was observed in the urine between 2 and 8 weeks, decreasing to minimal values after this time. This elimination was probably caused by residual monomers or low-molecular weight components present in the polymer films. After 54 weeks, however, considerable radioactivity suddenly started to be eliminated (8), indicating a degradation of the polymer. This study investigates the elimination pattern and distribution

After an initial urinary and fecal excretion of ~1% of the administered dose per day, the rate of elimination dropped to a low level (~0.005%/day *via* the feces and ~0.0005%/day *via* the urine) within 70 days. After 200 days, the fecal elimination increased exponentially until a >100-fold increase was observed after 287 days in one rat. After this time, a tendency for an increase in fecal elimination was also observed in the other animals, and the radioactivity in all organs and tissue increased by ~100 times in all animals in comparison with the organ radioactivity determinations at earlier times.

Keyphrases □ Poly(methyl methacrylate)—^{14}C-labeled nanoparticles, distribution and elimination in rats, subcutaneous administration □ Distribution—^{14}C-labeled poly(methyl methacrylate) nanoparticles, subcutaneous administration in rats □ Elimination—^{14}C-labeled poly(methyl methacrylate) nanoparticles, subcutaneous administration in rats

Poly(methyl [1-^{14}C]methacrylate) nanoparticles were shown to be promising adjuvants for vaccines (1–4). In contrast to the rapidly biodegradable cyanoacrylates, they achieve a good adjuvant effect. The reproducibility of the adjuvant effect was much better than that of the presently widely used aluminum hydroxide (5). Moreover, in preliminary experiments (2), poly(methyl [1-^{14}C]methacrylate) nanoparticles seem to cause much milder tissue reactions than aluminum hydroxide.

However, the distribution and elimination of these nanoparticles after subcutaneous administration so far has not been studied. In a previous study (6) concerning the fate of poly(methyl [1-^{14}C]methacrylate) nanoparticles after intravenous administration, a strong affinity of the nanoparticles to the reticuloendothelial system, especially to the liver, was observed.

The elimination of radioactivity after implantation of poly(methyl [1-^{14}C]methacrylate) films was investigated in two studies (7, 8). In one study (7), an elevated elimination rate of radioactivity was observed in the urine between 2 and 8 weeks, decreasing to minimal values after this time. This elimination was probably caused by residual monomers or low-molecular weight components present in the polymer films. After 54 weeks, however, considerable radioactivity suddenly started to be eliminated (8), indicating a degradation of the polymer. This study investigates the elimination pattern and distribution

of radioactivity in the body after subcutaneous administration of poly(methyl methacrylate) nanoparticles.

EXPERIMENTAL

Preparation of Poly(methyl [1-^{14}C]methacrylate) Nanoparticles—Methyl [1-^{14}C]methacrylate was prepared in a three-step reaction sequence starting from barium [^{14}C]carbonate. Carboxylation of isopropylmagnesium iodide, bromination of the resulting [1-^{14}C]isobutyric acid, and subsequent methanolysis gave methyl 2-bromo[1-^{14}C]isobutyrate (9). Hydrogen bromide elimination in 1,5-diazabicyclo[5.4.0]-undec-5-ene at 110° led to methyl [1-^{14}C]methacrylate, which was continuously removed from the reaction mixture by a slow stream of helium, and collected at −196°. The ester was vacuum-transferred into phosphate-buffered saline to give a 0.5% solution. The chemical identity and chemical and radiochemical purity (>95%) were confirmed by GC after ether extraction.

The monomeric methyl [1-^{14}C]methacrylate saline solution was used for the preparation of two nanoparticle suspensions, with and without influenza virions, for subcutaneous administration. The nanoparticles were produced by γ-irradiation-initiated polymerization with 500 krad (2.2 krad/min) in a ^{60}Co-source. Thus, the following suspensions were obtained:

1. Polymerization in the presence of influenza virions afforded a 0.35% suspension at a specific activity of (5.30 ± 0.82) × 10^8 dpm/ml in which all virions were incorporated into the nanoparticles.

2. Polymerization in the absence of influenza virions afforded a 0.35% suspension of virus-free nanoparticles at a specific activity of (5.22 ± 0.46) × 10^8 dpm/ml.

That the nanoparticles tended to flocculate led to difficulties in the reproducibility of the radioactivity measurements and the determination of the exact amount of the administered nanoparticles. Although the suspensions were permanently stirred during sampling of the aliquots for calibration or administration, the relative standard deviations were 14% for 0.1-ml samples of the virus-free nanoparticle suspension (26 determinations) and 9% for 0.1-ml samples containing the virion-incorporated nanoparticles (14 determinations). The addition of substituted methyl cellulose[2] as a stabilizer did not reduce the variation. The previously used technique of freeze-drying the suspensions (6) to obtain a homogeneous distribution of radioactivity within the resulting nanoparticle powder was not applicable because the virions would have been destroyed by this technique.

Although the animals obtained a fivefold higher volume than that used for calibration, similar variations in the dose actually administered have to be taken into consideration. Nevertheless, the material balance (the mean from the calibration experiments) is satisfactory (Table I). Since no apparent differences in the distribution and elimination of the nanoparticle preparations could be observed, both preparations were treated together as one set of data.

Excretion and Tissue Distribution after Subcutaneous Administration—A 0.5-ml aliquot of the thoroughly stirred suspension was subcutaneously injected into the neck of Sprague–Dawley rats, weighing 170–207 g, at the beginning of the study. One group of five male and five female rats received the virus-containing preparation and a second group of the same composition received the preparation with virus-free nanoparticles. The animals were kept in metabolism cages and had free access to water and food.

The elimination of radioactivity of two animals per group was measured in urine and feces up to 287 days after administration. For the determination of radioactivity in the organs, two animals per group were sacrificed at 15, 45, 66, 157, and 287 days after dosing.

Urine was collected separately from feces and stored at ~ −60°. The storage container contained 100 μl of diethylamine to maintain the urine at a pH ≥ 9, thus ensuring the binding of the radioactivity excreted as carbonate. After each collection period, the cage was rinsed with water (30–40 ml) to wash out dried urine residues. The collected feces were homogenized with approximately the same weight of water. Three samples (200–400 mg) of each homogenate were analyzed.

The radioactivity in the organs was measured after sacrificing the animals by an ~0.5 ml ip injection of euthanasia solution[3]. From the adrenal glands, epididymis, ovary, thyroid gland, lymph nodes, and bone marrow one sample of 7–130 mg was taken; from the other organs two samples of 50–400 mg each were taken. At the application site, remaining depots were dissected and combusted[4]. The resulting carbon dioxide was absorbed in a mixture of absorber solution and scintillation cocktail[5] and diluted up to 100 times before counting with the same mixture.

The radioactivity of the excreta, blood, plasma, and organs was determined after predrying and combustion in oxygen using a sample oxidizer (recovery of radioactivity 92–100%). The resulting [^{14}C]carbon dioxide was absorbed in the aforementioned scintillation cocktail. The samples were then counted in a liquid scintillation counter for 20 min. The counting efficiency was determined by the external standard method; the detection limit was 4 ng/g for the bone marrow, lymph nodes, and thyroid gland and 2 ng/g for all other organs and tissue.

RESULTS AND DISCUSSION

The organ and tissue distribution after subcutaneous administration of the poly(methyl [1-^{14}C]methacrylate) nanoparticles is shown in Table II. With the exception of the injection site, <0.1% of the administered dose could be found in the rest of the body within 15 and 157 days. The major amount of the radioactive material remained at the injection site (Tables I and III), where a hard yellow disk, ~5 mm, was found. The formation of this disk is probably caused by encapsulation with collagenous tissue, which represents the normal reaction of the body (10–12). Even after 287 days, 55–71% of the administered dose remained at the site of injection. This finding confirms previous macroautoradiographic studies in mice, in which radioactivity was detectable only at the injection site for 70 days.

In the rest of the body, the highest amounts of radioactivity were observed in the liver, spleen, lymph nodes, bone marrow, renal fatty tissue, skin, and pancreas. The comparatively high radioactivity levels in the liver, spleen, and bone marrow were not unexpected, since this was also

287	69.4	71.1	61.9	55.4

seen after intravenous administration. In contrast to the intravenous study, the radioactivity in the lymph nodes was high in some cases.

The radioactivity in the organs decreased from day 15 until day 157. Between day 157 and day 287, a sudden ~100-fold increase in radioactivity occurred in all organs of all animals. The ratio of blood radioactivity to organ radioactivity, however, remained largely unaltered (Table IV). This indicates that nanoparticles or their degradation products were transported *via* the blood.

The excretion of the radioactivity in the urine of four rats is shown in Fig. 1; the excretion in the feces is shown in Fig. 2. Initially, the excretion of radioactivity was rapid: approximately 1% of the administered dose was excreted per day in the urine, with approximately the same amount excreted in the feces. Consequently, ~6% of the dose was eliminated *via* the urine and 5% *via* the feces within 7 days. However, the excretion rate dropped very rapidly until a very slow constant logarithmic decline of the excretion rate was reached after ~70 days. At this stage, only ~0.005% of the administered dose was eliminated per day, mainly *via* the feces ($t_{1/2}$ ~ 140 days) where the level of excretion was ~10 times higher than in the urine ($t_{1/2}$ ~ 170 days). After ~200 days, however, the rate of excretion started to increase continuously in one rat until a >100-fold increase was reached after 287 days. At this stage, the elimination rate amounted to 1% of the administered dose per day. A tendency for an increase in the excretion rate also could be observed in the three other animals at the end of the observation period.

The observed increases in the excretion rate do not seem to be coincidental, since they were accompanied by the aforementioned 100-fold increase in the radioactivity level of all organs in all four rats. The ob-

servation of a lag phase for the elimination of implanted material is not new. In 1955, Oppenheimer *et al.* (8) observed a lag period of 54 weeks after implantation of poly(methyl [1-^{14}C]methacrylate) films into rats, until suddenly the excretion of radioactivity started and continued for 40 weeks. When the films were removed, the excretion of radioactivity disappeared. Schindler *et al.* (13) observed with polylactide implants that degradation of the polymer, measured by the decrease in the molecular weight *via* the viscosity of the implant, started soon after administration. The removal of material from the administration site, however, occurred only after a certain molecular weight was reached. After implantation of poly(ε-caprolactone-co-DL-lactic acid) capsules for instance, the viscosity decreased by 75%, while only 1% of the injected capsule material was removed from the injection site. Since the viscosity is directly related to the molecular weight, a comparable reduction of ~75% in the molecular weight has to be assumed. Over the following 8 weeks, the residual polymer disappeared totally from the site of administration, while the viscosity decreased only slowly.

A similar process possibly occurred after subcutaneous administration of poly(methyl [1-^{14}C]methacrylate) nanoparticles and films. The degradation might have started rather early after injection or implantation, but the removal from the site of administration and the excretion began only when a certain molecular weight of the degradation products was reached. The faster excretion rate during the first couple of days can also be explained by the limitation of the transportation and excretion process by the molecular weight. The initially excreted total amount of ~13% far exceeds the possible amount of residual monomers. As mentioned previously, ≤1% residual monomers are contained in the polymer. However, as shown by gel permeation chromatography (14), the molecular weight distribution of the poly(methyl [1-^{14}C]methacrylate) nanoparticles prepared by γ-irradiation is rather wide, allowing for a considerable amount of low-molecular weight polymer, some of which could be readily excreted.

Solid-State Decomposition of Alkoxyfuroic Acids in the Presence of Microcrystalline Cellulose

J. T. CARSTENSEN ˣ and ROHIT C. KOTHARI *

Received April 9, 1982, from the *School of Pharmacy, University of Wisconsin, Madison, WI 53706.* Accepted for publication August 24, 1982. * Present address: Riker Laboratories, St. Paul, MN 55119.

Abstract □ A solid–solid interaction between alkoxyfuroic acids and microcrystalline cellulose has been studied. The decomposition of the mixture differs from that of the drug(s) alone, in that carbon monoxide (not carbon dioxide) is the high-temperature decomposition product. A model is proposed in which interaction occurs at contact points. A liquid decomposition product, dissolving part of the alkoxyfuroic acid (to the extent of its solubility) serves as a carrier, so that the number of contact points increases, thus accelerating the reaction. Both the main and ancillary parameters have calculated values that are consistent with the model.

found to contain 3% water as determined by (*a*) use of a vacuum electrobalance and (*b*) Karl Fischer titration. To eliminate the effect of water, the microcrystalline cellulose was dried *in vacuo* on a high-vacuum rack for 10 hr just prior to the preparation of the sample for kinetic studies.

The kinetic studies were carried out by mixing furoic acid with microcrystalline cellulose (see below) and placing the powder mixture in the sidearm of a fused manometer as described by Carstensen and Kothari (5). This was then placed in a constant-temperature bath as shown in Fig. 1, and the level of the mercury was determined as a function of time. The volumes of sample bulb and of the high-pressure side of the manometer (as a function of level) were determined as described by Carstensen and Musa (6). Knowledge of the density of mercury at the temperature in question allows conversion of mercury level to pressure, and hence the number of moles of gas produced can be calculated by means of the ideal gas law.

Although the decomposition of the two solids takes place in the absence of air, there is mercury vapor in the atmosphere above the solids which has been shown to effect some systems (7). The decomposition was, therefore, carried out in breakseal tubes (7) for certain samples. In a breakseal tube sample there is no mercury vapor in the head space. No significant difference was observed in decomposition rates, so that, unless otherwise noted, the studies were done in the fused manometer as shown in Fig. 1.

Since intimacy of mixing is important, a variety of mixing methods were tested:

1. Physical mixtures of the two compounds were made in various proportions and were mixed using a quartering technique. Some samples were ground in a ball mill. The ratios used are shown in Table I.

2. The alkoxyfuroic acid was weighed and dissolved in a solvent (methanol or acetone). Weighed amounts of microcrystalline cellulose were then added, and the suspension was stored in a closed container for 12 hr. The solvent was evaporated and then the samples were tested by the fused manometer and breakseal techniques. The surface area of the samples was tested by krypton adsorption[3]. The Brunauer–Emmett–Teller equation (8) was used for calculation of the surface from the adsorption data.

The gas evolved was carbon monoxide (not carbon dioxide) at elevated temperatures[4]. This identification was carried out in two ways. At the end of the kinetic study the sample bulb was immersed in a toluene slush (9) in a Dewar flask. The toluene slush (a mixture of ~80% solid toluene and 20% liquid toluene at the melting point of toluene, 178°K) was prepared by adding liquid nitrogen to toluene in a Dewar flask while stirring the liquid. The toluene eventually started freezing, and addition of liquid nitrogen was stopped when a "slush" was obtained giving a constant temperature reservoir as long as solid toluene was present. If the evolved gas is condensable at 178°K (*e.g.*, carbon dioxide), then the gas in the head space should condense and the pressure in the manometer equilibrate to zero. The gas, however, was not condensable at 178°K. Samples of the head space gas were analyzed by MS and identified as carbon monoxide.

[3] Quantasorb; Quantachrome Corp. Syosset, NY 11791.

[4] The conclusions refer to the temperatures used here only. It is doubtful that measurable amounts of carbon monoxide would be formed at room temperature.

RESULTS AND DISCUSSION

A typical pattern of decomposition of alkoxyfuroic acid in the presence of microcrystalline cellulose is shown in Fig. 2. The fraction decomposed (x) as a function of time (t) is a sigmoid curve, as in the case of the pure furoic acids themselves (4). A few obvious possibilities for this are delineated below. As for the case of the pure furoic acids, the decomposition could be directed by Bawn kinetics (10) in which case:

$$\ln(1 + Ax) = Kt + c'' \qquad \text{(Eq. 1)}$$

where A, K, and c'' are constants. This model relies on decomposition

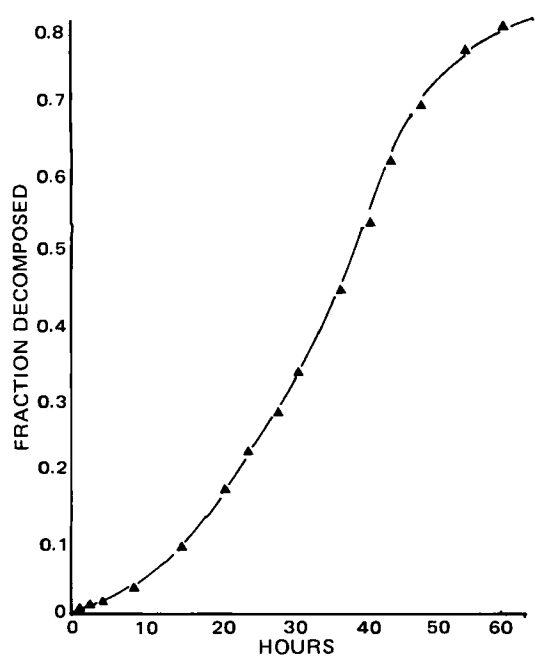

Figure 2—*Typical decomposition profile of an alkoxyfuroic acid–microcrystalline cellulose mixture, with 40% alkoxyfuroic acid (C_{18}) at 90°.*

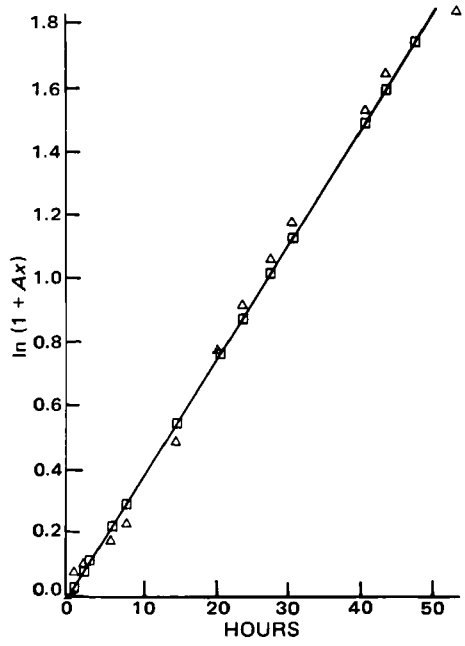

Figure 3—*Data in Fig. 2 plotted according to Eq. 1. In the ordinate,* x *is fraction decomposed and* A *(Eq. 1 and Table IV) is a floating parameter. Key: (△) = actual values; (□) = values according to least-squares fit.*

of the furoic acid in the solid state as well as in solution of the furoic acid in its (liquid) decomposition product. There is also the possibility that the decomposition occurs *via* the vapor phase, which results in zero-order kinetics (11), *i.e.*:

$$x = kt + c \qquad \text{(Eq. 2)}$$

where k and c are constants. That this is not the case is graphically obvious (Fig. 2), but it has been included as a possibility in the statistical evaluation in Table I. Finally, there is the possibility of Prout–Tompkins-type kinetics (12) where:

$$\ln|x/(1-x)| = -k't + c' \qquad \text{(Eq. 3)}$$

Unlike the decomposition of the pure furoic acids, the presence of a liquid phase was not visually obvious. This, however, could be due to adsorptive and absorptive properties of the microcrystalline cellulose. For decompositions where a solid decomposes to a solid plus a gas, Eq. 3 could be expected to hold.

For the sake of comparison, least-squares fits were performed of all data according to the three equations, and the residual sum of squares (s_{yx}^2) calculated for fits *via* Eq. 2 and from Eqs. 1 and 3 in the forms:

$$x = \exp(Kt + c'') - 1 \qquad \text{(Eq. 1A)}$$

$$x = \exp(-k't + c')/\{1 + \exp(-k't + c')\} \qquad \text{(Eq. 3A)}$$

In this manner the values of s_{yx}^2 are comparable (being in the same dimensionless unit). It is obvious from Table I (Fig. 3) that Eq. 1 (Eq. 1A) fits the data better than the two other equations. Values of K and c from the various mixtures of furoic acid and microcrystalline cellulose studied are shown in Table II. For reasons that will be dealt with later, these evaluations were carried out only through 80% of the decomposition. Beyond this point there was distinct deviation from all three models.

Solid-state interactions have been covered in the past in descriptive and qualitative fashions (13–15), but in a quantitative sense physical models of interactions between two solids have only occurred infrequently in the literature (16, 17). In the following an explanation for the kinetic scheme is sought using models. The first point to notice is that the decomposition of the furoic acids (RCOOH) differs when microcrystalline cellulose (R'CHOHR") is present. Furoic acids alone decompose in the following manner:

$$\text{RCOOH} \rightarrow \text{RH(liquid)} + \text{CO}_2\text{(gas)} \qquad \text{(Eq. 4)}$$

i.e., carbon dioxide is formed. Part of the decomposition occurs in the solid RCOOH and part in a saturated solution of RCOOH in RH. In the presence of microcrystalline cellulose, however, carbon monoxide is

[a] Data treated according to Eq. 1. [b] Correlation coefficient squared. [c] Ground in ball mill. [d] Hand ground with a mortar and pestle. [e] Applied as a methanolic solution. [f] Applied as a solution in acetone.

formed. Without any kind of speculation as to the actual interaction between the two solids, it may be stated generally that:

$$\text{RCOOH} + \text{R'CHOHR''} \rightarrow \text{Q}_1 + \text{Q}_2 + \text{CO} \qquad \text{(Eq. 5)}$$

where Q_1 and Q_2 are decomposition products. One of these (or both of them) could be liquid.

Cellulose, of course, decomposes at elevated temperatures, but usually not until >140° (18) within the time periods used in this study. The usual decomposition path is one of loss of water, leading to the formation of dehydrocellulose.

It is possible to visualize reaction schemes including microcrystalline cellulose, such as:

$$\text{RCOOH} + \text{R'CHOHR''} \rightarrow \text{RH} + \text{CO} + \text{H}_2\text{O} + \text{R'(C:O)R''} \qquad \text{(Eq. 6)}$$

where RH is liquid. It is also possible to visualize schemes where the microcrystalline cellulose does not take part in the overall reaction, *i.e.*, where it serves as a catalyst:

$$\text{RCOOH(+ R'CHOHR'')} \rightarrow \text{ROH} + \text{CO(+ R'CHOHR'')} \qquad \text{(Eq. 7)}$$

It should be pointed out that neither of these two schemes have been substantiated, and they are mentioned solely to show that reactions of the type in Eq. 5 are feasible stoichiometrically.

At first thought, reactions such as Eqs. 4 and 5 would not seem to differ widely. RCOOH could dissolve in Q_1 and justify the Bawn-type kinetics which apply to such a situation. But in that case it should not matter if the materials were ground or not. It is noted from Table II that grinding gives an increased decomposition rate (0.057 *versus* 0.036 hr^{-1} for 40% acid and 0.107 *versus* 0.049 hr^{-1} for 20% acid). Hence, contact points between the alkoxyfuroic acid and the microcrystalline cellulose must be involved. A model which accounts for this is:

1. At contact points (the number of which is denoted N in the following) a reaction of the type shown in Eq. 5 takes place giving at least one liquid decomposition product (*e.g.*, Q_1).
2. The furoic acid will dissolve in the Q_1 to the extent of its solubility (S moles per mole of Q_1) and will start covering the surface (a, cm^2) of the microcrystalline cellulose.
3. The reaction then accelerates because of increased contact points between the (now dissolved) furoic acid and the microcrystalline cellulose.
4. Due to crowding there will, eventually, be a deceleration period.

It might be argued that the external surface of the microcrystalline cellulose would be insufficient to account for the total decomposition. There are, however, two "types" of surface present in microcrystalline cellulose: nitrogen adsorption gives low surface areas, whereas water isotherms give surface areas 100 times as large (19–22).

By the decomposition at a contact point, it is assumed that the decomposition, creating one Q_1 molecule, will dislodge (dissolve) S molecules of RCOOH at the contact point. If the initial number of contact points is N_0 and if there is a reaction possibility of α at each contact point,

[a] Coefficient of correlation squared. [b] Ground in ball mill. [c] Hand ground with a mortar and pestle. [d] Applied as a methanolic solution. [e] Applied as a solution in acetone. [f] Data not included in D *versus* $\phi L_0/N_0$ correlation.

then:

$$dN/dt = \alpha \cdot (S-1) \cdot N \qquad \text{(Eq. 8)}$$

since, when α molecules react, $\alpha \cdot S$ new contact points are created, and one (the one at which the reaction takes place) is lost.

At some point in time there will arise the distinct probability of "overcrowding," *i.e.*, saturated Q_1 will start getting in contact with sites already reacted (containing Q_2 and not native microcrystalline cellulose). If this probability is proportional to N, with proportionality constant β [similar to a termination probability in a Prout–Tompkins-type reaction (12)], then Eq. 8 becomes:

$$dN/dt = q \cdot N \qquad \text{(Eq. 9)}$$

where:

$$q = \alpha \cdot (S-1) - \beta \qquad \text{(Eq. 10)}$$

There would be an initial value of α denoted α_0, and initially the value of β would be zero. In Prout–Tompkins reactions it takes considerable time before β becomes sizable. However, in the model proposed here, the external surface is relatively small (compared with the total surface) so that the crowding may be assumed to occur rapidly, and if it is assumed that β has a finite value from the onset, then considering $\alpha = \alpha_0$ and $\beta = \beta_0$ throughout the process may be acceptable. This allows integration of Eq. 9, which with imposition of initial conditions yields:

$$N = N_0 \cdot e^{qt} \qquad \text{(Eq. 11)}$$

Since the rate of decomposition is proportional to the number of contact points at a given time t, then denoting by L the number of molecules of alkoxyfuroic acid that are intact at time t:

$$dL/dt = -\gamma \cdot N \qquad \text{(Eq. 12)}$$

where γ is a constant. From the definition of L it follows that:

$$x = (L_0 - L)/L_0 \qquad \text{(Eq. 13)}$$

This inserted in Eq. 12 yields:

$$dx/dt = -(1/L_0)dL/dt \qquad \text{(Eq. 14)}$$

which inserted in Eq. 12 gives:

$$dx/dt = (1/L_0) \cdot \gamma \cdot N \qquad \text{(Eq. 15)}$$

Substituting Eq. 11 into Eq. 15 then gives:

$$dx/dt = (\gamma N_0/L_0)e^{qt} \qquad \text{(Eq. 16)}$$

Integration of this (with imposition of initial conditions) yields:

$$x = (\gamma N_0/\{L_0 q\})(e^{qt} - 1) \qquad \text{(Eq. 17)}$$

If:

$$A = \{L_0 q/(\gamma N_0)\} \qquad \text{(Eq. 18)}$$

then the logarithmic form of Eq. 18 is identical to the Bawn equation (Eq. 1):

$$\ln(1 + Ax) = qt \qquad \text{(Eq. 19)}$$

Eq. 19 differs from Eq. 1 in the sense that the intercept is zero. It is seen from Table II, that this indeed is the case: all the intercepts listed fail to differ significantly from zero. q is hence equal to K in Eq. 1 (Table II).

Even though Eq. 19 is of the general form of a Bawn equation, the argumentation leading to its derivation is quite different. The fact that the data fit Eq. 19 is no proof of the proposed model. In fact, a model can never be proven correct, one can only fail to show that it contradicts a particular set of data, and this, in itself, does not guarantee that other models (not thought of) might not prove to be better. To lend credence to a model it is worthwhile to ascertain that it is consistent in as many respects as can be thought of.

There are two distinct cases in the aforementioned model: (*a*) the number of surface sites of the microcrystalline cellulose (N_0) is larger than the initial number of alkoxyfuroic acid molecules (L_0), or (*b*) the opposite is the case. The former (*a*) is the case in this study. In general a model has a certain domain in which it applies, and beyond which other mechanisms take over. In the case in point, there will be a given point in time, t', at which all the furoic acid will have dissolved; *i.e.*, beyond this point there is no more solid furoic acid in the system, it is all dissolved, and adsorbed at sites on the microcrystalline cellulose.

If there are L' intact furoic acid molecules left at t', then $(L_0 - L')$ molecules of Q_0 will have been formed, so that (by definition of S):

$$S = L'/(L_0 - L') \qquad \text{(Eq. 20)}$$

or:

$$L' = L_0 S/(1 + S) \qquad \text{(Eq. 21)}$$

After t' the rate of decrease in number of furoic acid molecules would simply be proportional to the number of intact furoic acid molecules, *i.e.*:

$$dL/dt = -K' \cdot L \qquad \text{(Eq. 22)}$$

since there is no longer a termination probability. (The molecules are visualized as situated at microcrystalline cellulose sites with a probability of K' of reacting.) Integrating this and imposing that $L = L'$ at $t = t'$ then gives:

$$\ln L = -K'(t - t') + \ln[SL_0/(1 + S)] \qquad \text{(Eq. 23)}$$

or:

$$(L/L_0) = (1 - x) = [S/(1 + S)] \cdot e^{-K'(t-t')} \qquad \text{(Eq. 24)}$$

The logarithmic form of this is:

$$\ln(1 - x) = -K' \cdot t + D \qquad \text{(Eq. 25)}$$

where:

$$D = K't' + \ln[S/(1 + S)] \qquad \text{(Eq. 26)}$$

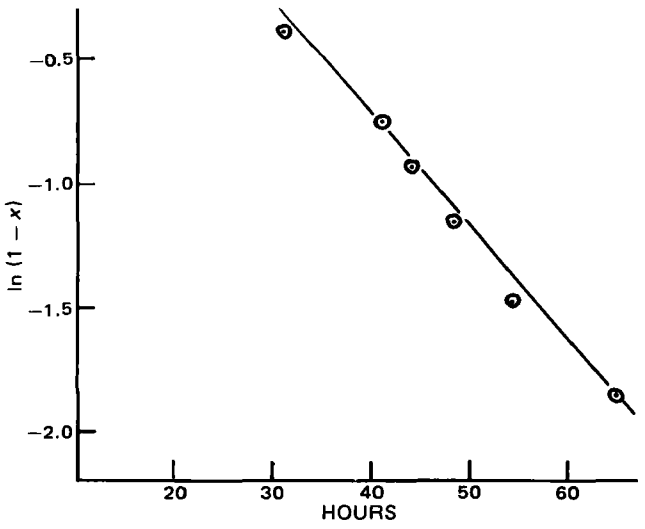

Figure 4—*The late phase of decomposition, which is supposed to be first order. ln(1 − x) is plotted* versus *time for a C_{14} alkoxyfuroic acid–microcrystalline cellulose mixture (40:60).*

Hence the latter part of the curve should be an exponential decay curve. Data treated in this fashion are shown in Fig. 4, and least-squares fit values are shown in Table III.

Precision in this range is, of course, less than the remainder of the data, since all the x values are between 0.8 and 1.0. Nevertheless fits are good (as judged by visual inspection of the figure, as well as from correlation coefficients in the table).

At a particular temperature, the solubility S is constant. It is noted that at time t' (Eq. 17):

$$(L_0 - L')/L_0 = x' = \{\gamma N_0/(L_0 q)\} \cdot (e^{qt'} - 1) \qquad \text{(Eq. 27)}$$

This may be rearranged to read:

$$t' = (1/q) \cdot \{1 + \ln[(L_0 - L') \cdot q/(\gamma \cdot N_0)]\} \sim (1/q) \cdot \ln(L_0/N_0) + (1/q) \cdot \ln(q/\gamma) \qquad \text{(Eq. 28)}$$

where the approximation $e^{qt'} \gg 1$[5] and $L' \ll L_0$. N_0 is proportional to the amount of microcrystalline cellulose (M_1,g) and L_0 is proportional to the amount of furoic acid (M_0,g). Hence (L_0/N_0) is proportional to M_2/M_1, *i.e.*:

$$M_2/M_1 = \phi \cdot (L_0/N_0) \qquad \text{(Eq. 29)}$$

where ϕ is a constant. When Eqs. 28 and 29 are inserted in Eq. 26, the following expression emerges:

$$D = (K'/q)[(\ln(M_2/M_1) - \ln q + \ln(\gamma\phi)] + \ln(S/\{1 + S\}) \qquad \text{(Eq. 30)}$$

If S is sizable (as in the case of the pure furoic acids), then $\ln\{S/(1 + S)\}$ is approximately zero, so that Eq. 29, may be written (in rearranged form):

$$(D \cdot q/K') - \ln q = \ln(M_2/M_1) + \ln(\gamma\phi) \qquad \text{(Eq. 31)}$$

A plot of $(D \cdot q/K') - \ln q$ as a function of $\ln(M_2/M_1)$ should therefore be linear. The values of these two parameters are shown in Table IV, and a plot according to Eq. 31 is shown in Fig. 5. It should again be stressed that the extraction of information from the data at this point is at the limit of precision, but that it is done to check the model for consistency, not to obtain values of parameters. It is seen from Fig. 5 that a fairly good straight line ensues. The least-squares fit is:

$$(D \cdot q/K') - \ln q = 0.7 \ln(M_2/M_1) + 3.9 \qquad \text{(Eq. 32)}$$

The 95% confidence limits on the slope are ± 0.4, so that 1.0 is in this interval, hence Eq. 31 is not contradicted. Aside from operating at the limit of precision, the confidence limits on the slope are large because only five points are involved. In this treatment the milled samples were omitted for reasons mentioned earlier, and the solvent-deposited samples were omitted as well, because they appear to give lower rate constants

[5] For the data in Fig. 3, for instance, $q = 0.036$ and $t' = 50$ so that $\exp(qt') = 6$.

Table IV—ln A as a Function of $\ln(qM_2/M_1)$ [a]

Derivative	Furoic Acid, %	M_2/M_1	A	ln A	$\ln(qM_2/M_1)$

C_{14}	20[e]	0.25	1.62	0.48	−5.73

[a] Data treated according to Eq. 31, least-squares fit: $\ln A = 0.73 \cdot \ln(qM_2/M_1) + 4.68$ with a correlation coefficient of 0.93. [b] Ground with a ball mill. [c] Hand ground with a mortar and pestle. [d] Applied as a methanolic solution. [e] Applied as a solution in acetone.

as shown in Table II (0.13 *versus* 0.049 hr^{-1} for 20% acid in acetone, 0.017 *versus* 0.036 hr^{-1} for 40% acid in acetone, and 0.042 *versus* a prorated 0.046 for 47% acid in methanol).

A further consistency check exists in the following consideration: Eq. 18 suggests that the parameter A in Eq. 19 (listed in Table III) should be proportional to q and to the ratio M_2/M_1. In logarithmic form Eq. 18 becomes:

$$\ln A = \ln(qL_0/N_0) - \ln\gamma = \ln(qM_2/M_1) - \ln(\phi/\gamma) \qquad \text{(Eq. 33)}$$

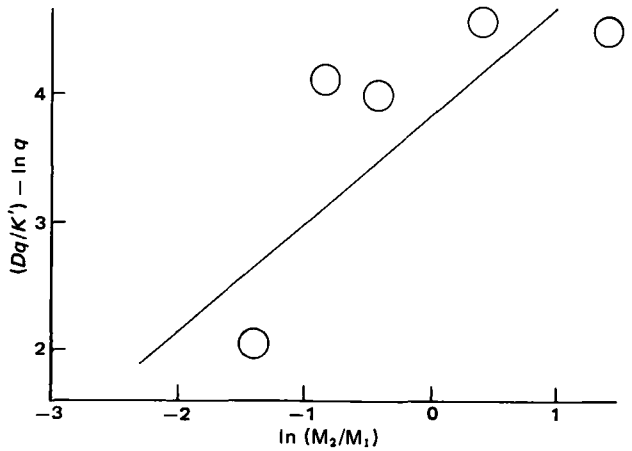

Figure 5—*Eq. 31 may be written: (Dq/K′) = ln (qM₂/M₁) + ln(φγ); the data from Table IV are presented in this fashion. Data from Table IV plotted according to Eq. 31.*

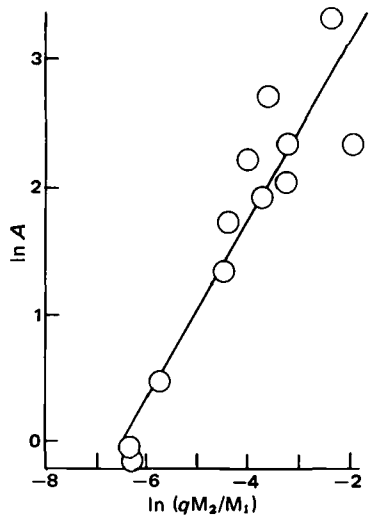

Figure 6—*The floating parameter, A, according to Eq. 33 should be a linear function of ln(qM₂/M₁); the data from Table IV are shown in this fashion.*

Table V—Temperature Dependence of K Values of C_{14} Derivative–Microcrystalline Cellulose Mixtures [a]

Temperature	1000/T	K (q)	ln K(ln q)	K'	ln K'
85°	2.792	0.0039	−5.55	0.0104	−4.56
90°	2.754	0.0360	−3.32	0.0405	−3.21
95°	2.716	0.0688	−2.67	0.0807	−2.52
100°	2.680	0.5836	−0.54	0.3940	−0.93

[a] Least-squares fit according to Eq. 33 for $K(q)$ $R^2 = -0.980$, slope = −41.88, and intercept = 111.55; for K', $R^2 = -0.989$, slope = −30.92, and intercept = 81.77.

where Eq. 30 has been introduced for the last step. Values of q are found in Table II, and values of $\ln(qM_2/M_1)$ are listed in the last column of Table III. A plot according to Eq. 33 is shown in Fig. 6. Linearity is plausible from the figure, and the correlation coefficient (0.93) is of satisfactory magnitude. The least-squares fit equation is:

$$\ln A = 0.73 \ln(qM_2/M_1) + 4.68 \qquad \text{(Eq. 34)}$$

The slope, again, does not differ significantly from unity. The values of (ϕ-γ) from Figs. 5 and 6 should be identical but as shown they differ, but (*a*) there is no actual value in obtaining the figures (other than ascertaining that they are of reasonable orders of magnitude), and (*b*) it should be stressed again, that they are obtained at the limit of precision. The restraints on ϕ and γ are that ϕ be positive and (from the argumentation leading to Eq. 12) that γ be between zero and one. The consequences of the model and the data, therefore, do not lead to contradiction in this respect either.

As a final check, the temperature dependence of the K and K' values is according to an Arrhenius equation, *i.e.*:

$$\ln K = -(E_a/R)(1/T) + \ln Z \qquad \text{(Eq. 35)}$$

where E_a is activation energy, R the gas constant, T the absolute temperature, and Z a collision factor. One composition was tested at four temperatures; the data are shown in Table V and graphically in Fig. 7. The least-squares fit parameters of these data according to Eq. 33 are shown as well. The values of E_a are 5.0 and 3.72 kJ/mole, respectively. These values are much lower than for the pure compound and are in the range expected for solution kinetics and chemisorption.

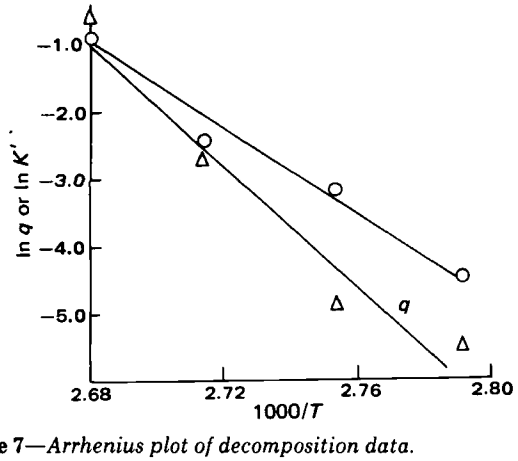

Figure 7—*Arrhenius plot of decomposition data.*

CONCLUSIONS

If microcrystalline cellulose is mixed with an alkoxyfuroic acid, an interaction takes place that could result from a direct reaction of the two components. A liquid decomposition product is formed and this serves as a carrier to increase the number of contact points and (as long as solid alkoxyfuroic acid is present) accelerate the reaction. Once all solid alkoxyfuroic acid is dissolved, the reaction becomes a reaction of adsorbed alkoxyfuroic acid.

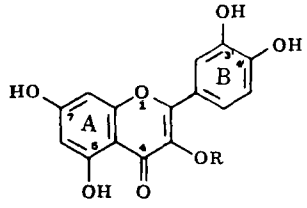
Abstract □ Analysis of urinary metabolites of orally administered rutin (I) labeled with deuterium ([2′,5′,6′-^{2}H]rutin, rutin-*d*) was carried out by GLC–MS. In rat urine, 3-hydroxyphenylacetic acid (III), 3-methoxy-4-hydroxyphenylacetic acid (IV), 3,4-dihydroxyphenylacetic acid (V), 3,4-dihydroxytoluene (VI), and 3-(*m*-hydroxyphenyl)propionic acid (VIII) were identified as rutin metabolites and were differentiated from the corresponding endogeneous compounds. Unchanged I and quercetin (II) were not present in the urine. Rutin-*d* was injected intraperitoneally in rats, administered orally to neomycin-treated rats, and incubated *in vitro* with the intestinal contents of rats. The experiments suggested the involvement of intestinal microflora in the metabolism of orally administered I.

Keyphrases □ Rutin—metabolites in rat urine, GLC–MS analysis, role of intestinal microflora □ Metabolites—rutin, analysis in rat urine, role of intestinal microflora □ Intestinal microflora—role in rutin metabolism, *in vitro* analysis with rat intestinal contents, GLC–MS detection

The metabolic fate of orally administered [2′,5′,6′-^{2}H]rutin (rutin-*d*) in humans was elucidated using GLC–MS (1, 2). 3-Hydroxyphenylacetic acid (III), 3-methoxy-4-hydroxyphenylacetic acid (IV), 3,4-dihydroxyphenylacetic acid (V), 3,4-dihydroxytoluene (VI), and β-*m*-hydroxyphenylhydracrylic acid (VII) were identified as urinary metabolites of rutin (I) and were differentiated from the corresponding endogenous compounds. All of these urinary metabolites were formed *via* reduction of the double bond of the γ-pyranone ring; III and VII were formed *via* dehydroxylation at the 4′-position of the B-ring.

The metabolism of I has been studied extensively in animals. In rat urine, III, IV, and V were identified as rutin metabolites after oral administration of I (3). Evidence for the involvement of the intestinal microflora in the metabolism of I was suggested by some investigators (4–8). These authors reported that anaerobic incubation of I with extracts of rat intestinal contents resulted in the formation of ring-fission metabolites (III and VIII). The intestinal origin of these metabolites was also demonstrated indirectly by the fact that excretion of the phenolic acids in the urine was suppressed when I was administered orally to neomycin-treated or germ-free rats (8, 9). However, an accurate determination of III–V derived from administered I is not possible, because the phenolic acids in question are also endogenous metabolites excreted in the ordinary urine and feces.

A radioactive isotope tracer technique is useful for the metabolic studies. Several radioactive metabolites were found in the urine after oral administration of [G-^{3}H]I in rats, but the structures were not elucidated (10). A mass chromatographic method using I labeled with stable isotopes is superior to a radioactive tracer technique in the structural elucidation of I metabolites. This report identifies the urinary metabolites of I in rats and elucidates the role of the intestinal microflora in the metabolism of I using a stable isotope tracer technique.



I: R = rutinose
II: R = H

EXPERIMENTAL[1]

Materials—Rutin[2] (I), quercetin[2] (II), 3-hydroxyphenylacetic acid[2] (III), 3-methoxy-4-hydroxyphenylacetic acid[2] (IV), 3,4-dihydroxyphenylacetic acid[2] (V), 3,4-dihydroxytoluene[3] (VI), 3-(3,4-dihydroxyphenyl)propionic acid[4] (IX), *p*-hydroxyphenyllactic acid[5] (X), neomycin sulfate[6], yeast extract[7], and peptone[7] were obtained commercially.

[2′,5′,6′-^{2}H]Rutin (Rutin-*d*)—A solution of NaOH (0.58 g) and I (6.0 g) in D_2O[8] (60.0 g) was heated at 95° for 8 hr in a sealed tube in a nitrogen atmosphere. The mixture was lyophilized, and D_2O (60.0 g) was added. The solution was heated for 8 hr in a similar manner and was acidified with 10% AcOH (200 ml). The resultant yellow solid was collected, washed with H_2O, dried, and then chromatographed using cross-linked dextran gel[9] with CH_3OH as eluant. Recrystallization from CH_3OH–H_2O (1:1) gave [2′,5′,6′,6,8-^{2}H]rutin as yellow needles (4.80 g). To a solution of NaOH (0.64 g) and H_2O (50.0 g) was added [2′,5′,6′,6,8-^{2}H]rutin (4.80 g). The mixture was stirred for 1 hr at 25° and then was acidified with 10% AcOH (150 ml). After repeating this procedure, the crude solid was purified as above for [2′,5′,6′,6,8-^{2}H]rutin to give [2′,5′,6′-^{2}H]rutin (rutin-*d*), 3.60 g (60.0% yield), mp 193°; ^{1}H-NMR(CD_3OD): δ 1.15 (d, 3, J = 6.0 Hz, rhamnosyl-CH_3), 6.16 (d, 1, J = 2.5 Hz, 6-CH), and 6.38 ppm (d, 1, J = 2.5 Hz, 8-CH). The ^{1}H-NMR spectrum showed that the isotopic composition (d_1, d_2, and d_3) was 1:6:3.

β-*m*-Hydroxyphenylhydracrylic Acid (VII)—To a solution of *m*-benzyloxyphenylhydracrylic acid (11) (1.0 g) in EtOH (70 ml) was added 5% Pd-C (0.25 g). The solution was stirred under a hydrogen atmosphere for 3 hr. The uptake of hydrogen was ~90 ml (theoretical 82 ml). The catalyst was removed by filtration. The filtrate was concentrated to dryness under reduced pressure, and the residue was crystallized from *n*-hexane–Et_2O (1:1) to give 0.65 g (97.1% yield). Recrystallization from *n*-hexane–EtOAc (1:1) gave V, 0.50 g (75% yield), mp 158–159° dec. [lit. (11) 159°]; ^{1}H-NMR (DMSO-d_6): δ 6.50–7.20 (m, 4, ArH), 4.84 (t, 1, J = 6.0 Hz, 3-CH), 2.48 ppm (d, 2, J = 6.0 Hz, 2-CH_2), and OH exchangeable; MS: m/z 182 (M^+).

[1] Melting points were determined in open-glass capillaries and are uncorrected. ^{1}H-NMR spectra were determined on a JEOL JM-MH-100 spectrometer using deuterated methanol for rutin-*d* and deuterated dimethyl sulfoxide for VII and VIII as solvents, with tetramethylsilane as the internal standard. Elemental analyses were performed by Analytical Center, Tokyo College of Pharmacy, Tokyo, Japan.

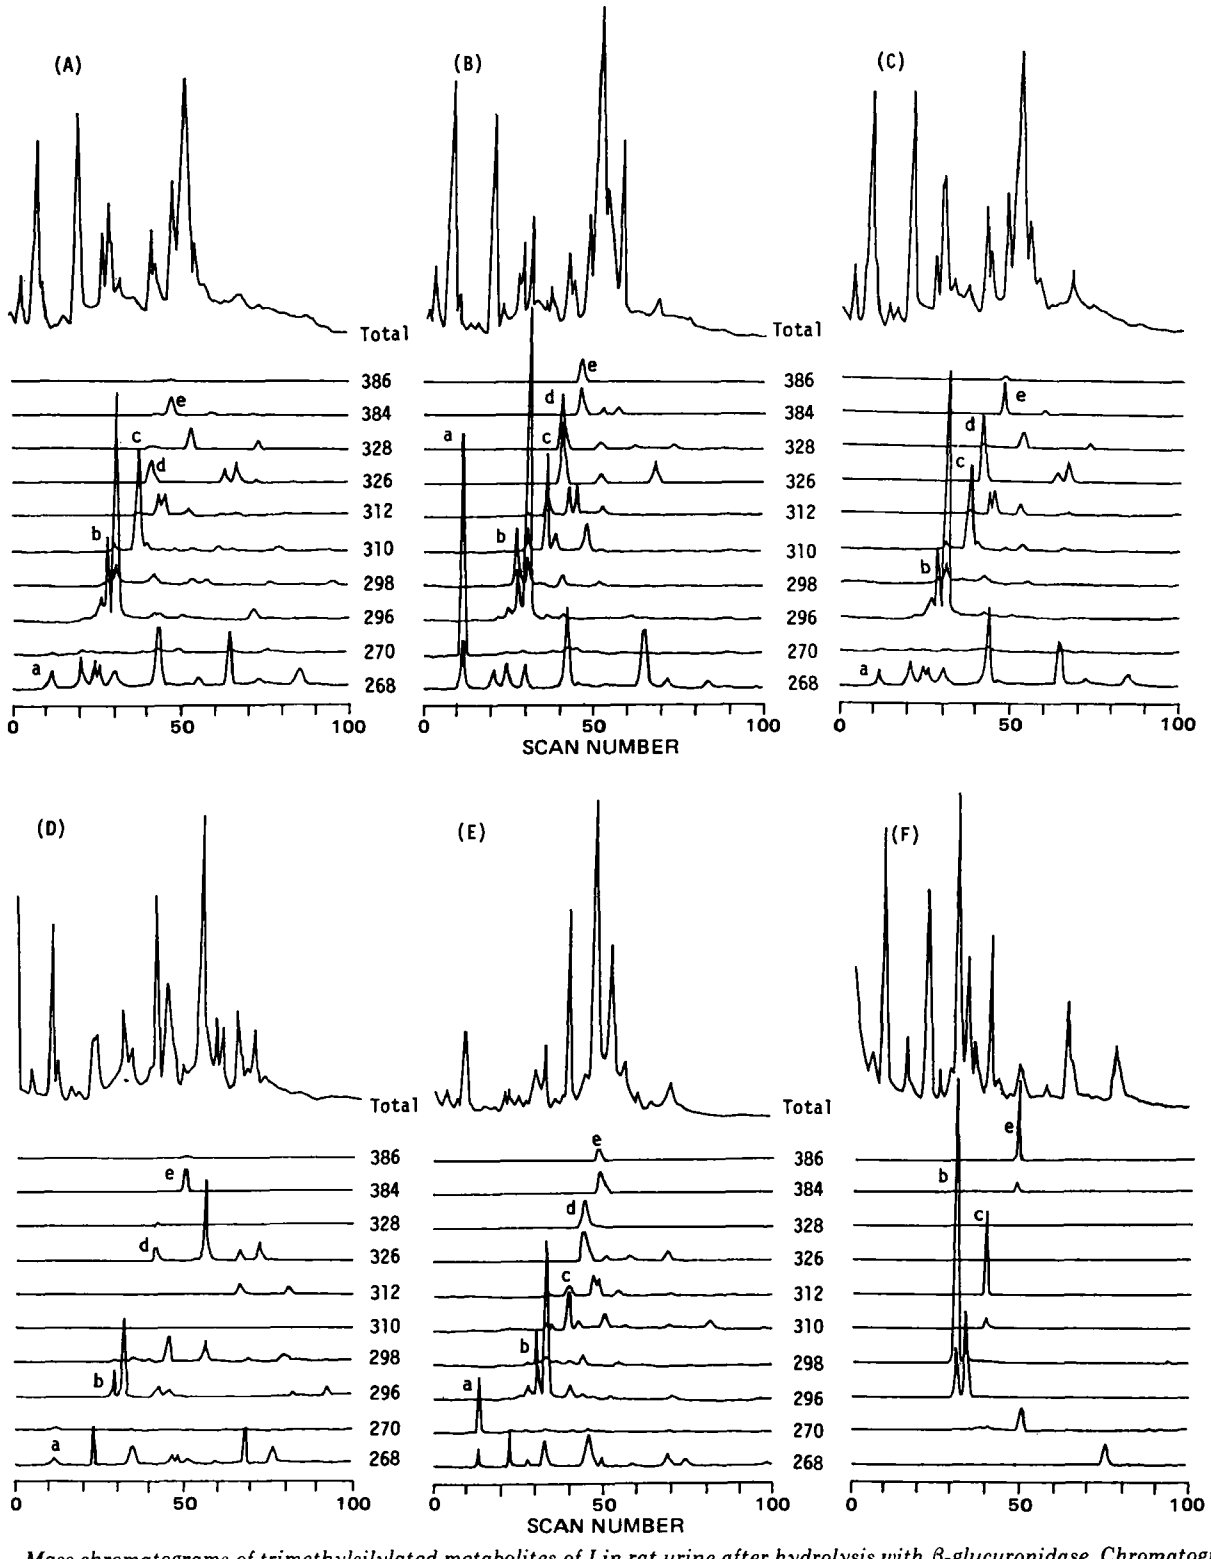

Figure 1—*Mass chromatograms of trimethylsilylated metabolites of I in rat urine after hydrolysis with β-glucuronidase. Chromatograms were obtained from the 24-hr urine of rats prior to (A) and after (B) oral administration of rutin-d and after intraperitoneal injection of rutin-d (C) before neomycin treatment. Chromatograms also were obtained from the 24-hr urine after oral administration of rutin-d in rats on the 2nd (D) and 14th (E) days after neomycin treatment. Chromatogram F was obtained from the incubation mixture of rutin-d and rat intestinal contents. Key: (a) VI [M^+:268, $(M+2)^+$:270]; (b) III [M^+:296, $(M+2)^+$:298]; (c) VIII [M^+:310, $(M+2)^+$:312]; (d) IV [M^+:326, $(M+2)^+$:328]; (e) V [M^+:384, $(M+2)^+$:386].*

Anal.—Calc. for $C_9H_{10}O_4$: C, 59.34; H, 5.53. Found: C, 59.38; H, 5.43.

3-(*m*-Hydroxyphenyl)propionic Acid (VIII)—To a solution of *trans*-*m*-hydroxycinnamic acid[5] (1.0 g) in EtOH (70 ml) was added 5% Pd-C (0.30 g). The solution was stirred under a hydrogen atmosphere for 2 hr. The uptake of hydrogen was ~150 ml (theoretical 137 ml). The catalyst was removed by filtration. The filtrate was concentrated under reduced pressure to give 1.0 g (100% yield) of VIII which was recrystallized from Et_2O–benzene (1:1) to give white needles (VIII), 0.94 g (94% yield), mp 111°; ^{1}H-NMR (DMSO-d_6): δ 6.50–7.15 (m, 4, ArH), 2.40–2.84 ppm (A_2B_2 4, CH_2CH_2), and exchangeable OH; MS: *m/z* 166 (M^+).

Anal.—Calc. for $C_9H_{10}O_3$: C, 65.05; H, 6.07. Found: C, 65.15; H, 6.02.

GLC–MS—A GLC–mass spectrometer[10] and a data processing system[11] connected to a minicomputer[12] were used. The GLC system employed a 2 m × 3-mm i.d. glass column packed with 2% OV-105 on 60–80 mesh Chromosorb W[13]; it was packed with 1.5% OV-1 on 80–100 mesh Shimalite[3] for analysis of II. The columns were preconditioned with a helium flow of 30 ml/min at 230° (OV-105) and 280° (OV-1) for 24 hr, or until the baseline was stable. The column, flash heater, and separator temperatures were 160°, 180°, and 280°, respectively. The helium flow rate was 20 ml/min. The mass spectometer employed an ionization-source temperature of 310° and ionization energy of 20 eV.

One minute following injection of the sample, automatic magnet scanning was initiated, covering an m/z range of 50–500 every 8 sec. All scanning data were stored in the data processing system. Mass chromatograms were obtained on a digital plotter by monitoring the molecular ions of the $d_0(M^+)$ and $d_2[(M + 2)^+]$ forms of the trimethylsilylated derivatives of possible metabolites of I.

Drug Administration and Urine Collection—Three male Wistar albino rats, weighing 180–220 g, orally received 100 mg of rutin-*d*/kg. Urine was collected for 24 hr prior to and 24 hr after oral administration of rutin-*d*. Seven days later each animal was injected intraperitoneally with rutin-*d* (20 mg/kg). Urine was collected for 24 hr after the administration.

To inhibit the action of intestinal microflora, neomycin sulfate (100 mg/kg) was orally administered twice a day for 4 days to an additional three rats. Rutin-*d* (100 mg/kg) was administered orally to the rats on the 2nd and 14th day after treatment with neomycin ended. Urine was collected for 24 hr after each administration of rutin-*d*. Urine samples were diluted with distilled water to 30 ml and were kept frozen until analysis.

***In Vitro* Experiments**—The incubation medium was composed of 0.5% (w/v) yeast extract and 0.5% (w/v) peptone in 0.1 *M* phosphate buffer (pH 7.4). The rat intestinal contents were well mixed with 50 ml of the medium. The resulting suspension was centrifuged at low speed (500× *g*) for 1 min. To 5 ml of the supernatant thus obtained was added 3.0 mg of rutin-*d*. The mixture was incubated for 12 hr at 37° under anaerobic conditions.

Identification of I Metabolites by TLC—Urine samples (10 ml) collected prior to and after rutin-*d* administration were incubated at 37° for 24 hr with 10 ml of 0.1 *M* acetate buffer (pH 5.0) containing 3000 U of β-glucuronidase[14]. The incubation mixture was lyophilized and suspended in CH_3OH (10 ml). The suspension was centrifuged (1500× *g*) and the supernatant layer mixed with Et_2O (10 ml). The resulting suspension was centrifuged, and the precipitate was dissolved in CH_3OH (0.5 ml). A 0.1-ml volume of this solution was subjected to TLC[15]. Control urine (10 ml), collected prior to the rutin-*d* administration, was mixed with 200 μg of I and a sample (0.1 ml) was subjected to the TLC procedure. The TLC plate was developed with 1-butanol–AcOH–H_2O (4:1:2) and the spots were visualized by aluminum chloride (12), R_f 0.45 (I).

Identification of I Metabolites by GLC–MS—Urine samples (10 ml) collected prior to and after rutin-*d* administration were incubated at 37° for 24 hr in 10 ml of 0.1 *M* acetate buffer (pH 5.0) containing 3000 U of β-glucuronidase. Portions (10 ml) of urine obtained prior to and after the rutin-*d* administration and the incubation samples were subjected to the separation and extraction procedures without β-glucuronidase hydrolysis. Urine and incubation samples were acidified with 10% HCl (pH 1.0) and extracted with ether. The ether layer was concentrated to dryness under reduced pressure. The residue was dissolved in dry pyridine (0.1 ml), and *N,O*-bis(trimethylsilyl)acetamide[5] (0.05 ml) was added. The silylated derivatives were injected in the GLC–MS.

RESULTS AND DISCUSSION

The urine samples (10 ml) collected prior to and after I administration were subjected to TLC after extraction and separation procedures. The TLC results revealed that I was not present in the urine. To a 10-ml portion of the urine collected prior to the administration was added 200 μg of I; this urine sample was also subjected to TLC as above and I was detected. The results showed that the excretion of I in the urine after the I administration to rats was >20 μg/ml and suggested that orally administered I might be completely metabolized, as in humans (1).

[a] Urine and incubation samples obtained after the extraction and separation procedures were analyzed by GLC–MS or TLC. Key: (+) metabolite was detected; (—) metabolite was not detected. [b] Rutin-*d* was administered orally (po) or intraperitoneally (ip) to untreated rats and orally to neomycin-treated rats on the 2nd and 14th day after neomycin treatment ended. [c] Rutin-*d* was incubated with rat intestinal contents under anaerobic conditions.

The isotopic composition (d_1, d_2, and d_3) in rutin-*d* was 1:6:3. Therefore, particular attention was paid to the d_2 form for the determination of I metabolites by GLC–MS. The urine samples collected prior to and after the rutin-*d* administration were subjected to silylation with *N,O*-bis(trimethylsilyl)acetamide and analyzed by the GLC–MS computer system. Mass chromatograms were obtained by monitoring the molecular ions of the $d_0(M^+)$ and $d_2[(M + 2)^+]$ forms of the silylated derivatives of possible I metabolites. A metabolite was identified by examining the presence of duplicate peaks at the same retention time in the mass chromatogram.

Typical mass chromatograms obtained from the urine after hydrolysis with β-glucuronidase are given in Fig. 1A and B. The ratios of the peak intensities $[(M + 2)^+/M^+]$ shown in Fig. 1A were practically the same as those estimated from control urine. On the other hand, the ratios of the peak intensities $[(M + 2)^+/M^+]$ were larger in peaks a–e in Fig. 1B than those in the peaks shown in Fig. 1A, indicating the increment of the peak intensity in each $(M + 2)^+$ peak. These findings made it evident that orally administered rutin-*d* was metabolized to give five metabolites which were also present in the urine as endogenous materials.

These metabolites were identified as III (peak b), IV (peak d), V (peak e), VI (peak a), and VII (peak c). Identification was made by comparing the mass spectra and GLC retention times of the respective mass chromatogram peaks with the corresponding silylated authentic compounds. The five metabolites identified in the urine after hydrolysis with β-glucuronidase were also found in the urine without β-glucuronidase treatment. Four of these metabolites, *i.e.*, III–VI, were the same as those found in human urine. β-*m*-Hydroxyphenylhydracrylic acid (VII), detected in human urine, 3-(3,4-dihydroxyphenyl)propionic acid (IX), *p*-hydroxyphenyllactic acid (X), and β-*p*-hydroxyphenylhydracrylic acid (XI) were excluded from the metabolites of rutin-*d* by the mass spectra of the corresponding authentic compounds or the results of one investigation (13). Quercetin, an aglycone of I, was not found in the urine. It was impossible to follow the metabolic change occurring in the A-ring on which no atoms were deuterium labeled.

Rutin-*d* was injected intraperitoneally in rats on the 7th day after oral administration of rutin-*d*. The urine samples from the rats injected with rutin-*d* were subjected to the GLC–MS analysis. The mass chromatogram (Fig. 1C) thus obtained was similar to that obtained prior to oral administration of rutin-*d* (Fig. 1A). The five metabolites detected in urine after the oral administration of rutin-*d* were not excreted in the urine after the intraperitoneal injection of rutin-*d* (Fig. 1B and C). The results indicated that orally administered I must be metabolized by intestinal microflora or by enzymes in the intestinal walls. Petrakis *et al.* (14) injected [G-^{14}C]quercetin into rats intraperitoneally and found radioactive vanillic acid only in the urine. In the case of the rutin-*d* injection, this metabolite, though endogenously present, could not to be found in the urine.

The absorption of I in the GI tract has been investigated (10, 15–19). It has been reported that [G-^{3}H]I (10) and [G-^{14}C]II (14) are absorbed very slowly from the GI tract when administered orally to rats. Because of the slow absorption of I and II by the intestines, the intestinal microflora play a significant role in the metabolism of orally administered I.

Rutin-*d* was administered to another group of rats orally. The mass chromatogram thus obtained was similar to that shown in Fig. 1B and showed the presence of five metabolites derived from rutin-*d*. The rats then received neomycin orally twice a day for 4 days to inhibit the action of the intestinal microflora. Rutin-*d* was administered to the rats on the

2nd day after treatment with neomycin ended. The mass chromatogram is given in Fig. 1D. In peaks a, b, d, and e in Fig. 1D, the ratios of the peak intensities $[(M + 2)^+/M^+]$ were much smaller than those of the corresponding peaks in the mass chromatogram obtained when rutin-*d* was administered to untreated rats (Fig. 1B). In addition, peak c did not appear in Fig. 1D. Rutin-*d* was also administered to rats on the 14th day after neomycin treatment when the action of the intestinal microflora had been restored. In the mass chromatogram thus obtained (Fig. 1E), the $[(M + 2)^+/M^+]$ ratios were larger than those in the mass chromatogram obtained from neomycin-treated rats (Fig. 1D). The five metabolites were detected in the untreated rats. They were reduced or disappeared in the neomycin-treated rats and were increased on the 14th day after neomycin treatment. The results obtained from the intraperitoneal injection and the subsequent neomycin-treatment experiments showed that intestinal microflora greatly influence the metabolism of orally administered I.

Rutin-*d* was incubated with extracts of rat intestinal contents under anaerobic conditions. As shown in the mass chromatogram (Fig. 1F) thus obtained, three metabolites, *i.e.*, III (peak b), V (peak e), and VIII (peak c), appeared. Compound II and unchanged I were also found in the incubation mixture. The *in vitro* experiments suggested direct involvement of the intestinal microflora in the metabolism of I, even though all of the metabolites detected in the urine after oral administration of rutin-*d* were not found. The lack of formation of metabolites IV and VI in the mixture indicated that they were excreted in the urine *via* methylation or decarboxylation by enzymes in the intestinal walls or in other tissues after the absorption of orally administered I from the GI tract.

It has been reported that I was metabolized to give phenolic acids such as III, IV, VIII, *etc.* by the isolated perfused rat liver (19). These phenolic acids should be excreted in the urine *via* liver metabolism if I is absorbed as such from the GI tract after oral administration of rutin-*d* in neomycin-treated rats. However, these metabolites were not found in the urine from neomycin-treated rats (Fig. 1D), and neither I nor II was present. It is then reasonable to assume that orally administered I could not be absorbed from the GI tract *per se*. 3,4-Dihydroxyphenyl[carboxy-^{14}C]acetic acid (V), when administered to rats orally, was almost completely excreted in the urine in the form of III, IV, and V (20). Thus, I must be metabolized to the phenolic acids by intestinal microflora, with subsequent absorption from the GI tract.

In this study, five metabolites (III–VI and VIII) derived from orally administered rutin-*d* were differentiated from these compounds endogenously present in the urine and successfully identified by the mass chromatographic method. In addition, the involvement of intestinal microflora in the metabolism of I was investigated by this method (Table I). It is possible that the human intestinal microflora may also play a significant role in the formation of urinary metabolites of I (III–VII) in humans.

Antitumor Agents LXII: Synthesis and Biological Evaluation of Podophyllotoxin Esters and Related Derivatives

RON K. LEVY, IRIS H. HALL, and KUO-HSIUNG LEE ˣ

Received June 11, 1982, from the *Department of Medicinal Chemistry, School of Pharmacy, University of North Carolina at Chapel Hill, Chapel Hill, NC 27514.* Accepted for publication August 17, 1982.

Abstract □ Synthetic esters of the C-4 hydroxyl group of podophyllotoxin (I) were prepared. In addition, esters were synthesized using the diol system of tetrahydropyranyl podophyllol (XV), produced by reducing the lactone ring of tetrahydropyranyl podophyllotoxin with lithium aluminum hydride. Six compounds, the acrylate (IV), 3,3-dimethyl acrylate (V), phenoxyacetate (IX), and ethyl adipate (XI) of I as well as podophyllol (XIV) and tetrahydropyranyl podophyllol dimesylate (XVIII), showed significant activity when tested using the P-388 lymphocytic leukemia screen at 3 mg/kg/day. None of the esters showed higher activity than that shown by the parent molecule I when tested at the same dosage level.

Keyphrases □ Podophyllotoxin—esters, synthesis, antileukemic activity in mice □ Synthesis—podophyllotoxin esters, antileukemic activity in mice □ Antileukemic agents—potential, podophyllotoxin esters, synthesis

The development of teniposide (VM-26) and etoposide (VP-16-213), two glucopyranosyl derivatives related to the lignan podophyllotoxin (I), as clinically effective anticancer drugs has been reviewed recently (1). An examination of the structural features of teniposide and etoposide indicated that a free hydroxyl group at C-4 in epipodophyllotoxin is not essential for potent activity. Thus, it was considered that further modification of the C-4 hydroxyl group of I or epipodophyllotoxin could yield additional potent antitumor agents. In view of the importance of an

2nd day after treatment with neomycin ended. The mass chromatogram is given in Fig. 1D. In peaks a, b, d, and e in Fig. 1D, the ratios of the peak intensities $[(M + 2)^+/M^+]$ were much smaller than those of the corresponding peaks in the mass chromatogram obtained when rutin-*d* was administered to untreated rats (Fig. 1B). In addition, peak c did not appear in Fig. 1D. Rutin-*d* was also administered to rats on the 14th day after neomycin treatment when the action of the intestinal microflora had been restored. In the mass chromatogram thus obtained (Fig. 1E), the $[(M + 2)^+/M^+]$ ratios were larger than those in the mass chromatogram obtained from neomycin-treated rats (Fig. 1D). The five metabolites were detected in the untreated rats. They were reduced or disappeared in the neomycin-treated rats and were increased on the 14th day after neomycin treatment. The results obtained from the intraperitoneal injection and the subsequent neomycin-treatment experiments showed that intestinal microflora greatly influence the metabolism of orally administered I.

Rutin-*d* was incubated with extracts of rat intestinal contents under anaerobic conditions. As shown in the mass chromatogram (Fig. 1F) thus obtained, three metabolites, *i.e.*, III (peak b), V (peak e), and VIII (peak c), appeared. Compound II and unchanged I were also found in the incubation mixture. The *in vitro* experiments suggested direct involvement of the intestinal microflora in the metabolism of I, even though all of the metabolites detected in the urine after oral administration of rutin-*d* were not found. The lack of formation of metabolites IV and VI in the mixture indicated that they were excreted in the urine *via* methylation or decarboxylation by enzymes in the intestinal walls or in other tissues after the absorption of orally administered I from the GI tract.

It has been reported that I was metabolized to give phenolic acids such as III, IV, VIII, *etc.* by the isolated perfused rat liver (19). These phenolic acids should be excreted in the urine *via* liver metabolism if I is absorbed as such from the GI tract after oral administration of rutin-*d* in neomycin-treated rats. However, these metabolites were not found in the urine from neomycin-treated rats (Fig. 1D), and neither I nor II was present. It is then reasonable to assume that orally administered I could not be absorbed from the GI tract *per se*. 3,4-Dihydroxyphenyl[carboxy-^{14}C]acetic acid (V), when administered to rats orally, was almost completely excreted in the urine in the form of III, IV, and V (20). Thus, I must be metabolized to the phenolic acids by intestinal microflora, with subsequent absorption from the GI tract.

In this study, five metabolites (III–VI and VIII) derived from orally administered rutin-*d* were differentiated from these compounds endogenously present in the urine and successfully identified by the mass chromatographic method. In addition, the involvement of intestinal microflora in the metabolism of I was investigated by this method (Table I). It is possible that the human intestinal microflora may also play a significant role in the formation of urinary metabolites of I (III–VII) in humans.

ester group in the cytotoxicity and antileukemic activity of compounds in certain classes (2–5), a series of C-4 hydroxyl esters of I were prepared and examined for their antileukemic activity against *in vivo* P-388 lymphocytic leukemia cell growth. The effect of the ester group on the antileukemic activity of I has not yet been studied (1). In addition, modification of the podophyllotoxin nucleus by substituting an ester moiety at the diol system of tetrahydropyranyl podophyllol (XV), as well as the antileukemic activity of the resulting products are reported.

RESULTS AND DISCUSSION

Several esters of podophyllotoxin (I) and tetrahydropyranyl podophyllol (XV) were prepared by a general method and assayed for *in vivo* antileukemic activity against P-388 lymphocytic leukemia growth in mice according to the standard National Cancer Institute procedures (6). The antileukemic activity of I–XIX are shown in Table I and are compared to podophyllotoxin (I) at the same dosage levels. The maximum observed T/C% value of 171 for I at 3 mg/kg/day compares favorably with that reported in the literature (7). This dosage was therefore chosen for a study of the structure–activity relationship of the various esters.

Generally, every compound tested showed a significant decrease in antileukemic activity compared with I when administered at 3 mg/kg/day. Compounds II, III, VI–VIII, X, XII, XIII, XV–XVII, and XIX were found to be inactive. Compounds which showed significant (T/C ≥ 120%) (6, 8) antileukemic activity included IV, V, IX, XI, XIV, and XVIII with respective T/C% values of 135, 121, 133, 120, 120, and 130 at 3 mg/kg/day. These data indicate that the introduction of an ester moiety into I and XV does not enhance the antileukemic activity (P-388), but in general causes a loss of activity.

EXPERIMENTAL[1]

Podophyllotoxin (I)—Podophyllotoxin was isolated from the chloroform extract of *Podophyllum peltatum*[2] according to literature methods (9, 10).

[1] Unless otherwise specified, microanalyses were performed by M-H. W. Laboratories, Phoenix, Ariz. or Integral Microlab, Inc., Raleigh, N.C. Mass spectral data were recorded using an A.E.I. MS-902 mass spectrometer. Melting points were determined on a Thomas-Hoover melting point apparatus. IR spectra were recorded in chloroform on a Perkin-Elmer 257 grating spectrophotometer. ^{1}H-NMR spectra were measured in deuterated chloroform either on a JEOL C-60HL or a JEOL FX-60 NMR spectrometer. All NMR data are given in parts per million and reported as downfield from the internal standard, tetramethylsilane. The abbreviations s, d, t, q, and m refer to single, doublet, triplet, quartet, and multiplet, respectively. Silica gel refers either to Mallinckrodt Silicar CC-7 (200–325 mesh) or Merck Silica gel 60 GF-254. TLC refers to precoated plates available from Analtech, which were developed in 15:1 chloroform–methanol. Visualization of TLC spots was performed in one or more of the following manners: (*a*) iodine vapor; (*b*) spraying with 40% sulfuric acid or 1% ceric sulfate in 10% sulfuric acid followed by heating; or (*c*) viewing under UV light.

[a] Average value. [b] A compound is active if it exhibits a T/C ≥ 120% (6, 8). [c] Toxic.

Synthesis of Esters—Except for bis(podophyllotoxinyl) succinate (XII), all compounds were synthesized by the following general procedures: To 200 mg (0.48 mmole) of podophyllotoxin in 10 ml of dry benzene and 5 ml of pyridine was added 2.4 mmoles of the appropriate acid chloride. The mixture was stirred at room temperature until TLC indicated that the reaction was complete. At that time, 5 ml of 5% sulfuric acid was added in a dropwise manner and the mixture was stirred for an additional hour. The organic layer was then removed, and the aqueous layer was extracted twice with chloroform. The organic layers were combined, dried over magnesium sulfate, filtered, and then evaporated *in vacuo*. The residue was column chromatographed on silica gel eluted with chloroform. The first fraction collected contained the desired compound with analytical data as specified.

Podophyllotoxinyl Acetate (II)—Colorless needles (175 mg, 80% from EtOH), mp 177–179° [lit. mp 179–181° (11), 204° (12), and 209–210° (13)]; IR (nujol): 1775 (γ-lactone), 1715 (ester), and 1230 (acetate) cm^{-1}; ^{1}H-NMR ($CDCl_3$): δ 1.98 (3, s, $OCOCH_3$), 2.70–2.90 (2, m, H-2 and H-3), 3.78 (6, s, OCH_3-3′ and OCH_3-5′), 3.81 (3, s, OCH_3-4′), 4.00–4.70 (4, unresolved m, H-1, H-4, and H-11), 5.98 (2, s, OCH_2O), 6.38 (2, s, H-2′ and H-6′), 6.52 (1, s, H-8), and 6.77 ppm (1, s, H-5).

Anal.—Calc. for $C_{24}H_{24}O_9$: *m/z* 456.1418 (M^+). Found: *m/z* 456.1424.

Podophyllotoxinyl Butyrate (III)—White amorphous solid (217 mg, 93% yield), mp 57–61° (sintered at 44–46°); R_f 0.62; IR: 1770 (γ-lactone), 1735, and 1235 (ester) cm^{-1}; ^{1}H-NMR: δ 1.01 (3, t, J = 7.0 Hz, CH_2CH_3), 1.40–2.00 (2, m, $CH_2CH_2CH_3$), 2.44 (2, t, J = 7.0 Hz, $CH_2CH_2CH_3$), 2.75–3.05 (2, m, H-2 and H-3), 3.78 (6, s, OCH_3-3′ and OCH_3-5′), 3.83 (3, s, OCH_3-4′), 4.00–4.70 (4, m, H-1, H-4 and H-11), 5.98 (2, s, OCH_2O), 6.39 (2, s, H-2′ and H-6′), 6.53 (1, s, H-8), and 6.75 ppm (1, s, H-5).

Anal.—Calc. for $C_{26}H_{28}O_9$: *m/z* 484.1732 (M^+). Found: *m/z* 484.1739.

Podophyllotoxinyl Acrylate (IV)—White amorphous powder (150 mg, 66% yield), mp 86–90° (sintered at 68°); R_f 0.64; IR: 1770 (γ-lactone), 1720 (ester), 1410, 1290, 995, and 935 (terminal olefin) cm^{-1}; ^{1}H-NMR: δ 2.80–3.10 (2, m, H-2 and H-3), 3.78 (6, s, OCH_3-3′ and OCH_3-5′), 3.81 (3, s, OCH_3-4′), 4.00–4.70 (4, unresolved m, H-1, H-4, and H-11), 6.04 (2, s, OCH_2O), 6.53 (1, s, H-8), 6.80 (1, s, H-5), 5.98 (2, m, $C{=}CH_2$), 6.41 (2, s, H-2′ and H-6′), and 6.15–6.65 ppm (1, overlapped m, $OCH{=}CH_2$).

Anal.—Calc. for $C_{25}H_{24}O_9$: C, 64.10; H, 5.13. Found: C, 64.11; H, 5.45.

Podophyllotoxinyl 3,3-Dimethyl Acrylate (V)—Colorless oil (66 mg, 27% yield); R_f 0.64; IR: 1765 (γ-lactone), 1700, 1230, and 1120 (acrylate) cm^{-1}; ^{1}H-NMR: δ 1.95 (3, d, J = 1.2 Hz, $=C{-}CH_3$), 2.22 (3, d, J = 1.2 Hz, $=C{-}CH_3$), 2.70–3.05 (2, m, H-2 and H-3), 3.78 (6, s, OCH_3-3′ and OCH_3-5′), 3.82 (3, s, OCH_3-4′), 4.15–4.70 (4, m, H-1, H-4, and H-11), 5.75 [1, m, $CH{=}C(CH_3)_2$], 5.98 (2, s, OCH_2O), 6.39 (2, s, H-2′ and H-6′), 6.53 (1, s, H-8), and 7.78 ppm (1, s, H-5).

Anal.—Calc. for $C_{27}H_{28}O_9$: C, 65.32; H, 5.64. Found: C, 65.68; H, 5.71.

Podophyllotoxinyl Benzoate (VI)—White amorphous solid (197 mg, 70% yield), mp 72–74° (sintered at 55–57°) [lit. (14) mp 113–117° as needles from EtOH]; R_f 0.65; IR:1770 (γ-lactone), 1710, 1250, 1120 (benzoate), 750, and 710 (monosubstituted aromatic ring) cm^{-1}; ^{1}H-NMR: δ 2.90–3.10 (2, m, H-2 and H-3), 3.69 (6, s, OCH_3-3′ and OCH_3-5′), 3.81 (3, s, OCH_3-4′), 4.25–4.75 (4, m, H-1, H-4, and H-11), 6.00 (1, s, H-8), 6.88 (1, s, H-5), and 7.30–8.40 ppm (5, m, COC_6H_5).

Anal.—Calc. for $C_{29}H_{26}O_9$: *m/z* 518.1576 (M^+). Found: *m/z* 518.1572.

Podophyllotoxinyl 3,5-Dinitrobenzoate (VII)—Yellow powder (110 mg, 37% yield), mp 153–156° (sintered at 149°); R_f 0.64; IR: 1775 (γ-lactone), 1730 (ester), 1540, and 1340 (aromatic nitro group) cm^{-1}; ^{1}H-NMR: δ 2.90–3.20 (2, m, H-2 and H-3), 3.83 (9, s, OCH_3-3′, OCH_3-4′, and OCH_3-5′), 4.20–4.80 (4, m, H-1, H-4, and H-11), 6.04 (2, s, OCH_2O), 6.45 (2, s, H-2′ and H-6′), 6.63 (1, s, H-8), 6.80 (1, s, H-5), and 9.01–9.41 ppm [3, m, $C_6H_3(NO_2)_2$].

Anal.—Calc. for $C_{29}H_{24}N_2O_{13}$: *m/z* 608.1275 (M^+). Found: *m/z* 608.1269.

Podophyllotoxinyl Hydrocinnamate (VIII)—Colorless oil (171 mg, 65% yield); R_f 0.62; IR: 1770 (γ-lactone), 1725, and 1235 (ester) cm^{-1}; ^{1}H-NMR: δ 2.70–3.10 (6, m, $COCH_2CH_2$-Ph, H-2, and H-3), 3.75 (6, s, OCH_3-3′ and OCH_3-5′), 3.81 (3, s, OCH_3-4′), 3.90–4.70 (4, m, H-1, H-4, and H-11), 5.94 (2, s, OCH_2O), 6.35 (2, s, H-2′ and H-6′), 6.50 (2, br s, H-5 and H-8), and 7.22 ppm (5, s, C_6H_5).

Anal.—Calc. for $C_{31}H_{30}O_9$: *m/z* 546.1889 (M^+). Found: *m/z* 546.1897.

Podophyllotoxinyl Phenoxyacetate (IX)—White amorphous solid (252 mg, 95% yield), mp 71–74° (sintered at 59–62°); R_f 0.65; IR: 1765 (γ-lactone), 1730, 1240 (ester), and 1040 (aromatic ether) cm^{-1}; ^{1}H-NMR: δ 2.80–3.10 (2, m, H-2 and H-3), 3.75 (6, s, OCH_3-3′ and OCH_3-5′), 3.82 (3, s, OCH_3-4′), 4.00–4.70 (4, m, H-1, H-4, and H-11), 4.76 (2, s, $COCH_2O$), 5.98 (2, s, OCH_2O), 6.36 (2, s, H-2′ and H-6′), 6.52 (1, s, H-8), 6.62 (1, s, H-5), and 6.70–7.50 ppm (5, m, OC_6H_5).

Anal.—Calc. for $C_{30}H_{28}O_{10}$: *m/z* 548.1683 (M^+). Found: *m/z* 548.1685.

Podophyllotoxinyl Ethyl Malonate (X)—White amorphous compound (169 mg, 64% yield), mp 68–70° (sintered at 54°); IR: 1775 (γ-lactone), 1730, and 1745 (slight shoulder) (esters) cm^{-1}; ^{1}H-NMR: δ 1.20 (3, t, J = 7.0 Hz, OCH_2CH_3), 2.70–3.00 (2, m, H-2 and H-3), 3.43 (2, s, $COCH_2CO$), 3.67 (6, s, OCH_3-3′ and OCH_3-5′), 3.43 (3, s, OCH_3-4′), 4.15 (2, overlapped q, J = 7.0 Hz, OCH_2CH_3), 4.00–4.65 [4, m (overlapped by q), H-1, H-4, and H-11], 5.90 (2, s, OCH_2O), 6.30 (2, s, H-2′ and H-6′), 6.45 (1, s, H-8), and 6.76 ppm (1, s, H-5).

Anal.—Calc. for $C_{27}H_{28}O_{11}$: *m/z* 528.1629 (M^+). Found: *m/z* 528.1625.

Podophyllotoxinyl Ethyl Adipate (XI)—Colorless oil (72 mg, 26% yield); IR:1770 (γ-lactone), 1720, and 1235 (ester) cm^{-1}; ^{1}H-NMR: δ 1.28 (3, t, J = 7.0 Hz, OCH_2CH_3), 1.50–2.00 (4, m, $CH_2CH_2CH_2CH_2$), 2.00–2.65 (4, m, $COCH_2(CH_2)_2CH_2CO$), 2.75–3.00 (2, m, H-2 and H-3), 3.78 (6, s, OCH_3-3′ and OCH_3-5′), 3.83 (3, s, OCH_3-4′), 4.15 (2, q, J = 7.0 Hz, OCH_2CH_3), 4.00–4.70 (4, m, H-1, H-4, and H-11), 6.00 (2, s, OCH_2O), 6.40 (2, s, H-2′ and H-6′), 6.54 (1, s, H-8), and 6.75 ppm (1, s, H-5).

Anal.—Calc. for $C_{30}H_{34}O_{11}$: *m/z* 570.2101 (M^+). Found: *m/z* 570.2106.

Bis(podophyllotoxinyl) Succinate (XII)—To 200 mg (0.48 mmole)

of podophyllotoxin (I) dissolved in 10 ml of dry benzene was added 100 mg (0.65 mmole) of succinyl chloride in 10 ml of benzene. The mixture was refluxed until TLC indicated the reaction was complete. Ten milliliters of water was added and the reaction was stirred for an additional hour, after which time the organic layer was removed, washed twice with saturated sodium bicarbonate solution, dried over magnesium sulfate, filtered, and then evaporated *in vacuo*. The oily residue was dried under high vacuum to give 97 mg (44%) of XII, mp 154–157°; IR:1765 (γ-lactone) and 1735 (ester) cm^{-1}; ^{1}H-NMR: δ 2.80 (4, br s, $COCH_2CH_2CO$), 2.70–2.95 (4, m, two H-2 and H-3), 3.77 (12, s, two OCH_3 at C-3′ and C-5′), 3.82 (6, s, two OCH_3 at C-4′), 4.20–4.70 (8, m, two H-1, H-4, and H-11), 5.98 (4, br s, two OCH_2O), 6.39 (4, s, two H-2′ and H-6′), 6.53 (2, two H-8), and 6.81 ppm (2, s, two H-5). Reactions attempted using a small amount of pyridine to improve the yield of XII were unsuccessful.

Anal.—Calc. for $C_{48}H_{46}O_{18}$: *m/z* 910.2680 (M^+). Found: *m/z* 910.2691.

Tetrahydropyranyl Podophyllotoxin (XIII)—Podophyllotoxin (200 mg, 0.48 mmole) was suspended in 10 ml of anhydrous ether and stirred at room temperature. *p*-Toluenesulfonic acid monohydrate (8 mg) and 530 mg (6 mmoles) of dihydropyran were added. As the reaction continued, the product dissolved in the ether, leaving a colorless solution. When TLC showed that the reaction was complete, the ether solution was washed twice with 5 ml of saturated sodium bicarbonate followed by water, dried over magnesium sulfate, filtered, and then evaporated *in vacuo*. Petroleum ether caused XIII, a white amorphous compound (185 mg 77% yield), to precipitate out of an ether solution of the resulting residue, observed mp 93–95° (effervescing from 65°) [lit. (15) mp 90–100°]; R_f 0.51; IR: 1775 (γ-lactone), 1130, and 1075 (aliphatic ether) cm^{-1}; ^{1}H-NMR: δ 1.65 [6, m, $C(CH_2)_3C$ (THP)], 2.83 (2, m, H-2 and H-3), 3.75 (6, s, OCH_3-3′ and OCH_3-5′), 3.80 (3, s, OCH_3-4′), 3.30–5.00 [7, overlapped br m, H-1, H-4, H-11, $—OCH_2$ (THP) and O—CH—O (THP)], 5.96 (2, s, OCH_2O), 6.40 (2, s, H-2′ and H-6′), 6.84 (1, s, H-8), and 7.12 ppm (1, s, H-5).

Anal.—Calc. for $C_{27}H_{30}O_9$: *m/z* 498.1889 (M^+). Found: *m/z* 498.1892.

Podophyllol (XIV)—This was prepared from podophyllotoxin by lithium aluminum hydride reduction according to a literature method (16).

Tetrahydropyranyl Podophyllol (XV)—Tetrahydropyranyl podophyllotoxin (XIII) (440 mg, 0.88 mmole) was dissolved in 10 ml of dry ether. This solution was added dropwise to an ice-cold suspension of 44 mg (1.1 mmoles) of 95% lithium aluminum hydride and stirred at room temperature. When TLC indicated completion, the reaction was cooled to 0° with ice, and a few drops of water were added slowly. After the initial vigorous reaction subsided, an additional 10 ml of water was added slowly, and the entire mixture was stirred for 1 hr. The mixture was filtered through a pad of diatomaceous earth[3] to remove the solids, and the aqueous layer was separated from the organic layer. The aqueous layer was extracted twice with ether and the organic phase was washed with water, dried over magnesium sulfate, filtered, and evaporated *in vacuo*, to give 416 mg (93%) of a white amorphous solid (XV), mp 61–63° (sintered at 41–42°) [lit. (15) mp 75–90°]; R_f 0.67; IR: 3200–3600 (OH), 1130 (ether), and 1040 (primary OH) cm^{-1}; ^{1}H-NMR: δ 1.45–2.50 [8, m, H-2, H-3, and $—C(CH_2)_3C—$ (THP)], 3.75 (6, s, OCH_3-3′ and OCH_3-5′), 3.82 (3, s, OCH_3-4′), 5.90 (2, s, OCH_2O), 6.33 (2, s, H-2′ and H-6′), 6.40 (1, s, H-8), 6.78 (1, s, H-5), and 3.00–5.00 ppm [9, overlapped m, H-1, H-4, H-11, H-13, $—OCH_2$ (THP), and —OCHO— (THP)].

Anal.—Calc. for $C_{27}H_{34}O_9$: *m/z* 502.2201 (M^+). Found: *m/z* 502.2206.

Tetrahydropyranyl Podophyllol Di-(2-bromoacetate) (XVI)—White oily gummy solid (157 mg, 53% yield); R_f 0.66; IR: 1740 (ester) and 1235 (CH_2Br) cm^{-1}; ^{1}H-NMR: δ 1.65 [6, m, $C(CH_2)_3C$ (THP)], 2.20–2.70 (2, m, H-2 and H-3), 3.78 (6, s, OCH_3-3′ and OCH_3-5′), 3.83 (3, s, OCH_3-4′), 3.76 (4, br s, $COCH_2Br$), 3.00–5.08 [9 (exclusive of above), m, H-1, H-4, CH_2OCO, CH_2O (THP), and OCHO (THP)], 5.91 (2, s, OCH_2O), and 6.10–6.80 ppm (4, m, H-5, H-8, H-2′, and H-6′).

Anal.—Calc. for $C_{31}H_{36}Br_2O_{11}$: *m/z* 742.0624 (M^+). Found: *m/z* 586 (corresponds to $[M - 2\,Br]^+$). M^+ was not observed, but M+2 and M+4 peaks were both observed indicating the presence of two bromine atoms.

Tetrahydropyranyl Podophyllol Di-(3-bromopropionate) (XVII)—Colorless oil (85 mg, 39% yield); R_f 0.72; IR: 1735 (ester) and 1215 (alkyl bromide) cm^{-1}; ^{1}H-NMR: δ 1.65 [6, m, $(CH_2)_3C$ (THP)], 2.80 (4, m, two $OCOCH_2CH_2$), 2.30–3.10 (2, m, H-2 and H-3), 3.58 (4, overlapped t, two CH_2Br), 3.79 (6, s, OCH_3-3′ and OCH_3-5′), 3.83 (3, s, OCH_3-4′), 3.00–5.00 [9 (exclusive of above), m, H-1, H-4, CH_2OCO, CH_2O (THP), and OCHO (THP)], 5.91 (2, s, OCH_2O), and 6.10–6.85 ppm (4, m, H-5, H-8, H-2′, and H-6′).

Anal.—Calc. for $C_{33}H_{40}Br_2O_{11}$: *m/z* 770.0937 (M^+). Found: *m/z* 691 (corresponds to $[M - Br]^+$). Although M^+ was not observed, M+2 and M+4 were also detected indicating the presence of two bromine atoms.

Tetrahydropyranyl Podophyllol Dimesylate (XVIII)—White amorphous solid (90 mg, 79.5% yield), mp 47–50° (dec.); R_f 0.72; IR: 1370, 1245, and 1175 (SO_2) cm^{-1}; ^{1}H-NMR: δ 1.65 [6, m, $C—(CH_2)_3—C$ (THP)], 3.01 (3, s, $SO_2—CH_3$), 3.19 (3, s, SO_2CH_3), 2.00–3.00 (2, m, H-2 and H-3), 3.78 (6, s, OCH_3-3′ and OCH_3-5′), 3.82 (3, s, OCH_3-4′), and 5.92 ppm (2, s, OCH_2O).

Anal.—Calc. for $C_{29}H_{38}O_{13}S_2$: C, 52.88; H, 5.81; S, 9.75. Found: C, 52.97; H, 5.85; S, 9.85.

Tetrahydropyranyl Podophyllol Ditosylate (XIX)—White amorphous solid (384 mg, 57% yield), mp 70–72° (sintered at 56–58°) [lit. (15) mp 76–88°]; R_f 0.77; IR: 1360, 1235, and 1187 (SO_2) cm^{-1}; ^{1}H-NMR: δ 1.58 [6, m, $C—(CH_2)_3—C$ (THP)], 2.45 (6, s, $ArCH_3$), 2.00–3.00 (2, m, H-2 and H-3), 3.00–5.00 [9 (exclusive of below), m, H-1, H-4, $CH_2O—S$, $—OCH_2$ (THP), and OCHO (THP)], 3.75 (6, s, OCH_3-3′ and OCH_3-5′), 3.82 (3, s, OCH_3-4′), 5.88 (2, s, OCH_2O), 6.30 (2, s, H-2′ and H-6′), 6.20–7.00 [2 (exclusive of above), m, H-5 and H-8], and 6.50 ppm (4, q, J = 8.5 Hz, $SO_2C_6H_4CH_3$).

Anal.—Calc. for $C_{41}H_{46}O_{13}S_2$: *m/z* 810.2381 (M^+). Found: *m/z* 810.2376.

Biological Assay—The antileukemic activity was assessed against the P-388 lymphocytic leukemia growth in BDF_1 male mice (~22 g). In this screen, 10^6 cells were implanted on day 0. The test compounds were administered intraperitoneally from day 1 to day 9. T/C values were calculated according to the protocol of the National Institutes of Health (14). 5-Fluorouracil was used as the internal standard in the screen.

Simultaneous Determination of Tegafur and 5-Fluorouracil in Serum by GLC Using Nitrogen-Sensitive Detection

NOBUO KAWABATA *, SEIYU SUGIYAMA *x, TSUKASA KUWAMURA *, YOSHICHIKA ODAKA *, and TETSUO SATOH ‡

Received November 30, 1981, from the **Central Research Laboratory, SS Pharmaceutical Co., Ltd., Narita, Chiba 286, Japan*, and ‡*Laboratory of Biochemical Pharmacology and Biotoxicology, Department of Drug Evaluation and Toxicological Sciences, Faculty of Pharmaceutical Sciences, Chiba University, 1-33 Yayoicho, Chiba 280, Japan.* Accepted for publication August 4, 1982.

Abstract □ A sensitive assay of both tegafur (I) and 5-fluorouracil (5-FU) using GLC with a nitrogen–phosphorus-sensitive detector is described. The drugs were extracted from rabbit serum with ethyl acetate and methylated with diazomethane. Linearity was obtained over the concentration ranges of 3.13–200 μg/ml for I and 0.0313–2 μg/ml and 10–50 ng/ml for 5-FU. The detection limits of I and 5-FU in serum were 50 and 8 ng/ml, respectively. The serum concentrations of the drugs determined by the present method closely agreed with those obtained by spectrophotometry for I and microbial assay for 5-FU.

Keyphrases □ Tegafur—simultaneous determination with 5-fluorouracil, rabbit serum, GLC using nitrogen-sensitive detection □ 5-Fluorouracil—simultaneous determination with tegafur, rabbit serum, GLC using nitrogen-sensitive detection □ GLC—nitrogen-sensitive detection, tegafur and 5-fluorouracil, simultaneous determination in rabbit serum

Tegafur [5-fluoro-1-(tetrahydro-2-furyl)uracil (I)], a prodrug of 5-fluorouracil (5-FU), is widely used as an antitumor agent (1–3). Various assays for I and/or 5-FU in biological fluids, such as spectrophotometry (4), microbial (4, 5), GLC (6–15), GLC–mass spectrometry (6, 16–20), and high-performance liquid chromatography (HPLC) (20–30), have been reported. All of these methods either lack adequate sensitivity and specificity and/or involve complicated and lengthy procedures. This paper describes a highly sensitive GLC method using a nitrogen–phosphorus-sensitive detector for simultaneously determining I and 5-FU.

EXPERIMENTAL

Materials—Tegafur (I)[1], 5-fluorouracil (5-FU)[2], and orotic acid[2] were used as received. Ethereal diazomethane solution was prepared according to the method of Arndt (31). All other chemicals and solvents were analytical reagent grade.

GLC Determination—The serum sample (1 ml) was adjusted to pH 6.3 with 0.1 ml of 0.5 *M* NaH_2PO_4 and extracted with 8 ml of ethyl acetate. After centrifugation at 2500 rpm for 10 min, the organic layer was removed and then evaporated to dryness under vacuum at room temperature. (With the lower concentration of 5-FU, <30 ng/ml, it was necessary to extract the serum sample with 8 ml of ethyl acetate twice.) The residue was dissolved in 0.1 ml of 30-μg/ml methanolic orotic acid and then 0.1 ml of ethereal diazomethane was added. The mixture was allowed to stand at room temperature for 30 min and then was evaporated to dryness under vacuum at room temperature. The residue was dissolved in 100 μl of acetone, and 1–2 μl of this solution was injected into a gas chromatograph[3] equipped with a nitrogen–phosphorus-sensitive detector for the measurement of I and 5-FU.

A 2 m × 3-mm i.d. glass column packed with 1% PEG-HT on 60–80 mesh Uniport HP[4] was used for the chromatography. The temperatures of the injection port, column, and detector were 300°, 175°, and 300°, respectively. Helium, the carrier gas, was maintained at a flow rate of 20 ml/min. The flow rates of air and hydrogen were optimized at 60 and 3 ml/min, respectively.

The sensitivities for the measurement of 5-FU and I were set at 1 × 16 and 10 × 32, respectively. The serum concentrations of I were ~100 times higher than those of 5-FU, so the sensitivity of the instrument was lowered to 1/20 for I after 5-FU and orotic acid were detected. Quantitation was carried out by studying the calibration curves obtained by plotting the ratio of the peak area of the methylated derivative of I to that of orotic acid, or the ratio of the peak height of the methylated derivative of 5-FU to that of orotic acid against the concentrations of these two compounds.

Analysis of Methylated Derivative Structures by GLC-Mass Spectrometry (MS)—A 0.1-ml aliquot of I, 5-FU, or orotic acid in acetone solution (1000 μg/ml) was added to 0.1 ml of ethereal diazomethane. After standing for 30 min at room temperature, the mixture was evaporated to dryness under vacuum at room temperature. The residue was dissolved in 100 μl of acetone, and 1 μl of this solution was injected into a gas chromatograph–mass spectrometer[5].

A 1 m × 3-mm i.d. glass column packed with 3% OV-17 on 80–100 mesh Chromosorb W HP[4] was used. The temperatures of the injection port, column, and separator were 260°, 200°, and 220°, respectively. The flow rate of helium, the carrier gas, was 30 ml/min. Electron-impact mass spectra were measured with 70-eV ionization energy, 60-μA ionization current, and 3500-V acceleration voltage.

Spectrophotometric and Microbial Determination—The assays were conducted according to the method of Yasuda *et al.* (4). Concentrations of I were measured by UV absorption at 270 nm after extraction from serum samples with chloroform at pH 2.0. The aqueous phase was assayed microbiologically after the pH was adjusted to 7.0.

Drug Administration—Male albino rabbits weighing 2.0–2.5 kg were used. Animals were administered I in a 1 *M* sodium carbonate solution (pH 9.0) at a dose level of 50 mg/kg iv. Blood samples were taken from the ear vein at appropriate time intervals up to 8 hr after drug administration and were centrifuged after coagulation. The serum obtained was frozen at −20° for subsequent analysis.

RESULTS

Identification of Methylated Derivatives of I, 5-FU, and Orotic Acid by GLC–MS—The MS data for the methylated derivatives of I, 5-FU, and orotic acid are shown in Table I. The structures of these methylated derivatives were shown to be 1-(tetrahydro-2-furyl)-3-*N*-methyl-5-fluorouracil (II), 1,3-dimethyl-5-fluorouracil (III), and methyl 1,3-dimethylorotate (IV), respectively.

Calibration Curves—For the construction of calibration curves, blank rabbit serum was spiked with known amounts of I and 5-FU and subjected to the GLC determination procedure described above. The calibration curves obtained from serum were $y = 0.0251x + 0.0462$ ($r = 0.9988$) for I, $y = 0.8615x + 0.0082$ ($r = 0.9991$) for 5-FU, and $y = 0.0036x + 0.0013$ ($r = 0.9981$) for the lower concentration of 5-FU over the concentration ranges of 3.13–200 μg/ml, 0.0313–2 μg/ml, and 10–50 ng/ml, respectively.

These calibration curves were compared with those obtained with the samples of I or 5-FU dissolved in acetone without the extraction step. Linear relationships were obtained in samples both from the serum and those dissolved in acetone. The mean recoveries of I and 5-FU from the serum were 99 and 75%, respectively. The detection limits of I and 5-FU

in the serum were 50 and 30 ng/ml, respectively. When the extraction procedure was performed twice (the lower concentration of 5-FU), the mean recovery increased to 94% with a detection limit of 8 ng/ml. The limits per injection of I and 5-FU on the column were 50 and 8 pg, respectively. In the triplicate determinations of the serum samples containing various concentrations of I or 5-FU, the coefficients of variation (*CV*) indicated high accuracy and good reproducibility (Table II).

GLC Chromatogram—A typical chromatogram, obtained with the serum sample taken at 2 hr after intravenous administration of I at a dose level of 50 mg/kg, is shown in Fig. 1. The retention times of III, IV, and II were 7.2, 12.4, and 24.0 min, respectively. An unknown endogenous component was detected in the serum with a retention time of 6.0 min, but this peak was well separated from the analyzing compounds. In addition to this peak originating from the endogenous component, another peak with a retention time of 16.4 min was detected in the serum after the administration of I, which might be one of the metabolites of I.

Serum Concentrations of I and 5-FU—The mean serum concentrations of I and 5-FU as a function of time obtained by the present GLC nitrogen–phosphorus-detector method, the spectrophotometric assay method, and the microbial assay method after administration of I at a dose level of 50 mg/kg iv are shown in Fig. 2. Slightly higher concentrations of 5-FU were obtained by the microbial assay method, especially at low levels, than by the present method. The mean serum concentration of I obtained by the present method declined gradually with an elimination half-life of 2.8 hr (Table III). For 5-FU, the peak of serum concentration was at 2 hr after the administration of I, and the elimination half-life was 2.3 hr (Table III).

DISCUSSION

Compound I has been widely used in cancer chemotherapy as a prodrug of 5-FU and is less toxic than 5-FU (32, 33). Compound I is slowly metabolized primarily in the liver to 5-FU. The hepatic microsomal drug-metabolizing enzymes such as cytochrome P_{450} may play a very significant role in this activation (1).

As reported previously (16, 34), when 5-FU is administered, it is rapidly eliminated from the blood with an elimination half-life of 10–30 min. But in the case of the administration of I, 5-FU is released little by little from I for a fairly long period *in vivo*. Various sensitive assay methods for blood

concentrations of I and 5-FU have been investigated. However, there have been no reports showing simultaneous measurement of the amount of I and 5-FU in biological fluids, except for an HPLC method (24, 27) which resulted in poor separation of 5-FU from the endogenous components. In the present study, I and 5-FU could be detected simultaneously in

[a] β = first-order elimination rate constant. [b] $t_{1/2}$ = biological half-life calculated by $0.693/\beta$. [c] $AUC_{0-\infty}$ = area under the serum concentration–time curve calculated by the trapezoidal rule. [d] V_{CL} = total body clearance, calculated by dose/AUC. [e] $V_{d\beta}$ = volume of distribution during the elimination phase calculated by V_{CL}/β.

serum with high sensitivity and well separated from the endogenous components by the GLC nitrogen–phosphorus-detector method.

5-FU was extracted from serum using the method described in a previous paper (6), on the basis of a pK_a of 8.1 to minimize the concomitant extraction of other acidic compounds contained in the serum that might interfere with the chromatographic assay procedure. Ethyl acetate was used for the extraction solvent. The recoveries of I and 5-FU from serum were 99 and 75%, respectively, which are slightly higher than the values reported by previous investigators (27) who obtained 85 and 60% for I and 5-FU, respectively, using HPLC. The detection limits of I and 5-FU in serum were 50 and 30 ng/ml, respectively. In the case of the lower concentration of 5-FU, the recovery rate increased to 94% by extracting twice with a detection limit of 8 ng/ml in serum. The determinations of the serum samples were conducted in triplicate on the same day using various concentrations of I or 5-FU, covering the range expected for *in vivo* experiments. The results obtained here indicated a satisfactory reproducibility as judged by the coefficients of variation (*CV*).

Compound I and 5-FU cannot be detected with high sensitivity by GLC if not converted to appropriate derivatives. Many derivatizing reagents have been reported (8, 11, 14, 15). When these reagents are injected directly into the GLC after the derivatizing reaction is completed, the peaks of the reagents become broad, and the detector may be contaminated, resulting in shortened column life. The separation of the compounds from the reagents used is difficult. It was reported that the trimethylsilylation of I causes the decomposition of I with 10–30% formation of the trimethylsilylated derivative of 5-FU (6, 13). For these reasons, I and 5-FU were subjected to quantitative methylation with diazomethane, which could be removed after the reaction was complete. No decomposition of I to 5-FU was observed during methylation, and the sample was stable at −20° for ~10 days without any decrease in the methylated derivatives of I and 5-FU. Even if decomposition of the methylated derivative of I occurred, the subsequent conversion to the methylated derivative of 5-FU could not occur because of the removal of diazomethane after derivatization. The calibration curves obtained with these methylated derivatives showed good linearity.

Previous investigators (8, 14) used thymine as an internal standard. However, thymine did not separate completely from 5-FU, either then or in the present study. Therefore, orotic acid was used instead of thymine in the present study; orotic acid showed a satisfactory separation from I, 5-FU, and other endogenous components in serum.

Compound I and 5-FU concentrations in rabbit serum after intravenous administration of I at a dose level of 50 mg/kg could be measured as the methylated derivatives by the present method using a column packed with 1% PEG-HT on Uniport HP. The pharmacokinetic parameters are summarized in Table III; the $t_{1/2}$, V_{CL}, and $V_{d\beta}$ of I were 2.8 hr, 0.14 liter/kg/hr, and 0.43 liter/kg, respectively. These values are fairly consistent with those reported by Au and Sadée (26) who obtained $t_{1/2}$ = 1.4–2.1 hr, V_{CL} = 0.18–0.20 liter/kg/hr, and $V_{d\beta}$ = 0.40–0.54 liter/kg in rabbit plasma by HPLC after intravenous administration of I at a dose level of 60 mg/kg. The elimination half-life of 5-FU derived from I was 2.3 hr, almost equivalent to the value of 2.6 hr in the dog (34).

Good correlations were obtained between the concentrations of I and 5-FU obtained by the present method and by the spectrophotometric assay method (I) ($y = 1.1243x - 6.4795$, $r = 0.9717$) or by the microbial assay method (5-FU) ($y = 0.9265x + 0.0936$, $r = 0.9081$), approximating a theoretical slope of 45°. The 5-FU concentrations obtained by the microbial assay method were slightly higher than those obtained by the present method, especially in the low concentrations, suggesting that the accuracy of the microbial assay method is not as good at low 5-FU levels. 5-FU released *in vivo* is further metabolized to other antibacterial compounds such as 5-fluorouridine, 5-fluorouridine-5′-monophosphate, 5-fluoro-2′-deoxyuridine, 5-fluoro-2′-deoxyuridine-5′-monophosphate, *etc.*, which may result in the higher concentrations obtained by the microbial assay method than those by the present method.

In the present studies, an unknown compound with a retention time of 16.4 min was detected, probably a dehydrogenated metabolite of I as reported in previous papers (24, 27). Dehydrogenated I is more labile than I and could be decomposed to 5-FU *in vivo* (27). But nonenzymatic decomposition of dehydrogenated I was not detected after incubation in 0.1 *M* phosphate buffer (pH 6.0) at 25° (27). On the other hand, in a previous study (6) I was decomposed 0.03% to 5-FU during analysis employing an evaporation procedure under nitrogen at 50° after extraction. Since I is thermally labile, the analytical procedure should be conducted at as low a temperature as possible. In the present study, the overall procedure was carried out at room temperature, resulting in no decomposition of I to 5-FU. This perhaps prevents decomposition of dehydrogenated I, which causes the increased concentration of 5-FU. Furthermore, no decrease of the peak possibly corresponding to the methylated derivative of dehydrogenated I was observed during the analysis. Investigation of valid evidence of this unknown compound as dehydrogenated I is in progress.

Comparative Assays for Doxepin and Desmethyldoxepin Using High-Performance Liquid Chromatography and High-Performance Thin-Layer Chromatography

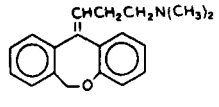
R. D. FAULKNER and C. LEE ˣ

Received July 12, 1982, from the *Department of Pharmaceutics, College of Pharmacy, University of Houston, Houston TX 77030.* Accepted for publication September 1, 1982.

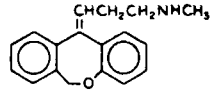
Abstract □ Two chromatographic methods, high-performance liquid chromatography (HPLC) and high-performance thin-layer chromatography (HPTLC) were compared for sensitivity and reproducibility in the analysis of the tricyclic antidepressant doxepin and its metabolite, desmethyldoxepin, in plasma. The HPLC procedure yielded a better reproducibility, as reflected by the coefficient of variation, and a higher sensitivity, as reflected by the minimum detectable quantity. The application of these methods for therapeutic and subtherapeutic monitoring of plasma levels of the drug is described.

Keyphrases □ Doxepin—high-performance thin-layer and liquid chromatographic methods, comparison, human plasma, desmethyldoxepin metabolite □ High-performance liquid chromatography—doxepin and desmethyldoxepin in human plasma, comparison with high-performance thin-layer chromatography □ Thin-layer chromatography—high-performance, doxepin and desmethyldoxepin in human plasma, comparison with high-performance liquid chromatography

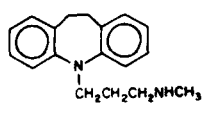
Doxepin (I) is a tricyclic antidepressant commonly prescribed for the treatment of endogenous depression. Increasing evidence of a correlation between the total tricyclic plasma level [doxepin plus desmethyldoxepin (II)] and the antidepressant effect suggests that monitoring tricyclic plasma levels may be beneficial in the clinical management of depression.



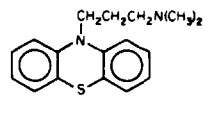
I



II



III



IV

Several assay methods for I and II have been reported, including GLC (1–3), radioimmunoassay (4), GC–mass fragmentography (5), and high-performance liquid chromatography (HPLC) (6–9). Most of these methods either require extensive sample preparation or lack the necessary specificity and sensitivity for pharmacokinetic studies. This paper compares two chromatographic procedures, HPLC and high-performance thin-layer chromatography (HPTLC), for sensitivity and reproducibility in the analysis of I and II in plasma. Desipramine (III) and promazine (IV) were used as internal standards in HPLC and HPTLC, respectively.

EXPERIMENTAL

Materials—A high-performance liquid chromatograph[1] equipped with a variable-wavelength UV detector[2], a sample loop injection valve[3], and a 5-μm octadecylsilane column[4] (150 mm × 4.6-mm i.d.) was used for HPLC analyses. A scanning spectrophotometer–densitometer[5] was used for HPTLC measurements.

Doxepin[6], desmethyldoxepin[6], desipramine[7], and promazine[8] were obtained as hydrochloride salts. Toluene[9], chloroform[9], pentane[9], and 2-propanol[9] were reagent grade and were glass-distilled before use. HPLC-grade acetonitrile[10] and reagent-grade *N*-nonylamine[11] were used as supplied. All glassware used for samples or extracts were silylated with hexamethyldisilazine at elevated temperature and reduced pressure. Working standard solutions were prepared in the following strengths: I, 1 μg/ml; II, 1 μg/ml; III, 2μg/ml; IV, 1 μg/ml.

HPLC Procedures—Analyses were performed using a modified procedure of Kabra *et al.* (10). Plasma standards were prepared by spiking known quantities of I and II in 1 ml of plasma containing 0.1 μg of desipramine internal standard (III). To the spiked plasma samples were added 0.25 ml of saturated sodium carbonate and 4.5 ml of pentane. The sample mixture was rotated for 45 min and then centrifuged. The pentane phase was transferred into a silylated conical vial[12] and back-extracted with 0.1 ml of 0.1 *N* HCl. The organic layer was discarded, and aliquots of the aqueous phase were injected into the liquid chromatograph. The mobile phase was 45% acetonitrile in 0.01 *M* phosphate buffer containing 600 ppm of *N*-nonylamine (pH 3.1). The deaerated and fil-

[a] Absorbance measured at 200 nm. [b] Mean of six determinations. [c] Coefficient of variation.

tered mobile phase was pumped through the column at 2.5 ml/min, and the effluents were detected at 200 and 240 nm.

HPTLC Procedures—Analyses were performed following a modified procedure of Fenimore *et al.* (11). To plasma standards containing various amounts of I and II were added 50 ng of promazine internal standard (IV), 0.25 ml of saturated sodium carbonate, and 4.5 ml of pentane. The mixture was gently shaken for 45 min and then centrifuged. The aqueous layer was frozen in an acetone–dry ice bath, and the organic phase was decanted into a silylated conical vial. After complete evaporation of the organic phase, the residue was dissolved in 60 μl of heptane–ethanol (3:1), and 50 μl of the reconstituted sample was spotted onto the HPTLC plate[13]. Development of the plate was carried out in a twin-trough chamber[14] using two solvent systems: toluene–chloroform–2-propanol (20:20:10) and toluene–chloroform–2-propanol–ammonium hydroxide (20:20:10:1). The developed plates were air dried prior to UV scanning.

RESULTS AND DISCUSSION

Figure 1 shows representative liquid chromatograms of a control plasma blank, plasma spiked with III, and plasma to which I, II, and III were added. The retention times were 4.6, 3.3, and 6.3 min for I, II, and III, respectively. As indicated in Fig. 1a, no interfering peaks were found in the control plasma.

The peak height ratios obtained following HPLC analyses of I and II in control plasma are summarized in Table I. The calibration curves were characterized by linear regression equations of $y = 0.0156x + 0.0345$, $r^2 = 0.9981$ for I, and $y = 0.0177x + 0.0480$, $r^2 = 0.9983$ for II. The reproducibility in concentration measurements, as reflected by the coefficient of variation, was 6.3 ± 2.2% for I and 7.2 ± 2.9% for II. The lower detection limit was 5 ng for both I and II.

Figure 2 depicts the thin-layer chromatograms of a control plasma blank, plasma to which promazine internal standard (IV) was added, and

[a] Absorbance measured at 240 nm. [b] Mean of four determinations. [c] Coefficient of variation. [d] II not distinguishable from baseline at 10 ng.

plasma with added I, II, and IV. No interfering signals were detected in the blank plasma at R_f values of 1.6 cm for I, 0.6 cm for II, and 1.0 cm for IV.

The peak height ratios derived at 240 nm following HPTLC analyses of various amounts of I and II in control human plasma are presented in Table II. In the 10 to 100-ng range, the assay reproducibility was 6.5 ± 2.4% for I and 9.8 ± 2.2% for II. Typical calibration curves were characterized by $y = 0.0099x + 0.0551$, $r^2 = 0.9951$ for I, and $y = 0.0057x - 0.0190$, $r^2 = 0.9980$ for II. The sensitivity of measurements was 10 ng for I and 20 ng for II at 200 nm, which decreased to 20 ng for I and 30 ng for II at 240 nm.

Since a common internal standard was not available for both chromatographic procedures, each method requires its own internal standard.

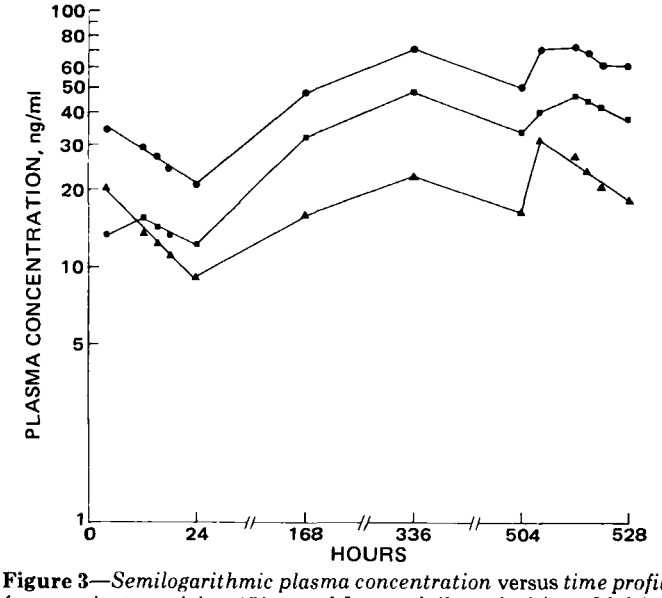

Figure 3—*Semilogarithmic plasma concentration* versus *time profile for a patient receiving 150 mg of I once daily at bedtime. Multiple samples were collected for the 24-hr periods following the 1st and 21st doses. Key: (▲) I; (■) II; (●) I and II.*

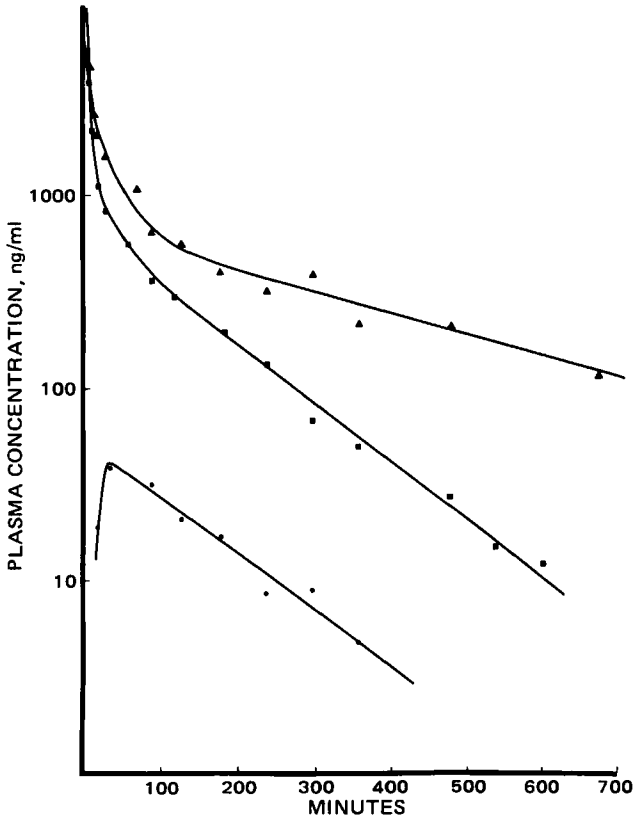

Figure 4—*Semilogarithmic plasma concentration* versus *time plots for I and II in a normal dog following intravenous administrations of 50 mg of I and 50 mg of II on two occasions separated by 2 weeks. Key: (▲) I; (●) II generated from I; (■) II given as a separate dose.*

Promazine was selected as the internal standard for HPTLC method because of the proximity of its R_f value to that of I and II. Similarly, desipramine was used in the HPLC procedure because of its relatively short retention time: 6 min as opposed to 13 min for promazine.

When both chromatographic procedures were compared for detection sensitivity at 200 nm on an equivalent weight basis, the HPLC method appeared to be superior. Since back-extraction was carried out in the HPLC procedure, which could conceivably reduce the extraction recovery, the lower sensitivity of the HPTLC method could not be attributed to the extraction process. One possibility is that the HPLC mobile phase favors the UV absorbance for I and II compared with the silica gel of the HPTLC plate.

In an attempt to compare the reproducibility of the HPTLC procedure at two different wavelengths (200 and 240 nm), coefficients of variation were determined: 10.3 ± 5.0% for I and 12.4 ± 5.6% for II at 200 nm as opposed to 6.5 ± 2.4% for I and 9.8 ± 2.2% for II at 240 nm. The reproducibility was less impressive at 200 nm; however, it was comparable with HPLC at 240 nm. The detecting sensitivity, on the other hand, notably decreased at the longer wavelength.

Figure 3 shows the plasma concentration *versus* time plot for a patient receiving 150 mg of I once daily at bedtime. Multiple samples were collected for 24-hr following the 1st and the 21st doses. Half-lives of I and II were 17.3 and 35.5 hr, respectively, after the first dose, and 23.8 and 40.6 hr following the last dose. It is not clear, based on this patient study, whether multiple dosing of I alters its metabolism.

Figure 4 presents plasma concentration *versus* time plots for a normal dog intravenously administered a 50-mg dose of I and a 50-mg dose of II on two occasions separated by 2 weeks. The β-phase half-life of I in the dog, 2.5 hr, was considerably shorter than that of the depressed human, 17.2 hr. In contrast to the human, the dog exhibited a shorter half-life for II than for I [17.3/35.5 (I/II) in the human *versus* 3.3/2.1 in the dog]. In addition, the dog presented a substantially lower fraction of II in the plasma. These observations suggest an interspecies difference in the metabolic and excretory patterns of I between dogs and humans.

In summary, for measurements of therapeutic levels of I and II in plasma, both HPLC and HPTLC provide adequate sensitivity and reproducibility. The HPLC method offers a higher detection sensitivity and is suggested for pharmacokinetic studies in which subtherapeutic concentrations are to be measured. On the other hand, the HPTLC procedure offers a greater processing capacity and a shorter turnaround time, which are preferred in a clinical setting for the routine monitoring of tricyclic plasma levels.

Determinations of Tiodazosin and Levulinic Acid from Tablets by High-Performance Liquid Chromatography

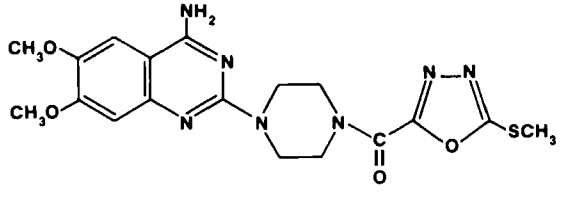
B. C. PROSSER, B. J. FLOOR, A. E. KLEIN, and N. MUHAMMAD ˣ

Received July 15, 1982, from the *Analytical Research and Development Department, Bristol Laboratories—Division of Bristol-Myers Co., Syracuse, NY 13201.* Accepted for publication September 7, 1982.

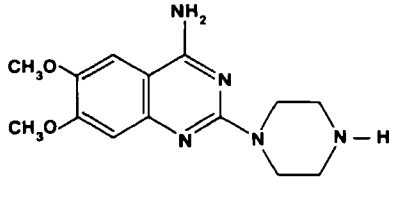
Abstract □ Specific assays of tiodazosin and levulinic acid from tablet preparations were developed using high-performance liquid chromatography. Tiodazosin was determined with acetonitrile 50% (v/v) in pH 5.7 acetate buffer on a 300 × 3.9-mm i.d. microparticulate C-18 column using 254 nm detection with butylparaben as the internal standard. Levulinic acid was determined at 280 nm with 1 *N* acetic acid on a 300 × 3.9-mm i.d. microparticulate phenyl column using an external standard. The assays were run sequentially. The relative standard deviations of sample variability (2σ, $n = 6$) and recoveries from synthetic preparation were ±1.6 and ~95%, respectively, for both assays.

Keyphrases □ Tiodazosin—tablets, high-performance liquid chromatographic assay, sequential with levulinic acid □ Levulinic acid—in tiodazosin tablets, sequential high-performance liquid chromatographic assay □ High-performance liquid chromatography—tiodazosin and levulinic acid from tablets, sequential assay

Tiodasozin, 1-(4-amino-6,7-dimethoxy-2-quinazolinyl) -4- [[5-(methylthio) -1,3,4- oxadiazol-2-yl]carbonyl]-piperazine (I), is an orally active hypertensive agent currently undergoing clinical trials. It is formulated in tablets with levulinic acid (4-oxopentanoic acid). A reported high-performance liquid chromatographic (HPLC) assay method for tiodazosin (1) is limited to biological samples and involves work-up procedures and a fluorescence detection system that would not be suitable for the dosage form.



I



II

Levulinic acid has been quantitatively assayed as the methyl ester by GC (2). This method was found to be unsuitable, however, for the acid in the presence of the tablet excipients due to the incompleteness of the derivatization reaction. A simplified analytical method that does not employ derivatization is described in this study. The method utilizes the relatively weak UV absorptivity of the acid in methanol (3), which is ~20 liters/mole·cm at the 270-nm UV maxima and 15 liters/mole·cm at 280 nm.

Two simple HPLC procedures for the quantitative assay of tiodazosin and levulinic acid are described in the present report. The methods are accurate and specific in the presence of the tablet matrix ingredients.

EXPERIMENTAL

Apparatus—A modular HPLC system consisting of a pump[1], a septumless loop injector[2], and a fixed-wavelength detector[3] was used. Peak elution times and areas were obtained with a reporting integrator system[4].

Reagents and Materials—Tiodazosin[5] and levulinic acid[6] were used without further purification. Sodium acetate[7] and glacial acetic acid[7] were ACS reagent grade. Butylparaben NF[8] was used as received. Acetonitrile[9] was obtained as distilled-in-glass chromatographic grade, and water was distilled and deionized.

Sample Preparation—Ten tablets of tiodazosin were accurately weighed and then ground and blended to a uniform fine powder. A portion of the powdered blend was accurately weighed for each assay.

HPLC column (30 cm × 3.9-mm i.d.) prepacked with bonded octadecylsilane on silica[10] (10% loading by weight, 10-μm mean particle size) was used with a mobile phase of 50% by volume acetonitrile in 0.1 *M* sodium acetate, previously adjusted to pH 5.7 with glacial acetic acid. A flow rate of 1.5 ml/min and a loop injection volume of 20 μl were employed with the detector set at 254 nm.

Standard Solution—A solution of butylparaben in acetonitrile was prepared at a concentration of 100 μg/ml for use as an internal standard. A stock solution of tiodazosin reference material was prepared at a concentration of 50 μg/ml in mobile phase, and a 5-ml aliquot of this stock solution together with 5 ml of the internal standard solution were transferred to a 50-ml volumetric flask and diluted to volume with mobile phase for use as a standard.

Analytical Procedure—The powdered tablet sample equivalent to a theoretical level of ~5 mg of tiodazosin was transferred to a 100-ml volumetric flask. A 50-ml portion of mobile phase was added, the solution sonicated[11] for 5 min, and diluted to volume with mobile phase. A portion of this solution was filtered[12], discarding the first few milliliters, and a 5-ml portion of the filtrate was transferred to a 50-ml volumetric flask. The internal standard (5 ml) was added, and the solution was diluted to volume with mobile phase. Successive injections of the standard and sample solutions were made onto the chromatographic system at room temperature. The peak areas generated were applied to the calculation of milligrams tiodazosin per average tablet weight (ATW) using the formulas:

$$\text{Factor (F) for Tiodazosin} = \frac{\text{Peak Area Internal Standard} \times \text{mg/ml Tiodazosin Standard} \times \text{Purity of Standard}}{\text{Peak Area Tiodazosin Standard} \times \text{mg/ml Internal Standard}}$$

$$\text{mg Tiodazosin per ATW} = \frac{\text{F} \times 1000 \times \text{mg/ml Internal Standard} \times \text{Peak Area Tiodazosin} \times \text{mg per ATW}}{\text{Peak Area Internal Standard} \times \text{mg Sample}}$$

Levulinic Acid Assay—*Chromatographic Conditions*—A prepacked bonded phenyl on silica[13] (10% loading by weight, 10-μm mean particle size) HPLC column (30 cm × 3.9-mm i.d. stainless steel) was employed with a mobile phase of 1.0 *N* acetic acid. The mobile phase was filtered through a 0.45-μm membrane filter[14] prior to use. A flow rate of 1.0 ml/min and a loop injection volume of 200 μl were used with the detector set at 280 nm.

Standard Solution—A standard levulinic acid solution was prepared containing 0.26–0.30 mg of the acid per milliliter of mobile phase. To ensure noninterference, a 500-mg portion of placebo tablet granulation (containing all the tiodazosin tablet excipients) was mixed with 10 ml of the mobile phase. The resulting suspension was filtered[15], and an aliquot was injected into the chromatographic system.

Analytical Procedure—The powdered tablet sample, equivalent to one average tablet weight, was transferred to a 20-ml vial, 10 ml of mobile phase was added, the vial capped, and the suspension was mixed by shaking mechanically for 15 min in a reciprocating shaker. The contents of the vial was filtered[15] prior to chromatographic injection. Successive injections of the standard and sample were made at room temperature. The levulinic acid peak areas were used for the calculation of milligrams levulinic acid per ATW using the formulas:

$$\text{Factor (F) for Levulinic Acid} = \frac{\text{mg/ml Levulinic Acid Standard} \times 10 \times \text{Purity of Standard}}{\text{Peak Area Levulinic Acid}}$$

$$\text{mg Levulinic Acid per ATW} = \frac{\text{F} \times \text{Peak Area Levulinic Acid} \times \text{mg per ATW}}{\text{mg Sample}}$$

RESULTS AND DISCUSSION

The described HPLC method elutes levulinic acid in ~5.8 min and employs the relatively weak UV absorption of the acid at ~280 nm for determinations at concentration levels of $\geq 3 \times 10^{-4}$ *M*. The relatively larger injection volume of 200 μl was required for detectability of levulinic acid below the millimolar level. Figure 1 shows representative chromatograms for a placebo with no levulinic acid and a typical tablet sample.

The tiodazosin content can be determined sequentially from the same powdered tablet sample by employing the described, independent assay procedure. Figure 2 shows a typical chromatogram for this assay, with tiodazosin eluting at ~3.2 min and the internal standard at ~5.8 min. The total analysis time for a typical tablet sample is ~7 min.

Standard linearity was checked over the range 1.00–10.00 mg/ml for tiodazosin and 0.03–1.5 mg/ml for levulinic acid. Both compounds responded linearly over the stated concentration ranges, with least-squares regression analysis of the peak area responses producing correlation coefficients >0.999 in both cases. The difference in the slopes of the regression lines for levulinic acid in the presence of a placebo granulation compared with that in the absence of the placebo was <1% of the mean slope value. This implies a levulinic acid recovery of ~99% from the placebo matrix.

Chromatographic variability was determined by six identical injections of the standard preparations of tablet samples with a label claim of either 10 mg of tiodazosin or 7 mg of levulinic acid. Relative standard deviations (2*s*%) for chromatographic variability and sample variability are ±0.50

and ±1.6% for the tiodazosin assay or ±1.8 and ±1.6% for the levulinic acid assay.

Accuracy of the assays was determined by recoveries of individual tiodazosin additions to spiked placebo formulation equivalent to 1, 2, 5, 10, and 20 mg of tiodazosin per tablet. Recoveries for the five spiked samples ranged from 95.7 to 99.3% with a mean recovery of 96.7% (s = ±1.8%), calculated from the regression line generated from the linearity study. The spiking of levulinic acid over the concentration range from 0.5 to 1.5 mg per tablet into a placebo matrix produced recovery results, calculated using the regression line generated in the absence of the placebo, of 87.5% at the 0.5-mg level, 95.6% at the 5-mg level, and 99.6% at the 15-mg level.

The forced degradation of 1-mg tiodazosin tablets under conditions of heat (100° for 20 hr), light (~15 W at 300 nm for 1 week), acid (1 N HCl for 20 hr), and base (1 N NaOH for 20 hr) was performed to test the specificity of the tiodazosin assay method. Absorbance ratios were calculated from chromatograms generated at 220, 254, or 340 nm from both undegraded and degraded samples. No apparent interference was observed from any of the degraded samples, and the relative standard deviations of the 254/220-nm and 254/340-nm absorbance ratios was ±1.2 and ±0.7%, respectively. For the levulinic acid assay, no apparent interferences were observed for degraded samples, where the degradation conditions were adjusted to produce a maximum acid degradation of 10%.

Specificity of the tiodazosin method was also demonstrated by the resolution of the principal known decomposition product, 4-amino-6,7-dimethoxy-2-(1-piperazinyl)quinazoline (II), from the active drug under the assay conditions. A chromatographic tracing of a mixture of I and II is shown in Fig. 3. The results of typical tablet blend analyses gave mean recoveries of 103% for tiodazosin and 99.7% for levulinic acid based on the label claims for a nominal 10 mg of tiodazosin per tablet level. In summary, the reverse-phase HPLC methods described in this paper provide simple, rapid, and quantitative methods for the determination of tiodazosin and levulinic acid from the tablet matrix.

General Definition of Valence Delta-Values for Molecular Connectivity

LEMONT B. KIER *ˣ and LOWELL H. HALL ‡

Received March 31, 1982 from the **Department of Pharmaceutical Chemistry, Virginia Commonwealth University, Richmond, VA 23298* and the ‡*Department of Chemistry, Eastern Nazarene College, Quincy, MA 02170.* Accepted for publication August 26, 1982.

Abstract □ The molecular connectivity valence delta-values have been defined in terms of the count of nonhydrogen valence electrons on a valence-state atom as screened from the nucleus by the core electrons. The core is defined as the nonvalence electrons minus 1. This general definition expresses the valence delta-values for second and third quantum level atoms and halogens. Valence delta-values have been derived for higher oxidation states of sulfur and phosphorus. The internal consistency of these delta-values is tested by their ability to closely correlate molar refraction values with $^1\chi^v$. It is found that a second variable, the count of the number of α hydrogen atoms, greatly increases the quality of the correlation. Some biological SAR applications reveal the general utility of these findings.

Keyphrases □ Molecular connectivity—valence delta-values, definition, applications to structure–activity relationships, comparison with molecular refractivity □ Structure–activity relationships—applications of molecular connectivity valence delta-values, comparison with molecular refractivity □ Molecular refractivity—comparison with molecular connectivity valence delta-values, structure–activity relationships

A major advance in the general applicability of molecular connectivity arose from the introduction of valence molecular connectivity indexes by Kier and Hall (1, 2). This innovation made it possible to encode information about heteroatoms and unsaturated features and to correlate this with the relative differences in properties among such molecules. The subsequent use of valence molecular connectivity has been summarized (3).

BACKGROUND

Early Estimates of δ^v—In the initial description of the valence connectivity delta a bonded atom was described by a count of the valence electrons other than those bonding hydrogen (1). This value, designated δ_i^v for atom i was incorporated into the valence connectivity index, $^1\chi^v$, using the same algorithm as for the simple connectivity index, $^1\chi^v = \Sigma(\delta_i^v\delta_j^v)^{-1/2}$. The structural information encoded in the simple δ, a count of σ bonds (electrons) other than those bonding hydrogen, and the δ^v-value was evident from an inspection of a matrix of the two values (3). The sum of the delta-values ($\delta^v + \delta$) for a hybrid atom relates closely to estimates of the hybrid atom volume. It was also shown that the difference between the delta-values ($\delta^v - \delta$) for a hybrid atom is a count of π and lone-pair electrons, referred to as "exterjacent" to describe their relationship to internuclear axes. A count of exterjacent electrons on an atom in its hybrid state, within a quantum level, bears a close relationship to the Mulliken–Jaffe electronegativity (3).

In the earliest consideration of heteroatoms (1), the δ^v-values for second quantum level atoms were verified by relating the calculated $^1\chi^v$ values to molar refraction (MR) data for substituted benzenes (4). The correlation was good, however the experimental value of fluorobenzene presented a problem. The fact that it has a value of 0.4 less than benzene led to the rejection of the logical $\delta_F^v = 7$ and to the derivation of an empirical value of −20. Thus the $(\delta_i^v\delta_F^v)^{-1/2}$ would have a negative value. This subtraction of the modest value of this term in the calculation of $^1\chi^v$ permitted a fairly accurate reproduction of the effect of fluorine in molecules as far as certain physical property values. Using the same approach, empirical values were derived for the other halogens (1) and sulfur (2). These are shown in Table I, column 1.

The Quantum Level Effect on δ^v—Following these initial empirical assignments of higher level atom δ^v-values, a fundamental significance for these numbers was sought. This led to the realization that the empirical δ^v-values for Cl, Br, I, and S were close to the numbers derived by a general expression:

$$\delta^v = \frac{Z^v - h}{Z - Z^v} \qquad \text{(Eq. 1)}$$

where h is the count of hydrogen atoms, Z^v is the count of valence electrons, and Z is the count of all electrons (5). The value $Z - Z^v$ is the count of all nonvalence electrons on the atom; thus, it constitutes information on the principal quantum number of the atom. The denominator in Eq. 1 may be viewed as simulating a radial dimension or a valence orbital screening factor associated with the particular quantum level. Indeed this influence on the valence electrons has been approximated by the use

0022-3549/83/1000-1170$01.00/0

and ±1.6% for the tiodazosin assay or ±1.8 and ±1.6% for the levulinic acid assay.

Accuracy of the assays was determined by recoveries of individual tiodazosin additions to spiked placebo formulation equivalent to 1, 2, 5, 10, and 20 mg of tiodazosin per tablet. Recoveries for the five spiked samples ranged from 95.7 to 99.3% with a mean recovery of 96.7% (s = ±1.8%), calculated from the regression line generated from the linearity study. The spiking of levulinic acid over the concentration range from 0.5 to 1.5 mg per tablet into a placebo matrix produced recovery results, calculated using the regression line generated in the absence of the placebo, of 87.5% at the 0.5-mg level, 95.6% at the 5-mg level, and 99.6% at the 15-mg level.

The forced degradation of 1-mg tiodazosin tablets under conditions of heat (100° for 20 hr), light (~15 W at 300 nm for 1 week), acid (1 N HCl for 20 hr), and base (1 N NaOH for 20 hr) was performed to test the specificity of the tiodazosin assay method. Absorbance ratios were calculated from chromatograms generated at 220, 254, or 340 nm from both undegraded and degraded samples. No apparent interference was observed from any of the degraded samples, and the relative standard deviations of the 254/220-nm and 254/340-nm absorbance ratios was ±1.2 and ±0.7%, respectively. For the levulinic acid assay, no apparent interferences were observed for degraded samples, where the degradation conditions were adjusted to produce a maximum acid degradation of 10%.

Specificity of the tiodazosin method was also demonstrated by the resolution of the principal known decomposition product, 4-amino-6,7-dimethoxy-2-(1-piperazinyl)quinazoline (II), from the active drug under the assay conditions. A chromatographic tracing of a mixture of I and II is shown in Fig. 3. The results of typical tablet blend analyses gave mean recoveries of 103% for tiodazosin and 99.7% for levulinic acid based on the label claims for a nominal 10 mg of tiodazosin per tablet level. In summary, the reverse-phase HPLC methods described in this paper provide simple, rapid, and quantitative methods for the determination of tiodazosin and levulinic acid from the tablet matrix.

General Definition of Valence Delta-Values for Molecular Connectivity

LEMONT B. KIER *ˣ and LOWELL H. HALL ‡

Received March 31, 1982 from the **Department of Pharmaceutical Chemistry, Virginia Commonwealth University, Richmond, VA 23298* and the ‡*Department of Chemistry, Eastern Nazarene College, Quincy, MA 02170.* Accepted for publication August 26, 1982.

Abstract □ The molecular connectivity valence delta-values have been defined in terms of the count of nonhydrogen valence electrons on a valence-state atom as screened from the nucleus by the core electrons. The core is defined as the nonvalence electrons minus 1. This general definition expresses the valence delta-values for second and third quantum level atoms and halogens. Valence delta-values have been derived for higher oxidation states of sulfur and phosphorus. The internal consistency of these delta-values is tested by their ability to closely correlate molar refraction values with $^1\chi^v$. It is found that a second variable, the count of the number of α hydrogen atoms, greatly increases the quality of the correlation. Some biological SAR applications reveal the general utility of these findings.

Keyphrases □ Molecular connectivity—valence delta-values, definition, applications to structure–activity relationships, comparison with molecular refractivity □ Structure–activity relationships—applications of molecular connectivity valence delta-values, comparison with molecular refractivity □ Molecular refractivity—comparison with molecular connectivity valence delta-values, structure–activity relationships

A major advance in the general applicability of molecular connectivity arose from the introduction of valence molecular connectivity indexes by Kier and Hall (1, 2). This innovation made it possible to encode information about heteroatoms and unsaturated features and to correlate this with the relative differences in properties among such molecules. The subsequent use of valence molecular connectivity has been summarized (3).

BACKGROUND

Early Estimates of δ^v—In the initial description of the valence connectivity delta a bonded atom was described by a count of the valence electrons other than those bonding hydrogen (1). This value, designated δ_i^v for atom i was incorporated into the valence connectivity index, $^1\chi^v$, using the same algorithm as for the simple connectivity index, $^1\chi^v = \Sigma(\delta_i^v\delta_j^v)^{-1/2}$. The structural information encoded in the simple δ, a count of σ bonds (electrons) other than those bonding hydrogen, and the δ^v-value was evident from an inspection of a matrix of the two values (3). The sum of the delta-values ($\delta^v + \delta$) for a hybrid atom relates closely to estimates of the hybrid atom volume. It was also shown that the difference between the delta-values ($\delta^v - \delta$) for a hybrid atom is a count of π and lone-pair electrons, referred to as "exterjacent" to describe their relationship to internuclear axes. A count of exterjacent electrons on an atom in its hybrid state, within a quantum level, bears a close relationship to the Mulliken–Jaffe electronegativity (3).

In the earliest consideration of heteroatoms (1), the δ^v-values for second quantum level atoms were verified by relating the calculated $^1\chi^v$ values to molar refraction (MR) data for substituted benzenes (4). The correlation was good, however the experimental value of fluorobenzene presented a problem. The fact that it has a value of 0.4 less than benzene led to the rejection of the logical $\delta_F^v = 7$ and to the derivation of an empirical value of −20. Thus the $(\delta_i^v\delta_F^v)^{-1/2}$ would have a negative value. This subtraction of the modest value of this term in the calculation of $^1\chi^v$ permitted a fairly accurate reproduction of the effect of fluorine in molecules as far as certain physical property values. Using the same approach, empirical values were derived for the other halogens (1) and sulfur (2). These are shown in Table I, column 1.

The Quantum Level Effect on δ^v—Following these initial empirical assignments of higher level atom δ^v-values, a fundamental significance for these numbers was sought. This led to the realization that the empirical δ^v-values for Cl, Br, I, and S were close to the numbers derived by a general expression:

$$\delta^v = \frac{Z^v - h}{Z - Z^v} \qquad \text{(Eq. 1)}$$

where h is the count of hydrogen atoms, Z^v is the count of valence electrons, and Z is the count of all electrons (5). The value $Z - Z^v$ is the count of all nonvalence electrons on the atom; thus, it constitutes information on the principal quantum number of the atom. The denominator in Eq. 1 may be viewed as simulating a radial dimension or a valence orbital screening factor associated with the particular quantum level. Indeed this influence on the valence electrons has been approximated by the use

(6) of the atomic radius (r), the use (7) of r^2, or the use (8, 9) of the square of the quantum number (N^2) in estimating orbital electronegativity or boundary potentials. The values derived from the use of Eq. 1 are listed in Table I, column 2.

Equation 1 now may be viewed as an attempt to simultaneously model two characteristics of valence orbitals: the distance from the nucleus and their boundary potential or electronegativity. The value of $^1\chi^v$ derived from these delta-values contains information related to both of these properties. Recent applications of this information to molecular volume (10), orbital electronegativity (3), and molecular polarity (11) have been published.

THEORETICAL

General Equation for δ^v—The generality of Eq. 1 within the third quantum level is evident; however, it does not correctly describe the previously established δ^v-values for second quantum level atoms. The value $Z - Z^v = 2$ is not correct in Eq. 1 for these atoms. The denominator term $Z - Z^v - 1$ reproduces the δ^v-values for C, N, and O in their various valence states. This is equivalent to counting (or weighting) the pair of $1s^2$ electrons of oxygen as one. To make this count of screening electrons equivalent for both the second and third quantum levels, a general expression for δ^v is necessary:

$$\delta^v = \frac{Z^v - h}{Z - Z^v - 1} \qquad \text{(Eq. 2)}$$

This count of screening electrons, $(Z - Z^v - 1)$, can be explained in two ways. First, there can be invoked an assumption of a difference in the screening contributions of the $1s^2$ electrons relative to the contributions of 2s and 2p electrons. This is a notion embodied in Slater's rules for the same structural characteristic (12). A second explanation arises from the fact that hydrogen atoms are suppressed in formulating δ^v. Thus, the hydrogen electron structure may be viewed as the zero-value reference structure in the count of screening electrons. From this basis, oxygen would have a count of one screening electron while sulfur would have a count of nine electrons. The values of δ^v using Eq. 2 differ very little from those derived from Eq. 1 (Table I, column 3).

The Special Case of Fluorine—The estimation of electronegativity from $\delta^v - \delta$, or a count of exterjacent electrons (3), for the second quantum level leads to the relationship:

$$\epsilon_M(\text{eV}) = 2.05(\delta^v - \delta) + 6.99 \qquad \text{(Eq. 3)}$$

The assumption that fluorine is sp^3 hybridized results in $\delta^v = 7$ and $\delta^v - \delta = 6$. From Eq. 3, this electronic structure predicts an electronegativity for fluorine in its bonding state of 19.3 eV. Hinze and Jaffe report an electronegativity of only 12.18 eV using $s^2p^2p^2p$ as the bonding state of the atom (13). Considerable work confirms the assumption that bound fluorine has little or no sp^3 character. Recalculating $\delta^v - \delta$ for fluorine from the unhybridized structure gives a value of 4 which, from Eq. 3, predicts an electronegativity of 15.2 eV. To reproduce the Mulliken–Jaffe fluorine electronegativity of 12.18 eV would require fluorine to have a δ^v-value of 3.5, corresponding to a fractional hybridization of the valence electrons.

The matter is further complicated by the awareness that in calculating electronegativities, Hinze and Jaffe (13) used ground-state ionization potentials and electron affinities; thus, the actual promotion process may not be faithfully reproduced by their model in the case of fluorine. A comparison of other electronegativity scales suggests that the value of 19 eV is not unreasonable in the Mulliken–Jaffe scale. Fully aware of these complications, we adopt at this time, the nonempirical value of 7 for δ^v_F.

Third Quantum Level Atom Deltas—Applying Eq. 3 to third-level atoms, chlorine, sulfur, and phosphorus atoms have values of 0.78, 0.67, and 0.55, respectively, for δ^v (when there are no bonded hydrogens). These are listed in column 3 of Table I.

The higher oxidation states of sulfur and phosphorus present a new

problem. Vogel has shown that the fragment contributions to the molar refraction made by —S—, —SO—, and —SO_2— are nearly identical at 7.92, 7.98, and 7.84, respectively (14). This suggests that the groups —SO— and —SO_2— may be described by the same δ^v used for —S—. It also indicates that the value of δ_S^S for the sulfur atom in each of these groups would be different than the δ_S^S for a sulfide sulfur atom. One may choose the expedient of adopting $\delta_S^S = 0.67$ for —S—, —SO—, and —SO_2—, which subsumes the presence of the oxygen atom(s). The assumption implies that the volume occupied by each sulfur lone-pair orbital is the same as the volume occupied by each oxygen atom bonded to sulfur in —SO— and —SO_2—. This is what Vogel's molar refraction fragment values reveal. The use of $\delta_S^S = 0.67$ as a group value for all three classes of sulfur compounds accurately reproduces MR data for these molecules.

A more useful alternative is to explicitly consider the oxygens bonded to sulfur in SO and SO_2 and to derive from theory, or to calculate empirically, values of δ_S^S in each oxidation state. From molar refractivities of several sulfites and sulfates, averaged values have been found which are close to:

$$\delta^v(\text{S in SO}) = 2\delta^v(\text{—S—}) = 12/9 = 1.333 \quad \text{(Eq. 4)}$$

$$\delta^v(\text{S in } SO_2) = 4\delta^v(\text{—S—}) = 24/9 = 2.666 \quad \text{(Eq. 5)}$$

The theoretical justification for these values is evident from the relative contribution of each sulfur atom to the volume and the relative polarity of one and two S—O bonds. From molar refractivity values, one can also derive a δ^v-value for each sulfur in the disulfide group. This is close to δ^v(S in—S—S—) = 8/9 = 0.888. Finally, the δ^v for phosphorus in orthophosphates is described by δ^v(P in PO) = $4\delta^v(-\underset{|}{P}-) = 20/9 = 2.222$.

It is generally accepted that these S—O and P—O bonds are semipolar. As a consequence, one could expect an appreciably different (increased) value for the δ^v-value for S and P relative to the values in alkyl analogues, reflecting the increased valence state electronegativity.

DISCUSSION

Test of δ^v-Values—A meaningful way of evaluating the interrelationship of the δ^v-values is to relate the molar refraction (MR) values for a mixed group of molecules to molecular connectivity indices. If the δ^v-values encode structural information in an accurate manner among atoms in the second and third quantum levels, it is to be expected that the first-order valence connectivity index, $^1\chi^v$, should bear a close relationship to this physical property. These values have been tested on a set of single function molecules, embracing the important, covalent bonding atoms in the second and third quantum level. These are classified by heteroatom in Table II. (Specific entries are available on request.) Using the δ^v-values shown in column 3 of Table I, the relationship is found to be:

$$MR = 8.444\,^1\chi^v + 5.360$$
$$r = 0.979, s = 2.39, n = 101, F = 2327 \quad \text{(Eq. 6)}$$

It came to our attention in the course of the study on third quantum level atoms that an additional structural feature is important in influencing the MR-value. This feature is the number of hydrogen atoms α to certain heteroatoms, which cannot be accounted for in the δ^v description of the heteroatoms. It was found in the case of the halides beyond fluorine, sulfides and disulfides, and secondary and tertiary phosphines, that the MR-value is diminished roughly in proportion to the number of α hydrogens. The inclusion of the count of α hydrogens for these atoms makes a marked improvement in the correlation with MR:

$$MR = 9.042\,^1\chi^v - 1.286\alpha H + 4.777$$
$$r = 0.996, s = 1.038, n = 101, F = 6397 \quad \text{(Eq. 7)}$$

The αH term is independent of the $^1\chi^v$ index and describes a structural feature not encoded in $^1\chi^v$ or the values of δ^v used in its calculation. It is further of note that the coefficient of the αH term in Eq. 7 is close to the Vogel estimate of the hydrogen contribution to molar refraction (14). This analysis constitutes a valid test of the δ^v-value internal relationship. The correlation with MR-values leads to a degree of confidence in the δ^v-values, and they are proposed for use at this time.

Biological Applications—This demonstrated ability of $^1\chi^v$ to relate to MR stimulates the test of $^1\chi^v$ in biological studies in which MR has been used in property–activity analyses. There has been some recent interest in MR as a surrogate for molecular structure in structure–activity relationship (SAR) analyses (15). In several of these studies, values of MR for substituent groups have been employed. These have been derived from MR-values of whole molecules by partitioning (14). The absolute values of these substituent contributions may vary depending on the method of calculation, although the correlation of values is usually good. A few examples of χ *versus* activity illustrate the capability of this index.

Binding of Substituted Phenyl Glycosides to Concanavalin A—Loonteins *et al.* (17) have reported a study of glycosides binding to the hemagglutinin, concanavalin. Hansch and Leo have shown that MR of the substituent groups on the phenyl ring of the glycosides correlates well with the binding parameters, M_{50} (16).

$$\log M_{50} = 0.0188\,MR + 2.23$$
$$r = 0.954, s = 0.038, n = 19 \quad \text{(Eq. 8)}$$

A single connectivity index $^1\chi^v$, correlates with log M_{50} almost as well:

$$\log M_{50} = 0.181\,^1\chi^v + 2.246$$
$$r = 0.945, s = 0.041, n = 19 \quad \text{(Eq. 9)}$$

The influence of heteroatoms is directly apparent from Eq. 9 as is molecular size (Table III). A second connectivity index would certainly contain more information about influential structure; however, the quality of the data would probably not be compatible with this further refinement.

Quinoline Carboxylic Acids as Cell Respiration Inhibitors—Shah and Coats (18) have reported on a series of 7-substituted 4-hydroxyquinoline-3-carboxylic acids as cell respiration inhibitors. They reported a correlation of inhibitory potency (pI_{50}) and MR:

$$pI_{50} = 0.70MR + 2.29$$
$$r = 0.935, s = 0.318, n = 19 \quad \text{(Eq. 10)}$$

Using $^1\chi^v$ reveals a relationship:

$$pI_{50} = 0.785\,^1\chi^v + 2.82$$
$$r = 0.916, s = 0.360, n = 19 \quad \text{(Eq. 11)}$$

The results are in Table IV. The role of heteroatoms and group size is clearly encoded in the $^1\chi^v$ index.

Local Anesthetic Activity of Arylamines—In a recent study by Heymans *et al.* (19), a series of arylamines were tested for local anesthetic potency (pAD).

$$pAD = 0.497MR - 0.0028(MR)^2 - 20.02$$
$$r = 0.951, s = 0.16, n = 12 \quad \text{(Eq. 12)}$$

Using $^0\chi^v$ in a quadratic equation, we find a relationship:

$$pAD = 2.99\,^0\chi^v - 0.116(^0\chi^v)^2 - 17.5$$
$$r = 0.964, s = 0.14, n = 12 \quad \text{(Eq. 13)}$$

The equation is of sufficient quality to predict the activity of three additional compounds, as shown by the last three entries in Table V.

CONCLUSION

The interpretation of structural influence on activity from an MR *versus* activity relationship is not direct. In contrast, a connectivity index *versus* activity relationship permits a direct assessment of the important structural features influencing activity. Further, it is possible to make predictions of structures with favorable characteristics from a good χ *versus* activity equation. Finally, the use of molecular connectivity in structural quantitation makes it possible to employ more than one index, all of which have a logical and consistent derivation from structure and which guide the investigator to an interpretation of structure, meeting the objectives of the study.

This study presents new delta-values for the higher oxidation states of sulfur and phosphorus, atoms which occur on occasion in biological studies. These findings have broadened the utility of χ^v indices.

It has been shown that valence molecular connectivity indices, calculated from delta-values derived in a consistent manner, can closely reproduce molecular properties such as molar refraction. This leads to the direct correlation of biological activity with valence connectivity indices rather than attempting to relate them to molar refraction.

Maintenance-Dose Prediction Based on a Single Determination of Concentration: Dose of Parent Drug Required to Give a Desired Steady-State Concentration of Metabolite

JOHN M. WILSON and JOHN T. SLATTERY ˣ

Received April 16, 1982, from the *School of Pharmacy, Department of Pharmaceutics, University of Washington, Seattle, WA 98195.* Accepted for publication August 27, 1982.

Abstract □ A method for predicting the maintenance dose of parent drug required to give a desired steady-state concentration of metabolite, using a single determination of metabolite concentration in serum following the first dose of parent drug, is described. Clinical evidence that such a method is feasible for the drug–metabolite pair imipramine–desipramine has been reported. The error inherent in an estimation of maintenance dose based on a single determination of metabolite concentration is a function of sampling time and the first-order elimination rate constants for parent drug and metabolite (K and k_m, respectively). The method is applicable to drug–metabolite pairs in general by selecting the sampling time (t^*) to give minimum error: $t^* = 1/\bar{k}_m + 1.3/\bar{K}$, when $\bar{k}_m \leq \bar{K}$, and $t^* = 1/\bar{K} + 1.3/\bar{k}_m$, when $\bar{k}_m > \bar{K}$ (bars denote population mean value). The error expected to be encountered in the application of the method to specific drug–metabolite pairs can be analyzed by the graphical methods described.

Keyphrases □ Imipramine—steady-state concentration of desipramine in serum, maintenance dose, single-point prediction method, pharmacokinetics □ Desipramine—steady-state concentration in serum with imipramine administration, maintenance dose, single-point prediction method, pharmacokinetics □ Pharmacokinetics—single-point prediction method for desired steady-state concentration, maintenance dose, drug–metabolite pairs

The use of a single determination of drug concentration in serum at some time after the initial dose to predict the maintenance dose required to give a desired steady-state concentration has become quite popular since Cooper *et al.* (1, 2) first reported its use for lithium in 1973. The method has been applied to drugs with long half-lives [nortriptyline (3–5) and imipramine (6)] as well as drugs with short half-lives [chloramphenicol (7, 8) and theophylline (7, 9)]. A theoretical basis for such a relationship has been described, showing that the method is capable of giving accurate estimates of the maintenance dose needed if the sample is obtained at the appropriate time (10). The error of the method was shown to be a function of the elimination rate constant for the drug in the individual patient. It was later shown that the optimum sampling time (t^*) was equal to $1/\bar{K}$, where $\bar{K}$ is the mean value of the elimination rate constant for parent drug in the population (11).

There have been two instances in which data suggest that the single-point method can be used to predict the maintenance dose of parent drug to give a desired steady-state concentration of metabolite following administration of the parent drug: chloramphenicol following dosing with the succinate ester (7, 8) and desipramine following dosing with the parent drug imipramine (6). In the first case, the optimal sampling time for predicting the maintenance dose was found to be 6 hr, corresponding to the inverse of the mean metabolite elimination rate constant ($1/\bar{k}_m$). In the second case, that of imipramine–desipramine, no optimal sampling time was presented; a good correlation ($r = 0.92$) was noted between the logarithm of the steady-state desipramine concentration and the logarithm of the desipramine concentration obtained 24 hr after a single dose of imipramine. In the imipramine–desipramine case, $1/\bar{k}_m$ would indicate an optimal sampling time of 33 hr. Prediction on the basis of imipramine elimination would suggest a sampling time of 13 hr.

The strength of the correlation between the concentration determined in a single serum sample obtained 24 hr after the first dose and the eventual steady-state concentration of desipramine following administration of imipramine, and the demonstrated success of single-point dose prediction with chloramphenicol suggested that a theoretical framework could be developed to predict the dose of parent drug necessary to achieve a desired concentration of metabolite at steady-state. This report describes the framework and uses it to examine the error inherent in the method, under optimal conditions.

THEORETICAL

The development of an equation relating the maintenance dose of parent drug (D_m) needed to obtain a desired steady-state concentration of metabolite ($C_{ss,m}$) to the concentration of metabolite in serum (C^*_m) at time t^* after administration of an initial dose of parent drug (D^*) proceeds in much the same manner as previously described for parent drug maintenance-dose prediction (10, 11). For simplicity, the kinetics of all species are assumed to conform to linear one-compartment behavior; intravenous injection of the parent drug is also assumed. The general scheme for the elimination of drug is given in Scheme I. Under these conditions, the concentration of metabolite at a specific time after administration of the parent drug is given by:

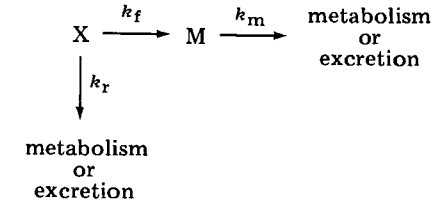
$$C^*_m = \frac{k_f D^*}{V_m(K - k_m)}(e^{-k_m t^*} - e^{-K t^*}) \qquad \text{(Eq. 1)}$$

where V_m is the apparent volume of distribution of the metabolite and K and k_m are the elimination rate constants for parent drug and metabolite, respectively.

The average concentration of metabolite at steady state is:

$$\bar{C}_{ss,m} = \frac{k_f D_m}{K V_m k_m \tau} \qquad \text{(Eq. 2)}$$

where k_f is the formation rate constant of metabolite from parent drug



Scheme I—Model for single-point dose prediction. Key: (X) parent drug; (M) metabolite; (k) first-order rate constant; (subscript r) remainder; (subscript f) formation; (subscript m) metabolite.

0022-3549/83/1000-1174$01.00/0

and τ is the dosing interval. The ratio $\overline{C}_{ss,m}/C^*_m$ is therefore:

$$\frac{\overline{C}_{ss,m}}{C^*_m} = \frac{D_m(K - k_m)}{Kk_m\tau D^*(e^{-k_m t^*} - e^{-Kt^*})} \quad \text{(Eq. 3)}$$

The relationship between the maintenance dose and the single concentration determined after the initial dose is:

$$\frac{1}{D_m} = \left[\frac{K - k_m}{\overline{C}_{ss,m}D^*\tau Kk_m(e^{-k_m t^*} - e^{-Kt^*})}\right] C^*_m \quad \text{(Eq. 4)}$$

The term in brackets can be represented by a proportionality factor, Ψ_m:

$$\frac{1}{D_m} = \Psi_m C^*_m \quad \text{(Eq. 5)}$$

where:

$$\Psi_m = \frac{K - k_m}{\overline{C}_{ss,m}D^*\tau Kk_m(e^{-k_m t^*} - e^{-Kt^*})} \quad \text{(Eq. 6)}$$

It should be realized that Ψ_m varies among individuals only as a function of K and k_m; $\overline{C}_{ss,m}$, D^*, t^*, and τ are chosen and held constant for all individuals. The proportionality factor, Ψ_m, is independent of the fraction of dose metabolized to the metabolite of interest (or to other metabolites) and the formation rate constant of the metabolite. The rate constants K and k_m might be more appropriately written as the ratio of clearance to volume of distribution, but the rate constants are written because clearance and volume of distribution do not appear in Ψ_m except as the ratio, K or k_m. This has been addressed in greater detail in the case of single-point parent drug maintenance-dose prediction (11). Since the maintenance dose is determined for an average steady-state concentration, it can be varied if the dosing rate (D_m/τ) is kept constant.

When $K \gg k_m$, as in the case of a prodrug, Ψ_m as defined in Eq. 6 reduces to:

$$\Psi_{m,K\gg km} = \frac{e^{k_m t^*}}{\overline{C}_{ss,m}D^*\tau k_m} \quad \text{(Eq. 7)}$$

which more appropriately defines the proportionality factor Ψ previously described for the metabolite chloramphenicol of the prodrug chloramphenicol succinate. When parameter values are substituted, $\Psi_m = \Psi$ as previously defined (10). It is also of interest to note the definition of Ψ_m at the opposite extreme, namely where $k_m \gg K$:

$$\Psi_{m,km\gg K} = \frac{e^{Kt^*}}{\overline{C}_{ss,m}D^*\tau K} \quad \text{(Eq. 8)}$$

As described previously for parent drug (10), Eq. 5 will serve to predict accurate values of D_m when Ψ_m remains reasonably constant throughout the population. Thus, t^* must be chosen in such a manner to result in minimum variability of Ψ_m as a function of K and k_m. This, by definition, will be the optimum value of t^*. When the sample is obtained at the optimum t^*, a population average value of Ψ_m will have the best chance of working for maintenance-dose prediction purposes.

Figure 1 shows how t^* can be chosen such that Ψ_m is kept reasonably constant as K and k_m vary through the population. Ranges of K and k_m approximate population values for imipramine–desipramine (6). In this figure $\Psi_m/\overline{\Psi}_m$ is plotted to allow direct comparison between the plots. $\overline{\Psi}_m$ is the average value of Ψ_m throughout the population. Also, the lowest values of the axes are at the far right corner in each plot; this departure from convention is made to afford the clearest view of the surface. Among the three values of t^* examined the optimum value of t^* (to the nearest hour) is 48 hr (Fig. 1b) where the plot of $\Psi_m/\overline{\Psi}_m$ is relatively flat compared to t^* = 36 hr (Fig. 1a) and t^* = 60 hr (Fig. 1c). In this case, the maximum error is an ~25% overprediction of dose at low values of k_m in combination with low values of K.

Figure 1 also shows that the greatest error of the method is encountered at the extremes of the values of K and k_m[1]. As the range of values considered here is exceeded, the error will increase (see below). However, if a Gaussian distribution of these rate constants is assumed, it is evident that a very small fraction of the population will be represented by these extreme values. Thus, the method can be expected to work well for a very large majority of the population.

Optimization of Sampling Time—The optimum time for obtaining the sample for maintenance-dose prediction can be determined by constructing plots such as those in Fig. 1 and selecting as t^* the sampling time

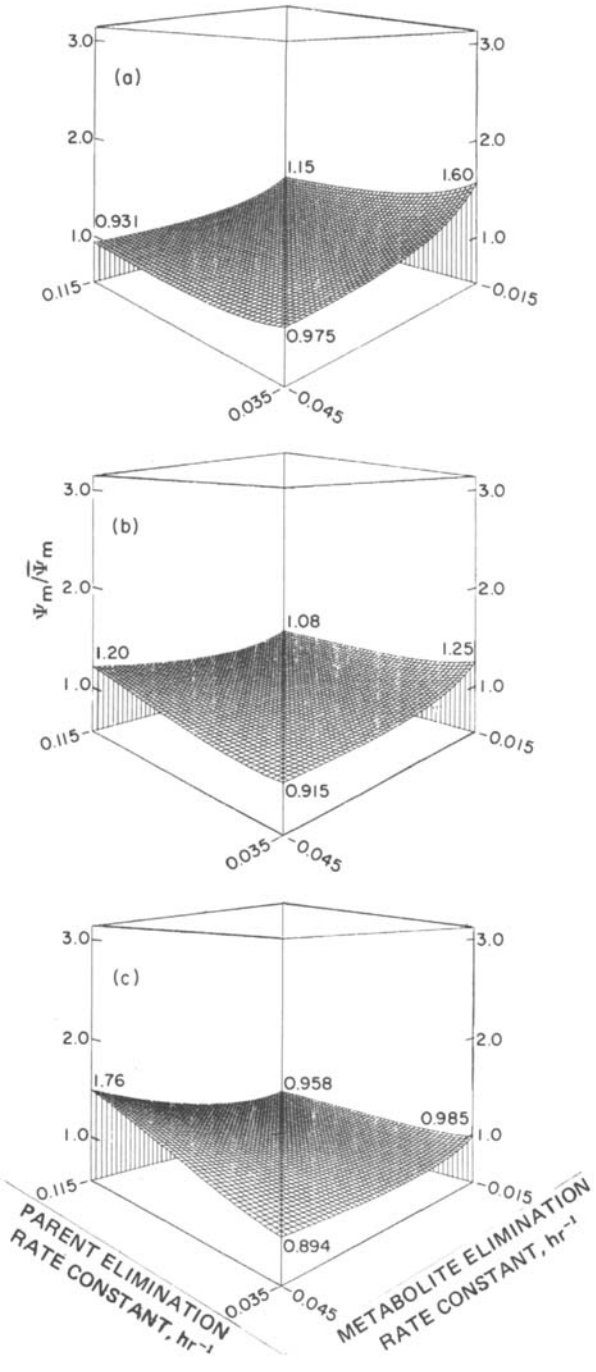


Figure 1—*Relationships between $\Psi_m/\overline{\Psi}_m$ and the elimination rate constants for metabolite (k_m) and parent drug (K) for the parent drug–metabolite pair imipramine–desipramine at t* = 36 (a), 48 (b), and 60 hr (c). The optimum value of t*, 48 hr, gives the most nearly planar surface. The lowest values of all axes appear at the far right corner of each figure.*

which gives the least variability in $\Psi_m/\overline{\Psi}_m$ as a function of K and k_m. This is rather cumbersome and time consuming because of the need for accurate three-dimensional plotting capability.

The problem can be simplified to two dimensions. Ψ_m is a ratio, and the variables K and k_m appear in both the numerator and denominator. For Ψ_m to be constant throughout a population, the numerator and denominator must change in proportion to one another since K and k_m assume different values from one individual to another. A plot of the numerator of Ψ_m (Eq. 6) *versus* its denominator should be as nearly linear as possible at the optimum choice of t^*. Since the value of Ψ_m varies among individuals as a function of K and k_m only, $D^*\tau\overline{C}_{ss,m}$ can be assigned a value of 1 for the purpose of sampling time optimization.

Figure 2 shows such plots for the case of imipramine–desipramine.

[1] In Fig. 1, error is reflected by the degree of curvature of the surface. If there was no inherent error, every individual would have the same value of Ψ_m and $\Psi_m/\overline{\Psi}_m$ would equal 1 at all combinations of K and k_m. As the surface becomes more curved, error increases.

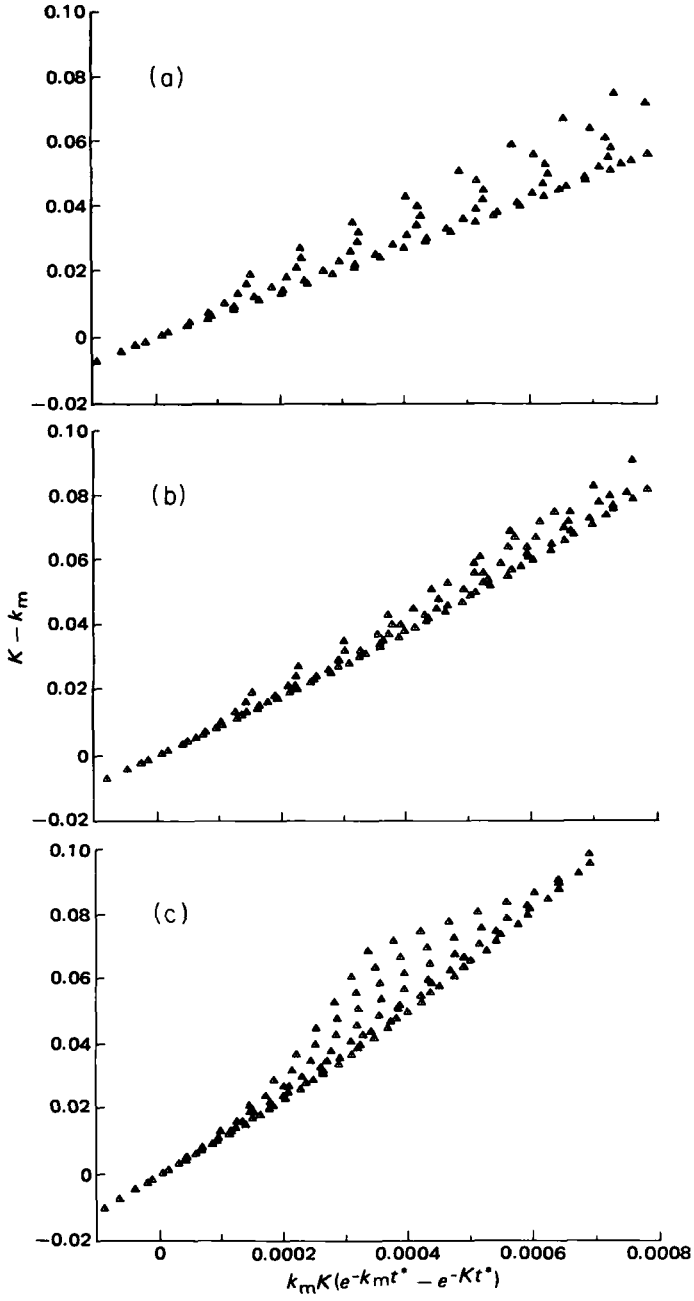

Figure 2—*Plots of the numerator of Eq. 6* versus *the denominator for the parent drug–metabolite pair imipramine–desipramine at* t* = *36 (a), 48 (b), and 60 hr (c). The optimum value of* t* *has the minimum scatter of points, which can be judged numerically as described in the text. This plot represents an alternative optimization method to Fig. 1.*

Points are chosen in this plot by selecting values of K and k_m in nested loops at fixed intervals; plots a, b, and c in Fig. 2 correspond to the respective three-dimensional plots in Fig. 1. The plots in Fig. 2 take the form of scatter plots because of the complex nature of the variability of the numerator and denominator of Ψ_m as a function of K and k_m. Figure 2 shows minimum scatter for $t^* = 48$ hr (Fig. 2b); more scatter is evident for $t^* = 36$ and 60 hr in Fig. 2a and c, respectively. Thus, the outcome of optimization schemes shown in Figs. 1 and 2 is the same.

It is not necessary to rely on a visual comparison of plots to select optimum values of t^* for a given set of values of K and k_m. Since a plot of the numerator of Eq. 6 *versus* the denominator will have a slope equal to Ψ_m, the optimum t^* will result in minimum scatter about a regression line. Measures of relative goodness of fit can therefore be used for optimization purposes. This method has been used for the case of imipramine–desipramine, and 48 hr was again obtained for the optimum value of t^*. Agreement was verified to an accuracy of 1 hr. The coefficients of

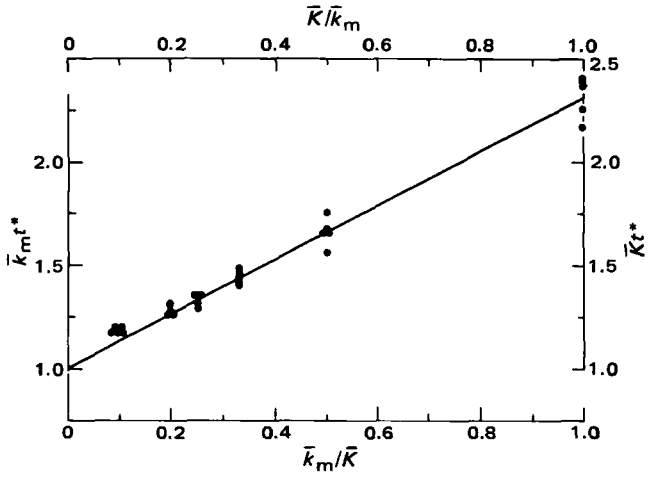

Figure 3—*Relationship between optimum* t* *and the ratio of mean elimination rate constant values. If* $\bar{K} > \bar{k}_m$, *read* $\bar{k}_m$t* *from the left axis from the point on the line corresponding to the appropriate value of the ratio* $\bar{k}_m/\bar{K}$; *if* $\bar{k}_m > \bar{K}$, *read* $\bar{K}$t* *corresponding to the value of the ratio* $\bar{K}/\bar{k}_m$ *from the axis on the right. variation of the slopes of the plots in Fig. 2 (as %) are 24.7, 12.7, and 22.2 for $t^* = 36$, 48, and 60 hr, respectively.

In the case of maintenance-dose prediction for the parent drug, it was possible to arrive at a simple calculation for the optimum value of t^*; *i.e.*, $t^* = 1/K$ where K is the population mean elimination rate constant for the parent drug. The case of maintenance dose of parent drug to give a desired metabolite concentration at steady state is analytically somewhat more complex. However, using either of the techniques described above, a general solution can be obtained.

In the course of these investigations, we determined the optimum value of t^* for a number of combinations of K and $\bar{k}_m$ (bars denote mean). It was apparent that as the ratio of $\bar{k}_m/K$ increased, the optimum value of t^* increased. Previous experience indicated that a plot of optimum t^* as a function of the ratio $\bar{k}_m/K$ would not be linear and its slope at any point would be a function of the absolute values of $\bar{k}_m$ and K. We therefore constructed a plot of $\bar{k}_m t^*$ as a function of the ratio $\bar{k}_m/K$ and found it to be linear and to serve for predictive purposes whenever $K \geq \bar{k}_m$. A plot of this empirical relationship is shown in Fig. 3. The points in the plot represent the results of optimizations using the technique described above for various ranges of K and k_m. In this figure, t^* could be calculated by reading the value of $\bar{k}_m t^*$ of the left vertical axis for a given value of $\bar{k}_m/K$ when $K \geq k_m$. Conversely, when $k_m > K$, $\bar{K}t^*$ can be read off the plot corresponding to a given value of $\bar{K}/\bar{k}_m$. Thus, given the population mean value of K and k_m, the optimum value of t^* can be estimated from the regression coefficients of Fig. 3. For $\bar{K} \geq \bar{k}_m$:

$$\bar{k}_m t^* = 1 + 1.3\bar{k}_m/\bar{K} \qquad \text{(Eq. 9)}$$

or

$$t^* = \frac{1}{\bar{k}_m} + \frac{1.3}{\bar{K}} \qquad \text{(Eq. 10)}$$

and when $\bar{k}_m > \bar{K}$:

$$\bar{K}t^* = 1 + 1.3\bar{K}/\bar{k}_m \qquad \text{(Eq. 11)}$$

or

$$t^* = \frac{1}{\bar{K}} + \frac{1.3}{\bar{k}_m} \qquad \text{(Eq. 12)}$$

In the case of a prodrug, $K \gg k_m$ and Eq. 9 becomes $t^* \simeq 1/\bar{k}_m$, which is the clinical observation with chloramphenicol when the prodrug, chloramphenicol succinate, is given (8).

The slope of the line in Fig. 3 varies slightly with the range of rate constant values encountered for a particular drug–metabolite pair; *i.e.*, the optimum value of t^* is slightly affected by the range of K and k_m encountered. Figure 4, where $\bar{k}_m/\bar{K} = 0.5$, shows this effect. t^* (44 hr) is optimized for a fourfold variability in K and k_m and is 4 hr too long for a threefold range and 1 hr too early for a fivefold range. Such an effect has been noted by others when considering t^* in the case of parent drug (12). In Figure 5, where $\bar{k}_m/\bar{K} = 0.1$, this effect is not evident. Thus, use of Fig. 3 or Eqs. 9–12 gives an approximate value for optimum t^*; other

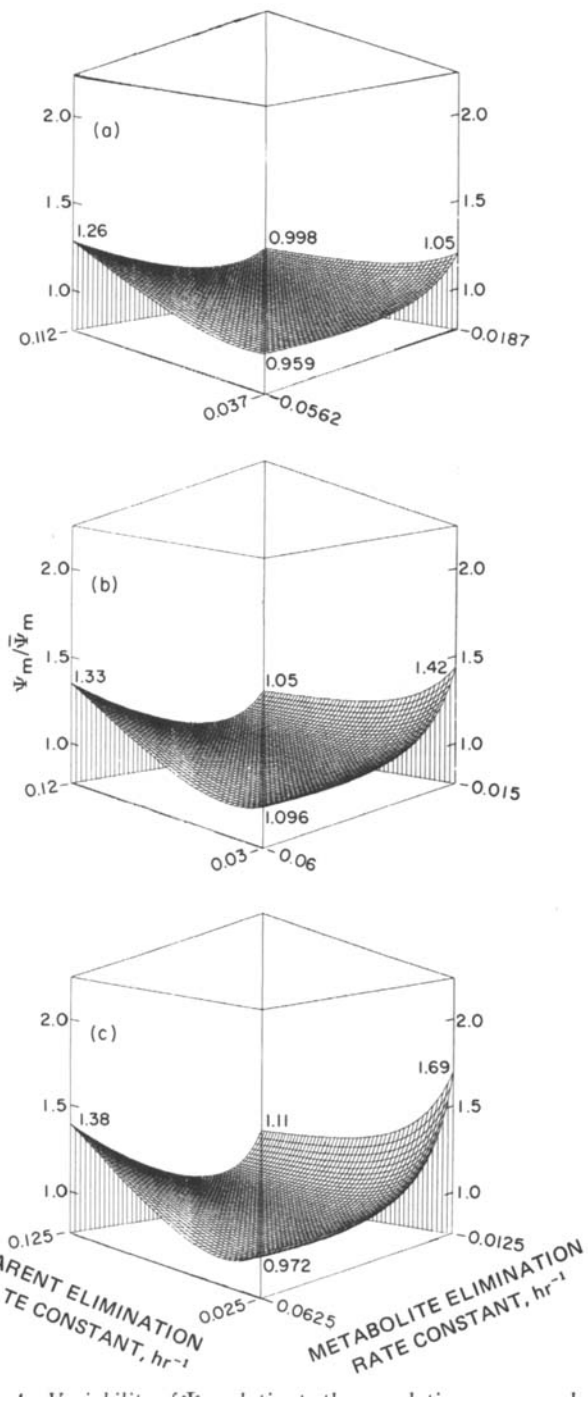

Figure 4—*Variability of Ψ_m relative to the population average value, $\bar{\Psi}_m$, as the range of* K *and* k_m *increases, $\bar{k}_m/\bar{K}$ = 0.5. methods would give more accurate results. Figure 3 and Eqs. 9–12 will give a quick indication as to the possibility of choosing a clinically convenient or feasible sampling time for a particular drug–metabolite pair.

Analysis of Error—Although the optimum value of t^* can be read directly from Fig. 3 or calculated from Eqs. 9–12, that information does not give any insight into the *error* of the method. A direct indication of the magnitude and source of inherent error is obtained from the three-dimensional plots of the type used for optimization in Fig. 1.

These plots for arbitrary cases are presented in Figs. 4 and 5 for cases with $\bar{k}_m/\bar{K}$ = 0.5 and $\bar{k}_m/\bar{K}$ = 0.1, respectively. Actual values of the rate constants cover ranges of three-, four-, and fivefold, respectively, in plots a, b, and c of both figures. Error is greatest as the extreme values of K and k_m are approached in Fig. 4, where the ranges of the two elimination rate constants overlap. Accordingly, as the range is increased, the maximum error increases from 27% at threefold to 69% at fivefold. These errors would result in an overprediction of maintenance dose of the same magnitude.

In Fig. 5 ($\bar{k}_m/\bar{K}$ = 0.1), the ranges of K and k_m do not overlap and at large values of K, the error in maintenance-dose prediction is a function of k_m only and independent of K, as required by Eq. 7. As in Fig. 4, error increases as the range of K and k_m increases, but as the ratio of $\bar{k}_m/\bar{K}$ decreases, the error of the method decreases and is less sensitive to increases in the range of elimination rate constant values.

Neither of these figures gives an indication of the role of the distribution of values of the elimination rate constants in the population. If the

distribution was assumed to be Gaussian, a small fraction of the population would be represented by the values of elimination rate constants at the extreme of the range. Very few individuals would be subjected to the maximum error of the method. Figs. 4 and 5 represent error patterns of specific cases for certain values of K and k_m; they have not been constructed to represent general cases. For any given case, similar plots should be constructed to evaluate error.

DISCUSSION

The optimum sampling time for determining the maintenance dose of parent drug required to give a desired steady-state concentration of metabolite for the drug–metabolite pair imipramine–desipramine indicated by this analysis is 48 hr. A linear relationship between the log of the 24-hr concentration of desipramine following the first dose of imipramine and the log of the eventual steady-state concentration of the drug, if the same dose is kept constant and administered daily, has been found clinically (6). The mathematical basis for relating these two concentrations arises from a rearrangement of Eq. 6 that gives rise to a proportionality factor with the general behavior of Ψ_m (10). The results of the present analysis suggest that the relationship between concentration at 24 hr and eventual steady-state concentration would be curvilinear. A log–log transformation might linearize such a plot. It is expected that a sample collected 48 hr after the first dose would appear to be linearly related to the eventual steady-state concentration.

There are two critical considerations in applying this method to any drug–metabolite pair: (*a*) the error which will be encountered as a function of the elimination kinetics of the pair and (*b*) the possibility that the elimination kinetics may dictate a value of t^* that is not clinically feasible. The variability of Ψ_m is a function of the elimination kinetics of the pair in the population and cannot be overcome when single-point prediction schemes are used. Thus, a poor estimate of maintenance dose will always be obtained for some fraction of the population. When the optimum value of t^* is not used because it is too short to be clinically convenient and a longer time is adopted, the error of the method increases but in a somewhat conservative manner. Patients who eliminate the drug and metabolite slowly will tend to be underdosed and those who eliminate the drug quickly (requiring a relatively larger maintenance dose) tend to be overdosed. This situation is perhaps more tolerable than the converse: when a t^* shorter than the optimum is adopted, patients who eliminate the drug most slowly will tend to be overdosed and those who eliminate it more quickly will tend to be underdosed. Another observation may be more to the point: when the optimum value of t^* is not used, the relationship between $1/D_m$ and C^*_m will become less well-characterized by a straight line. If the curvilinear nature of the relationship can be taken into account, reasonably accurate dose prediction may still be possible.

Single-point dose prediction methods appear to be applicable to most drugs and their metabolites. However, the optimum sampling time for the dose required to give a desired steady-state concentration of the parent drug may be quite different than that required to give a target metabolite concentration. If dosage prediction is warranted for a particular drug (10) and the kinetics of the drug are linear, it appears likely that a single-point method could be developed to suit using the techniques described here. However, it must be remembered that the predicted dose is an estimate that must be confirmed by obtaining samples at steady state.

Bayesian Approach to Bioequivalence Assessment: An Example

H. FLUEHLER *x, A. P. GRIEVE *, D. MANDALLAZ ‡, J. MAU §, and H. A. MOSER *

Received February 22, 1982, from the **Scientific Computing Centre, CIBA-GEIGY AG, Basel, Switzerland;* ‡*Essex Chemie AG, Luzern, Switzerland;* and §*Rheinisch-Westfälische TH, Aachen, West Germany.* Accepted for publication August 26, 1982.

Abstract □ The statistical methods required for a Bayesian analysis of bioequivalence are outlined and numerically illustrated. The analysis consists of the calculation of the posterior probability, given the experimental results, that the ratio of true means of a new and a standard formulation of a drug with respect to some biological response lies in a given interval. Nomograms helpful for the calculation of these probabilities are provided.

Keyphrases □ Bioequivalence—assessment by Bayesian analysis, statistical methods, example and nomograms □ Bayesian analysis—bioequivalence assessment, statistical methods, example, and nomograms

Comparative bioavailability studies serve to investigate the pharmaceutical properties of two or more formulations of the same drug. Decisions on whether two formulations are bioequivalent are usually made by comparing biological responses such as area under the plasma concentration curve or the maximum peak concentration. Since in many instances the objective of a bioavailability study is not to show a difference between formulations, but rather to investigate whether any difference is of practical importance, Westlake (1) and Metzler (2) suggest that hypothesis tests of no difference are of little value.

In this paper the statistical methods needed to perform a Bayesian analysis of bioequivalence given by Mandallaz and Mau (3) are outlined. This method has been illustrated

0022-3549/83/1000-1178$01.00/0

distribution was assumed to be Gaussian, a small fraction of the population would be represented by the values of elimination rate constants at the extreme of the range. Very few individuals would be subjected to the maximum error of the method. Figs. 4 and 5 represent error patterns of specific cases for certain values of K and k_m; they have not been constructed to represent general cases. For any given case, similar plots should be constructed to evaluate error.

DISCUSSION

The optimum sampling time for determining the maintenance dose of parent drug required to give a desired steady-state concentration of metabolite for the drug–metabolite pair imipramine–desipramine indicated by this analysis is 48 hr. A linear relationship between the log of the 24-hr concentration of desipramine following the first dose of imipramine and the log of the eventual steady-state concentration of the drug, if the same dose is kept constant and administered daily, has been found clinically (6). The mathematical basis for relating these two concentrations arises from a rearrangement of Eq. 6 that gives rise to a proportionality factor with the general behavior of Ψ_m (10). The results of the present analysis suggest that the relationship between concentration at 24 hr and eventual steady-state concentration would be curvilinear. A log–log transformation might linearize such a plot. It is expected that a sample collected 48 hr after the first dose would appear to be linearly related to the eventual steady-state concentration.

There are two critical considerations in applying this method to any drug–metabolite pair: (*a*) the error which will be encountered as a function of the elimination kinetics of the pair and (*b*) the possibility that the elimination kinetics may dictate a value of t^* that is not clinically feasible. The variability of Ψ_m is a function of the elimination kinetics of the pair in the population and cannot be overcome when single-point prediction schemes are used. Thus, a poor estimate of maintenance dose will always be obtained for some fraction of the population. When the optimum value of t^* is not used because it is too short to be clinically convenient and a longer time is adopted, the error of the method increases but in a somewhat conservative manner. Patients who eliminate the drug and metabolite slowly will tend to be underdosed and those who eliminate the drug quickly (requiring a relatively larger maintenance dose) tend to be overdosed. This situation is perhaps more tolerable than the converse: when a t^* shorter than the optimum is adopted, patients who eliminate the drug most slowly will tend to be overdosed and those who eliminate it more quickly will tend to be underdosed. Another observation may be more to the point: when the optimum value of t^* is not used, the relationship between $1/D_m$ and C^*_m will become less well-characterized by a straight line. If the curvilinear nature of the relationship can be taken into account, reasonably accurate dose prediction may still be possible.

Single-point dose prediction methods appear to be applicable to most drugs and their metabolites. However, the optimum sampling time for the dose required to give a desired steady-state concentration of the parent drug may be quite different than that required to give a target metabolite concentration. If dosage prediction is warranted for a particular drug (10) and the kinetics of the drug are linear, it appears likely that a single-point method could be developed to suit using the techniques described here. However, it must be remembered that the predicted dose is an estimate that must be confirmed by obtaining samples at steady state.

Bayesian Approach to Bioequivalence Assessment: An Example

H. FLUEHLER *x, A. P. GRIEVE *, D. MANDALLAZ ‡, J. MAU §, and H. A. MOSER *

Received February 22, 1982, from the **Scientific Computing Centre, CIBA-GEIGY AG, Basel, Switzerland;* ‡*Essex Chemie AG, Luzern, Switzerland;* and §*Rheinisch-Westfälische TH, Aachen, West Germany.* Accepted for publication August 26, 1982.

Abstract □ The statistical methods required for a Bayesian analysis of bioequivalence are outlined and numerically illustrated. The analysis consists of the calculation of the posterior probability, given the experimental results, that the ratio of true means of a new and a standard formulation of a drug with respect to some biological response lies in a given interval. Nomograms helpful for the calculation of these probabilities are provided.

Keyphrases □ Bioequivalence—assessment by Bayesian analysis, statistical methods, example and nomograms □ Bayesian analysis—bioequivalence assessment, statistical methods, example, and nomograms

Comparative bioavailability studies serve to investigate the pharmaceutical properties of two or more formulations of the same drug. Decisions on whether two formulations are bioequivalent are usually made by comparing biological responses such as area under the plasma concentration curve or the maximum peak concentration. Since in many instances the objective of a bioavailability study is not to show a difference between formulations, but rather to investigate whether any difference is of practical importance, Westlake (1) and Metzler (2) suggest that hypothesis tests of no difference are of little value.

In this paper the statistical methods needed to perform a Bayesian analysis of bioequivalence given by Mandallaz and Mau (3) are outlined. This method has been illustrated

0022-3549/83/1000-1178$01.00/0

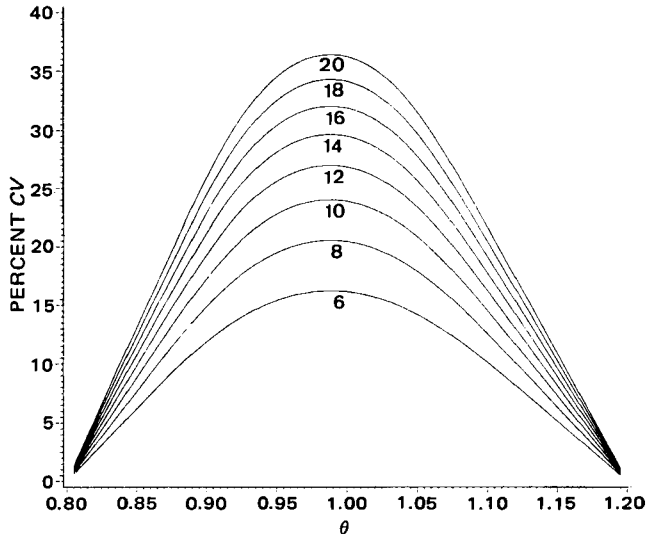

Figure 1—*Values of observed ratios and percent* CV *giving a posterior probability of 0.90 that the true ratio lies between 0.8 and 1.2 for various values of* n.

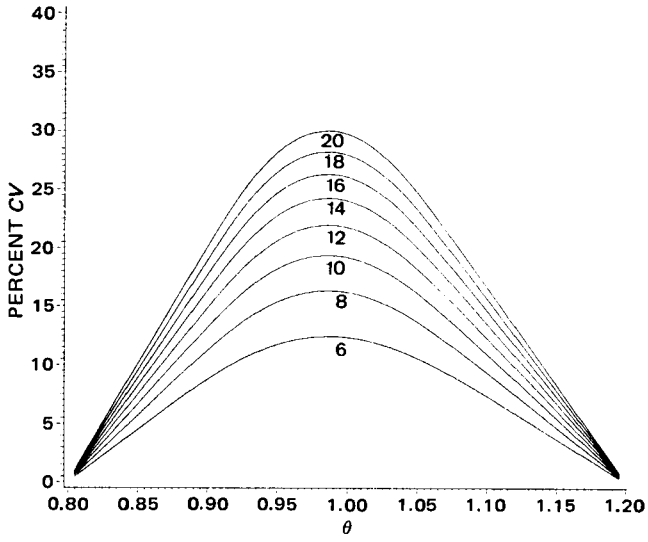

Figure 2—*Values of observed ratios and percent* CV *giving a posterior probability of 0.95 that the true ratio lies between 0.8 and 1.2 for various values of* n.

by Fluehler *et al.* (4) using historical data. The numerical calculations required are illustrated by an example. Readers interested in a general introduction to statistical considerations involved in bioequivalence assessment are referred to Metzler (2) or Westlake (1). An alternative Bayesian approach has been developed by Selwyn *et al.* (5).

THEORETICAL

It is assumed that a new formulation of a drug has been developed and that it is to be compared with the standard formulation of the drug. The comparison will focus on the area under the blood concentration curve (AUC) and the maximum concentration of that curve (C_{max}). If the ratio, θ, of the true means of the new to the standard formulation of the chosen measure (AUC or C_{max}) lies between given limits r_1 and r_2, that is:

$$r_1 \leq \theta \leq r_2 \qquad \text{(Eq. 1)}$$

then the formulations are said to be bioequivalent. The choice of r_1 and r_2 is made on medical and/or regulatory grounds. Thus, for AUC, one might set $r_1 = 0.8$ and $r_2 = 1.2$, which correspond to the AUC of the new formulation differing by at most ±20% from that of the standard formulation. It should be noted that r_1 and r_2 need not be the same for AUC and C_{max} and in general they need not be symmetric about 1.

To provide evidence for or against the bioequivalence statement given in Eq. 1, estimates of the true means of either AUC or C_{max} for both formulations and an estimate of their variance are needed. Because of the large intersubject variation with respect to the absorption, distribution, and elimination of a drug, the crossover design is usually considered the most appropriate for comparative bioavailability studies. In such a design each of n subjects receives each formulation with a sufficiently large time lag to ensure an adequate washout period. The statistical model for a two-way crossover design is:

$$x_{ijk} = \mu + \xi_i + \pi_j + \phi_k + \epsilon_{ijk} \qquad \text{(Eq. 2)}$$

where x_{ijk} are the observed values, μ is the overall mean, ξ_i is the ith subject effect ($i = 1, \ldots, n$), π_j is the jth period effect ($j = 1, 2$), ϕ_k is the kth formulation effect ($k = 1, 2$), and ϵ_{ijk} are experimental errors associated with the x_{ijk} values, which are assumed to be independently normally distributed with zero means and common variance σ^2.

The AUC values are assumed to be normally distributed according to the model in Eq. 2. The C_{max} values, however, are assumed to be log-normally distributed so that $\ln(C_{max})$, instead of C_{max}, obeys the aforementioned model. The analysis of variance (ANOVA) for the crossover design is outlined in basic statistical texts, *e.g.*, Cochran and Cox (6). The error mean square from the ANOVA gives an estimate of the experimental error variance.

A Bayesian approach (3, 4) is used to investigate bioavailability defined in Eq. 1. In this approach the posterior distribution of θ given the experimental results is obtained, from which the posterior probability that θ lies between r_1 and r_2 is calculated; if this probability is large enough, bioequivalence is accepted. The advantage of a Bayesian approach is that the whole distribution of θ may be examined either through the posterior distribution itself or by calculating the cumulative distribution function.

The posterior probability that θ lies between r_1 and r_2 is calculated by:

$$Pr(r_1 \leq \theta \leq r_2) = \int_B^A t_\nu(\tau)d\tau \qquad \text{(Eq. 3)}$$

where $t_\nu(\tau)$ is the density function of Student's t distribution with ν degrees of freedom (DF) and ν is the number of DF of the error mean square (MSQ) from the ANOVA. The integration limits for AUC, normally distributed data, are given by:

$$A = \frac{(\hat{\theta} - r_1)n^{1/2}}{CV(1 + r_1^2)^{1/2}} \qquad \text{(Eq. 4)}$$

$$B = \frac{(\hat{\theta} - r_2)n^{1/2}}{CV(1 + r_2^2)^{1/2}} \qquad \text{(Eq. 5)}$$

with

$$\hat{\theta} = \frac{\bar{X}_{NEW}}{\bar{X}_{STD}} \qquad \text{(Eq. 6)}$$

$$CV = \frac{S}{\bar{X}_{STD}} \qquad \text{(Eq. 7)}$$

$$S = \sqrt{\text{Error (MSQ) from ANOVA}} \qquad \text{(Eq. 8)}$$

$\bar{X}_{NEW}$ and $\bar{X}_{STD}$ are the observed arithmetic formulation means; n is the number of subjects. The integration limits for C_{max}, log-normally distributed data, are given by:

$$A = \frac{[\bar{X}_{NEW} - \bar{X}_{STD} - \ln(r_1)]n^{1/2}}{2^{1/2}S} \qquad \text{(Eq. 9)}$$

$$B = \frac{[\bar{X}_{NEW} - \bar{X}_{STD} - \ln(r_2)]n^{1/2}}{2^{1/2}S} \qquad \text{(Eq. 10)}$$

where now $\bar{X}_{NEW}$ and $\bar{X}_{STD}$ denote the observed arithmetic means of the log-transformed C_{max} values. The cumulative posterior distribution function $Pr(\theta < \theta_0)$, is calculated by setting $r_1 = 0$ and $r_2 = \theta_0$ in Eq. 3.

Alternative methods of displaying information from the posterior distribution are available. Fluehler *et al.* (4) show how Eq. 3 may be used to display posterior probabilities of given intervals in histogram form, while the posterior density function itself may be calculated from the results of Mandallaz and Mau (3).

Although the calculation of the posterior probabilities are straightforward, the nomograms shown in Figs. 1 and 2 are useful tools for the practitioner using the normal model (Eqs. 3–8). In these nomograms the bioequivalence range was chosen to be 0.8–1.2, although nomograms for

other ranges and for the log-normal model can be produced. The nomograms give the sample sizes required to achieve posterior probabilities of 0.90 and 0.95 as a function of the observed ratio and percentage coefficient of variation ($100 \times CV$). For instance, suppose an experiment with 12 subjects was carried out and an observed ratio of 1.1 with an observed coefficient of variation of 15% was obtained. From Fig. 2 it is seen that, with this data, a sample size of between 16 and 18 is necessary to achieve a posterior probability of 0.95. However Fig. 1 shows that 12 subjects yield, with the same data, a posterior probability >0.90.

RESULTS

The theoretical results presented are now illustrated by an example. Assume that a slow-release formulation of a drug (NEW) has been developed with the aim of producing markedly lower peak concentrations than the standard drug (STD), while at the same time delivering a similar amount of active ingredient to the circulation. Medical considerations, therefore, lead to the following conditions for bioequivalence:

$$\text{AUC: } 0.8 \le \theta \le 1.2 \qquad \text{(Eq. 11)}$$

and

$$C_{max}\text{: } \theta \le 0.6 \qquad \text{(Eq. 12)}$$

A comparative bioavailability study with 12 subjects is conducted in a two-period crossover design. The design information and observed data [AUC, C_{max}, and $\ln(C_{max})$] are shown in Table I, together with the formulation mean values. The analyses of variance used to estimate the experimental errors are given in Tables II and III for AUC and $\ln(C_{max})$, respectively. The validity of the assumed model (Eq. 2) may be verified by examination of the ANOVA residuals. Interested readers will find appropriate procedures in Belsley *et al.* (7).

Bioequivalence Assessment with Respect to AUC—The estimated ratio, given by Eq. 6 is $\hat{\theta} = 90.10/98.35 = 0.916$. The estimated experimental error from the ANOVA (Table II) is 690.4, so that the estimated coefficient of variation (CV) given by Eq. 7 is $\sqrt{690.4}/98.35 = 0.267$. The posterior probability that θ lies in the interval 0.8–1.2 (Eq. 11) may then be calculated from Eqs. 3–5 to give $Pr(0.8 \le \theta \le 1.2) = 0.846$. The cumulative posterior distribution function is shown in Fig. 3; this may also be used, as illustrated, to calculate the probability of the bioequivalence condition.

Bioequivalence Assessment with Respect to C_{max}—The estimated ratio for log-normally distributed data (3) is given by:

$$\hat{\theta} = \exp[\overline{\ln(C_{max})_{NEW}} - \overline{\ln(C_{max})_{STD}}]$$
$$= \exp[4.658 - 5.391] = 0.481 \qquad \text{(Eq. 13)}$$

The estimated error standard deviation from the ANOVA (Table III) is $S = \sqrt{0.147} = 0.383$. The posterior probability that $\theta \le 0.6$ (Eq. 12) may then be calculated from Eqs. 3, 9, and 10 to give $Pr(\theta \le 0.6) = 0.906$. The cumulative posterior distribution function for θ is shown in Fig. 4.

DISCUSSION

Analysis of the example presented shows the main advantages of a Bayesian approach over previous approaches:

1. Earlier methods for bioequivalence assessment consisted of testing the null hypothesis of no difference between formulations. In the present example this null hypothesis would be rejected for C_{max} since the F-ratio in the ANOVA (Table III) is large, but not for AUC, since the F-ratio in the ANOVA (Table II) is small.
2. The assessment of the bioequivalence condition with respect to AUC for the specified interval 0.8–1.2 (Eq. 11) yielded a posterior probability of 0.846. There is, therefore, not enough evidence for claiming bioequivalence. However, the calculation of the cumulative distribution function allows other aspects of interest to be investigated. Thus it may

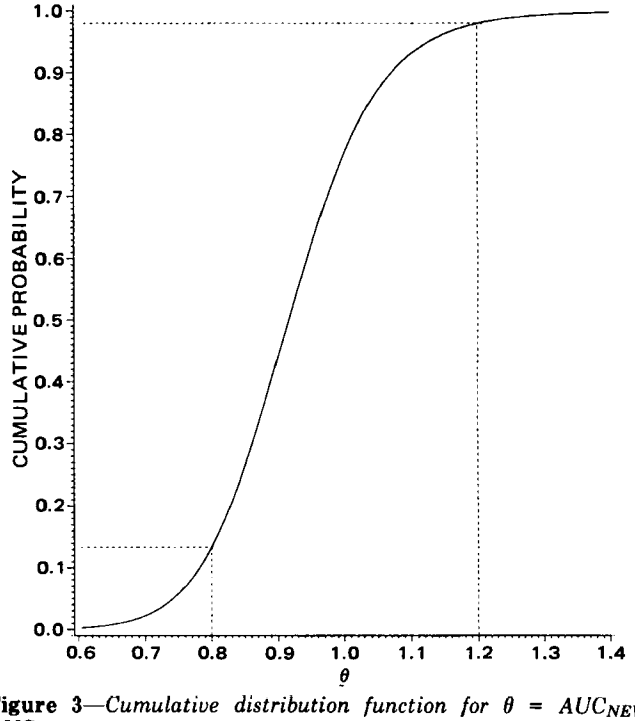

Figure 3—*Cumulative distribution function for* $\theta = AUC_{NEW}/AUC_{STD}$.

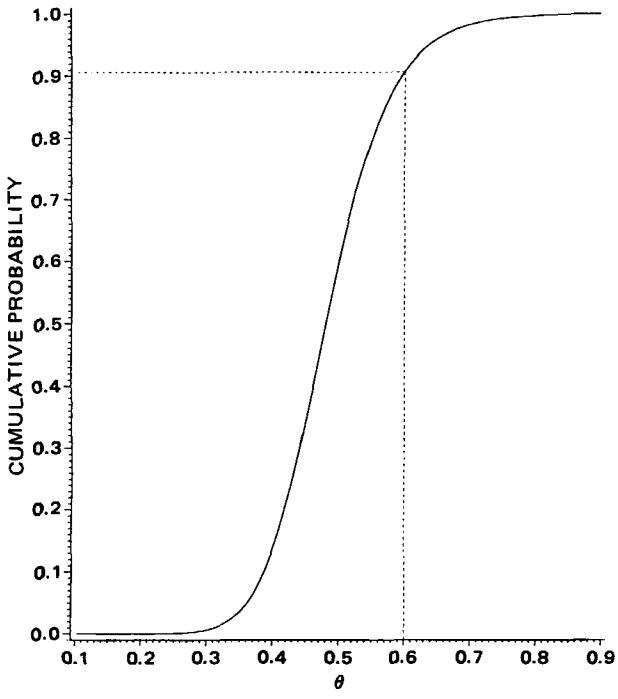

Figure 4—*Cumulative distribution function for* $\theta = (C_{max})_{NEW}/(C_{max})_{STD}$.

be of interest to know the probability that θ is >0.8. This may be read from Fig. 3 and is 0.866—a probability which still might not be high enough to state bioequivalence. In addition it might be desirable to know the probability of θ being >0.7, which also may be read from Fig. 3 and is 0.98.

3. The assessment with respect to C_{max}, that θ is <0.6 (Eq. 12) yielded a posterior probability of 0.906. Similarly it might be desirable to know the probability of θ being >0.7. This probability can be read from Fig. 4 and is 0.02.

4. The method of symmetrical confidence limits proposed by Westlake (1) causes the loss of information since it gives the false impression that the ratio is symmetric about 1. As Mandallez and Mau (3) have shown, the symmetric confidence interval approach may give exactly the same 95% confidence intervals for two sets of data while having completely different posterior distributions for θ, because of the differing variances and locations of the posterior distributions.

In Vivo and *In Vitro* Release of Macromolecules from Polymeric Drug Delivery Systems

L. R. BROWN *‡, C. L. WEI *‡, and R. LANGER *x

Received January 26, 1982, from the **Department of Nutrition and Food Science, Massachusetts Institute of Technology, Cambridge, MA 02139* and ‡*Department of Surgery, Children's Hospital Medical Center, Boston, MA 02115.* Accepted for publication August 30, 1982.

Abstract □ *In vivo* release rates of a macromolecule from an ethylene–vinyl acetate copolymer have been shown to be indistinguishable from those of identical implants tested *in vitro*. The studies were conducted for ~2 months, and two different techniques were used to assess release rates. One of these techniques, using [^{3}H]inulin as a marker, may be particularly useful in future studies assessing *in vivo* release rates from drug delivery systems. The appearance of [^{3}H]inulin in the urine of rats bearing implants allowed continuous monitoring of release. A histological evaluation of tissue sections surrounding polymer implanted for 7 months showed no inflammatory cell reaction.

Keyphrases □ Drug delivery systems—ethylene–vinyl acetate copolymer matrix, inulin, release kinetics, *in vitro–in vivo* comparison □ Ethylene–vinyl acetate copolymer—sustained release of inulin, release kinetics, *in vitro–in vivo* comparison □ Inulin—sustained release using polymeric matrices, release kinetics, *in vitro–in vivo* comparison

Since the first report that biocompatible polymers such as ethylene–vinyl acetate copolymer could be used for the controlled release of macromolecules (mol. wt. > 1000) (1), these systems have been used by different investigators in biological (2–11), ophthalmological (12–17), neurological (18, 19),and microbiological research (20, 21). Macromolecules such as enzymes (22), antigens (23), and insulin (24) have been released in biologically active form for up to 6 months *in vivo*. Extensive studies *in vitro* have demonstrated that the release rates of drugs from these devices can be adjusted over a 2000-fold range by simple alterations in the fabrication procedures of the macromolecule–polymer matrices (25).

The macromolecules incorporated into these polymer matrices are usually proteins. Thus, once released *in vivo*, they are degraded to amino acids and recycled to other body proteins. Neither the native proteins nor their metabolites are excreted. For this reason, it has been difficult to directly measure the absolute release rates of such macromolecules *in vivo*. We now report two new methods to measure *in vivo* release which demonstrate that release kinetics from ethylene–vinyl acetate copolymer implants *in vivo* are indistinguishable from identical implants tested *in vitro*. In one method, release rates of ^{14}C-labeled proteins were determined by assaying the remaining radiolabeled protein in the implants at various time points *in vivo* and *in vitro*. In the second method, the use of the polysaccharide inulin, which is totally excreted (26, 27), permitted direct *in vivo* monitoring of release kinetics by collecting urine and assaying for inulin. These studies should enable investigators to employ ethylene–vinyl acetate copolymer matrices with the knowledge that predetermined *in vitro* release kinetics will be followed *in vivo*.

EXPERIMENTAL

Isotope Preparation—Bovine serum albumin[1] (12.2 g) was dissolved in 100 ml of double glass-distilled water. [^{14}C]Methyl bovine serum albumin[2] (1 μCi) was added, and the solution was stirred for 1 hr at 23° with a magnetic stirrer[3]. The solution was then lyophilized[4] yielding a final specific activity for the [^{14}C]methyl bovine serum albumin of 0.082 nCi/mg. β-Lactoglobulin A[1] (6.02 g) was dissolved in 100 ml of double glass-distilled water, and 5 μCi of [^{14}C]methyl β-lactoglobulin A[2] was added. The solution was then lyophilized yielding a final specific activity for [^{14}C]methyl β-lactoglobulin A of 0.83 nCi/mg. Inulin[1] (1.43 g) was suspended in 50 ml of reagent-grade acetone[5] in an Erlenmeyer flask. [^{3}H]Inulin[2] (5 mCi) was added, and the suspension was stirred for 1 hr at 23° with a magnetic stirrer. The suspension was collected on filter paper[6] in a Büchner funnel, rinsing the flask with acetone to remove residual [^{3}H]inulin. The [^{3}H]inulin was collected and dried overnight in a dessicator; the resulting specific activity was 3.44 μCi/mg.

Matrix Preparation—Ethylene–vinyl acetate copolymer[7] was rinsed with water and alcohol to remove inflammatory impurities (2) and dissolved in methylene chloride. The three radioactive macromolecule powders were pulverized with a spatula to produce a normal distribution of particle sizes. As a safety precaution, the powders were not sieved to varying particle size ranges as is often done (25), due to the aerosol effect of shaking radioactive powders.

Fifteen milliliters of 10% (w/v) polymer solution was added to each of six glass vials[8] containing 807 ± 3.1 mg of the pulverized [^{14}C]methyl bovine serum albumin. The polymer–protein mixture was poured into a rectangular mold precooled to −80° and then freeze-dried, at −20° (25). The resulting matrices were 35% (w/w) loaded with [^{14}C]methyl bovine serum albumin. Sixty-seven 1 cm × 1-cm squares were excised from the six slabs (25) with a surgical scalpel blade[9]. The mean weight and standard deviation of the 67 matrices were 67.9 ± 2.9 mg.

Fifteen milliliters of 10% (w/v) polymer solution was added to each of five glass vials containing 989.0 ± 74.0 mg of pulverized [^{14}C]methyl β-lactoglobulin A. The procedure for matrix formation was followed as above, yielding five 40% loaded (w/w) protein polymer matrix slabs. Sixty-seven 0.8 cm × 0.8-cm squares were excised from the five slabs. The mean weight and standard deviation of the 67 matrices were 44.5 ± 1.2 mg.

Fifteen milliliters of 5% (w/v) polymer solution was added to each of three glass vials containing 568 ± 25.4 mg of [^{3}H]inulin. Three 44% loaded (w/w) [^{3}H]inulin polymer matrices were formed. Twenty-nine 1 cm × 1-cm squares were excised from the three slabs. The mean weight and standard deviation of the 29 matrices were 82.00 ± 8.0 mg.

Release of Macromolecules—Kinetic studies, both *in vitro* and *in vivo*, were conducted on the release of three radioactively labeled macromolecules: [^{14}C]methyl bovine serum albumin (mol. wt. 68,000), [^{14}C]methyl β-lactoglobulin A (mol. wt. 18,000), and [^{3}H]inulin (mol. wt. 5200). For the *in vitro* studies, 30 of each set of the ^{14}C-labeled protein–polymer squares and 12 [^{3}H]inulin–polymer squares were placed in glass vials containing 5 ml of sterile phosphate-buffered saline[10] (pH 7.4) and 0.1% sodium azide[5] (release media). The vials were placed on a shaker[11] at 37°. At various time points during the experiment, five polymer squares were removed from the release experiment for the determination of unreleased ^{14}C-labeled protein in the polymer matrices using an isotope recovery method (see below). The remaining polymer squares were transferred to fresh release media to continue the *in vitro* release.

For the *in vivo* studies, 30 ^{14}C-labeled protein–polymer squares identical to those used *in vitro* were implanted into 100- to 150-mg male CD rats[12]. The polymer squares were implanted by making a 2-cm incision in the lower abdominal area of the rat with a scalpel. A pair of sterile round-edged scissors was then used to create a pocket in the subcutaneous tissue ~5 cm from the incision. The polymer square was placed into the pocket with sterile forceps. The wound was closed with animal wound clips[13]. Five polymer squares were removed at the same time points as in the *in vitro* experiments for the determination of unreleased ^{14}C-labeled protein in the polymer matrices.

Thirteen [^{3}H]inulin polymer matrices were implanted into 100- to 150-g male CD rats in the manner described above. The rats were housed in metabolism cages[14] for the duration of the experiment. Urine was collected daily in 15-ml graduated collection tubes[15]. The urine volumes were read directly off the graduated urine collection tubes.

Release Kinetics—*Isotope Recovery Method*—Release rates for the ^{14}C-labeled protein experiments were determined by assaying the remaining radiolabeled bovine serum albumin or β-lactoglobulin A in each polymer square. At various time points during the experiment, five polymer squares were removed from both the rats and the release media. They were placed in scintillation vials, lyophilized to remove residual water, and dissolved in 1 ml of xylene[16]. When the polymer dissolved, the unreleased macromolecule precipitated to the bottom of the vial. One milliliter of distilled water was added to the vial to dissolve the precipitate. Ten milliliters of xylene-based scintillation fluor[17] was added to the dissolved precipitate, and the radioactivity was measured by liquid scintillation counting[18]. The radioactivity remaining in the matrix at any given time was subtracted from the average amount of radioactivity remaining at the previous time point; release rates are expressed as dpm/hr. The procedure described above was used to dissolve the polymer and to precipitate unreleased [^{3}H]inulin in each of two polymer squares at each time point. Then, 10 ml of warm distilled water (70–80°) was added to the dissolved [^{3}H]inulin–polymer matrix to solubilize the inulin precipitate. A 200-μl aliquot of water was then removed and counted[18].

Before the start of the ^{14}C-labeled protein release experiments, 7 of the 67 polymer squares were assayed by the above method to establish the initial dpm per polymer matrix. In a similar manner 4 of the 29 [^{3}H]inulin–polymer squares were assayed to determine the mean dpm per polymer matrix.

Isotope Release Method—In the *in vitro* studies, the amount of radiolabeled macromolecule released was determined by removing a 250-μl aliquot from the release media, adding 4 ml of scintillation fluor, and counting the solution[18]. For the *in vivo* studies [^{3}H]inulin–polymer matrix squares were implanted into five rats housed in metabolism cages. Urine was collected and measured daily. A 250-μl aliquot of urine was added to 4 ml of scintillation fluor plus 400 μl of distilled water in a glass miniscintillation vial[19] and the solution was counted[18]. The channels ratio method of quench correction was used to determine the counting efficiency of the urine samples (28).

Statistics—*In vivo* and *in vitro* release rates were compared by an analysis of covariance on a log transformation of the release rate data (29). The natural logarithms of the release rates and times were calculated. This transformation resulted in a linear relationship for each data set with r^2 ranging from 0.89 to 0.96 for the regression lines. The *in vivo* and *in vitro* regression lines were then compared as follows: The mean square error from the regression model with a separate slope and intercept for each trial condition (there were three trial conditions for bovine serum albumin, three trial conditions for β-lactoglobulin A, and two trial conditions for inulin) was compared with the mean square error for the regression model with common slopes and intercepts for all trial conditions pertaining to a specific macromolecule. The resulting test statistic was compared to the F distribution (30). The regression lines were considered indistinguishable if $p > 0.05$.

Histology—Histology was performed on tissues surrounding washed (2) ethylene–vinyl acetate copolymer subcutaneous implants containing bovine serum albumin after 7 months. The polymer matrices were implanted into male CD rats. An unwashed industrial grade ethylene–vinyl acetate copolymer[7] was used as a control to exhibit an inflammatory response. Sections (5 μm) were prepared using hematoxylin and eosin staining.

RESULTS

Comparison of Release Rates of ^{14}C-Labeled Proteins *In Vitro* and *In Vivo*—Figure 1 compares the release rates of the 35% loaded (w/w) [^{14}C]methyl bovine serum albumin–polymer matrices *in vivo* and *in vitro* as measured by the recovery of unreleased protein in the polymer and as measured directly in the *in vitro* release media. Figure 1—In vivo *and* in vitro *comparison of release rates from 35% loaded (w/w) [^{14}C]methyl bovine serum albumin polymer matrices. Each point represents the average release of five polymer squares. Key: (▲) in vivo recovery; (△) in vitro recovery; (○) in vitro release.*

experiment, *in vivo* and *in vitro* release rates were not statistically different ($p > 0.05$). Figure 2 shows that the release rates of 40% loaded (w/w) [^{14}C]methyl β-lactoglobulin A–polymer matrices *in vivo* and *in vitro* also were not statistically different ($p > 0.05$). At each time point

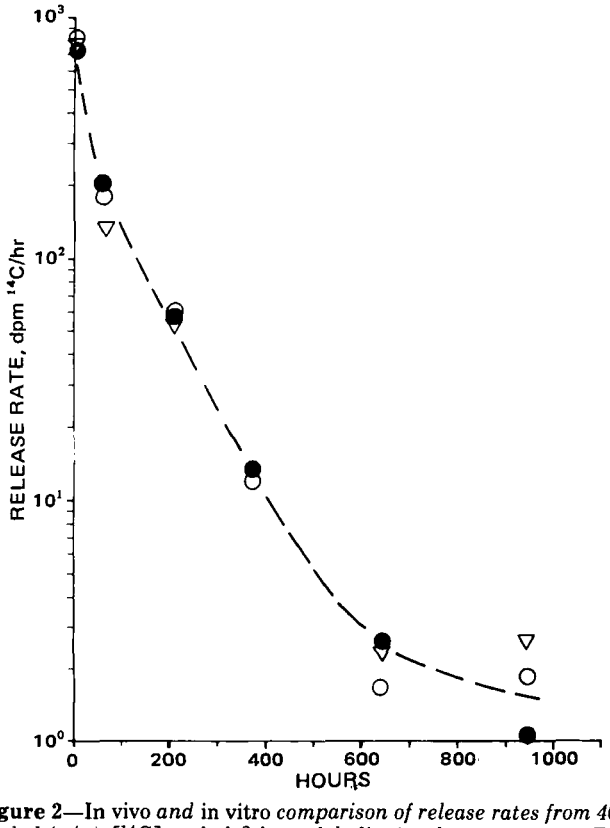

Figure 2—In vivo *and* in vitro *comparison of release rates from 40% loaded (w/w) [^{14}C]methyl β-lactoglobulin A polymer matrices. Each point represents the average of five polymer squares. Key: (○) in vitro recovery; (●) in vitro release; (▽) in vivo recovery.*

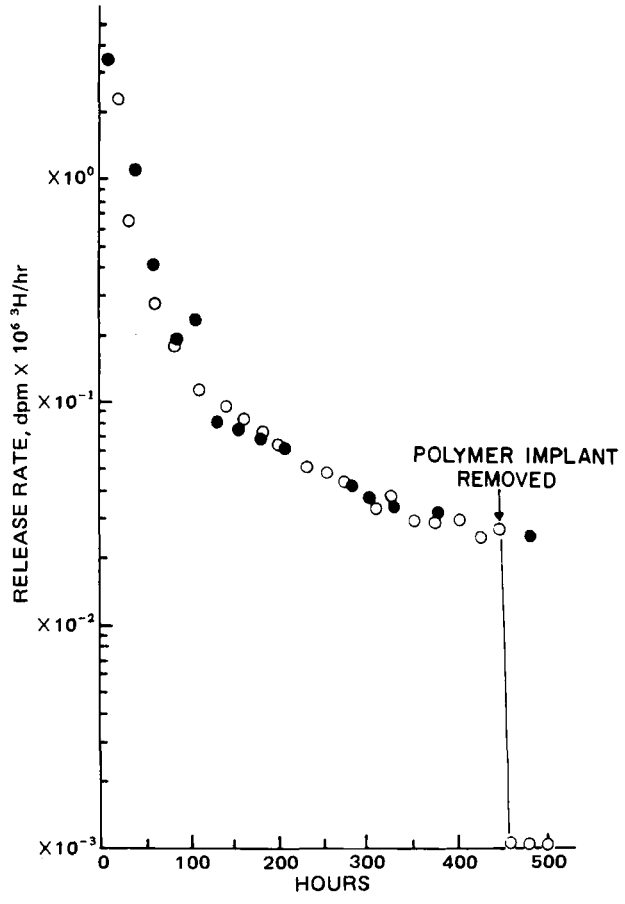

Figure 3—In vivo *and* in vitro *comparison of release rates from 44% loaded (w/w) [^{3}H]inulin. Each* in vivo *point (○) represents the average release rate obtained by the collection of urine from five rats. Each* in vitro *point (●) represents the average release rate from four polymer squares into phosphate-buffered saline. The polymer squares were removed from the rats after 450 hr.*

the recovered and released radioactivity were totaled for each polymer square. Complete material balance was demonstrated as this total equaled (±7%) the initial amount of radioactivity incorporated into each polymer square. The material balance can also be seen by the equivalent *in vitro* release rates obtained by both the recovery and release methods (Figs. 1 and 2).

Comparison of [^{3}H]Inulin Release *In Vivo* and *In Vitro*—Figure 3 compares the release rates of [^{3}H]inulin analyzed directly by the collection of urine from five implanted rats and four polymer squares releasing *in vitro*. Release rates *in vivo* and *in vitro* were indistinguishable ($p > 0.05$). As an internal control, the polymer implants were removed from the rats at 450 hr into the experiment. The rats were placed in the metabolism cages for an additional 50 hr. Within 4.5 hr after the explant of the polymer, recovery of [^{3}H]inulin dropped 51-fold as measured in the urine of the animals. Release rates decreased for the remainder of the experiment (Fig. 3). An additional experiment was conducted over a 1500-hr period with a smaller sample size and showed an *in vitro–in vivo* relationship similar to the above (data not shown).

The possibility of artifacts in the amount of inulin recovered due to tritium exchange with surrounding aqueous media was checked by lyophilizing a known amount of [^{3}H]inulin. If exchange did occur, the water removed during the lyophilization procedure would cause a reduction in the dpm in the sample. No such reduction in the amount of radioactivity was observed, confirming that tritium exchange did not occur.

In a separate experiment, the recovery of unreleased [^{3}H]inulin from polymer matrices releasing *in vivo* and *in vitro* was compared at five different time points over a 30-day period. The amounts of [^{3}H]inulin recovered at various times in both cases were not statistically different ($p > 0.05$).

Histology—Figure 4A shows the tissue response to the washed (2) polymer implants containing bovine serum albumin which were removed after 7 months. The polymer implant (P) was surrounded by a very thin capsule of connective tissue. There was no inflamatory reaction, and the

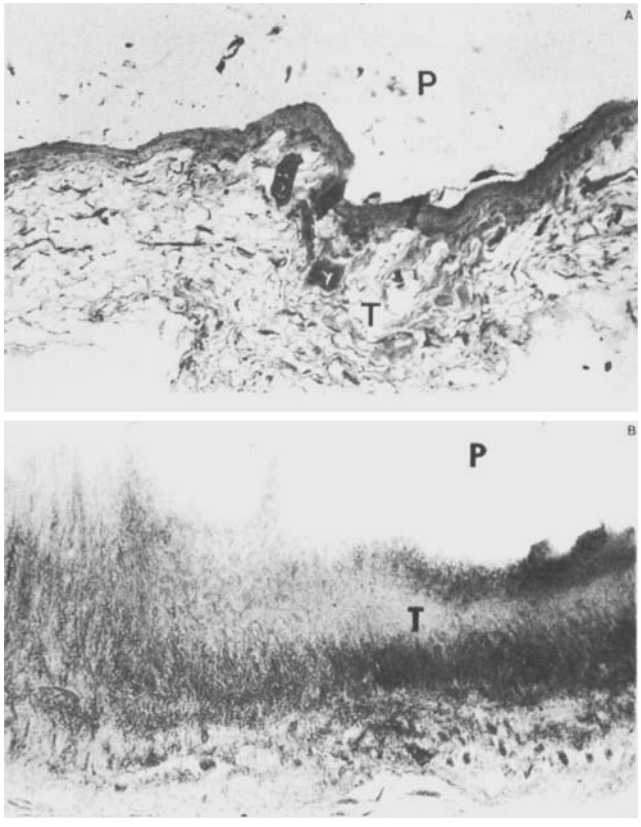

Figure 4—*(A) The washed implant (P) is surrounded by a thin capsule of dense connective tissue (T). There is virtually no inflammatory reaction, and the adjacent loose connective tissue is normal. Original magnification 100×. (B) The tissue (T) surrounding the control unwashed implant (P) shows an extensive inflammatory reaction. The granulation tissue is thick and shows multiple layers, some infiltrated with abundant polymorphonuclear leukocytes. Original magnification 100×.*

adjacent loose connective tissue was normal. As a control, unwashed polymer resulted in tissue sections that showed an extensive inflammatory reaction. The granulation tissue surrounding the control polymer was thick and showed multiple layers, some infiltrated with abundant polymorphonuclear leukocytes (Fig. 4B).

DISCUSSION

These results demonstrate that *in vivo* release kinetics of a particular macromolecule from ethylene–vinyl acetate copolymer matrices closely follow *in vitro* release kinetics of identical implants under physiological conditions. These studies were carried out for three macromolecules with a wide range of molecular weights (5200–68,000) and loadings (35–44%).

Many macromolecules incorporated into the ethylene–vinyl acetate copolymer matrix are proteins or other biological substances (2–25) that are metabolized and redistributed into other body tissues. In these cases, *in vivo* release rates cannot be measured directly. To circumvent this problem, a procedure had to be developed for the recovery of radioactively labeled macromolecules from the ethylene–vinyl acetate copolymer matrix. The implants were removed from the experimental animals, or from the release media in the *in vitro* studies. The squares were first lyophilized to improve the solubility of the polymer in xylene. Xylene was the solvent of choice for two reasons:

1. On dissolution of the polymer, the protein remaining in the polymer precipitated to the bottom of the glass vial. The addition of water to dissolve the precipitated protein was facilitated by the greater density of water compared with xylene. Thus, the ethylene–vinyl acetate copolymer in xylene floated on the upper organic phase, while the water dissolved the precipitated protein in the bottom aqueous phase.
2. The scintillation fluor used to count the radioactivity in the dissolved polymer was a xylene-based fluor. Thus, it was completely compatible with both the xylene–ethylene–vinyl acetate copolymer phase and the aqueous phase. This resulted in a homogeneous translucent emulsion, suitable for liquid scintillation counting. Control studies demonstrated that there was no quenching due to the polymer in the scintillation fluor.

Using this technique, *in vivo* release rates of ^{14}C-labeled proteins were shown to be statistically indistinguishable from *in vitro* release rates with identical implants (Figs. 1 and 2). However, this technique had several disadvantages: (*a*) the need for a large sample size of polymer matrices and animals (30 rats were used in each experiment), (*b*) the use of long half-life ^{14}C-labeled proteins, and (*c*) the inability to directly measure release rates from polymer implants *in vivo*.

In contrast to the proteins, the polysaccharide inulin (mol. wt. 5200) is not metabolized *in vivo* nor reabsorbed by the kidney tubules. Once absorbed into the bloodstream, inulin is totally excreted in the urine (26, 27). Thus, inulin seemed to be an ideal model drug with which to measure *in vivo* release directly by simply collecting urine from [^3H]inulin–polymer-implanted rats housed in metabolism cages. Figure 3 clearly demonstrated that *in vivo* and *in vitro* release rates of [^3H]inulin are indistinguishable. The value of using inulin as a model drug to compare *in vivo* and *in vitro* macromolecule release was shown by its nearly instantaneous appearance in the urine after polymer implantation. When the polymer implant was removed after 450 hr (Fig. 3), release rates dropped 51-fold within 4.5 hr. This was further evidence that inulin release was only associated with the presence of the polymer implant. In addition, the use of [^3H]inulin allowed the continuous monitoring of release *in vivo*. The use of five rats in this experiment *versus* the 30 rats needed for the ^{14}C-labeled protein recovery experiments provided for a simpler experiment design.

The continuous decrease in release rates of macromolecules from the ethylene–vinyl acetate copolymer matrix is predictable from the flat-slab geometry used in these experiments (31). It has been suggested that release occurs through a porous network of tortuous channels created by the powdered drug during the fabrication procedure of the polymer matrix (32). Thus, drug release rates decrease due to increasing diffusion distance through the pores of the matrix as time increases. Constant release rates have been obtained with appropriate geometric design (33). The relationship of *in vivo* and *in vitro* release rates are now being studied for these alternative geometries.

The excellent biocompatibility of washed ethylene–vinyl acetate copolymer was demonstrated by a 7-month polymer implant into subcutaneous rat tissue (Fig. 4). This is consistent with previous studies in which this polymer was shown to be inert in rabbit corneal implants (34). It is conceivable that other polymers may either be subject to bioerosion or induce significant fibrous encapsulation that could cause *in vivo* and *in vitro* release rates to differ. Thus, ethylene–vinyl acetate copolymer may prove to be a useful standard for judging other polymers with respect to biocompatibility and *in vivo* release kinetics.

The results presented here demonstrate that *in vivo* release kinetics are statistically indistinguishable from *in vitro* release kinetics using identical implants for macromolecules with a wide range of molecular weights and loadings. The implication is that a desired *in vivo* release rate could be manipulated through *in vitro* testing. This is of particular importance if these polymer matrices are to be used experimentally (24) or clinically for the delivery of macromolecules such as insulin. Furthermore, the inulin–polymer model establishes a methodology that can be easily applied for *in vivo–in vitro* comparisons for any controlled-release system. Tracer amounts of inulin could be mixed with any drug to monitor the continual effectiveness of an implant in animals or humans. Small implantable sustained-release inulin–polymer matrices may also be useful for extended studies of glomerular filtration. These data show that *in vivo* release can be accounted for by the same mechanisms operating *in vitro;* this should now make possible the further development and increased use of ethylene–vinyl acetate copolymer drug delivery systems.

Absorption of Triazolam from Pelleted Drug–Diet Mixtures by the Mouse: Quantitation of α-Hydroxytriazolam in Urine

WADE J. ADAMS ˣ, PAUL A. BOMBARDT, and ROBERT A. CODE

Received January 6, 1982, from *Pharmaceutical Research and Development, The Upjohn Company, Kalamazoo, MI 49001.* Accepted for publication September 14, 1982.

Abstract □ The absorption of triazolam from pelleted drug–diet mixtures by mice under steady-state conditions was determined for doses up to 150 mg/kg/day by measuring α-hydroxytriazolam, the principal urinary metabolite of triazolam in the mouse, in urine samples collected over a 24-hour period. Following β-glucuronide glucuronosohydrolase hydrolysis of the urine, quantitation of α-hydroxytriazolam was accomplished using a specific reverse-phase liquid chromatographic method which utilized UV detection at 214 nm. Assay precision was >2.7% (*CV*) over the concentration range of interest. Statistical analysis of the excretion data indicated that the mathematical relationship between the triazolam dose and the quantity of α-hydroxytriazolam excreted was linear for female mice and nonlinear for male mice. Triazolam absorption, as reflected by α-hydroxytriazolam urinary excretion data, increased with triazolam dose.

Keyphrases □ Triazolam—absorption from drug–diet mixtures by mice, determination by metabolite excretion in urine, α-hydroxytriazolam □ α-Hydroxytriazolam—urinary excretion, use to measure triazolam absorption in mice, drug–diet mixtures □ Absorption—triazolam in mice, drug–diet mixtures, measurement by α-hydroxytriazolam excretion in urine

The incorporation of drugs into the laboratory diet of mice and rats is a convenient and commonly used method of administering drugs in chronic toxicology studies since it eliminates the need for time-consuming daily administration of aqueous solutions or suspensions by gavage. In addition to its convenience, this mode of administration also eliminates the daily trauma and danger of pulmonary complications associated with dosing by gavage. As is well known, however, the administration of a drug in a carrier, such as laboratory diet, may affect drug absorption. Information concerning the absorption of a drug from the carrier over the range of dosages administered in toxicological studies may be useful, if not essential, in assessing the significance of study results. It should also be noted that the Food and Drug Administration's recently instituted Good Laboratory Practice regulations may require that the degree of absorption of a drug from a carrier be determined (1).

Several methods have been reported for determining the relative absorption of drugs following administration of pulverized drug–diet mixtures. Van Harken and Hottendorf (2) determined the exposure of rats to cefatrizine, under steady-state conditions, by comparing the area

Keyphrases □ Triazolam—absorption from drug–diet mixtures by mice, determination by metabolite excretion in urine, α-hydroxytriazolam □ α-Hydroxytriazolam—urinary excretion, use to measure triazolam absorption in mice, drug–diet mixtures □ Absorption—triazolam in mice, drug–diet mixtures, measurement by α-hydroxytriazolam excretion in urine

The incorporation of drugs into the laboratory diet of mice and rats is a convenient and commonly used method of administering drugs in chronic toxicology studies since it eliminates the need for time-consuming daily administration of aqueous solutions or suspensions by gavage. In addition to its convenience, this mode of administration also eliminates the daily trauma and danger of pulmonary complications associated with dosing by gavage. As is well known, however, the administration of a drug in a carrier, such as laboratory diet, may affect drug absorption. Information concerning the absorption of a drug from the carrier over the range of dosages administered in toxicological studies may be useful, if not essential, in assessing the significance of study results. It should also be noted that the Food and Drug Administration's recently instituted Good Laboratory Practice regulations may require that the degree of absorption of a drug from a carrier be determined (1).

Several methods have been reported for determining the relative absorption of drugs following administration of pulverized drug–diet mixtures. Van Harken and Hottendorf (2) determined the exposure of rats to cefatrizine, under steady-state conditions, by comparing the area

0022-3549/83/1000-1185$01.00/0

under the 24-hr plasma concentration–time curves of the antibiotic after feeding a pulverized cefatrizine–diet mixture *ad libitum* and administering a suspension of the drug once daily. Although satisfactory results were obtained, the authors indicated that it was a very laborious procedure that required a team of technicians working overnight to collect the blood samples. This procedure also places the animals under a great deal of stress, particularly if a sufficient number of blood samples are collected to characterize the blood level profile adequately, and the analysis of a large number of samples is required. To overcome these problems, Smyth *et al.* (3) studied the absorption of several drugs in rats by comparing the urinary excretion of radioactivity after feeding radiolabeled drug–diet mixtures and administering a solution/suspension of each drug. Difficulties may be encountered using this procedure also, since incorporation of radiolabeled drug into the diet using the same techniques that were used to prepare drug–diet mixtures for the corresponding toxicological study may not be possible. In addition, adequate quantities of radiolabeled drug must be available.

The present report describes a study of the absorption of triazolam[1] (I), a potent new hypnotic with a short duration of action (4), from pelleted drug–diet mixtures by mice under steady-state conditions. The extent of triazolam absorption was determined by quantitating α-hydroxytriazolam, 8-chloro-6-(2-chlorophenyl)-1-(hydroxymethyl) - 4*H*-*s*-triazolo[4,3 - *a*][1,4]benzodiazepine (I-a), the principal urinary metabolite of triazolam in the mouse[2], in 0 to 24-hr urine samples following β-glucuronide glucuronosohydrolase hydrolysis.

EXPERIMENTAL

Study Protocol—One week prior to the termination of a 24-month carcinogenicity study of triazolam in $B_6C_3F_1$ mice, three male and three female mice were randomly selected from among surviving mice in each dosage group of the study and placed in individual stainless steel metabolism cages equipped with urine and feces separators. As in the carcinogenicity study, water and pelleted food[3] containing sufficient drug to provide approximately 0-, 10-, 30-, and 100-mg/kg/day triazolam doses were provided *ad libitum* to mice in each dosage group. The potency, content uniformity, and stability of the pelleted triazolam–diet mixtures were determined using a high-performance liquid chromatographic (HPLC) assay[4]. Food consumption was measured daily by weighing tared feed cups. Following a 2-day acclimatization period, urine samples were collected over two consecutive 24-hr periods in screw-capped vials fitted with aluminum-lined caps. Any urine remaining in the cages was rinsed into the containers with deionized water. The samples were stored at −20°.

Reagents—The solvents used in the study were distilled-in-glass UV grade[5]. Analytical reagent-grade inorganic chemicals[6] were prepared in distilled, deionized water. The reference standard, α-hydroxytriazolam, and the internal standard, alprazolam (8-chloro-1-methyl-6-phenyl-4*H*-*s*-triazolo[4,3-*a*][1,4]benzodiazepine), were used without further purification[7]. The β-D-glucuronide glucuronosohydrolase preparation[8] (E.C. 3.2.1.31) was used as received.

Standards—A 20-μg/ml stock solution of α-hydroxytriazolam was prepared by dissolving an accurately weighed sample of the reference standard in acetonitrile. Calibration curve standards containing 20, 14, 10, 7, 5, 3, 2, 1, and 0.5 μg/ml of α-hydroxytriazolam were prepared by making appropriate dilutions of the stock solution with acetonitrile. A 1-μg/ml working internal standard solution was prepared by dissolving the reference standard, alprazolam, in acetonitrile.

Calibration Curves—Calibration curves were prepared each day of sample analysis to establish the linearity and reproducibility of the method. One-milliliter aliquots of the internal standard and the appropriate calibration curve standard were added to 16 × 125-mm screw-capped culture tubes fitted with polytef-lined caps, and the acetonitrile was evaporated to dryness at 50° under a gentle stream of dry nitrogen[9]. A 500-μl aliquot of blank mouse urine was added to each tube prior to enzymatic hydrolysis.

Sample Preparation—One milliliter of internal standard was added to 16 × 125-mm screw-capped culture tubes fitted with polytef-lined caps, and the acetonitrile was evaporated to dryness at 50° under a gentle stream of dry nitrogen. The urine samples were thoroughly mixed, and 500-, 175-, and 50-μl aliquots of the samples collected from animals administered 0 and ~10, ~30, and ~100 mg/kg/day of triazolam, respectively, were transferred to the sample tubes for analysis. The 175- and 50-μl samples were diluted to 500-μl with 0.05 *M* acetate buffer (pH 4.5) prior to enzymatic hydrolysis.

Enzymatic Hydrolysis—The calibration curve standards and unknowns were hydrolyzed in a water bath[10] at 37° for 24 hr following addition of 100 μl of 2 *M* acetate buffer (pH 4.5) and 400 μl of 0.05 *M* acetate buffer (pH 4.5) containing 30,000 Fishman units of β-D-glucuronide glucuronosohydrolase.

Extraction—The hydrolyzed samples were buffered with 2 ml of 4 *M* NaOH and extracted twice with 5-ml aliquots of methylene chloride–toluene (1:1, v/v) for 15 min at 280 cpm on a two-speed reciprocating shaker[11]. Following centrifugation for 10 min at 2000 rpm, the organic phase was transferred to 15-ml conical tubes and evaporated to dryness at 50° under a gentle stream of dry nitrogen. The resulting residues were reconstituted in 4 ml of chromatographic mobile phase, thoroughly mixed on a high-speed vortex mixer[12], and chromatographed (250-μl samples).

Chromatographic Analysis—A constant-flow liquid chromatograph[13] equipped with a loop injection valve[14] and a 214-nm UV detector[15] was used for the analysis. The samples were chromatographed on a commercially prepared reverse-phase column[16], thermostated[17] at 50°, using a mobile phase containing water–acetonitrile (7:3, v/v) at a flow rate of 2.0 ml/min. Under these chromatographic conditions the retention times of the α-hydroxytriazolam and internal standard were ~9.5 and 14 min, respectively.

Mass Spectrometry—Chromatographic fractions collected at the retention times of major peaks in chromatograms of enzymatically hydrolyzed urine extracts were lyophilized, and electron-impact mass spectra (EI/MS) (70 eV) were recorded using a magnetic sector mass spectrometer[18].

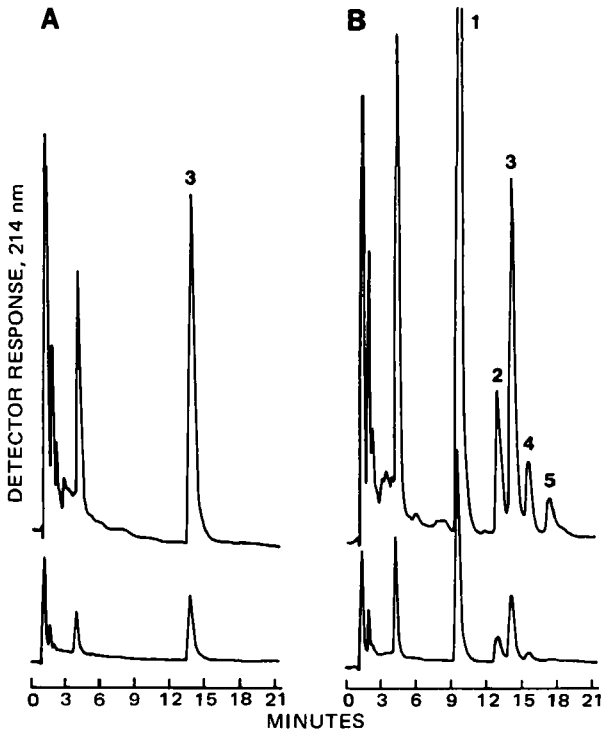

Figure 1—*Chromatograms of extracts of hydrolyzed mouse urine from (A) a control mouse and (B) a mouse administered ~10 mg/kg triazolam. Key: (1) α-hydroxytriazolam; (2) 1-demethyltriazolam; (3) internal standard; (4) triazolam; and (5) 5-chloro-2-(3-methyl-4H-1,2,4-triazol-4-yl)-2′-chlorobenzophenone.*

Calculations—The α-hydroxytriazolam concentrations of the unknown samples were calculated from peak height ratios using the slope computed by linear regression analysis of the unweighted calibration curve data. Peak height ratios were calculated by dividing the α-hydroxytriazolam peak heights by the internal standard peak heights. The quantity of α-hydroxytriazolam excreted over a 24-hr period, expressed as milligrams of α-hydroxytriazolam per kilogram of body weight, was calculated from the α-hydroxytriazolam concentration, the volume of urine collected over the 24-hr period, and the mean body weight.

The triazolam dose received by each animal, expressed as milligrams of triazolam per kilogram of body weight, was calculated from the quantity of food consumed over the 24-hr period in which the urines were collected and the mean body weight. No attempt was made to correct the diet consumption data for the amount of food dropped through the bottom of the cage. The quantity of food dropped into the urine appeared to be small and evenly distributed among the dosage groups.

Statistical Analysis—Statistical analyses of the experimental data were performed using the SAS statistical analysis programs (5) and NONLIN (6), a computer program for parameter estimation in nonlinear situations.

RESULTS AND DISCUSSION

The measurement of drug levels in the blood following single- or multiple-dose administration of drugs is the experimental approach most frequently used in relative bioavailability studies in humans and large animals, where sequential sampling at precisely known times is possible. This approach is also feasible for bolus drug administration to mice, but has the disadvantage of requiring the sacrifice of several mice at each time point for which data are needed. In the case of *ad libitum* administration of drug–diet mixtures to mice or rats, however, drug ingestion occurs over an extended period instead of precisely known times; therefore, it is difficult and extremely laborious to obtain reliable estimates of relative bioavailability by analysis of blood samples.

An alternative to the determination of relative bioavailability from drug levels in the blood is the measurement of the urinary excretion of intact drug or of a principal drug metabolite (7). A recent single-dose metabolism study of [^{14}C]triazolam in $B_6C_3F_1$ mice established that although there is no urinary excretion of intact drug, ~17% of the orally administered dose of triazolam is excreted in the urine as α-hydroxytriazolam[2]. Excretion of all drug-related materials was complete within 72 hr. Under the chronic-dosing conditions of this study, α-hydroxytriazolam was the major extractable metabolite. Therefore, quantitation of α-hydroxytriazolam in 24-hr urine samples under steady-state conditions was the logical experimental approach for the determination of the relative bioavailability of triazolam in mice. An HPLC method utilizing UV detection was developed for the quantitation of α-hydroxytriazolam in mouse urine.

Table I—Chromatographic Retention Times of Triazolam and Selected Triazolam Metabolites [a]

Compound	Retention Time, min[b]
I	15.5
I-a	9.5
I-b	6.0
I-c	12.8
I-d	10.6
II	11.9
II-a	17.4
II-b	10.0

[a] Samples chromatographed on a 5-μm LiChrosorb RP-8 reverse-phase column thermostated at 50° using a mobile phase containing water–acetonitrile (7:3, v/v): at a flow rate of 2.0 ml/min. [b] The void volume of the column was 1.2 ml.

Chromatographic Analysis—Resolution of α-hydroxytriazolam and the internal standard from coextracted endogenous interferences was accomplished using a 5-μm LiChrosorb RP-8 reverse-phase column thermostated at 50° and a mobile phase containing water–acetonitrile (7:3, v/v) at a flow rate of 2.0 ml/min. Thermostating the column at 50° reduced column back-pressure and shortened the retention times of the compounds of interest. Typical chromatograms of extracts of urine from a control mouse and from a mouse administered ~10 mg/kg/day of triazolam are shown in Fig. 1. The internal standard was added to both samples. The α-hydroxytriazolam and internal standard eluted at ~9.5 and 14.0 min, respectively.

Comparison of chromatograms of urine extracts from control and triazolam-dosed mice indicated that significant quantities of triazolam and several metabolites in addition to α-hydroxytriazolam had been extracted from the urine of the triazolam-dosed mice. Although triazolam was not detected in the urine of mice in the recently conducted metabolism study[2], its presence in the urine samples collected in this study was not unexpected, since it was apparent that all collected urine samples had been contaminated with small pieces of pelleted food which had dropped through the bottom of the cage. The triazolam eluted at ~15.5 min and did not interfere in the analysis. Chromatography of authentic samples of triazolam metabolites that had been identified in mice[2], rats[2,19], dogs (8), or humans (9) provided tentative evidence that the metabolites eluting at ~6.0, 11.9, 12.8, and 17.4 min were α,4-dihydroxytriazolam (I-b), 5-chloro-2-(3-hydroxymethyl-5-methyl-4*H*-1,2,4-triazol-4-yl)-2′-chlorobenzophenone (II), 1-demethyltriazolam (I-c), and 5-chloro-2-(3-methyl-4*H*-1,2,4-triazol-4-yl)-2′-chlorobenzophenone (II-a), respectively (Table I). fractions collected at the retention times of major peaks in the chromatograms confirmed the presence of α-hydroxytriazolam (Table II, peak 1), 1-demethyltriazolam (Table II, peak 2), triazolam (Table II, peak 4), and 5-chloro-2-(3-methyl-4*H*-1,2,4-triazol-4-yl)-2′-chlorobenzophenone (Table II, peak 5) in extracts of the enzymatically hydrolyzed urine. No attempt was made to confirm the identity of minor metabolites. However, a minor metabolite that eluted as a shoulder on the trailing edge of the α-hydroxytriazolam peak in some chromatograms was collected in the same chromatographic fraction as α-hydroxytriazolam (Fig. 1; peak 1, 9–11 min) and was tentatively identified as 5-chloro-2-(3-hydroxymethyl-4*H*-1,2,4-triazol-4-yl)-2′-chlorobenzophenone (II-b). In addition to α-hydroxytriazolam, 4-hydroxytriazolam (I-d) and α,4-dihydroxytriazolam were also isolated from urine and identified by GC/MS in the recently conducted metabolism study of triazolam in the mouse[2]; 5-chloro-2-(3-methyl-4*H*-1,2,4-triazol-4-yl)-2′-chlorobenzophenone was tentatively identified. The low extraction efficiencies of 4-hydroxytriazolam and α,4-dihydroxytriazolam in toluene–methylene chloride (1:1, v/v) precluded isolation of sufficient quantities of these metabolites to allow confirmation by MS in the present study.

Assay Recovery—The absolute recovery of α-hydroxytriazolam from hydrolyzed urine was determined by comparing the slopes of standard curves for which the α-hydroxytriazolam standards were added prior to and following the extraction step in the sample preparation procedure. Alprazolam was added as an external standard in the recovery experiments.

Extraction of the hydrolyzed urine with toluene provided excellent recoveries of triazolam, as had been found in previously developed analytical methods for triazolam in serum (10, 11); however, the recovery of α-hydroxytriazolam was <30%. Addition of methylene chloride to the toluene (1:1, v/v) increased the recovery to 94.5 ± 2.7% and provided an extract that was free of endogenous interferences. Furthermore, the recoveries of the internal standard, triazolam, 5-chloro-2-(3-hydroxymethyl-5-methyl-4*H*-1,2,4-triazol-4-yl)-2′-chlorobenzophenone, and 5-chloro-2-(3-methyl-4*H*-1,2,4-triazol-4-yl)-2′-chlorobenzophenone were all >90%. However, the recoveries of α,4-dihydroxytriazolam and 4-hydroxytriazolam were <3 and 45%, respectively.

Assay Linearity and Precision—The linearity and precision of the method were established by analyzing standard curve samples on each day that unknowns were analyzed. Linear regression analysis of calibration curve data indicated no significant deviations from linearity ($r^2 \geq 0.9962$, $n = 3$) for α-hydroxytriazolam concentrations ranging from 0.5 to 20 μg/ml. The standard curve intercepts were not significantly different from zero ($p > 0.05$) for all three curves.

An estimate of the interassay reproducibility and precision was obtained by comparison of standard curves prepared over a 3-day period. The slopes of the three curves ranged from 1.0703 to 1.2145 ml/μg with a mean slope ± percent relative standard deviation of 1.1563 ± 0.0097 ml/μg and a mean correlation coefficient (r^2) of 0.9994. The percent relative standard deviations of the interassay ordinate values for the three curves were ± 3.3, 3.4, 3.2, 4.9, 8.4, 3.6, 6.3, 10.8, and 5.7 for concentrations (abscissa) of 0.5, 1.0, 2.0, 3.0, 5.1, 7.1, 10.2, 14.3, and 20.4 μg/ml, respectively. The limit of detection of the method was ~6 ng/ml (0.5 ng on-column; signal/noise, 3/1).

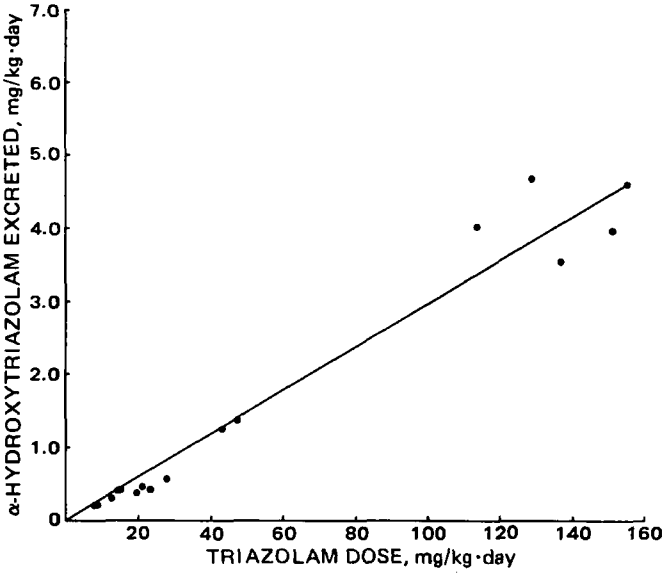

Figure 2—*Plot of the α-hydroxytriazolam excretion data for female mice. The solid line is a plot of the theoretical model which gave the best fit of the experimental data;* $E = C_1(dose)$, *where* E *represents the milligrams of α-hydroxytriazolam excreted per kilogram body weight per day and* $C_1 = 0.0298 \pm 0.0011$ *(ESD) mg of α-hydroxytriazolam/mg of triazolam.*

Triazolam Absorption—Plots of the quantity of α-hydroxytriazolam excreted in urine over a 24-hr period *versus* triazolam dose for the female and male mice are shown in Figs. 2 and 3, respectively. Regression analysis of the female excretion data (5) indicated that the quantity of α-hydroxytriazolam excreted (E) was proportional to the triazolam dose. That is, coefficients for the $n = 0, 2, 3, 4$, *etc.* terms in the polynomial expression, $E = \sum_{n=0}^{N} C_n \cdot (\text{dose})^n$, were not statistically significant ($p > 0.05$). The root-mean-square (RMS) deviation for the linear function, $E = C_1 \cdot (\text{dose})$, was 0.301 mg of α-hydroxytriazolam/kg·day, with $C_1 = 0.0298 \pm 0.0011$ (*ESD*) mg of α-hydroxytriazolam/mg of triazolam. Regression analysis of the male α-hydroxytriazolam excretion data (5), assuming dose proportionality, indicated that the slope of the line, 0.0428 ± 0.0047 (*ESD*) mg of α-hydroxytriazolam/mg of triazolam, was greater than that found for the female excretion data. More important, however, a distinct

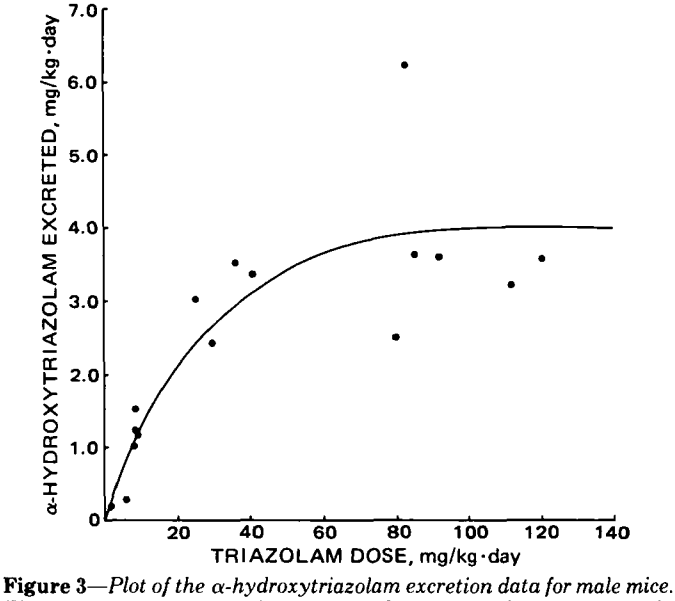

Figure 3—*Plot of the α-hydroxytriazolam excretion data for male mice. The solid line represents the theoretical model which gave the best fit of the experimental data:* $E = A[1 - e^{-B(\text{dose})}]$, *where* E *represents the milligrams of α-hydroxytriazolam excreted per kg body weight per day,* $A = 4.02 \pm 0.40$ *(ESD) mg of α-hydroxytriazolam/kg-day, and* $B = 0.038 \pm 0.010$ *(ESD) kg·day/mg.*

nonlinear trend in the male excretion data was apparent, reflected in the RMS deviation (1.162 mg of α-hydroxytriazolam/kg·day) which was nearly four times greater than that for the female data. A plausible nonlinear model of the male excretion data is one in which the quantity of α-hydroxytriazolam excreted approaches an asymptotic value with increasing doses of triazolam. An exponential function of the dose was adopted, $E = A[1 - e^{-B \cdot (\text{dose})}]$, where A and B are adjustable parameters. The best fit parameters for the male excretion data, estimated using NONLIN (6), were $A = 4.02 \pm 0.40$ mg of α-hydroxytriazolam/kg·day and $B = 0.038 \pm 0.010$ kg·day/mg; the associated RMS deviation was 0.70 mg of α-hydroxytriazolam/kg·day, a significantly better fit of the experimental data than that afforded by the one-parameter linear model ($F_{\text{statistic}} = 34.6$; $n = 22$).

In conclusion, triazolam absorption, as reflected by α-hydroxytriazolam urinary excretion data for female and male mice, increased with triazolam dose. The quantity of α-hydroxytriazolam excreted by female mice was proportional to the triazolam dose, while the male excretion data were adequately represented by a model which predicts that the quantity of α-hydroxytriazolam excreted approaches an asymptotic value with increasing doses of triazolam.

Mechanisms of Potassium Chloride Release from Compressed, Hydrophilic, Polymeric Matrices: Effect of Entrapped Air

R. W. KORSMEYER ‡, R. GURNY *x, E. DOELKER *, P. BURI *, and N. A. PEPPAS ‡

Received June 28, 1982, from the *School of Pharmacy, University of Geneva, CH-1211 Geneva 4, Switzerland and the ‡ School of Chemical Engineering, Purdue University, West Lafayette, IN 47907. Accepted for publication September 14, 1982.

Abstract □ The release of potassium chloride from hydroxypropyl methylcellulose matrices was investigated for tablets prepared with several different compression forces. It was determined that the release kinetics for these systems deviates significantly from the classical $t^{1/2}$ dependence. This behavior was attributed to air entrapped in the matrix during preparation. Removal of the air prior to release restored the traditional $t^{1/2}$ behavior.

Keyphrases □ Potassium chloride—release from hydroxypropyl methylcellulose matrices, effect of entrapped air, kinetics □ Matrices, hydroxypropyl methylcellulose—release of potassium chloride, effect of entrapped air, kinetics □ Kinetics—release of potassium chloride from hydroxypropyl methylcellulose matrices, effects of entrapped air

Compressed, hydrophilic, polymeric matrices provide a convenient method for achieving sustained release of highly water-soluble drugs (1, 2). Release profiles are usually analyzed using equations derived by T. Higuchi (3) and W. Higuchi (4) and adapted by Lapidus and Lordi (5, 6). However, such systems often exhibit complex kinetics (7, 8) that are poorly explained by these traditional models of drug release. Modeling efforts in this area may be assisted by better understanding of the physical factors that contribute to (*a*) the swelling of the polymeric matrix due to transport of the penetrating species into the porous system and (*b*) the initial dissolution and release of the incorporated drug.

The goal of this work was to investigate some of the factors affecting the overall release behavior, especially the importance of entrapped air in the porous structure. The model system chosen consisted of potassium chloride as the water-soluble drug and hydroxypropyl methylcellulose as the hydrophilic polymer. Some of the technological factors influencing the overall potassium chloride release profile in this system have been analyzed by Salomon *et al.* (9–11). Their studies revealed that the release deviates significantly from the traditional $t^{1/2}$ dependence called for by the Higuchi and Lapidus–Lordi models during the early stages of the experiments. Even improved mathematical models especially developed for this system (12) could not fully describe the release behavior. To investigate this physical phenomenon more thoroughly, the experimental procedure of Salomon *et al.* (9–11) was followed with improved time resolution.

EXPERIMENTAL

Materials—The materials used were potassium chloride[1] (water solubility, 332 mg/cm³ at 37°) and hydroxypropyl methylcellulose[2]. This polymer had the following characteristics according to the manufacturer:

[1] Ph. Helv./Ph. Eur. grade; Siegfried, Zofingen, Switzerland.
[2] Methocel K 15M Premium; Dow Chemical Co., Midland, MI 48640.

0022-3549/83/1000-1189$01.00/0

nonlinear trend in the male excretion data was apparent, reflected in the RMS deviation (1.162 mg of α-hydroxytriazolam/kg·day) which was nearly four times greater than that for the female data. A plausible nonlinear model of the male excretion data is one in which the quantity of α-hydroxytriazolam excreted approaches an asymptotic value with increasing doses of triazolam. An exponential function of the dose was adopted, $E = A[1 - e^{-B \cdot (\text{dose})}]$, where A and B are adjustable parameters. The best fit parameters for the male excretion data, estimated using NONLIN (6), were $A = 4.02 \pm 0.40$ mg of α-hydroxytriazolam/kg·day and $B = 0.038 \pm 0.010$ kg·day/mg; the associated RMS deviation was 0.70 mg of α-hydroxytriazolam/kg·day, a significantly better fit of the experimental data than that afforded by the one-parameter linear model ($F_{\text{statistic}} = 34.6$; $n = 22$).

In conclusion, triazolam absorption, as reflected by α-hydroxytriazolam urinary excretion data for female and male mice, increased with triazolam dose. The quantity of α-hydroxytriazolam excreted by female mice was proportional to the triazolam dose, while the male excretion data were adequately represented by a model which predicts that the quantity of α-hydroxytriazolam excreted approaches an asymptotic value with increasing doses of triazolam.

Mechanisms of Potassium Chloride Release from Compressed, Hydrophilic, Polymeric Matrices: Effect of Entrapped Air

R. W. KORSMEYER ‡, R. GURNY *x, E. DOELKER *, P. BURI *, and N. A. PEPPAS ‡

Received June 28, 1982, from the *School of Pharmacy, University of Geneva, CH-1211 Geneva 4, Switzerland and the ‡ School of Chemical Engineering, Purdue University, West Lafayette, IN 47907. Accepted for publication September 14, 1982.

Abstract □ The release of potassium chloride from hydroxypropyl methylcellulose matrices was investigated for tablets prepared with several different compression forces. It was determined that the release kinetics for these systems deviates significantly from the classical $t^{1/2}$ dependence. This behavior was attributed to air entrapped in the matrix during preparation. Removal of the air prior to release restored the traditional $t^{1/2}$ behavior.

Keyphrases □ Potassium chloride—release from hydroxypropyl methylcellulose matrices, effect of entrapped air, kinetics □ Matrices, hydroxypropyl methylcellulose—release of potassium chloride, effect of entrapped air, kinetics □ Kinetics—release of potassium chloride from hydroxypropyl methylcellulose matrices, effects of entrapped air

Compressed, hydrophilic, polymeric matrices provide a convenient method for achieving sustained release of highly water-soluble drugs (1, 2). Release profiles are usually analyzed using equations derived by T. Higuchi (3) and W. Higuchi (4) and adapted by Lapidus and Lordi (5, 6). However, such systems often exhibit complex kinetics (7, 8) that are poorly explained by these traditional models of drug release. Modeling efforts in this area may be assisted by better understanding of the physical factors that contribute to (*a*) the swelling of the polymeric matrix due to transport of the penetrating species into the porous system and (*b*) the initial dissolution and release of the incorporated drug.

The goal of this work was to investigate some of the factors affecting the overall release behavior, especially the importance of entrapped air in the porous structure. The model system chosen consisted of potassium chloride as the water-soluble drug and hydroxypropyl methylcellulose as the hydrophilic polymer. Some of the technological factors influencing the overall potassium chloride release profile in this system have been analyzed by Salomon *et al.* (9–11). Their studies revealed that the release deviates significantly from the traditional $t^{1/2}$ dependence called for by the Higuchi and Lapidus–Lordi models during the early stages of the experiments. Even improved mathematical models especially developed for this system (12) could not fully describe the release behavior. To investigate this physical phenomenon more thoroughly, the experimental procedure of Salomon *et al.* (9–11) was followed with improved time resolution.

[a] Average of three experiments (± *SD*).

number average molecular weight $\overline{M}_n$ = 120,000, intrinsic viscosity [η] = 11.0 dl/g, number average degree of polymerization $\overline{DP}_n$ = 650, viscosity of a 2% solution at 20° η = 150 poises, and degree of substitution 19–24% methoxy and 4–12% hydroxypropoxy (based on total weight of polymer). In addition, this resin is completely amorphous and remained so during these experiments, as verified by X-ray diffraction.

Diffusion Experiments—Equal amounts by weight of potassium chloride and hydroxypropyl methylcellulose of particle size 63–100 μm were combined using a tridimensional mixer[3]. A 500-mg portion of the resulting mixture was compressed with the desired force (5,10, 27, or 50 kN corresponding to pressure of 28, 56, 150, and 280 MPa, respectively) in a 15-mm acrylic die on a hydraulic press[4] equipped with flat-faced punches. The tablet was left within the die and one face was sealed with a plastic stopper. The assembly was then placed in 500 ml of distilled water at 37° as described previously (9, 11). The release of potassium chloride was followed by continuous monitoring of the conductivity[5] of the release medium. Tablets prepared in the same manner as those used in the release experiments were characterized using the method of Gupte (13) (see Table I).

Samples were also prepared at 28 and 280 MPa using the same procedure as before but removing the air entrapped in the tablets by a modification of the technique developed by Desai *et al.* (14). The tablet holder was placed in a filter flask which was sealed, placed in a 37° water bath, and evacuated to a pressure of 0.03–0.06 mm Hg. Distilled water (500 cm³) was aspired into the flask, stirring begun, and the contents circulated through the conductivity cell as above.

RESULTS AND DISCUSSION

The results of the release experiments are summarized in graphical form in Fig. 1, which represents the fractional release, M_t/M_∞, as a function of time. The most striking feature is the increase in release rate after 1.4–4.0 hr (depending on the pressure used). In addition, the release from tablets compressed at 280 MPa is significantly faster than the others, in the range of $M_t/M_\infty < 0.2$. For $M_t/M_\infty > 0.2$, the release rate from all tablets except those compressed at 28 MPa is quite similar.

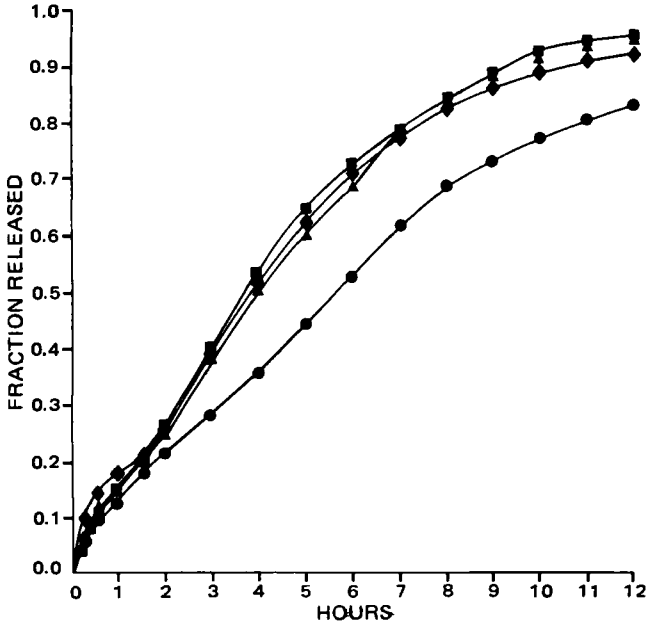

Figure 1—*Potassium chloride release profiles from tablets prepared at different pressures. Key: (●) 28 MPa; (■) 56 MPa; (▲) 150 MPa; (◆) 280 MPa.*

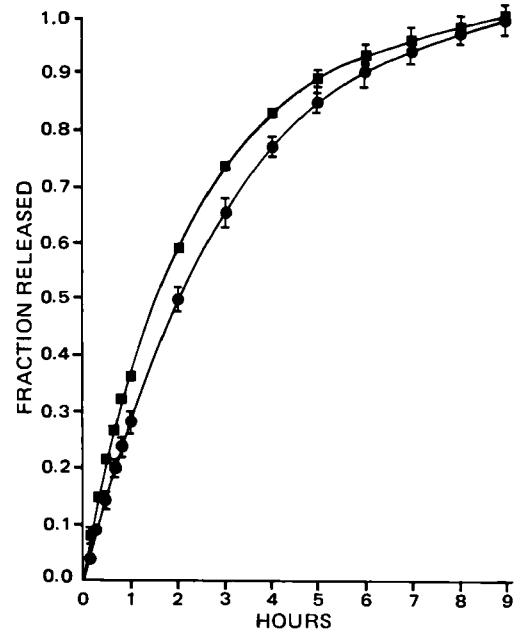

Figure 2—*Potassium chloride release profiles from evacuated tablets prepared at 28 MPa (●) and 280 MPa (■).*

In the systems studied, the release rate was found to vary inversely with tablet porosity and mean pore diameter. Since the opposite effect is normally expected, one must infer that release is not governed by the traditional porous-diffusion mechanism. One possible explanation is that air trapped within the tablets acts as a transport barrier. Consequently, as the initial porosity of the tablets increases, the initial air content increases leading to slower release of the drug.

To test this assumption, a new series of experiments using tablets prepared at the two extreme pressures was undertaken utilizing the modification of the technique developed by Desai *et al.* for polyethylene matrices (14) (Fig. 2). This technique effectively eliminated all observed anomalies in the release rate. Moreover, only a small difference was observed between the tablets prepared at 28 MPa and those prepared at 280 MPa. The release behavior could be fitted well to the equation:

$$\frac{M_t}{M_\infty} = a + bt^{1/2} \qquad \text{(Eq. 1)}$$

for values of $M_t/M_\infty \leq 0.6$.

When the experimental data were fitted to Eq. 1, the average values obtained for the coefficients *a* and *b* and the corresponding lag times were as shown in Table II. The fact that the values of the intercept, *a*, are not equal to zero could reasonably be attributed to the time lag associated with tablet swelling, although the physical manipulation of the equipment at the beginning of each experiment introduces uncertainty at these very short times.

Table II—Fitting of Release Data from Fig. 2 to a Square-Root of Time Release Behavior

Pressure, MPa	Intercept (*a*)	Slope (*b*), $hr^{-1/2}$	Time lag, hr	*r*
28	−0.181 ± 0.0009	0.476 ± 0.032	0.145	0.996–0.998
280	−0.127 ± 0.017	0.502 ± 0.014	0.064	0.998–0.999

Table III—Characteristic Time of Increase in Release Rate Due to Entrapped Air as a Function of Void Fraction of the Tablets

Pressure, MPa	Void Fraction	Characteristic Time, hr
28	0.385	3.5–4.0
56	0.275	1.9–2.5
150	0.178	1.7–1.8
280	0.166	1.4–1.5

Even though the values of the volume and porosity of these tablets are continuously changing during swelling and release, owing to the short time-scale of the experiment, the changes are not large and therefore one may obtain an approximate value for the effective solute diffusivity D' by use of an equation adapted by Lapidus and Lordi (6):

$$\frac{M_t}{M_\infty} = \frac{S}{M_\infty}\left[D'\epsilon C_s\left(\frac{2M_\infty}{V} - \epsilon C_s\right)\right]^{1/2} t^{1/2} \qquad \text{(Eq. 2)}$$

where S is the surface area available for release (1.767 cm^2), V is the volume of the tablet (0.477 cm^3 at 28 MPa and 0.362 cm^3 at 280 MPa), C_s is the solubility of the active agent (332 mg/cm^3), ϵ is the tablet porosity (0.17 at 280 MPa and 0.38 at 28 MPa), and D' is expressed as D/τ, where τ is the tortuosity of the matrix and D is the effective diffusivity of the drug. Using these values, D' could be calculated from the slope of the plot of M_t/M_∞ *versus* $t^{1/2}$ yielding $D' = 1.04 \times 10^{-5}$ cm^2/sec for systems prepared at 28 MPa and $D' = 1.83 \times 10^{-5}$ cm^2/sec for systems prepared at 280 MPa.

The unusual release behavior of compressed hydroxypropyl methylcellulose tablets is attributed to the entrapped air. The characteristic time at which the increase in release rate is observed can be roughly correlated with the initial tablet porosity (Table III), although the observed increase was sharp only for systems prepared at 150 and 280 MPa. The correlation of this characteristic time with tablet void volume may be interpreted as representing pore filling with gradual displacement of entrained air (see Fig. 3). It is observed that air continues to escape from the tablet throughout most of the drug release. After ~2 hr a nonflat moving front has been formed at the polymer–water interface (Fig. 3c). On complete release of the drug (Fig. 3d), the tablet is not at mechanical equilibrium, although swollen. The outermost portion of the tablet is transparent, but a large amount of air remains entrapped.

Consequently, the inflection in the release curves does not represent the point at which all the air has been displaced, but probably a point at which the pressure of the entrained air (which is compressed as water enters the tablet) equals the pressure of the incoming water. The air then escapes gradually through the pores of the tablet, aided by the softening of the polymer as it absorbs water.

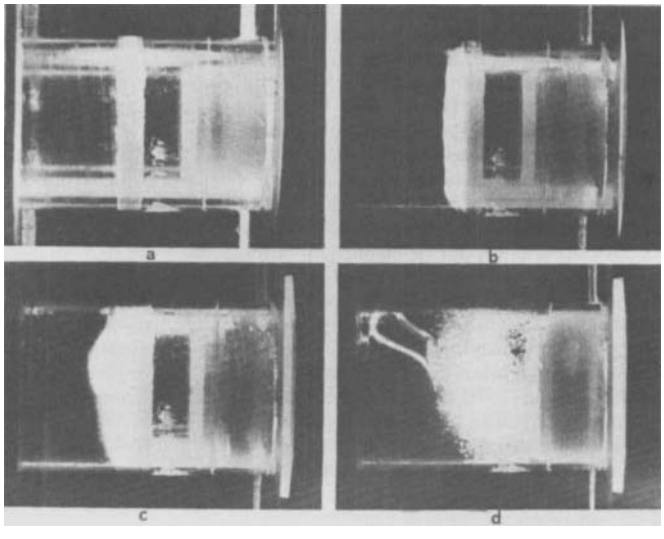

Figure 3—*Sequential swelling of potassium chloride–hydroxypropyl methylcellulose systems at* t = *0 (a),* t = *0.17 hr (b)* t = *2.50 hr (c), and* t = *24 hr [complete potassium chloride release (d)].*

Table IV—Fitting of Release Data from Fig. 1 to Eq. 3 for $M_t/M_\infty \leq 0.7$

Pressure, MPa	Intercept (a)	Slope (b), hr^{-1}	r
28	0.034	0.083	0.998
56	0.019	0.125	0.999
150	0.030	0.113	0.997
280	0.045	0.118	0.994

In contrast, when the tablets are evacuated prior to the introduction of water, the water is forced into the pores rather quickly by atmospheric pressure, as calculated by standard equations for flow in porous media (15). This results in the introduction of a saturated aqueous phase throughout the tablet at the beginning of the experiment. Release then proceeds by a purely diffusive mechanism. An additional simplification effected by this treatment in the case of hydroxypropyl methylcellulose is that potassium chloride release occurs quickly relative to the swelling so that volume changes of the tablet are less important.

It is interesting to observe that the effect of the entrained air is to improve the release profile as compared with traditional $t^{1/2}$ release. For example, although the release profiles are obviously not truly linear with time, the release curve may be fitted to:

$$\frac{M_t}{M_\infty} = a + bt \qquad \text{(Eq. 3)}$$

with $r > 0.99$ up to $M_t/M_\infty = 0.7$, as shown in Table IV. These systems therefore represent an approximation to zero-order release kinetics, although no physical significance should be given at this point to the values of the intercept and the slope reported.

We can conclude that air entrapped during preparation can have a significant effect on the release of drugs from hydrophilic matrices such as hydroxypropyl methylcellulose. This factor is therefore an important consideration in the design of *in vitro* release experiments.

Antihyperlipidemic Activity of Saccharin Analogues in Rodents

I. H. HALL ˣ, P. JOSÉE VOORSTAD, JAMES M. CHAPMAN, Jr., and GEORGE H. COCOLAS

Received January 28, 1982, from the *Division of Medicinal Chemistry, School of Pharmacy, University of North Carolina, Chapel Hill, NC 27514.* Accepted for publication August 27, 1982.

Abstract □ Saccharin analogues were observed to be potent antihyperlipidemic agents at 20 mg/kg/day in rodents, significantly reducing both serum cholesterol and triglyceride levels in both normal and atherogenic mice. The saccharin analogues suppressed *in vitro* and *in vivo* liver enzymatic activity of acetyl-CoA synthetase, citrate lyase, and mitochondrial citrate exchange leading to a reduction of available cytoplasmic acetyl-CoA, which is required for the synthesis of cholesterol and fatty acids. Liver acetyl-CoA carboxylase, phosphatidate phosphohydralase, and glycerol-3-phosphate acyl transferase activities were markedly reduced by the saccharin analogues. Suppression of these enzymes would lead to a reduction of triglyceride synthesis. The saccharin analogues accelerated bile excretion of cholesterol metabolites and increased the fecal excretion of the cholesterol, triglycerides, neutral lipids, and phospholipids. The liver and plasma lipoprotein lipid content (including cholesterol, triglycerides, and neutral lipids) was markedly reduced by the saccharin analogues, whereas phospholipid content was elevated. The reduction of lipid content of serum chylomicron, very low-density, low-density, and high-density lipoprotein fractions by the saccharin analogues indicates that these agents may be useful in controlling hyperlipidemic diseases where specific lipoprotein fractions are elevated.

Keyphrases □ Saccharin—analogues, antihyperlipidemic activity, cholesterol and triglyceride reduction □ Antihyperlipidemic agents—saccharin analogues, cholesterol and triglyceride reduction □ Cholesterol—antihyperlipidemic effect of saccharin analogues □ Triglycerides—antihyperlipidemic effect of saccharin analogues

The antihyperlipidemic activity of saccharin and 1-*N*-(*o*-benzosulfimido)butan-3-one has been reported previously (1) in mice at 20 mg/kg/day ip. Saccharin afforded a 33% reduction in serum cholesterol after 16 days and a 49% reduction in serum triglyceride levels after 14 days, whereas 1-*N*-(*o*-benzosulfimido)butan-3-one resulted in a 38% reduction of serum cholesterol and a 49% reduction of serum triglyceride levels (1). Saccharin derivatives were examined for their hypolipidemic effects because of their structural similarity to phthalimide (2) and *N*-phenyl-bridged isoindoline ketones (3), which have been reported previously to have hypolipidemic action in rodents. The purpose of this study was to examine the antihyperlipidemic activity of saccharin and its derivatives in detail, as well as their mode of action on cellular lipid metabolism in rodents.

EXPERIMENTAL

Source of Compounds—Saccharin was purchased commercially[1]. The syntheses and chemical characterizations of 1-*N*-(*o*-benzosulfimido)butan-3-one(1) and 3-*N*-(*o*-benzosulfimido)propionic acid have been reported previously (2).

Antihyperlipidemic Screens in Normal Rodents—Compounds were suspended in 1% carboxymethylcellulose–water and administered to male CF_1 mice (~25 g in weight) intraperitoneally or Holtzman male rats (~200 g in weight) orally by an intubation needle for 16 days. On days 9 and 16, blood was obtained by tail vein bleeding, and the serum was separated by centrifugation for 3 min. The serum cholesterol levels were determined by a modification of the Liebermann–Burchard reaction (4). Serum was also collected on day 14, and the triglyceride content was determined using a commercial kit[2].

Testing in Atherogenic Mice—Male CF_1 mice (~25 g) were placed on a commercial diet[3] that contained butterfat (400 g), cellulose[4] (60 g), cholesterol (53 g), choline dihydrogen citrate (4 g), salt mixture oil[5] (40 g), sodium cholate (20 g), sucrose (223 g), vitamin-free casein (200 g), and total vitamin supplement for a 2-week period. After the cholesterol and triglyceride levels were assayed and observed to be elevated, the mice were administered test drugs at 20 mg/kg/day for an additional 2-week period. Serum cholesterol and triglyceride levels were measured after 14 days of drug administration.

Animal Weights and Food Intake—Periodic animal weights were obtained during the experiments and expressed as a percentage of the animal's weight on day 0. After dosing for 16 days with test drugs, selected organs were excised, trimmed of fat, and weighed. The organ weights were expressed as a percentage of the total body weight of the animal. The average food intake[6] in g/rat/day was determined over the 16-day dosing period.

Toxicity Studies—The acute toxicity (LD_{50} value) (5) was determined in male CF_1 mice by administering test drugs intraperitoneally from 100 mg to 2 g/kg as a single dose. The number of deaths recorded in the group over 7 days was determined for each dosage.

Enzymatic Studies—*In vitro* enzymatic studies were determined using 10% homogenates of male CF_1 mouse liver with 2.5 μmoles of the test drugs and male Holtzman rat livers with 0.100–10 m*M* concentration of the test drugs. *In vivo* enzymatic studies were determined using 10% homogenates of liver from male CF_1 mice obtained after administering the agents for 16 days at a dose of 10–60 mg/kg/day. The liver homogenates for both *in vitro* and *in vivo* studies were prepared in 0.25 *M* sucrose and 0.001 *M* EDTA[(ethylenedinitrilo)tetraacetic acid].

Acetyl-CoA synthetase (6) and adenosine triphosphate-dependent citrate lyase (7) activities were determined spectrophotometrically at 540 nm as the hydroxamate of acetyl-CoA formed after 30 min at 37°. Mitochondrial citrate exchange was determined by the procedure of Robinson *et al.* (8, 9) using sodium [^{14}C]bicarbonate (41 mCi/mmole) incorporated into mitochondrial [^{14}C]citrate after isolating the mitochondria (9000×*g* for 10 min) from the homogenates. The exchange of the [^{14}C]citrate was determined after incubating the mitochondrial fraction, which was loaded with labeled citrate, and the test drugs for 10 min. Then the radioactivity was measured in the mitochondrial and supernatant fractions in scintillation fluid[7] and expressed as a percentage. Cholesterol side-chain oxidation was determined by the method of Kritchevsky and Tepper (10) using [26-^{14}C]cholesterol (50 mCi/mmole) and mitochondria isolated from rat liver homogenates. After an 18-hr incubation at 37° with the test drugs, the generated $^{14}CO_2$ was trapped in the center well in [2-[2-(*p*-1,1,3,3-tetramethylbutylcresoxy)ethoxy]-ethyl]dimethylbenzylammonium hydroxide[8] and counted[7]. 3-Hydroxy-3-methylglutaryl-CoA reductase (HMG-CoA reductase) was measured using [1-^{14}C]acetate (56 Ci/mmole) using a postmitochondrial supernatant (9000×*g* for 20 min) incubated for 60 min at 37° (11). The digitonide derivative of cholesterol was isolated and counted (12). Acetyl CoA carboxylase activity was measured by the method of Greenspan and Lowenstein (13). Initially, the enzyme had to be polymerized for 30 min at 37°, and then the assay mixture containing sodium [^{14}C]bicarbonate (41.0 mCi/mmole) was added and incubated for 30 min at 37° with the test drugs. Fatty acid synthetase activity was determined by the method

[a] Expressed as percentage of control (mean ± *SD*); $n = 6$. [b] $p \leq 0.001$ [c] $p \leq 0.005$. [d] 73 ± 7 mg%. [e] 78 ± 6 mg%. [f] 110 ± 9 mg%. [g] 118 ± 6 mg%. [h] 122 ± 7 mg%. [i] 137 ± 8 mg%.

of Brady *et al.* (14) using [2-^{14}C]malonyl-CoA (37.5 mCi/mmole) incorporated into newly synthesized fatty acids, which were extracted with ether and counted. Acyl transferase activity was determined with L-[2-^{3}H]glycerol-3-phosphate (7.1 Ci/mmole) and the microsomal fraction of the liver homogenates (15). The reaction was terminated after 10 min, and the lipids were extracted with chloroform–methanol (1:2) containing 1% concentrated HCl and counted. Phosphatidate phosphohydralase activity was measured as the inorganic phosphate released after 30 min from phosphatidic acid by the method of Mavis *et al.* (16). The released inorganic phosphate after development with ascorbic acid and ammonium molybdate was determined at 820 nm.

The *in vitro* oxidative phosphorylation process in male CF_1 mouse liver was also examined with an oxygen electrode[9] connected to an oxygraph[10] at 37°. The reaction vessel typically contained 55 μmoles of sucrose, 22 μmoles of monobasic potassium phosphate, 22 μmoles of potassium chloride, 90 μmoles of succinate or 60 μmoles of α-ketoglutarate as substrate, 2 μmoles of adenosine triphosphate, and 2.5 μmoles of the test compounds in a total volume of 1.8 ml. After the basal metabolic (state 4) rate was obtained, 0.257 μmole of adenosine diphosphate was added to obtain the adenosine diphosphate-stimulated respiration (state 3) rate (17). The rates were calculated as μl of oxygen consumed/mg of liver/hr.

Liver, Small Intestine, and Fecal Lipid Extraction—In male CF_1 mice that had been administered test drugs for 16 days, the liver, small intestine, and fecal materials (24-hr collection) were removed and a 10% homogenate in 0.25 *M* sucrose and 0.001 *M* EDTA was prepared. An aliquot (2 ml) of the homogenate was extracted by the methods of Floch *et al.* (18) and Bligh and Dyer (19) and the number of milligrams of lipid weighed. The lipid was taken up in methylene chloride, and the cholesterol level (4), triglyceride levels[11], neutral lipid content (20), and phospholipid content (21) were determined.

[^{14}C]Cholesterol Distribution in Mice and Rats—Male CF_1 mice (~25 g) were administered test agents intraperitoneally for 14 days and rats were administered test agents orally. On day 13, 10 μCi of [4-^{14}C]-cholesterol (52.5 mCi/mmole) was administered intraperitoneally in mice and orally in rats, and feces were collected for 0–6, 6–12, and 12–24 hr postadministration. Twenty-four hours after cholesterol administration, the major organs were excised and samples of blood, chyme, and urine were obtained. Homogenates (10%) were prepared of the tissues which were combusted[12] and counted. Some tissue samples were plated on filter paper[13], dried, and digested for 24 hr in base[8] at 40° and counted. Results were expressed as dpm/mg of wet tissue and dpm/mg of total organ.

Cholesterol Absorption Study—Male Holtzman rats (~400 g) were administered test drug intraperitoneally for 14 days at 20 mg/kg/day. On day 13, 10 μCi of [1,2-^{3}H]cholesterol (40.7 Ci/mmole) was administered to the rat orally. Twenty-four hours later, the blood was collected and the serum was separated by centrifugation (22). Both the serum and the precipitate were counted.

Bile Cannulation Study—Male Holtzman rats (~400 g) were treated with test drugs at 20 mg/kg/day orally for 14 days. The rats were anesthetized with chlorpromazine[14] (25 mg/kg) followed after 30 min by pentobarbital[15] (22 mg/kg ip). The duodenum section of the small intestine was isolated and ligatures were placed around the pyloric sphincter and at a site distally approximately one-third of the way down the duodenum. Sterile isotonic saline was injected into the sectioned off duodenum segment. The saline expanded the duodenum and the common bile duct. After the bile duct was identified, a loose ligature was placed around the duct, an incision was made, the plastic tubing[16] was introduced into the duct. Once past the ligature, the tubing was tied in place and the ligatures around the duodenum were removed. When bile was freely moving down the cannulated tube, [1,2-^{3}H]cholesterol (40.7 Ci/mmole) was injected intravenously into the rats. The bile was collected over the next 6 hr and measured (in ml). Aliquots were counted as well as analyzed for cholesterol content (4).

Plasma Lipoprotein Fractions—Male Holtzman rats (~400 g) were administered test drugs at 20 mg/kg/day for 14 days. On day 14, blood was collected from the abdominal aorta. Serum was separated from whole blood by centrifugation at 3500 rpm. Aliquots (3 ml) were separated by density gradient ultracentrifugation according to the methods of Hatch and Lees (23) and Havel *et al.* (24) into the chylomicrons, very low-density lipoproteins, high-density lipoproteins, and low-density lipoproteins. Each of the fractions was analyzed for cholesterol (4), triglyceride[11], neutral lipids (20), phospholipids (21), and protein levels (25).

RESULTS

Saccharin, 1-*N*-(*o*-benzosulfimido)butan-3-one, and 3-*N*-(*o*-benzosulfimido)propionic acid markedly reduced the serum lipid levels in normal rodents after intraperitoneal administration. In CF_1 mice, saccharin afforded a 38% reduction of serum cholesterol after 16 days of dosing at the 60-mg/kg dose (Table I). In the triglyceride screen in mice, the 10- and 20-mg/kg doses resulted in a reduction of 53 and 52%, respectively. Saccharin was also active as a hypolipidemic agent orally in rats at 20 mg/kg, suppressing serum cholesterol levels 44% and serum triglyceride levels 45%. 3-*N*-(*o*-Benzosulfimido)propionic acid was active in the mouse screen. The maximum suppression of serum cholesterol levels in mice was at 20 mg/kg/day, with 44% reduction. In the triglyceride screen, the 20-, 40-, and 60-mg/kg/day doses caused >40% reduction. 3-*N*-(*o*-Benzosulfimido)propionic acid was active orally in the rat. The serum cholesterol levels were suppressed 37% at 20 mg/kg/day in the rat, while triglyceride levels were suppressed 52%. 1-*N*-(*o*-Benzosulfimido)-butan-3-one in the mouse screen reduced serum cholesterol 38% and triglyceride 49%, whereas in the rat, serum cholesterol was reduced 44% and triglyceride level was reduced 35%. In mice that had been rendered atherogenic by a high lipid diet, after 2 weeks of administration it can be observed that saccharin and the propionic analogue suppressed the induced cholesterol levels by >170% resulting in serum cholesterol only slightly above normal levels (Table II). In the triglyceride screen, levels

[o] 11.31 ± 0.67 μl of oxygen consumed/hr/mg of tissue.

were reduced to normal levels by saccharin and 12% below normal (control) levels by the propionic acid derivative.

Saccharin and the propionic acid derivative did not affect the daily food intake over the 16-day dosing period, nor was the increase in body weight significantly different from the control rats (Table III). The acute toxicity studies demonstrated that the LD_{50} values in mice as a single intraperitoneal injection exceeded 2 g/kg which was the limit of solubility of the agents in carboxymethylcellulose. *In vitro* enzymatic studies of liver from CF_1 mice at 2.5 μmoles of the test agents, demonstrated that mitochondrial [^{14}C]citrate exchange was inhibited markedly by all three agents: 93% by saccharin and the butanone derivative and 80% by the propionic acid derivative (Table IV). Acetyl-CoA synthetase activity was suppressed 26–47% by these agents. Saccharin suppressed citrate lyase activity 35%, and the butanone derivatives suppressed citrate lyase activity 53%. HMG-CoA reductase activity was inhibited 29% by saccharin, but was essentially unaffected by the other two compounds. Cholesterol side-chain oxidation was inhibited 28% by the butanone derivative and 30% by the propionic analogue, but was unaffected by saccharin. Saccharin was more active and caused a 91% reduction of acetyl-CoA carboxylase activity; butanone caused 38% reduction, whereas 3-*N*-(*o*-benzsulfimido)propionic acid caused only 57% reduction. Fatty acid synthetase activity was not affected by any of the saccharin agents. Phosphatidate phosphohydralase activity was reduced 39–51%, and acyl transferase activity was reduced 75–92% by these test agents.

The saccharin agents suppressed basal respiration (state 4) rates. When succinate was used as substrate, saccharin derivatives reduced basal respiration 22–36%. When α-ketoglutarate was used as substrate, a reduction of 18–31% in basal respiration occurred. For the adenosine diphosphate-stimulated respiration (state 3) rate using succinate as substrate, a reduction of 34–37% was observed; with α-ketoglutarate substrate, a reduction of 20–39% was noted.

ID_{50} values obtained for *in vitro* enzymatic studies on rat liver ho-

mogenate were calculated from a semilogarithmic plot. In the acetyl-CoA synthetase assay, saccharin afforded an $ID_{50} \simeq 6.61$ m*M*. For the acetyl-CoA carboxylase assay, an $ID_{50} \simeq 1.26$ m*M* was obtained for saccharin, and an $ID_{50} \simeq 1.36$ m*M* was obtained for the propionic acid derivative. For the phosphatidate phosphohydralase assay, saccharin afforded an $ID_{50} \simeq 3.56$ m*M* and the propionic acid derivative an $ID_{50} \simeq 1.68$ m*M*. For the acyl transferase assay, saccharin gave an ID_{50} value of 3.26 m*M* and the propionic analogue gave a value of 1.93 m*M*.

In vivo studies on the enzymatic activities of liver from mice treated with test agents for 16 days showed that saccharin at doses from 10 to 60 mg/kg suppressed acetyl-CoA synthetase activity ~25% (Table V). *In vivo* HMG-CoA reductase activity was suppressed 23–24% at 20 and 40 mg/kg/day. Acetyl-CoA carboxylase activity was suppressed maximally at the lower doses; *i.e.*, 10 and 20 mg/kg/day afforded a 50–56% reduction. Fatty acid synthetase activity was not affected by *in vivo* administration of the drugs. Phosphatidate phosphohydralase activity was reduced 70% by saccharin at 10 mg/kg/day and 55% at 20 mg/kg/day. Liver lipids were reduced 53–39% by *in vivo* administration of 10–60 mg/kg/day of saccharin. 3-*N*-(*o*-Benzosulfimido)propionic acid *in vivo* administration resulted in a dose-related reduction of acetyl-CoA synthetase activity, with 60 mg/kg/day causing the maximum inhibition, *i.e.*, 36%. HMG-Co-A reductase activity was reduced 25 and 28% at 20 and 60 mg/kg/day, respectively. The propionic acid derivative caused marked reduction of acetyl-CoA carboxylase activity, with 20 mg/kg/day resulting in the maximum inhibition of 55%. Fatty acid synthetase activity was not affected by the propionic acid analogue. Phosphatidate phosphohydralase

activity was reduced 37 and 27% at 10 and 20 mg/kg/day, respectively.

Liver lipids were reduced by the propionic acid derivative, with doses >20 mg/kg/day causing at least 50% reduction. The liver cholesterol and neutral lipids, including triglyceride levels, were reduced by saccharin and the propionic acid derivative (Table VI). Saccharin at 10 mg/kg reduced liver cholesterol levels 66% and at 20 mg/kg caused 45% reduction. Liver neutral lipid levels at 20–40 mg/kg were reduced >80% by saccharin. Liver triglyceride levels were reduced maximally at 20 mg/kg of saccharin, resulting in 72% reduction. Liver phospholipid levels were elevated significantly by saccharin at 40 and 60 mg/kg/day. The propionic acid analogue at all doses employed caused >40% reduction of liver cholesterol content. Liver neutral lipids were reduced 50% at 20 mg/kg/day by the propionic acid derivative, whereas liver triglyceride levels were reduced 51% at 40 mg/kg/day. Liver phospholipid levels were elevated at the lower doses (*i.e.*, 10 and 20 mg/kg/day) by the propionic acid analogue. Extracted lipids from the small intestine of mice treated for 16 days with saccharin at 20 mg/kg/day showed a reduction of triglyceride, but an elevation of cholesterol and neutral lipids. The phospholipid content was essentially not altered in the small intestine tissue.

Table X—Effect of Saccharin on Bile Secretion and Cholesterol Absorption in Rats After Administration of Saccharin for 15 Days[a]

	Bile Secretion Over 6 Hr		
	Bile flow, ml/hr	Total cpm for 6 hr	Cholesterol Content, mg%
Control (1% carboxymethylcellulose)	0.560 ± 0.042	1016 ± 81	111 ± 8
Saccharin (20 mg/kg/day)	0.675 ± 0.036	1858 ± 129[c]	194 ± 10[c]

	[^{3}H]Cholesterol Absorption 24 Hr After Administration	
	Plasma dpm[b]	Percent of Control
Control (1% carboxymethylcellulose)	14280 ± 385	100 ± 5
Saccharin (20 mg/kg/day)	9568 ± 463[c]	67 ± 5[c]

[a] Mean ± *SD*; $n = 6$. [b] Plasma volume assumed to be 17 ml for rats. [c] $p \leq 0.001$.

Examination of the lipid content of the fecal material (Table VII) excreted after administration of saccharin at 20 mg/kg/day indicated that the amount of lipid per gram of fecal material as well as cholesterol, triglyceride, and phospholipid contents were elevated in 0 to 6-, 6 to 12-, and 12 to 24-hr fecal collections. The fecal triglyceride content was markedly increased in the 12 to 24-hr sample. The distribution study in mice with [^{3}H]cholesterol (Table VIII) indicated that the cholesterol in bile was elevated 5.5 to 25.92% of the total recovered cholesterol content in the 0 to 6-hr fecal sample. The excretion of cholesterol in the feces tended to equilibrate over the 24-hr period so that the control mice excreted 65.5% of the cholesterol or bile acids in 24 hr, whereas the saccharin-treated mice excreted 71.6% of the labeled cholesterol or bile acids. From Table VIII, it can also be seen that after administration of saccharin, there was less accumulation of radiolabeled cholesterol in the major organs (brain, lung, heart, liver, kidney, stomach, and large intestine) compared with the control. Increases in labeled cholesterol were observed in the spleen and small intestines. The distribution of cholesterol in rats after 14 days of saccharin administration, again showed that there was no accumulation of cholesterol in the major organs (Table IX). Higher concentrations of cholesterol were found in the intestine and chyme after oral administration of the labeled cholesterol compared with control values.

The cannulation studies (Table X) demonstrate that after saccharin administration, there is an increase in bile flow from 0.560 to 0.675 ml/hr with an increase in cholesterol content, *i.e.*, 82% in dpm and 75% increase in mg%. After administering saccharin for 14 days to rats, it can be observed that there was a 33% reduction of cholesterol absorption from the gut over a 24-hr period.

The lipoprotein fractions of rat blood (Table XI) collected after a 2-week administration of saccharin demonstrated that cholesterol, neutral lipid, and triglyceride contents were reduced in the chylomicrons and very low-density, low-density, and high-density lipoprotein fractions. The phospholipid content of the individual fractions was not reduced significantly in all fractions; in fact, the high-density lipoprotein fraction showed a 148% increase in phospholipid content. The protein content of all fractions was reduced; particularly significant were the chylomicron, very low-density, and high-density lipoprotein fractions.

Data are expressed in the Tables I–XI as percent of control ± the standard deviation. The probable significant level (p) between each test group and the control group was determined by the Student's t test.

DISCUSSION

Saccharin, 1-*N*-(*o*-benzosulfimido)butan-3-one, and 3-*N*-(*o*-benzosulfimido)propionic acid were demonstrated to be very potent antihyperlipidemic agents in rodents at 20 mg/kg/day. The dosage required to induce reductions of plasma lipids was low compared with clofibrate

Table XI—Effect of Saccharin on Lipoprotein Fractions of Blood from Holtzman Rats After 14 Days of Dosing [a]

Compound	Cholesterol	Neutral Lipids	Triglyceride	Phospholipids	Protein
			Chylomicrons

(100–200 mg/kg), which induces only marginal changes (15–20%) in serum and liver cholesterol and total lipid levels (26). The dose required for antihyperlipidemic activity of the saccharin analogues was in a safe therapeutic range compared with the observed LD_{50} values. The saccharin analogues were observed to be equally effective in rats and mice by either the oral or intraperitoneal administration routes. The agents were markedly effective in atherogenic mice in lowering the blood lipids, which approached normal levels after 2 weeks of drug administration.

The saccharin analogue did not bring about this reduction of lipids due to suppression of appetite in rats. Rather, saccharin analogues suppressed key enzymes in the early synthesis of cholesterol and fatty acids and in the synthesis of triglycerides. The enzymes include acetyl-CoA synthetase, citrate lyase, and mitochondrial citrate exchange. All of the enzymes play a role in synthesizing cytoplasmic acetyl-CoA, an intermediate precursor in cholesterol and fatty acid syntheses. The inhibition of these enzymes appeared to be related more with the suppression of serum cholesterol levels. The inhibition of mitochondrial citrate exchange by the saccharin analogues is a key regulatory site for the conversion of excess carbohydrates in the diet to lipids for storage. The inhibition of the acetyl-CoA carboxylase enzyme by saccharin analogues reduces the available fatty acids for triglyceride and cholesterol ester syntheses. The suppression of the acyl transferase and phosphatidate phosphohydralase enzymes correlates with the reduction of serum triglyceride levels, since the former enzyme is responsible for the addition of fatty acid to glycerol-3-phosphate for *de novo* triglyceride synthesis and the latter enzyme allows the synthesis of triglycerides from phospholipids. The same enzymes were inhibited in both rat and mice livers. Furthermore, the same enzymes were inhibited *in vivo* after 16 days of dosing with the saccharin analogues in mice. The ID_{50} estimates obtained from the rat liver enzyme assay are realistic values considering the dose required in the *in vivo* hydrolipidemic screen.

Clofibrate has been shown to accelerate basal respiration (state 4) and to inhibit adenosine diphosphate-stimulated respiration, thus uncoupling oxidative phosphorylation and reducing available energy for synthetic process in the cell (17). This may be due to the detergent-type effect of clofibrate. The saccharin analogues did not uncouple oxidative phosphorylation. They did reduce both states 3 and 4 respiration, interfering with the availability of adenosine triphosphate for enzymatic reaction, which requires energy.

It is interesting to note that the lipids being removed from the plasma compartment are not deposited in the major organs. Clearly the cholesterol, neutral lipids, and triglyceride levels are being reduced in the liver; however, the phospholipid content is elevated, probably indicative of inhibition of phosphatidate phosphohydralase activity by the saccharin analogues. In the treated animal, there was no indication of major changes in the body weight or major organ weights after administering the agents for 16 days. Rather, the cholesterol or bile acids were excreted in the bile at a fast rate and were cleared in the feces at an early time segment. Saccharin did decrease cholesterol absorption from the gut, which may explain the reduction of cholesterol in the tissues and the increase in the small intestine and feces.

Human chylomicrons and very low-density lipoproteins contain a high concentration of triglycerides. The low- and high-density lipoprotein fractions contain high concentrations of cholesterol ester and phospholipids. The saccharin analogues in the future may be helpful in Type I hyperlipidemic disease which is a state of hyperchylomicronemia. Types IIa, IIb, IV, and V hyperlipidemic states have increased levels of either low-density or very low-density lipoproteins, or both. Saccharin analogues were shown to suppress both of these lipoprotein fractions.

It would appear that saccharin analogues are more potent antihyperlipidemic agents in rodents than many of the current agents on the market today. A relatively low dose of the analogues was required to observe the lipid-lowering effect. It has been reported previously (1) that no deleterious side effects were observed in the rodent after short-term administration of these agents.

Photostability of Solid-State Ubidecarenone at Ordinary and Elevated Temperatures under Exaggerated UV Irradiation

YOSHIHISA MATSUDA ˣ **and REIKO MASAHARA**

Received June 15, 1982, from the *Kobe Women's College of Pharmacy, Higashinada, Kobe 658, Japan.* Accepted for publication September 1, 1982.

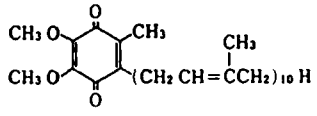
Abstract □ The photostability of ubidecarenone was investigated. Two irradiation apparatus, a grating monochromator and a high-pressure mercury vapor lamp, were employed at ordinary and elevated temperatures. Both physicochemical and chemical stabilities were significantly affected by irradiation wavelength, with UV light causing the greatest changes. The degree of degradation was a function of the light absorption properties of the substrate and markedly increased when the absorption became >30%. The photolytic degradation followed apparent first-order kinetics at all wavelengths and was promoted with temperature elevation. The Arrhenius plot gave an activation energy in the solid state different from that in the liquid state. These activation energies linearly decreased with increasing intensity of UV light.

Keyphrases □ Ubidecarenone—photostability, ordinary and elevated temperatures, exaggerated UV irradiation, activation energies □ Photostability—solid-state ubidecarenone, ordinary and elevated temperatures, exaggerated UV irradiation, activation energies □ Degradation—ubidecarenone photostability, ordinary and elevated temperatures, exaggerated UV irradiation

Preformulation study is of prime importance in the rational development of dosage forms for drug substances labile against various environmental factors. In designing a solid dosage form, it is necessary to know the inherent stability of the drug substance. There have been many reports concerning the behavior of organic compounds when subjected to heat or moisture. Photochemical mechanisms of solid-state reactions also have been reviewed (1), but not from the viewpoint of stabilization. Because of the complexity of photochemical reactions, there has been very little reported on the photostability of solid dosage forms (2–9).

Ubidecarenone [2,3-dimethoxy-5-methyl-6-decaprenylbenzoquinone (I)], a lipid-soluble benzoquinone derivative with a melting point of ~48° (10), is widely used in Japan for the treatment of angina. It is a yellow or orange crystalline powder; on exposure to light, I gradually decomposes and the color changes to dark yellow (10). The dosage forms commercially available are tablets, granules, and hard or soft gelatin capsules; these are photo-protected with a package system using light-resistant films.

The objective of the present investigation was to obtain useful informations on the behavior of I in the presence of light and heat under ordinary and accelerated storage conditions as the first step toward photostabilization.



I

Emphasis was placed on the photostability of the drug itself.

EXPERIMENTAL

Samples—Ubidecarenone, 170 mg, was accurately weighed and compressed into a flat-faced tablet 15 mm in diameter, using a compression-tension testing machine[1]. To keep the surface condition constant, a fixed compression force of 200 kg was used. Tablets were used for the quantification of appearance change by light irradiation. For the kinetic study 50 mg of ubidecarenone was dissolved in 50 ml of *n*-hexane–ether (1:1). Sixty microliters was placed on a quartz-glass plate (26 × 38 mm) and evaporated at room temperature. The oily sample was then cooled to 0–4° for 24 hr and allowed to crystallize. A 60-μg sample (<70 μm in diameter) was dispersed over the plate to illuminate all molecules as uniformly as possible. Samples were stored over silica gel in a desiccator in the dark until the irradiation test.

UV Irradiation—Two irradiation apparatus were employed. To investigate the effect of irradiation wavelength on the appearance change or photolytic degradation, a grating monochromator[2] with a 5-kW xenon lamp adjusted for 290–500 nm, a 5- to 21-nm intervals, was used (8). A band width of 5 nm was employed at all wavelengths. The amount of energy irradiated to each sample was calculated from the counts of the integrating photometer attached to the monochromator. Tablets or crystalline samples were attached to the front of the sample holder of the monochromator and exposed to UV rays. Elevation of temperature in the monochromator was prevented by a cooling water jacket surrounding the light source; the surface of samples was maintained at 25°.

In the accelerated irradiation test at ordinary and elevated temperature, the samples were placed in a thermostated jacket (Fig. 1). Water at the prescribed temperature was allowed to circulate through the jacket, and the temperature in the sample chamber was monitored with a thermocouple sensor. The jacket was placed in a fading tester[3] equipped with a 400-W mercury vapor lamp for color fading, as reported previously (11), and exposed to UV rays. The distance between the light source and the sample was 30 cm. The temperature in the fading tester was maintained below 27° by a constant-operating fan. To control the UV intensity irradiated to the sample, several optical filters[4] having various light transmission properties were attached to the front of the sample chamber.

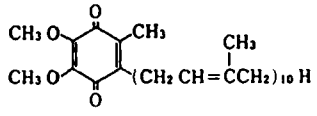
Ubidecarenone [2,3-dimethoxy-5-methyl-6-decaprenylbenzoquinone (I)], a lipid-soluble benzoquinone derivative with a melting point of ~48° (10), is widely used in Japan for the treatment of angina. It is a yellow or orange crystalline powder; on exposure to light, I gradually decomposes and the color changes to dark yellow (10). The dosage forms commercially available are tablets, granules, and hard or soft gelatin capsules; these are photo-protected with a package system using light-resistant films.

The objective of the present investigation was to obtain useful informations on the behavior of I in the presence of light and heat under ordinary and accelerated storage conditions as the first step toward photostabilization.



I

Emphasis was placed on the photostability of the drug itself.

EXPERIMENTAL

Samples—Ubidecarenone, 170 mg, was accurately weighed and compressed into a flat-faced tablet 15 mm in diameter, using a compression-tension testing machine[1]. To keep the surface condition constant, a fixed compression force of 200 kg was used. Tablets were used for the quantification of appearance change by light irradiation. For the kinetic study 50 mg of ubidecarenone was dissolved in 50 ml of *n*-hexane–ether (1:1). Sixty microliters was placed on a quartz-glass plate (26 × 38 mm) and evaporated at room temperature. The oily sample was then cooled to 0–4° for 24 hr and allowed to crystallize. A 60-μg sample (<70 μm in diameter) was dispersed over the plate to illuminate all molecules as uniformly as possible. Samples were stored over silica gel in a desiccator in the dark until the irradiation test.

UV Irradiation—Two irradiation apparatus were employed. To investigate the effect of irradiation wavelength on the appearance change or photolytic degradation, a grating monochromator[2] with a 5-kW xenon lamp adjusted for 290–500 nm, a 5- to 21-nm intervals, was used (8). A band width of 5 nm was employed at all wavelengths. The amount of energy irradiated to each sample was calculated from the counts of the integrating photometer attached to the monochromator. Tablets or crystalline samples were attached to the front of the sample holder of the monochromator and exposed to UV rays. Elevation of temperature in the monochromator was prevented by a cooling water jacket surrounding the light source; the surface of samples was maintained at 25°.

In the accelerated irradiation test at ordinary and elevated temperature, the samples were placed in a thermostated jacket (Fig. 1). Water at the prescribed temperature was allowed to circulate through the jacket, and the temperature in the sample chamber was monitored with a thermocouple sensor. The jacket was placed in a fading tester[3] equipped with a 400-W mercury vapor lamp for color fading, as reported previously (11), and exposed to UV rays. The distance between the light source and the sample was 30 cm. The temperature in the fading tester was maintained below 27° by a constant-operating fan. To control the UV intensity irradiated to the sample, several optical filters[4] having various light transmission properties were attached to the front of the sample chamber.

Table I—Irradiation Energies after 1 hr of Irradiation Through Various Glass Optical Filters

Filter	Irradiation Energy (300–400 nm), erg/cm^2
None	1.21×10^8
UV-25	1.02×10^8
UV-D25	9.97×10^7
UV-35	7.60×10^7
VY-42	2.09×10^5

The irradiation energies (300–400 nm) through these filters at the surface of a sample were measured with a UV intensity meter[5] (Table I). Samples were withdrawn from the monochromator or fading tester at designated time intervals for tristimulus colorimetry or high-performance liquid chromatographic (HPLC) analysis.

Colorimetric Measurements—To follow a quantitative change in surface color of the sample, a color and color difference meter[6] equipped with a halogen lamp as the light source was employed, and the surface color of the tablets in the L,a,b coordinate system was measured as reported previously (11). The Hunter's color difference ΔE (12) before and after irradiation was calculated to evaluate color darkening. After the measurement, samples were returned to the monochromator and irradiation was continued.

Absorption Measurements—At every irradiation, UV absorption spectra [semi-integral attenuance spectra (13)] of the sample powders in the gas phase were measured by a multipurpose recording spectrophotometer[7] with an end-on type photomultiplier. Air was used as the absorption control in accordance with the method described previously (5).

HPLC Analysis—A liquid chromatograph[8] equipped with a fixed-wavelength UV detector[9] was used for HPLC analysis. Ubidecarenone was quantified at 254 nm. The prepacked column[10] (30 cm × 3.9-mm i.d.) was operated at ambient temperature at a flow rate of 1.4 ml/min. The mobile phase consisted of a solvent system of n-hexane–ether (85:15). The internal standard solution of benzophenone was prepared at a concentration of 100 μg/ml. All solvents and reagents were HPLC and analytical grade, respectively, and were used as received.

After irradiation, samples on the plate were washed several times with ether, 30 μl of the internal standard solution was added, and the mixed solution was evaporated to dryness under vacuum. The residue was then dissolved in 300 μl of n-hexane–ether (1:1); 2 μl of this solution was injected onto the chromatograph with a 10-μl syringe by the on-flow technique. A typical chromatogram of the sample obtained after 15-min irradiation is shown in Fig. 2. The amount of ubidecarenone was the mean of three determinations.

RESULTS AND DISCUSSION

Color Darkening of the Tablet Surface—The coloration reaction of solid pharmaceutical preparations by light may be localized on the surface, differing from that of liquid preparations in which all drug molecules take part in the reaction. It is nevertheless possible to qualitatively estimate the photostability of the drug by the extent of coloration or color fading.

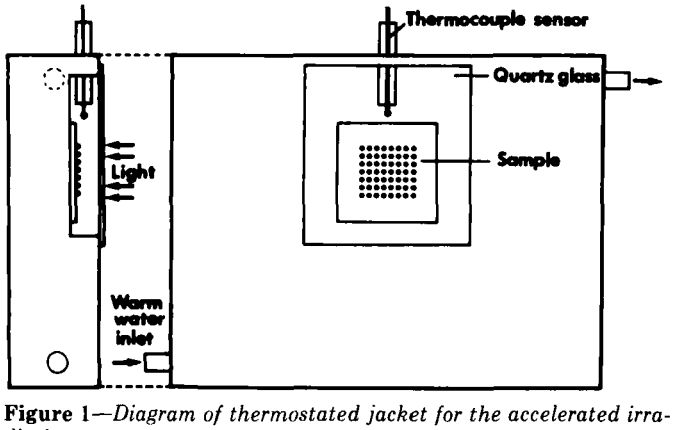

Figure 1—*Diagram of thermostated jacket for the accelerated irradiation test.*

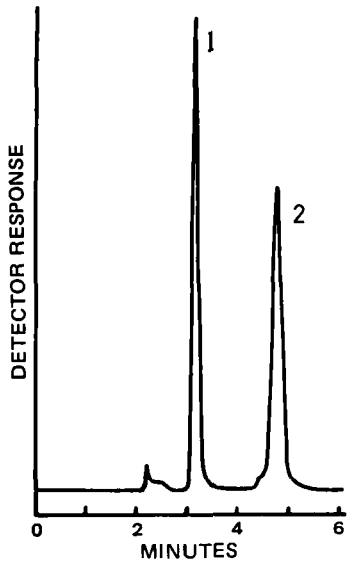

Figure 2—*Typical chromatogram of photodegraded ubidecarenone. Key: (1) benzophenone (internal standard); (2) ubidecarenone.*

Figure 3 shows the action spectrum for color darkening of a tablet surface irradiated under an intensity of 3.49×10^8 erg/cm^2. The color difference (ΔE) increased with decreasing irradiation wavelength and reached its maximum at ~350 nm. The color darkening was observed also in the visible region over 400 nm and resulted in a significant color difference even at ~450 nm. Above 480 nm, ΔE remained <2 NBS units, indicating that apparent color darkening did not occur in this wavelength region in view of the relationship between visual perception and color difference (14). Such behavior in coloration was strikingly different from the results obtained for sulfisomidine (8) and indomethacin (15), which were photostable against visible light. The photostability of ubidecarenone over a wide range of irradiation wavelength suggests that the selection of a desirable light source and the optimization of illumination conditions are necessary for studying the photoreaction of pharmaceuticals.

The process of these color changes was examined under irradiation with a mercury vapor lamp, and the change in ΔE against time was followed up to the maximum irradiation energy of 2.62×10^8 erg/cm^2 (after 120-min irradiation). For the kinetic interpretation of this process, the increase in ΔE against time may be expressed as (9):

$$\frac{d\Delta E}{dt} = k(\Delta E)^n \qquad \text{(Eq. 1)}$$

where t and k are irradiation time and the color-darkening rate constant, respectively, and n is constant. Integrating Eq. 1 under the initial condition ($\Delta E = 0$ at $t = 0$), we obtain:

$$\log \Delta E = \frac{1}{1-n} \log t + \frac{1}{1-n} \log [(1-n)k] \quad (n \neq 1) \qquad \text{(Eq. 2)}$$

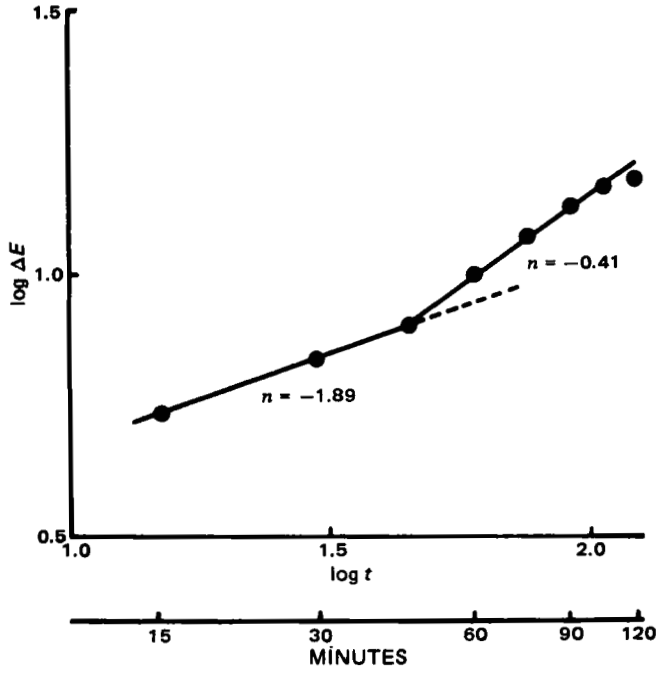

Figure 4—*Double-logarithmic plot for the color change process (cf. Eq. 2).*

Equation 2 indicates that a linear relationship with a slope of $1/(1 - n)$ should hold between ΔE and t on the double-logarithmic scale. The double-logarithmic plot of the color darkening process gave two excellent straight lines with different slopes (Fig. 4); the color darkening rate in the latter period was much higher than that in the earlier period of irradiation.

Physicochemical Change of Crystals—The results shown in Fig. 4 suggest that the mechanism of color darkening may undergo a change during the process of irradiation. The color darkening may be attributable to change in the surface condition of the tablet in addition to structural change of the drug molecules. Figure 5 shows photomicrographs of ubidecarenone crystals irradiated for various times. No change in appearance of the wrinkled surface was observed up to 30 min of irradiation, but after 50 min liquefaction of the surface layer of crystals began and gradually extended inward. After 90 min all crystals were liquefied to oily droplets. This may be due to the formation of a photoproduct with a lower melting point than the original substance. These physicochemical changes must affect the UV absorption properties of solid-state samples. Figure 6 shows the absorption spectra obtained under the same irradiation condition as Fig. 5. The spectrum of the original state before irradiation gave an absorption maximum and minimum at 278 and 236 nm, respectively. As

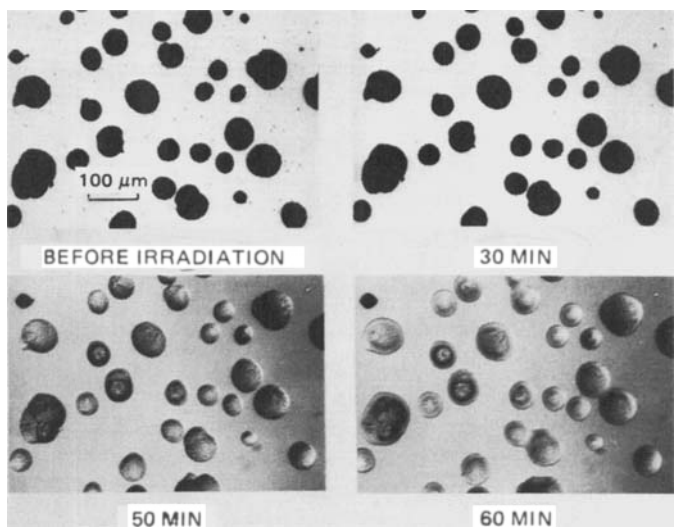

Figure 5—*Liquefaction of ubidecarenone crystals irradiated using a mercury vapor lamp.*

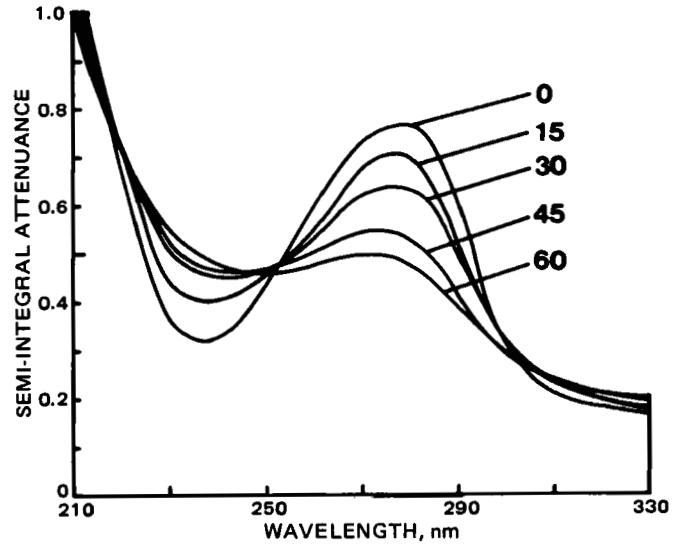

Figure 6—*Effect of irradiation time on the absorption spectrum of solid-state ubidecarenone. Numbers on the graph refer to irradiation time in minutes.*

the irradiation time proceeded, the absorption curve showed a flattening tendency, increase in the minimum and decrease in the maximum. The isosbestic points were confirmed at 254 and 300 nm up to 30 min of irradiation. After 45 min, however, these points were not obtained, and the absorption maximum and minimum shifted to shorter and longer wavelengths, respectively. The disappearance of isosbestic points after 45 min was closely related to the alteration in color-darkening rate (Fig. 4) and the beginning of liquefaction (Fig. 5). The presence and absence of isosbestic points suggest occurrence of a photochemical reaction on the crystal surface.

Photolytic Degradation at Various Irradiation Wavelengths—The photolytic degradation is also believed to be affected by irradiation wavelength. Figure 7 shows the semilogarithmic plot of percent remaining ubidecarenone against irradiation energy at several representative wavelengths. Good linear relationships existed between both parameters at every wavelength, indicating that the photolytic degradation followed apparent first-order kinetics. The irradiation energy was directly proportional to time. Even under the same irradiation energy, the degree

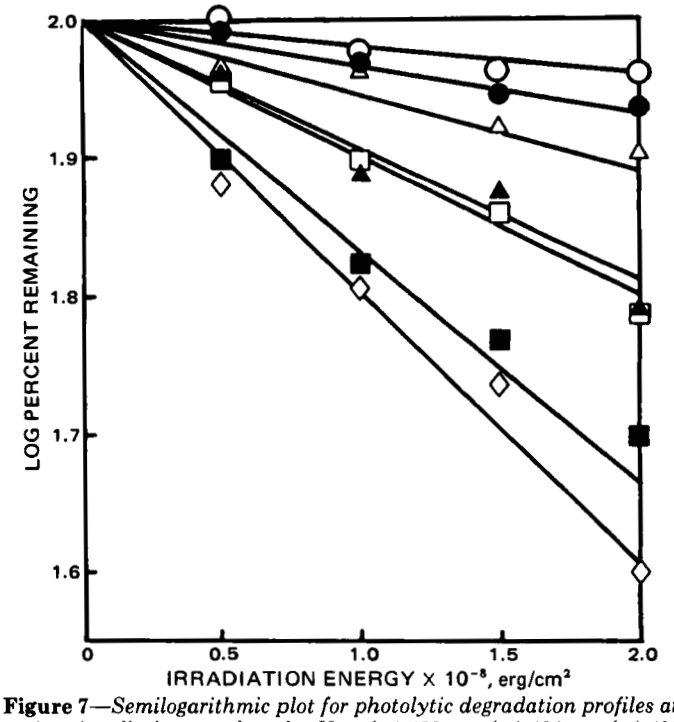

Figure 7—*Semilogarithmic plot for photolytic degradation profiles at various irradiation wavelengths. Key: (○) 480 nm; (●) 464 nm; (△) 426 nm; (▲) 400 nm; (□) 373 nm; (■) 347 nm; (◇) 290 nm.*

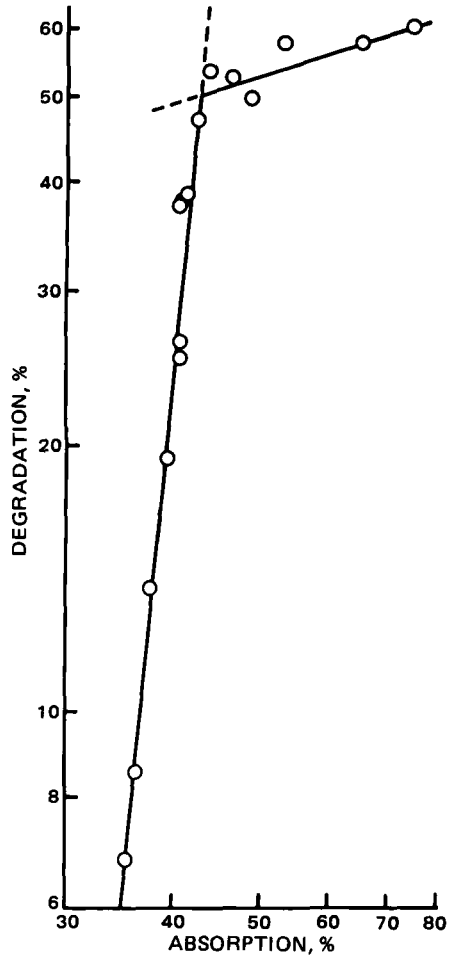

Figure 8—*Relationship between percent degradation and percent absorption of irradiated light energy.*

of degradation varied largely depending on the wavelength: it increased with decreasing irradiation wavelength. According to Grottus–Draper's law, only the light absorbed by a substrate can subject it to chemical change. Therefore, the results obtained in Fig. 7 may be attributed to the fact that the semi-integral attenuance increased with decreasing wavelength above 290 nm, as recognized in Fig. 6.

Supposing that the intensity of reflected light at the surface of substrate is negligibly low compared with that of light either absorbed by or transmitted through the substrate, the absorbance may be replaced

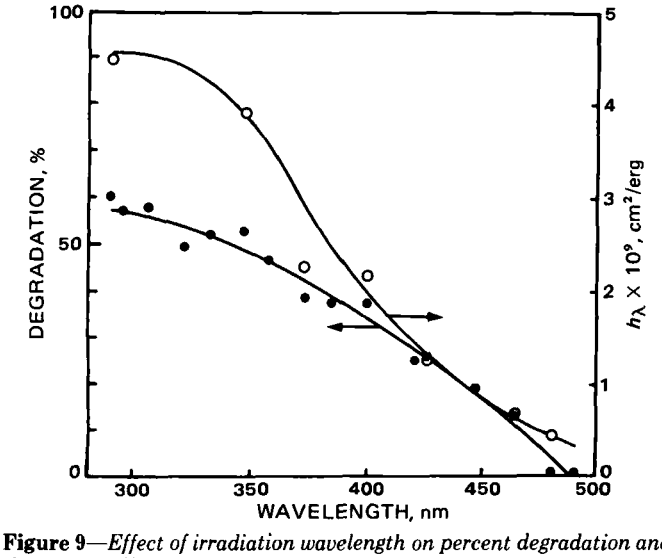

Figure 9—*Effect of irradiation wavelength on percent degradation and the energy efficiency constant,* h_λ.

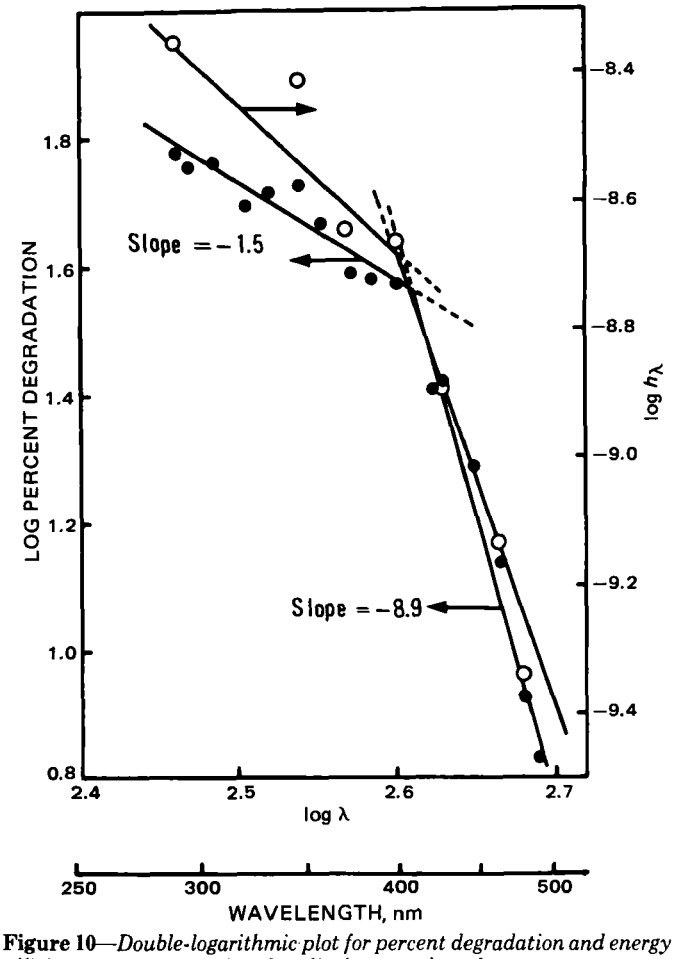

Figure 10—*Double-logarithmic plot for percent degradation and energy efficiency constant against irradiation wavelength.*

with semi-integral attenuance, ${}_pE_t$. The percent absorption, A, is then given by:

$$A\ (\%) = 100 - 10^{\log T} \qquad \text{(Eq. 3)}$$

where, $\log T = 2 - {}_pE_t$. Thus, the quantitative relationship between the degree of degradation and light absorption can be given as in Fig. 8; the percent degradation under the same irradiation energy of 2.0×10^8 erg/cm^2 in the range of 290–500 nm is plotted in this graph against percent absorption at that irradiation wavelength, using ${}_pE_t$ values of the original curve before irradiation in Fig. 6. It is clear that the percent degradation is quite sensitive to light absorption in the region of lower percent absorption, whereas it is less sensitive for higher percent absorption: the critical point existed at ~43% absorption. Photolytic degradation could no longer take place below 30% absorption. This result indicates that the absorption of light by ubidecarenone is not necessarily effective in producing degradation. In such a situation after a molecule had absorbed a quantum of light energy, it might collide with other molecules to raise their kinetic energy, resulting in only an elevation of the system temperature.

The slope of each line in Fig. 7 is equivalent to a degradation rate constant with a unit of min^{-1} at one irradiation wavelength. However, due to the spectral irradiation energy distribution of the light source, the required irradiation time differs depending on the irradiation wavelength even though under the same irradiation energy. It is not, therefore, reasonable to regard the slope as the degradation rate constant. In this case, an energy efficiency constant, h_λ, with a unit of cm^2/erg is used for convenience. Figure 9 shows the dependencies of the percent degradation and the energy efficiency constant obtained from Fig. 7 on the irradiation wavelength under the irradiation energy of 2.0×10^8 erg/cm^2. The percent degradation decreased with increasing wavelength, and no degradation occurred >480 nm. This pattern was in agreement with that of appearance change in Fig. 3. The energy efficiency constant was also reduced significantly with increasing irradiation wavelength. These parameters were replotted on the double-logarithmic scale (Fig. 10). For all parameters, good regression lines with an intersection at ~410 nm were estab-

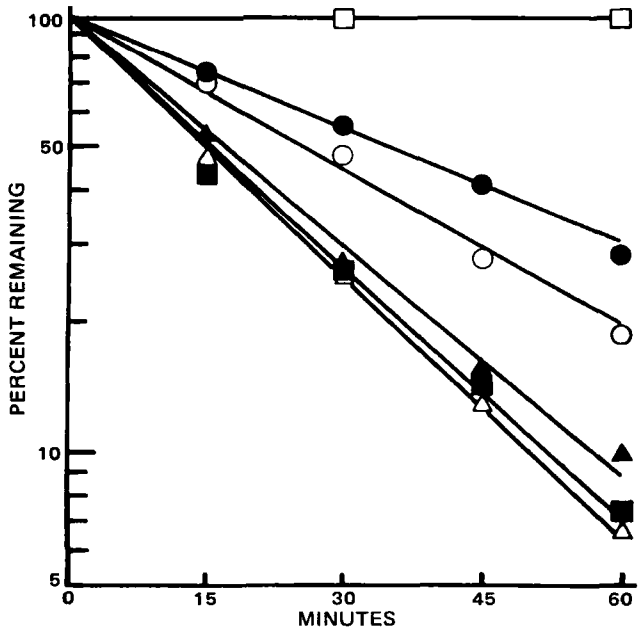

Figure 11—*Semilogarithmic plot for photolytic degradation profiles at various temperatures. Key: (□) 60° in the dark; (●) 25°; (○) 35°; (▲) 45°; (■) 55°; (△) 60°.*

lished over the whole range of wavelengths, but the slopes in two wavelength regions differed markedly. On the basis of this fact, we can deduce that though ubidecarenone is highly degraded by UV light, the effect of irradiation wavelength is much greater in the visible region than in the UV region.

Effect of Temperature on Photolytic Degradation—In examining the photostability of solid drugs with low melting point, it is of value to know how the photostability will be affected by temperature, as drugs stored at higher than melting point may degrade. Very little has been reported concerning the effect of temperature in photochemical reactions. In such cases the contributions of elevated temperature were promotive (16) or repressive (17–19) to the reaction.

Figure 11 shows the semilogarithmic plot of percent residual ubidecarenone against irradiation time at various temperatures. The time

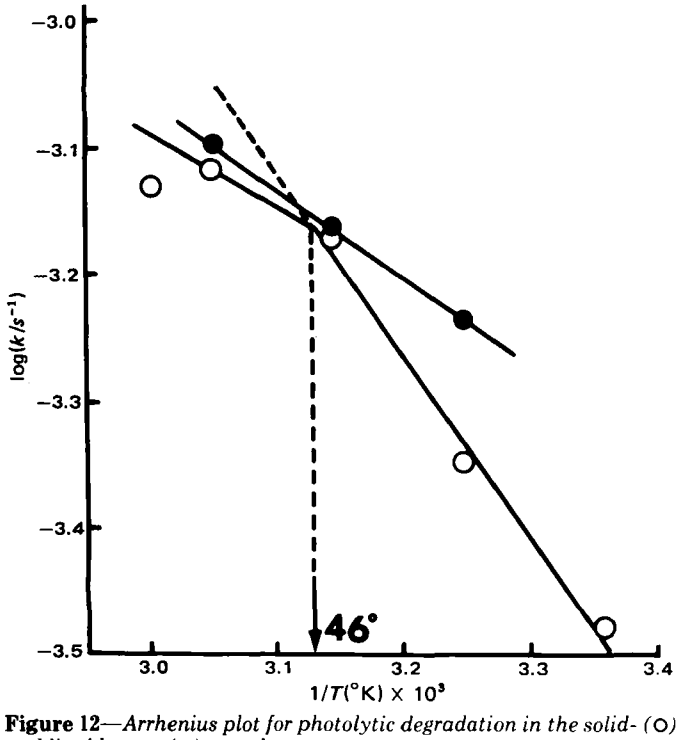

Figure 12—*Arrhenius plot for photolytic degradation in the solid- (○) and liquid-state (●) samples.*

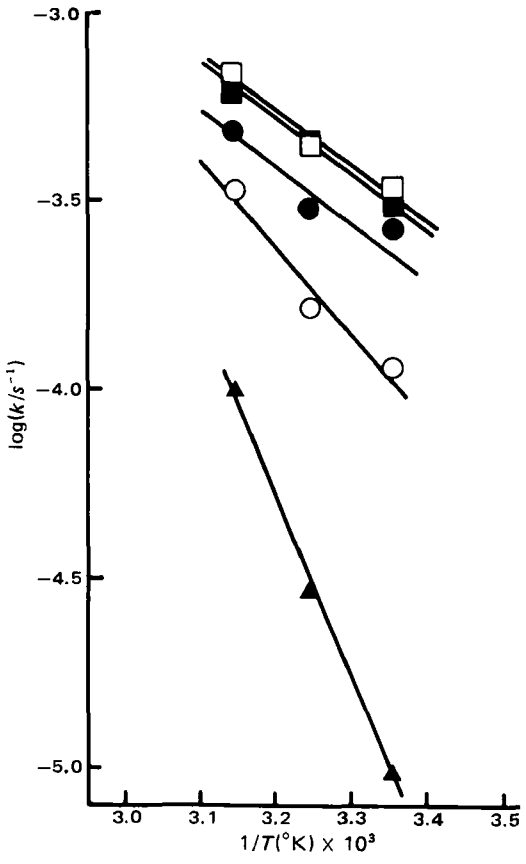

Figure 13—*Arrhenius plot for the photolytic degradation of ubidecarenone covered with various optical filters (see Table I). Key: (□) without filter; (■) UV-25; (●) UV-D25; (○) UV-35; (▲) VY-42.*

dependency of degradation was confirmed to follow apparent first-order kinetics at every temperature, as expected from Fig. 7. The degradation was significantly accelerated by elevation of temperature. It was evident that even at 60°, no degradation occurred at all in the dark, which suggests that the thermal reaction by itself cannot participate in the chemical degradation.

These degradation rate constants are given as an Arrhenius plot in Fig. 12. In the case of a liquid-state sample which was not allowed to recrystallize, the plots gave only one satisfactory line over the whole range of temperatures. In contrast, the plots for a solid sample gave two straight lines with different slopes; a critical temperature of 46° obtained as an intersection of two lines agreed with the initiating temperature for melting on the differential thermal analysis (DTA) curve of the sample. The slopes of these lines, therefore, indicate the activation energies for photodegradation in the solid and liquid states. The line in the range of temperatures higher than the melting point was adjacent and parallel to that of the liquid-state sample, giving an activation energy of 3.14 kcal/mole, which was much lower than that of 6.67 kcal/mole in the solid state. The liquid-state sample was far more prone to photodegradation than the solid sample. The difference in the activation energy depending on the existing states of sample seems to rely on the mobility of molecules subjected to the reaction in addition to the light absorption properties. In any case, these activation energies were much lower than the reported activation energies for typical drug decomposition in the liquid phase (20). It is worthy to note that reactions with such low activation energy take place so readily that photostable pharmaceutical preparations may not be able to be formulated without extreme care.

Under the various irradiation energies using several optical filters (Table I), the time dependency of degradation was examined at 25°, 35°, and 45°. The results are summarized as an Arrhenius plot in Fig. 13. This graph reveals a thermodynamic relationship between the tendency of degradation and UV intensity. As expected from the foregoing discussions, the higher the UV intensity, the more rapid the degradation. In contrast, the effect of temperature on the degradation rate constant was more significant with decreasing UV intensity. The ratios of the degradation rate constant for the sample without a filter to that for the sample covered with a VY-42 filter at 25° and 45° were 34.5 and 8.6, respectively.

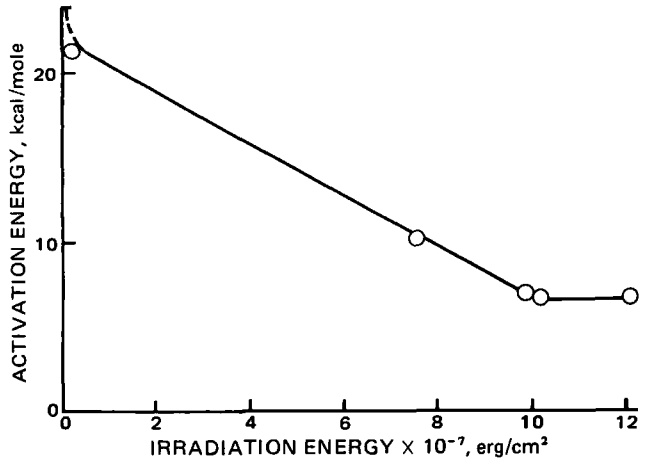

Figure 14—*Effect of UV intensity on the activation energy.*

These values were smaller by one or two orders of magnitude in comparison with the UV intensity ratio of 579, irradiated on each sample. In this respect, the elevation of temperature could be verified again to have a synergistic effect on the chemical degradation of ubidecarenone. The effect of UV irradiation energy on the activation energy calculated from the slope of each regression line is shown in Fig. 14. The activation energy linearly decreased up to $\sim 1.0 \times 10^8$ erg/cm^2; with values larger than this it was no longer dependent on the UV intensity. It should be pointed out that even under very low intensity (in the case of filter VY-42), the activation energy approached a finite value of 21.3 kcal/mole, which is within the usual range of activation energies for hydrolysis or oxidation (21).

Determination of Busulfan in Plasma by GC–MS with Selected-Ion Monitoring

HANS EHRSSON ˣ **and MOUSTAPHA HASSAN**

Received May 25, 1982, from *Karolinska Apoteket, Box 60024, S-104 01 Stockholm, Sweden.* Accepted for publication September 15, 1982.

Abstract □ A GC–MS technique with selected-ion monitoring is described for the determination of busulfan in plasma. Busulfan is extracted from plasma with methylene chloride and converted to 1,4-diiodobutane. Analysis by GC–MS with selected-ion monitoring (m/z 183) gave a relative standard deviation of ±4.3% (n = 5) at the 10-ng/ml level.

Keyphrases □ Busulfan—determination in human plasma, GC–MS with selected-ion monitoring of 1,4-diiodobutane □ GC–MS analysis—selected-ion monitoring, determination of busulfan in human plasma

The alkylating agent, busulfan, 1,4-butanediol dimethanesulfonate, is the drug of choice in the treatment of chronic myeologenous leukemia. The drug has been in clinical use since the 1950's, but the fate of the drug in humans has only been studied by administering radioactively labeled compound and measuring total radioactivity in plasma and urine (1, 2). This paper describes the conversion of busulfan to 1,4-diiodobutane, and the subsequent quantitation of this material by GC–MS with selected-ion monitoring.

EXPERIMENTAL

Synthesis of 1,5-Pentanediol Dimethanesulfonate (Internal Standard)—Methanesulfonic anhydride (9 g) was added carefully to a stirred mixture of 1,5-pentanediol (5.5 g) in pyridine–methylene chloride (40 ml, 1:1). After stirring overnight at 25° the mixture was filtered, and the organic phase was washed with water. The organic phase was evaporated to ~5 ml and left at 4° for 48 hr. The crystals which formed were separated, washed with ice-cold water, and dried (yield: 9%); mp 35° [lit. (3) 34–35°]. The compound was identified by GC–MS[1] after conversion to the corresponding 1,5-diiodo derivative according to the procedure given below. There were prominent peaks at m/z 324 (M^+, 8%), 199 (5), 197 (53), 169 (5), 155 (26), 70 (8), and 69 (100).

Conversion of Busulfan to 1,4-Diiodobutane—Busulfan was con-

Table I—Stability of Busulfan at 37.0° [a]

Medium	$t_{1/2}$ (±SE), hr
Whole blood	8.7 ± 0.4 (n = 10)
Plasma	12.2 ± 0.1 (n = 10)
Phosphate buffer (pH 7.0)	16.0 ± 0.7 (n = 7)

[a] Busulfan concentration: 2.8×10^{-4} M.

verted to 1,4-diiodobutane using 1 M sodium iodide in acetone (0.1 ml), with a reaction time of 20 min at 70°. After addition of n-hexane (0.05 ml) and water (0.1 ml), an aliquot (1–2 μl of hexane) was removed for analysis.

Determination of Partition Coefficient—The distribution of busulfan was studied using phosphate buffer (pH 7.0, μ = 0.1) as the aqueous phase and methylene chloride as the organic phase with an equilibrium time of 30 min at 25.0 ± 0.1°. The concentration of busulfan in the organic phase was determined after addition of the internal standard, evaporation, and conversion to 1,4-diiodobutane as above. The concentration of busulfan in the aqueous phase was determined after transfer into methylene chloride by extraction of the aqueous phase three times with equal volumes of the solvent. The analyses were performed by GC–FID[2].

Determination of Rate Constants for the Formation of 4-iodo-1-butanol Methanesulfonate (I) and 1,4-Diiodobutane—At appropriate times 1.00-ml samples were withdrawn from an acetone solution of busulfan (4×10^{-3} M) in 1 M sodium iodide at 50.0 ± 0.5°. The reaction was stopped by rapid cooling (−70°), and the acetone was evaporated to near dryness. The residue was mixed with 1.00 ml of methylene chloride and 1.00 ml of water. The concentration of 1,4-diiodobutane was determined by mixing 0.100 ml of the organic phase with 1,5-diiodopentane and analyzing by GC–FID. The concentrations of busulfan and I were determined using the following procedure. The methylene chloride phase (0.500 ml) was evaporated to dryness, the residue was mixed with 0.500 ml of ethanol–water (1:1), and an aliquot (0.100 ml) was injected into the liquid chromatograph[3]. The fractions containing busulfan and I were collected, mixed with the internal standard and extracted with methylene chloride. The organic phase was evaporated to dryness, and busulfan and I were converted to 1,4-diiodobutane and analyzed by GC.

The mass spectrum of I was consistent with the expected structure. Peaks were located at m/z 278 (M^+, 1%), 183 (1), 151 (10), 86 (13), 84 (20), 79 (14), 56 (5), 55 (100), and 51 (9). The mass spectrum of the prepared 1,4-diiodobutane was identical with that of a commercially available reference compound. Peaks were located at m/z 310 (M^+, 2%), 184 (5), 183 (81), 155 (10), 137 (8), 135 (8), 56 (10), and 55 (100).

Determination of Busulfan in Plasma—Plasma (1.00 ml) was mixed with 0.100 ml of the internal standard (1.00 μg/ml) in acetone and extracted with methylene chloride (4.00 ml) for 30 min using a mechanical shaker (100 strokes/min). The organic phase was separated and evaporated to dryness, and the derivatization was performed using the aforementioned procedure. The analysis was carried out by GLC–MS[4] focusing at m/z 183 (1,4-diiodobutane) and m/z 197 (1,5-diiodopentane).

RESULTS AND DISCUSSION

Stability of Busulfan—The stability of busulfan in whole blood and plasma is lower than in phosphate buffer, pH 7.0 (Table I). Busulfan differs in this respect from the nitrogen mustards, chlorambucil and melphalan, where an increased stability has been observed in samples containing albumin (4, 5). The stability of busulfan was also studied in plasma at a concentration of 4×10^{-7} M and was not significantly different from that observed at 2.8×10^{-4} M. The degradation of busulfan in human blood samples was minimized by rapidly cooling the blood to 4° and freezing the plasma fraction (−20°) within 1 hr after the blood collection.

Extraction—Methylene chloride was used in the extraction of busulfan because of its favorable extraction properties (k_d = 28.7) and high

[2] Varian 3700; the column (1.5-m × 2-mm i.d.) was packed with 10% SP-2401 on 100–120 Supelcoport and was operated at 130°.

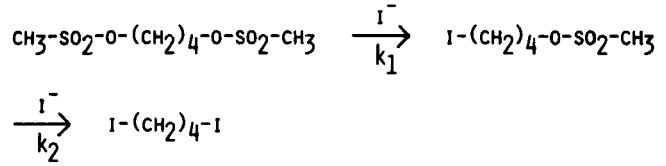
[3] The column (150-mm × 4-mm i.d.) was packed with LiChrosorb RP-8. Ethanol–water (1:1) was used as the mobile phase. The detection was performed by an Altex model 153 detector measured at 254 nm (1,4-diiodobutane and I) and by an LDC Refracto Monitor III (busulfan). The capacity factors were 0.3 (busulfan), 0.9 (I), and 4.6 (1,4-diiodobutane).

[4] LKB 2091 with an ionizing energy of 70 eV. The column (1.5-m × 2-mm i.d.) was packed with 10% SP-2401 on 100–120 Supelcoport and was operated at 140° using a helium flow rate of 20 ml/min. The injector and the ion source temperatures were 230° and 270°, respectively.

Table II—GC of busulfan [a]

Busulfan Injected, μg	Peak Height Ratio[b]	Column Temperature
1	0.80 ± 0.11	190°
0.2	0.23 ± 0.04	190°
1	0.97 ± 0.09	175°
0.2	0.44 ± 0.13	175°

[a] The column was 3% OV-17 on 100–120 Gas Chrom Q (1.5 m) with injector and detector (FID) temperatures of 210° and 270°, respectively. The carrier gas flow was adjusted to give the same retention time (5.2 min) for busulfan at 190° and 175°. [b] The mean peak height ratio of busulfan to 9-bromophenanthrene (±SD; n = 6). The busulfan–9-bromophenanthrene ratio was kept constant.



Scheme I—Reaction of busulfan with sodium iodide.

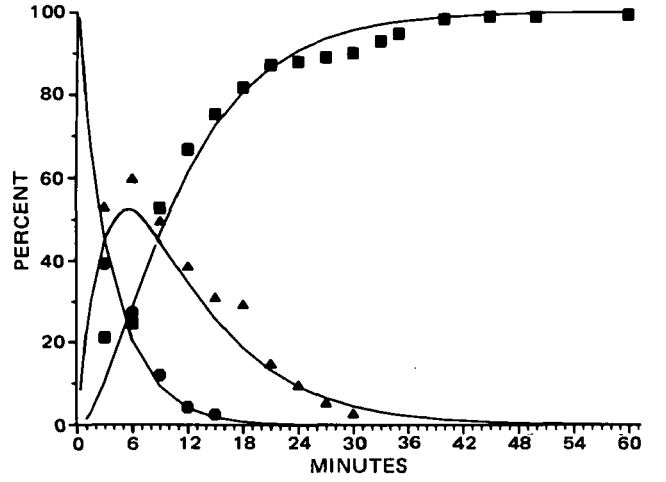


Figure 1—*Time course for the reaction of busulfan with 1 M sodium iodide in acetone at 50°. The solid lines are constructed from the rate constants obtained by nonlinear regression analysis. Key: (●) busulfan; (▲) 4-iodo-1-butanol methanesulfonate; (■) 1,4-diiodobutane.*

Figure 2—*Chromatogram obtained from plasma containing 10 ng of busulfan/ml using selected-ion monitoring with a 1.5-m column packed with 10% SP-2401 at 140°. Key: (A) busulfan as 1,4-diiodobutane; (B) 1,5-pentanediol dimethanesulfonate as 1,5-diiodopentane.*

volatility, being readily evaporated prior to the derivatization step. Using a V_{org}/V_{aq} ratio of 4.98 ± 1% of busulfan (n = 5) was extracted from plasma (busulfan concentration 50 ng/ml).

GC of Intact Busulfan—The peak height ratios of busulfan to 9-bromophenanthrene obtained after injections of different amounts of the compounds at two column temperatures were drastically reduced when lower amounts of busulfan were chromatographed; in all cases poor precision was obtained (Table II). Analysis of busulfan at the lower temperature (175°), keeping the retention time the same by adjustment of the carrier gas flow, gave the highest peak height ratio, which indicates that the results obtained are primarily due to degradation of busulfan in the chromatographic system and not to adsorption phenomena (6). This assumption is also supported by the fact that when using different batches of OV-17 column packing material, multiple asymmetric peaks were occasionally observed.

Conversion of Busulfan to 1,4-Diiodobutane—The reaction of busulfan with sodium iodide proceeds according to Scheme I. The reaction was performed in acetone since nucleophilic substitution reactions are known to be rapid in this solvent (7). The time course for busulfan, I, and 1,4-diiodobutane using 1 M sodium iodide in acetone is given in Fig. 1. Evaluation of the apparent first-order rate constants by nonlinear regression analysis gave $k_1 = 0.266 \pm 0.013$ and $k_2 = 0.124 \pm 0.008$ min^{-1}. Since the ratio between the constants is ~2, it follows that the methanesulfonate ester group of busulfan and that of I have similar reactivity (3). A quantitative reaction was obtained after 20 min using 1 M sodium iodide and a temperature of 70°.

Chromatographic Properties—1,4-Diiodobutane had excellent GC properties giving a symmetric peak (Fig. 2). No indications of decomposition in the chromatographic system were observed.

Detection, Selectivity, and Precision—The minimum detectable concentration (MDC) value obtained by electron-capture detection (ECD) was ~10 times lower than that obtained by selected-ion monitoring (SIM), 0.6×10^{-16} and 5.7×10^{-16} mole/sec, respectively[5]. However, analysis of plasma samples revealed that the higher sensitivity of the ECD could not be utilized because of interfering peaks in the chromatograms. The blanks varied considerably between patients and, in most cases, it was not possible to perform quantitations <10 ng/ml. Since the plasma peaks after administration of therapeutic doses (2 mg) of busulfan are 20–30 ng/ml, meaningful pharmacokinetic studies require determinations in the low nanogram range. A chromatogram obtained from plasma using SIM is given in Fig. 2. The standard curve obtained from plasma using SIM was linear within the range studied (10–400 ng/ml). A least-squares analysis gave a correlation coefficient of 0.9997, a slope of $2.12 \times 10^{-2} \pm 0.03 \times 10^{-2}$, and an intercept of $4.7 \times 10^{-2} \pm 7.6 \times 10^{-2}$. The relative standard deviation was ±2.6% at 100 ng/ml and ±4.3% at 10 ng/ml (n = 5).

[5] Signal to noise ratio = 3. ECD: A Varian ^{63}Ni-detector (DC) operating at a foil temperature of 200°. SIM: LKB 2091, focusing at m/z 183 (70 eV).

Steroidal Thiourea and Thiazoline Derivatives: Synthesis and *In Vitro* Effects on Bovine Pancreatic Ribonuclease Activity

EL-SEBAII A. IBRAHIM *, A.-MOHSEN M. E. OMAR *x, N. S. HABIB *, OMAIMA M. ABOULWAFA *, S. M. EL-SEWEDY ‡, and J. BOURDAIS §

Received February 24, 1982, from the **Pharmaceutical Chemistry Department, Faculty of Pharmacy*, the ‡*Department of Applied Medical Chemistry, Medical Research Institute, University of Alexandria, Egypt* and the §*Laboratorie de Chimie des Hétérocycles d'Intérêt Biologique, Université d'Aix-Marseille II, Faculté de Medecine Nord, 13326 Marseille, Cédex 15, France.* Accepted for publication August 16, 1982.

Abstract □ Two novel series of steroidal derivatives containing various thiourea and substituted thiazoline moieties attached to the 2- or 4-position of estrone were synthesized and examined for *in vitro* effect on bovine pancreatic ribonuclease activity. All compounds studied exhibited a catabolic activity. The steroidal thiazoline derivatives were more potent activators of ribonuclease than the steroidal thioureas.

Keyphrases □ Steroids—thiourea and thiazoline derivatives, synthesis, *in vitro* effect on bovine pancreatic ribonuclease activity □ Synthesis—steroidal thiourea and thiazoline derivatives, *in vitro* effect on bovine pancreatic ribonuclease activity □ Catabolic activity—steroidal thiourea and thiazoline derivatives, *in vitro*, bovine pancreatic ribonuclease activity

Recent reports from this laboratory have described the synthesis and pharmacological properties of a variety of androgenic and estrogenic thiosemicarbazones (1), acylhydrazones (2–5), and several steroidal heterocycles (6, 7). Further interest in structure–activity relationships (SAR) of steroidal heterocyclics prompted the preparation of XVIII–XXXII (Scheme I) to evaluate the changes in the endocrinological activity caused when the 2- or 4-position of estrone-3-methyl ether is blocked by variously substituted thiazoline moieties. Some of the steroidal thioureas (VIII–XVI), prepared as starting materials, and the thiazoline derivatives were found to possess catabolic-like properties as indicated from their *in vitro* effect on the activity of bovine pancreatic ribonuclease.

RESULTS AND DISCUSSION

Synthesis—The designed compounds (XVIII–XXXII) were prepared in accordance with the sequence of reactions shown in Scheme I. The 2-

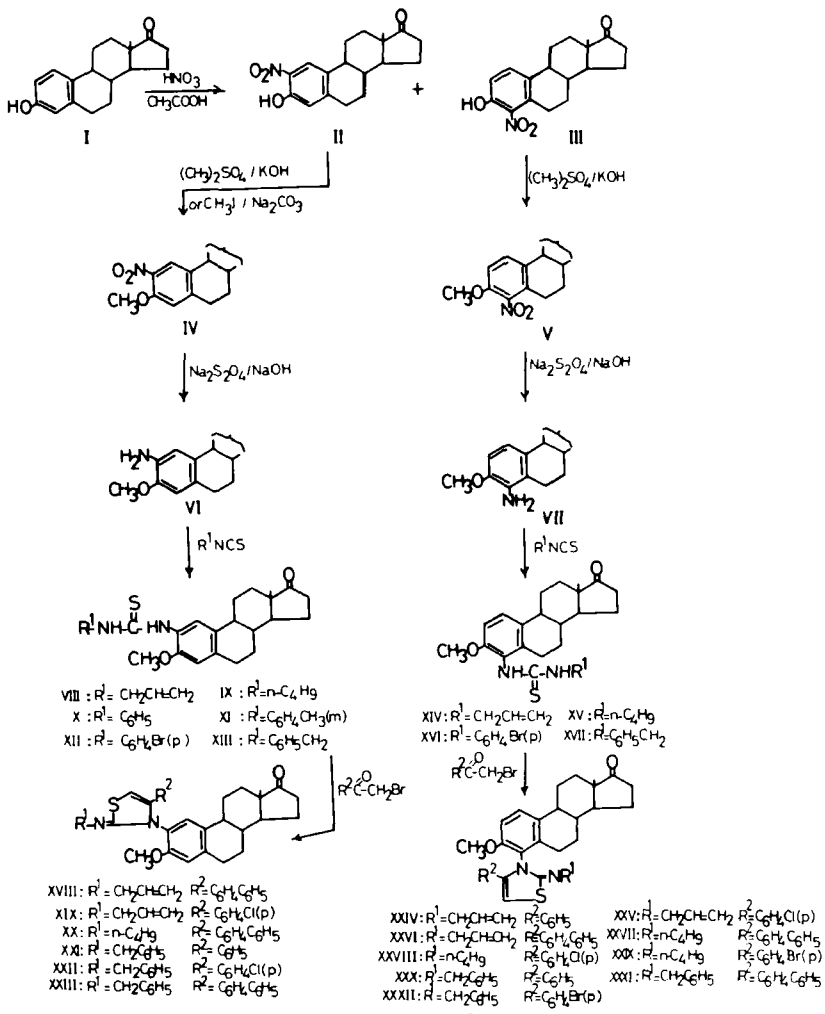
Recent reports from this laboratory have described the synthesis and pharmacological properties of a variety of androgenic and estrogenic thiosemicarbazones (1), acylhydrazones (2–5), and several steroidal heterocycles (6, 7). Further interest in structure–activity relationships (SAR) of steroidal heterocyclics prompted the preparation of XVIII–XXXII (Scheme I) to evaluate the changes in the endocrinological activity caused when the 2- or 4-position of estrone-3-methyl ether is blocked by variously substituted thiazoline moieties. Some of the steroidal thioureas (VIII–XVI), prepared as starting materials, and the thiazoline derivatives were found to possess catabolic-like properties as indicated from their *in vitro* effect on the activity of bovine pancreatic ribonuclease.

RESULTS AND DISCUSSION

Synthesis—The designed compounds (XVIII–XXXII) were prepared in accordance with the sequence of reactions shown in Scheme I. The 2-

0022-3549/83/1000-1205$01.00/0



Scheme I

and 4-mononitroestrones (II and III), prepared by nitration of estrone (I) with a mixture of nitric acid and acetic acid (8), were methylated to the corresponding 3-methyl ethers (IV and V) using dimethyl sulfate and potassium hydroxide (9) or methyl iodide and sodium carbonate (10). The products were reduced by sodium dithionite in alkaline medium (9) to give the required 2-amino- (VI) and 4-aminoestrone-3-methyl (VII) ethers in good yields.

Treatment of the amines (VI and VII) with the appropriate alkyl, aryl, or aralkylisothiocyanate derivatives in absolute ethanol (11) gave, respectively, the *N*-substituted *N'*-(3-methoxy-17-oxoestra-1,3,5(10)-trien-2-yl)thioureas (VIII–XIII) and *N*-substituted *N'*-(3-methoxy-17-oxoestra-1,3,5(10)-trien-4-yl)thioureas (XIV–XVII) (Table I). The reaction of VIII, IX, XIII–XV, and XVII, in which R^1 was an alkyl or aralkyl function, with the selected phenacyl bromide in refluxing absolute ethanol (12) proceeded smoothly and gave high yields of the required 2-(2',4'-disubstituted thiazolin-3'-yl)-3-methoxyestra-1,3,5(10)-trien-17-ones (XVIII–XXIII) and the corresponding 4-(2',4'-disubstituted thiazolin-3'-yl)-3-methoxyestra-1,3,5(10)-trien-17-ones (XXIV–XXXII) (Table II). When R^1 was an aryl moiety, as in X–XII and XVI, the reaction with phenacyl bromide gave a mixture of two products that could not be separated. In addition, in one case, when IX was treated with *p*-chlorophenacyl bromide, the *S*-alkylpseudothiourea hydrobromide salt (XXXIII) was obtained (Scheme II).

The products were identified by elemental analyses, IR, UV, and ^{1}H-NMR spectra and, for representative examples, by mass spectra (Tables I, II, and III). The UV spectra showed two absorption maxima at 245–253 and 290–295 nm for VIII and XIII, a single absorption maximum at 276–286 nm for X–XII, and two absorption maxima at 244–251 and 277–282 nm for the thioureas XIV–XVII. The steroidal thiazolines, on the other hand, showed one absorption maximum at ~295 nm for XIX and XXI, while XXV and XXX absorbed at 288 nm. The remainder of the thiazoline derivatives showed two absorption maxima, sometimes as a shoulder, at 256–266 and 290–320 nm. The addition of hydrochloric acid caused a hypsochromic shift of the absorption maxima of all thiazoline derivatives (Tables I and II).

^{1}H-NMR spectra of the steroidal thiourea derivatives (Table I) showed the signals for the common protons of the C_{18}—CH_3, C_3—OCH_3, C_1—H, C_2—H, and C_4—H of the steroidal nucleus (13) at the expected chemical shift. The N—H proton attached to ring A of estrone resonated downfield between 7.25 and 7.97 ppm and was shown as a singlet disappearing on deuteration. The chemical shift of the other N—H proton was dependent on the nature of the substituent present. In the allyl (VIII and XIV), butyl (IX and XV), and benzyl (XIII and XVII) derivatives, the proton was shown at a multiplet at 5.65–6.25 ppm, while in the *p*-bromophenylthiourea (XII), it appeared as a singlet at 7.88 ppm. The ^{1}H-NMR spectra of the steroidal thiazolines (XVIII–XXXI), on the other hand, lacked the signals due to N—H protons, but showed a singlet between 5.72 and 5.83 ppm for the thiazoline C_5—H (13). The chemical shifts of the other protons were almost the same as those of the thiourea derivatives (Table III).

The ^{1}H-NMR spectrum of the steroidal pseudothiourea derivative (XXXIII) did not show the signal of the butyl-NH proton, indicating that this proton was involved in the enolization of the thiourea (IX) from the thione to the thiol form. In addition, the absence of a distinct signal for the two methylenic protons of the S—CH_2—CO function suggested that enolization of XXXIIIa to XXXIIIb had taken place (Scheme II). As a result, the olefinic C—H proton has been identified at low field at ~6.56 ppm while the OH proton was included in the fingerprint area of the steroidal skeleton.

The mass spectra of XV and XVII, as representative examples of the synthesized thioureas, showed the molecular ion peak at *m/z* 414 and 448, respectively (Scheme III). A common fragmentation pattern of these compounds was found to be the elimination of the 3-OCH_3 group followed by cyclization of the produced ion to give the base peak A at *m/z* 383 for the butyl derivative and 417 for the benzyl derivative (Scheme III, Pathway 1). In accordance with Pathway 2, the compounds underwent

Table I—Synthesized *N*-Substituted *N'*-(3-Methoxy-17-oxoestra-1,3,5(10)-trien-2-yl)thioureas (VIII–XIII) and *N*-Substituted *N'*-(3-Methoxy-17-oxoestra-1,3,5(10)-trien-4-yl)thioureas (XIV–XVII)

[a] The products were crystallized from benzene–light petroleum except XII and XVII which were crystallized from ethanol–benzene.

cleavage of C_6 and C_7 from the steroidal nucleus to give ion B at m/z 385 and 419, which on losing the thiourea function gave ion C at m/z 256. The thiourea functions in XV and XVII were found to undergo elimination of hydrogen sulfide giving the carbodiimide ion D, at m/z 380 and 414, fission of the isothiocyanate function (14) giving ion E at m/z 299, and cleavage of a butyl or benzylamino function to yield ion F at m/z 341. Ion E in turn, lost an NH function giving ion G at m/z 284, while ion F cleaved sulfur to give the isocyanide ion H at m/z 309.

[a] With crystallization solvent in parentheses. [b] The first row are calculated values; the second row are the values found. [c] Using ethanol/using ethanol + HCl.

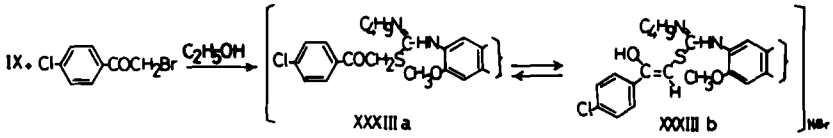
The mass spectrum of 2-(2′-benzylamino-4′-biphenylthiazolin-3′-yl)-3-methoxyestra-1,3,5(10)-trien-17-one (XXIII) showed the molecular ion peak at *m/z* 624 (Scheme IV). In accordance with Pathway 1 (Scheme IV), the fragmentation of the molecule was found to be elimination of an ethylene function from ring B and three hydrogens giving ion A at *m/z* 593. This pathway was confirmed by the appearance of the metastable peak at 563.75. In Pathway 2, the molecule fragmented through elimination of a benzyl function to yield ion B at *m/z* 533, while in Pathway 3 the biphenyl group of the thiazoline moiety was eliminated and ring D removed to give ion C, as the base peak, at *m/z* 373. Ion C, in turn, was found to undergo cleavage through removal of the phenyl group of the benzyl moiety, a thioketene function from the thiazoline ring, and the methoxyl group and then cyclized to ion D at *m/z* 209. The removal of only the phenyl and thioketene moieties from ion C gave the carbodiimide ion F at *m/z* 238, which after cleaving carbon and a methyl radical produced ions G and H at *m/z* 226 and 211, respectively. The spectra of all examined compounds have also shown the different ions corresponding to the reported fragmentation of the steroidal nucleus (15), as well as those of susbstituted thiazoline ring (16–18) (Table III).

Biological Screening—Compounds VIII, X, XVI–XVIII, XX, XXII, XXV, XXIX, and XXX were tested *in vitro* for possible anabolic–catabolic activity by measuring their effect on the activity of bovine pancreatic ribonuclease, as previously reported (7, 19). The results (Table IV) indicated that the steroidal thiazoline derivatives caused a more potent activation of the enzyme than the corresponding steroidal thioureas. In addition, the fact that the thiourea XVI and the thiazolines XXV and XXX caused the highest percentage activation of the enzyme suggested that substitution, especially with the bulky thiazoline moieties, in the 2-position of estrone greatly hinders the binding of the hormonal derivative with the enzyme. The high percentage of enzyme activation caused by the pseudothiourea XXXIII has been attributed to its high polar structure and malleability in spatial arrangement, which allows maximum contact with the enzyme. The thiazoline derivatives XVIII and XXV, having allyl and biphenyl or *p*-chlorophenyl moieties in the heterocyclic ring, as well as XXX, containing the benzyl and phenyl groups, and the steroidal pseudothiourea XXXIII are most likely to possess catabolic activity being the most potent activators of the enzyme. Such a property, effective in suppressing cancer metastasis (20, 21), has recommended such compounds for evaluation for anticancer activity. Compared with these results, the correlative studies from this laboratory indicated that the fusion of a substituted oxazole or oxazoline ring to the 2,3- or 3,4-positions of estrone causes the products to induce a mild or similar percentage of enzyme activation (6, 7).

EXPERIMENTAL[1]

Steroidal Thiourea Derivatives (VIII–XVII)—A solution of the steroidal amines VI and VII (9) (200 mg, 0.66 mmole) and the selected alkyl, aryl, or aralkylisothiocyanate derivative (1.5 *M* equivalent) in ethanol (20 ml) was left at room temperature or heated under reflux as specified in Table I. Ethanol was removed under reduced pressure, and the residue was covered with light petroleum and stored in the refrigerator for 1 hr. The solvent was decanted, and the residue was treated with fresh light petroleum and scratched to deposit the solid. This was filtered, crystallized from the proper solvent, and identified by elemental analysis and IR, UV, and ^{1}H-NMR spectra (Table I). IR (mineral oil): ν 3380–3140 (N—H), 1735–1710 (C=O), 1605–1585 and 1500–1480 (C=C, aromatic), 1535–1520, 1340–1310, 1190–1170, and 950–905 (N—C=S amide I, II, III, and IV bands, respectively), and 1290–1240 and 1080–1050 cm^{-1} (C—O—C). The mass spectrum of XV showed *m/z* (relative abundance %): M^+ at 414(18), 385(10), 384(28), 383(100), 382(15), 381(47), 380(55), 342(22), 341(98), 324(3), 309(10), 300(18), 299(78), 298(6), 285(10), 284(18), 283(5), 256(10), 243(12), 231(10), 230(12), 228(6), 217(17), 216(7), 215(6), 213(5), 212(6), 211(7), 199(7), 198(10), 197(6), 186(10), 185(8), 184(11), 175(8), 174(10), 173(11), 172(13), 171(10), 160(13), 159(10), 158(17), 147(8), 146(15), 145(6), 144(8), 143(10), 142(8), 141(11), 131(12), 130(3), 129(13), 128(17), 116(12), 115(30), 103(12), 102(5), 97(10), 81(8), 79(8), 72(5), 57(25), 55(23), 53(12), and 41(43); the mass spectrum of XVII showed *m/z* (relative abundance %): M^+ at 448(15), 419(10), 418(32), 417(100), 416(13), 415(42), 414(48), 342(4), 341(17), 309(2), 300(10), 299(37), 298(4), 285(3), 284(8), 283(3), 256(3), 243(3), 231(3), 230(3), 228(3), 217(4), 216(3), 215(3), 213(4), 212(4), 211(6), 199(5), 198(6), 197(42), 186(6), 185(5), 184(7), 175(5), 174(6), 173(6), 172(8), 171(6), 165(6), 160(10), 159(5), 158(10), 149(3), 147(4), 146(8), 145(4), 144(6), 143(7), 142(6), 141(72), 131(8), 130(12), 129(10), 128(12), 117(7), 107(6), 106(27), 97(5), 92(18), 91(100), 79(13), 78(7), 77(7), and 41(23).

[1] All melting points are uncorrected. IR spectra were measured as Nujol mulls on a Beckmann 4210 IR Spectrophotometer, and UV spectra for ethanol solution were measured on a Shimadzu double-beam spectrophotometer (Model UV-200S). ^{1}H-NMR and mass spectra were measured on a Perkin-Elmer R32 and an AEI-MS-50, respectively.



Scheme II

2- and 4-(2′,4′-Disubstituted thiazoline-3′-yl)-3-methoxyestra-1,3,5(10)-trien-17-ones (XVIII–XXXII)—A mixture of the thiourea derivatives (VIII, IX, XIII–XV, and XVII) (200 mg) and the molar equivalent of substituted phenacyl bromide in absolute ethanol (10 ml) was heated under reflux for the specified time (Table II). Ethanol was removed under reduced pressure, and the oily residue was dissolved in chloroform (75 ml). The solution was washed with water (3 × 50 ml), dried (anhydrous sodium sulfate), and evaporated to give an oily residue. On scratching with light petroleum, the products deposited in solid form; they were crystallized from the proper solvents and identified by elemental analysis and IR, UV, ^{1}H-NMR, and mass spectra (Tables II and III). IR (mineral oil): ν 1735–1725 (C=O), 1620–1610 (C=N), 1595–1560 and 1500–1490 (C=C, aromatic), and 1265–1235 and 1090–1075 cm^{-1} (C—O—C).

Table III—^{1}H-NMR and Mass Spectral Data of the Steroidal Thiazoline Derivatives

Anal. —Calc. for $C_{32}H_{40}BrClN_2O_2S \cdot \frac{1}{2} H_2O$: C, 59.03; H, 6.30; N, 4.30. Found: C, 59.19; H, 6.88; N, 4.67.

***In Vitro* Anabolic–Catabolic Activities**—Four sets of solutions and media (7) were used in the evaluation procedures. After mixing the components of each set, the tubes were incubated at 37° for 15 min and then treated with 4 ml of ethanol–glacial acetic acid (15:1, v/v) to terminate the reaction. After storage for 1 hr in the refrigerator, the tubes were centrifuged for 15 min and the clear supernatants were measured spectrophotometrically at 260 nm. The results of the effect of VIII, X, XVI–XVIII, XX, XXII, XXV–XXIX, XXX, and XXXIII on the activity of bovine pancreatic ribonuclease are shown in Table IV.

High-Performance Liquid Chromatographic Determination of Cyproheptadine Hydrochloride in Tablet Formulations

GREGORY W. BURROWS ˣ **and CHERYL L. ALLIGER**

Received November 6, 1981, from the *Analytical Chemistry Department, Food and Drug Research Laboratories, Inc., Waverly, NY 14892.* Accepted for publication August 26, 1982

Abstract □ A high-performance liquid chromatographic method is described which determines cyproheptadine hydrochloride in tablet formulations. Tablets were dissolved in water–acetonitrile (50:50) and analyzed using an octadecylsilane column with a mobile phase of 85% acetonitrile and 15% of an aqueous solution of 0.01 *M* 1-octanesulfonic acid, 0.5% triethylamine, and 1% acetic acid using UV absorbance detection at 280 nm.

Keyphrases □ Cyproheptadine hydrochloride–high-performance liquid chromatography, tablet formulations □ High-performance liquid chromatography—cyproheptadine hydrochloride in tablet formulations

Cyproheptadine hydrochloride, an oral antihistamic agent used in the treatment of perennial and seasonal rhinitis and other allergic reactions (1), is formulated in various ways. In this analysis, cyproheptadine was separated from vitamins, plant extracts, and fillers. The standard spectrophotometric analysis described in USP XX (2) proved unsatisfactory with these formulations. Excipients coeluting from the silica gel column caused an elevated absorbance and erroneous assay.

Various authors have described separations of antihistamines and cyproheptadine hydrochloride by GLC (3, 4) and reverse-phase high-performance liquid chromatography (HPLC) (5, 6). A buffered, normal phase, ion-paired separation has also been reported (7). The purpose of this study was to develop a chromatographic analysis to separate a complex mixture of ingredients in a tablet formulation.

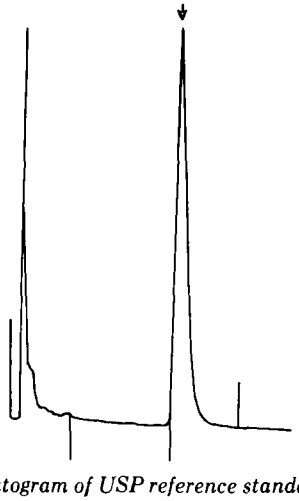

Figure 1—*Chromatogram of USP reference standard cyproheptadine hydrochloride.*

EXPERIMENTAL

The high-performance liquid chromatograph[1] with an octadecylsilane column[2] was used for all separations. The detector was equipped with a 280-nm filter and set at 0.05 AUFS. Mobile phase at ambient temperature was pumped at 2 ml/min. (500–1000 psi) until the baseline was stable.

Chemicals and Reagents—Acetonitrile[3] was HPLC grade, 1-octanesulfonic acid[4] and glacial acetic acid[5] were reagent grade, triethylamine[5] was reagent grade and redistilled in glass, and cyproheptadine HCl[6] was USP reference standard.

Mobile Phase—The mobile phase was delivered using two pumps and a solvent programmer. The programmer was set to pump a mixture of 85% acetonitrile and 15% aqueous phase. The aqueous phase consisted of a solution of 0.01 *M* 1-octanesulfonic acid, 0.5% triethylamine, and 1% acetic acid.

Standard Curve—Standard solutions were prepared to concentrations ranging from 26.68 to 80.04 μg/ml representing results of 40 to 120% of theoretical. A plot of concentration *versus* area was linear (correlation coefficient = 0.99997). The line equation is $y = mx + b$, where m (slope) = 1.06×10^7 and b (intercept) = -0.005×10^7. Run on 3 successive days, the average slope had an *RSD* of 0.43%.

Table I—Dissolution of Cyproheptadine Hydrochloride

Dissolution Medium	Sample Identification	Peak[a] Area ($\times 10^6$)	Cyproheptadine Hydrochloride Available, %
Distilled water	USP reference standard	6.859	100
Distilled water	Cyproheptadine hydrochloride (used in tablet formulation)	6.410	93.4
Distilled water	Blank powder	None detected	
Simulated gastric fluid	USP reference standard	2.973	43.3
Simulated gastric fluid	Tablets	2.932	42.7
Simulated intestinal fluid	USP reference standard	3.369	49.1
Simulated intestinal fluid	Tablets	0.784	11.4

[a] One determination each.

Analytical Procedure—Five tablets (each containing approximately 0.7 mg cyproheptadine hydrochloride) were placed in a 50-ml volumetric flask. Twenty-five ml 50:50 (v/v) acetonitrile–water was added and swirled until the tablets were completely dissolved and then brought to volume with acetonitrile–water. The amount of cyproheptadine in the tablets was calculated from the linear regression of the standard curve.

A solution of powdered excipients without cyproheptadine hydrochloride was prepared at a concentration equal to five tablets in a 50-ml solution. No interferences from other ingredients or contaminants in the analysis were detected in the blank solution.

Three samples of the powdered excipient spiked with cyproheptadine gave recoveries of 100.4, 100.0, and 99.8% (mean = 100.1 ± 0.3%).

RESULTS AND DISCUSSION

Cyproheptadine (a weak aliphatic base) pairs with octanesulfonate in a weakly acidic mobile phase. A mobile phase of acetonitrile–aqueous solution (85:15) (0.01 *M* octanesulfonic acid, 1% acetic acid, 0.5% triethylamine) gave the best separation (Fig. 1) with cyproheptadine resolved from other ingredients (Fig. 2) with no interferences from contaminants or excipients.

Table II—Assays of Three Production Lots

No. Lot	Theoretical Concentration, mg/tablet	Obtained Concentration, mg/tablet Replicate Analyses 1	2	3	Mean	*SD*
1	0.667	0.639	0.635	0.637	0.637	0.002
2	0.667	0.649	0.628	0.667	0.648	0.020
3	0.667	0.616	0.653	0.627	0.632	0.019

A comparison of analyses of cyproheptadine dissolved in distilled, deionized water, simulated gastric fluid [USP XX (2)], and simulated intestinal fluid [USP XX (2)] showed irregular results (Table I). Preliminary results indicate that dissolution is slow in the simulated fluids with total release times of several hours.

Since water appeared to be the best dissolution solvent, a mixture of acetonitrile–water was used, which made the resultant solution more compatible with the mobile phase. The assay of three production lots of tablets was measured to be 95.5, 97.2, and 94.8% of theoretical content (Table II). The method precision by triplicate assays was 0.3, 3.1, and 3.0%, respectively.

Synthesis and Anticonvulsant Testing of 4-Phenylsemicarbazides

MILTON J. KORNET ˣ and JOHN YEOU-RUOH CHU

Abstract □ A series of compounds based on the semicarbazide structure have been synthesized. Anticonvulsant activity was found in a majority of the compounds using both the maximal electroshock seizure and the subcutaneous pentylenetetrazol seizure threshold tests. Activity of the compounds was weaker than the 1,1,2-trisubstituted semicarbazides previously reported.

Keyphrases □ 4-Phenylsemicarbazides—synthesis and anticonvulsant activity □ Anticonvulsants—synthesis of 4-phenylsemicarbazides

Earlier work (1–5) on the synthesis and anticonvulsant activity of 4-phenylsemicarbazides was concerned primarily with compounds in which N-1 and N-2 are fully substituted by alkyl or aryl residues. To obtain additional information regarding structure–activity relationships for these types of compounds, it was desirable to prepare the series of compounds represented by III. This series differs from all of the previous series in that the compounds contain a hydrogen atom at N-2. This series includes 2-methyl, 2,6-dimethyl, and 2-chloro-6-methyl substituents in the aromatic ring since such substitution generally proved to be optimal in the previous series of 4-phenylsemicarbazides studied (1, 3).

RESULTS AND DISCUSSION

1,1-Disubstituted hydrazines (II) readily added to aryl isocyanates (I) and afforded III in good yields (Scheme I, Table I). Several different 1,1-disubstituted hydrazines were used (Table I) including the cage-like compound, 3-amino-3-azabicyclo[3.2.2]nonane. The latter compound

0022-3549/83/1000-1213$01.00/0

Table I—Dissolution of Cyproheptadine Hydrochloride

Dissolution Medium	Sample Identification	Peak[a] Area ($\times 10^6$)	Cyproheptadine Hydrochloride Available, %
Distilled water	USP reference standard	6.859	100
Distilled water	Cyproheptadine hydrochloride (used in tablet formulation)	6.410	93.4
Distilled water	Blank powder	None detected	
Simulated gastric fluid	USP reference standard	2.973	43.3
Simulated gastric fluid	Tablets	2.932	42.7
Simulated intestinal fluid	USP reference standard	3.369	49.1
Simulated intestinal fluid	Tablets	0.784	11.4

[a] One determination each.

Analytical Procedure—Five tablets (each containing approximately 0.7 mg cyproheptadine hydrochloride) were placed in a 50-ml volumetric flask. Twenty-five ml 50:50 (v/v) acetonitrile–water was added and swirled until the tablets were completely dissolved and then brought to volume with acetonitrile–water. The amount of cyproheptadine in the tablets was calculated from the linear regression of the standard curve.

A solution of powdered excipients without cyproheptadine hydrochloride was prepared at a concentration equal to five tablets in a 50-ml solution. No interferences from other ingredients or contaminants in the analysis were detected in the blank solution.

Three samples of the powdered excipient spiked with cyproheptadine gave recoveries of 100.4, 100.0, and 99.8% (mean = 100.1 ± 0.3%).

RESULTS AND DISCUSSION

Cyproheptadine (a weak aliphatic base) pairs with octanesulfonate in a weakly acidic mobile phase. A mobile phase of acetonitrile–aqueous solution (85:15) (0.01 *M* octanesulfonic acid, 1% acetic acid, 0.5% triethylamine) gave the best separation (Fig. 1) with cyproheptadine resolved from other ingredients (Fig. 2) with no interferences from contaminants or excipients.

Table II—Assays of Three Production Lots

No. Lot	Theoretical Concentration, mg/tablet	Obtained Concentration, mg/tablet Replicate Analyses 1	2	3	Mean	*SD*
1	0.667	0.639	0.635	0.637	0.637	0.002
2	0.667	0.649	0.628	0.667	0.648	0.020
3	0.667	0.616	0.653	0.627	0.632	0.019

A comparison of analyses of cyproheptadine dissolved in distilled, deionized water, simulated gastric fluid [USP XX (2)], and simulated intestinal fluid [USP XX (2)] showed irregular results (Table I). Preliminary results indicate that dissolution is slow in the simulated fluids with total release times of several hours.

Since water appeared to be the best dissolution solvent, a mixture of acetonitrile–water was used, which made the resultant solution more compatible with the mobile phase. The assay of three production lots of tablets was measured to be 95.5, 97.2, and 94.8% of theoretical content (Table II). The method precision by triplicate assays was 0.3, 3.1, and 3.0%, respectively.

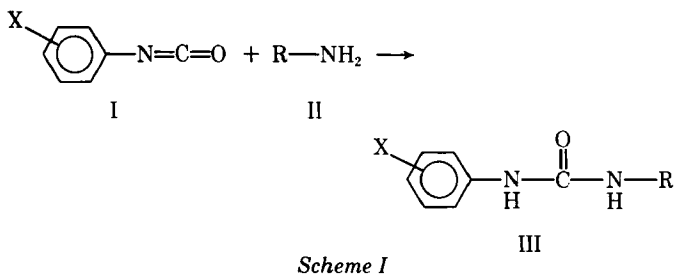
[a] A, ethyl acetate; B, ethyl acetate–methanol. [b] M. Wilcox, *J. Med. Chem.*, 11, 171 (1968) reported mp, 142–143°.

was obtained in two steps *via* the intermediate *N*-nitroso derivative from commercially available 3-azabicyclo[3.2.2]nonane (6). Additionally, ethyl (1-methylhydrazino)acetate was prepared from methylhydrazine and ethyl bromoacetate (7).



Scheme I

Compounds IIIa–IIIt were tested in the maximal electroshock seizure (MES) and subcutaneous pentylenetetrazol seizure threshold (scMet) tests for anticonvulsant activity and in the rotorod test for neurotoxicity in male Carworth Farms No. 1 mice by reported procedures (1). In the MES test, compounds IIIb, IIId, IIIg, IIIi, IIIj, IIIk, IIIl, and IIIn exhibited activity at 300 mg/kg at 30 min. Only IIIb showed toxicity at this dosage level. Compounds IIIb, IIIc, and IIIh showed activity at the same dosage at 4 hr. Compound IIIc was the only compound active at 100 mg/kg (30 min).

Five compounds (IIIb, IIIg, IIIh, IIIi, and IIIm) were active in the scMet test at 300 mg/kg at 30 min. Compound IIIh was also active at this same dosage at 4 hr. Two compounds underwent further testing. Compounds IIIc and IIIh exhibited MES ED_{50} = 76 (61–90, 95% C.I. [confidence interval]) and 282 (244–319, 95% C.I.) mg/kg; scMet ED_{50} = 222 (146–326, 95% C.I.) and 424 (240–695, 95% C.I.) mg/kg and TD_{50} = 210 (165–272, 95% C.I.) and 528 (390–698, 95% C.I.) mg/kg, respectively.

These data indicate that 4-phenylsemicarbazides derived from 1,1-dialkylated hydrazines possess anticonvulsant activity; however, it is of a lower order than that shown by 4-phenylsemicarbazides derived from 1,1,2-trialkylated hydrazines (1, 3). The cage compounds IIIq, IIIr, and IIIs were uniformly inactive and these results are consistent with the poor activity found for other cage compounds (4, 5).

EXPERIMENTAL[1]

Ethyl (1-Methylhydrazino)acetate—A solution of 16.7 g (0.1 mole) of ethyl bromoacetate in 17 ml of benzene was added dropwise with magnetic stirring over a 90-min period to a solution of 9.2 g (0.2 mole) of methylhydrazine in 50 ml of benzene. After the reaction mixture had stirred overnight at room temperature, the benzene phase was decanted and the salt residue was washed three times with 15 ml of benzene. The benzene was distilled through a 1-ft Vigreux column at 42 mm Hg. The residue was then distilled and afforded 8.82 g (67%) of a colorless oil, bp 88° (21 mm); IR (film): 1740 cm^{-1} (C=O).

Anal.—Calc. for $C_5H_{12}N_2O$: C, 45.44; H, 9.15; N, 21.20. Found: C, 45.29; H, 9.26; N, 21.31.

[1] Melting points were determined on a Thomas-Hoover melting point apparatus and are uncorrected. The IR spectra were taken on a Perkin-Elmer 700 spectrophotometer as either liquid films or potassium bromide pellets. NMR spectra were recorded on a Varian EM-360 or T-60 spectrometer, using tetramethylsilane as the internal reference. Mass spectra were obtained on a RMU-7 double-focusing spectrometer by Hitachi/Perkin-Elmer. Elemental analyses were performed by Baron Consulting Co., Orange, Conn. All compounds exhibited ^{1}H-NMR and mass spectra consistent with the structures shown.

4-Phenylsemicarbazides (III)—Compound IIIb was prepared by the dropwise addition of a solution of 2.66 g (0.0180 mole) of 2,6-dimethylphenyl isocyanate (I) in 6 ml of dry benzene to a solution of 1.20 g (0.020 mole) of 1,1-dimethylhydrazine in 10 ml of dry benzene at room temperature. After ~10 min heat was evolved. The mixture was heated for 2.5 h in an oil bath (85°). The solvent was evaporated under reduced pressure, and the residue was recrystallized from ethyl acetate and gave 3.40 g (91%) of white crystalline product, mp 156–158°.

Investigation of the β-Cyclodextrin–Hydrocortisone Inclusion Compound

SYLVAN G. FRANK ˣ and DALIA R. KAVALIUNAS *

Received March 25, 1982, from the *Division of Pharmaceutics and Pharmaceutical Chemistry, College of Pharmacy, The Ohio State University, Columbus, OH 43210.* Accepted for publication September 8, 1982.

*Present Address: Vicks Division, Richardson-Merrell Inc., Wilton, CT 06897.

Abstract □ The formation of an inclusion compound by β-cyclodextrin with hydrocortisone has been studied by proton magnetic resonance (^{1}H-NMR) and phase solubility analysis. The magnitude of the chemical shifts of the interior and exterior β-cyclodextrin protons in the presence of hydrocortisone indicated that hydrocortisone is included within the β-cyclodextrin cavity and probably interacts with protons on the edge of the torus. The overall stoichiometry of the inclusion compound was not a single, simple relationship, but was unusual in that it was variable and apparently dependent on the relative amounts of hydrocortisone and β-cyclodextrin in the system.

Keyphrases □ Inclusion complexes—β-cyclodextrin–hydrocortisone, phase solubility analyses, ^{1}H-NMR □ β-Cyclodextrin–hydrocortisone—inclusion complexes, phase solubility analyses, ^{1}H-NMR □ Phase solubility analyses—β-cyclodextrin–hydrocortisone, ^{1}H-NMR

The formation of an inclusion compound by dinoprostone (prostaglandin E_2) with β-cyclodextrin has been reported earlier (1). From phase solubility analysis and ^{1}H-NMR spectroscopy it was concluded that a 1:1 complex formed, with the dinoprostone molecule partially included within the β-cyclodextrin cavity and the remainder of the molecule extended to the exterior of the torus.

In the present study attention has been directed to the formation of an inclusion complex between hydrocortisone and β-cyclodextrin. Such an inclusion compound by itself is not necessarily unique; however, these initial studies indicated that an unusual dependence apparently existed between the stoichiometry of the interaction and the concentration of β-cyclodextrin.

EXPERIMENTAL

The experimental procedure was similar to that employed previously (1). β-Cyclodextrin[1] was recrystallized twice from distilled water and dried under vacuum at 60°; hydrocortisone USP[2], was used as received; and water was double-distilled and deionized. Samples for ^{1}H-NMR spectroscopy were prepared by saturating a 2% w/v solution of β-cyclodextrin in D_2O[3] with hydrocortisone. Excess complex was allowed to precipitate and the supernatant solution of the inclusion compound was decanted. ^{1}H-NMR spectra at 100 MHz[4] were determined on the supernatant in standard 5-mm tubes.

Samples for phase solubility analysis were prepared by placing excess quantities of hydrocortisone (0.021, 0.040, or 0.060 g) with increasing amounts of β-cyclodextrin into 20-ml culture tubes containing 10 ml of water. The samples were sealed (with screw caps[5]) and rotated end-over-end at ~41 rpm for 24 hr in a thermostated water bath at 30 ± 0.1°. Aliquots of the supernatant were filtered through a prerinsed membrane filter (0.45 μm)[6] and spectrophotometrically assayed at 248 nm.

The formation of an inclusion compound by dinoprostone (prostaglandin E_2) with β-cyclodextrin has been reported earlier (1). From phase solubility analysis and ^{1}H-NMR spectroscopy it was concluded that a 1:1 complex formed, with the dinoprostone molecule partially included within the β-cyclodextrin cavity and the remainder of the molecule extended to the exterior of the torus.

In the present study attention has been directed to the formation of an inclusion complex between hydrocortisone and β-cyclodextrin. Such an inclusion compound by itself is not necessarily unique; however, these initial studies indicated that an unusual dependence apparently existed between the stoichiometry of the interaction and the concentration of β-cyclodextrin.

EXPERIMENTAL

The experimental procedure was similar to that employed previously (1). β-Cyclodextrin[1] was recrystallized twice from distilled water and dried under vacuum at 60°; hydrocortisone USP[2], was used as received; and water was double-distilled and deionized. Samples for ^{1}H-NMR spectroscopy were prepared by saturating a 2% w/v solution of β-cyclodextrin in D_2O[3] with hydrocortisone. Excess complex was allowed to precipitate and the supernatant solution of the inclusion compound was decanted. ^{1}H-NMR spectra at 100 MHz[4] were determined on the supernatant in standard 5-mm tubes.

Samples for phase solubility analysis were prepared by placing excess quantities of hydrocortisone (0.021, 0.040, or 0.060 g) with increasing amounts of β-cyclodextrin into 20-ml culture tubes containing 10 ml of water. The samples were sealed (with screw caps[5]) and rotated end-over-end at ~41 rpm for 24 hr in a thermostated water bath at 30 ± 0.1°. Aliquots of the supernatant were filtered through a prerinsed membrane filter (0.45 μm)[6] and spectrophotometrically assayed at 248 nm.

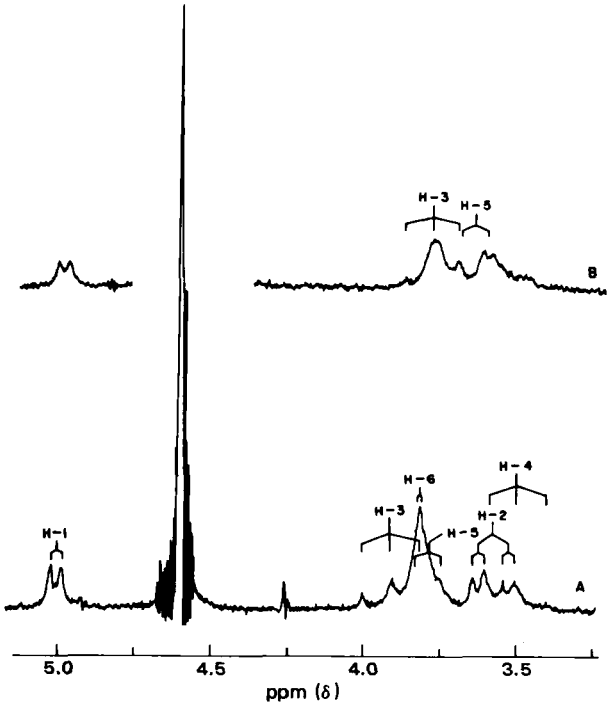

Figure 1—*^{1}H-NMR spectra of β-cyclodextrin (A) and the β-cyclodextrin–hydrocortisone inclusion compound (B) in D_2O.*

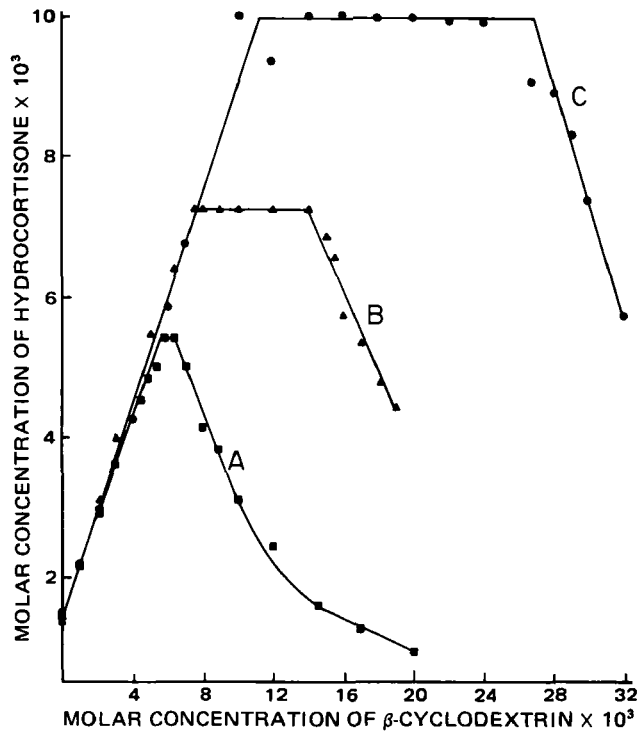

Figure 2—*Phase solubility diagram of β-cyclodextrin–hydrocortisone inclusion compounds at 30 ± 0.1°. Concentrations of hydrocortisone in excess of its solubility (per 10 ml of solution) and the stoichiometries of the soluble complexes (in moles of β-cyclodextrin/mole of hydrocortisone) were: A, 0.021 g and 1.4; B, 0.040 g and 1.7; and C, 0.060 g and 2.4, respectively.*

RESULTS AND DISCUSSION

The ^{1}H-NMR spectra of β-cyclodextrin and of the β-cyclodextrin–hydrocortisone inclusion compound are shown in Fig. 1. The β-cyclodextrin spectrum (Fig. 1A) is presented as a continuous spectrum; however, the spectrum of the inclusion compound (Fig. 1B) is broken for ease in comparison of the two spectra. Except for the HDO and HOH peaks, at ~4.6 ppm in both spectra, all of the peaks shown in Fig. 1 are those of β-cyclodextrin. In the case of the β-cyclodextrin–hydrocortisone inclusion compound, the hydrocortisone protons would be expected to appear further upfield, but due to their low concentration they were not detected.

From NMR and X-ray studies, the glucose units of β-cyclodextrin have been found to be in the C-1 chair configuration (2, 3), with primary and secondary hydroxyl groups around the opening of the torus. H-1, H-2, and H-4 are on the exterior and H-3, H-5, and possibly H-6 are located within the cavity. Other studies have shown that H-3 and H-5 undergo shielding by the guest component upon inclusion compound formation (3).

In the presence of hydrocortisone, the β-cyclodextrin spectrum is shifted upfield and reduced in magnitude due to the lower solubility of the inclusion compound compared with that of β-cyclodextrin alone. Similar behavior was found earlier for the dinoprostone–β-cyclodextrin systems (1). The anomeric hydrogens, H-1, appear as a doublet at the farthest downfield position and are gauche, whereas the rest of the β-cyclodextrin protons are axial. Due to their fixed position, the HDO and HOH peaks were used as internal standards in the measurement of the chemical shifts of the β-cyclodextrin protons in the presence of hydrocortisone, relative to their positions in the absence of hydrocortisone. Still farther upfield is a sideband (Fig. 1A), followed by a group of peaks corresponding to the remaining β-cyclodextrin protons. The sideband appeared only in the β-cyclodextrin spectrum.

The chemical shifts of the β-cyclodextrin protons in the presence of hydrocortisone are given in Table I. The H-3 and H-5 protons, which are located within the β-cyclodextrin cavity, show significant chemical shifts, and therefore underwent the greatest shielding effect due to the presence of the guest component. By contrast, H-1 and H-6 show much lower shifts, indicating a lower probability of interaction with hydrocortisone. The greater chemical shift of the H-5 protons compared with that of the H-3 protons suggest that on the ^{1}H-NMR time scale, more hydrocortisone entered the cavity from the H-5 side of the torus than from the H-3 side. Inclusion compounds of this type can be expected to occur by penetration from either side; however, complexes formed with hydrocortisone partially included on the H-5 side are apparently in greatest abundance. Although the stoichiometry of the β-cyclodextrin–hydrocortisone complex cannot be determined conclusively from ^{1}H-NMR observations, the strong chemical shifts of H-3 and H-5 suggest that the included portion of one hydrocortisone molecule fits snugly within the cavity, in close proximity to these protons. This observation is supported by a CPK space-filling model of the inclusion compound, which suggests that more than one molecule of hydrocortisone per molecule of β-cyclodextrin (each partially within the cavity) would result in a poor fit of either guest molecule, giving a very loosely bound complex.

Table I—Hydrocortisone-Induced Chemical Shifts of β-Cyclodextrin Protons

Proton	Δδ, ppm
H-1	0.03
H-2	0.01
H-3	0.11
H-4	0.01
H-5	0.13
H-6	0.02

Phase solubility analysis indicated, however, that the inclusion compound was not of simple 1:1 stoichiometry, but that the nature of the complex apparently was dependent on the total amount of hydrocortisone present relative to that of β-cyclodextrin (Fig. 2). While the general characteristics of portions of the phase solubility diagram in Fig. 2 follow that of the *p*-aminobenzoic acid–caffeine system reported by Higuchi and Lach (4), the molar concentration of hydrocortisone at the plateau region anomalously increased as the total amount of hydrocortisone increased. The approximate stoichiometries of the three β-cyclodextrin–hydrocortisone inclusion compounds represented by curves A, B, and C in Fig. 2 are 1.4, 1.7, and 2.4 molecules of β-cyclodextrin per molecule of hydrocortisone, respectively. Obviously these are difficult systems to interpret, and additional studies are in order to confirm the nature of the complex(es) and the mechanism of formation.

Metabolism of Cathinone to *d*-Norpseudoephedrine in Humans

A. N. GUANTAI and C. K. MAITAI ˣ

Received August 7, 1981, from the *Department of Pharmacy, University of Nairobi, Nairobi, Kenya.* Accepted for publication September 16, 1982.

Abstract □ Cathinone, a potent psychostimulant isolated from young shoots of *Catha edulis* was given to four human volunteers. Examination of urine collected from the volunteers at predetermined intervals showed the presence of unchanged cathinone, *d*-norpseudoephedrine, and two unidentified basic substances. The observed biotransformation of cathinone to the less potent psychostimulant, *d*-norpseudoephedrine involves reduction of a ketone group to alcohol, a common metabolic pathway in humans.

Keyphrases □ Cathinone—metabolism to *d*-norpseudoephedrine in humans □ *Catha edulis*—metabolism in humans

Catha edulis Forsk grows well in several countries of Eastern, Central, and Southern Africa. Because of the psychostimulant and mental dependence associated with habitual chewing of young shoots of this plant, it has been investigated extensively. Although chemical investigation of *C. edulis* goes back to the 19th century, the most significant result was obtained by Wolfes in 1930 (1) when he isolated and identified *d*-norpseudoephedrine, a CNS stimulant with amphetamine-like properties. There was some controversy as to whether the amount of *d*-norpseudoephedrine present in *Catha* material could account wholly for the observed psychostimulant effect, thus providing impetus for further chemical investigation (2). Several years later, a second phenylalkylamine closely related to *d*-norpseudoephedrine was isolated and named "cathinone" (3). This compound is a much more potent psychostimulant than *d*-norpseudoephedrine, and has attracted much attention as a potential drug of abuse (4).

The excretion of *d*-norpseudoephedrine in human urine has been investigated (5). In preliminary investigations involving known habitual chewers of *C. edulis*, *d*-norpseudoephedrine was shown to be the major compound present in urine when it was collected several hours after chewing *C. edulis*. Since cathinone is a major constituent of the young shoots of *C. edulis*, it seemed odd that it was absent or present only in trace amounts in several urine samples examined. A literature survey showed that the fate of cathinone in humans has not been investigated and accordingly this work was undertaken.

EXPERIMENTAL

Collection of Urine Samples—Four volunteers who had never chewed the material before participated in the experiment. Two volunteers were given 16 mg of cathinone extracted from young shoots of *C. edula* by preparatory TLC (3, 6), while the other two were given 16 mg of synthetic cathinone. All four volunteers had only milk for breakfast. Urine samples were collected at the following intervals: 0 (control), 0–4, 4–8, 8–12, 12–15, and 15–24 hr. Each urine sample was examined for the presence of cathinone and related substances as described below.

Examination of Urine for Cathinone, *d*-Norpseudoephedrine, and Related Basic Substances— Approximately 40 ml of urine was taken, 2–3 ml of strong lead acetate solution (7) was added, and after thorough mixing the precipitated proteins were removed by centrifugation. The supernatant was acidified to pH 5–6 with 0.1 *N* sulfuric acid and any precipitate removed by centrifugation. The acidified urine sample was extracted with chloroform, four times to remove acids and neutrals. The aqueous urine portion was then alkalinized (pH 9) using dilute ammonia solution and extracted with 4 × 100 ml of chloroform. The combined chloroform was distilled off at 40° using a rotary evaporator and the residue examined by TLC.

Examination of residue for *d*-norpseudoephedrine, cathinone, and related basic substances using TLC was carried out as follows. The residues were taken up in 2 ml of chloroform and ~10 μl was spotted on TLC plates coated with silica gel[1], and activated at 100° for 1 hr. Cathinone and *d*-norpseudoephedrine were spotted on the same TLC plates as the basic residues from urine. The plates were developed in either of the following solvent systems: (*A*) ethyl acetate–methanol–ammonia (17:2:1) or (*B*) cyclohexane–chloroform–diethylamine (5:4:1). Usually the plates were developed for 35–45 min. After development the plates were examined under UV light, then sprayed with 0.3% ninhydrin solution (8) after which they were heated at 105° for 10 min. The intensity of fluorescence under UV light and that of color after spraying with ninhydrin solution were judged on a 3-point scale as shown in the results. Where cathinone or *d*-norpseudoephedrine (or both) was not detected, the chloroform basic residue was concentrated almost to dryness and the experiment repeated.

The presence of *d*-norpseudoephedrine and cathinone in the basic residue extracted from urine was also investigated with a gas–liquid chromatograph[2] equipped with a flame ionization detector. The GLC column used was glass, 4-mm i.d. × 1.5 m long, packed with nonacid washed Chromosorb W (100–200 mesh)[3] coated with 1% polyethylene glycol 20 *M* (carbowax 20 *M*)[4]. The column was conditioned for 8–10 hr at 230°. The experimental operating conditions were as follows: hydrogen pressure, 1.4 kg/cm^2; condensed air pressure, 0.65 kg/cm^2; nitrogen flow rate 30 ml/min; column temperature programmed from 80–200° at 5°/min and finally left at 200° for 10 min; chart speed, 1 cm/2 min. The retention times and peaks were recorded[5].

For quantitative analysis, the areas under the curves were measured by the method of triangulation (9) and compared with areas obtained with standard solutions of cathinone and *d*-norpseudoephedrine. The standard solutions were prepared by dissolving 5 mg of either cathinone or *d*-norpseudoephedrine in 40 ml of control urine and subjecting this to the same extraction procedure as the experimental urine. It was then assumed that the percentage recovery of both compounds from experi-

Table I—TLC Examination of Basic Residue from Urine of Volunteers who had Ingested Cathinone[a]

Urine Sample	Collection Time, hr[b]	Substance Detected Cathinone	Substance Detected *d*-norpseudoephedrine
1	0 (control)	none	none
2	0–4	++[c]	++
3	4–8	++	++
4	8–12	+[d]	++
5	12–15	0[e]	+
6	15–24	0	+

[a] Two unidentified substances in trace amount, associated with cathinone were observed in samples 2, 3, 4 and 5. The R_f values of unidentified substances in solvent system *A* were 0.71 and 0.85. [b] After ingestion of cathinone. [c] ++ = Easily detected. [d] + = Trace amount. [e] 0 = not detected.

mental and control urine was approximately the same. Control experiments had shown recovery of >90% under the standardized conditions.

RESULTS

Both cathinone and *d*-norpseudoephedrine separated well in solvent systems *A* and *B*, the R_f values being as follows: *A*-cathinone 0.55, *d*-norpseudoephedrine 0.42; *B*-cathinone 0.38, *d*-norpseudoephedrine 0.47. Results of TLC are summarized in Table I. Results of GLC were in agreement with those obtained with TLC. With GLC only one *d*-norpseudoephedrine peak was observed at 165° (retention time 7.5 min) while the major cathinone peak was observed at 151° (retention time 5.1 min). Another peak associated with cathinone appeared at 145° (retention time 3.7 min). The results were fairly reproducible, and it was possible to calculate the amount of cathinone and *d*-norpseudoephedrine excreted in the urine. There was no significant variation in the excretion pattern of either cathinone or *d*-norpseudoephedrine in the four volunteers even when the experiment was repeated after 4 weeks. The amount of cathinone and *d*-norpseudoephedrine recovered from the urine of each of the volunteers agreed to within 20% and the results are summarized in Table II.

DISCUSSION

Results obtained in the present study show that some of the cathinone ingested by humans is metabolized to *d*-norpseudoephedrine and possibly two other unidentified metabolites. Metabolism of cathinone to *d*-norpseudoephedrine involves reduction of a ketone group to alcohol, a fairly common metabolic pathway in humans, catalyzed by liver microsomal enzymes. In several drugs (*e.g.*, cortisone and warfarin) reduction of a ketone or aldehyde to an alcohol is often associated with significant change in potency. Usually both the parent drug and the metabolite will contribute to the biological activity, the net result often being determined by such pharmacokinetic parameters as the rate of elimination. The finding that little, if any cathinone is excreted in human urine after 15 hr, may be important in forensic toxicology since *d*-norpseudoephedrine, also present in *C. edulis*, is known to be excreted over a much longer period.

Table II—Amount of Cathinone and *d*-Norpseudoephedrine Excreted in Human Urine (Result of GLC)

Urine Sample(s)	Cathinone Recovered, mg	*d*-norpseudoephedrine Recovered, mg
2 (0–4 hr after ingestion of cathinone)	0.72 ± 0.12 (4.4% of amount ingested)	3.2 ± 0.3 (equivalent to 20% ingested cathinone)
3, 4, 5, 6 (4–24 hr after ingestion of cathinone)	1.04 ± 0.08 (6.5% of amount ingested)	9.9 ± 0.6 (equivalent to 61.9% ingested cathinone)
2, 3, 4, 5, 6 (0–24 hr)	1.765 (11% of amount ingested)	13.12 (equivalent to 81.9% ingested cathinone)

Nonparametric Pharmacokinetic Calculations: One-Compartment Open Model

WILLIAM H. SHELVER ˣ and FRED F. FARRIS

Received May 25, 1982, from *North Dakota State University, Department of Pharmaceutical Sciences, College of Pharmacy, Fargo, ND 58105.* Accepted for publication September 8, 1982.

Abstract □ A nonparametric method suitable for estimation of parameters in nonlinear problems was developed for one-compartment pharmacokinetic data. The method was tested by running 500 simulations with various types of error and comparing the results with a standard nonlinear regression computation. The nonparametric method was superior to nonlinear regression techniques if the assumptions for the error structure of the regression were not true.

Keyphrases □ One-compartment pharmacokinetic model—nonparametric method, comparison with standard nonlinear regression procedure, estimation of parameter

Calculating the parameters of a pharmacokinetic model containing more than one exponential term requires the use of either the method of residuals (sometimes referred to as stripping or feathering) or one of various nonlinear regression techniques. As they have been applied classically, both general techniques have proven somewhat

Talalaj for identifying the plant material used in the present work. A specimen of the plant is deposited in the Department of Pharmacy, University of Nairobi.

Nonparametric Pharmacokinetic Calculations: One-Compartment Open Model

WILLIAM H. SHELVER ˣ and FRED F. FARRIS

Received May 25, 1982, from *North Dakota State University, Department of Pharmaceutical Sciences, College of Pharmacy, Fargo, ND 58105.* Accepted for publication September 8, 1982.

Abstract □ A nonparametric method suitable for estimation of parameters in nonlinear problems was developed for one-compartment pharmacokinetic data. The method was tested by running 500 simulations with various types of error and comparing the results with a standard nonlinear regression computation. The nonparametric method was superior to nonlinear regression techniques if the assumptions for the error structure of the regression were not true.

Keyphrases □ One-compartment pharmacokinetic model—nonparametric method, comparison with standard nonlinear regression procedure, estimation of parameter

Calculating the parameters of a pharmacokinetic model containing more than one exponential term requires the use of either the method of residuals (sometimes referred to as stripping or feathering) or one of various nonlinear regression techniques. As they have been applied classically, both general techniques have proven somewhat

[a] Variance = 0.2, k_a = 2, K = 0.2, FD/V = 3.0, the outlier randomly selected from one of the seven points with a variance from 1 × 0.2 (no outlier) to 8 × 0.2. The concentrations were computed at t = 0.5, 1.0, 1.5, 2.0, 4.0, 8.0, and 12 hr. [b] Numbers in parentheses are coefficients of variation.

unsatisfactory. The method of residuals lacks objectivity and may be theoretically biased, and the nonlinear regression techniques may fail to converge under certain circumstances (1).

Recently, several investigators have examined the use of nonparametric methods and have found them to be superior to parametric regression techniques in the analysis of enzyme kinetic (2) and receptor-binding data (3). Indeed, some statisticians are beginning to question the general application of conventional regression procedures. Endrenyi and Tang (4) found that a nonparametric method was superior to conventional linear regression techniques when applied to the analysis of a single exponential kinetic model. Koup (5) used a similar technique, in combination with the method of residuals, to solve for the parameters in a biexponential model using a nonparametric method to determine the best fit for the terminal portion of the curve. The second linear component was determined by the method of residuals and the appropriate parameters ascertained. It was found that, for his system, the nonparametric results were markedly superior for two constants and slightly inferior for the remaining two constants.

The purpose of this paper is to formulate a nonparametric method for the solution of nonlinear equations. The method is tested by its performance with a conventional nonlinear regression technique, using data with different error structures and in the presence of outliers of increasing importance.

BACKGROUND

In 1974, Eisenthal and Cornish-Bowden (6) developed a nonparametric method for processing enzymatic data. The method, frequently referred to as a "direct linear plot," was originally devised as a graphical procedure for estimating enzyme kinetic parameters. Basically it involves plotting all possible sets of data in parameter space. This plot leads to a series of line intersections, where each intersecting point represents a different estimate of the desired parameters. The median value of this series of parameters is then selected as the best estimate. Since medians rather than means are used, the method is extremely resistant to the effects of outliers, providing at least the majority of points are good. In searching the literature, no reference applying this nonparametric technique to determine the parameters of nonlinear equations was found.

One approach is to divide the experimental data into sets, which allows the determination of the desired parameters and the estimation of the parameter values for each set. The selected nonparametric technique is then applied to the resultant list of estimates. The most complex problem is determining the parameter estimates for each set. This can be accomplished by using numerical solutions to solve the nonlinear equations. Application of this technique to the one-compartment, first-order absorption pharmacokinetic model follows.

THEORETICAL

The one-compartment, first-order absorption model in pharmacokinetics is described by the general equation:

$$C = \frac{FD}{V}\frac{k_a}{k_a - K}(e^{-Kt} - e^{-k_a t}) \qquad \text{(Eq. 1)}$$

where C corresponds to the plasma drug concentration at time t, F is the fraction of dose absorbed, D is the dose, V is the volume of distribution, and k_a and K are the absorption and elimination rate constants, respectively. If FD/V is treated as a single value, then the equation can be solved once we know the three parameters FD/V, K and k_a. The determination of three parameters requires the solution of three simultaneous equations of the form:

$$C_1 = \frac{FD}{V}\frac{k_a}{k_a - K}(e^{-Kt_1} - e^{-k_a t_1}) \qquad \text{(Eq. 2)}$$

$$C_2 = \frac{FD}{V}\frac{k_a}{k_a - K}(e^{-Kt_2} - e^{-k_a t_2}) \qquad \text{(Eq. 3)}$$

$$C_3 = \frac{FD}{V}\frac{k_a}{k_a - K}(e^{-Kt_3} - e^{-k_a t_3}) \qquad \text{(Eq. 4)}$$

Equations 2–4 are generated by substituting the values for three data points (time and concentation) into the general equation (Eq. 1). Unfortunately, the nonlinear nature of these equations makes them difficult to solve algebraically. To simplify the problem, ratios of the above equations were taken to give Eqs. 5 and 6:

$$\frac{C_1}{C_2} = \frac{e^{-Kt_1} - e^{-k_a t_1}}{e^{-Kt_2} - e^{-k_a t_2}} = R_1 \qquad \text{(Eq. 5)}$$

$$\frac{C_2}{C_3} = \frac{e^{-Kt_2} - e^{-k_a t_2}}{e^{-Kt_3} - e^{-k_a t_3}} = R_2 \qquad \text{(Eq. 6)}$$

This step eliminates FD/V from the equations, and yields two equations and two unknowns which can be solved using the Newton-Raphson method (7) for approximating the roots of simultaneous equations. This technique uses expressions in the form of those shown in Eqs. 7 and 8:

$$X = X_0 - \frac{\frac{F\partial G}{\partial Y} - \frac{G\partial F}{\partial Y}}{\frac{\partial G}{\partial Y}\frac{\partial F}{\partial X} - \frac{\partial F}{\partial Y}\frac{\partial G}{\partial X}} \qquad \text{(Eq. 7)}$$

$$Y = Y_0 + \frac{\frac{F\partial G}{\partial X} - \frac{G\partial F}{\partial Y}}{\frac{\partial G}{\partial Y}\frac{\partial F}{\partial X} - \frac{\partial F}{\partial Y}\frac{\partial G}{\partial X}} \qquad \text{(Eq. 8)}$$

where X is unknown 1, *i.e.*, K_1; Y is unknown 2, *i.e.*, k_{a_1}, and F and G are Eqs. 5 and 6. Once the appropriate partial derivatives are taken then the parameters K and k_a are estimated by iteration until they do not change significantly. The third parameter, FD/V, is then determined by substituting the estimated values of K and k_a into Eq. 9.

$$FD/V = \frac{C(k_a - K)}{k_a(e^{-Kt} - e^{-k_a t})} \qquad \text{(Eq. 9)}$$

The above process gives one set of parameter estimates corresponding to the use of one set of three data points. Another combination of three

[a] Coefficient of variation = 5%, $k_a = 2$, $K = 0.2$, $FD/V = 3.0$, the outlier randomly selected from one of the seven points with a coefficient of variation from $1 \times 0.05 \times C$ (no outlier) to $8 \times 0.05 \times C$. The concentrations were computed at $t = 0.5$, 1.0, 1.5, 2.0, 4.0, 8.0, and 12 hr. [b] Numbers in parentheses are coefficients of variation.

data points is selected and the procedure repeated to give a new set of parameter estimates. The process is again repeated until all possible combinations of data have been used. In the present paper, seven data points (seven time and concentration combinations) were used. This gave a list of 35 estimates (all combinations of seven items taken three at a time). The median value from each list was then selected as the best estimate for that particular parameter. If desired, confidence limits can be obtained by the method of Cornish-Bowden *et al.* (8).

In their comparison of methods of analyzing enzyme kinetic data, Atkins and Nimmo (2) emphasize the importance of thoroughly testing new methods by simulation before applying them in practice. To test the present method, 500 simulations were performed as described in the *Experimental* section.

EXPERIMENTAL

To provide an adequate test for the method, two computer programs[1] were formulated to generate data and determine parameters. Both programs generated data by taking assumed constants ($k_a = 2.00$, $FD/V = 3.00$ and $K = 0.200$), calculating the concentration seven times ($t = 0.5$, 1.0, 1.5, 2.0, 4.0, 8.0, and 12.0), and adding randomly generated, normally distributed error with a mean of 0 and a variance of one times either a percentage (5%) of the generated concentration (constant coefficient of variation) or a constant (0.02) (constant variance), depending on the error structure desired. Both programs generated the same set of data points. Outliers were produced by randomly selecting one of the times and multiplying the error added to the term by a constant (1, 2, 4, 6, or 8). The outlier concentration thus generated had a larger error than the rest of the points. One program analyzed the data by a standard nonlinear regression procedure (9), and the other program utilized the proposed nonparametric method. Five hundred simulations were carried out and the average of each parameter was computed along with the coefficient of variation and other summary statistics.

RESULTS AND DISCUSSION

The use of nonweighted, nonlinear regression assumes a constant variance and, as expected in the nonlinear regression technique, performed well with this error structure when no outliers or only a small outlier was present (Table I). As the size of the outlier was increased, the nonparametric method demonstrated its superiority by showing a much smaller coefficient of variation. The presence of one outlier with a variance eight times the variance of the other points gave coefficients of variation for the nonlinear regression twice the corresponding nonparametric coefficients of variation. Neither computational procedure demonstrated appreciable bias.

When an error structure with a constant coefficient of variation was analyzed (Table II) (which violates the assumptions of nonweighted, nonlinear regression), the nonparametric method was slightly superior when no outliers were present, and markedly superior when outliers reached moderate size with regard to coefficients of variation. Although a weighted nonlinear regression would have improved the performance of the nonlinear regression technique, the proper use of weighting is nearly impossible in practice because of lack of knowledge of the appropriate weights. Consequently, the superiority of the nonparametric method is clearly demonstrated. The nonparametric method demonstrated a slight bias.

The nonparametric method is not a panacea for all the ills of pharmacokinetic data processing because of two concerns. Since all possible sets of three data points are utilized in the calculations, a problem exists if these data points do not contain the proper information. For example, the later points in a collection do not contain information concerning k_a if the data are collected after the absorption phase is essentially complete. Consequently, k_a values computed from the later data points will be essentially meaningless and will probably be represented at the extremes of the distribution. Should a sufficient number of these occur, the median may be affected. A second deficiency of the nonparametric method arises from data points too close together. This problem is similar to determining the slope of a line using two points close together. The slope in the case of the line, or the parameter estimates in the case of the nonparametric method, will be determined more by error than by the location of the points. For our simulation, we chose a conventional experimental design, with points selected at short intervals at the onset to ensure a reasonable determination of k_a, and the time period extending over sufficient time to ensure adequate determination of K (roughly 3.5 half-lives). While this experimental design is not optimum for either nonlinear regression or nonparametric determinations, it approximates data normally used for the determination of nonparametric parameters, without straining either computational technology.

Occasionally the nonparametric method will not converge because of either excessive error in the points or too little information for calculating one of the parameters. In our computer program, if the estimated parameter is 100 or 0.01 times the original estimate, the iteration is stopped and the values of 0.01 times or 100 times the original estimate are assigned. This places these values at the extremes (where they would normally be), and the median is relatively unaffected. The Newton–Raphson method is unstable if the estimate is not close to the true value, so the above safeguard prevents instability of the computer program during the simulations. In actual practice, although these results would produce outliers and hence not affect the results, a different algorithm might be beneficial.

In conclusion, the utility of a nonparametric technique for the determination of parameters of nonlinear equations is demonstrated. As anticipated, the nonparametric technique outperforms conventional nonlinear regression computations unless the error structure coincides with the weighting used for the nonlinear regression technique. The general method developed is anticipated to be applicable to other nonlinear problems although appropriate numerical techniques for solving simultaneous nonlinear equations must be developed for the particular model under examination.

Abstract □ UV and fluorescence spectrophotometry were used to establish the analytical profile of a potent myotonia inducer, anthracene-9-carboxylic acid (I). UV spectrophotometry is useful for the determination of I when it is dissolved in physiological solutions (Ringer's, Tyrode's, *etc*). In these fluids there is a linear relationship between UV absorption and I concentration between 500 and 2000 ng/ml ($2.25–9.0 \times 10^{-6}$ *M*). However, in biological fluids there are interferences in the UV absorption due to organic substances. On the other hand, fluorescence spectrophotometry is more sensitive than UV for determinations in plasma and urine. Within the range of 200–1000 ng/ml ($0.9–4.5 \times 10^{-6}$ *M*) fluorescence intensity increases linearly with concentration. Furthermore, when both emission and excitation spectra are combined there are no interferences due to organic substances normally present in those fluids. An extraction procedure of I from plasma and urine is also described, and the importance of I determinations in relation to the problem of this myotonia-inducing aromatic monocarboxylic acid is discussed.

Keyphrases □ Fluorescence spectrophotometry—comparison of UV for quantification of a potent myotonia inducer

Several classes of chemical agents can produce, both *in vivo* and *in vitro*, changes in the function of mammalian skeletal muscle resembling the condition known as myotonia congenita in humans and in goats (1, 2). These agents include the veratrum alkaloids (3), the substitution of chloride ion by other ions that do not cross the muscle membrane (4, 5), a group of hypocholesterolemic substances (6, 7), clofibric acid that reduces the triglyceride levels (8), and other aromatic monocarboxylic acids (9–11). All these substances act directly on the membrane of mammalian skeletal muscle. However, an increasing number of studies in recent years (12–14) have confirmed the early proposal of Bryant and Morales-Aguilera (15) that aromatic monocarboxylic acids induce in mammalian muscle fibers a state that more closely resembles naturally occurring myotonia congenita than do the other agents. Bryant and Morales-Aguilera (15) and Palade and Barchi (16) showed that anthracene-9-carboxylic acid (I) is the most potent inducer of myotonia among the tested aromatic monocarboxylic acids and also that these substances very specifically block the chloride channel. The availability of chemical agents whose effects resemble the naturally occurring condition is important in the development of animal models that can give information as to the mechanisms of the disease. With the exception of clofibric acid (17), there is a lack of quantitative studies regarding the *in vivo* kinetics of the myotonia-inducing aromatic monocarboxylic acids. Also, methods are not available for their chemical determination in biological fluids. In this paper we report UV and fluorescence spectrophotometric methods for I determination and compare them in blood, plasma, urine, and saline perfusates, covering most of the present analytical needs of biomedical researchers interested in the study of myotonia induced by I.

EXPERIMENTAL

Determination of I by UV Spectrophotometry—*Sodium Bicarbonate Buffer*—Fifty milligrams of I[1] and 1.5 g of sodium bicarbonate were placed in a 100-ml volumetric flask and brought to volume with water. Since I is almost insoluble in water (the concentration of a saturated water solution is 1.88×10^{-4} *M*), it was necessary to alkalinize the medium with sodium hydroxide to pH 8–9 (22°)[2] and stir vigorously for at least 20 min. This solution has 320 mosm[3]. By successive dilutions of the isotonic alkaline solution of I the following concentrations were obtained: 0.5, 1.0, 1.5, and 2.0 μg/ml. The absorbance of these solutions was measured relative to an isotonic solution blank at 255 nm[4]. These solutions are unstable in light, so it is necessary to proceed immediately; the solutions must be protected from light.

Chloroform—A 50-mg volume of I was placed in a 100-ml volumetric flask, and brought to volume with chloroform. The dilutions to 0.5, 1.0, 1.5, and 2.0 μg/ml were made with the same solvent. Their absorbance was measured *versus* a chloroform blank at 255 nm.

Excitation/Emission Spectrum of I in Chloroform—In a 50-ml volumetric flask, 25 mg of I was added, brought to volume with chloroform, and diluted to a final concentration of 10 μg/ml. The spectra of excitation and emission were obtained in a spectrophotofluorometer[5], and the results are shown in Fig. 1. The excitation spectrum exhibits a clear absorption peak at 355 nm. This wavelength was used subsequently for excitation of the samples. The fluorescence spectrum manifests an enhanced emission at 470 nm, and the peak at this wavelength was used to quantify I in blood, plasma, and urine.

This solution has 320 mosm[3]. By successive dilutions of the isotonic alkaline solution of I the following concentrations were obtained: 0.5, 1.0, 1.5, and 2.0 μg/ml. The absorbance of these solutions was measured relative to an isotonic solution blank at 255 nm[4]. These solutions are unstable in light, so it is necessary to proceed immediately; the solutions must be protected from light.

Chloroform—A 50-mg volume of I was placed in a 100-ml volumetric flask, and brought to volume with chloroform. The dilutions to 0.5, 1.0, 1.5, and 2.0 μg/ml were made with the same solvent. Their absorbance was measured *versus* a chloroform blank at 255 nm.

Excitation/Emission Spectrum of I in Chloroform—In a 50-ml volumetric flask, 25 mg of I was added, brought to volume with chloroform, and diluted to a final concentration of 10 μg/ml. The spectra of excitation and emission were obtained in a spectrophotofluorometer[5], and the results are shown in Fig. 1. The excitation spectrum exhibits a clear absorption peak at 355 nm. This wavelength was used subsequently for excitation of the samples. The fluorescence spectrum manifests an enhanced emission at 470 nm, and the peak at this wavelength was used to quantify I in blood, plasma, and urine.

0022-3549/83/1000-1221$01.00/0

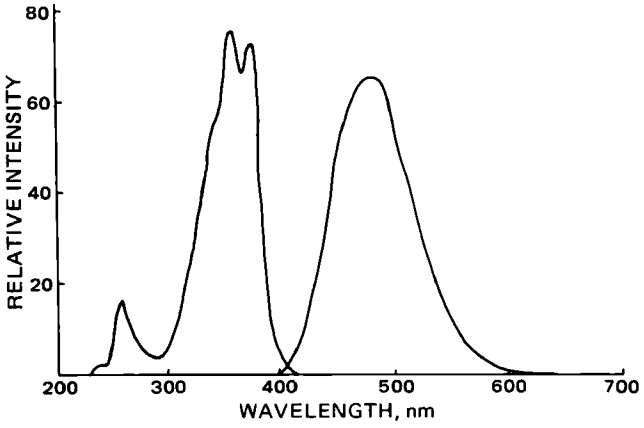

Figure 1—*Wavelength maxima for excitation (left) and emission (right) of I in chloroform (10 μg/ml).*

Standard Curve—Twenty-five milligrams of I was dissolved in chloroform and diluted to 50 ml in a volumetric flask, and then diluted with chloroform to the following concentrations: 0.2, 0.4, 0.6, 0.8, 1.0, and 1.25 μg/ml. The emission spectrum was determined for each dilution, and the intensity of fluorescence was plotted *versus* I concentration.

Spectrophotofluorometric Quantification of I in Blood, Plasma, and Urine of Rabbits—*Stock Standard*—Fifty milligrams of I and 0.75 g of sodium bicarbonate were dissolved in water and adjusted to 50 ml in a volumetric flask. This solution had 320 mosm and the pH was 8.5.

Blood, Plasma, and Urine Samples—With a syringe containing an anticoagulant[6] 10 ml of blood was drawn from the marginal vein of the ear from each of nine healthy New Zealand White rabbits. Plasma was obtained from 5 ml of this blood by centrifugation at 2000 rpm during 10 min[7]. The urine of the rabbits was collected by a catheter placed in the urinary bladder[8] and diluted 10-fold with water before analyses.

Sample Preparation—Two milliliters of whole blood were pipetted into a 15-ml centrifuge tube and mixed with 2 ml of stock standard previously diluted 10-fold. The plasma and urine were prepared in the same way.

Extraction Procedure—To 1.0 ml of blood, plasma, or urine prepared sample was added 0.5 ml of 3 *M* HCl, 0.5 g of sodium chloride, and 50 ml of chloroform in a Erlenmeyer flask. The contents were ultrasonicated[9] for 15 min, then centrifuged (full speed for about 10 min) to separate the immiscible liquid. The water layer was removed and the fluorescence of I was determinated in chloroform. The reproducibility of the assay was assessed by calculating the standard deviation of the mean value of the individual determinations.

RESULTS AND DISCUSSION

Solubility of I in chloroform is greater than in methanol or water. Therefore it is easier to work with chloroformic solutions since the extraction of I from biological fluids is faster and more efficient with this solvent.

3	101.2	97.7	52.1
4	101.3	98.4	72.2
5	102.0	98.4	74.1
6	101.3	100.7	76.8
7	100.5	97.8	61.3
8	105.0	102.1	63.3
9	105.0	102.1	63.3
Mean ± *SD*	101.0 ± 2	98.0 ± 2	66.5 ± 6

[a] To each of nine samples there was added 50.0 μg of I/ml. Standard curve for I using 1.0 μg/ml as a reference.

UV Spectrophotometry—Concentrations of I in sodium bicarbonate buffer and chloroform were determined by measuring the increase in absorbance at 255 nm. With the procedure for measuring I by UV detection, the peak height and the amount of I in the standards as well as in the sample are linearly related to concentration in the two solvents. The absorbance is directly proportional to I concentration of 0.5 to 2.0 μg/ml ($r^2 = 0.99$). The use of UV spectrophotometry for the determination of I is convenient when saline-perfused preparations are used because the composition of the saline solutions (Ringer's, Tyrode's, Locke's, *etc*) does not interfere with the readings. The detection limits of this method are 0.5–2.0 μg/ml ($2.25–9.0 \times 10^{-6}$ *M*). This range is within the one found in saline-perfused preparations (10^{-6}–10^{-4} *M*). In other words, in those preparations it is possible to quantify directly or after one dilution the I concentration by UV detection. On the other hand, in the case of chloroform extracts of normal blood, plasma, and urine, some constituents of those fluids gave large interfering peaks near, or at the point of maximal I absorbance in UV, interfering with its quantification. Furthermore, urine is often contaminated with blood.

Spectrophotofluorometric Determination of I—Excitation and emission spectra of I in chloroform were established because these data were not found in the literature (Fig. 1). The fluorescence spectrum obtained by this laboratory is similar to the one reported by Werner and Hercules in ethanol, although the absorption spectrum is different (18). There is a linear relationship over the range of 0.2–1.0 μg/ml, whereas higher concentrations are off because of self-quenching (19).

Compound Recovery—Table I shows the quantitative results obtained by spectrophotofluorometry for blood, plasma, and urine samples obtained from nine rabbits. The percent recovery of I added to samples and extracted with chloroform was in whole blood, plasma, and urine, 66.5 ± 7%, 98.0 ± 1%, and 101.0 ± 2%, respectively. Figure 2 shows the spectrum of a sample of plasma analyzed in triplicate. Similar results were obtained with urine (Table I).

UV Spectrophotometric *versus* Spectrophotofluorometric Assay—The sensitivity of these two formes of detection of I in chloroform were compared. The spectrophotofluorometric detection limit was found to be 200 ng/ml. The spectrophotometric UV limit was 500 ng/ml. Thus, the fluorometric method is at least twice as sensitive.

The recovery of I from plasma and urine averages 98.0 ± 1% and 101.0 ± 2%, respectively. These results indicate that the fluorometric method for plasma and urine is precise at low concentrations (Table I). However, the fluorometric method is not satisfactory for whole blood because recovery of added purified I averages only 66.5 ± 7% for whole blood.

Sensitivity—The detection limit of the fluorometric method lies in the nanogram range. This sensitivity is satisfactory because lower concentrations of I do not affect biological preparations *in vitro* (14, 15). *In vivo* a 8.0-mg/kg dose of I administered intraperitoneally to rats or intravenously to goats or rabbits elicits a clear myotonic state as well as "percussion myotonia" and the "warm-up" phenomenon. Pharmacokinetic studies in rabbits (20) shows that the same dose (8 mg/kg) produces at 1 and 120 min plasma concentrations of 1.63×10^{-4} and 1.0×10^{-5} *M*, respectively. These concentrations are similar to the ones found as active *in vitro*, and can be determined by the fluorometric method. Furthermore, the emission spectra of the chloroformic extracts of plasma and urine are clean (Fig. 2).

Specificity—To rule out interferences from other substances present in plasma or urine, we performed determinations in blank samples (without I) and found no fluorescence at the wavelength used with this method. Therefore, the method is also specific for I. Under the assay conditions which we have described, the precision and the sensitivity of the present method was found to be reliable for I determinations in some

biological liquids. It is possible to perform 14 assays in ~3 hr including reagent blanks, standards, and controls. Thus, our method should be suitable both for research in pharmacology and in a chemistry laboratory.

Determination of Azobenzene and Hydrazobenzene in Phenylbutazone and Sulfinpyrazone Products by High-Performance Liquid Chromatography

F. MATSUI ˣ, E. G. LOVERING, N. M. CURRAN, and J. R. WATSON †

Received April 28, 1982, from the *Bureau of Drug Research, Health Protection Branch, Health and Welfare Canada, Tunney's Pasture, Ottawa, Ontario K1A OL2.* Accepted for publication August 27, 1982. † Deceased.

Abstract □ A high-performance liquid chromatographic method has been developed for the simultaneous determination of azobenzene and hydrazobenzene in phenylbutazone and sulfinpyrazone raw materials and formulations. The drug raw material or formulation is shaken with 1 *N* NaOH and *n*-hexane and centrifuged. The *n*-hexane layer is injected into a chromatograph equipped with a 10-μm cyano-amino bonded phase column. Azobenzene and hydrazobenzene are detected at 313 and 254 nm, respectively; the sensitivities are ~1 and 2 ppm, respectively, in the raw materials and formulations.

Keyphrases □ Azobenzene—determination in phenylbutazone and sulfinpyrazone products by high-performance liquid chromagraphy □ Hydrazobenzene—determination in phenylbutazone and sulfinpyrazone products by high-performance liquid chromatography □ High-performance liquid chromatography—determination of azobenzene and hydrazobenzene in phenylbutazone and sulfinpyrazone products

Hydrazobenzene is an intermediate in the manufacture of phenylbutazone and sulfinpyrazone (1). These drugs may be contaminated with hydrazobenzene as a result of incomplete clean up after manufacture or if the drugs degrade by hydrolytic ring opening and subsequent cleavage of the residual amido function (2). Azobenzene forms readily by autoxidation of hydrazobenzene (2); its presence in drugs may be due to the use of impure hydrazobenzene during manufacture or to the oxidation of hydrazobenzene (2). Recent work indicates that hydrazobenzene is a carcinogen in rats and mice (3) and that azobenzene is a carcinogen in rats, but not in mice (4).

There appear to be few available methods for the determination of azo- and hydrazobenzene. Hydrazobenzene (5) and azobenzene (6, 7) have been detected in phenylbutazone formulations by TLC, and a high-performance liquid chromatography (HPLC) method for the determination of hydrazobenzene in aqueous media (8) has been reported. An HPLC method for the simultaneous determination of azo- and hydrazobenzene in phenylbutazone and sulfinpyrazone drug raw materials and formulations is described here.

EXPERIMENTAL

Materials—Azobenzene[1], hydrazobenzene[2] (1,2-diphenylhydrazine), sodium hydroxide[3], HPLC-grade *n*-hexane[4], and absolute ethanol[5] were used as received. All solvents were flushed with nitrogen prior to use.

Apparatus—The liquid chromatograph consisted of a single-piston metering pump[6], an injector[7] equipped with a 100-μl sample loop, a dual-channel UV detector[8] (254 nm, 0.02 AUFS and 313 nm, 0.05 AUFS) and two 10-mV strip chart recorders[9] (chart speed of 0.5 cm/min). A Partisil-10 PAC[10] analytical column (25 cm × 4.6-mm i.d.) and a Porasil 400[11] (37–75 μm) precolumn (10 cm × 4 mm-i.d.) were used at ambient temperature with a mobile phase flow rate of 2 ml/min. The mobile phase was a solution of 2.5% absolute ethanol in *n*-hexane (v/v) flushed with nitrogen.

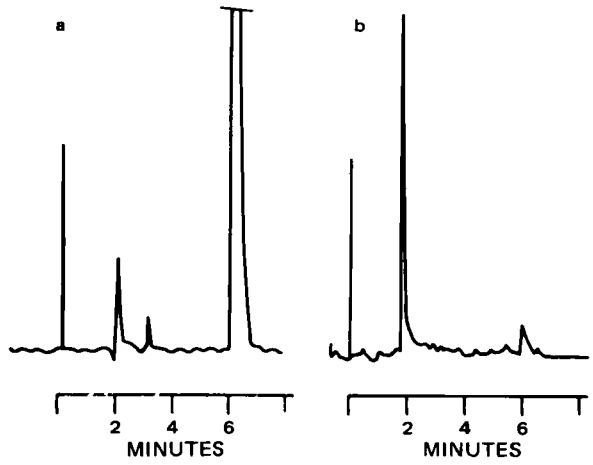

Figure 1—*Chromatograms of azobenzene (2.0 min) and hydrazobenzene (6.1 min). Key: (a) detection at 254 nm, (b) detection at 313 nm.*

n-hexane (1.6 μg/ml) was diluted with the same solvent to obtain five standard solutions ranging from 0.048 to 0.80 μg/ml. Duplicate 100-μl aliquots representing on-column amounts of 0.0048–0.080 μg of azobenzene were chromatographed at 313 nm with the signal attenuated to 0.05 AUFS.

Hydrazobenzene—A solution of hydrazobenzene in *n*-hexane (1.6 μg/ml) was diluted with the same solvent to obtain five standard solutions ranging from 0.10 to 1.6 μg/ml. Duplicate 100-μl aliquots representing on-column amounts of 0.010–0.160 μg of hydrazobenzene were chromatographed at 254 nm with the signal attenuated to 0.02 AUFS.

Daily Calibration—Two standard solutions of each compound (azo- and hydrazobenzene) were prepared fresh each day. The concentrations of the standards were such that the on-column levels were ~0.006 and 0.060 μg for azobenzene and ~0.016 and 0.120 μg for hydrazobenzene.

System Check Sample—Powdered, well-mixed composites were prepared from 50 capsules (or tablets) of phenylbutazone or sulfinpyrazone products which were known to contain azobenzene and hydrazobenzene. These were analyzed periodically to check the reproducibility of the chromatographic system and the sampling procedures.

Analysis of Phenylbutazone or Sulfinpyrazone Preparations—Phenylbutazone or sulfinpyrazone drug raw material (100 mg), or an aliquot of a composite of powdered tablets or capsule contents equivalent to 100 mg of the drug substance, was shaken with 10.0 ml of 1 *N* NaOH just long enough to wet the solid mass. To this was added 5.0 ml of *n*-hexane, and the mixture was shaken for 5 min on a horizontal shaker. After centrifuging at 4000 rpm for 1 min, the upper organic layer containing the azobenzene and/or hydrazobenzene was immediately separated from the aqueous phase containing the drug. Duplicate 100-μl aliquots of the organic phase were chromatographed with the 254- and 313-nm detectors in series. When the peak for the azobenzene and/or hydrazobenzene was off-scale, the sample was diluted with *n*-hexane and injected again. Quantitation was by the peak height technique for both impurities. Calibration standards of azobenzene and hydrazobenzene in *n*-hexane were used as the external reference solutions.

RESULTS AND DISCUSSION

During development of the method it was found that some sulfinpyrazone samples contained an impurity which was eluted at 1.8 min and was incompletely resolved from azobenzene at 2.0 min. This impurity was shown to be toluene by GC–MS. Toluene and azobenzene were resolved at retention times of 2.8 and 4.0 min, respectively, by elimination of ethanol from the mobile phase. This, however, delayed the elution of hydrazobenzene to such an extent that there was an unacceptable loss of sensitivity. Therefore, ethanol was retained in the mobile phase and the azobenzene was quantitated at 313 nm, where absorption by toluene is insignificant. The hydrazobenzene, which was eluted at 4.9 min, was quantitated by measurements at 254 nm. Typical chromatograms at both wavelengths are presented in Fig. 1.

Hydrazobenzene is reported to be oxidized readily in solvents such as benzene, methylene chloride, and methanol (8). In *n*-hexane in equilibrium with the atmosphere, hydrazobenzene was oxidized to azobenzene at a rate of ~5%/hr at room temperature. In nitrogen-flushed *n*-hexane there was no increase in the azobenzene level during the first 30 min and only a 4% conversion after ~2 hr. In addition it was found that azo- and hydrazobenzene in the nitrogen-flushed calibration solutions were stable over a period of 1 hr, as indicated by the constancy of the response factors of the five calibration solutions. Over the period of the extraction neither drug was degraded sufficiently to cause detectable increases in the azo- and hydrazobenzene levels. For phenylbutazone, the levels began to increase after 15 min, but no change was observed in sulfinpyrazone after 50 min.

The reproducibility of the procedure used for the extraction of azo- and hydrazobenzene from formulations was investigated using phenylbutazone and sulfinpyrazone formulations known to contain azo- and hydrazobenzene. Using 10 ml of 1 *N* NaOH and 5 ml of *n*-hexane as provided for by the method, the extraction of both contaminants was invariant between 50 and 250 mg of phenylbutazone and 50 and 150 mg of sulfinpyrazone. Increasing the amount of *n*-hexane used in the extraction from 5 to 10 and 5 to 20 ml for sulfinpyrazone and phenylbutazone, respectively, had no effect on the amounts of azo- and hydrazobenzene detected. The partition of azo- and hydrazobenzene into *n*-hexane from sodium hydroxide solution is virtually complete. This was demonstrated by shaking a solution of the contaminants dissolved in *n*-hexane with 1 *N* NaOH. There was no detectable change in the observed levels of azo- and hydrazobenzene after shaking with the base. Drug raw materials and formulations were spiked with known amounts of azo- and hydrazobenzene. Recoveries ranged between 85 and 110%.

The response of the chromatographic system was linear from 4 to 70 ng of azobenzene on-column, with an intercept that did not vary significantly from zero. The relative standard deviation of the ratio of the peak height to the weight of azobenzene was 2.3% for five calibration points. For hydrazobenzene the linear range was from 10 to 150 ng with a corresponding relative standard deviation of 3.5%. These ranges would correspond to azo- and hydrazobenzene levels of 2–35 ppm and 5–75 ppm, respectively, in 100 mg of drug when assayed by the procedure described in this paper. The chromatographic reproducibilities were established by injecting six aliquots of each of two solutions of azo- and hydrazobenzene. On-column amounts of 0.0057 and 0.032 μg of azobenzene gave relative standard deviations of the peak height–weight ratio of 2.34 and 0.53%, respectively. For hydrazobenzene, the relative standard deviations were 5.99 and 3.12% for on-column quantities of 0.0737 and 0.145 μg, respectively. The reproducibility of the assay for azo- and hydrazobenzene in formulations of phenylbutazone and sulfinpyrazone ranged between 4 and 13%, in general agreement with recoveries from the spiked samples.

The minimum detectable amounts of azobenzene and hydrazobenzene on column are ~1.5 and 4 ng, respectively. These levels corresponded to ~1 and 2 ppm of azobenzene and hydrazobenzene, respectively, for an on-column equivalent of 2000 μg of the drug. The minimum quantifiable levels were about twice these amounts.

Increased Cytotoxicity of N^6-(Δ^2-Isopentenyl)adenosine in Combination with Pentostatin Against L-1210 Leukemia Cells

BRUCE HACKER and YUNIK CHANG ˣ

Received June 4, 1982, from the *College of Pharmacy, University of Oklahoma, Oklahoma City, OK 73190.* Accepted for publication September 21, 1982.

Abstract □ Pentostatin (I), a tight-binding inhibitor of adenosine deaminase, was evaluated in combination with the partially effective antitumor nucleoside N^6-(Δ^2-isopentenyl)adenosine (II) for cytotoxic activity against cultured L-1210 lymphocytic mouse leukemia cells. Although I alone (≤ 10 μg/ml) was ineffective, it significantly potentiated and prolonged the cytotoxic and cytostatic activities of II. The combination of I (2–10 μg/ml) with II (25 μg/ml) resulted in inhibition of cellular proliferation (80–96%) within 24 hr with maintenance at that level for an extended period of time due to the continued ability of I to prevent the facile deamination of the allylic side chain of II. This type of adjuvant chemoprotection has potential use for other labile oncologic agents.

Keyphrases □ Pentostatin—potentiation of N^6-(Δ^2-isopentenyl)-adenosine, cytotoxicity, mouse L-1210 leukemia cells □ N^6-(Δ^2-isopentenyl)adenosine—potentiation by pentostatin, cytotoxicity, mouse L-1210 leukemia cells □ Cytotoxicity—N^6-(Δ^2-isopentenyl)adenosine, potentiation by pentostatin, mouse L-1210 leukemia cells

Since its initial characterization by Woo *et al.* (1), pentostatin (2′-deoxycoformycin) (I), the tight-binding inhibitor of adenosine deaminase, has been shown to possess both antilymphocytic (2) and immunosuppressive activity (3) in several animal test systems. The ability of I to oppose or block the enzymatic deamination of several adenosine analogues to inactive forms (4) prompted clinical interest and utilization of the drug in the treatment of human chronic and acute lymphocytic leukemia. Recent studies have shown that I is of particular use in the treatment of acute lymphoblastic leukemia (5), as well as for chronic T-cell lymphocytic leukemia (6). Of special interest has been combination of I with the antiviral and antitumor agent vidarabine (7).

Other studies have revealed the existence of a correlation between the cytotoxicity of I and the accumulation of deoxyadenosine-5′-triphosphate in acute lymphocytic leukemia (8, 9), as well as the ratio of deoxyadenosine-5′-triphosphate to adenosine-5′-triphosphate in red blood cells. Another adenosine nucleoside analogue N^6-(Δ^2-isopentenyl)adenosine (II), used in the present investigation, has also been shown previously to possess growth-inhibitory effects on sarcoma-180 cells as well as some cytostatic action in treating human myeloblastic leukemia (10). Its immunosuppressive activity (11) has been linked to its ability to block the transport of preformed nucleosides at the level of transmembrane translocation in several mammalian species (11, 12). Moreover, it has been possible to prepare a serologically specific antibody to II (13).

Despite their potential for treating human leukemias, use of II and other adenosine antimetabolites has been limited due to their susceptibility to enzymatic degradation and subsequent inactivation by an enzyme system related to adenosine deaminase [N^6-(Δ^2-isopentenyl)-adenosine-aminohydrolase (14)]. This difficulty has been overcome, in great measure, by release of II at a controllable and predictable rate from a silicone rubber monolithic polymer matrix (15–17). This represented a successful attempt to match the rate of release of II against the aminohydrolase activity in tumor cells. The present study using I was begun to establish a means of preventing the degradation of II, thereby potentiating and prolonging its effectiveness against L-1210 leukemia cells.

EXPERIMENTAL

Drug Agents—The preparation of N^6-(Δ^2-isopentenyl)adenosine (II) was conducted as described elsewhere (11, 12, 16). Pentostatin [(*R*)-3-(2-deoxy-β-D-*erythro*-pentofuranosyl)-3,6,7,8-tetrahydroimidazo-[4,5-*d*][1,3]diazepin-8-ol; I] was supplied[1]. Both agents were stored at −20° over silica gel.

Culturing of L-1210 Cells and Determination of Cell Number—Mouse lymphocytic leukemia cells (L-1210) were routinely cultured under sterile conditions in a 5% carbon dioxide atmosphere at 37°, with transfer during the mid-log phase of growth into 5 ml of fresh medium[2] (RPMI 1640 supplemented with L-glutamine plus 10% fetal calf serum) as described elsewhere (16), using wide-mouth culture flasks[3] to accommodate silicone polymeric membranes when used. Total cell number and viability values were determined using Turk's solution and trypan blue exclusion, respectively (16). Aliquots of each cell suspension, to which II and/or I was added at time zero, were aseptically removed for the determination of cell number and for centrifugation–filtration[4] to yield cell-free filtrates for high-performance liquid chromatographic (HPLC) determinations.

Analysis of I and II Content in Cell Growth Medium—High performance liquid chromatography using two reverse-phase columns[5] eluted with varying methanolic solutions, as described in part previously (15, 16), was used to determine the stability and metabolism of both nucleoside drug agents in the cell culture medium at various intervals. This was accomplished during continuous incubation conditions by removal of aliquots (0.05–0.20 ml) for centrifugation–filtration (16).

Determination of the Cytotoxicity of I and II—Solutions of I or II were freshly prepared by dissolving the drugs in RPMI 1640 without serum, with sterile-filtration followed by aseptic addition at time zero.[6] At appropriate times thereafter, aliquots of each cell suspension were removed for determination of cell number, viability, and/or required analytical studies (16).

RESULTS AND DISCUSSION

Adenosine deaminase and a related aminohydrolase for II not only have important roles in normal catabolic pathways for adenine nucleosides, but are capable of deaminating N^6-(Δ^2-isopentenyl)adenosine (II) (14). Deamination of II to inosine greatly reduces its ability to interfere with nucleic precursor transport and synthesis (11, 12) and its immunosuppressive activity (11, 13), thereby diminishing its chemotherapeutic potential as an anticancer agent (10). The present investigation demonstrates that a natural product, the potent adenosine deaminase inhibitor pentostatin (1–9), can potentiate and prolong the antileukemic effect of

[a] Each T-flask initially contained 2 × 10^5 L-1210 mouse leukemia cells per milliliter (100% viability by trypan blue exclusion) in 5 ml of growth medium (RPMI 1640 plus 10% fetal calf serum). Experiments were conducted using 2 or 3 replicates for each type of determination. [b] Additions (0.1–0.3 ml) of each agent dissolved in RPMI 1640 medium followed by sterile filtration were made at time zero to yield final concentrations of I (2 μg/ml) and/or II (25 μg/ml). [c] Aliquots (0.1–0.2 ml) of each cell suspension were removed aseptically at various time intervals for the following determinations: total cell count using Turk's solution, cell viability (trypan blue exclusion), and HPLC (15, 16). [d] Mean ± *SD*.

II against cultured L-1210 cells (Table I). Although I alone (≤10 μg/ml) does not interfere with L-1210 cellular proliferation, it is capable of enhancing the antileukemic effects of II (25 μg/ml). At an optimal concentration of 5–10 μg/ml, I in combination with II results in almost total cell death (96%) within 24 hr. The few remaining cells have viability values of 40–50%. The most impressive effect of I (2 μg/ml) is its ability to prevent the cytotoxic capacity of II from declining at longer intervals of incubation time, when L-1210 leukemia cells are in the stationary phase of growth. This effect is discernible at concentrations of as low as 0.2 μg/ml[7]. These results suggest that inhibition of N^6-(Δ^2-isopentenyl)-adenosine-aminohydrolase prevents the inactivation of II, thereby enhancing and prolonging its effectiveness as an antitumor drug agent. In other recent studies (15–17), it has been demonstrated that the usefulness of II against L-1210 cells may also be potentiated by controlled release of this nucleoside from a polymeric silicone matrix.

Arylidenepyruvic Acid Thiosemicarbazone and Thiazoline Derivatives As Potential Antimicrobial Agents

A.-MOHSEN M. E. OMAR *x, IBRAHIM M. LABOUTA *, M. GABR KASEM *, and J. BOURDAIS ‡

Received May 25, 1982, from the **Pharmaceutical Chemistry Department, Faculty of Pharmacy, University of Alexandria, Egypt* and ‡*Laboratoire de Chimie des Hétérocycles d'Intérêt Biologique, Université d'Aix-Marseille II, Faculté de Médecine Nord, 13326 Marseille, Cedex 15, France.* Accepted for publication August 16, 1982.

Abstract □ Two novel series of arylidenepyruvic acid thiosemicarbazone and thiazoline derivatives were synthesized and evaluated as potential antimicrobial agents. These substances did not exhibit any significant antibacterial effects when tested against a variety of microorganisms.

Keyphrases □ Antimicrobial agents, potential—arylidenepyruvic acid thiosemicarbazone and thiazoline derivatives, synthesis, evaluation for antibacterial activity □ Arylidenepyruvic acids—thiosemicarbazones and thiazolines derivatives, synthesis, antimicrobial effects.

The introduction of a thiosemicarbazone moiety to alter the pharmacological activity of a variety of biologically active compounds has been demonstrated recently in several studies from this laboratory (1–5). Continuing such studies, the thiosemicarbazones (II–XIV) derived from various arylidenepyruvic acids and the corresponding thiazolines (XV–XXVII, Scheme I) were synthesized and tested for antimicrobial activity.

RESULTS AND DISCUSSION

Chemistry—The thio compounds (II–XXVII) were prepared as shown in Scheme I. A mixture of pyruvic acid or the properly substituted arylidenepyruvic acid (I), prepared through Claisen condensation of pyruvic acid and various aryl aldehydes (6), and an equivalent amount of 4-substituted 3-thiosemicarbazide was heated under reflux in aqueous acetic acid. The products (II–XIV) which separated on concentrating and cooling the mixtures, were crystallized from ethanol. The reaction of these

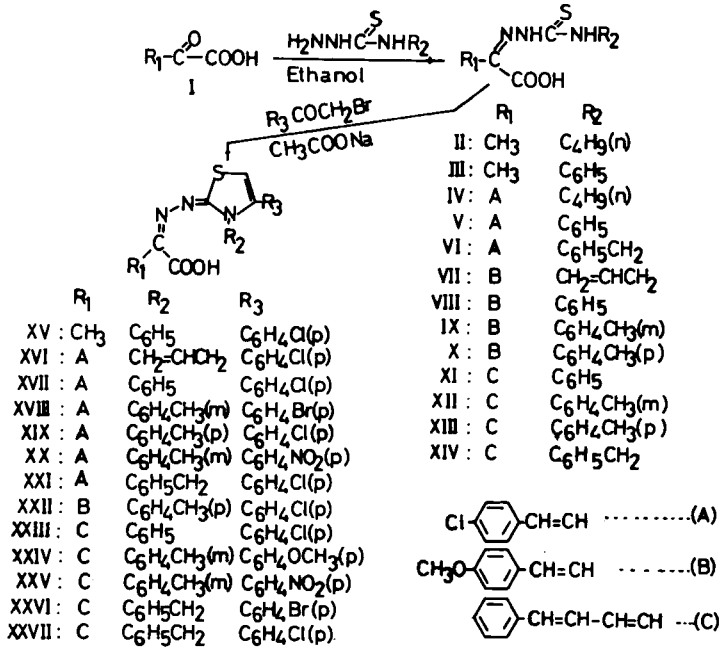
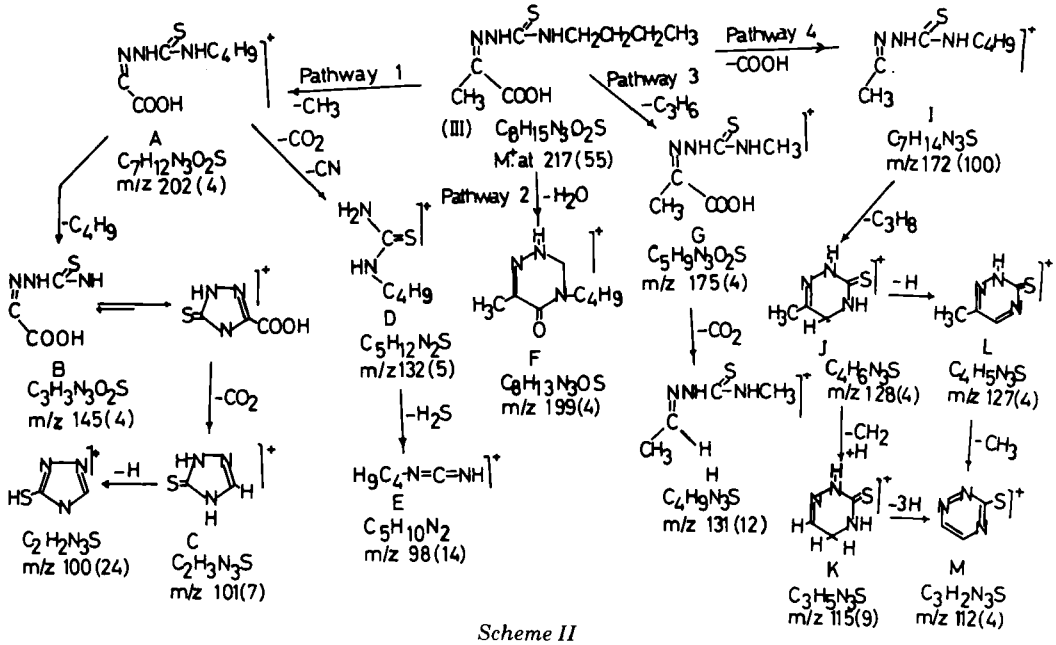


Scheme I



Scheme II

thiosemicarbazones with phenacyl bromide or the appropriately substituted phenacyl bromide and sodium acetate under reflux in ethanol yielded the arylidenepyruvic acid thiazoline derivatives (XV–XXVII).

The structure of the products was confirmed by IR and, for some representative examples, by ^{1}H-NMR spectral data. The IR spectra of the thiosemicarbazones (II–XIV) showed the bands characterizing the OH, NH, C=O, C=N, and NCS groups. Compounds XV–XXVII, on the other hand, lacked the NH absorption while showing absorption for C=O and C=N groups. The ^{1}H-NMR spectrum of III showed the CH_3 protons as a singlet at 2.21, the aromatic protons as a multiplet between 7.1 and 7.9, and the two NH and COOH protons as two singlets at 10.92 and 11.24 ppm, respectively. The spectrum of V showed the aromatic and the unsaturated side-chain protons as a multiplet between 7.0 and 8.1, while the protons of the COOH and the two NH functions appeared as singlets (disappearing on deuteration) at 10.92, 12.15, and 12.8 ppm, respectively. The spectra of the thiazolines XV and XXIV lacked the NH protons and showed the triazoline proton at 6.79 ppm.

The mass spectrum of III, as a representative example, showed the molecular ion peak at *m/z* 217 (Scheme II). This indicated that the molecule had undergone cleavage of a methyl group from the pyruvic acid portion to give ion *A* at *m/z* 202, (pathway 1). Ion *A* eliminated a butyl group forming the triazole ion *B*, at *m/z* 145, which eliminated carbon dioxide to give ion *C* at *m/z* 101. In an alternate way, ion *A* was found to eliminate carbon dioxide and a cyanide function to form the butylthiourea ion *D*, at *m/z* 132, which lost hydrogen sulfide to yield the carbodiimide ion *E* at *m/z* 98. In pathway 2, the molecule lost water to produce the triazine ion *F*, at *m/z* 199, while in pathway 3, the successive loss of propane and carbon dioxide gave ions *G* and *H* at *m/z* 175 and 131, respectively. The loss of a carboxylic function from the main product III (pathway 4) gave ion *I*, as the base peak, at *m/z* 172. This ion on losing propane gave ion *J*, at *m/z* 128, which on elimination of methylene and acceptance of hydrogen gave the triazine ion *K* at *m/z* 115. The loss of hydrogen from ion *J* followed by cleavage of the methyl group produced ions *L* and *M* at *m/z* 127 and 112, respectively.

Antimicrobial Screening—Using the serial dilution method in nutrient agar[1], all the products in concentrations of 100, 10, and 1 μg/ml were found to be inactive against *Escherichia coli* (NCTC 10418), *Klebsiella aerogenes* A, *Pseudomonas aeruginosa* (NCTC 10662), *Serratia mar-*

[1] The tests were performed in accordance with the protocol of antimicrobial screening of the Chemotherapeutic Research Centre, Beecham Pharmaceuticals, Brockham Park, Betchworth, Surrey, RH3 7AJ, United Kingdom.

[a] Calc. over found.

cescene (US32), *Staphylococcus aureus* Oxford, and *Candida albicans* (W97). Such inactivity, despite the antifungal and antimicrobial properties reported for arylidenepyruvic acid (7) and a variety of thiosemicarbazones (8–13), has been attributed to the bulk of the thiosemicarbazone moieties and the electronic changes caused by the presence of these groups on the α-carbon of the various arylidenepyruvic acids used. In the thiazoline derivatives (XV–XXVII), in which the 3- and 4-substituents were selected to fulfill the maximum requirement for hydrophobic π, electronic δ, and steric E_s factors in accordance with Topliss (14), the inactivity was assumed to be due to the bulky arylidenepyruvic acid hydrazone chains which, through intramolecular association with the remainder of the molecule, have hindered the permeability of tested compounds.

EXPERIMENTAL[2]

Substituted Thiosemicarbazone Arylidenepyruvic Acid Derivatives (II–XIV)—Equimolar amounts of pyruvic acid or the appropriately substituted arylidenepyruvic acid (I) (6) and the selected substituted thiosemicarbazides were heated under reflux in 80% aqueous acetic acid for 15–20 min. The mixtures were partially concentrated *in vacuo*, cooled, and the separated products recrystallized from ethanol. The yield and physical data of the products are recorded in Table I. IR (mineral oil): 3520–3420 (OH), 3360–3200 (NH), 1750–1690 (C=O), 1660–1580 (C=N and C=C), 1550–1515, 1315–1240, 1175–1157, and 970–930 cm^{-1} (NCS amide I, II, III, and IV bands, respectively). ^{1}H-NMR (III, DMSO-d_6): δ 2.21 (s, 3, CH_3), 7.1–7.9 (m, 5, Ar-H), and 10.92 and 11.24 ppm (2s, broad, 3, 2 × NH + COOH, disappearing on deuteration). ^{1}H-NMR (V, DMSO-d_6): δ 7.0–7.3 (m, 2, ethylene-H), 7.68 (s, 5, Ar-H), 7.5–8.1 (m, 4, Ar-H), and 10.9, 12.15, and 12.8 ppm (3s, 3, 2 × NH + COOH, disappearing on deuteration). Mass spectrum for III: *m/z* (relative abundance %) M^+ at 217 (65), 202 (4), 199 (4), 174 (22), 172 (100), 171 (4), 145 (4), 144 (5), 132 (5), 131 (12), 130 (20), 129 (4), 128 (4), 127 (4), 117 (4), 116 (59), 115 (9), 112 (4), 101 (7), 100 (24), 98 (14), 96 (31), 89 (13), 88 (59), 75 (19), 74 (11), 73 (14), 72 (61), and 70 (13).

Arylidenepyruvic Acid (3,4-Disubstituted 4-Thiazolin-2-ylidene)hydrazones (XV–XXVII)—An equimolar amount of the thiosemicarbazone derivatives (II–XIV) and phenacyl bromide or substituted phenacyl bromide and sodium acetate was heated under reflux in ethanol for 2–4 hr. The mixture was cooled, diluted with water, and the product removed by filtration. Recrystallization from ethanol or 90% aqueous ethanol gave XV–XXVII. The yields and physical constants of the synthesized thiazolines are recorded in Table I. IR (mineral oil): 3400–3200 (OH, associated), 1740–1660 (C=O), and 1620–1570 cm^{-1} (C=N and C=C).

Models of Hepatic Drug Elimination

Keyphrases □ Hepatic drug clearance—saturation kinetics, sinusoidal perfusion model, venous equilibrium model □ Heterogeneity of organ extraction—intrahepatic shunts

To the Editor:

In a recent communication (1) Morgan and Raymond identify observable quantities which would help to discriminate between two models of drug uptake by the intact liver: the venous equilibration model (2) and the undistributed sinusoidal perfusion model (3, 4). Several comments are necessary in light of recent results.

In the case of hepatic elimination of galactose, the two models have already been refuted experimentally: the first at 0.01 (5) and the second at 0.002 (6, 7) levels of statistical significance. To be so decisive, these experiments involved substrate concentrations across the entire Michaelis–Menten range, whereas Morgan and Raymond (1) confine their considerations to the limiting forms of the models at substrate concentrations so low that the hepatic uptake kinetics become linear (first order).

The quantitative results which refute the undistributed sinusoidal perfusion model give strong support to the distributed sinusoidal perfusion model (7, 8) not discussed by Morgan and Raymond (1). Michaelis–Menten uptake by a single perfused sinusoid is treated the same in the undistributed (4) and distributed (8) models, but the distributed model drops the biologically incredible assumption that all sinusoids extract equally: it incorporates and quantifies functional heterogeneity of sinusoids and its effect on organ uptake.

Envisage an intact liver with hepatic blood flow rate F and, for some enzyme–substrate combination, the Michaelis constants, V_{max} and K_m (intrinsic hepatic clearance V_{max}/K_m), resulting in a steady uptake rate:

$$V = F(C_i - C_o) \qquad \text{(Eq. 1)}$$

when the substrate concentration is C_i at the inlet and C_o at the outlet of the liver. For N sinusoids acting in parallel, the undistributed model asserts that the corresponding quantities for each sinusoid are:

$$f = F/N = \bar{f},\ v_{max} = V_{max}/N = \bar{v}_{max},\ v = V/N = \bar{v} \qquad \text{(Eq. 2)}$$

By contrast, the distributed model works with statistical dispersions of v_{max} and f (about their means $\bar{v}_{max}$ and $\bar{f}$) over the assembly of sinusoids comprising a liver. It is, in fact, the dispersion of the ratio v_{max}/f that controls deviations from the undistributed model in the context of uptake (7).

Now, let an arbitrary distribution of v_{max}/f over the sinusoids of an intact liver have the variance σ^2. A remarkable feature of Michaelis–Menten kinetics [and of more general saturation kinetics (7, 9)] is that when it is put in the hepatic setting, the rate of uptake by an undistributed liver, $V(\sigma^2 = 0)$, is always greater than the rate of uptake by a distributed liver, $V(\sigma^2)$, which has the same values of the macroscopic parameters F, V_{max}, K_m. The rate $V(\sigma^2 = 0)$ is thus an *upper limit* of the rate $V(\sigma^2)$; it is remarkably close in some cases (7, 10). There is also a lower limit of $V(\sigma^2)$ valid for any shape of the v_{max}/f distribution (7). For Michaelis–Menten kinetics:

$$V(\sigma^2 = 0) \geqq V(\sigma^2) \geqq V(\sigma^2 = 0) - 2F\sigma^2/(27K_m) \qquad \text{(Eq. 3)}$$

This exact result will suffice to indicate how functional heterogeneity of the intact liver can be studied in terms of the distributed model. A clinically interesting problem of this kind is the quantification of intrahepatic shunts (8), since such shunts are kinetically equivalent to a fraction of sinusoids with $v_{max} = 0, f \neq 0$.

The study by Keiding and Chiarantini (5) went beyond merely refuting the venous equilibration model: it set a calculable upper limit on the possible values of σ^2 in the rat liver (10). An altogether different attempt at discriminating between the venous equilibration model and the undistributed perfusion model has been made by Pang and Gillette using the hepatic conversion of a substrate into a metabolite, which is in turn conjugated in liver cells (11). When suitably interpreted, the results of the experiment neither refute nor confirm the sinusoidal perfusion model, but rather give information about functional heterogeneity of the liver along the blood flow [zones of liver function (12 and references therein)].

The aforementioned comments emphasize the fruitfulness of the controversy touched upon recently (1), which is surely a sufficient consolation for the refutation of both the contending models.

Models of Hepatic Drug Elimination: A Response

Keyphrases □ Hepatic drug clearance—sinusoidal perfusion model, venous equilibrium model

To the Editor:

Although the distributed sinusoidal perfusion model of hepatic elimination described by Bass (1) appears more physiologically realistic than the two previous models, the statement that these latter models have been refuted experimentally should be challenged. First, the data on which this statement is based arise from only two studies (2, 3) and are not as conclusive as implied (1). The study design used in one of these studies (2) has already been acknowledged as not very useful for discriminating among the models in an earlier publication (4). In the other study (3) hepatic venous outflow concentrations of galactose were examined in the perfused rat liver under the influence of two perfusate flow rates (11 ml/min for 50 min, followed by 7 ml/min for 40 min, followed by 11 ml/min for 40 min). The sinusoidal models predict a lowering of the outflow substrate concentration at the lower flow rate, while the venous equilibrium model predicts no change in the outflow substrate concentration. A significant drop in outflow concentration was reported (3), but this was largely determined by averaging the data from the two periods of higher flow even though in about half the 10 experiments the outflow concentration during the second period was considerably greater than the outflow concentration during the first period.

One of the reviewers of this report has highlighted this fact by showing that a paired t test of outflow concentration during the two 11-ml/min flow periods, which were separated by 40 min of perfusion at 7 ml/min (or a constant flow of 11 ml/min in the three control studies), yields a statistically significant difference at the $p < 0.05$ level ($t = 2.19$ $DF = 12$). Similarly, when inflow concentration from these two time periods with a flow at 11 ml/min are tested, a statistically significant difference $p < 0.05$ ($t = 2.24$, $DF = 12$) is observed. One assumption necessary to ensure the legitimacy of all of the calculations performed by Bass is that the liver preparation is physiologically stable over the course of the experiment. Specifically, if a liver is infused with substrate at a constant rate, inflow and outflow concentrations should depend only on hepatic blood flow rate (*i.e.* V_{max} and K_m should not vary as a function of time).

Comparing the first two flow periods only (11 ml/min and 7 ml/min), during which the preparation is more reliable, the outflow of galactose concentrations actually increased in three experiments, decreased by no more than that of control livers (about 10%) in two livers, and decreased more substantially in the other five. Thus, the data could be viewed as inconclusive. Bass has also used the data from the earlier study (3) to support the distributed sinusoidal model (4) which predicts an increase in the logarithmic average of perfusate inflow and outflow concentrations of substrate with decreasing flow. The logarithmic average concentration, however, increased in only 5 of the 10 experiments, the mean change being 0.0009 mM ($SD = 0.0267$), a change of barely 1%: again not conclusive.

The other point that should be made is that the published data on lidocaine (5) supporting the venous equilibrium model have never been refuted by further experimentation with that drug. The studies with galactose cannot be assumed to automatically hold for all other substrates because the experiments were carried out under Michaelis–Menten conditions, galactose is an endogenous substance, and the zone of the liver in which a substance is eliminated (6) may dictate which model applies. For example, a substance, such as galactose, that is eliminated in the periportal region may be expected to follow the distributed sinusoidal model, whereas the venous equilibrium model may be appropriate for drugs that are eliminated in the centrilobular region where the enzymes for drug biotransformation are predominant (6). Therefore, in view of the functional hepatocellular heterogeneity it is naive to assume that all observed phenomena can be explained in terms of a single model as suggested (1). Models will, however, have served their function if they provide inspiration for further experimentation, as suggested previously (7), that ultimately results in more refined and physiologically meaningful models.

Hepatic Extraction of Free Fatty Acids in Pregnant and Nonpregnant Female Rats

Keyphrases □ Free fatty acids—hepatic extraction □ Plasma protein binding—role of free fatty acids □ Hepatic drug clearance, intrinsic—role of drug protein binding and influence of free fatty acids

To the Editor:

Plasma protein binding can have important effects on the metabolic and excretory clearance of drugs (1, 2). Free fatty acids, whose concentrations in plasma can vary appreciably due to stress, diet, and other physiological variables (3), can competitively inhibit the plasma protein binding of many drugs (4, 5). Wiegand and Levy (6) have pointed out previously that extensive hepatic extraction of a protein binding inhibitor could cause an increase in the steady-state plasma concentration of unbound drug, with little or no effect on the concentration of total (free plus bound) drug, if the plasma protein binding of the drug

[a] Results are reported as mean ± SD, $n = 5$. [b] Significantly different from corresponding value in pregnant rats ($p < 0.05$).

is decreased with increasing inhibitor concentration. Such a change in drug concentration, apart from its pharmacodynamic implications (6), could be interpreted as a decrease in the drug's intrinsic clearance. Based on these considerations, we have determined the hepatic extraction of the four major endogenous free fatty acids in rats. Since the hepatic extraction of compounds is affected by their plasma protein binding and intrinsic hepatic clearance, studies were conducted also on pregnant rats, because pregnancy is associated with decreased plasma albumin concentration and decreased activity of certain oxidative metabolic processes (7, 8).

Female Sprague–Dawley rats (same age), both nonpregnant (≃200 g) and 20-days pregnant, had a cannula inserted in the femoral vein under ether anesthesia. The liver was then exposed through a midline abdominal incision. The liver lobules were reflected with wet gauze and the hepatic vein was clamped near its junction with the vena cava to avoid mixing blood from the liver with blood from the general circulation. Either 1 or 2 ml of blood was obtained from the hepatic vein by direct insertion of a 22-gauge hypodermic needle pointing toward the liver (9). Simultaneously, a blood sample from the femoral vein was obtained through the indwelling cannula. The blood was collected in plastic syringes containing EDTA (≃2 mg/ml of blood) and the plasma separated by centrifugation. The plasma was extracted into hexane within 5 min after blood collection, and the concentrations of the free fatty acids (as their methyl esters) were determined by GC by the method of Brunk and Swanson (10), but using smaller sample volumes and n-heptadecanoic acid rather than n-pentadecanoic acid as the internal standard.

The results of the study are summarized in Table I. The concentrations of the four major endogenous free fatty acids were considerably lower in hepatic venous plasma than in plasma from blood taken from the femoral vein. Linoleic acid was most extensively extracted, while the hepatic extraction of stearic acid was least pronounced. Plasma from pregnant rats is subject to rapid *in vitro* lipolysis which was minimized by rapid extraction of the plasma with organic solvent (11). Under these conditions the fatty acid concentrations in plasma of pregnant rats were similar to those in plasma of nonpregnant animals. There was no significant difference between pregnant and nonpregnant animals with respect to the hepatic extraction ratio of the individual free fatty acids. Hepatic vein–femoral vein albumin concentration ratios, determined in another experiment, were (mean ± SD) 1.03 ± 0.13, n = 4, for pregnant rats and 0.998 ± 0.056, n = 11, for nonpregnant animals.

The hepatic extraction values reported here are based on net concentration differences caused by hepatic extraction, and by hepatic output of free fatty acids synthesized by the liver (12). A contribution by extrahepatic tissues to the observed net concentration changes is also possible since solute concentrations in the femoral venous blood may not be the same as the concentrations in blood entering the liver (13). However, the femoral vein sampling site is appropriate because the usual pharmacokinetic studies involve blood sampling from a peripheral vein.

It has been reported (9) that ether anesthesia caused liver blood flow in rats to decrease from an average of 60.5 to 33.8 ml/min/kg. Unless ether anesthesia also causes a corresponding decrease in the intrinsic hepatic clearance of fatty acids, the extraction ratios reported here may be somewhat higher than the hepatic extraction ratios in nonanesthetized rats.

It is customary to determine the intrinsic clearance of drugs on the basis of the infusion rate and the steady-state concentration of unbound drug in plasma of blood taken from a peripheral vein. If the plasma protein binding of the drug is inhibited by free fatty acids in a concentration-dependent manner, then the free fraction of the drug in the blood entering the liver (and in the systemic circulation) is higher than that in blood leaving the liver, due to the decrease of the free fatty acid concentrations across the liver. Under these conditions, estimates of a drug's intrinsic clearance may be lower than the true value. This is particularly troublesome since free fatty acids are known to inhibit certain drug biotransformation processes (14, 15). An apparent decrease in the intrinsic clearance of a drug due to elevation of free fatty acids (5, 16) may represent the combined effects of metabolic inhibition and a change in plasma protein binding in the blood as it passes through the liver.

Albumin Binding and Hepatic Uptake: The Importance of Model Selection

Keyphrases □ Albumin—effect on removal of taurocholate by the liver □ Taurocholate—removal by liver, albumin

To the Editor:

Dr. Colburn's letter to the *Journal* in March 1982 (1) purports to invalidate a conclusion we published earlier in the *Journal of Clinical Investigation* (2) concerning the role of albumin binding on the removal of taurocholate by the perfused rat liver. Having just learned of Colburn's communication we offer the following rebuttal. Better late than never!

The observations we reported (which are not in contention) show that the extraction fraction of taurocholate declines only slightly when the perfusate albumin concentration is increased, even though this maneuver reduces the free (unbound) fraction of taurocholate by a factor of five. The table shows the data for rat livers perfused at the same flow rate and with the same total concentration of taurocholate (18 μM).

Albumin Concentration (g/dl)	Free Fraction of Taurocholate in Perfusate	Taurocholate Extraction Fraction
0.5	0.57	0.97
5.0	0.11	0.86

The objective of the experiment was to learn what these numbers imply about the apparent rate constant for hepatic uptake, given that the low concentration of taurocholate ensures that both the binding reaction in extracellular fluid and the removal process are operating far removed from saturation and that the binding reaction is fast enough compared with the removal rate to be considered at equilibrium. These stipulations are also not in contention. Instead the controversy focuses on the choice of an appropriate model with which to interpret the data.

Colburn prefers to model the extracellular fluid as a single homogeneous compartment in which each liver cell is exposed to the same taurocholate concentration—the so-called "lumped" or "venous equilibrium model." In this case the steady-state conservation equation is:

$$Fu_0 = \psi VKu_v + Fu_v \qquad \text{(Eq. 1)}$$

in which ψ is the free fraction, F is perfusate flow, K is the rate constant for removal of free taurocholate, and V is the extracellular volume. The terms, u_0 and u_v, in Eq. 1 are the inflow and outflow concentrations of total taurocholate, respectively. Rearranging Eq. 1 yields:

$$K = FE/[\psi V(1 - E)] \qquad \text{(Eq. 2)}$$

in which the extraction fraction, E, is $(u_0 - u_v)/u_0$. Equation 2 is the one suggested by Wilkinson and Shand (3) to whom Colburn appeals for support.

We have preferred to use a so-called "distributed" model accounting for the decline in taurocholate concentration that occurs along each sinusoid. The conservation relation for a single sinusoid is in this case:

$$F\frac{du}{dx} = -\psi\gamma Ku \qquad \text{(Eq. 3)}$$

where x is the sinusoidal volume running from $x = 0$ at the portal inlet to $x = V$ at the hepatic venous outlet and γ is the ratio of the sinusoidal volume to the volume of the Disse space divided by the sinusoidal volume. The solution to Eq. 3 is:

$$K = -F\ln(1 - E)/\psi\gamma V \qquad \text{(Eq. 4)}$$

If one now computes the ratio of the K values from the observations made with high and low concentrations of albumin, the results are strikingly different depending on the choice of the model.

$\frac{K \text{ at high albumin}}{K \text{ at low albumin}}$	Lumped Model	Distributed Model
	0.98	2.9

The interest in these calculations derives from the fact that both models are constructed on the conventional teaching that only free taurocholate is available for removal. If we accept Colburn's model this assumption appears confirmed because the calculations yield the expected identity of the rate constants. If we accept the distributed model, however, the data contradict the conventional teaching because in this case the rate constants differ by nearly a factor of three. The direction of the discrepancy is such that liver cells appear to enjoy some special mechanism for enhancing the dissociation of the albumin–ligand complex—in effect making more free taurocholate available to liver cells than the conventional teaching would predict. There is, in fact, a growing body of additional evidence to support this conclusion (4–7), but our concern here is with the question of which model to accept.

Those who choose the Colburn model will have to decide where the change from u_0 to u_v occurs. Plainly it cannot be attributed to the removal of taurocholate by hepatocytes because the model requires that all liver cells be exposed to the same concentration. Alternative choices that the drop in concentration occurs in the presinusoidal portal circulation or in the postsinusoidal hepatic veins would not only be anatomic nonsense but would imply that the calculated rate constant has nothing whatever to do with the transport function of liver cells. On this basis we conclude that although Colburn's analysis of the data appears to confirm a widely held preconception, it is physiologically irrelevant. His model simply does not describe a real liver.

0022-3549/83/1000-1232$01.00/0

The distributed model, though possibly oversimplified as well, is certainly a much better representation of the physiological facts. It may even be correct, because on closer inspection (2, 4) the distributed model turns out to be free of restrictive assumptions that the sinusoids are of uniform bore or that each liver cell has the same transport capacity. The interpretation moreover is virtually independent of variations in the distribution of flow to a large population of sinusoids.

Compartmental analysis is a powerful tool for gaining new physiological insights. Its utility, however, depends critically on the validity of the underlying assumptions. If these are wrong so will be the results. The worst of this is that model-dependent interpretations of the data can rarely, if ever, be used to validate the preconceptions on which the model was constructed. We suggest that Colburn may wish to reconsider the simplistic assumptions on which his model rests before taking too seriously the conclusions that flow from it.

Albumin Binding and Hepatic Uptake: The Importance of Model Selection—A Response

Keyphrases □ Albumin—effect on removal of taurocholate by the liver □ Taurocholate—removal by liver, albumin

To the Editor:

Forker and Luxon have written an interesting rebuttal to my earlier communication (1). However, it only serves to confuse the issue even more.

Forker and Luxon presented data in their original report, which they interpreted using the parallel tube or "distributed" model (2). They concluded that albumin helps mediate the removal of taurocholate from a perfused liver preparation. Using the same data, I presented an alternate interpretation using the widely used and accepted well-stirred, venous equilibrium or "lumped" model. I concluded that albumin does not mediate taurocholate removal.

In their rebuttal (3) Forker and Luxon attempt to lend physiological credence to the parallel tube model at the expense of the well-stirred model. Neither model is physiologically realistic in that the liver is neither a well-stirred beaker nor is it a series of parallel tubes.

The theoretical basis for each of these two models has been developed and discussed in depth (4–6). Although the well-stirred model has been shown to be more predictive than the parallel tube model, in some cases (7–8) it would seem that neither model holds a universally distinct advantage over the other and that attributing physiological meaning to parallel tube model-based conclusions, which contradict previous work in the area, would seem unjustified without further substantiation. Unless the data are unequivocal, parsimony should rule, and if a model must be chosen the one that is time proven (7–9) should prevail.

REVIEWS

Proceedings of the First International Symposium on Cyclodextrins. (Budapest, Hungary, 30 September–2 October 1981). Edited by J. SZEJTLI. D. Reidel Publishing Co., 1300AA Dordrecht, Holland. (U.S. Distributor, Kluwer Boston, Inc., 190 Old Derby St., Hingham, MA 02043.) 1982. 544 pp. 17 × 24 cm. Price $84.50.

The cyclodextrins (cycloamyloses) are cyclic oligomers of D-glucose produced by the action of cyclodextrin glycosyltransferases on starch. The products consisting of 6, 7, and 8 glucose units are called α-, β-, and γ-cyclodextrins, respectively; these substances are commercially available, and have attracted the interest of many researchers because the cyclodextrin molecule possesses a cavity of molecular dimensions and is capable of forming an inclusion complex, by acting as the "host," with "guest" species small enough to enter the cavity. In the autumn of 1981, a conference was held in Budapest, Hungary at which workers in the cyclodextrin field presented their results; this book is the proceedings of the conference.

The symposium, and the book, was organized into six parts: Chemistry and Production of Cyclodextrins (7 papers); Enzymology, Toxicology, and Metabolism (10); Cyclodextrin Complexes (16); Cyclodextrin Derivatives (8); Cyclodextrins in Pharmaceuticals (13); and Applications of Cyclodextrins in Foods, Agriculture, and Other Industries (9). Most of the commercial production and applications research is being carried out in Hungary and Japan, and these countries were well represented at the symposium. Only two U.S. laboratories presented papers, so the book does not give a balanced view of the world-wide activity in the field.

Many of the papers will interest pharmaceutical researchers, because the cyclodextrins' capability of forming inclusion complexes can alter the effective properties of a guest drug molecule. This "molecular encapsulation" can affect drug solubility, volatility, dissolution rate, chemical reactivity, and even biological activity. Although cyclodextrins are unlikely ever to become widely used formulation ingredients, it is probable that they will merit occasional specialized application, and laboratories working with drug delivery systems will find this book a useful introduction to current ideas, literature, and workers in the field.

Formulation of Veterinary Dosage Forms. Edited by JACK BLODINGER. Marcel Dekker, New York, NY 10016. 1983. 316 pp. 15 × 23 cm. Price $48.50 (20% higher outside the U.S. and Canada).

This book is a member of a continuing set, which until now collectively comprises 17 volumes of text books and monographs entitled "Drugs and Pharmaceutical Sciences." As stated in the preface of this volume, the book describes the types of drug formulations administered to animals, the art and science used in their development, and the techniques needed to administer them so as to ensure optimum efficacy.

The first five chapters of this volume cover the details of all phases of veterinary dosage formulation from initial development to final stability testing. They are "The Basis For Selection Of The Dosage Form," "Specialized Dose Dispensing Equipment," "Formulation of Drug Dosage Forms For Animals," "Formulation of Drugs For Administration *Via* Feed Or Drinking Water," and "Stability Studies Of Veterinary Formulation." The sixth chapter, "Regulatory Clearance," is well placed at the end and covers the requirements for registration of animal health products in the United States, Australia, Brazil, the European Economic Community, and Japan.

Each chapter is written by an expert on the subject in a crisp, authoritative, and comprehensive manner. Useful details on the development of drug forms for animals which differ from those known in the human field are presented in a logical and succinct manner. Each chapter is well referenced through 1980. The index is extensive and good, providing the reader with cross-referencing to both specific and broad general categories.

This book fills a previous void, and anyone actively involved in formulation of veterinary dosage forms will find it to be of great value.

Radioimmunoassay and Related Procedures in Medicine–1982. Proceedings series; International Atomic Energy Agency. 1983. 823 pp. 15 × 24 cm.

This volume resulted from an international symposium on radioimmunoassay and related procedures in medicine held in Vienna, Austria in June 1982. The symposium was organized and the book edited by the International Atomic Energy Agency. The volume consists of 9 review papers, abstracts of 65 presentations, 23 poster presentations, and edited summaries of the discussions. Areas that were reviewed and had original research presentations include: reagents and separation procedures, assays for free hormones, receptors, biological substances, and drugs. Other areas covered include data processing, intralaboratory control, automation, external surveillance of assay performance, assay services in developing countries, public health, and clinical applications and alternatives to radioassays.

The review papers in this volume are relatively complete discussions of specialized topics in radioimmunoassay technology. The scientific and poster presentations are sufficiently detailed that meaningful scientific information on methods, results, and discussion can be extracted. Because of the large cross section of radioimmunoassay concepts and technology that are covered in this volume, potential readers should carefully examine the specific topics of review or original research to be certain that individual areas of interest are present prior to purchasing or reading this book.

Central Analgetics. Edited by DANIEL LEDNICER. Wiley-Interscience, New York, N.Y., 1982. 219 pp. 15 × 23 cm. Price $47.50.

Central Analgetics is the inaugural volume in the *Chemistry and Pharmacology of Drugs* series under the editorship of Daniel Lednicer. This book provides for the first time a comprehensive collection of reviews of the physiology, pharmacology, and chemistry involved in the transmission of pain, as well as its alleviation by drug therapy.

The book is divided into four chapters, each contributed by an author active in the forefront of the field chosen for critical review. In the first chapter, by J. S. Mohrland, basic physiology of pain is outlined; this includes the complex network of neural pathways, transmitters, and modulators which interact prior to the sensation of pain. Of special interest are discussions pertaining to the interplay between pain stimuli and other central nervous system functions. The second chapter, by P. F. Von Voigtlander, is a compilation of animal models, both *in vivo* and *in vitro*, which have proven usefulness in predicting clinically effective analgetics. In examining the various test methods for abuse potential, dysphoria, and other side effects, the author also presents an overview of current concepts of opioid receptors, thus adding new dimensions and greater depth to his discussions. Chapter 3, by J. S. Morley, deals with

REVIEWS

Proceedings of the First International Symposium on Cyclodextrins. (Budapest, Hungary, 30 September–2 October 1981). Edited by J. SZEJTLI. D. Reidel Publishing Co., 1300AA Dordrecht, Holland. (U.S. Distributor, Kluwer Boston, Inc., 190 Old Derby St., Hingham, MA 02043.) 1982. 544 pp. 17 × 24 cm. Price $84.50.

The cyclodextrins (cycloamyloses) are cyclic oligomers of D-glucose produced by the action of cyclodextrin glycosyltransferases on starch. The products consisting of 6, 7, and 8 glucose units are called α-, β-, and γ-cyclodextrins, respectively; these substances are commercially available, and have attracted the interest of many researchers because the cyclodextrin molecule possesses a cavity of molecular dimensions and is capable of forming an inclusion complex, by acting as the "host," with "guest" species small enough to enter the cavity. In the autumn of 1981, a conference was held in Budapest, Hungary at which workers in the cyclodextrin field presented their results; this book is the proceedings of the conference.

The symposium, and the book, was organized into six parts: Chemistry and Production of Cyclodextrins (7 papers); Enzymology, Toxicology, and Metabolism (10); Cyclodextrin Complexes (16); Cyclodextrin Derivatives (8); Cyclodextrins in Pharmaceuticals (13); and Applications of Cyclodextrins in Foods, Agriculture, and Other Industries (9). Most of the commercial production and applications research is being carried out in Hungary and Japan, and these countries were well represented at the symposium. Only two U.S. laboratories presented papers, so the book does not give a balanced view of the world-wide activity in the field.

Many of the papers will interest pharmaceutical researchers, because the cyclodextrins' capability of forming inclusion complexes can alter the effective properties of a guest drug molecule. This "molecular encapsulation" can affect drug solubility, volatility, dissolution rate, chemical reactivity, and even biological activity. Although cyclodextrins are unlikely ever to become widely used formulation ingredients, it is probable that they will merit occasional specialized application, and laboratories working with drug delivery systems will find this book a useful introduction to current ideas, literature, and workers in the field.

Central Analgetics. Edited by DANIEL LEDNICER. Wiley-Interscience, New York, N.Y., 1982. 219 pp. 15 × 23 cm. Price $47.50.

Central Analgetics is the inaugural volume in the *Chemistry and Pharmacology of Drugs* series under the editorship of Daniel Lednicer. This book provides for the first time a comprehensive collection of reviews of the physiology, pharmacology, and chemistry involved in the transmission of pain, as well as its alleviation by drug therapy.

The book is divided into four chapters, each contributed by an author active in the forefront of the field chosen for critical review. In the first chapter, by J. S. Mohrland, basic physiology of pain is outlined; this includes the complex network of neural pathways, transmitters, and modulators which interact prior to the sensation of pain. Of special interest are discussions pertaining to the interplay between pain stimuli and other central nervous system functions. The second chapter, by P. F. Von Voigtlander, is a compilation of animal models, both *in vivo* and *in vitro*, which have proven usefulness in predicting clinically effective analgetics. In examining the various test methods for abuse potential, dysphoria, and other side effects, the author also presents an overview of current concepts of opioid receptors, thus adding new dimensions and greater depth to his discussions. Chapter 3, by J. S. Morley, deals with

one of the most interesting aspects of analgesic research: the endogenous, pain-regulating peptides and their synthetic analogues. This chapter should be of prime interest to those who seek the new challenges (and opportunities) of designing enkephalin releasers, metabolic inhibitors, as well as antagonists for substance P as analgetics of the future. The book concludes with a chapter by D. Lednicer on the evolution and SAR of major synthetic analgetics based on morphine. Although a good portion of the material treated in this chapter is historical in nature, it nonetheless serves as a useful guide to medicinal chemists and pharmacologists who are embarking on analgesic research. One minor blemish in this otherwise comprehensive coverage lies in the omission of some recently disclosed tricyclic analgetics, which deviate considerably from the partial morphine derivatives, both in structure and in activity profile.

Overall, the quality of production of this volume is excellent; figures and structures are clearly drawn and errors are minimal. It is a fine reference book which fulfills its purpose.

Chromatography of Alkaloids, Part A: Thin-Layer Chromatography. (*Journal of Chromatography*, Vol. 23A). By A. BAERHEIM SVENDSEN and R. VERPOORTE. Elsevier Science Publishing Co., New York, NY 10017. 1982. 533 pp. 16 × 24 cm. Price $104.25 (Dfl. 245).

Although this is the twenty-third volume in a continuing series which began in 1973 with the publication of "Chromatography of Antibiotics" (Volume 1), this is the first volume that is exclusively devoted to the discussion of the chromatography of alkaloids. Because of the large amount of information available, it was decided to publish this volume in two parts: Part A (thin-layer chromatography) and Part B (gas-liquid and high-performance liquid chromatography).

The book is divided into two major portions entitled a "General Part" and a "Special Part." The "General Part," consists of four chapters covering about 60 pages. Chapter 1 includes a discussion of adsorbents, solvent systems, development techniques, sample application, and several tables describing solvent classification and selectivity. Chapter 2 presents a discussion of the various methods of detection, including reagents, tables with color reactions, and a consideration of nonalkaloidal components capable of eliciting false-positive reactions with Dragendorff Reagent. Chapter 3 consists of a general consideration of thin-layer chromatographic separation and identification of alkaloids. This chapter also discusses the use of various reagents, solvent systems, fluorescence, ion-pair adsorption, and ion-exchange thin-layer chromatography. Finally, Chapter 4 includes a discussion of isolation methods and artifact formation resulting from different isolation techniques.

The "Special Part" of the book consists of 17 chapters, about 420 pages, which are devoted to the following classes of alkaloids: pyrrolidine, pyrrolizidine, pyridine, piperidine, quinolizidine, tropane, quinoline, phenethylamine and isoquinoline-derived, indole, steroidal, and miscellaneous. Each chapter consists of an extensive discussion of adsorbents, developing solvents, R_f values, detecting reagents, and references and is richly endowed with tables.

The Appendix alphabetically lists the 106 different reagents that have been discussed throughout the book and includes detailed instructions for their preparation. Finally, the Index is composed of a Subject Index, which contains general topics and classes, and a Compound Index, which contains only compounds.

This is a well-referenced and richly tabled book which should be extremely useful to anyone involved with the detection, isolation/separation, and identification of alkaloids from any source. It is not highly theoretical, nor is it intended to be, and is a practical work which addresses the subject concisely. The price is steep for the individual scientist, but certainly departmental, school, and institutional libraries would want this book in their collection.

Controlled Release Delivery Systems. Edited by THEODORE J. ROSEMAN and S. Z. MANSDORF. Marcel Dekker, Inc., 270 Madison Ave., New York, N.Y. 10016. 1983. 402 pp. 15 × 23 cm. Price $57.50 (20% higher outside the U.S. and Canada).

The book, which contains 25 chapters, describes the proceedings of the Eighth International Symposium on Controlled Release of Bioactive Materials held in Fort Lauderdale, Florida, July 26–29, 1981. The editors of the book are recognized leaders in the field of polymeric controlled-release systems, and the authors selected to contribute full-length manuscripts represent a broad international array of experts in this area.

The topics covered in the book range from biomedical applications to agricultural uses for release vehicles for pesticides and herbicides. Heavy emphasis is placed on polymeric delivery systems with only one chapter on the use of prodrugs and one on liposomes. Subjects covered in the book include liposomes, microencapsulation, reservoir and monolithic devices, biodegradable and swellable matrices, prodrugs, and a contribution on magnetically controlled polymeric systems. All chapters contain a discussion section and all are adequately referenced. A subject index is also included.

This is a useful book, providing a reader with an overview of the various applications in controlled-release technology. It cannot be recommended for an individual seeking an in-depth discussion on any one given subject. However, it is well written and serves to elucidate the current status of this rapidly growing field.

Chromatography of Alkaloids, Part A: Thin-Layer Chromatography. (*Journal of Chromatography*, Vol. 23A). By A. BAERHEIM SVENDSEN and R. VERPOORTE. Elsevier Science Publishing Co., New York, NY 10017. 1982. 533 pp. 16 × 24 cm. Price $104.25 (Dfl. 245).

Although this is the twenty-third volume in a continuing series which began in 1973 with the publication of "Chromatography of Antibiotics" (Volume 1), this is the first volume that is exclusively devoted to the discussion of the chromatography of alkaloids. Because of the large amount of information available, it was decided to publish this volume in two parts: Part A (thin-layer chromatography) and Part B (gas-liquid and high-performance liquid chromatography).

The book is divided into two major portions entitled a "General Part" and a "Special Part." The "General Part," consists of four chapters covering about 60 pages. Chapter 1 includes a discussion of adsorbents, solvent systems, development techniques, sample application, and several tables describing solvent classification and selectivity. Chapter 2 presents a discussion of the various methods of detection, including reagents, tables with color reactions, and a consideration of nonalkaloidal components capable of eliciting false-positive reactions with Dragendorff Reagent. Chapter 3 consists of a general consideration of thin-layer chromatographic separation and identification of alkaloids. This chapter also discusses the use of various reagents, solvent systems, fluorescence, ion-pair adsorption, and ion-exchange thin-layer chromatography. Finally, Chapter 4 includes a discussion of isolation methods and artifact formation resulting from different isolation techniques.

The "Special Part" of the book consists of 17 chapters, about 420 pages, which are devoted to the following classes of alkaloids: pyrrolidine, pyrrolizidine, pyridine, piperidine, quinolizidine, tropane, quinoline, phenethylamine and isoquinoline-derived, indole, steroidal, and miscellaneous. Each chapter consists of an extensive discussion of adsorbents, developing solvents, R_f values, detecting reagents, and references and is richly endowed with tables.

The Appendix alphabetically lists the 106 different reagents that have been discussed throughout the book and includes detailed instructions for their preparation. Finally, the Index is composed of a Subject Index, which contains general topics and classes, and a Compound Index, which contains only compounds.

This is a well-referenced and richly tabled book which should be extremely useful to anyone involved with the detection, isolation/separation, and identification of alkaloids from any source. It is not highly theoretical, nor is it intended to be, and is a practical work which addresses the subject concisely. The price is steep for the individual scientist, but certainly departmental, school, and institutional libraries would want this book in their collection.

Controlled Release Delivery Systems. Edited by THEODORE J. ROSEMAN and S. Z. MANSDORF. Marcel Dekker, Inc., 270 Madison Ave., New York, N.Y. 10016. 1983. 402 pp. 15 × 23 cm. Price $57.50 (20% higher outside the U.S. and Canada).

The book, which contains 25 chapters, describes the proceedings of the Eighth International Symposium on Controlled Release of Bioactive Materials held in Fort Lauderdale, Florida, July 26–29, 1981. The editors of the book are recognized leaders in the field of polymeric controlled-release systems, and the authors selected to contribute full-length manuscripts represent a broad international array of experts in this area.

The topics covered in the book range from biomedical applications to agricultural uses for release vehicles for pesticides and herbicides. Heavy emphasis is placed on polymeric delivery systems with only one chapter on the use of prodrugs and one on liposomes. Subjects covered in the book include liposomes, microencapsulation, reservoir and monolithic devices, biodegradable and swellable matrices, prodrugs, and a contribution on magnetically controlled polymeric systems. All chapters contain a discussion section and all are adequately referenced. A subject index is also included.

This is a useful book, providing a reader with an overview of the various applications in controlled-release technology. It cannot be recommended for an individual seeking an in-depth discussion on any one given subject. However, it is well written and serves to elucidate the current status of this rapidly growing field.

one of the most interesting aspects of analgesic research: the endogenous, pain-regulating peptides and their synthetic analogues. This chapter should be of prime interest to those who seek the new challenges (and opportunities) of designing enkephalin releasers, metabolic inhibitors, as well as antagonists for substance P as analgetics of the future. The book concludes with a chapter by D. Lednicer on the evolution and SAR of major synthetic analgetics based on morphine. Although a good portion of the material treated in this chapter is historical in nature, it nonetheless serves as a useful guide to medicinal chemists and pharmacologists who are embarking on analgesic research. One minor blemish in this otherwise comprehensive coverage lies in the omission of some recently disclosed tricyclic analgetics, which deviate considerably from the partial morphine derivatives, both in structure and in activity profile.

Overall, the quality of production of this volume is excellent; figures and structures are clearly drawn and errors are minimal. It is a fine reference book which fulfills its purpose.

Improving the Reliability of Clinical Investigators

[Editor's note: The May 1983 editorial triggered an exchange of letters between former FDA Commissioner Jere E. Goyan and the author of the editorial, Edward G. Feldmann. In the interest of stimulating further thought on the important subject dealt with in the editorial, they have agreed to publication of their correspondence which follows herewith.]

Goyan letter to Feldmann, dated June 2, 1983:

Just a note to let you know that I read your editorial[1] entitled "The 'Weak Link' in Drug Research." I was somewhat astonished at your analysis and conclusions but understand your concerns. Indeed, one of the biggest shocks of my life was the opportunity to review some of the proposed disciplinary actions against clinical investigators. It is distressing to learn that many of the people in the "white hats" are at least somewhat gray, if not black. However, I am a little hard pressed to understand what alternatives we might have in this regard. It seems to me that we are going to have to make use of clinical investigators in academic settings, but unfortunately we may have to devote more resources to their policing. In any case, it was as usual a very provocative and worthwhile editorial.

Received June 6, 1983.

[1] E. G. Feldmann, *J. Pharm., Sci.*, **72**, 463 (1983).

Feldmann letter to Goyan, dated June 7, 1983:

Last week I attended an FDA retirement dinner and reception and had an opportunity to chat with various FDA staff members from new drug officers to enforcement/compliance people to legal staff, and I was frankly surprised at how many of them apparently had read the editorial, brought it up in conversation with me, and expressed their personal concerns regarding the reliability of clinical investigators and their data submitted in support of NDAs. It was quite apparent to me that I had hit a responsive chord among the FDA staff.

I fully understand your comments as to the difficulty in identifying alternatives to our present system. I am not sure that I have any magical answers either, and for that reason did not attempt to include any in the editorial.

However, it would seem to me that arrangements could be worked out which would involve individuals (clinical investigators) who are *employees* of drug firms being based physically at hospitals or in academic settings which would enable them to conduct investigations in much the same environment and with the same basic *modus operandi* that is presently utilized—the only significant difference being that rather than functioning as independent contractors, they would actually be employed by the drug company involved.

In a sense, it might be argued that this kind of arrangement would result in somewhat less "independence" or "independent authority" on the part of the clinical investigator. Although that argument (for "independence") sounds good in theory, in practice there appear to be certain drawbacks:

(a) The company, *per se*, is not responsible for the actions of the clinical investigator, and it can readily disclaim responsibility if there is any "hanky panky."

(b) A conscientious drug firm has its hands tied and cannot have complete access to the data to the degree that it would have if the investigator were a paid employee; hence, it cannot fully assure itself of the completeness, adequacy, and suitability of the data.

(c) Under the present system, independent investigators feel pressured to provide favorable reports to their sponsoring or contracting companies if they hope to generate future "business." However, if they were on the regular payroll, they would have no more pressure in this regard than other comparable departments within the firm, such as the other divisions within the research and development department.

(d) The clinical investigations could be made a much more intimate part of the comprehensive NDA in that they would be simply another part of the company's overall research effort rather than a separate sort of "appendage" to the NDA, as many of them are currently.

I realize that some may object to such an arrangement in that it tends to reduce "academic freedom." On the other side of the coin, however, it also tends to result in better cooperation and interchange between industry and academia—a goal or objective that we frequently hear and read is being currently encouraged. As I noted above, I am not sure this is either the preferred or even a feasible idea, but it is one alternative to our present system.

Goyan letter to Feldmann, dated June 14, 1983:

Thank you for your letter of June 7. I hope you will see fit to publish your thoughts, as outlined in the letter, in the *Journal* in the near future. They are both interesting and provocative and may well be the way of the future. In any case, you have struck a responsive chord in a number of us, and I, for one, would like to see some sort of debate initiated in this regard.

Kavanagh letter to Feldman

Your editorial "The Weak Link in New Drug Research" [1] points to an old problem well known to drug makers which is now receiving public attention. I see no way to improve the quality of clinical testing and its evaluation. My reasons are the following.

These observations are based on approximately 28 years of experience with two drug companies and rely on material provided to me by employees of other companies. In general, the opinion among scientists employed by drug companies is that physicians make very poor directors of research, at any level, since they have neither the aptitude for scientific work nor the training as scientists. My experience leads me to agree with this opinion.

A physician from Parke-Davis said in 1960 that he envied Eli Lilly and Co. because it had its own clinical facilities, in operation since 1926. This in-house clinical facility was to evaluate clinical reports submitted by outside physicians who were clinically evaluating Lilly products. The availability of this monitoring function should make clinical investigations more efficient.

Here are some specific examples. Around 1960, pediatricians in San Francisco were treating neonates routinely with 20 mg/kg chloramphenicol (twice the dose recommended by Parke-Davis for adults), and approximately one-third of the infants died. Parke-Davis, of course, was blamed. Another drug company informed me they could use only about one-third of the results from their contracted clinical studies. An analyst for another company visited six clinicians who were studying a new antibiotic and found that only one was using an assay that would give meaningful data. During the study of a new antibiotic, an assay laboratory found interfering material in the urine of patients being treated with the new antibiotic. Paper chromatography revealed as many as seven foreign antibiotics in the urine samples. The physicians were amazed that the laboratory discovered they were using more than one drug.

I wonder how much of this kind of information ever gets back to anyone in charge of clinical testing. What could be done with the

information? Obviously, this system of testing is expensive, time consuming, and frustrating for the drug companies, but what can they do as long as physicians dominate clinical testing?

The basic problem with clinical testing is the assumption that physicians are scientists. There is no reason to expect a physician to be a scientist.

Clinical testing will improve only when properly qualified people do the work. The physicians who are members of a testing team should be selected for scientific aptitude and then given the needed training. The team should include a physician, a pharmacist (preferably Pharm.D.), an experienced technical writer (to help organize data and prepare the reports), and such other support personnel as needed for that particular study. In the case of antibiotic testing, the team should include someone experienced in the principles and practices of using a microbiological assay for antibiotics (these people are rare).

One reason I am pessimistic about the possibility of improving clinical testing is the difficulty in getting physicians to give up the power they now possess. The ego problem could be minimized by selecting the physician members from among those who have a Ph.D. degree in a related subject such as zoology or physiology. Their previous experience in a laboratory would assure their understanding the importance of scientific protocol, the awareness that correlation and cause are not synonymous, and the effects of genetic makeup of the patients on results.

Many more examples could be given, but these are sufficient to indicate what some of the problems are. Obviously, no drug firm would dare make public these complaints. The firms doing the research are dependent on the good will of physicians for their success.

Pharmaceutical Analysis and Control Award

Members of the Pharmaceutical Analysis and Control (PAC) Section of the APhA Academy of Pharmaceutical Sciences are concerned about the paucity of students choosing to study pharmaceutical analysis at the doctoral level. As a means of promoting graduate study in this discipline, the PAC Section is offering an undergraduate award in pharmaceutical analysis for 1984. Applications are currently being invited from undergraduate students enrolled in the last two years of baccalaureate or equivalent degree programs in accredited schools or colleges of pharmacy and departments of chemistry who have demonstrated interest and potential for a career in pharmaceutical analysis. The Award will consist of scholarship support ($1,000) for a ten-week summer period or equivalent (NLT 400 hrs) of laboratory research in pharmaceutical analysis. Applications are due in the Academy Office by December 31, 1983. Notice of awards will be mailed by March 31, 1984. Application instructions and application forms are available by calling or writing: APhA Academy of Pharmaceutical Sciences, Undergraduate Award in Pharmaceutical Analysis, 2215 Constitution Avenue, N.W., Washington, D.C., 20037, (202) 628-4410.

We encourage faculty and students to apply for the PAC Award in Pharmaceutical Analysis. Thank you.

Keeping Current With Technology

"Technology." Over the years, we have all heard and used this term many times. But yet, during the past year or two, it has virtually burst onto the contemporary scene with a whole new dimension and depth of meaning.

To compare the technology in our daily lives of five years ago *versus* that of today, is almost like comparing flight by hot air balloon to flight by supersonic jet aircraft. Simply put, recent changes in technology have been that great.

Every facet of our lives from work to play, to recreation, to personal living has been affected, and the developments have occurred with astonishing swiftness. Indeed, the rate of change has been as mind-boggling as the degree of change.

For example, just about a year ago, video games arrived and mushroomed with such attraction and public acceptance that investment counselors were touting the stock of all their manufacturers, the games were by far the biggest seller of the 1982 Christmas season, and video game parlors were popping up in almost every neighborhood shopping center. But now, less than a year later, we just heard a report that video games have peaked in popularity, and predictions are that the games, their franchise operations, and their manufacturers will soon experience a severe decline that will be every bit as rapid and intense as their recent, rocketing popularity.

One of the most innovative and revolutionary computer manufacturers, Osborne Computer Corporation, had a similar rapid ascendancy as it carved out a major share of the computer market of two to four years ago. But just as this column was being written, business and financial reports in the public press are describing the sudden demise of that company. It went from one of the most popular growth stocks to filing for bankruptcy within the short period of approximately six months. In explanation, a security analyst said that "time had simply passed them by." Their relatively small, portable units were a dramatic breakthrough compared with the large, floor model consoles previously available; but, in turn, those table model units were made equally obsolete by the much smaller, lighter, and more portable units that competitors came out with just a few months later.

In the pharmaceutical field, the impact of rapidly changing technology is almost as dramatic.

At a corporate level, there have been some mergers and acquisitions that at first seem strange, but upon reflection make a great deal of sense. Witness the marriage of Smith Kline & French Laboratories, and Beckman Instruments Company. Ten years ago, we could never have visualized any common denominator between a "Spansule® Capsule" and a "DU Spectrophotometer." But today is a completely different story.

And at the level of drug dosage forms, we increasingly hear of "new drug delivery systems." Time-release implants, transdermal absorption, nasal administration, implanted drug pumps, and various other approaches to *in vivo* biological drug delivery are no longer either dreams, speculations, or theory, but are now being routinely used in patients.

Again, the suddenness of this change is literally breathtaking. Scientists and practitioners who were up-to-date a few short years ago, today find themselves embarrassingly obsolescent if they have not kept abreast of these developments.

For this reason in particular, the American Pharmaceutical Association and its subdivisions—including the Academy of Pharmaceutical Sciences—have chosen the theme of "Technology 2000" for the APhA and APS Annual Meeting to be held May 5–10, 1984, in Montreal, P.Q., Canada.

All aspects of the meeting—from exhibitors, to general sessions, to special presentations—will focus on and emphasize technology, its recent advances, and its impact on current pharmaceutical research, development, and practice. With respect to exhibits in particular, a special effort is being put forth to attract technology-oriented exhibitors so that the Exposition at the 1984 Annual Meeting will constitute a convenient, ready-made opportunity to see first-hand the most up-to-date equipment being put through its paces in providing modern technological benefits.

All of these offerings should go far in assisting the meeting registrants to put this new technology into mental perspective and to relate it to the way that pharmacy will be practiced and pharmaceutical research will be conducted in the 21st century.

We strongly urge all of our readers to plan to attend the 1984 Annual Meeting in order that, individually, they will not find themselves suffering the fate of some of the recently high-flying computer manufacturers who suddenly found to their dismay that "time had simply passed them by."

Physiologically Based Pharmacokinetic Model for β-Lactam Antibiotics I: Tissue Distribution and Elimination in Rats

AKIRA TSUJI *x, TAKAYOSHI YOSHIKAWA *, KAZUNORI NISHIDE *, HIDEMI MINAMI *, MOTONOBU KIMURA *, EMI NAKASHIMA *, TETSUYA TERASAKI *, ETSUKO MIYAMOTO *¶, CHARLES H. NIGHTINGALE §, and TSUKINAKA YAMANA ‡

Received April 5, 1982, from the *Faculty of Pharmaceutical Sciences and ‡Hospital Pharmacy, Kanazawa University, Kanazawa 920, Japan and §Hartford Hospital, Hartford, CT 06115 and University of Connecticut, School of Pharmacy, Storrs, CT 06268. Accepted for publication September 2, 1982. ¶Present address: School of Pharmacy, Hokuriku University, Kanazawa 920-11, Japan.

Abstract □ The disposition characteristics of β-lactam antibiotics in rats were investigated, and a physiologically based pharmacokinetic model capable of predicting the tissue distribution and elimination kinetics of these drugs was developed. Protein-binding parameters in rat serum were determined by equilibrium dialysis. Linear binding was found for penicillin G, methicillin, dicloxacillin, and ampicillin; however, nonlinear binding was observed for penicillin V and cefazolin. After intravenous bolus dosing, cefazolin was recovered almost completely in urine and bile, while for the penicillins, penicilloic acid was found to be the major metabolite. Biliary excretion of cefazolin followed Michaelis-Menten kinetics, and no significant inhibition of urinary secretion was observed after probenecid administration. The renal clearance of unbound drug was 0.82 ml/min with a reabsorption ratio (R) of 0.22. Tubular secretion was inhibited for the penicillins by probenecid plasma concentrations of 50 μg/ml, resulting in an R-value of 0.32. Erythrocyte uptake, serum protein binding, and tissue-to-plasma partition coefficient (K_p) were measured. Theoretical K_p values were calculated and found to be in good agreement with the K_p values for three of the antibiotics. Plasma and tissue concentrations (lung, heart, muscle, skin, gut, bone, liver, and kidney) were measured as a function of time at various doses for inulin and cefazolin in rats after an intravenous bolus dose, and were found to be in reasonable agreement with concentrations predicted by the model. These correlations demonstrate that the proposed model can accurately describe the plasma and tissue contributions of inulin and cefazolin in the rat and suggest that this model could have utility in predicting drug distribution in humans.

Keyphrases □ β-Lactam antibiotics—protein binding and metabolism, rats, pharmacokinetics, physiologically based model □ Pharmacokinetics—β-lactam antibiotics, protein binding and metabolism in rats, physiologically based model □ Metabolism—β-lactam antibiotics in rats, pharmacokinetics, physiologically based model

Serum or plasma levels of antibiotics are often used as indices of pharmacological efficacy. However, since bacterial infections are generally localized in the extravascular space, it is important to know the antibiotic concentration in the interstitial fluid. Numerous pharmacokinetic studies on penicillins and cephalosporins have been published (1–6); however, few compare kinetically the levels of these antibiotics in plasma and tissues. Physiologically based pharmacokinetic models (7–12) have been developed using data obtained from animals such as tissue binding or tissue-to-plasma partition coefficients (K_p). Some of these studies have been used successfully to predict both plasma and tissue levels in humans (7–9, 11). Recently, Greene *et al.* (13) reported that using serum protein binding and renal clearance data, the novel physiological pharmacokinetics of cephalosporins could be adapted to predict plasma concentration–time profiles after bolus intravenous injections in humans.

This study describes the metabolism and tissue binding behavior of several β-lactam antibiotics in rats, establishes a mathematical model for the interpretation of tissue distribution and elimination kinetics of these antibiotics, and describes the use of inulin as a model drug for verification of the present model.

EXPERIMENTAL

Materials—Penicillin G potassium (1595 U/mg)[1], methicillin sodium (843 μg/mg)[2], penicillin V potassium (1490 U/mg)[1], propicillin potassium (888 μg/mg)[3], dicloxacillin sodium (884 μg/mg)[1], ampicillin sodium (959 μg/mg)[3], 6-aminopenicillanic acid (97.6% pure)[1], cefazolin sodium (945

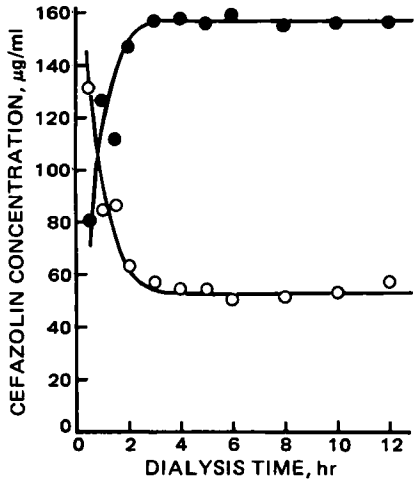

Figure 1—*Cefazolin concentrations in buffer (○) and rat serum (●) compartments at 37° during the protein binding experiment. The initial concentration of cefazolin in the buffer compartment was 200 μg/ml.*

μg/mg)[4], *and indocyanine green*[5] were used as received. [^{14}C]Cefazolin[4] with a specific activity of 2.04 μCi/mg was supplied, and [^{14}C]inulin (2.4 μCi/mg) was purchased from a commercial source[6]. Unless otherwise specified, the radiolabeled drug was used in conjunction with a cold carrier.

Solutions of the penicilloic acids of dicloxacillin, propicillin, penicillin V, ampicillin, and 6-aminopenicillanic acid were prepared according to the method of Schwartz and Delduce (14). All other chemicals were reagent grade and were used without further purification.

Animals—Male albino Wistar rats, weighing ~240 g, and a 9-kg beagle dog were fasted for 20 hr prior to the experiment, with free access to water. The rats were anesthetized with urethane (1.3 g/kg ip) ~1 hr prior to surgery. The dog was anesthetized with sodium pentobarbital[7] administered intravenously at a dose of 25 mg/kg.

Intravenous Bolus Injection—The ureters and bile ducts of rats were catheterized with polyethylene tubing[8], and the drugs were injected (over 5 sec) through the femoral vein. The β-lactam antibiotics or inulin were dissolved in 0.5 ml of normal saline. For the plasma and tissue concentration studies, blood samples (~0.2 ml) were withdrawn from the jugular vein at designated times after drug administration and collected in heparinized tubes. The blood was centrifuged at 3000 rpm, and plasma

separated. The total blood volume taken from any rat in a single experiment was ≤1.6 ml.

For tissue sampling, the rats were sacrificed, and the lung, heart, skeletal muscle, bone, gut (from duodenum to the cecum), liver, and kidney were quickly excised, rinsed with ice-cold saline, blotted dry, and weighed. These tissues were homogenized with a two- to fivefold excess of isotonic phosphate buffer (pH 7.4) in a polytef homogenizer. The entire skin was stripped from the rat carcass. Sections of the skin from the flank regions were sampled and cut into small pieces. Bone samples were taken from the femoral and foreleg portions and crushed. The chips of skin and bone were weighed and extracted with isotonic phosphate buffer (pH 7.4) by shaking for 4 hr. The fluids were then centrifuged at 3000 rpm for 10 min, and the supernatant was removed for microbiological assay of cefazolin and for the colorimetric assay of inulin.

In the experiments using radioactive drugs, the rats were injected with a 10- to 200-mg/kg dose of cefazolin or a 20-mg/kg dose of inulin, each of which contained radiolabeled drug. The excised tissue samples were rinsed with ice-cold saline and blotted dry. One-half of the dry tissue was used for analysis.

Determination of Hepatic Blood Flow—The hepatic blood flow of rats under urethane or ether anesthesia was estimated using the method of Yokota *et al.* (15). A priming dose of indocyanine green was injected into the femoral vein of the rat and immediately followed by a constant infusion[9] of the dye into the opposite femoral vein at a rate of 13–27 μg/min, yielding a steady-state plasma level of ~10 μg/ml. Three blood samples (0.2 ml each) were simultaneously withdrawn from the hepatic vein and femoral artery every 10 min starting 60 min after the initiation of the dye injection. The plasma was separated by centrifugation and stored at 4° until assayed. Aliquots (50–100 μl) of the plasma were diluted 10- to 20-fold with distilled water and quantified by measurement of the absorbance at 800 nm[10]. Hematocrits (Hct, %) were measured[11] using the first and last arterial and hepatic venous blood samples, and averaged. The hepatic plasma and blood flows were calculated with the equation of Bradley *et al.* (16).

Determination of Tissue-to-Plasma Partition Coefficients—The equilibrium tissue-to-plasma concentration ratios, K_p, of penicillin V, dicloxacillin, cefazolin, and [^{14}C]inulin were obtained experimentally for each of the tissues used in the pharmacokinetic model. Solutions of the penicillins, cefazolin with or without added [^{14}C]cefazolin, and inulin containing [^{14}C]inulin prepared with saline were infused[9] at a rate of 0.5 ml/hr through the femoral vein of rats. Based on the preliminary experimental data collected after intravenous bolus injection of each drug, a priming dose was administered to quickly attain a steady-state condition.

Blood samples were withdrawn periodically through the jugular vein. After 2 or 3 hr of infusion, blood samples from the femoral artery, renal vein, and hepatic vein were taken. The animals were sacrificed immediately by exsanguination *via* the carotid artery. Tissue samples taken at the steady-state plasma level were prepared in the same manner as described above for bolus-dose experiments.

The distribution of antibiotics into erythrocytes and bone marrow were studied under the conditions described above. In addition, a beagle dog was infused with cefazolin at a rate of 180 mg/hr, without a priming dose,

Table I—Binding Parameters [a] of β-Lactam Antibiotics with Rat Serum Protein

β-Lactam Antibiotic	n [b]	$10^{-4} K_B$ [b], M^{-1}	$10^{-4} K_{B,app}$ [c], M^{-1}
Penicillin G	—	—	1.132 ± 0.048
Penicillin V	2.78 ± 0.26	0.109 ± 0.014	—
Methicillin	—	—	0.656 ± 0.070
Ampicillin	—	—	1.322 ± 0.048
Dicloxacillin	—	—	7.434 ± 0.448
Cefazolin	0.63 ± 0.03	2.980 ± 0.479	—

[a] The binding parameters were determined by the equilibrium dialysis method at 37°. An albumin concentration of 5.00×10^{-4} M was used for calculation. [b] Defined by Eq. 1. [c] Defined by Eq. 2.

over a 10-hr period. After achievement of steady-state levels, aliquots of blood were withdrawn periodically through a cannula inserted into the saphenous vein of the dog. Bone marrow fluids were withdrawn periodically from a portion of femoral bone using the usual puncture technique. The hematocrits of the blood samples were determined[11]. Antibiotic concentrations of the whole blood and whole bone marrow were determined after hemolysis with an equivalent volume of distilled water. The results were used to estimate the partition coefficients of these antibiotics between plasma and erythrocytes and between plasma and bone marrow.

Determination of Renal and Hepatic Clearances—Intravenous infusions were performed to measure the renal and hepatic clearances of penicillin G or cefazolin at steady state in rats. In the renal clearance measurements, the femoral artery, femoral vein, left renal vein, and ureters were cannulated. Antibiotic solutions containing inulin to estimate the glomerular filtration rate (GFR) were prepared with 3% mannitol and infused[9] at a rate of 3.7 ml/hr through the femoral vein using a priming dose for each drug. After constant urine flow and steady-state levels of the antibiotic and inulin were achieved, urine was collected over 30-min intervals and blood was withdrawn through the femoral artery and renal vein at the midpoint of the urine collection period. The renal excretion rate (dX_u/dt) was calculated from $dX_u/dt = C_u UF$, where C_u and UF indicate the urine concentration of drug and urine flow in ml/min, respectively.

The inhibitory effect of probenecid on the tubular secretion of penicillin G and cefazolin were examined as follows. Probenecid was dissolved in aqueous sodium hydroxide and then neutralized with hydrochloric acid. A 3% mannitol solution containing penicillin G, cefazolin, or inulin, and probenecid was infused at a rate of 3.7 ml/hr. In each experiment, the steady-state plasma concentration of probenecid was assayed.

The procedure used to measure the hepatic clearance of cefazolin, was essentially the same as that described for determining hepatic plasma flow. At steady state, the total plasma concentration (bound and unbound) of cefazolin in the femoral artery, hepatic vein, and bile were determined by microbiological assay.

Determination of Serum Protein Binding—Acrylic resin plates with four compartments of 5 mm depth and 25 mm diameter were used for the dialysis studies. Two plates were joined tightly, holding a cellulose membrane[12] between them. An 0.8-ml aliquots of rat serum was put into one compartment and, unless otherwise specified, 0.8 ml of pH 7.4 isotonic phosphate buffer containing an appropriate concentration of antibiotic was put into the other compartment. The plates were incubated for 6 hr at 37°. After appropriate dilution of equilibrated samples with the isotonic phosphate buffer, the antibiotic concentrations in both compartments were measured by microbiological assay. The concentration of the antibiotic bound to serum protein was obtained by subtracting the concentration of unbound drug from the total drug concentration. When the effect of the buffer component on the binding ratio was investigated, the following solutions were used instead of isotonic phosphate buffer: Tris-hydrochloride buffer (pH 7.4), 0.067 M phosphate buffer (pH 7.4), and protein-free rat serum obtained by ultrafiltration[13] of pooled serum.

Paper Chromatography—Paper chromatography was conducted in a cold room according to the method of Thomas (17). The developing solvent was n-butyl alcohol–pyridine–water (1:1:1). A portion of the urine or bile sample was treated with 1 N NaOH for 20 min at room temperature followed by neutralization with 1 N HCl, and 10 μl was spotted on the paper[14]. Ten microliters of the untreated portion was spotted directly on the paper. The chromatograms were visualized by spraying with 1% starch in acetic acid–0.1 N I_2–4% KI (50:3:1). For detection of intact penicillin V, the paper was sprayed with 0.1 N NaOH and after 20 min sprayed with 0.1 N HCl. Standard samples of each penicillin and penicilloic acid were prepared using normal urine and bile and were chromatographed similarly as a reference marker.

Table II—Urinary and Biliary Recoveries (Percent of Dose) of Penicillin V and Its Metabolites after Intravenous Administration in Rats [a]

Compound	Urine, %	Bile, %	Total, %
Penicillin V	13.8 ± 6.6	29.5 ± 3.1	43.3 ± 7.3
Phenoxymethylpenicilloic acid	17.1 ± 2.2	18.7 ± 1.0	35.8 ± 2.4
6-Aminopenicillanic acid and its penicilloic acid	6.9 ± 2.8	15.1 ± 2.0	22.0 ± 3.4
Total			101.1 ± 8.4

[a] The urine and bile collection periods were 0–9 hr and the dose was 100 mg/kg. Each point represents the mean of three rats ± SD.

Analytical Procedures—*Microbiological Assay*—Plasma, urine, bile, and tissue samples from rats administered β-lactam antibiotics were assayed (unless otherwise specified) by the microbiological paper disk diffusion method using *Sarcina lutea*[15], *Staphylococcus aureus*[16], or *Bacillus subtilis*[17] as the test organism. In the determination of drug distribution into erythrocytes, blood samples used for plasma quantification were hemolyzed with an equal volume of distilled water and analyzed. Calculation of the antibiotic concentration was made from standard curves prepared using pooled blood, urine, bile, and the corresponding tissue homogenates. The accuracy of the microbiological assay was ±5%.

Spectrofluorometric Assay—Spectrofluorometric methods were utilized for simultaneous analysis of a penicillin and the penicilloic acid metabolite in whole blood, urine, and bile. The blood was hemolyzed with an equal volume of distilled water. The analytical method employed for samples taken after intravenous administration of penicillin V, propicillin, or dicloxacillin was based on the formation of a fluorescent Schiff-base resulting from the reaction between penicilloaldehyde and 0.1% 5-dimethylaminonaphthalene-1-sulfonylhydrazine. After acylation with phenoxyacetic anhydride at pH 9.0, 6-aminopenicillanic acid and its cleaved β-lactam ring product were assayed as described previously[18] (18). The method of Miyazaki *et al.* (19) was used for quantification of ampicillin. The accuracy of the fluorometry assay was ±4%.

Radiochemical Assay—The radioactivity of [^{14}C]cefazolin and [^{14}C]inulin in plasma was determined by direct liquid scintillation counting[19]. Triplicate 50–250-μl aliquots of plasma were added to glass counting vials containing 10 ml of dioxane-based scintillation fluid. Quenching was corrected by the external standard method. Tissue samples after intravenous bolus dosing or constant infusion were oxidized[20] to $^{14}CO_2$, and radioactivity was determined by liquid scintillation counting[19].

Determination of Inulin—The method used for the determination of inulin in plasma, urine, and lung tissue was a modified form of the colorimetric assay developed by Waugh (20). Reagents and standard solutions of inulin were prepared as described previously (20). Samples of plasma (0.1 ml), 0.3 ml of distilled water, and 0.1 ml of zinc sulfate reagent were added to centrifuge tubes, followed by the addition (with continuous agitation) of 0.1 ml of 0.5 N NaOH. After centrifugation at 3000 rpm for 10 min, the supernatant was removed for analysis. Urine was assayed by adding 0.5 ml of zinc sulfate reagent and 0.5 ml of 0.5 N NaOH to 1.0 ml of urine, yielding a protein-free supernatant. For tissue sample assay, the tissue was cut into small pieces. The chips were weighed and extracted with saline by shaking for 4 hr. The fluids were then centrifuged at 3000 rpm for 10 min, and the supernatant was analyzed.

Aliquots (0.2 ml) of the supernatant from plasma, urine, or tissue samples were placed in a test tube, 0.2 ml of 1.8 N NaOH was added, and

Table III—Urinary and Biliary Recoveries (Percent of Dose) of Penicillins and Their Penicilloic Acids after Intravenous Administration in Rats [a]

Penicillin	Intact Penicillin, %			Penicilloic Acid, %		
	Urine	Bile	Total	Urine	Bile	Total
Penicillin G [b]	30.0 ± 13.8	25.7 ± 3.6	55.7 ± 14.3	3.7 ± 1.0	12.9 ± 2.9	16.6 ± 3.1
Propicillin	19.1 ± 11.1	24.2 ± 2.4	43.3 ± 11.4	4.4 ± 1.3	21.0 ± 2.0	25.4 ± 2.4
Dicloxacillin	9.6 ± 6.0	14.4 ± 7.1	24.0 ± 9.3	5.5 ± 3.1	24.4 ± 3.4	29.9 ± 4.6
Ampicillin	34.9 ± 13.2	19.5 ± 2.3	54.4 ± 13.4	3.2 ± 1.4	9.9 ± 4.1	13.1 ± 4.3

[a] The urine and bile collection periods were 0–3 hr; the dose was 100 mg/kg. Each point represents the mean of three rats ± *SD*. [b] The urine and bile collection periods were 0–24 hr; the dose was 100 mg/kg. Each point represents the mean of eight rats ± *SD*.

the mixture was heated at 100° for 10 min. The mixture was cooled and 3 ml of 70% (v/v) H_2SO_4 and 0.3 ml of cysteine–tryptophan reagent was added. After heating at 50° for 25 min, the solution was cooled to room temperature and the color was evaluated against a blank[11] at 515 nm.

Determination of Probenecid—Concentrations of probenecid in plasma and urine were determined by a high-performance liquid chromatographic (HPLC) assay (21). Samples were prepared as described previously (21), but the chromatographic conditions were modified slightly. A reverse-phase column[21] (25 cm × 4.6-mm i.d.), packed in this laboratory, was used in conjunction with a chromatograph[22] equipped with a variable-wavelength detector[23]. The mobile phase was acetonitrile–0.014 *M* pH 6.0 phosphate buffer (3:7). The column and solvent were kept at ambient temperature. A flow rate of 2.5 ml/min was used, yielding an operating pressure of 110 kg/cm^2. The spectrophotometric detector had an 8-μl flow cell and was operated at 254 nm; the injection volume was 50 μl. Complete peak resolution was obtained with a retention time of 4 min. Peak heights were used for quantification; standard curves were generated by blank plasma and urine samples spiked with varying amounts of probenecid as described previously (21).

Data Analysis—The data were analyzed using a digital computer[24]. The program used for the physiologically based pharmacokinetic models was designed in-house by incorporating the NUMINT program, a subroutine in NONLIN (22).

RESULTS

Serum Protein Binding—Cefazolin diffused rapidly from the buffer compartment into the serum compartment (Fig. 1). Equilibrium was established within 4 hr and was maintained for the 12-hr duration of the experiment. The effect of buffer components on the binding behavior of cefazolin was also examined. The percentage of cefazolin bound at a total concentration of 70 μg/ml was determined to be 85.6 ± 3.4, 86.8 ± 3.6, 88.3 ± 1.8, and 85.1 ± 3.0 in isotonic phosphate buffer (pH 7.4), 0.067 *M* phosphate buffer (pH 7.4), Tris-hydrochloride buffer, and protein-free rat serum, respectively. These differences were not statistically significant.

Figure 2 illustrates the protein binding profiles for each of the studied β-lactam antibiotics as a function of the postdialysis antibiotic concentration. The protein binding behavior varied among antibiotics. Nonlinear protein binding was observed for cefazolin and penicillin V, whereas apparent linear binding was found for penicillin G, methicillin, dicloxacillin, and ampicillin. Assuming that albumin is the sole binding protein for β-lactam antibiotics, then:

$$C_B = \frac{nPK_BC_F}{1 + K_BC_F} \qquad \text{(Eq. 1)}$$

where C_B and C_F are the concentrations of antibiotic bound and unbound with serum protein, n is the number of binding sites on the albumin molecule, K_B is the affinity constant for albumin, and P is the albumin concentration (mol. wt. 69,000) in serum. (Measured values for P averaged 5.0×10^{-4} *M*.) The nonlinear least-squares regression computer program, NONLIN, was used to fit the data to Eq. 1. In the case of linear binding, simplification of Eq. 1 yields:

$$C_B = K_{B,app}PC_F \qquad \text{(Eq. 2)}$$

where $K_{B,app}$ is the apparent affinity constant for albumin. The binding parameters are presented in Table I.

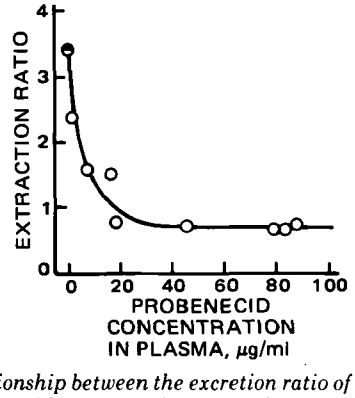

Figure 4—*Relationship between the excretion ratio of penicillin G and the plasma probenecid concentration at steady state after the constant and simultaneous infusion of penicillin G, probenecid, and inulin to rats. The point for the control experiment without probenecid (●) represents the mean value (3.41 ± 0.96) of five rats.*

Metabolic Elimination After Intravenous Bolus Injection—Paper chromatography of rat urine and bile samples after the intravenous administration of penicillin V detected penicilloic acid (R_f 0.72) and the β-lactam ring-cleaved product of 6-aminopenicillanic acid (R_f 0.35). English *et al.* (23) previously found 6-aminopenicillanic acid as well as penicilloic acid in urine after intravenous and oral administration of some penicillins in animal species. Table II shows that unchanged penicillin V (43%), penicilloic acid (36%), and the sum of 6-aminopenicillanic acid and the β-lactam ring-cleaved product (22%) were excreted over 9 hr both in urine and bile after a single dose of penicillin V. Total recovery in urine and bile was 101 ± 8%. The penicilloic acids were found to be the major metabolites of penicillin G, propicillin, dicloxacillin, and ampicillin (Table III). Kind *et al.* (24) demonstrated that penicillin G and ampicillin were inactivated at different rates by isolated rat liver cells; this suggests a metabolic route for these compounds.

Cafazolin, on the other hand, was recovered almost completely in the intact form in urine and bile after intravenous single-dose administration in rats (Fig. 3). Nishida *et al.* (25) have shown that the amount of recovered cefazolin in 24-hr urine and bile samples were 81 and 17%, respectively, after intramuscular administration to rats. These results show that the metabolism of cefazolin is negligible in rats, similar to other species including the human (5).

Extraction of Antibiotics from the Circulation by Kidney and

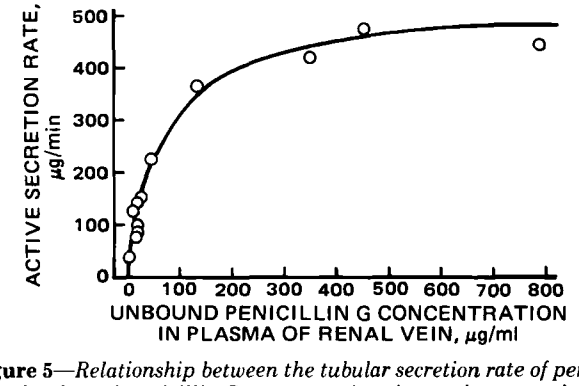

Figure 5—*Relationship between the tubular secretion rate of penicillin G and unbound penicillin G concentrations in renal venous plasma at steady state after the constant and simultaneous infusion of penicillin G and inulin to rats. Figure 6—*Relationship between the urinary excretion rate of cefazolin and the unbound cefazolin concentration in arterial plasma at steady state after the constant and simultaneous infusion of cefazolin and inulin to rats. The renal clearance was evaluated from the slope of the line drawn through the experimental points.*

Liver—*Renal Clearance*—To clarify the renal excretion mechanism of β-lactam antibiotics in rats, the renal clearances of penicillin G and cefazolin were measured. Studies on the relationship between serum protein binding and the renal clearance of drugs are limited. Recently, Levy (26) suggested that the renal tubular secretion rate is a function of the concentration of free drug in the renal venous plasma except for the case of blood flow rate-limited secretion. Hori *et al.* (27) demonstrated that the tubular secretion of sulfathiazole is dependent on the unbound sulfathiazole in plasma. If the renal excretion rate of β-lactam antibiotics is governed by the sum of the rates of glomerular filtration (G) [which is dependent on the unbound antibiotic in the arterial plasma ($C_{F,p}$)] and the capacity-limited tubular secretion (S) [which, in turn, depends on the unbound antibiotic concentration ($C_{F,kd}$) in the renal venous plasma], then the rate expression for urinary excretion may be written as:

$$\frac{dX_u}{dt} = (G + S)(1 - R) \quad \text{(Eq. 3)}$$

$$G = GFR \cdot C_{F,p} \quad \text{(Eq. 4)}$$

$$S = \frac{Vu \cdot C_{F,kd}}{K_{m,u} + C_{F,kd}} \quad \text{(Eq. 5)}$$

where R, Vu, and $K_{m,u}$ represent the reabsorption fraction, the maximum rate of tubular secretion, and the Michaelis constant, respectively, and X_u is the amount of antibiotic excreted in the urine.

It was reported that some β-lactam antibiotics are actively secreted into renal tubules in rats, dogs, rabbits, and humans, and that the secretion is completely inhibited by probenecid (4–6). A preliminary experiment was performed to examine the effect of probenecid on the secretion of penicillin G in the rat kidney. The ratio of plasma renal clearance of penicillin G to inulin clearance (the conventional measure of overall renal excretion) was 2.19 ± 0.62 (n = 5) during the control period, where penicillin G was infused at a rate of 12.5 mg/hr. The clearance ratio decreased dramatically (79%) to 0.46 (n = 1) in the period of simultaneous infusion of probenecid at a rate of 2.4 mg/hr. To obtain more precise information for the tubular secretion and reabsorption of penicillins, probenecid was simultaneously infused with penicillin G and inulin to achieve various steady-state probenecid levels. The plots of the steady-state excretion ratio, $(dX_u/dt)_{ss}/G_{ss}$, *versus* the steady-state plasma concentration of probenecid (Fig. 4) show that as the plasma concentration of probenecid increased, the excretion ratio of penicillin G decreased markedly. There was no significant change in the serum protein binding of penicillin G in the presence of probenecid. It is obvious from these results that penicillin G is actively secreted in rats. Since a complete inhibition of the tubular secretion of this antibiotic was attained at >50-μg/ml probenecid levels in plasma, the reabsorption fraction of penicillin G could be obtained from the mean of the data of $(dX_u/dt)_{ss}/G_{ss}$ at >50-μg/ml probenecid levels. This was found to be 0.33 ± 0.03 (n = 4). Decreasing the urine flow by 85% did not significantly change the reabsorption fraction (0.32 ± 0.15, n = 4) of penicillin G in rats, although urine flow rate is known to be one of the factors influencing the tubular reabsorption of drugs (27).

The secretion rate was, therefore, calculated for the data under steady-state conditions and without the administration of probenecid using:

$$S_{ss} = \left(\frac{dX_u}{dt}\right)_{ss}/(1 - R) - GFR(C_{F,p})_{ss} \quad \text{(Eq. 6)}$$

The relationship between the unbound concentration in the renal venous plasma at steady state $(C_{F,kd})_{ss}$ and the steady-state secretion rate S_{ss} of penicillin G (Fig. 5) clearly indicates the saturable secretion of penicillin G. The Michaelis–Menten kinetic parameters for penicillin G tubular secretion, obtained by NONLIN, were Vu = 530.1 ± 49.4 μg/min and $K_{m,u}$ = 69.6 ± 13.8 μg/ml.

Similar experiments were also made for cefazolin. The observed ratio of plasma renal clearance to inulin clearance was 0.35 ± 0.04 (n = 4) in the control period. After probenecid infusion, the value was 0.31 ± 0.03 (n = 4) (probenecid steady-state plasma level of 88 μg/ml), with the differences being statistically insignificant. The results indicate a negligible contribution of the tubular secretion of cefazolin in rats. When the steady-state excretion rates, $(dX_u/dt)_{ss}$, were plotted *versus* the unbound cefazolin concentrations, $(C_{F,p})_{ss}$, there was a linear relationship with a zero intercept and a slope of 0.82 ml/min (Fig. 6). By employing a GFR value of 1.06 ± 0.15 ml/min (n = 4), the R-value for cefazolin was determined to be 0.22. These results demonstrate that cefazolin is excreted mainly by glomerular filtration and then reabsorbed in part by the renal tubules.

Hepatic Clearance—Cefazolin was infused into rats with bile fistules to achieve various steady-state plasma levels. Since metabolism of cefazolin was found to be negligible (as described in a previous section), the steady-state biliary secretion rate, $(dX_{bi}/dt)_{ss}$, may be attributed to the uptake of this antibiotic into hepatocytes or biliary secretion itself. If the hepatic uptake is not the rate-limiting step and the biliary secretion rate is capacity limited, the rate can be described by a Michaelis–Menten equation:

$$\left(\frac{dX_{bi}}{dt}\right)_{ss} = \frac{V_{bi}(C_{F,1v})_{ss}}{K_{m,bi} + (C_{F,1v})_{ss}} \quad \text{(Eq. 7)}$$

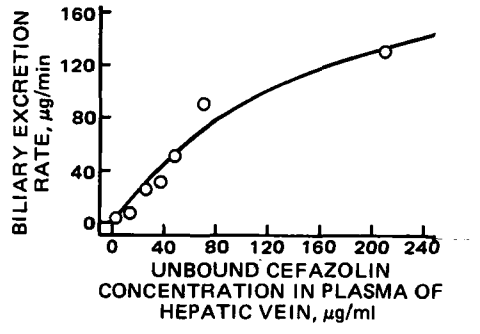

Figure 7—*Relationship between the biliary excretion rate of cefazolin and unbound cefazolin concentrations in hepatic venous plasma at steady state after the constant infusion of cefazolin to rats. The points represent the experimental values; the solid line was generated from Eq. 7 and the Michaelis–Menten kinetic parameters of* V_{bi} = 238.8 μg/min *and* $K_{m,bi}$ = 163.3 μg/ml.

Table IV—Tissue-to-Plasma Partition Coefficients (Kp) of β-Lactam Antibiotics for Various Tissues of Rats

Tissue	K_p[a] Penicillin V	Dicloxacillin	Cefazolin
Lung	0.157 ± 0.078 (n = 14)	0.123 ± 0.027 (n = 5)	0.154 ± 0.078 (n = 8)
Heart	0.095 ± 0.024 (n = 12)	0.074 ± 0.014 (n = 4)	0.101 ± 0.022 (n = 15)
Muscle	0.062 ± 0.017 (n = 10)	0.051 ± 0.014 (n = 4)	0.077 ± 0.029 (n = 18)
Bone	—	—	0.111 ± 0.021 (n = 15)
Skin	—	—	0.303 ± 0.058 (n = 11)
Spleen	0.096 ± 0.020 (n = 12)	0.088 ± 0.031 (n = 5)	—
Gut	0.966 ± 0.452 (n = 14)	1.357 ± 0.590 (n = 12)	0.114 ± 0.029 (n = 10)
Liver	0.250 ± 0.052 (n = 12)[b]	0.430 ± 0.287 (n = 9)[c]	0.788 ± 0.354 (n = 10)[b]
Kidney	3.70 ± 0.87 (n = 14)[b]	1.27 ± 0.44 (n = 10)[c]	2.79 ± 1.05 (n = 10)[b]

[a] The value of K_p is the ratio of tissue concentration to the venous outflow plasma concentration at steady state, as defined by Eq. 8. [b] Corrected by using the corresponding plasma flow rate and the elimination clearance according to the technique described by Chen and Gross (28). [c] Apparent value calculated from the ratio of tissue concentration to the arterial plasma concentration at steady state.

Table V—*In Vivo* Uptake of β-Lactam Antibiotics into Erythrocytes of Rats

β-Lactam Antibiotic	No. of Experiments	Rat Weight, g	$(C_{T,p})_{ss}$,[a] μg/ml	$(C_{WB})_{ss}$,[b] μg/ml	Hematocrit, %	K_p[c]
Penicillin G	4	255 ± 5	105.9 ± 13.3	48.8 ± 5.0	54.8 ± 2.1	0.016
Penicillin V	3	242 ± 1	29.8 ± 4.2	12.0 ± 3.2	51.3 ± 4.6	0
Methicillin	3	254 ± 10	63.1 ± 9.0	31.2 ± 2.8	51.7 ± 2.2	0.022
Dicloxacillin	3	241 ± 2	36.6 ± 9.4	17.4 ± 3.3	51.1 ± 3.3	0
Ampicillin	3	243 ± 2	99.9 ± 14.4	44.5 ± 7.4	52.2 ± 2.5	0
Cephaloridine	4	240 ± 5	52.0 ± 8.4	26.3 ± 3.2	51.5 ± 2.8	0.040
Cefazolin	3	238 ± 2	77.5 ± 12.3	32.9 ± 2.9	53.2 ± 3.4	0

[a] Total antibiotic concentration in arterial plasma at steady state. [b] Total antibiotic concentration in whole blood at steady state. [c] Mean value calculated from Eq. 9. All negative K_p values were listed as zero.

where V_{bi} and $K_{m,bi}$ represent the maximum rate and Michaelis constant, respectively, for the biliary secretion, and $(C_{F,1v})_{ss}$ represents the free antibiotic concentration in hepatic venous plasma at steady state.

Plotting the relationship between $(dX_{bi}/dt)_{ss}$ and $(C_{F,1v})_{ss}$ yielded a convex curvature (Fig. 7). The values of V_{bi} and $K_{m,bi}$ were 238.8 ± 56.8 μg/min and 163.3 ± 65.4 μg/ml, respectively, using NONLIN according to Eq. 7. The magnitudes of the apparent renal clearance of 0.82 ml/min and the biliary secretion parameters of V_{bi} and $K_{m,bi}$ predict that at high cefazolin free levels, urinary excretion is superior to biliary secretion, and at low levels both excretions may be comparable.

Tissue-to-Plasma Partition Coefficient—The steady-state tissue-to-plasma concentration ratios, K_p, of penicillin V, dicloxacillin, and *cefazolin were measured* experimentally for each rat tissue compartment (Table IV). The K_p for any organ is defined by:

$$K_{p,i} = \frac{(C_{T,i})_{ss}}{(C_{F,i} + C_{B,i})_{ss}} \quad \text{(Eq. 8)}$$

where $(C_{T,i})_{ss}$ and $(C_{F,i} + C_{B,i})_{ss}$ represent the total antibiotic concentration in a whole tissue (excluding blood) and total antibiotic concentration in the tissue venous plasma, respectively, at steady state. For noneliminating organs, the steady-state arterial plasma concentration, $(C_{T,p})_{ss}$, was used for the calculation as $(C_{T,p})_{ss} = (C_{F,i} + C_{B,i})_{ss}$. When an antibiotic concentration in the venous plasma of kidney or liver was not measured, the K_p value was corrected by using the corresponding plasma flow rate and clearance, as suggested by Chen and Gross (28).

The K_p values of β-lactam antibiotics in all tissues except gut and kidney were found to be <1. The antibiotics studied were highly concentrated in the kidney, which is the major eliminating organ. Penicillin V and dicloxacillin exhibited extremely higher K_p values in gut tissue than cefazolin. This phenomenon may be the result of an extensive contribution of enterohepatic recirculation of the former two antibiotics (12). Because of the almost negligible intestinal absorption of cefazolin in rats (29), cefazolin provided the true K_p value for gut tissue.

Distribution of several β-lactam antibiotics into erythrocytes was evaluated by measuring the steady-state concentrations in whole blood and plasma of rats. The K_p value for erythrocytes was calculated from:

$$K_p = 1 + \left[\frac{(C_{WB})_{ss}}{(C_{T,p})_{ss}} - 1\right] \Big/ (\text{Hct}/100) \quad \text{(Eq. 9)}$$

where $(C_{WB})_{ss}$ is the whole blood concentration at steady state. The results (Table V) indicate negligible distribution of β-lactam antibiotics into the rat erythrocyte compartment. Nishida *et al.* (30) previously demonstrated that distribution of penicillins into rabbit erythrocytes was <3% or negligible after intravenous bolus administration; their results are consistent with our observations.

Development of the Physiologically Based Pharmacokinetic Model—Figure 8 is a diagrammatic representation of a noneliminating organ subdivided anatomically into three fluid compartments: (*a*) the capillary blood volume, (*b*) the interstitial fluid, and (*c*) the intracellular space. In formulating the kinetics of β-lactam antibiotics in these tissues (except the liver and kidney), the following assumptions, based on the experimental evidence described in the previous and subsequent sections, were made.

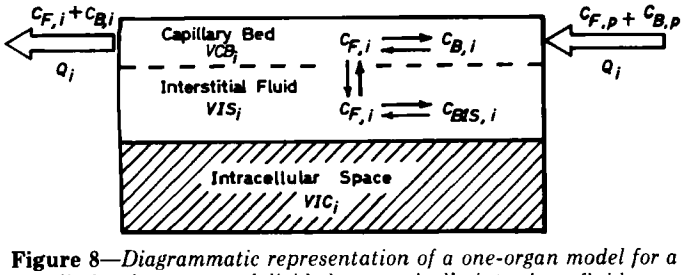

Figure 8—*Diagrammatic representation of a one-organ model for a noneliminating organ subdivided anatomically into three fluid compartments.*

1. Free and bound antibiotics entering with arterial plasma mix with the antibiotics in the tissue capillary bed.
2. Only the mixed antibiotics in the capillary bed, which is free from plasma protein binding, can diffuse rapidly in the tissue (except bone).
3. Entrance into the intracellular space by the antibiotic is negligible; therefore, the diffused antibiotic is restricted to the interstitial fluid of the tissue.
4. The antibiotic diffused into the interstitial fluid can bind only with albumin existing in this compartment, in a similar manner as with plasma albumin.
5. Bone tissue is divided into three compartments consisting of capillary bed, bone marrow, and bone cortex. The bone marrow-to-plasma ratio is assumed to be 1. The antibiotic binds in the bone marrow exactly as in the plasma, and only unbound antibiotics can diffuse into the bone cortex fluid space.
6. A well-mixed state exists in the capillary bed, interstitial fluid, and bone regions.
7. Free and bound antibiotic concentrations in venous plasma leaving the tissues are the same as those in the capillary bed.

From the above assumptions regarding the distribution of β-lactam antibiotics in noneliminating organs (except bone), a mass balance equation can be expressed as:

$$VCB_i\left(\frac{dC_{F,i}}{dt} + \frac{dC_{B,i}}{dt}\right) + VIS_i\left(\frac{dC_{F,i}}{dt} + \frac{dC_{BIS,i}}{dt}\right) = Q_i(C_{F,p} + C_{B,p}) - Q_i(C_{F,i} + C_{B,i}) \quad \text{(Eq. 10)}$$

The nomenclature for this equation and others is given in Appendix I (Glossary). The two terms of the left-hand side of Eq. 10 represent the accumulation rates of free and bound antibiotics in the capillary bed and interstitial fluid, respectively. Differentiation of the plasma binding equations (Eqs. 1 and 2) yields:

$$\frac{dC_{B,i}}{dt} = \alpha_i \frac{dC_{F,i}}{dt} \quad \text{(Eq. 11)}$$

In the case of nonlinear binding behavior:

$$\alpha_i = \frac{nPK_B}{(1 + K_B C_{F,i})^2} \quad \text{(Eq. 12)}$$

Similarly, linear binding yields:

$$\alpha_i = K_{B,app}P \quad \text{(Eq. 13)}$$

Taking the tissue-to-plasma albumin concentration ratio, AR_i, for *i*-type tissue and using assumption 4, Eq. 10 can be simplified to:

$$[VCB_i(1 + \alpha_i) + VIS_i(1 + \alpha_i AR_i)]\frac{dC_{F,i}}{dt} = Q_i[(1 + \beta_p)C_{F,p} - (1 + \beta_i)C_{F,i}] \quad \text{(Eq. 14)}$$

where β_i can be defined for the nonlinear binding case as:

$$\beta_i = \frac{nPK_B}{1 + K_B C_{F,i}} \quad \text{(Eq. 15)}$$

and in the linear binding case, $\beta_i = \alpha_i$. If assumption 5 is valid, the mass

balance in the bone compartment can be written as Eq. II-5 (Appendix II).

In the mathematical description for the eliminating organs such as the liver and kidney, K_p values were employed to predict the tissue concentrations, because uptake and accumulation of antibiotics into the intracellular spaces appeared to be difficult to evaluate at the present time. Okada *et al.* (31) demonstrated recently that the extent of binding of cefazolin, cephaloridine, cephalexin, and cloxacillin with 90% of liver and kidney homogenates was 2~65% for rats and beagle dogs, and that the tissue binding appears to be unrelated to the binding of the drugs to serum albumin. β-Lactam antibiotics are highly protein-bound with the water-soluble hepatic and renal intracellular protein, ligandin (32). The binding between the drugs and ligandin may correlate with their hepatic and renal uptakes from plasma.

A full diagram of blood circulation through various tissues is represented in Fig. 9. All pertinent tissues for which antibiotic concentrations are known, except for carcass (fat and others), have been included. The plasma flow of the liver (Table VI) and the tissue volumes of the heart, liver, and kidney used for the calculations were experimental values determined in this laboratory. The organ flow rates, except for the liver, and volumes of the other tissues were taken from published physiological values (8, 10, 33–35), adjusted to reflect the size of the animals studied. Sapirstein *et al.* (34) determined that in rats, bronchial blood flow constituted only 3% of cardiac output. Based on this simulation study, the contribution of the bronchial circulation to antibiotic distribution into lung tissue was assumed to be negligible. The physiological parameters employed in this study are listed in Table VII.

Binding to the Interstitial Protein—If assumptions 2 and 3 are valid for β-lactam antibiotics in noneliminating organs (except bone), the following mass balance equation can be written:

$$C_{T,i} = IS_i(C_{F,i} + C_{BIS,i}) \qquad \text{(Eq. 16)}$$

where IS is the interstitial space expressed by:

$$IS_i = \frac{VIS_i}{VIS_i + VIC_i} \qquad \text{(Eq. 17)}$$

From assumption 3, for the antibiotics showing nonlinear serum protein binding behavior, Eq. 1 can be written as:

$$C_{BIS,i} = \frac{n \cdot AR_i \cdot PK_B C_{F,i}}{1 + K_B C_{F,i}} \qquad \text{(Eq. 18)}$$

Since $C_{F,i} = C_{F,p}$ in noneliminating organ regions, except bone, at steady state, Eqs. 16 and 18 can be expressed as:

$$(C_{T,i})_{ss} = IS_i \cdot \left[1 + \frac{n \cdot AR_i \cdot PK_B}{1 + K_B(C_{F,p})_{ss}}\right](C_{F,p})_{ss} \qquad \text{(Eq. 19)}$$

Similarly in the case of linear binding:

$$(C_{T,i})_{ss} = IS_i \cdot (1 + AR_i \cdot PK_{B,app})(C_{F,p})_{ss} \qquad \text{(Eq. 20)}$$

The interstitial space (IS_i) of lung, heart, skin, bone, gut, and liver in rats was estimated from the distribution of inulin or [^{14}C]inulin. The value of IS_i for each tissue was calculated as the ratio of tissue to plasma concentrations at steady state (Table VIII). The interstitial water content of most tissues was 10–20%. The IS value of skin, however, was 30% of the blood-free organ, much higher than that found in the other tissues studied. Our results were consistent with those reported by Higaki and Fujimoto (36) using data after intravenous bolus injection of [^{14}C]inulin in kidney-ligated rats, but were less than IS values evaluated (37) from the mannitol and thiosulfate spaces. The reason for larger spaces determined by the latter two compounds may be due to their partial distribution into the intracellular compartment.

Cefazolin seems to be a good model to test the validity of Eq. 19 or 20, because of its remarkable nonlinear binding characteristics with rat albumin. Figure 10 illustrates plots of the steady-state tissue concentration $(C_{T,i})_{ss}$ *versus* the steady-state arterial plasma free concentration $(C_{F,p})_{ss}$ obtained for heart, muscle, skin, and gut.

When we used the AR_i values of 0.5, 0.6, and 0.9 reported (37) for heart, muscle, and gut, respectively, the curves generated from Eq. 19 using the binding parameters of cefazolin listed in Table I and the corresponding interstitial space in Table VIII were in good agreement with the experimental tissue levels of cefazolin. Katz *et al.* (37) demonstrated that AR values for muscle and skin were ~0.55, but the interstitial albumin content of skin and gut was twice that of muscle in rats. Rothschild *et al.* (38) found that most of the extravascular albumin was located in the skin in humans, and the concentration of albumin in the extravascular and extracellular skin approaches that in the plasma. The high level of albumin in skin is likely to be related to the high interstitial space of this tissue (Table VIII). The observed skin levels fit well with the curves generated from Eq. 19 with the reasonable assumption of AR = 1. Figure 10 clearly indicates that the free concentration of cefazolin in plasma at <20 μg/ml had a greater effect on the tissue levels than did cefazolin plasma concentrations >50 μg/ml. This is a result of the nonlinear binding with rat plasma albumin and is described by Eq. 19.

Little basic information has been reported concerning antibiotic concentrations in bone, especially bone marrow. Pitkin *et al.* (39) found that cefazolin levels were detected in bone and bone marrow of normal rabbits dosed intramuscularly even in the absence of detectable levels in serum. However, the concentration ratio of bone cortex to bone marrow of this antibiotic was ~0.05 (39). More recently, it was found (40) that the concentrations of cefazolin in bone marrow were equal to or exceeded that in serum 60 min after the administration of 50 mg/kg iv in rabbits. Because bone marrow sampling was difficult in rats, we used a beagle dog to evaluate assumption 5. The results (Table IX) indicate that the observed cefazolin levels in whole bone marrow, although somewhat scattered, were almost equal to the whole blood levels at steady state. Since the mean whole blood levels were well described using Eq. 9 with the mean steady-state plasma levels and hematocrit of 41% (assuming K_p

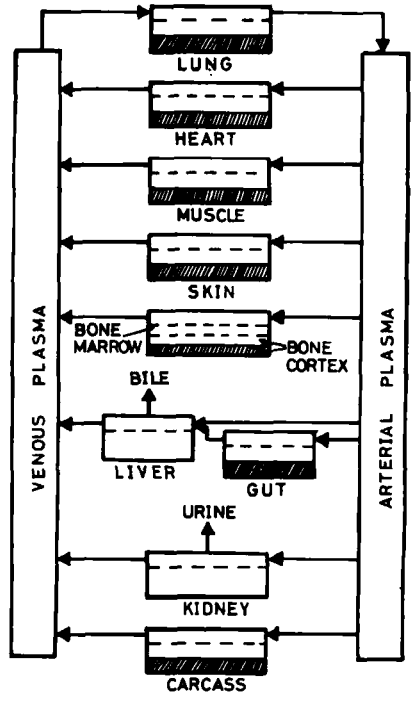

Figure 9—*Physiological pharmacokinetic model fully diagramming the blood circulation through various tissues.*

Table VII—Physiological Parameters for 240-g Rats [a]

Tissue	Total Tissue Volume (V), ml	Interstitial Fluid Volume (VIS)[b], ml	Plasma Volume in Capillary Bed (VCB)[c], ml	Plasma Flow Rate (Q), ml/min	Tissue-to-Plasma Albumin Ratio (AR)
Venous blood pool	2.9	—	1.4[d]	30.0	1.0
Arterial blood pool	1.5	—	0.8[d]	30.0	1.0
Lung	1.6	0.3	0.3	30.0	0.5
Heart	1.0[e]	0.1	0.2	0.8	0.5
Muscle	108.0	13.0	0.7	3.6	0.6
Skin	43.0	13.0	0.2	2.4	1.0
Bone	26.0	3.0	1.1[f]	0.8	1.0[g]
Gut	16.0	1.5	3.0	2.6	0.9
Liver	8.0[e]	1.3	1.0	3.7	0.5
Kidney	2.0[e]	0.4	2.5	7.3	0.5
Carcass (fat, others)	14.0	2.0	0.1	11.4	0.5

[a] Based on the values in Refs. 8, 10, 33–35, and 37. [b] Calculated from the equation: $VIS = V \times$ (Inulin space). The inulin spaces for various tissues except kidney and carcass are listed in Table VIII. For kidney tissue, the inulin space of 19.6% is reported in Ref. 36. For carcass, 15% inulin space was assumed. [c] Estimated from the values reported in Refs. 10 and 56 under the assumption that rats, dogs, and humans have the same ratio of blood volume in capillary bed-to-tissue volume without blood. [d] 50% hematocrit was assumed. [e] Determined experimentally in this laboratory. [f] Including bone marrow. [g] Bone marrow.

= 0), it is safe to conclude that the bone marrow-to-plasma concentration ratio was almost unity, consistent with previous observations in humans (41, 42).

The validity of Eq. 19 or 20 was also tested by comparing the K_p values observed for dicloxacillin and penicillin V as well as cefazolin (Table IV) and those calculated by combining Eqs. 1, 8, and 19:

$$(K_{p,i})_{calc} = IS_i \frac{1 + K_B(C_{F,p})_{ss} + n \cdot AR_i \cdot PK_B}{1 + K_B(C_{F,p})_{ss} + nPK_B} \quad \text{(Eq. 21)}$$

or Eqs. 2, 18, and 20:

$$(K_{p,i})_{calc} = IS_i \frac{1 + AR_i \cdot PK_{B,app}}{1 + PK_{B,app}} \quad \text{(Eq. 22)}$$

For bone tissue, Eq. 21 may be rewritten using assumption 5 for the nonlinear binding case:

$$(K_{p,bn})_{calc} = \frac{IS_{bn}[1 + K_B(C_{F,p})_{ss}] + S_{bnm}nPK_B}{1 + K_B(C_{F,p})_{ss} + nPK_B} \quad \text{(Eq. 23)}$$

where IS_{bn} and S_{bnm} represent inulin space and bone marrow space, respectively, in bone tissue. The AR values of lung and S_{bnm} were assumed to be 0.5 and 0.038 (Table VII), respectively; the binding parameters were taken from Table I. There is a good agreement between observed (Table IV) and calculated K_p values in all cases (Fig. 11), indicating that assumptions 3–5 made for tissue distribution of β-lactam antibiotics are reasonable and applicable, at least for noneliminating organs.

Application to Tissue Distribution Kinetics of Inulin—Prior to testing the validity of the physiologically based pharmacokinetic model developed for the body distribution of β-lactam antibiotics, the model was used to simulate the tissue distribution kinetics of inulin in rats. Since inulin is known to be excreted almost completely by glomerular filtration and its distribution is restricted only to plasma and tissue interstitial fluid, the present model has an intrinsic ability to predict the concentration–time profiles of inulin in any tissue.

In the adaptation of this model to a compound having a large molecular size such as inulin, however, the capillary wall permeability must be handled somewhat differently. The capillary walls in lung, heart, muscle, skin, and gut are composed of an interlocking mosaic of endothelial cells with slits (43). Therefore, the restricted transport of inulin through the capillary walls in these tissues does not allow the instantaneous establishment of the equilibrium of inulin between the capillary bed and interstitial fluid. Such a restricted transport of inulin has been apparently described by Fick's law of diffusion (43c–45). The mass balance equations for lung, muscle, skin, and gut tissues are shown in Appendix III. By using values of 20 ml/min/100 g of tissue for lung and heart, 10 ml/min/100 g of tissue for gut, and 2 ml/min/100 g of tissue for muscle and skin as the permeability constants K_i (44, 45); 1.20 ml/min as the GFR (determined for 240-g rats from repeated experimental trials in our laboratory); and the tissue volumes and plasma flows listed in Table VII, the 16 differential equations were solved numerically by a digital computer. The results of the simulations are shown in Figs. 12 and 13. The predicted curves, except for muscle, are in good agreement with the mean values of the experimentally determined tissue levels of inulin after a 20-mg/kg dose and the plasma levels after both 20- and 200-mg/kg iv doses. The predicted peak inulin concentrations for the poorly perfused muscle and skin are reached relatively late, *i.e.*, 10–15 min after the bolus administration. However, the experimental concentration–time profiles in muscle and skin did not show such slow appearance of inulin. This may be the result of a more rapid uptake of inulin into the muscle and skin interstitial fluids from the capillary walls in rats than that reported for rabbits and dogs (44).

Application to Tissue Distribution Kinetics of Cefazolin—The differential equations described for cefazolin in Appendix II were solved numerically by incorporating various constants listed in Tables I, IV, and VII. Figures 14 and 15 show the predicted and observed concentration profiles for plasma, lung, heart, muscle, skin, bone, liver, and kidney tissues after the intravenous bolus injection of cefazolin to the urethane-anesthetized rats. Figure 16 also compares the simulation results from the model and the experimental tissue levels of plasma, muscle, skin, and kidney 60 min after the administration of cefazolin at various doses. As seen in these figures, there was reasonable agreement between the model predictions and the experimental concentrations in plasma and in various tissues at any time after any dose.

The physiological parameters in Table VII are statistical average values, and the plasma flow rates (except for liver) are those under unanesthetized conditions. It is, therefore, necessary to test the stability of the present model by comparing the numerical results derived from standard values for all parameters with the numerical results derived

Table VIII—[^{14}C]Inulin Space of Various Tissue of Rats

Tissue	Steady-State Concentration, μg/ml or μg/g						Inulin Space[a], %

from ±10% variation of standard values for each of the parameters. Such variation in any body region of the tissue, capillary volumes, and plasma flow rates did not significantly affect the simulation results, indicating that the model is quite stable within ±10% of the physiological parameters.

DISCUSSION

The binding of antimicrobial agents to plasma protein and tissues is considered to be an important factor in antimicrobial activity and pharmacokinetics. Much of the research effort has been directed toward determining the binding to plasma protein, uptake by erythrocytes, and the extravascular binding of β-lactam antibiotics. Nevertheless, the data are still incomplete in certain aspects: the published reports are sometimes in conflict. This study investigates the full disposition characteristics of β-lactam antibiotics in rats and describes a pharmacokinetic model that is capable of predicting tissue distribution and elimination kinetics not only in rats, but also in other species including humans.

β-Lactam antibiotics bind to serum protein, mainly albumin, in a reversible manner (46). It is generally accepted that such a binding equilibrium occurs within microseconds. Greene *et al.* (47) confirmed the rapid binding of cefazolin to canine serum, the binding equilibrium being attained as fast as the sample could be ultrafiltered. There is a general lack of agreement in the literature regarding the extent of binding for β-lactam antibiotics obtained from experiments carried out by different methods and even by the same method. The equilibrium dialysis method is known to be very reliable for determining quantitative binding of stable drugs, but has disadvantages for unstable drugs due to the time requirement to complete the diffusion equilibrium processes. However, use of microdiffusion cells in this study achieved the complete diffusion equilibrium within 4 hr (Fig. 1).

The serum protein binding ratio of β-lactam antibiotics varies with the species of animal and the total concentration of antibiotic. Shimizu (48) compared the protein binding of penicillins and cephalosporins in the sera of different animals using centrifugal ultrafiltration techniques. The extent of binding of cefazolin was ≥90% in humans, rabbits, and rats (equivalent to that of dicloxacillin), but only ~50% in dogs, horses, and bovines. The percent of cefazolin bound to human serum albumin significantly decreased with increases in the total antibiotic concentration (48). Similar results were obtained in this study using rat serum. The free fraction of cefazolin is 11% at 10 μg/ml, 20% at 100 μg/ml, and 41% at 200 μg/ml. Since the free fraction more than doubled between 10 and 100 μg/ml and increased by a factor of >4 between 10 and 200 μg/ml, the

distribution of cefazolin into tissue regions in rats will change radically. Other β-lactam antibiotics studied did not show such a remarkable nonlinear binding behavior.

The binding behavior of β-lactam antibiotics could be explained by the nonlinear binding equation (Eq. 1), where the magnitude of the binding constant (K_B) and the drug concentration (C_F) are very important parameters. If K_B is sufficiently small, Eq. 1 becomes Eq. 2, which expresses an apparent linear binding. Nayler (49) reported that the apparent binding constant of penicillins in human serum correlated quantitatively with the lipophilicity of the antibiotics. The experimental results shown in Fig. 2 and Table I demonstrate that the extent of binding of the five penicillins studied in rat serum correlates qualitatively with their lipophilicity. Dicloxacillin, which is the most lipophilic, has the largest $K_{B,app}$ value, whereas the more hydrophilic methicillin has a smaller $K_{B,app}$ value.

The mechanism of hepatic elimination of β-lactam antibiotics is not clearly understood. Although the penicillin derivatives studied were subjected to extensive metabolism to the penicilloic acids (4), cefazolin did not exhibit such metabolism in rats. The reason for the resistance of cefazolin to metabolic degradation is not clear, but similar results have been reported in other species including humans (5, 6).

The processes concerned with the transport of drugs into bile have been studied (50). Although passive diffusion may play a part in the transport of drug into bile, it is generally believed that active transport is the primary process (50). The biliary secretion of some penicillins and cephalosporins in rats have been studied by Ryrfeldt (51) and Wright and Line

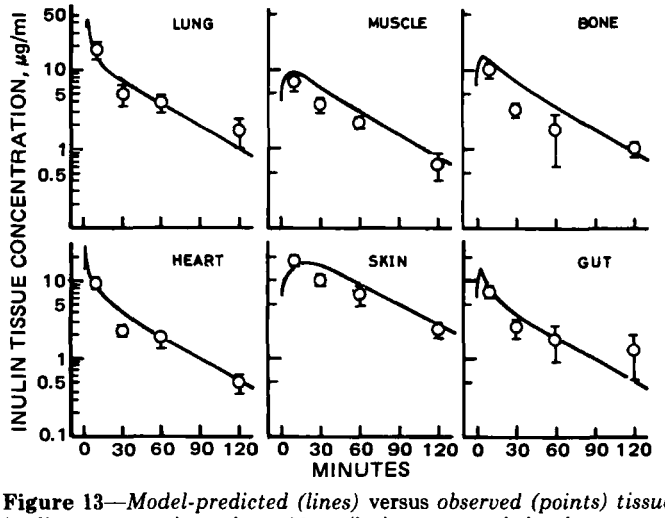

Figure 13—*Model-predicted (lines)* versus *observed (points) tissue inulin concentrations after a 20-mg/kg intravenous bolus dose to rats. Each point represents the mean of 3–5 rats; bars represent the standard deviations.*

(52). However, quantitative reports on the biliary excretion rate are limited. Previously, the biliary excretion of penicillin V was characterized by Michaelis–Menten kinetics (12). A similar capacity-limited excretion into bile was also observed for cefazolin, using Eq. 7.

The renal excretion of β-lactam antibiotics has been studied extensively. Using the micropuncture technique, Bergeron *et al.* (53) reported that penicillin G was excreted from plasma by glomerular filtration and active secretion from the proximal tubules, and that the respective contribution ratios were ~35 and 65%. The present study utilizing the net inhibitory effect of probenecid on the renal excretion of penicillin G into rat urine showed 35% glomerular filtration and 65% tubular secretion, consistent with the result of Bergeron *et al.* (53). On the other hand, the rate of cefazolin excretion into urine was unaffected by probenecid. The results indicate that the renal tubular secretion of cefazolin plays a minor role in the renal elimination process in rats. Our conclusion obtained for this antibiotic does not agree with the recent finding by Yamazaki *et al.* (54), who predicted a significant contribution of tubular secretion of cefazolin in rats. This apparent discrepancy cannot be explained completely by the difference in the protein binding ratio determined in both laboratories and needs to be investigated further. Therefore, until such time when a reliable urinary excretion mechanism of β-lactam antibiotics is established, we adopted the apparent renal clearance value of 0.82 ml/min (dependent on the unbound concentration in the arterial plasma) in this pharmacokinetic prediction for cefazolin in rats.

The kinetic behavior of antibiotics in an infected tissue fluid is important for antimicrobial chemotherapy. Classical approaches are usually based on the curve-fitting of plasma concentration data with multiexponential equations to construct the necessary compartment models. Sometimes, the compartments and parameters thus estimated have no physiological reality in the species being investigated. Therefore, it is difficult to use classical pharmacokinetics to interpret the differences between animal and human experiments.

To overcome this difficulty, physiological pharmacokinetic models have been developed and adapted for some drugs by several workers (7–12). These models are based on experimental data regarding tissue binding or tissue-to-plasma (or blood) partition coefficients (K_p) in laboratory animals, as with penicillin V (12). This approach has the potential advantages of predicting tissue drug levels and reflecting the variations in drug binding with different tissues of the animals investigated. However, because there are sometimes substantial differences in K_p values among species (11) and the property of K_p in each tissue is often obscure, this approach does not always allow us to predict the tissue concentration–time profiles of drugs in other species, *i.e.*, humans.

Our present goal was to make possible *a priori* predictions of β-lactam antibiotic levels in organs of any species, based on the knowledge of parameters easily determined for human subjects as well as experimental animals. This study was designed to use cefazolin, which exhibits interesting nonlinear binding with serum proteins and simpler elimination characteristics in rats than the other β-lactam antibiotics.

One of the key points in solving this problem is to clarify the exact nature of the K_p values of β-lactam antibiotics for various tissues. Peterson *et al.* (55) determined the binding of some β-lactam antibiotics

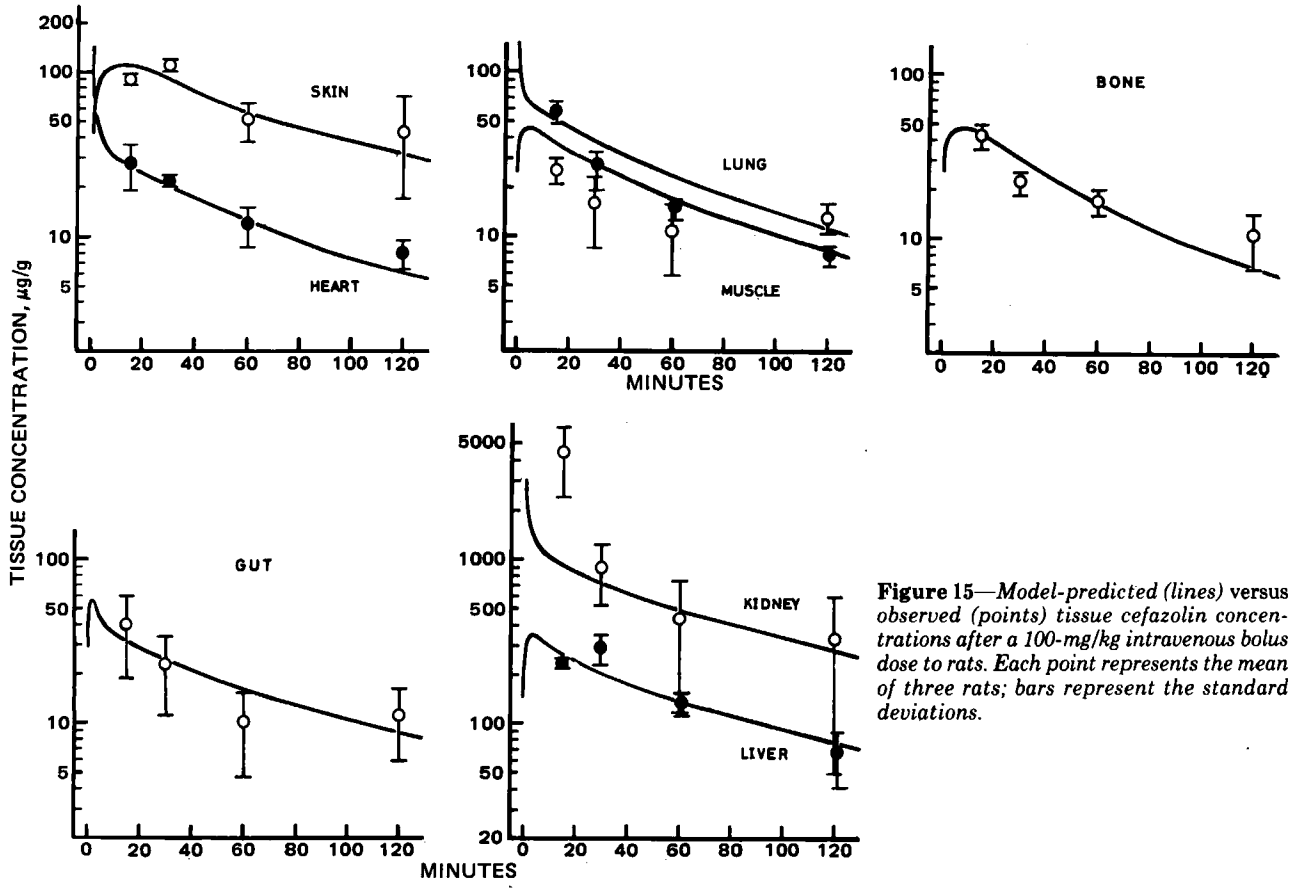

Figure 15—*Model-predicted (lines)* versus *observed (points) tissue cefazolin concentrations after a 100-mg/kg intravenous bolus dose to rats. Each point represents the mean of three rats; bars represent the standard deviations.*

in dilute homogenates of canine tissues and employed the results to predict the apparent volume of distribution after intravenous administration in dogs. The question may be raised whether binding data obtained *in vitro* with tissue homogenates are applicable to *in vivo* conditions. For a drug that is unable to penetrate into the tissue intracellular space, binding to tissue apparently was not the sole factor responsible for *in vivo* accumulation of the drug. With β-lactam antibiotics, however, due to the experimental difficulty in assessing the extent of antibiotic penetration into cells, the conclusions obtained from the various animal model studies differed among investigators. By determining the steady-state plasma and tissue levels of cefazolin in rats, we obtained evidence in support of our claim that this antibiotic cannot enter erythrocytes and tissue cells of noneliminating organs, and that albumin existing in these tissue interstitial fluids play a major role in determining antibiotic levels in various tissues. On this basis, the K_p values of β-lactam antibiotics could be successfully interpreted for not only cefazolin, but also penicillin V and dicloxacillin.

Despite the use of simplifying assumptions in formulating the antibiotic distribution in physiologically and anatomically complex body regions, there was a reasonably close fit between the simulation from the present model and the experimental tissue levels after intravenous bolus administration of cefazolin in rats. The simulations demonstrate that the tissue distribution of cefazolin in rats is complete within 15 min even in the slowly perfused muscle, skin, and bone tissues. The observed high cefazolin level in skin compared with the levels in the other noneliminating tissues is due to the higher content of albumin and the larger interstitial space. The time course of cefazolin in skin was also nicely predicted by the present pharmacokinetic model based on the assumption that albumin concentration in the skin interstitial fluid is equal to that in plasma. In addition to the examination for β-lactam antibiotics, this model could predict the tissue distribution profiles of inulin. The model, incorporating the slow diffusion of a large molecule from capillary membranes into the interstitial fluids of lung, heart, muscle, skin, and gut tissues, was able to adequately represent the concentrations of inulin in plasma and various tissues. As seen in Fig. 13, inulin in skin showed a markedly different behavior from cefazolin, and the concentration–time profile in skin was almost identical with those in heart, muscle, bone, and gut; this is the consequence of the lack of binding of inulin with albumin. This result supports the assumption made for the skin compartment in the present work.

Although our model was able to provide a good prediction of intravenous dosing data of cefazolin and inulin in rats, there are still a number of deficiencies. First, it is necessary to identify the magnitude of uptake clearance of antibiotics into hepatocytes compared with hepatic plasma flow rate. Second, we need to more fully characterize the kinetics and mechanisms not only of active transport into tubular cells and reabsorption from tubules in the kidney, but also biliary secretion and metabolism in the liver for the β-lactam antibiotics. The proposed model, nevertheless, is capable of predicting tissue concentrations as a function of time after a single bolus dose in normal animals and should be useful in predicting these levels in animals where renal and hepatic function, albumin concentration, extravascular space, and blood flow are altered due to disease states.

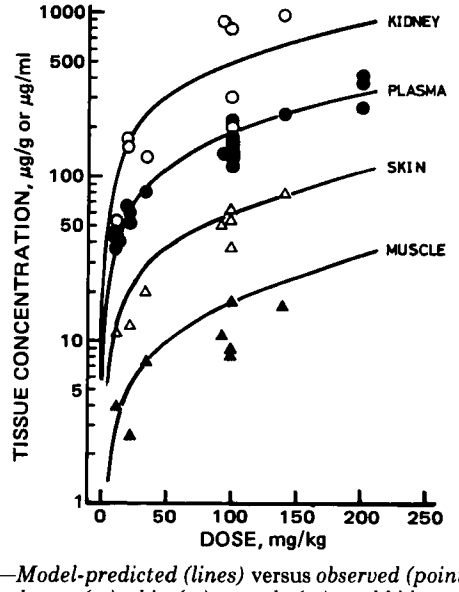

Figure 16—*Model-predicted (lines)* versus *observed (points) concentrations in plasma (●), skin (△), muscle (▲), and kidney (○) 60 min after intravenous bolus injections at various doses to rats.*

APPENDIX I: GLOSSARY

AR = Tissue-to-plasma albumin ratio
C_B = Bound concentration in plasma, μg/ml
C_{BIS} = Bound concentration in tissue interstitial fluid, μg/ml
C_F = Free concentration in plasma or in tissue interstitial fluid, μg/ml
C_T = Total concentration in tissue, μg/ml or μg/g
GFR = Glomerular filtration rate, ml/min
$I(t)$ = Dose input function, min^{-1}
IS = Tissue interstitial space
K = Permeability constant from capillary wall to interstitial fluid, ml/min
K_m = Michaelis constant, μg/ml
K_p = Tissue-to-plasma partition coefficient
P = Albumin concentration in serum, M
Q = Plasma flow rate, ml/min
R = Reabsorption ratio
UF = Urine flow rate, ml/min
V = Volume of tissue (excluding equilibrium blood), ml
∇_{bi} = Maximum rate of biliary secretion, μg/min
VCB = Plasma volume in capillary bed of tissue, ml
VIC = Volume of tissue intracellular water, ml
VIS = Volume of tissue interstitial fluid, ml
α = Coefficient in the differentiation of the plasma protein binding
β = *Bound-to-unbound* concentration ratio

Subscripts
b = blood
p = arterial plasma
u = urine
bi = bile
vp = venous plasma
lg = lung
lgi = lung interstitial fluid
ht = heart
hti = heart interstitial fluid
ms = muscle
msi = muscle interstitial fluid
sk = skin
ski = skin interstitial fluid
bn = bone
bnm = bone marrow
bnc = bone cortex
gt = gut
gti = gut interstitial fluid
cr = carcass
lv = liver
kd = kidney
wb = whole blood
ss = steady state

APPENDIX II: MODEL EQUATIONS FOR CEFAZOLIN

Venous plasma:

$$V_{vp}(1+\alpha_{vp})\frac{dC_{F,vp}}{dt} = Q_{ht}(1+\beta_{ht})C_{F,ht} + Q_{ms}(1+\beta_{ms})C_{F,ms} + Q_{sk}(1+\beta_{sk})C_{F,sk} + Q_{bn}(1+\beta_{bn})C_{F,bn} + Q_{cr}(1+\beta_{cr})C_{F,cr} + Q_{lv}(1+\beta_{lv})C_{F,lv} + Q_{kd}(1+\beta_{kd})C_{F,kd} - (Q_{ht}+Q_{ms}+Q_{sk}+Q_{bn}+Q_{cr}+Q_{lv}+Q_{kd})(1+\beta_{vp})C_{F,vp} + \text{Dose}\cdot I(t) \quad \text{(Eq. II-1)}$$

Arterial plasma:

$$V_p(1+\alpha_p)\frac{dC_{F,p}}{dt} = (Q_{ht}+Q_{ms}+Q_{sk}+Q_{bn}+Q_{cr}+Q_{lv}+Q_{kd}) \times [(1+\beta_{lg})C_{F,lg} - (1+\beta_p)C_{F,p}] \quad \text{(Eq. II-2)}$$

Lung:

$$[VCB_{lg}(1+\alpha_{lg}) + VIS_{lg}(1+\alpha_{lg}AR_{lg})]\frac{dC_{F,lg}}{dt} = (Q_{ht}+Q_{ms}+Q_{sk}+Q_{bn}+Q_{cr}+Q_{lv}+Q_{kd})[(1+\beta_{vp})C_{F,vp} - (1+\beta_{lg})C_{F,lg}] \quad \text{(Eq. II-3)}$$

Heart:

$$[VCB_{ht}(1+\alpha_{ht}) + VIS_{ht}(1+\alpha_{ht}AR_{ht})]\frac{dC_{F,ht}}{dt} = Q_{ht}[(1+\beta_p)C_{F,p} - (1+\beta_{ht})C_{F,ht}] \quad \text{(Eq. II-4)}$$

Muscle:

$$[VCB_{ms}(1+\alpha_{ms}) + VIS_{ms}(1+\alpha_{ms}AR_{ms})]\frac{dC_{F,ms}}{dt} = Q_{ms}[(1+\beta_p)C_{F,p} - (1+\beta_{ms})C_{F,ms}] \quad \text{(Eq. II-5)}$$

Skin:

$$[VCB_{sk}(1+\alpha_{sk}) + VIS_{sk}(1+\alpha_{sk}AR_{sk})]\frac{dC_{F,sk}}{dt} = Q_{sk}[(1+\beta_p)C_{F,p} - (1+\beta_{sk})C_{F,sk}] \quad \text{(Eq. II-6)}$$

Bone:

$$[(VCB_{bn}+V_{bnm})(1+\alpha_{bn}) + VIS_{bnc}]\frac{dC_{F,bn}}{dt} = Q_{bn}[(1+\beta_p)C_{F,p} - (1+\beta_{bn})C_{F,bn}] \quad \text{(Eq. II-7)}$$

Carcass:

$$[VCB_{cr}(1+\alpha_{cr}) + VIS_{cr}(1+\alpha_{cr}AR_{cr})]\frac{dC_{F,cr}}{dt} = Q_{cr}[(1+\beta_p)C_{F,p} - (1+\beta_{cr})C_{F,cr}] \quad \text{(Eq. II-8)}$$

Liver:

$$[(1+\alpha_{lv})(VCB_{lv}+V_{lv}K_{p,lv})]\frac{dC_{F,lv}}{dt} = (Q_{lv}-Q_{gt})(1+\beta_p)C_{F,p} + Q_{gt}(1+\beta_{gt})C_{F,gt} - Q_{lv}(1+\beta_{lv})C_{F,lv} - \frac{V_{biCF,lv}}{K_{m,bi}+C_{F,lv}} \quad \text{(Eq. II-9)}$$

Gut tissue:

$$[VCB_{gt}(1+\alpha_{gt}) + VIS_{gt}(1+\alpha_{gt}AR_{gt})]\frac{dC_{F,gt}}{dt} = Q_{gt}[(1+\beta_p)C_{F,p} - (1+\beta_{gt})C_{F,gt}] \quad \text{(Eq. II-10)}$$

Kidney:

$$[(1+\alpha_{kd})(VCB_{kd}+V_{kd}K_{p,kd})]\frac{dC_{F,kd}}{dt} = Q_{kd}[(1+\beta_p)C_{F,p} - (1+\beta_{kd})C_{F,kd}] - GFR(1-R)C_{F,p} \quad \text{(Eq. II-11)}$$

where the dose input function can be calculated as the function of the reciprocal of the injection time, λ (7):

$$I(t) = 30\lambda(\lambda t)^2(1-\lambda t)^2 \quad \text{(Eq. II-12)}$$

The values of α_i and β_i are defined by Eqs. 12 and 15, respectively, in the text.

Total concentration in plasma and total tissue concentration corresponding to the observed values in i-type tissue, except liver and kidney, can be calculated from Eqs. II-13 and II-14, respectively:

$$C_{T,p} = (1+\beta_p)C_{F,p} \quad \text{(Eq. II-13)}$$

$$C_{T,i} = IS_i(1+\beta_i AR_i)C_{F,i} \quad \text{(Eq. II-14)}$$

Calculation of total tissue concentration in liver and kidney is made from:

$$C_{T,i} = (1+\beta_i)K_{pi}C_{F,i} \quad (i = \text{liver, kidney}) \quad \text{(Eq. II-15)}$$

APPENDIX III: MODEL EQUATIONS FOR INULIN

Instead of Eqs. II-3 to II-6 and II-10 in Appendix II, the following mass balance equations can be written for the lung, heart, muscle, skin, and gut regions (see text).

Lung:

$$VCB_{lg}\frac{dC_{F,lg}}{dt} = Q_{lg}(C_{F,pv} - C_{F,lg}) - K_{lg}(C_{F,lg} - C_{F,lgi}) \quad \text{(Eq. III-1)}$$

$$VIS_{lg}\frac{dC_{F,lgi}}{dt} = K_{lg}(C_{F,lg} - C_{F,lgi}) \qquad \text{(Eq. III-2)}$$

Heart:

$$VCB_{ht}\frac{dC_{F,ht}}{dt} = Q_{ht}(C_{F,p} - C_{F,ht}) - K_{ht}(C_{F,ht} - C_{F,hti}) \qquad \text{(Eq. III-3)}$$

$$VIS_{ht}\frac{dC_{F,hti}}{dt} = K_{ht}(C_{F,ht} - C_{F,hti}) \qquad \text{(Eq. III-4)}$$

Muscle:

$$VCB_{ms}\frac{dC_{F,ms}}{dt} = Q_{ms}(C_{F,p} - C_{F,ms}) - K_{ms}(C_{F,ms} - C_{F,msi}) \qquad \text{(Eq. III-5)}$$

$$VIS_{ms}\frac{dC_{F,msi}}{dt} = K_{ms}(C_{F,ms} - C_{F,msi}) \qquad \text{(Eq. III-6)}$$

Skin:

$$VCB_{sk}\frac{dC_{F,sk}}{dt} = Q_{sk}(C_{F,p} - C_{F,sk}) - K_{sk}(C_{F,sk} - C_{F,ski}) \qquad \text{(Eq. III-7)}$$

$$VIS_{sk}\frac{dC_{F,ski}}{dt} = K_{sk}(C_{F,sk} - C_{F,ski}) \qquad \text{(Eq. III-8)}$$

Gut:

$$VCB_{gt}\frac{dC_{F,gt}}{dt} = Q_{gt}(C_{F,p} - C_{F,gt}) - K_{gt}(C_{F,gt} - C_{F,gti}) \qquad \text{(Eq. III-9)}$$

$$VIS_{gt}\frac{dC_{F,gti}}{dt} = K_{gt}(C_{F,gt} - C_{F,gti}) \qquad \text{(Eq. III-10)}$$

Elimination of inulin was negligible in the liver and occurs in the kidney through glomerular filtration, where negligible reabsorption (R = 0) can be assumed. Because there is no binding of inulin with any protein, $\alpha_i = 0$ and $\beta_i = 0$, then $C_{T,i} = IS_iC_{F,i}$ in every tissue region.

Solution Activity Product (K_{FAP}) and Simultaneous Demineralization–Remineralization in Bovine Tooth Enamel and Hydroxyapatite Pellets

JEFFREY L. FOX *‡¶ˣ, BALA V. IYER *‡, WILLIAM I. HIGUCHI *‡¶, and JOHN J. HEFFERREN §

Received May 17, 1982, from the **Dental Research Institute* and the ‡*College of Pharmacy, The University of Michigan, Ann Arbor, MI 48109* and the §*American Dental Association Health Foundation.* Accepted for publication August 26, 1982. ¶Present address: Dept. of Pharmaceutics, University of Utah, Salt Lake City, UT 84112.

Abstract □ The effects of changing the ion activity product of the remineralization solution at pH 4.5 (pK_{FAP} 108–118) on the remineralization behavior of demineralized bovine tooth enamel and hydroxyapatite pellets have been studied. Solutions containing calcium-45, phosphate, and fluoride in acetate buffers were used. The ^{45}Ca/F molar ratios indicated the formation of fluoridated hydroxyapatite in the enamel or the pellet when the pK_{FAP} values for remineralizing solutions were <112. When the pK_{FAP} values were >112, the ^{45}Ca/F ratios were found to be ≪5. Also, when the pK_{FAP} values were large (>112), the remineralization patterns based on the fluoride distribution in the tooth (or pellet) were found to be different than when the pK_{FAP} values were small (<112). The hypothesis that a pK_{FAP} value of 112 is the demarcation between remineralization only and simultaneous dissolution–remineralization has been proposed based on these results.

Keyphrases □ Tooth enamel—bovine, demineralization and remineralization, effect of bulk solution activity product □ Hydroxyapatite—pellets, demineralization and remineralization, effect of bulk solution activity product □ Remineralization—demineralized bovine tooth enamel, hydroxyapatite pellets, effect of bulk solution activity product

Previous studies conducted in these laboratories (1) indicated that both bovine tooth enamel and hydroxyapatite pellets could be extensively remineralized in a fluoride-containing remineralizing solution after prior demineralization treatments for various lengths of time. After 3 or 6 hr of prior demineralization in a partially saturated acetate buffer at pH 4.5, fluoride uptake levels on the order of 1000 ppm were found after remineralization, at depths up to ~50 μm from the surface. The stoichiometry of the remineralized phase was shown to be fluoridated hydroxyapatite rather than calcium fluoride based on the ^{45}Ca/F ratio and determination by X-ray diffraction analysis. All of the remineralization studies (1) were conducted in solutions at an ionic product ($K_{FAP} = a^{10}_{Ca^{2+}} a^{6}_{PO_4^{3-}} a^{2}_{F^-}$) of $\sim 1 \times 10^{-108}$.

The purpose of the present study was to investigate the influence of varying the K_{FAP} value for the remineralizing solution. A case of special interest was where the K_{FAP} values are $>10^{-120}$, the solubility product for fluorapatite (2), but $<10^{-114}$, the ion activity product value below which dissolution takes place with hydroxyapatite pellets (3). A question of great interest was how the concomittant dissolution of hydroxyapatite, if it were to occur, would influence the remineralization behavior in this K_{FAP} region.

EXPERIMENTAL

Materials—*Bovine Teeth*—Teeth from 8-week-old strictly kosher calves were obtained from packing houses in the Chicago area. From these incisors, only those without any visible surface defects and with a reasonably flat surface were used for the experiments. The labial surfaces of these selected teeth were then ground with rotating sandpaper (No. 400 first, then No. 600) to remove the pellicle.

Hydroxyapatite Pellet—Synthetic hydroxyapatite crystals prepared using the procedure developed by Moreno (4) were used in the preparation of the pellets. Approximately 50 mg of hydroxyapatite, preequilibrated in a humidity chamber containing saturated potassium nitrate aqueous solution to maintain the humidity at ~67%, was compressed in a 0.62-cm diameter die with a force of 4540 kg using a laboratory press[1].

Preparation of Buffer Solutions—As in a previous study (1) a solution ~16% saturated (on a molar basis) with respect to the thermodynamic solubility of hydroxyapatite was used for demineralization. The solution was a 0.1 *M* acetate buffer containing 3.5 m*M* each of total calcium and phosphate. The pH was adjusted to 4.5 with sodium hydroxide and the ionic strength to 0.5 *M* by the addition of sodium chloride. For remineralization 0.1 *M* acetate buffers (pH 4.5) containing differing amounts of total calcium and phosphate depending on the desired bulk solution activity product ($K_{FAP} = a^{10}_{Ca^{2+}} a^{6}_{PO_4^{3-}} a^{2}_{F^-}$) as shown in Table I, were employed. These solutions also contained 10 ppm of fluoride and sodium chloride to adjust the ionic strength to 0.5 *M*. All the chemicals used for the preparation of buffer solutions were analytical grade. A predetermined amount of calcium-45 as $^{45}CaCl_2$ in water[2] was added to these solutions.

Demineralization—A bovine tooth was covered with dental inlay wax except for a 0.25-cm^2 area in the labial surface. In the pellet experiments, a hydroxyapatite pellet was completely covered with inlay wax except for one exposed surface (area, 0.25 cm^2). The tooth or pellet was then demineralized in the 16% partially saturated buffer solution for a period of 6 and 3 hr, respectively, after attaching a thin glass rod to each (length, ~14 cm). The glass rod was used to ensure careful handling during demineralization and remineralization. The use of 6 and 3 hr as the demineralization times was based on previous experimental results (1) which clearly indicated that the demineralizing solution was not saturated

Solution Activity Product (K_{FAP}) and Simultaneous Demineralization–Remineralization in Bovine Tooth Enamel and Hydroxyapatite Pellets

JEFFREY L. FOX *‡¶ˣ, BALA V. IYER *‡, WILLIAM I. HIGUCHI *‡¶, and JOHN J. HEFFERREN §

Received May 17, 1982, from the **Dental Research Institute* and the ‡*College of Pharmacy, The University of Michigan, Ann Arbor, MI 48109* and the §*American Dental Association Health Foundation.* Accepted for publication August 26, 1982. ¶Present address: Dept. of Pharmaceutics, University of Utah, Salt Lake City, UT 84112.

Abstract □ The effects of changing the ion activity product of the remineralization solution at pH 4.5 (pK_{FAP} 108–118) on the remineralization behavior of demineralized bovine tooth enamel and hydroxyapatite pellets have been studied. Solutions containing calcium-45, phosphate, and fluoride in acetate buffers were used. The ^{45}Ca/F molar ratios indicated the formation of fluoridated hydroxyapatite in the enamel or the pellet when the pK_{FAP} values for remineralizing solutions were <112. When the pK_{FAP} values were >112, the ^{45}Ca/F ratios were found to be ≪5. Also, when the pK_{FAP} values were large (>112), the remineralization patterns based on the fluoride distribution in the tooth (or pellet) were found to be different than when the pK_{FAP} values were small (<112). The hypothesis that a pK_{FAP} value of 112 is the demarcation between remineralization only and simultaneous dissolution–remineralization has been proposed based on these results.

Keyphrases □ Tooth enamel—bovine, demineralization and remineralization, effect of bulk solution activity product □ Hydroxyapatite—pellets, demineralization and remineralization, effect of bulk solution activity product □ Remineralization—demineralized bovine tooth enamel, hydroxyapatite pellets, effect of bulk solution activity product

Previous studies conducted in these laboratories (1) indicated that both bovine tooth enamel and hydroxyapatite pellets could be extensively remineralized in a fluoride-containing remineralizing solution after prior demineralization treatments for various lengths of time. After 3 or 6 hr of prior demineralization in a partially saturated acetate buffer at pH 4.5, fluoride uptake levels on the order of 1000 ppm were found after remineralization, at depths up to ~50 μm from the surface. The stoichiometry of the remineralized phase was shown to be fluoridated hydroxyapatite rather than calcium fluoride based on the ^{45}Ca/F ratio and determination by X-ray diffraction analysis. All of the remineralization studies (1) were conducted in solutions at an ionic product ($K_{FAP} = a^{10}_{Ca^{2+}} a^{6}_{PO_4^{3-}} a^{2}_{F^-}$) of $\sim 1 \times 10^{-108}$.

The purpose of the present study was to investigate the influence of varying the K_{FAP} value for the remineralizing solution. A case of special interest was where the K_{FAP} values are $>10^{-120}$, the solubility product for fluorapatite (2), but $<10^{-114}$, the ion activity product value below which dissolution takes place with hydroxyapatite pellets (3). A question of great interest was how the concomittant dissolution of hydroxyapatite, if it were to occur, would influence the remineralization behavior in this K_{FAP} region.

EXPERIMENTAL

Materials—*Bovine Teeth*—Teeth from 8-week-old strictly kosher calves were obtained from packing houses in the Chicago area. From these incisors, only those without any visible surface defects and with a reasonably flat surface were used for the experiments. The labial surfaces of these selected teeth were then ground with rotating sandpaper (No. 400 first, then No. 600) to remove the pellicle.

Hydroxyapatite Pellet—Synthetic hydroxyapatite crystals prepared using the procedure developed by Moreno (4) were used in the preparation of the pellets. Approximately 50 mg of hydroxyapatite, preequilibrated in a humidity chamber containing saturated potassium nitrate aqueous solution to maintain the humidity at ~67%, was compressed in a 0.62-cm diameter die with a force of 4540 kg using a laboratory press[1].

Preparation of Buffer Solutions—As in a previous study (1) a solution ~16% saturated (on a molar basis) with respect to the thermodynamic solubility of hydroxyapatite was used for demineralization. The solution was a 0.1 *M* acetate buffer containing 3.5 m*M* each of total calcium and phosphate. The pH was adjusted to 4.5 with sodium hydroxide and the ionic strength to 0.5 *M* by the addition of sodium chloride. For remineralization 0.1 *M* acetate buffers (pH 4.5) containing differing amounts of total calcium and phosphate depending on the desired bulk solution activity product ($K_{FAP} = a^{10}_{Ca^{2+}} a^{6}_{PO_4^{3-}} a^{2}_{F^-}$) as shown in Table I, were employed. These solutions also contained 10 ppm of fluoride and sodium chloride to adjust the ionic strength to 0.5 *M*. All the chemicals used for the preparation of buffer solutions were analytical grade. A predetermined amount of calcium-45 as $^{45}CaCl_2$ in water[2] was added to these solutions.

Demineralization—A bovine tooth was covered with dental inlay wax except for a 0.25-cm^2 area in the labial surface. In the pellet experiments, a hydroxyapatite pellet was completely covered with inlay wax except for one exposed surface (area, 0.25 cm^2). The tooth or pellet was then demineralized in the 16% partially saturated buffer solution for a period of 6 and 3 hr, respectively, after attaching a thin glass rod to each (length, ~14 cm). The glass rod was used to ensure careful handling during demineralization and remineralization. The use of 6 and 3 hr as the demineralization times was based on previous experimental results (1) which clearly indicated that the demineralizing solution was not saturated

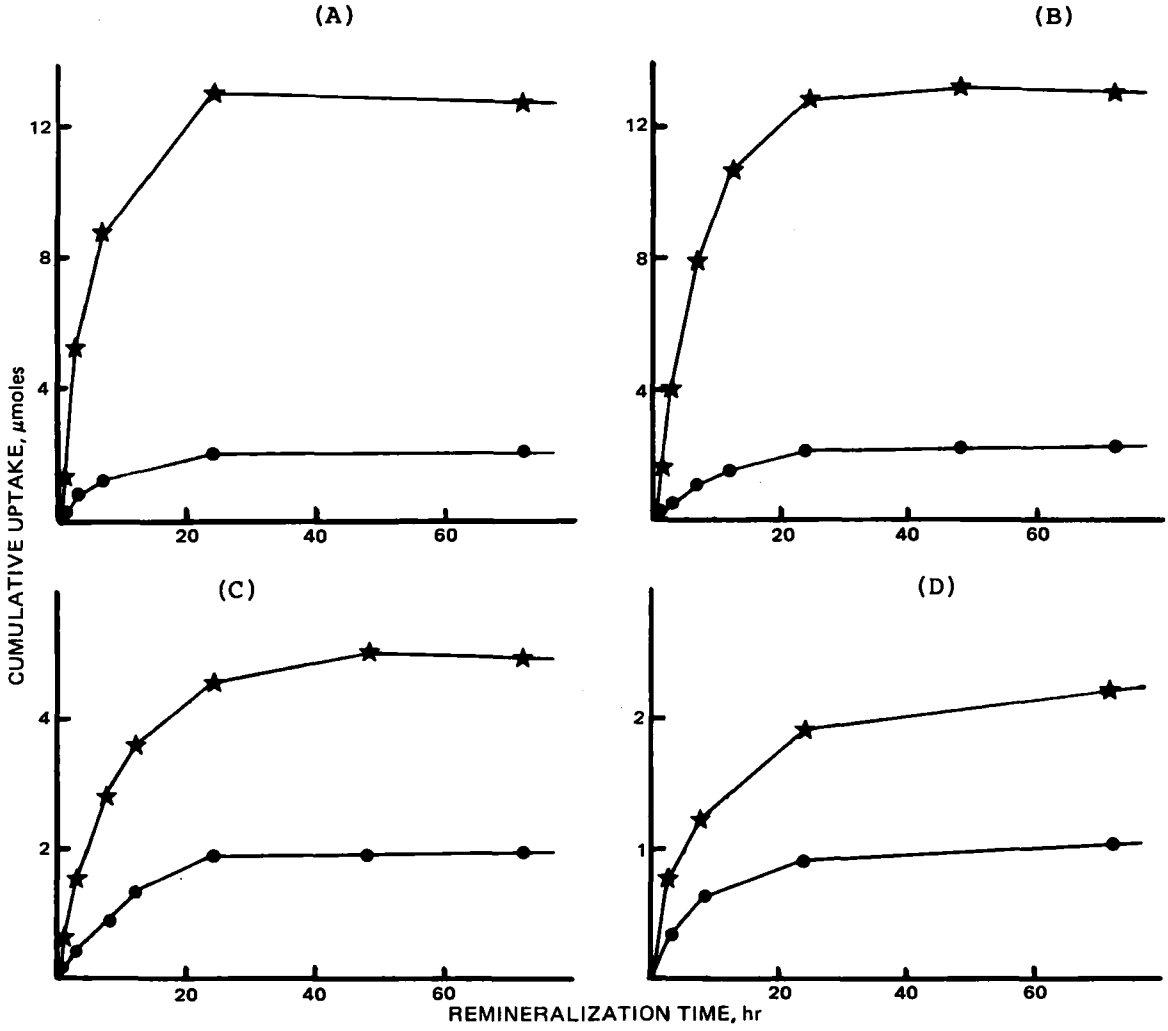

Figure 1—*Effect of remineralization time on the cumulative uptake of calcium-45 (★) and fluoride (●) ions in demineralized bovine tooth. Key: pK_{FAP} (A) 108; (B) 110; (C) 114; (D) 118.*

with respect to hydroxyapatite during that period. During demineralization the solution was shaken gently with a wrist action shaker[3] and kept at 30°. The volume of the buffer solution used was kept at 10 ml.

Remineralization—The demineralized tooth or pellet was washed completely with double-distilled water and dried. It was then subjected to the remineralization treatment for a period of 1–72 hr. During remineralization the solution was shaken gently in the wrist action shaker and kept at 30° as the remineralization proceeded.

Etching—The remineralized sample was thoroughly washed with double-distilled water and dried. The enamel was then etched in 1 ml of 0.5 *M* perchloric acid for successive periods of 30, 30, 120, 200, and 250 sec; the surface was washed with 1 ml of water after each etching and the washings were collected with the 0.5 *M* perchloric acid used for etching. In the case of pellets, the same procedure was repeated except the etchings were done for successive periods of 30, 30, 120, 200, 250, and 600 sec.

Analytical Techniques for the Estimation of Phosphate, Fluoride, and Calcium-45—Phosphate concentrations of the etching solutions were determined by the method of Gee *et al.* (5) in which the phospho-ammonium-molybdate complex formed was reduced by stannous chloride. The absorbance of the resulting blue solution was determined after 15 min at 720 nm[4]. Fluoride concentrations were determined by a fluoride ion electrode[5] using a low level total ionic strength-adjusting buffer. Concentrations of calcium-45 were determined using a scintillation counter[6].

Calculation of Layer Depth—The depth of the etched layers of the teeth were calculated from the amounts of phosphate removed from the etched layers, assuming the density of samples to be 2.95 g/ml. It was expected that this density value would be too large an estimate for the actual density near the surface; however, it is a convenient way to present the data and was adopted for this reason.

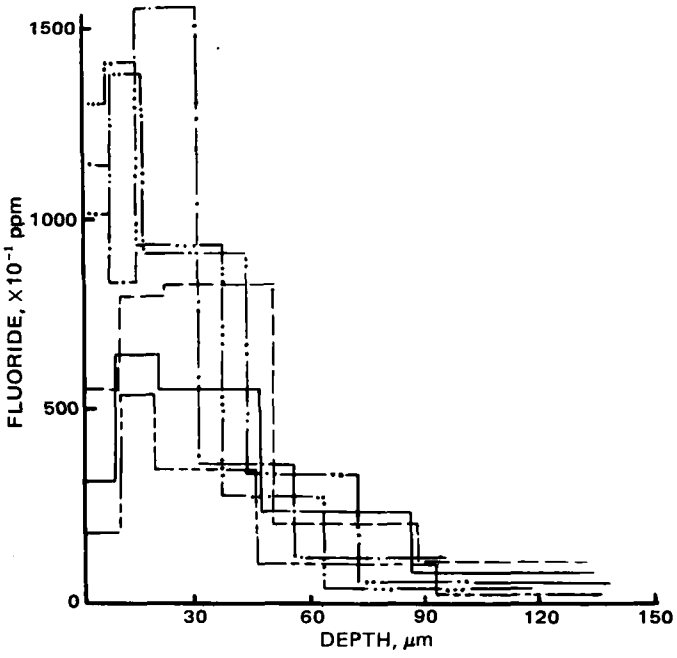

Figure 2—*The influence of driving force pK_{FAP} on the fluoride uptake of demineralized bovine teeth (pH 4.5, μ = 0.5, 0.1 M acetate buffer, Ca/P ratio = 1). Key: pK_{FAP} (— • • • —) 108; (— • • —) 110; (— • —) 112; (- - -) 114; (—) 116; (— - - —) 118.*

eralized for a period of 1–72 hr. For the purpose of remineralization, solutions with pK_{FAP} values of 108, 110, 114, and 118 were used. The effect of remineralization time on cumulative calcium-45 and fluoride uptake is shown in Fig. 1. These cumulative calcium-45 and fluoride uptake values were determined by summing the respective values obtained for each successive layer. Figure 1 clearly indicates that the remineralization is essentially complete in 24 hr except in the case where the remineralizing solution had a pK_{FAP} value of 118. In this case there was a slight increase in calcium-45 and fluoride concentrations from 24 to 72 hr of remineralization.

Effect of pK_{FAP} on Remineralization—To study the effect of the bulk solution activity product on remineralization, the remineralization studies were carried out by varying the pK_{FAP} values from 108 to 118. It was not possible to prepare a solution with a pK_{FAP} value <108 at pH 4.5 due to spontaneous precipitation during the pH adjustment. Calculations suggest that this may be due to the precipitation of dicalcium phosphate dihydrate.

All of the remineralization studies were carried out for a period of 24 hr. The cumulative uptake of calcium-45 and fluoride, and the ^{45}Ca/F molar ratio for each remineralized enamel layer and corresponding pK_{FAP} values, are shown in Table II. Calcium-45 uptake appeared to be constant at each pK_{FAP} value. Fluoride levels remained relatively constant until a pK_{FAP} of ~114 and seemed to drop somewhat at 116 and 118 (Table II). The ^{45}Ca/F molar ratios were near or somewhat above 5, which indicated the formation of fluoridated hydroxyapatite when the remineralizing solution had a pK_{FAP} of 108 or 110. At the larger pK_{FAP} values, however, the ratios decreased, reaching a value of 2.1 at pK_{FAP} 118.

A point of primary interest in this study was to determine the remineralization behavior when the pK_{FAP} value was >114. An attempt was made to determine whether the drop in the ^{45}Ca/F ratio at the higher pK_{FAP} values might be related to the system undergoing simultaneous dissolution of hydroxyapatite and remineralization (or recrystallization) of fluoroapatite[7]. The hypothesis that the deposited material in the enamel surface region actually had a Ca/F ratio of 10:2 was tested by varying the calcium-45 specific activity in the remineralizing solution. This was achieved by varying the bulk solution Ca/P ratios from 50 to 0.02 in the pK_{FAP} range of 114–118. As can be seen from Table III, there was an increase in the ^{45}Ca/F molar ratio with an increase in bulk solution Ca/P ratio and a decrease in the ^{45}Ca/F ratio with a decrease in Ca/P ratio in the remineralizing solution for the same pK_{FAP} value. This supported the idea that the deposited material in the enamel surface region actually had a Ca/F molar ratio close to 10:2 and that a simultaneous dissolution–remineralization process is occurring above a certain pK_{FAP} value. The results obtained were tested by correcting the results for the microenvironmental calcium-45 specific activity at the tooth surface as calculated by an approximate computer model. The details of the model parameters are as shown in the *Appendix*. The results obtained by assuming a surface pK_{FAP} of 110 at appropriate bulk solution concentration seemed to fit very well with the experimental values obtained. The theoretical values obtained from the model parameters are indicated in the last columns of Tables II and III.

Figure 2 gives the enamel fluoride concentration profiles for the bovine teeth experiments. While, as pointed out above, the cumulative uptakes are all of the same order of magnitude, it is seen that the remineralization pattern when the pK_{FAP} values are large is different from that when the pK_{FAP} values are small. At a pK_{FAP} of 108, there is significantly more remineralization near the tooth surface (~10–15 μm) than when the pK_{FAP} values of the solutions were large. These results are generally in agreement with a quantitative microradiographic study recently completed in these laboratories (7).

Hydroxyapatite pellets remineralized for 24 hr after 3 hr of demineralization were tested for calcium-45 and fluoride uptake as shown in Table IV. These results show that, as in the case of the bovine teeth experiments, calcium-45 uptake decreased with increasing pK_{FAP}, with no notable decrease in the fluoride uptake. The ^{45}Ca/F molar ratios also dropped below 5 with increasing pK_{FAP} of the remineralizing solutions, as was obtained in the case of bovine teeth.

Consideration of all the experimental results at pH 4.5 clearly indicates that the pK_{FAP} value of the remineralizing solution is the most important variable in determining the course of remineralization, with a pK_{FAP} of 112 being the demarcation between remineralization only and simulta-

[7] Although the conditions and the nature of the experiments were different, Thiradilok and Feagin (6) observed that remineralization and dissolution–remineralization occur under different conditions in bovine enamel experiments. For example, when calcium, phosphate, and fluoride were all present in the remineralizing solutions (pH 7), remineralization was found to occur. However, if only calcium and fluoride or only phosphate and fluoride were present (and therefore the solution was initially unsaturated with respect to hydroxyapatite) these investigators found both dissolution and remineralization may take place. Their findings therefore are generally in good agreement with the present results.

neous dissolution–remineralization. Further experimental studies are in progress to determine whether the present conclusions regarding the "critical" pK_{FAP} value applies under other conditions (*e.g.*, at other pH values of the remineralizing solution). Also the similarities between the hydroxyapatite pellet experiments and bovine and human teeth studies are being evaluated further.

APPENDIX

Estimation of Calcium-45 Specific Activity at the Bovine Enamel Surface During Simultaneous Demineralization–Remineralization

It has been shown previously (3) that a hydroxyapatite pellet dissolves in the presence of partially saturated buffer containing fluoride when the solution is unsaturated with respect to a pK_{FAP} of ~114. In this dissolution situation, the solution concentration of calcium is higher in the pellet and at the hydroxyapatite surface than in the bulk solution, whereas the fluoride gradient goes the other way, favoring uptake of fluoride from the solution.

In this paper, bovine enamel was studied under similar conditions with the partially saturated bulk solution containing both calcium-45 and fluoride, and the uptake of both species was monitored. If it is assumed that bovine enamel behaves similarly to hydroxyapatite, then when the bulk solution has a pK_{FAP} of >112, the calcium concentration will be higher at the enamel surface since its apparent solubility under these conditions is governed by a pK_{FAP} of ~112. The result is that calcium-45 coming to the surface from the bulk solution will be diluted out by the higher "cold" calcium supplied by hydroxyapatite demineralization. Thus, at sites where calcium and fluoride uptake occurs, it would be expected that measuring uptake of calcium-45 would give too low a value for the calcium uptake as a result of the dilution of calcium-45 by "cold" calcium. The dilution of calcium-45 has been estimated and therefore the expected $^{45}Ca/F$ uptake ratio (assuming total Ca/F uptake is 10:2) was calculated by using a physical model incorporating the following assumptions:

1. The bovine enamel is assumed to dissolve stoichiometrically.
2. Fluoride and calcium-45 concentrations at the enamel surface are assumed equal to the bulk concentrations.
3. At the enamel surface a suitable expression for describing the surface solution ion activity product is:

$$K_{FAP} = 10^{-110} \text{ or } K_{HAP}(a^{10}_{Ca}a^{6}_{PO_4}a^{2}_{OH}) = 10^{-122}$$

4. The remineralization process in the enamel occurs with the ratio of deposited total Ca/F being 10:2.

Using this model, the expected $^{45}Ca/F$ uptake ratios have been calculated and seem to agree quite well with the experimental results over a range of bulk solution K_{FAP} values and for solution Ca/P ratios from 1:50 to 50:1.

Analysis of Monobutyryl and Dibutyryl Derivatives of Adenosine 3′,5′-Monophosphate in Biological Samples Using Isocratic Ion Pair High-Performance Liquid Chromatography

VAL H. SCHAEFFER *, ASAAD N. MASOUD *‡ˣ, and ROBERT J. RUBIN *

Received June 17, 1982, from the **Division of Toxicology, Department of Environmental Health Sciences* and ‡*Department of Anesthesiology/Critical Care Medicine, Johns Hopkins Medical Institutions, Baltimore, MD 21205.* Accepted for publication September 1, 1982.

Abstract □ Adenosine 3′,5′-monophosphate (cyclic AMP), its dibutyryl and monobutyryl derivatives, and a number of other naturally occurring adenine-containing compounds were separated by isocratic ion pair high-performance liquid chromatography. A mobile phase consisting of 30% methanol in 0.1 *M* KH_2PO_4 (pH 4.0) containing 1 m*M* tetramethylammonium hydroxide as the counterion was used to separate the butyryl derivatives. To sufficiently separate cyclic AMP from other adenine-containing compounds, a mobile phase containing 6% methanol in the same aqueous buffer plus counterion was used. Extraction of these cyclic nucleotides from deproteinized biological samples using disposable reverse-phase extraction columns is described. This not only eliminated lipophilic contaminants, but also served to concentrate the samples. The outlined procedures were used to determine the concentrations of the butyryl derivatives in lung tissue and perfusate following a 35-min lung perfusion with 100 μM N^6-$O^{2'}$-dibutyryl cyclic AMP. The role of this technique in the analysis of cyclic nucleotide derivatives as compared with conventional assay procedures is discussed.

Keyphrases □ Adenosine 3′,5′-monophosphate—dibutyryl and monobutyryl derivatives, lung tissue and perfusate, separation by isocratic ion pair high-performance liquid chromatography □ Analogues—dibutyryl and monobutyryl cyclic AMP, lung tissue and perfusate, separation by isocratic ion pair high-performance liquid chromatography □ High-performance liquid chromatography—ion pair, isocratic, cyclic AMP and its dibutyryl and monobutyryl derivatives, lung tissue and perfusate

Analogues of adenosine 3′,5′-monophosphate (cyclic AMP) were first synthesized to selectively mimic the effects of this cyclic nucleotide in various biological systems. The most extensively used analogue has been N^6-$O^{2'}$-dibutyryl cyclic AMP (1). In most instances the dibutyryl derivative has proved to be more biologically active when

APPENDIX

Estimation of Calcium-45 Specific Activity at the Bovine Enamel Surface During Simultaneous Demineralization–Remineralization

It has been shown previously (3) that a hydroxyapatite pellet dissolves in the presence of partially saturated buffer containing fluoride when the solution is unsaturated with respect to a pK_{FAP} of ~114. In this dissolution situation, the solution concentration of calcium is higher in the pellet and at the hydroxyapatite surface than in the bulk solution, whereas the fluoride gradient goes the other way, favoring uptake of fluoride from the solution.

In this paper, bovine enamel was studied under similar conditions with the partially saturated bulk solution containing both calcium-45 and fluoride, and the uptake of both species was monitored. If it is assumed that bovine enamel behaves similarly to hydroxyapatite, then when the bulk solution has a pK_{FAP} of >112, the calcium concentration will be higher at the enamel surface since its apparent solubility under these conditions is governed by a pK_{FAP} of ~112. The result is that calcium-45 coming to the surface from the bulk solution will be diluted out by the higher "cold" calcium supplied by hydroxyapatite demineralization. Thus, at sites where calcium and fluoride uptake occurs, it would be expected that measuring uptake of calcium-45 would give too low a value for the calcium uptake as a result of the dilution of calcium-45 by "cold" calcium. The dilution of calcium-45 has been estimated and therefore the expected $^{45}Ca/F$ uptake ratio (assuming total Ca/F uptake is 10:2) was calculated by using a physical model incorporating the following assumptions:

1. The bovine enamel is assumed to dissolve stoichiometrically.
2. Fluoride and calcium-45 concentrations at the enamel surface are assumed equal to the bulk concentrations.
3. At the enamel surface a suitable expression for describing the surface solution ion activity product is:

$$K_{FAP} = 10^{-110} \text{ or } K_{HAP}(a^{10}_{Ca}a^{6}_{PO_4}a^{2}_{OH}) = 10^{-122}$$

4. The remineralization process in the enamel occurs with the ratio of deposited total Ca/F being 10:2.

Using this model, the expected $^{45}Ca/F$ uptake ratios have been calculated and seem to agree quite well with the experimental results over a range of bulk solution K_{FAP} values and for solution Ca/P ratios from 1:50 to 50:1.

Abstract □ Adenosine 3′,5′-monophosphate (cyclic AMP), its dibutyryl and monobutyryl derivatives, and a number of other naturally occurring adenine-containing compounds were separated by isocratic ion pair high-performance liquid chromatography. A mobile phase consisting of 30% methanol in 0.1 *M* KH_2PO_4 (pH 4.0) containing 1 m*M* tetramethylammonium hydroxide as the counterion was used to separate the butyryl derivatives. To sufficiently separate cyclic AMP from other adenine-containing compounds, a mobile phase containing 6% methanol in the same aqueous buffer plus counterion was used. Extraction of these cyclic nucleotides from deproteinized biological samples using disposable reverse-phase extraction columns is described. This not only eliminated lipophilic contaminants, but also served to concentrate the samples. The outlined procedures were used to determine the concentrations of the butyryl derivatives in lung tissue and perfusate following a 35-min lung perfusion with 100 μM N^6-$O^{2'}$-dibutyryl cyclic AMP. The role of this technique in the analysis of cyclic nucleotide derivatives as compared with conventional assay procedures is discussed.

Keyphrases □ Adenosine 3′,5′-monophosphate—dibutyryl and monobutyryl derivatives, lung tissue and perfusate, separation by isocratic ion pair high-performance liquid chromatography □ Analogues—dibutyryl and monobutyryl cyclic AMP, lung tissue and perfusate, separation by isocratic ion pair high-performance liquid chromatography □ High-performance liquid chromatography—ion pair, isocratic, cyclic AMP and its dibutyryl and monobutyryl derivatives, lung tissue and perfusate

Analogues of adenosine 3′,5′-monophosphate (cyclic AMP) were first synthesized to selectively mimic the effects of this cyclic nucleotide in various biological systems. The most extensively used analogue has been N^6-$O^{2'}$-dibutyryl cyclic AMP (1). In most instances the dibutyryl derivative has proved to be more biologically active when

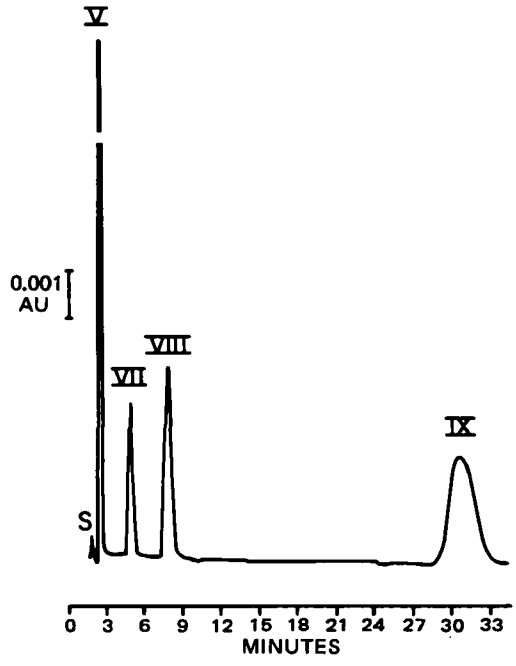

Figure 1—*Chromatogram of a mixture containing reference compounds V (346 pmole), VII (215 pmole), VIII (256 pmole), and IX (1000 pmole). Mobile phase was 30% methanol in 0.1 M KH_2PO_4–1 mM $(CH_3)_4NOH$. Other chromatographic conditions are as described under* Experimental.

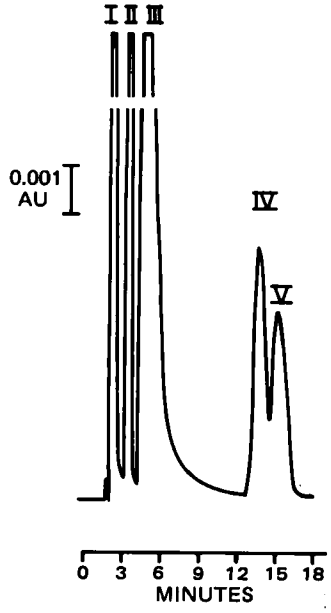

Figure 2—*Chromatogram of a mixture containing reference compounds I (500 pmole), II (1000 pmole), III (1200 pmole), IV (300 pmole), and V (285 pmole). Mobile phase was 6% methanol in 0.1 M KH_2PO_4–1 mM $(CH_3)_4NOH$. Other chromatographic conditions are as described under* Experimental.

administered *in vivo* than the unsubstituted cyclic nucleotide, presumably due to its increased lipophilicity (2). It is generally agreed that the dibutyryl cyclic nucleotide is metabolized by most cells to its two monobutyryl derivatives, N^6-monobutyryl cyclic AMP and $O^{2'}$-monobutyryl cyclic AMP (3).

Although the use of these particular cyclic nucleotide analogues has become widespread, the predominant analytical methods for determining the compounds still rely on paper chromatography and TLC (4, 5). These techniques are time consuming and lack the sensitivity and specificity necessary for highly complex mixtures such as biological samples. In recent years, separation by high-performance liquid chromatography (HPLC) has been described (6, 7). The systematic analysis of these compounds in biological extracts, however, has not been reported.

This paper describes the separation of dibutyryl cyclic AMP, its monobutyryl derivatives, cyclic AMP, and several selected adenine nucleotides, nucleosides, and bases most likely to be present in biological samples, using an isocratic ion pair HPLC system. Extraction and quantitation of these compounds from both a rat lung perfusate and lung tissue is also described.

Table I—Mean k' Values for the Four Cyclic Nucleotides Using Three Different Mobile Phases [a]

Compound	k' Mobile Phase A[b]	Mobile Phase B[c]	Mobile Phase C[d]
V	8.05 ± 0.20	0.33 ± 0.01	0.24 ± 0.01
VII	—[e]	6.79 ± 0.13	1.52 ± 0.02
VIII	—	—	3.07 ± 0.03
IX	—	—	14.97 ± 2.00

[a] k' is defined as $(t_R - t_0)/t_0$ where t_R = retention time of the compound and t_0 = retention time of unretained material (solvent front). k' values are the mean ± *SD* of five determinations representing day-to-day variation. [b] 6% Methanol in 0.1 *M* KH_2PO_4–1 m*M* $(CH_3)_4NOH$ (pH 4). [c] 20% Methanol in 0.1 *M* KH_2PO_4–1 m*M* $(CH_3)_4NOH$ (pH 4). [d] 30% Methanol in 0.1 *M* KH_2PO_4–1 m*M* $(CH_3)_4NOH$ (pH 4). [e] — not eluted.

EXPERIMENTAL

Reagents and Reference Standards—The following compounds were used as chromatographic standards: adenosine 5′-diphosphate sodium salt (I) from equine muscle[1], adenosine 5′-monophosphate sodium crystals[1] (II), assay 99%, adenine[2] (III), adenosine[2] (IV), adenosine 3′,5′-monophosphate sodium crystals[1] (V), theophylline[1] (VI), N^6-monobutyryladenosine 3′,5′-monophosphate sodium salt[1] (VII), $O^{2'}$-monobutyryladenosine 3′,5′-monophosphate sodium salt[1] (VIII), and N^6,$O^{2'}$-dibutyryladenosine 3′,5′-monophosphate sodium salt[1] (IX). All compounds are numbered according to their order of elution.

The following reagents were also used: bovine albumin fraction V[1] (96–99% pure), phosphoric acid[3] (85% pure), tetramethylammonium hydroxide pentahydrate[3], potassium phosphate[3] (reagent grade), 60% perchloric acid[4] (reagent grade), potassium hydroxide[5], and glass-distilled methanol[6]. In-house water was filtered, passed through a reverse osmosis system, glass-distilled, and then demineralized.

Stock solutions of reference standards were prepared at 100 μg/ml in purified water and stored frozen. The stock solutions were diluted to prepare various working standards for chromatography.

HPLC Apparatus and Procedures—The apparatus was similar to that described previously (8). This included an injector equipped with 20-μl loop[7] and a reciprocating pump[8], a 5000-psi gauge, a 1-m pulse damper, a reverse-phase 250 × 4-mm column packed in our laboratory with RP-18[9] (10 μm), and a UV variable-wavelength detector[10].

An aqueous stock solution was prepared containing 1 *M* KH_2PO_4 and 10 m*M* tetramethylammonium hydroxide adjusted to pH 4.0 with phosphoric acid (14.7 *M*). All mobile phases contained a 10-fold dilution of this stock solution, resulting in a final concentration in all mobile phases of 0.1 *M* KH_2PO_4 and 1 m*M* tetramethylammonium hydroxide (pH 4.0). Three mobile phases were used isocratically in this research,

Table II—Cyclic Nucleotide Extraction From Perfusate Using Octadecylsilane Disposable Columns [a]

Compound	Recovery, % 30% Methanol	75% Methanol
V	78 ± 2	—[b]
VII	9 + 1	69 ± 4
VIII	—	78 ± 2
IX	—	76 ± 2

[a] Control perfusate was spiked with the compounds. Following deproteinization with 0.6 *N* perchloric acid and neutralization, supernatant was passed through a C-18 disposable extraction column (1 ml). The column was eluted with 0.5 ml 30% methanol in 0.1 *M* KH_2PO_4–1 m*M* $(CH_3)_4NOH$ (pH 4) followed by 0.5 ml of 75% methanol in 0.1 *M* KH_2PO_4–1 m*M* $(CH_3)_4NOH$ (pH 4). These 0.5-ml eluates were collected separately and analyzed by HPLC. [b] — not detected.

all of which varied in the methanol concentration: (A) 6% methanol, (B) 20% methanol, and (C) 30% methanol. All mobile phases were filtered through a 0.22-μm membrane filter[11], then deaerated under vacuum prior to use. An aqueous buffer containing 45% methanol was used following chromatography of all tissue extracts to elute strongly retained contaminants. The column was stored in water–methanol (9:1) at the end of each day. The flow rate was 1.2 ml/min., the detector was set at 254 nm with either 0.02 or 0.01 AUFS, and the recorder chart speed was 0.25 cm/min. The void volume, determined by introducing pure methanol on the column, was 1.95 ml.

Preparation of Biological Samples—Perfusate and tissue samples were obtained following perfusion of Krebs–Henseleit buffer supplemented with 4.5% bovine albumin, 0.1 m*M* dibutyryl derivative (IX), and 0.2 m*M* theophylline (VI) through a recirculating isolated rat lung preparation for 35 min. After the perfusion, the lungs were immediately frozen in liquid nitrogen, and both the lung tissue and perfusate were stored at −60° until further preparation.

Approximately 1 g of lung tissue was homogenized at 4° with three volumes of 0.6 *N* perchloric acid. The precipitate was removed following centrifugation at 12,000×*g*, and the supernatant was neutralized with 10 *N* KOH. In a similar manner, aliquots of perfusate (0.5 ml) were deproteinized directly by addition of 50 μl of 6 *N* perchloric acid, and the resulting supernatant fraction was neutralized with 10 *N* KOH.

The total supernatant fraction was passed through 1-ml octadecylsilane (C-18) disposable extraction columns[12]. These columns were conditioned

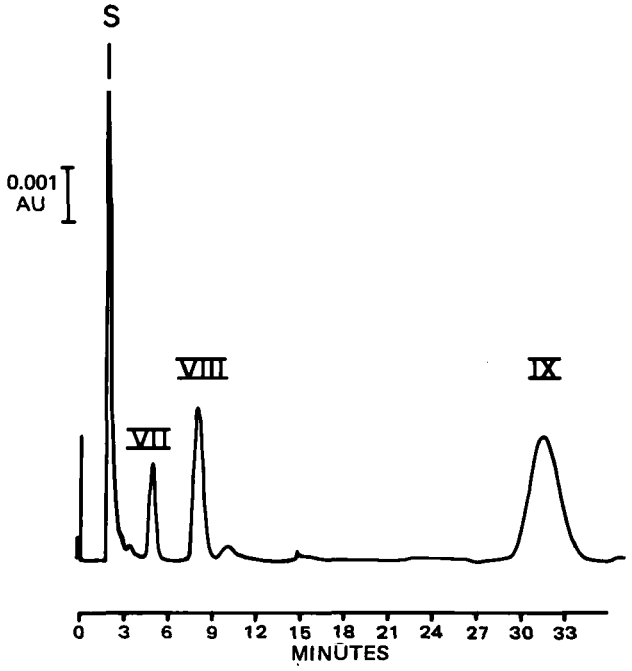

Figure 3—*Krebs buffer supplemented with 100 μM dibutyryl cyclic AMP was subjected to a 35-min sham perfusion, deproteinized in 0.6 N perchloric acid, and extracted on a C-18 disposable column (see text). by the introduction of several volumes of methanol followed by reequilibration with several volumes of the aqueous buffer, 0.1 *M* KH_2PO_4–1 m*M* tetramethylammonium hydroxide (pH 4.0). After sample introduction, the columns were first eluted with 0.5 ml of mobile phase C followed by 0.5 ml of 75% methanol in aqueous buffer. Each 0.5-ml fraction was separately collected for HPLC.

RESULTS

Chromatography of Cyclic AMP and Derivatives—Figure 1 illustrates the separation of cyclic AMP and its butyryl derivatives using mobile phase C (30% methanol). The dibutyryl derivative (IX), $O^{2'}$-monobutyryl derivative (VIII), and in most cases the N^6-monobutyryl derivative (VII) were sufficiently retained for analysis in biological samples. However, the unsubstituted cyclic nucleotide (V) eluted too close to the solvent front for adequate separation from the many other nucleotides, nucleosides, and nucleobases eluting at the solvent front and present in biological samples (data not shown). Figure 2 shows the separation of V from four other adenine-containing compounds using mobile phase A (6% methanol). Under these chromatographic conditions, the order of elution is as follows: nucleotide diphosphates, nucleotide monophosphates, nucleobases, nucleosides, and cyclic nucleotides, which possess the longest retention time. Nucleotide triphosphates elute before the diphosphates (data not shown). Since adenosine (IV) is the most retained of the common nucleosides found in biological systems using reverse-phase liquid chromatography (9, 10), all other biological nucleotides, nucleosides, and bases would presumably elute prior to V. Therefore, this procedure theoretically should produce a method suitable for cyclic AMP analysis in biological samples.

The *k'* values of the four cyclic nucleotide derivatives using three different mobile phases are presented in Table I. Mobile phase A was chosen for determinations of V in biological samples. Both mobile phases B and C were used for the analysis of VII. Compounds VIII and IX were separated using mobile phase C. Standard deviations reflect variation due, for the most part, to different batches of mobile phases, fluctuation in room temperature, and the degree of column equilibration with the mobile phase.

Extraction of Cyclic Nucleotides from Biological Samples—To purify the deproteinized biological material of lipophilic impurities that might shorten the useful lifetime of the chromatographic column, the

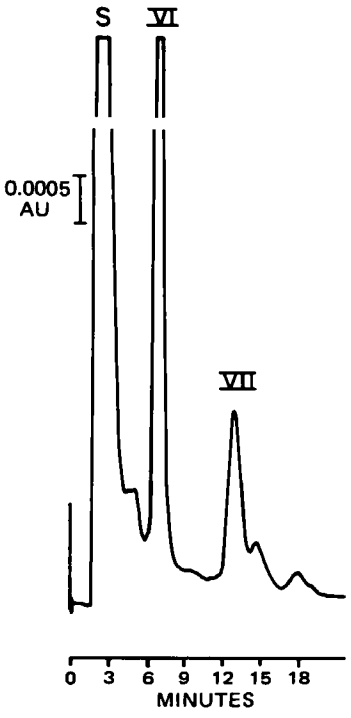

Figure 5—*Lung tissue following 35-min perfusion with 100 μM dibutyryl cyclic AMP and 200 μM theophylline was homogenized, deproteinized with 0.6* N *perchloric acid, and extracted on a C-18 disposable column (see text). samples were passed through the C-18 disposable extraction column described earlier. This purification procedure has two additional features that make it extremely attractive. First of all, it served to concentrate cyclic nucleotides by as much as sixfold. Secondly, a separation of V from the butyryl derivatives was accomplished.

Table II shows that 30% methanol in buffer will result in the elution of 78% of V from a lung perfusion medium, while most of VII, VIII, and IX are retained on the extraction column. Application of 75% methanol in buffer will then elute retained cyclic nucleotide analogues (69–78%). Initial elution using <30% methanol produces less recovery of V in the first fraction collected. Percentages of methanol <75% used in the second elution also results in less recovery of the butyryl derivatives. Greater than 75% methanol on the other hand causes increased elution of lipophilic impurities. Thus, the fraction eluted with 30% methanol in buffer was used for the analysis of V, while the butyryl derivatives were analyzed using the fraction eluted with 75% methanol buffer.

Analysis of Cyclic Nucleotides in Biological Samples—A perfusate containing 100 *μM* dibutyryl derivative (no theophylline) was circulated for 35 min in the perfusion apparatus in the absence of a lung. After deproteinization, the perfusate was extracted by the above procedure. The fraction eluted from the column with 30% methanol in buffer was analyzed by HPLC using mobile phase A and was calculated to contain 3.7 ± 1.00 μmoles of V/ml. The HPLC analysis of the 75% methanol fraction from the column using mobile phase C is shown in Fig. 3. It was calculated that each milliliter of the original sham perfusate contained 12.2 ± 0.8 μmoles of VII, 12.0 ± 0.7 μmoles of VIII, and 62.5 ± 2.6 μmoles of IX. Since only small amounts of impurities were found in the commercial supply of IX, these data reflect decomposition during deproteinization.

Figure 4 is a representative chromatogram of a similar perfusate following a 35-min perfusion through a lung. The additional presence of VI (k' = 1.0) should be noted. The perfusate analysis revealed that the concentration of the original dibutyryl derivative had fallen by 55%. Thirteen percent of the initial concentration of IX was recovered as VII. The remaining fraction had presumably entered the intracellular spaces of the lung and been metabolized.

Lung tissue following the 35-min perfusion with or without the dibutyryl derivative was also analyzed by the aforementioned procedures. Chromatographic data using mobile phase C revealed very small amounts of IX (1 nmole/g, wet weight) and VIII (0.5 nmole/g, wet weight) in tissue exposed to IX. The high theophylline content relative to the amounts of VII interfered with the determination of VII in these tissue extracts. To eliminate this problem, mobile phase B was used to analyze VII in lung tissue. Figures 5 and 6 are chromatograms of the tissue perfused with and without the dibutyryl derivative. Compounds VI and VII are well separated under these conditions (Fig. 5). Control tissues do not contain peaks that interfere with either VI or VII (Fig. 6). Following perfusion with 100 *μM* dibutyryl derivative, 10.55 ± 4.87 nmole/g (wet weight) of the monobutyryl derivative (VII) could be recovered from the lung tissue.

Analysis of the unsubstituted cyclic nucleotide (V) in lung tissue exposed to the dibutyryl derivative using mobile phase A was complicated by the fact that control lungs produced a complex chromatogram with one or more peaks coeluting with V. However, extracts of the tissue treated with IX do not consistently differ from unexposed tissue in the region in which V elutes. These results suggest that perfusion with the dibutyryl derivative does not result in significant accumulation of the unsubstituted cyclic nucleotide. However, this can not be established unequivocally until V is separated from the coeluting material.

DISCUSSION

The most common assay techniques for cyclic AMP in biological samples are radioimmunoassay, first described by Steiner *et al.* (11) and modified by Cailla and colleagues (12), and a competitive protein binding assay originally described by Gilman (13) and Brown *et al.* (14). These extremely sensitive methods (<0.1 pmole) appear to be more sensitive than current chromatographic techniques and also eliminate the necessity for complex separations from other nucleotides present in most cellular extracts. Unfortunately, the specificity of these assay systems is no longer adequate when cyclic nucleotide analogues are involved. For example, the affinity of the N^6-butyryl derivative (VII) for the cyclic AMP-dependent binding protein is ~30% of that for cyclic AMP itself (15). The $O^{2'}$-butyryl and dibutyryl derivatives have an even higher affinity than the unsubstituted cyclic nucleotide for the cyclic AMP-specific antibody (12). Therefore, these assay systems are not useful for determining the distribution of the butyryl derivatives.

The methods described here to separate the cyclic nucleotide derivatives do not have the problem of specificity inherent in the more conventional assay systems, since the butyryl groups caused a marked increase in lipophilicity making them easily separable from the parent compound and other nucleotides by HPLC. Although the chromatographic procedure as described here can only detect these compounds to the 0.01–0.1 nmole level, more sensitive UV detection settings, in-

creased amounts injected, and the use of larger extraction columns for trace enrichment of the samples may provide sensitivity comparable to that of the more conventional assays. The separation of cyclic AMP from other biological substances using a simple isocratic HPLC system may be a difficult task. However, the use of gradient elution with a reverse-phase column (10) or the use of ion-exchange chromatography may separate V from the coeluting compound(s) (16).

It should also be pointed out that the chromatogram in Fig. 2 is a good example of the extra dimension offered to the chromatographic process by ion pairing. All compounds analyzed with mobile phase A eluted in the reverse order of their polarity as expected in conventional reverse-phase chromatography. The only exceptions were V and IV. Although V is slightly less hydrophobic than IV, it has a greater retention under the conditions used due to the presence of tetramethylammonium hydroxide. The interaction of the tetramethyammonium cation with the negatively charged V increases its retention. On the other hand, the positively charged IV is not affected by this cation (7). The result is that while IV and V coelute without this cation, its presence causes V to elute after IV so that separation of these two compounds can be achieved.

By the use of the methods described here, it has been shown that the N^6-butyryl derivative is the major product formed following the perfusion of rat lung with dibutyryl cyclic AMP. It is estimated that ~24% of the dibutyryl derivative taken up by the lung during the perfusion period can be recovered as the N^6-monobutyryl analogue from the perfusate and lung compartments. The remaining portion has most likely been further metabolized to the straight-chain monophosphate by the action of phosphodiesterase, since it is not recovered in the lung as the unmetabolized dibutyryl cyclic AMP. We have also shown that 35-min perfusion with 100 μM dibutyryl derivative results in a sevenfold increase in the cyclic AMP content of the lung measured by the protein binding assay of Gilman (13) (data not shown). HPLC analysis reveals that 90% of this increased protein binding can be attributed to the formation of the N^6-butyryl derivative in the lung tissue.

In light of recent findings that different cyclic nucleotide analogues can selectively activate different isozymes of protein kinase (17, 18), it has become important to know the intracellular distribution of these analogues following treatment with cyclic nucleotide derivatives. This analytical procedure provides a specific, sensitive, and simple method for measuring dibutyryl cyclic AMP and its metabolites in biological systems. This technique can potentially be applied for analysis of many of the other cyclic nucleotide analogues. Also, not only can it be used for perfusion studies, but could also be adapted to cell culture and whole animal experiments.

Subnanogram Quantitation of Chlorpromazine in Plasma by High-Performance Liquid Chromatography with Electrochemical Detection

J. K. COOPER, G. McKAY, and K. K. MIDHA ˣ

Received March 23, 1982, from the *College of Pharmacy, University of Saskatchewan, Saskatoon, Saskatchewan, S7N OWO Canada.* Accepted for publication September 17, 1982.

Abstract □ A specific and sensitive high-performance liquid chromatographic (HPLC) method for the quantitative determination of subnanogram levels of chlorpromazine in plasma is described. Following extraction of chlorpromazine and the internal standard, prochlorperazine, HPLC analysis is carried out on a cyano column with a mobile phase consisting of 0.1 *M* ammonium acetate in acetonitrile (10:90 v/v). The use of oxidative thin-layer amperometric detection allowed the quantitation of 0.25 ng of chlorpromazine/ml of plasma with a coefficient of variation of 5.1%. The HPLC method has adequate sensitivity to follow plasma concentration–time profiles up to 24 hr following low single oral doses of chlorpromazine in healthy volunteers.

Keyphrases □ Chlorpromazine—human plasma, high-performance liquid chromatographic determination of subnanogram levels, electrochemical detection □ High-performance liquid chromatography—electrochemical detection, subnanogram levels, chlorpromazine, human plasma

Chlorpromazine is the most widely used phenothiazine antipsychotic agent. It is extensively metabolized (1–6) both systematically and presystemically (7, 8) to numerous metabolites, some of which are psychoactive. The quantitative analysis of chlorpromazine in plasma or serum has been achieved by several methods which include GLC–

0022-3549/83/1100-1259$01.00/0

creased amounts injected, and the use of larger extraction columns for trace enrichment of the samples may provide sensitivity comparable to that of the more conventional assays. The separation of cyclic AMP from other biological substances using a simple isocratic HPLC system may be a difficult task. However, the use of gradient elution with a reverse-phase column (10) or the use of ion-exchange chromatography may separate V from the coeluting compound(s) (16).

It should also be pointed out that the chromatogram in Fig. 2 is a good example of the extra dimension offered to the chromatographic process by ion pairing. All compounds analyzed with mobile phase A eluted in the reverse order of their polarity as expected in conventional reverse-phase chromatography. The only exceptions were V and IV. Subnanogram Quantitation of Chlorpromazine in Plasma by High-Performance Liquid Chromatography with Electrochemical Detection

J. K. COOPER, G. McKAY, and K. K. MIDHA ˣ

Received March 23, 1982, from the *College of Pharmacy, University of Saskatchewan, Saskatoon, Saskatchewan, S7N OWO Canada.* Accepted for publication September 17, 1982.

Abstract □ A specific and sensitive high-performance liquid chromatographic (HPLC) method for the quantitative determination of subnanogram levels of chlorpromazine in plasma is described. Following extraction of chlorpromazine and the internal standard, prochlorperazine, HPLC analysis is carried out on a cyano column with a mobile phase consisting of 0.1 *M* ammonium acetate in acetonitrile (10:90 v/v). The use of oxidative thin-layer amperometric detection allowed the quantitation of 0.25 ng of chlorpromazine/ml of plasma with a coefficient of variation of 5.1%. The HPLC method has adequate sensitivity to follow plasma concentration–time profiles up to 24 hr following low single oral doses of chlorpromazine in healthy volunteers.

Keyphrases □ Chlorpromazine—human plasma, high-performance liquid chromatographic determination of subnanogram levels, electrochemical detection □ High-performance liquid chromatography—electrochemical detection, subnanogram levels, chlorpromazine, human plasma

Chlorpromazine is the most widely used phenothiazine antipsychotic agent. It is extensively metabolized (1–6) both systematically and presystemically (7, 8) to numerous metabolites, some of which are psychoactive. The quantitative analysis of chlorpromazine in plasma or serum has been achieved by several methods which include GLC–

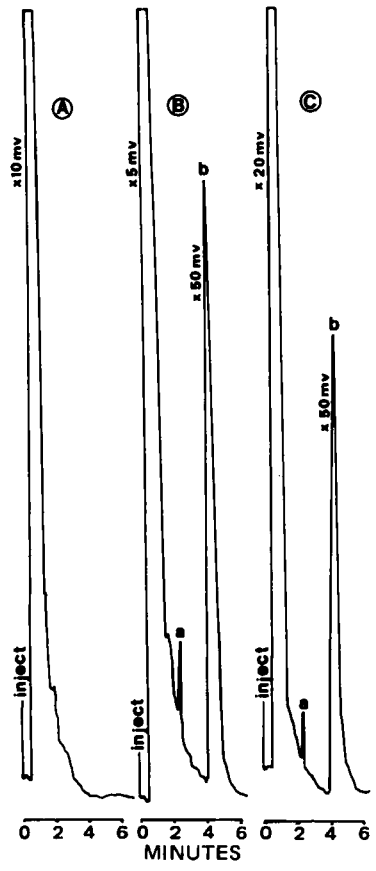

Figure 1—*Chromatograms of plasma extracted as outlined in* Experimental *with recorded sensitivity changes. Key: (A) blank plasma; (B) spiked plasma containing chlorpromazine (peak a, 0.5 ng/ml) and prochlorperazine (peak b, 50 ng/ml); (C) plasma sample 10 hr postdose from a volunteer (73.0 kg) who received 2 × 25-mg tablets orally of chlorpromazine hydrochloride. Chlorpromazine (peak a, 1.70 ng/ml) and prochlorperazine (peak b, 50 ng/ml).*

ECD (9), radioassay (10), radioimmunoassay (11, 12), fluorometry (13), GLC–NPD (14, 15), GLC–MS (1, 16, 17), and high-performance liquid chromatography (HPLC) (18–21).

HPLC methods, in general, are facile, easy to adopt, and are well suited for the therapeutic monitoring of drugs. Two of the HPLC procedures for chlorpromazine quantitation employ UV detection (18, 19), and the more sensitive (1 ng/ml) of these methods (18) was applicable to plasma level determinations in volunteers receiving chlorpromazine intravenously. Administration of chlorpromazine orally in low doses (25–50 mg), however, results in plasma levels that are generally in the subnanogram range at the end of the plasma concentration–time curve (7). Therefore, more sensitive analytical methods are needed to study the pharmacokinetics of this drug following low single oral doses. The development of such a method was achieved using electrochemical detection coupled with an improved extraction procedure that gave a greater recovery of the drug from plasma. Oxidative thin-layer amperometric detection (electrochemical detection) of chlorpromazine was investigated by Curry and Brown (20) and showed promise, but details of the assay were lacking. The procedure of Murakami *et al.* (21) was based on a reverse-phase HPLC system in which the extraction procedure was complex and plasma concentrations <1 ng/ml were not determined. The normal-phase HPLC method described here is simple, sensitive, and requires no specially treated glassware or apparatus. The improvement in the recovery of chlorpromazine from plasma was achieved by modification of an extraction procedure used for trifluoperazine (22).

Table I—HPLC Estimation of Chlorpromazine Added to Plasma [a]

Amount Added, ng	*n*	Mean Peak Height Ratio × 5	*SD*	*CV*[b]

EXPERIMENTAL

Materials—All solvents used both for extraction and in the HPLC mobile phase were HPLC grade[1]. Chlorpromazine hydrochloride[2], prochlorperazine mesylate[3], and 25-mg chlorpromazine tablets[4] were used as received. All other chemicals were commercial analytical grade.

HPLC—A liquid chromatographic pump[5] and valve loop injector[6] with a 500-μl sample loop was connected to an electrochemical detector[7]. The detector was fitted with a glassy carbon electrode and set at +0.9 V in the oxidation mode with a fixed 10-nA feed connected to a recorder[8]. All changes in attenuation were made only with the recorder to avoid baseline stabilization problems. The column (250 mm × 4.6-mm i.d.) was packed with 10-μm Spherisorb CN[9]. The mobile phase consisted of 0.1 *M* ammonium acetate–acetonitrile (1:9) and was deaerated before use by filtration[10]. The column was maintained at ambient temperature with a flow rate of 4 ml/min.

Preparation of Stock Solutions and Standard Curves—A stock solution of the internal standard, prochlorperazine mesylate (100 μg/ml, calculated as free base), was prepared monthly in double-distilled deionized water. The solution was stored in the dark at 4°. Daily dilutions were made in double-distilled deionized water to give a 100-ng/ml working solution. An aqueous solution of chlorpromazine hydrochloride (100 μg/ml, calculated as free base) was prepared monthly in double-distilled deionized water and stored as described for the internal standard. Daily dilutions of 100 ng/ml were made in 1:1 water–plasma and microliter amounts were added to give chlorpromazine concentrations of 0.25, 0.5, 1.0, 2.5, and 10 ng/ml in plasma.

Extraction of Samples—Plasma samples were extracted by a modification of a GLC–MS method developed for trifluoperazine (22). To a test tube[11] were added 2 ml of plasma and 1 ml of aqueous internal standard (prochlorperazine, 100 ng/ml). The sample was mixed[12] for 10 sec, and 0.5 ml of saturated sodium carbonate was then added. The sample was again mixed, and 5 ml of 3% isopropyl alcohol in pentane was added. The sample was capped and mixed for 20 min[13] and then centrifuged[14] at 1725×*g* for 5 min. The upper organic layer was transferred by Pasteur pipet to a clean 10-ml tube, and the extraction was repeated with another 5 ml of 3% isopropyl alcohol in pentane. The organic extracts were combined and a few antibumping granules[15] were added. The sample was evaporated to dryness at 65°[16]. To the cooled tube was added 200 μl of

Table II—Recovery of Chlorpromazine and Prochlorperazine from Plasma

Drug	Amount Added to 1 ml of Plasma, ng	n	Mean Amount Recovered, ng	Recovery, %[a]
Chlorpromazine	5.00	10	4.31	86.12 ± 2.26
	1.00	10	0.86	85.76 ± 2.90
Prochlorperazine	50.00	7	43.16	86.31 ± 1.33

[a] Mean ± *SD*.

HPLC-grade acetonitrile, the sample was mixed for 20 sec, and aliquots of 100 μl were injected into the chromatograph.

Plasma Level Study—Three healthy male volunteers weighing 73.0, 77.8, and 87.8 kg participated in the study, which was performed under medical supervision. Each volunteer was administered orally two 25-mg tablets of a commercial formulation of chlorpromazine with 250 ml of water. No xanthine-containing beverage was allowed during the study and no alcoholic beverages were allowed 24 hr before and 24 hr after the last blood sample. A lemon–lime beverage (200 ml) was provided 2 hr after dosing, and a standard lunch at 4.5 hr. Blood samples (10 ml each) were obtained at 0, 0.5, 1, 2, 3, 4, 6, 8, 10, 12, 15, and 24 hr following ingestion of the drug. The samples were collected by means of venipuncture into heparinized evacuated tubes[17] taking care to not allow the blood to come in contact with the rubber stopper[18]. After centrifugation the plasma was removed and stored at −20° until analysis; subsequently, thawed samples were stored at 4°.

Recovery Study—For the determination of the recovery of chlorpromazine and the internal standard, blank plasma was spiked at 1 and 5 ng/ml for chlorpromazine and 50 ng/ml for prochlorperazine. The samples were extracted as described and peak heights were compared with those obtained for absolute injection of the same amounts of chlorpromazine and prochlorperazine in acetonitrile.

Quantitation—Standard curves were constructed by chromatographing spiked plasma standards and plotting the peak height ratio of the drug to the internal standard *versus* the concentration of the drug. Unknown samples were analyzed along with calibration standards, and concentrations were determined by comparison of the peak height ratios to the standard curve obtained for that day. Patient samples above the stated linear range of 10 ng/ml were diluted as required with fresh blank control plasma and reanalyzed.

RESULTS AND DISCUSSION

Figure 1A shows a typical chromatogram of an extract of fresh blank plasma, and Fig. 1B shows a chromatogram obtained when the method was applied to spiked plasma containing 0.5 ng/ml of chlorpromazine and 50 ng/ml of the internal standard. Chlorpromazine and the internal standard gave well-separated sharp symmetrical peaks with retention times of 2.4 and 4.4 min, respectively. There were no extraneous peaks in chromatograms obtained for blank control plasma. Figure 1C shows a 10-hr postdose plasma sample (2 ml) of a volunteer (73.0 kg) who received 50 mg of chlorpromazine hydrochloride orally; the chlorpromazine concentration was estimated to be 1.7 ng/ml in this sample.

Mass spectral analysis of collected peaks from extracts of pooled plasma from volunteers and spiked samples were found to be identical and gave no evidence of possible interferences. The known metabolites of chlorpromazine either eluted in the same order and relative retention times as in the previous HPLC method using UV detection (18) or did not give any response with electrochemical detection. The use of a more concentrated ammonium acetate buffer increased the retention time of chlorpromazine by 2 min over that observed in the earlier study. This change in retention time resolved the peak due to chlorpromazine from components that eluted in the void volume. When the concentration of acetonitrile was decreased to 70%, no significant change in the retention time of chlorpromazine was observed; however, there was a significant decrease in the signal-to-noise ratio. Also, separation of chlorpromazine metabolites is best carried out using a 90% acetonitrile-based mobile phase. Linear extraction of chlorpromazine at low concentrations was observed to be a problem during the development of the HPLC–UV procedure reported from this laboratory (18). To correct this problem an extraction scheme was developed that provided linearity, but resulted in low recoveries: 34.5%. In the present method using 3% isopropyl alcohol in pentane increased the recovery to 86%, and produced reproducible results over the concentration range of 0.25–10.0 ng/ml. Furthermore, the use of the alternate detection system, electrochemical detection, allowed the quantitation of subnanogram amounts of chlorpromazine in plasma. In addition, no problems of occlusion, as observed in the HPLC–UV procedure (18), were encountered since deproteinization was unnecessary, and loss of drug due to adsorption to glass surfaces was not evident.

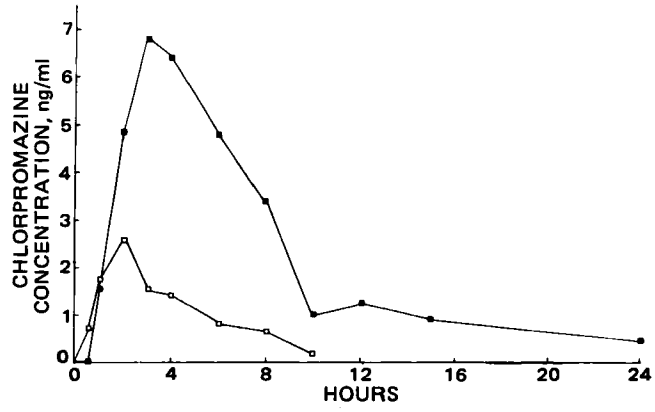

Figure 2—*Plasma concentration–time profiles for two volunteers (A = 77.8 kg, B = 87.8 kg) after each received a single oral dose of chlorpromazine (2 × 25-mg) tablets. Key: (■) volunteer A; (□) volunteer B.*

The electrochemical detector provides at least a 10-fold increase in sensitivity; this finding is in agreement with Curry and Brown (20). An apparent limitation of electrochemical detection is the presence of wide solvent fronts, which may be due to the response of endogenous materials coextracted from plasma. This limitation prevents operation of the detector at its lowest limits of detection. Despite this problem it is evident from Fig. 1B, where no appreciable interferences are observed with the recorder operated at 5 mV, that 0.5-ng amounts of drug can be measured.

Table I shows a composite standard curve obtained from the quantitation of chlorpromazine in plasma. The curve is linear in the range of 0.25–10 ng/ml. The ratio of chlorpromazine to prochlorperazine plotted against chlorpromazine concentration gave a straight line, which passed through the origin with a correlation coefficient of 0.999, a mean slope value of 0.1368, and an overall mean coefficient of variation of 3.47%. The limit of detection of this assay is ~0.1 ng/ml in plasma, and the limit of accurate quantitation is 0.25 ng/ml when 2-ml plasma samples are used. It is adequate for following plasma concentration–time profiles in patients receiving low oral doses of chlorpromazine.

The overall recoveries of chlorpromazine and the internal standard are shown in Table II. Results are based on at least 10 determinations at the 5- and 1-ng/ml levels for chlorpromazine and 7 determinations at the 50-ng/ml level for the internal standard. Mean recoveries of 85.94 ± 2.58% and 86.31 ± 1.33% were obtained for chlorpromazine and the internal standard (prochlorperazine), respectively. Application of this method is shown in Fig. 2, where plasma concentration *versus* time profiles are shown for two healthy male volunteers each receiving 2 × 25-mg tablets of chlorpromazine hydrochloride. Intersubject variability in plasma levels, as shown in Fig. 2, makes it clear that analysis of chlorpromazine should be carried out with the most sensitive procedure available especially when low oral doses are administered.

The described HPLC method is simple, requiring minimum sample handling and time. It is sensitive enough for single- as well as multiple-dose pharmacokinetic or bioavailability studies of low oral doses of chlorpromazine. Furthermore, multiple-dose studies and therapeutic monitoring could be carried out with smaller plasma sample volumes than previously required.

Maintenance-Dose Prediction Based on a Single Determination of Concentration: General Applicability to Two-Compartment Drugs with Reference to Lithium

CHERYL L. ZIMMERMAN and JOHN T. SLATTERY[x]

Received April 16, 1982, from the *School of Pharmacy, Department of Pharmaceutics, University of Washington, Seattle, WA 98195.* Accepted for publication September 21, 1982.

Abstract □ A general approach to the selection of the maintenance dose (D_m) required to give a desired steady-state concentration of drug based on a single determination of concentration after a test dose (C^*) is extended to drugs with two-compartment pharmacokinetic characteristics. Using the equation developed, the value of the proportionality factor relating $1/D_m$ to C^* was found to be within 3.2% of the value calculated from a published nomogram for lithium. The inherent error is shown to be a function of the value of the hybrid rate constants α and β, as well as the value of an intercompartmental transfer rate constant, k_{21}, in an individual.

Keyphrases □ Dose, maintenance—steady-state concentration, prediction by single determination of concentration, two-compartment pharmacokinetics, lithium □ Concentration, steady-state—maintenance dose, prediction by single determination of concentration, two-compartment pharmacokinetics, lithium □ Pharmacokinetics—two-compartment, maintenance dose for steady-state concentration, prediction by single determination of concentration, lithium

In 1973, Cooper *et al.* observed a correlation ($r = 0.972$) between the serum lithium concentration obtained 24 hr after the administration of a 600-mg dose of lithium carbonate and the eventual steady-state concentration if that dose were continued three times a day (1). From that observation, they constructed a nomogram that predicted the maintenance dose required to achieve a therapeutic steady-state concentration of lithium in plasma (0.6–1.2 meq/liter) based on the concentration determined 24 hr after administration of a test dose of the drug. The same group published a report 2 years later confirming the success of the method (2).

Similar techniques have since been proposed for drugs with widely differing pharmacokinetic characteristics (3–9). Montgomery *et al.* (5) proposed that blood samples taken 24 or 48 hr after an oral test dose of nortriptyline could adequately predict steady-state concentrations of that drug using a justification similar to that used by Cooper *et al.* Koup *et al.* suggested that a strong correlation between steady-state levels and drug concentrations 6 hr after administering a single dose of chloramphenicol or theophylline would exist based on a series of pharmacokinetic simulations (7), and later provided clinical data to support the method (8). The appropriate sampling times for those drugs seemed to correspond to their average half-life in the population. It thus became apparent that this approach to maintenance-dose prediction could be applied to many drugs, and that its successful use depended on implicit knowledge of the individual pharmacokinetic characteristics of a drug within the population.

A theoretical framework was provided to explain and evaluate the empirical clinical observations. The theory was founded on the essential clinical observation that there existed an optimal time at which a blood sample could be obtained from an individual, in which the concentration

Maintenance-Dose Prediction Based on a Single Determination of Concentration: General Applicability to Two-Compartment Drugs with Reference to Lithium

CHERYL L. ZIMMERMAN and JOHN T. SLATTERY[x]

Received April 16, 1982, from the *School of Pharmacy, Department of Pharmaceutics, University of Washington, Seattle, WA 98195.* Accepted for publication September 21, 1982.

Abstract □ A general approach to the selection of the maintenance dose (D_m) required to give a desired steady-state concentration of drug based on a single determination of concentration after a test dose (C^*) is extended to drugs with two-compartment pharmacokinetic characteristics. Using the equation developed, the value of the proportionality factor relating $1/D_m$ to C^* was found to be within 3.2% of the value calculated from a published nomogram for lithium. The inherent error is shown to be a function of the value of the hybrid rate constants α and β, as well as the value of an intercompartmental transfer rate constant, k_{21}, in an individual.

Keyphrases □ Dose, maintenance—steady-state concentration, prediction by single determination of concentration, two-compartment pharmacokinetics, lithium □ Concentration, steady-state—maintenance dose, prediction by single determination of concentration, two-compartment pharmacokinetics, lithium □ Pharmacokinetics—two-compartment, maintenance dose for steady-state concentration, prediction by single determination of concentration, lithium

In 1973, Cooper *et al.* observed a correlation ($r = 0.972$) between the serum lithium concentration obtained 24 hr after the administration of a 600-mg dose of lithium carbonate and the eventual steady-state concentration if that dose were continued three times a day (1). From that observation, they constructed a nomogram that predicted the maintenance dose required to achieve a therapeutic steady-state concentration of lithium in plasma (0.6–1.2 meq/liter) based on the concentration determined 24 hr after administration of a test dose of the drug. The same group published a report 2 years later confirming the success of the method (2).

Similar techniques have since been proposed for drugs with widely differing pharmacokinetic characteristics (3–9). Montgomery *et al.* (5) proposed that blood samples taken 24 or 48 hr after an oral test dose of nortriptyline could adequately predict steady-state concentrations of that drug using a justification similar to that used by Cooper *et al.* Koup *et al.* suggested that a strong correlation between steady-state levels and drug concentrations 6 hr after administering a single dose of chloramphenicol or theophylline would exist based on a series of pharmacokinetic simulations (7), and later provided clinical data to support the method (8). The appropriate sampling times for those drugs seemed to correspond to their average half-life in the population. It thus became apparent that this approach to maintenance-dose prediction could be applied to many drugs, and that its successful use depended on implicit knowledge of the individual pharmacokinetic characteristics of a drug within the population.

A theoretical framework was provided to explain and evaluate the empirical clinical observations. The theory was founded on the essential clinical observation that there existed an optimal time at which a blood sample could be obtained from an individual, in which the concentration

0022-3549/83/1100-1262$01.00/0

of drug would be related to the eventual steady-state concentration by a proportionality factor that could be regarded as being constant throughout the population (10, 11). The theory is consistent with the clinical observations made with chloramphenicol and theophylline. However, the theory suggested that the optimum sampling time for lithium would be ~16 hr after administration of the first dose of drug. The sampling time used clinically (with great success) was 24 hr. Thus, it was possible that the theory did not account for all factors in sampling time optimization. The most obvious shortcoming of the theory was that it was developed for drugs with one-compartment pharmacokinetic characteristics; lithium is a two-compartment drug. It is apparently necessary to extend the theoretical analysis to drugs with biexponential plasma concentration–time profiles, conventionally described by a two-compartment model.

The purpose of this report is to expand the theory to drugs with two-compartment characteristics and to evaluate the source and magnitude of error inherent in the method when it is employed under optimal conditions. We do not report a new dosing method.

THEORETICAL

The development of an expression that relates the maintenance dose (D_m) required to give a desired average steady-state concentration ($\overline{C}_{ss}$) to the concentration in plasma (C^*) at some time (t^*) after the first dose (D^*) for a drug with two-compartment pharmacokinetic characteristics is very similar to the development of the analogous expression for a one-compartment drug (10). Equations pertaining to the intravenous administration of the two-compartment drug will be used even though lithium itself is given orally. If, as in the case of lithium, absorption is rapid relative to distribution and elimination and the bioavailability does not vary between doses, the conclusions based on intravenous dosing will be valid for oral dosing as well. It is also assumed that the values of pharmacokinetic parameters describing the deposition of the drug do not change between the single dose and steady state.

The average concentration of a drug in plasma at steady state $\overline{C}_{ss}$, is defined as:

$$\overline{C}_{ss} = \frac{\int_0^{\infty} C\,dt}{\tau} \qquad \text{(Eq. 1)}$$

where C is the concentration of drug in plasma, t is time, and τ is the time between doses. For a drug with linear, two-compartment kinetics, Eq. 1 can be expressed as:

$$\overline{C}_{ss} = \frac{D_m(\alpha - k_{21})}{\alpha\tau V_c(\alpha - \beta)} + \frac{D_m(k_{21} - \beta)}{\beta\tau V_c(\alpha - \beta)} \qquad \text{(Eq. 2)}$$

where V_c is the volume of the central compartment, α and β are hybrid distribution- and elimination-phase rate constants, respectively, and k_{21} is a first-order rate constant for transfer of drug from the peripheral to the central compartment (12).

The concentration of drug following a single dose is:

$$C^* = \frac{D^*}{V_c}\left[\frac{(\alpha - k_{21})}{(\alpha - \beta)}e^{-\alpha t^*} + \frac{(k_{21} - \beta)}{(\alpha - \beta)}e^{-\beta t^*}\right] \qquad \text{(Eq. 3)}$$

The ratio $\overline{C}_{ss}/C^*$ is therefore:

$$\frac{\overline{C}_{ss}}{C^*} = \frac{D_m}{D^*\tau\alpha\beta}\left[\frac{k_{21}(\alpha - \beta)}{(\alpha - k_{21})e^{-\alpha t^*} + (k_{21} - \beta)e^{-\beta t^*}}\right] \qquad \text{(Eq. 4)}$$

By a rearrangement of Eq. 4, the maintenance dose can be related to C^* by a proportionality factor, ψ:

$$\frac{1}{D_m} = \psi C^* \qquad \text{(Eq. 5)}$$

where

$$\psi = \frac{k_{21}(\alpha - \beta)}{\overline{C}_{ss}\alpha\beta\tau D^*[(\alpha - k_{21})e^{-\alpha t^*} + (k_{21} - \beta)e^{-\beta t^*}]} \qquad \text{(Eq. 6)}$$

Equation 6 shows that the proportionality factor ψ relating maintenance dose to C^* is a complex function of α, β, and k_{21} in an individual. α and β are functions of the intercompartmental transfer and elimination rate microconstants, k_{12}, k_{21}, and k_{10} (12). Equations 5 and 6 will serve as an appropriate means of calculating maintenance dose for a drug with two-compartment behavior when ψ is relatively constant throughout the population, *i.e.*, when each individual's value of ψ is close to the population's mean value of ψ ($\overline{\psi}$). The values of the pharmacokinetic parameters k_{12}, k_{21}, and k_{10} (and therefore α and β) vary among individuals, and one can exert no control over them. The choice of $\overline{C}_{ss}$, τ, and D will depend on the drug used and will have no effect on the variability of ψ between individuals. By the choice of an appropriate value for t^*, the variability of ψ throughout the population can be minimized (10, 11).

Choice of Optimum Sampling Time (t^*)—In selecting the optimum sampling time for a one-compartment drug, the expression for ψ was recast in terms of clearance (CL) and volume of distribution (V). The partial first derivatives of ψ with respect to these independent variables were set at zero, and the resulting expressions were simultaneously solved for time. ψ was found to be minimally affected by interindividual variations in CL and V when t^* was $1/\overline{K}$, where $\overline{K}$ is the mean (or median) value of the elimination rate constant in the population (11). In attempting to do the same for ψ in the multicompartment case (Eq. 6), an explicit value for t^* was not found. Therefore, numerical approximation techniques were used to estimate a value of t^* at which variability of ψ throughout the population was minimal. This approach (described below) has the important benefit of allowing the examination of the behavior of ψ as it approaches its optimum, which provides some insight into the error of the method. By definition, the optimum value of t^* will be that value which produces the minimum variability of ψ throughout the population.

The optimum sampling time (t^*) was selected using parameter values for lithium based on data published by Amdisen (13) and Neilson-Kudsk and Amdisen (14). Fourfold ranges of α and k_{21} centered around mean values of 0.888 and 0.375 hr^{-1}, respectively, were considered. This encompassed the mean $\pm 2SD$ for both parameters. A histogram of β values was constructed from a published histogram of lithium half-life values in 226 patients. The fivefold range of β values was centered about a mean value of 0.065 hr^{-1}; this encompassed the mean $\pm 4SD$ for β. The broader range was used for β because preliminary studies showed that error was most sensitive to changes in β; it was therefore important to cover the entire range of values reported. A program was written to calculate ψ at a given t^* for 125 combinations of α, β, and k_{21}. The numerator of Eq. 6 was plotted against its denominator for various values of t^*. The slope of this plot is $\overline{\psi}$. The coefficient of variation of the estimate of the slope for the best-fit straight line was calculated for each t^* plot. Plots representing the analysis for t^* = 12, 16, 20, and 24 hr are shown in Fig. 1.

The t^* that gives the smallest amount of variation around the regression line, as measured by the smallest coefficient of variation of the slope[1] (or ψ) for the given ranges of α, β, and k_{21}, is the optimum sampling time. In this case, t^* = 16 hr shows the least amount of variation (29.9%) when compared with t^* = 12 hr (37.4%), t^* = 20 hr (33.0%), and t^* = 24 hr (43.8%). A value of 16 ± 1 hr is the optimum sampling time; the other values were chosen for illustrative purposes. This process could be summarized as a plot of the coefficient of variation of the slope *versus* time (which would actually be a plot of the relative variance of ψ as a function of time), where the minimum would represent the optimum sampling time.

Analysis of Error—The use of optimum t^* will give a minimum error in single-point dose prediction methods, but the choice itself does not give an indication of the magnitude or the source of error involved. It has been possible in previous descriptions of one-point maintenance-dose estimation to graphically examine the error of the method by plotting $\psi/\overline{\psi}$ as a function of the variables that determine the value of ψ (11, 16). In this case, $\psi/\overline{\psi}$ would be plotted as a function of α, β, and k_{21} and would therefore be four-dimensional. Such an approach would be helpful, however, if a majority of the variability of ψ among individuals was a function of only one or two of these parameters, allowing a two- or three-dimensional plot to be constructed.

Our investigations of the lithium case have shown that the majority of the variability in ψ through the population was a function of β rather than α or k_{21}. Thus, it would be possible to construct a plot of $\psi/\overline{\psi}$ *versus* β to more closely examine the influence of the major determinant of error. To view the whole problem, however, it is necessary to somehow incor-

[1] Percent coefficient of variation = (standard deviation/mean) × 100. Mean and standard deviation of the slope of the regression line were calculated according to standard methods (15).

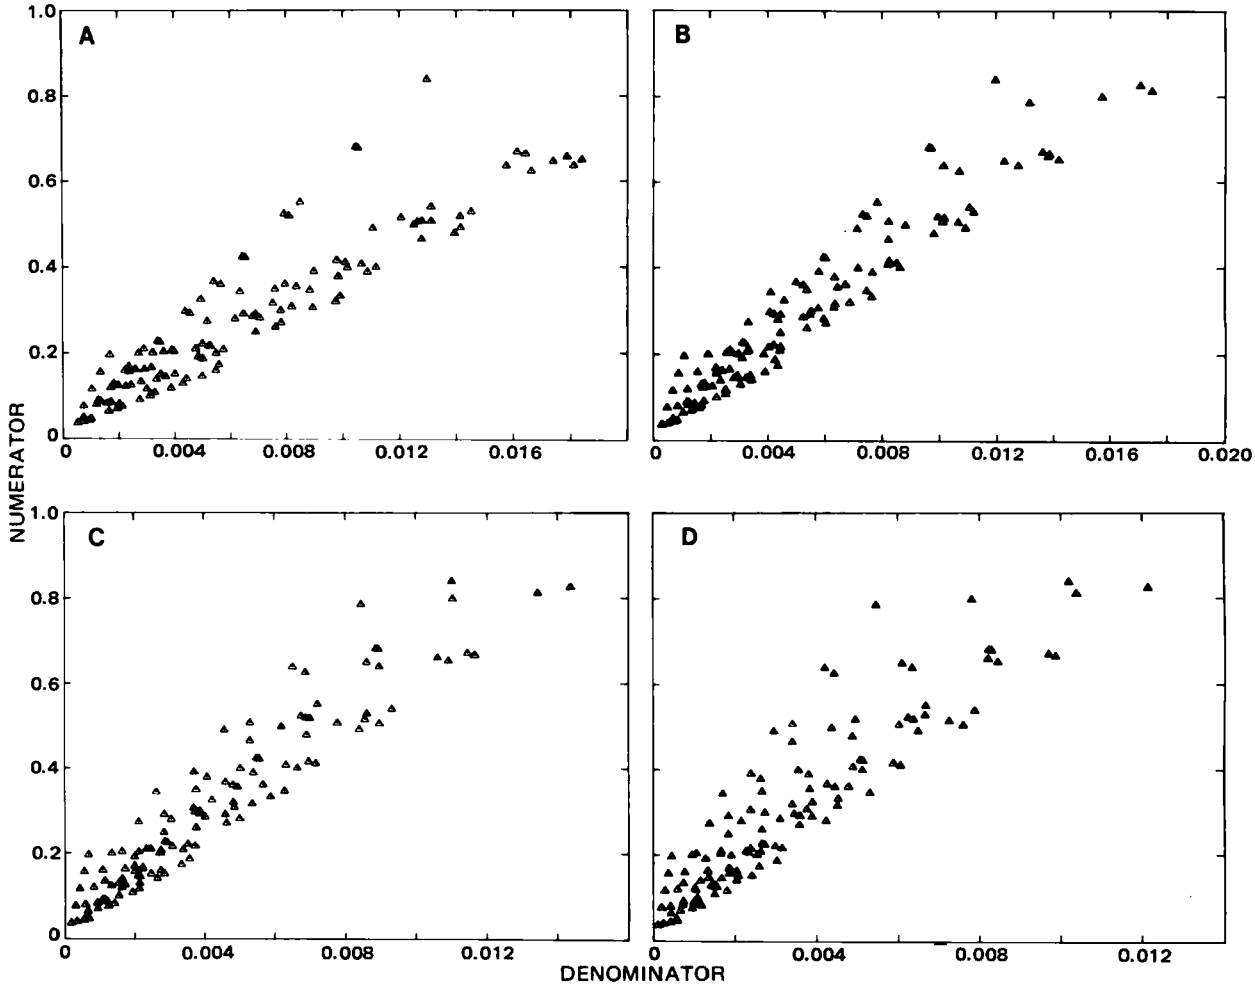

Figure 1—*Optimization of sampling time (t*) for lithium. The numerator of Eq. 6 is plotted* versus *the denominator for values of* α, β, *and* k_{21} *covering the range encountered through the population for lithium (13, 14). The minimum relative scatter is observed for the optimum value of* t*, *16 hr. Key: (A)* t* = *12 hr; (B)* t* = *16 hr; (C)* t* = *20 hr; (D)* t* = *24 hr.*

porate a depiction of the added error due to interindividual variation in α and k_{21}. This was accomplished by random selection of 100 values of α and k_{21} from a normal distribution (based on literature values of mean and standard deviation) for each value of β and calculating the value of $\psi/\overline{\psi}$ for each combination of α, β, and k_{21}. Figure 2 shows the mean values of $\psi/\overline{\psi}$ for each value of β and the magnitude of error due to interindividual variation in β alone, which is analogous to the graphical analysis of error for one-compartment drugs. With t^* = 16 hr, the departure of the plot of $\psi/\overline{\psi}$ from a value of 1 is minimal through the range of values of β covered in the plot. (If ψ did not vary through the population, $\psi/\overline{\psi}$ would always equal 1 and there would be no inherent error in the method.) Values of t^* at 12 and 24 hr give maximum errors of 50–60% at opposite extremes of β, and t^* = 20 hr gives a maximum error of ~40%. When t^* = 16 hr, the maximum error is ~25%.

A more complete analysis of error is obtained from the plots in Fig. 3. The mean value of $\psi/\overline{\psi}$ is again plotted as a function of β, but in this case the mean value is bracketed by ±2 *SD*, as calculated from the aforementioned 100 random combinations of α and k_{21} selected based on published values of their respective mean and standard deviation (13, 14). The maximum error expected to be encountered, taking the variability in ψ due to α and k_{21} into account, is ~40% for t^* = 16 hr and ~100% for t^* = 24 hr. Both of these errors would cause an overdose in patients with unusually large values of β, *i.e.*, individuals with unusually short half-life values.

This method of evaluation of error does not indicate the maximum error which could be encountered in the method, but it does indicate the maximum to be expected in ~95% of the population. Unusual patients could encounter greater error.

Comparison of Theory with a Published Nomogram—The single-point dose prediction for lithium proposed by Cooper *et al.* (1, 2) can be used as a basis for determining the validity of the equations developed here. Their nomogram consisted of seven maintenance doses recommended for seven respective ranges of C^*. Using that nomogram and Eq. 5, a value of ψ was calculated for each value of D_m and the mean C^* for which that dose was recommended. The mean of these values was 6.21 ml/meq·mg. Using Eq. 6; mean values of α, β, and k_{21}; and values of $\overline{C}_{ss}$, t^*, and D^* used by Cooper *et al.* in constructing the nomogram, the value calculated for $\overline{\psi}$ was 6.02 ml/meq·mg. Thus, Eq. 6 and literature data allowed the calculation of a value of ψ within 3.2% of the value found in the clinical experiment.

The agreement between the value of ψ implicitly used by Cooper *et al.* and that calculated using Eq. 6 and literature values of α, β, and k_{21} would seem to indicate that the theory is quantitatively valid. How then can the discrepancy between the optimum sampling time indicated by the theoretical analysis (16 hr) and the sampling time used by Cooper *et al.* (24 hr) in their successful nomogram be reconciled? The choice of optimum sampling time as described above is based on the assumed use of a constant value of ψ throughout the population.

The values of ψ corresponding to the higher ranges of C^* in the nomogram were quite close to one another (coefficient of variation, 11%). However, the value of ψ calculated for the lowest range of C^* for which dosing recommendations were made (mean of this range is 0.025 meq/liter) is 2.12 times the mean value for the higher ranges of concentration.

Patients with low values of concentration will tend to have larger values of β (shorter half-life values) than the population average. The theoretical analysis (Fig. 3) shows that patients with large values of β will tend to be overdosed using the population average value of ψ if the sample to be used for dose prediction purposes is obtained at 24 hr. The published nomogram corrects for this by using a larger value of ψ for these individuals, which reduces the recommended maintenance dose by approximately one-half of what it would be if the value of ψ used in other concentration ranges was retained. The published nomogram, therefore, corrects the error that would be encountered if a constant value of ψ were used

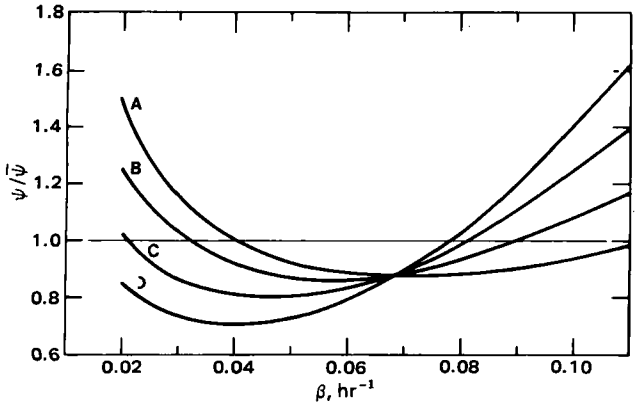

Figure 2—*Relationship between $\psi/\bar{\psi}$ and β for different values of sampling time (t*). α and k_{21} are kept constant at values of 0.888 and 0.375 hr^{-1}, respectively. Key: (A) t* = 12 hr; (B) t* = 16 hr; (C) t* = 20 hr; (D) t* = 24 hr.*

throughout the population by empirically raising the value of ψ in patients who would otherwise tend to be overdosed.

DISCUSSION

The principal purpose of this paper is to examine the single-point maintenance-dose prediction method proposed by Cooper *et al.* for lithium. A more flexible approach has since been described by Sheiner and Beal (17). The single-point method and the Bayesian approach to maintenance-dose selection (17) introduced by Sheiner and Beal have in common a dependence on the knowledge of the distribution of pharmacokinetic parameter values within the population. The Bayesian approach makes use of demographic and pathological information, which is particularly important in the selection of the first dose and in changing the dose as blood level data are obtained. The same sort of information could be incorporated into a single-point method where ψ, t^*, and D^* would be chosen with respect to disease and other factors that affect the relevant pharmacokinetic parameters.

The Bayesian method has additional advantages in that it does not require a sample to be obtained at a particular time and it adjusts the dose as follow-up concentration data are obtained. This method would probably give a more accurate prediction of maintenance dose earlier and with a minimal number of blood samples if the sample was obtained at the time after the first dose which gave the most information about clearance. The optimum t^* considered here and elsewhere (11) corresponds to a blood sample which will serve as the most accurate predictor of maintenance dose required to achieve a desired average concentration at steady state. The proportionality factor between dosing rate and steady-state concentration is clearance. It has been shown empirically and can be shown mathematically that a concentration obtained at t^* will also contain the most information about clearance.

The theory described here is based on the development of a relationship between $1/D_m$ and C^*, which can be described with minimum error by assuming a constant value of a proportionality factor (ψ) throughout the population. If this is done, the error of the method will increase as the extremes of parameter values are approached. A recent report described a case in which a patient with an unusually long half-life and unusually large volume of distribution of lithium was given a dose of lithium carbonate for maintenance of a steady-state concentration of 0.8–1.1 meq/liter which actually led to a steady-state concentration of 2.6 meq/liter and symptoms of toxicity (18). A complete characterization of the pharmacokinetics of lithium in the patient led to the readjustment of his dose to 1050 mg of lithium carbonate (he was given 1800 mg on the basis of the nomogram). Use of this dose led to the attainment of the target steady-state concentration. Substitution of his pharmacokinetic parameter values calculated from the concentration–time plot presented in the report into Eq. 6 led to the calculation of a maintenance dose in close agreement to the 1050-mg dose calculated by classical means. Thus, the failure of the nomogram to predict the correct dose required by this patient was due to his unusual values of β as well as α and k_{21} (all were unusually low). This case illustrates an important limitation of all single-point dose prediction methods: patients with unusual pharmacokinetic parameter values will be improperly dosed. Such methods should therefore be used only as an aid to the selection of a dose that will allow the attainment of a therapeutic concentration of drug with a minimum

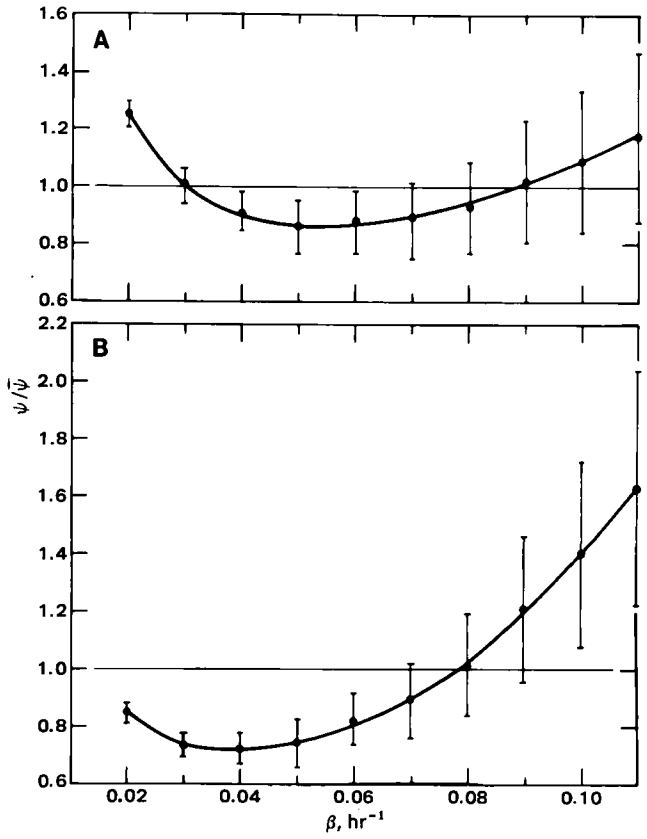

Figure 3—*Relationship between $\psi/\bar{\psi}$ and β for t* = 16 hr (A) and t* = 24 hr (B). Values of α and k_{21} were randomly selected from distributions described in the literature. Bars encompass mean (0) ± 2 SD of the value of the ratio due to variation in the values of α and k_{21}.*

of dosage adjustment. The appropriateness of the dose selected should be confirmed by the determination of concentration after the patient reaches steady state.

The key to the optimization of sampling time described here is the assumption that a single value of ψ will be used for dose prediction purposes for all individuals. The nomogram described by Cooper *et al.* is based on a sampling time 50% longer than the optimum if a constant value of ψ is used. The nomogram is successful because the nonlinearity of the relationship between $1/D_m$ and C^*, when C^* is determined 24 hr after the test dose, is accounted for by using a larger value of ψ in patients with low values of C^*. Such an approach should be possible with other drugs to the extent that low values of C^* correlate with large values of β, rather than large values of volume of distribution. If a low value of C^* is mostly a function of a large volume of distribution, an error due to this parameter will be introduced, which may increase the error beyond that which would be encountered if a constant value of ψ were used.

The theoretically optimum t^* has been shown previously to be the reciprocal of the population mean elimination rate constant based on equations developed for drugs that exhibit a monoexponential decline in plasma concentration. With such drugs, the optimum t^* is, therefore, equal to the harmonic mean of mean residence time (19) in the population. Since mean residence time is a model-independent parameter (its calculation assumes linear kinetics with elimination occurring from the central compartment), it is expected that the harmonic mean of the mean residence time would also be the optimum sampling time for maintenance-dose prediction or estimation of clearance for drugs that exhibit a biexponential decline in plasma concentration.

Corneal Penetration Behavior of β-Blocking Agents I: Physicochemical Factors

RONALD D. SCHOENWALD ˣ and HONG-SHIAN HUANG *

Received July 26, 1982, from the *Pharmaceutics Division, College of Pharmacy, University of Iowa, Iowa City, IA 52242.* Accepted for publication September 16, 1982. *Present Address: National Defense Medical Center, Taipei, Taiwan 107, ROC.

Abstract □ Rabbit corneas were excised and mounted in a chamber to determine the permeability characteristics of a group of β-blocking agents which varied in octanol–water partitioning over a fourfold logarithmic range. From the permeability rate at steady state, permeability coefficients (pH 7.65) were determined. For each drug the distribution coefficient and pK_a were measured, permitting the partition coefficients to be estimated. Various correlations were determined for the log permeability coefficient as a sum of log functions of the partition (or distribution) coefficient, molecular weight, and/or degree of ionization. The best fit, as judged by a high correlation coefficient ($r = 0.9756$) and lack of systematic deviation, was represented by: $\log P_T = 0.623 \log DC - 0.108(\log DC)^2 - 5.0268$.

Keyphrases □ β-Blocking agents—permeability characteristics, excised rabbit corneas, physicochemical factors □ Permeability—β-blocking agents, excised rabbit corneas, physicochemical factors □ Ophthalmic drugs—β-blocking agents, corneal permeability, rabbits, physicochemical factors

Whenever an ophthalmic drug is applied topically to the eye, only a small amount (<10%) actually penetrates the cornea and reaches the internal eye tissues (1–3). Precorneal factors, such as rapid drainage by the nasolacrimal apparatus and noncorneal absorption, account for the poor absorption (4). As a result, optimal absorption depends on achieving a rapid penetration rate across the cornea to minimize the competing, but nonabsorptive rate factors. Rapid penetration either permits a lower dose to be administered or, in the case of an inactive drug, leads to the development of a clinically effective drug.

The penetration potential of a drug with regard to its chemical structure can be assessed by the use of the partition coefficient of the drug. This has been shown for the cornea by Schoenwald and Ward (5) and by Mosher and Mikkelson (6). Schoenwald and Ward (5) determined the permeability rates across excised rabbit corneas for 11 steroids. Permeability coefficients for each steroid were calculated, and their logarithms were plotted against their respective log octanol–water partition coefficients. A parabolic relationship fit the data, with optimal permeability observed at a log partition coefficient of 2.9. Likewise, Mosher and Mikkelson (6) determined the *in vitro* corneal transport of *n*-alkyl-*p*-aminobenzoate ester homologues. For this series a parabolic equation also fit the data; optimal permeability was observed at a log partition coefficient of 2.5–2.6 (*n*-propyl homologue).

Although relative potency is a significant factor, a rapid penetration rate can contribute significantly to effectiveness. For example, prednisolone acetate (1% ophthalmic suspension) has been ranked as the most effective topical anti-inflammatory agent when the epithelium of the inflamed cornea is intact (7), whereas prednisolone (equally potent orally) is not effective topically. The prodrug di-

Corneal Penetration Behavior of β-Blocking Agents I: Physicochemical Factors

RONALD D. SCHOENWALD ˣ and HONG-SHIAN HUANG *

Received July 26, 1982, from the *Pharmaceutics Division, College of Pharmacy, University of Iowa, Iowa City, IA 52242.* Accepted for publication September 16, 1982. *Present Address: National Defense Medical Center, Taipei, Taiwan 107, ROC.

Abstract □ Rabbit corneas were excised and mounted in a chamber to determine the permeability characteristics of a group of β-blocking agents which varied in octanol–water partitioning over a fourfold logarithmic range. From the permeability rate at steady state, permeability coefficients (pH 7.65) were determined. For each drug the distribution coefficient and pK_a were measured, permitting the partition coefficients to be estimated. Various correlations were determined for the log permeability coefficient as a sum of log functions of the partition (or distribution) coefficient, molecular weight, and/or degree of ionization. The best fit, as judged by a high correlation coefficient ($r = 0.9756$) and lack of systematic deviation, was represented by: $\log P_T = 0.623 \log DC - 0.108(\log DC)^2 - 5.0268$.

Keyphrases □ β-Blocking agents—permeability characteristics, excised rabbit corneas, physicochemical factors □ Permeability—β-blocking agents, excised rabbit corneas, physicochemical factors □ Ophthalmic drugs—β-blocking agents, corneal permeability, rabbits, physicochemical factors

Whenever an ophthalmic drug is applied topically to the eye, only a small amount (<10%) actually penetrates the cornea and reaches the internal eye tissues (1–3). Precorneal factors, such as rapid drainage by the nasolacrimal apparatus and noncorneal absorption, account for the poor absorption (4). As a result, optimal absorption depends on achieving a rapid penetration rate across the cornea to minimize the competing, but nonabsorptive rate factors. Rapid penetration either permits a lower dose to be administered or, in the case of an inactive drug, leads to the development of a clinically effective drug.

The penetration potential of a drug with regard to its chemical structure can be assessed by the use of the partition coefficient of the drug. This has been shown for the cornea by Schoenwald and Ward (5) and by Mosher and Mikkelson (6). Schoenwald and Ward (5) determined the permeability rates across excised rabbit corneas for 11 steroids. Permeability coefficients for each steroid were calculated, and their logarithms were plotted against their respective log octanol–water partition coefficients. A parabolic relationship fit the data, with optimal permeability observed at a log partition coefficient of 2.9. Likewise, Mosher and Mikkelson (6) determined the *in vitro* corneal transport of *n*-alkyl-*p*-aminobenzoate ester homologues. For this series a parabolic equation also fit the data; optimal permeability was observed at a log partition coefficient of 2.5–2.6 (*n*-propyl homologue).

Although relative potency is a significant factor, a rapid penetration rate can contribute significantly to effectiveness. For example, prednisolone acetate (1% ophthalmic suspension) has been ranked as the most effective topical anti-inflammatory agent when the epithelium of the inflamed cornea is intact (7), whereas prednisolone (equally potent orally) is not effective topically. The prodrug di-

pivefrin is another example of a drug with improved corneal penetration when compared with the parent drug, epinephrine (8). A more rapid penetration rate for the prodrug has led to use of a reduced dosage and the observation of less ocular side effects.

The β-blocking agent timolol was introduced commercially to treat glaucoma following topical instillation of eye drops. Propranolol (9), atenolol (10), metoprolol (11), and practolol (10) also lower intraocular pressure, whereas nadolol and sotalol appear not to (12), even though nadolol is approximately equal in potency to propranolol. The purpose of this study was to compare the permeability of a series of β-blocking agents with a fourfold range in partitioning behavior across excised rabbit corneas to determine if optimal permeability can be identified.

EXPERIMENTAL

Drugs—β-Blocking agents used in the experiments included acebutolol hydrochloride[1], atenolol[2], beventolol hydrochloride[3], bufuralol hydrochloride[4], levbunolol hydrochloride[3], metoprolol tartrate[5], nadolol[6], oxyprenolol hydrochloride[5], penbutolol sulfate[7], propranolol hydrochloride[8], sotalol hydrochloride[9], and timolol maleate[10]. Structures of each drug are shown in Table I.

Potentiometric Titration Method for the Determination of pK_a—A pH meter[11] connected to a titrator[12] and equipped with a combination electrode[13] was used. The titrator was equipped with a 1.0-ml, syringe-type buret and was used for all titrations in the study. The buret was attached to a delivery tip capable of accurately metering 0.005

ml of titrant into the titration cell. The cell had a capacity of 50 ml and was surrounded by a jacket through which 35° water was circulating. A 0.29-mg/ml solution (1 m*M*) of a salt of each β-blocking agent was prepared for titration. In the event that the drug species was a free base, an equivalent amount of hydrochloric acid was added. For some highly lipophilic drugs, such as penbutolol and bufuralol, a concentration as low as 100 μg/ml was used to prevent precipitation during drug titration.

An aliquot (25–40 ml) of drug solution was accurately transferred to the titration cell, maintained at 35°. Nitrogen continuously flowed over the sample solution to prevent carbon dioxide absorption from the surrounding air. At each titration interval, a volume of 0.005–0.02 ml of titrant was added while stirring. For the majority of β-blocking agents, which have pK_a values of 8–9.4 at 35°, the titration usually started at pH ~6 and ended at pH 10 or 11. A modified Gran plot was used to determine the K_a for each compound (13) with the exception of sotalol, which contained two K_a values determined by the Speakman method (14).

Determination of Distribution Coefficients (15)—Sorensen's phosphate buffer (pH 7.38) was prepared from monobasic potassium phosphate and dibasic sodium phosphate. The buffer and octanol were mutually saturated at 35° before use. The distribution coefficient at 35° was determined by dissolving drug in the aqueous-buffer phase and shaking intermittently with octanol at 35° for 5 hr to reach a distribution equilibrium. The volume ratio of octanol and buffer depended on the lipophilicity of the drug. The volumes of each phase were chosen so that drug concentration in the aqueous phase, before and after extraction, could be measured by high-performance liquid chromatography (HPLC). Centrifugation was used to separate the two phases.

The distribution coefficient (DC) was calculated by:

$$DC = \frac{(C_b - C_a)V_w}{C_b V_o} \qquad \text{(Eq. 1)}$$

where C_b and C_a represent the concentrations in the aqueous-buffer phase before and after distribution, respectively; V_w represents the volume of the aqueous phase; and V_o, the volume of the octanol phase. The partition coefficient (PC) was calculated from the distribution coefficient by:

$$PC = DC\left(1 + \frac{1}{\text{antilog}\,(pH - pK_a)}\right) \qquad \text{(Eq. 2)}$$

The pH was measured from the buffered phase at 35° after distribution was complete. All distribution coefficients reported here were measured at pH 7.4, but through the use of Eq. 2 were converted to pH 7.65, the pH of the excised corneal experiments.

Excised Cornea Procedure—Male New Zealand White rabbits[14], weighing 1.6–2.0 kg each, were sacrificed by injecting a bolus of air into the marginal ear vein. The intact eye, along with the lids and conjunctival sac, was then enucleated. The exposed cornea of the enucleated eye was carefully placed on a corneal holder, which maintained the cornea curvature and held the eye in place (5, 16, 17). Various tissues of the eye were dissected leaving the cornea, a small ring of scleral tissue, and the palpebral conjunctiva, which was tied to the corneal ring (Fig. 1).

The conjunctival and scleral tissue served as a gasket and permitted the cornea to be suspended within the corneal ring, which was then positioned between rings 1 and 2 and placed in the center of the perfusion chamber. The chamber was made from acrylic plastic[15] and was jacketed to maintain the cornea and the perfusion solution at 35° (5, 16, 17).

Bicarbonated Ringer's solution was modified (17) to preserve tissue integrity of an excised cornea over 6 hr and used throughout the perfusion studies. It was prepared in two parts: Part I was composed of sodium chloride (12.4 g/liter), potassium chloride (0.716 g/liter), monobasic sodium phosphate monohydrate (0.206 g/liter), and sodium bicarbonate (4.908 g/liter); part II was composed of calcium chloride dihydrate (0.230 g/liter), magnesium chloride hexahydrate (0.318 g/liter), glucose (1.80 g/liter), and oxidized glutathione[16] (0.184 g/liter). Both parts were stored in the refrigerator and were used in ~3 weeks to prevent mold growth. Equal volumes of parts I and II were mixed prior to use.

Within 20–40 min of death, the cornea was mounted and clamped between two cylindrical compartments of the perfusion chamber. A measured volume (7.0 ml) of bicarbonated Ringer's solution was added first to the endothelial side as the receiving solution to prevent the cornea from buckling. An equal volume of solution containing a β-blocking agent was then added to the epithelial side as the drug solution. The perfusion chamber system was designed in such a way that the height of the receiving solution was slightly higher than that of the drug solution to ensure that the cornea would not buckle during the course of the experiment. A mixture of O_2–CO_2 (95:5) was bubbled through the fluids in both chambers for 10 min to achieve a pH of 7.65 before being added to the perfusion chamber. Circulation of fluid inside each half chamber was induced immediately by bubbling the same gas mixture through at a rate of three to five bubbles/sec to maintain the solution at a constant pH of 7.65.

Samples ranged from 0.1 to 0.5 ml depending on the assay sensitivity of each drug. Samples were withdrawn from the receiving chamber (*i.e.*, endothelial side) over a 4-hr period. An equal volume of solution was immediately added to the receiving solution to maintain a constant volume. The first sample was withdrawn within 2 min after starting the permeation and served as a control to detect leakage and rapid penetration. Subsequent samples were taken approximately every 40 min through the 4-hr period.

The sampling method for the corneal permeability experiments of levbunolol and nadolol varied from other drugs in that equal volumes of solutions (0.1 ml) were removed from both sides of cornea. In this way, equal volumes on both sides were maintained throughout the experiment.

After each permeability experiment, the cornea was trimmed of excess scleral tissue and conjunctiva, weighed, and dried in an oven overnight at 103°. After each cornea was dried, it was reweighed so that the hydration level of the wet cornea could be determined. The normal cornea has a hydration level of 76–80% (18). If manipulation of the cornea or if the drug itself led to damage of the epithelium and/or endothelium, then the hydration level would rise (83–92%) and the data were discarded.

Determination of Aqueous Diffusional Layer Resistance in the Perfusion Chamber—Fluid circulation in the chamber was provided

Table II—Experimental Conditions for the HPLC Assay of β-Blocking Agents

Drug	Column[a]	Wavelength, nm	Methanol, %[b]	Flow Rate, ml/min
Acebutolol	A	254	20, 38	2
Atenolol	A	254	20, 7.5	2
Bevantolol	B	254	28, 30	2
Bufuralol	B	254	28, 30	2
Levbunolol	B	254	28, 47	2

by maintaining a rate of three to five gas bubbles/sec. This maintains good mixing within each half chamber, as can be shown by adding a drop of colored solution into either half of the chamber and observing the homogeneous color that occurs in <1 min. However, to accurately determine the resistance of the cornea, it was necessary to detect and measure the magnitude of aqueous diffusional layer resistance, R_{aq}; consequently, the stirring was modified for these experiments.

The perfusion chamber was modified by installing two stirrers, one on each side of the cornea, with the center of each stirrer affixed 1 cm from the center of the corneal ring. Figure 2 depicts the modified perfusion chamber and rings used in mounting the cornea. In preliminary experiments it was observed that different rates of stirring induced varying degrees of swelling due to mechanical injury of the epithelium and endothelium.

An important purpose of the epithelium and endothelium is to control the thickness of the cornea by maintaining hydration levels at ~ 78%. By completely removing the epithelium and endothelium, the remaining stromal layer reached a constant and maximal thickness within the first 30 min of stirring such that subsequent changes in the stirring rate had no effect. The epithelium was removed by scraping with the blunt end of a scalpel blade. The endothelium was gently rubbed off with a cotton-tipped applicator (19). The removal of endothelium could be detected with the aid of a dissecting microscope. The epithelium was removed immediately following enucleation; the endothelium was removed just prior to mounting in the perfusion chamber. Atenolol (500 μg/ml) was chosen as the diffusing substance for these experiments. Since the aqueous diffusional barrier is independent of drug, these results were interpreted for the other β-blocking agents as well.

Once drug was placed adjacent to the cornea, the stirring speed was increased in steps every 30 min over a 4-hr period. The apparent permeability coefficients were determined for each 30-min increment. A sample was removed for atenolol analysis at the beginning and end of each 30-min period; both samples were used to calculate the permeability coefficient for each stirring speed. To minimize biological variability, each cornea was used to generate five or six permeability coefficients over a period of 4 hr.

Drug Assay—An HPLC method was used for analysis of each drug. The HPLC system included an injector[17], solvent delivery system, UV-absorption detector[17], column[18], and recorder[19]. The injector was equipped with different-sized loops, ranging from 50 μl to 200 ml, which enabled the injection of an accurate volume of sample solution. A solution of known concentration was used as an external standard. Each sample solution was divided so that two injections could be made and the results averaged.

[18] M-6000 A solvent delivery system, Model 440 absorbance detector, μ-Bondapak C18, and μ-Bondapak CN Columns; Waters Associates, Milford, MA 01757.
[19] Model 5211-1; OmniScribe; Houston Instruments, Austin, Tex.

The mobile phases consisted of varying ratios of methanol and deaerated, deionized water containing 1.5% acetic acid, adjusted to pH 4 using sodium hydroxide. One exception was the mobile phase for sotalol and timolol, which utilized 0.005 *M* heptanesulfonic acid (to increase retention time) and 1% acetic acid. Table II lists the types of columns used, wavelengths at which UV measurements were made, methanol content of the mobile phase, and mobile phase flow rate. Methanol percentages in the mobile phases varied depending on whether partitioning or permeability experiments had been conducted. Drug solutions withdrawn from the endothelial side following corneal permeability contain polar extracts from the cornea which were eluted from the column within 1–3 min. In all experiments the retention times for the drugs were between 4 and 12 min. Linearity existed over the concentrations employed for each β-blocking agent (correlation coefficients >0.99).

Calculation of Permeability Coefficients—The apparent permeability coefficient (P_{app}, cm/sec) was determined by (19):

$$P_{app} = \frac{\Delta Q}{\Delta t(3600)AC_0} \qquad \text{(Eq. 3)}$$

where the term $\Delta Q/\Delta t$ is the permeability rate (*i.e.*, steady-state flux, μg/hr) of drug across each excised cornea, C_0 is the initial drug concentration (μg/ml), A is the corneal surface area (cm²), and 3600 is the conversion of hours to seconds. Corrections of C_0 were made to account for the sample volume removed over time and subsequently replaced with blank solution.

The corneal thickness increases with hydration, and the permeability coefficient is inversely proportional to barrier thickness. Therefore, it was important to determine corneal thicknesses. For a 2-kg rabbit, the corneal thickness (h) can be determined by:

$$h\ (\text{cm}) = \frac{0.42 + \text{H}}{100} \qquad \text{(Eq. 4)}$$

where H is the mg of water/mg of dry tissue (20). When stromal thicknesses were swollen due to epithelial and endothelial removal, the stroma resistances, $R_{str,swl}$, that were used to assess the aqueous diffusional barrier were corrected to the normal stromal thickness as existing in intact cornea (*i.e.*, $R_{str,int}$) by:

$$R_{str,int} = R_{str,swl}\left(\frac{h_{int}}{h_{swl}}\right) \qquad \text{(Eq. 5)}$$

where subscripts int and swl represent intact cornea and swollen stroma, respectively.

RESULTS AND DISCUSSION

The pK_a and partition coefficients of each β-blocking agent are listed in Table I. Although the aromatic substituents varied substantially for the series, these were too far removed from the amino group to exert much

of an effect on the pK_a values. Therefore, most pK_a values were within a narrow range (8.97–9.65). The pK_a of bevantolol was slightly lower (8.38) because of the electron-withdrawing effect of the ethoxybenzyl substituent. Sotalol has two pK_a values, 8.15 and 9.72, which are close to one another and compare reasonably well to the values of 8.30 and 9.80 published by Garrett and Schnelle (21) using the potentiometric titration method at 25°. The anilino group in sotalol acts as a weak acid as a result of the electron-withdrawing effect of the neighboring sulfonyl group. Ionization of the anilino group accounts for spectral shifts (21) and correlates with the pK_a of 8.15. The second pK_a, 9.72, was then assigned to the protonated amine group in the alkyl side chain of sotalol.

The distribution coefficients obtained from the extraction method using octanol and Sorenson's buffer varied over a fourfold log range. The range in partitioning behavior of the series is a consequence of the differences in aromatic substitution. The partitioning results permitted the compounds to be grouped as very lipophilic, lipophilic, or hydrophilic, classifications which were predictable from structural considerations. In addition to the amino group, the hydrophilic compounds also contained relatively polar substituents on the aromatic ring. Therefore, hydrogen bonding interactions with water are greater for atenolol and acebutolol, which contain amido groups, for nadolol, which contains a dihydroxy function and for sotalol, which contains a sulfonamido moiety. The very lipophilic compounds, on the other hand, contain hydrophobic substituents. The cyclopentyl group on the benzene ring gives penbutolol a high distribution and partition coefficient, whereas the furanyl group imparts lipophilicity to bufuralol. The ethoxybenzyl substituent in bevantolol not only lowers its pK_a, but also increases its lipophilicity. The high partition coefficient of propranolol is a result of the high lipophilic contribution of naphthalene. Based on the partitioning results of the very lipophilic and hydrophilic compounds, the remaining compounds (levbunolol, oxyprenolol, timolol, and metoprolol) appear to contain substituents of an intermediate nature as far as polarity.

Corneal Permeability—The permeability coefficients of each β-blocking agent were obtained by linear regression of the steady-state flux. Figure 3 shows a plot of Q *versus* t for propranolol and atenolol across excised rabbit corneas. The data points closely fit the least-square regression line once steady state has been reached. The lag time, defined by the linear intercept on the time axis, is related to the time required to reach steady-state permeation; more specifically, it is inversely related to the permeability coefficient. Consequently, the more rapidly penetrating compounds will have a shorter lag time and a greater steady-state flux. The slope of the straight line ($\Delta Q/\Delta t$), was substituted into Eq. 3 to obtain the apparent permeability coefficient. The apparent permeability coefficient also contains any aqueous diffusional layers that may exist on each side of the cornea.

Mathematical Model Relating Stirring Rate to Aqueous Diffusional Layer Resistance—The total diffusional resistance, R_{app}, through a multilayered barrier is represented by (22):

$$R_{app} = \frac{1}{P_{app}} = \sum_{i=1}^{n} R_i = \sum \frac{h_i}{D_i A(\mathrm{PC})_i} \qquad \text{(Eq. 6)}$$

where i represents each homogeneous barrier in series, n represents the total number of barriers, h represents barrier thickness, A represents surface area, D represents the diffusion coefficient, and PC represents the partition coefficient (22). With regard to significant diffusional layers, the rabbit cornea possesses two main tissue types: the lipophilic epithelium and endothelium, and the hydrophilic stroma. Assuming the existence of an aqueous diffusional barrier, the apparent resistance of the cornea can be considered as layers in series (23, 24) or:

$$R_{app} = \frac{1}{P_{app}} = R_{epi} + R_{str} + R_{endo} + R_{aq} \qquad \text{(Eq. 7)}$$

or

$$R_{app} = R_T + R_{aq} \qquad \text{(Eq. 8)}$$

where R_{aq} represents the sum of aqueous diffusional resistances on each side of the cornea and R_T represents the sum of the resistances of the corneal layers (epithelium, stroma, and endothelium).

According to the Nernst theory (25), there is a thin layer of static liquid of thickness h_{aq} immediately adjacent to a solid body. Outside of the static liquid layer is the well-stirred bulk solution. Experimental determinations have shown that the aqueous diffusional layer thickness, h_{aq}, can be expressed as:

$$h_{aq} = V^{-n} \qquad \text{(Eq. 9)}$$

where V is the velocity of the moving liquid. The exponent n depends on the experimental conditions ranging from $n = 0.33$ to ≥ 1. The thickness measurements representing the diffusional layer are apparent and not real. For example, experimental measurements have shown that the liquid retains its mobility down to a distance from the solid surface smaller than h_{aq}. Despite the fact that the Nernst theory may not exactly represent the diffusional behavior at the interface of liquid and solid, it can be used empirically to calculate R_{aq} (25).

In determining the resistance of the β-blocking agents across excised rabbit corneas within the stirred perfusion chamber, the following equation, which combines Eqs. 6–9, was considered:

$$R_{app} = R_{str} + \frac{h_{aq1}}{DA(\mathrm{PC})} + \frac{h_{aq2}}{DA(\mathrm{PC})} \qquad \text{(Eq. 10)}$$

where h_{aq1} and h_{aq2} are the aqueous diffusional layer thicknesses on each side of the mounted cornea at a given stirring rate, and R_{str} represents the membrane resistance for the stroma. R_{app} is measured experimentally at a specific stirring rate, *i.e.*, $1/P_{app}$.

By assigning $h_{aq} = h_{aq1} + h_{aq2}$ and substituting V^{-n} for h_{aq}, then Eq. 10 can be expressed as:

$$R_{app} = R_{str} + \frac{V^{-n}}{DA(\mathrm{PC})} \qquad \text{(Eq. 11)}$$

In the modified perfusion chamber, the stirrer is at the center of a circle 1 cm in diameter which contacts tangentially with the membrane and the perfusion chamber wall. Assuming that the liquid velocity tangential to the membrane, V, is proportional to the angular velocity of stirring, v, then Eq. 9 becomes:

$$R_{app} = R_{str} + \frac{(mv)^{-n}}{DA(\mathrm{PC})} \qquad \text{(Eq. 12)}$$

where m is a proportionality factor between the liquid velocity (cm/sec) and the angular velocity (rad/sec)[20]. To perform the nonlinear regression analysis the diffusion coefficient (D) was approximated by 1×10^{-5} cm²/sec, an appropriate estimate for compounds of 200–300 molecular weight (22); PC was assigned a value of 1 for the aqueous system, and A was assigned a value 1.087 cm², which represented the surface area of the cornea used throughout the study. The remaining unknown parameter values (R_T, m, and n) were determined from the nonlinear regression analysis[21]. Figure 4 shows the results for atenolol permeation through excised stromal preparations with stirring rates varying from 425 to 1050 rpm. The computer-generated parameter values substituted into Eq. 10 become:

$$R_{app} = 26.8 \times 10^3 + 100{,}000\ (0.1006v)^{-1.67} \qquad \text{(Eq. 13)}$$

where 26.8×10^3 sec/cm represents the intrinsic stromal resistance, R_{str}. The apparent stromal resistance to atenolol permeation was 30.5×10^3 sec/cm. This latter value represents the experimental conditions for the perfusion chamber when stirred with the bubbling action of O_2–CO_2. The difference between the two resistances ($R_{app} - R_{str}$) is 3.7×10^3 sec/cm and represents the aqueous diffusional layer resistance, R_{aq}. This value was used in determining the intrinsic membrane resistances for the other β-blocking agents.

Permeability *versus* Partitioning Correlations—Figure 5 shows a plot of log P_T [22] against log PC; Table III contains the calculated parameter values. The data, although somewhat scattered, shows a plateau region for the very lipophilic compounds (propranolol, bufuralol, bevantolol, and penbutolol). The rate-determining factor responsible for the plateau region is not a result of the aqueous diffusion layer, since its contribution was subtracted from the experimentally determined permeability coefficients. The permeability rate is probably controlled by the hydrophilic stroma for these very lipophilic compounds. The relatively poor permeability shown for the hydrophilic compounds nadolol and sotalol possibly explains their poor potential for lowering intraocular pressure.

Multiple regression analyses[23] (26) were performed on the data to find the best set of parameters to describe the change in log P_T with a change in either log PC or log DC. Although the ranges in molecular weight and pK_a were relatively narrow for the β-blocking agents selected for study,

[20] rpm was converted to rad/sec by: rad/sec = rpm$(2\pi)/60$.

[21] Nonlinear regression was performed using the BMDP3R programs on an IBM370, at the University of Iowa Computer Center, University of Iowa, Iowa City, IA 52242.

[22] P_T represents the permeability coefficient across the intact excised rabbit cornea; $P_T = 1/R_T$.

[23] Multiple linear regression was performed using the BMDP1R, BMDP2R, and BMDP9R regression programs on an IBM370 computer.

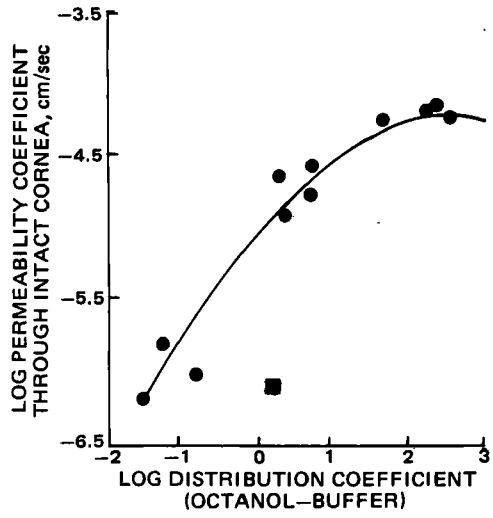

Figure 5—*Log–log plot of permeability coefficient (pH 7.65) and distribution coefficient (pH 7.65). The regression curve is represented by: log P_T = 0.623 log DC − 0.108 (log DC)^2 − 5.0268, where r = 0.9756 and* n = *11; acebutolol (■) is included in the figure, but not in the regression curve.*

a log MW term and a log DI[24] term were included in the analysis. Molecular weight (MW) is inversely related to diffusion and has been shown to improve correlations of this type (27, 28). Because of the plateau region (Fig. 5), a (log PC)^2 or (log DC)^2 term was also included. All possible subsets were analyzed, beginning with the intercept plus one parameter, then the intercept plus two parameters, *etc.*, up to the single set representing the intercept plus the maximum of four parameters. The correlation coefficient (r) and systematic deviation were used as the criteria to judge the best fit. The best fit for log P_T was represented as a function of all the parameters:

$$\log P_T = 1.01 \log PC - 0.115(\log PC)^2 - 5.64 \log MW - 10.4 \log DI + 7.27 \quad \text{(Eq. 14)}$$

$$r = 0.9272 \qquad p = 0.0041 \qquad n = 12$$

Both molecular weight and degree of ionization showed the expected inverse relationship to permeability. However, with either the molecular weight or degree of ionization term omitted from the regression analysis, the correlation coefficient was reduced only minimally to 0.8989 or 0.8678, respectively. With both molecular weight and degree of ionization removed, the correlation coefficient was 0.8560. With only the log PC term and the intercept, the regression analysis yielded a correlation coefficient of 0.8523. This latter linear regression line, however, shows systematic deviation at the plateau region and was not considered an acceptable fit to the data.

When DC was substituted for PC the multiple regression analyses produced an equally good fit:

$$\log P_T = 0.681 \log DC - 0.123(\log DC)^2 - 5.04 \log MW - 2.64 \log DI + 7.22 \quad \text{(Eq. 15)}$$

$$r = 0.9282 \qquad p = 0.0040 \qquad n = 12$$

When the degree of ionization was removed from consideration in Eq. 15, the correlation coefficient was reduced slightly to 0.9223. The lack of improvement from considering the degree of ionization is understandable, since the distribution and permeability coefficients represent the data at the same pH. By excluding the molecular weight term and (log DC)^2, the correlation coefficient was 0.8908 illustrating the small, but necessary, contribution of the squared term when systematic deviation is considered.

The hydrophilic acebutolol deviated the most from any regression line. By considering acebutolol as an outlier and excluding it from the regression analysis, the correlation coefficients increased. For example, the best regression lines yielded:

$$\log P_T = 0.972 \log PC - 0.112(\log PC)^2 - 2.71 \log MW - 9.26 \log DI + 0.219 \quad \text{(Eq. 16)}$$

[24] DI represents degree of ionization and was calculated from: DI = 1/[1 + antilog (pH − pK_a)].

Table III—Permeability Coefficients and Physical Constants of β-Blocking Agents[a]

Drug	log P_T, cm/sec	log DC	log PC	log MW	log DI
Penbutolol	−4.22	2.53	4.15	2.46	−0.0106
Bufuralol	−4.14	2.31	3.65	2.44	−0.0200
Bevantolol	−4.17	2.19	3.00	2.50	−0.0740
Propranolol	−4.24	1.62	3.21	2.41	−0.0114
Levbunolol	−4.76	0.72	2.40	2.51	−0.0092
Oxprenolol	−4.56	0.69	2.37	2.42	−0.0092
Timolol	−4.91	0.34	1.91	2.49	−0.0119
Metoprolol	−4.62	0.28	1.88	2.50	−0.0110
Acebutolol	−6.07	0.20	1.77	2.52	−0.0119
Nadolol	−5.99	−0.82	0.93	2.49	−0.0079
Sotalol	−5.79	−1.25	−0.62	2.43	−0.0040
Atenolol	−6.17	−1.52	0.16	2.42	−0.0092

[a] P_T represents the permeability coefficient across the intact excised rabbit cornea; DC represents distribution coefficient; PC represents partition coefficient; MW represents molecular weight; DI represents degree of ionization.

$$r = 0.9696 \qquad p = 0.0008 \qquad n = 11$$

$$\log P_T = 0.623 \log DC - 0.108(\log DC)^2 - 5.0268 \quad \text{(Eq. 17)}$$

$$r = 0.9756 \qquad p < 0.00009 \qquad n = 11$$

Equation 17 predicts an optimum log DC value of 2.88, determined by setting d log P_T/d log DC equal to zero and solving for log DC. However, there is no experimental evidence that a parabola would best describe the data. Compounds of greater lipophilicity than penbutolol could not be obtained to test this phenomenon.

Although correlations of this type are helpful in predicting useful molecular modifications, extrapolation to *in vivo* ophthalmic bioavailability must take into consideration solubility, the short residence time of instilled drops in the eye, and rapid metabolism or poor distribution to the target tissue. For example, a drug may have ideal partitioning behavior, but if it is not soluble, its concentration in tears will be too low to achieve an adequate penetration rate since the penetration rate is equal to the permeability coefficient multiplied by tear concentration. If a suspension is formulated because of the poor drug solubility, expulsion of the particles by the eye may take place before solubilization occurs, resulting in lower bioavailability.

Corneal Penetration Behavior of β-Blocking Agents II: Assessment of Barrier Contributions

HONG-SHIAN HUANG *, RONALD D. SCHOENWALD ˣ, and JOHN L. LACH

Received July 26, 1982, from the *Pharmaceutics Division, College of Pharmacy, University of Iowa, Iowa City, IA 52242.* Accepted for publication September 16, 1982. *Present Address: National Defense Medical Center, P.O. Box 8244-14, Taipei, Taiwan 107, ROC.

Abstract □ Rabbit corneas were excised and mounted in a chamber to determine the permeability characteristics of a group of β-blocking agents. By measuring the permeability rate of each drug across intact cornea, stroma alone, epithelium–stroma, and stroma–endothelium, it was possible to determine the resistance to penetration for each corneal layer. The reciprocal of the sum of resistances for the epithelium, stroma, and endothelium equaled the experimentally determined permeability coefficient for the intact cornea (104 ± 6.0%). Thus, the penetration of β-blocking agents through the excised rabbit cornea could be treated as three barriers in series. For hydrophilic compounds, the epithelium was the rate-determining barrier. The endothelium offered less resistance, whereas the stroma offered only very minimal resistance. The lipophilic compounds penetrated the excised cornea more rapidly. However, the stroma became rate-determining for the most lipophilic compounds (penbutolol, bufuralol, bevantolol, and propranolol). Although the octanol–buffer (pH 7.65) distribution coefficient of these compounds varied over a fourfold logarithmic range, the permeability coefficient was considered nearly constant [3.4×10^{-5} (±0.34) cm/sec] for stroma. Also, the ratios of tortuosity to porosity for the stromal layer were 1.58 ± 0.15. These results suggest that drug diffuses through an aqueous media of gel-like mucopolysaccharide interspersed by a matrix of collagen fibrils. From further analyses intra- and intercellular pathways for epithelium and endothelium were added to the model resulting in a sigmoidal representation of permeability coefficient *versus* distribution coefficient. However, the intercellular (pore) pathway could not be adequately quantified because of the variation in the data for very hydrophilic compounds.

To optimize the penetration rate of drugs across biological membranes, quantitative multiple regression analyses are conducted to relate permeability to various physicochemical factors (1–3). These factors are often related through a sum of log terms, including partition coefficient, molecular weight, and degree of ionization. With the use of a digital computer and the appropriate algorithms, the regression analysis can be performed by a stepwise addition or deletion of each term or by comparing all possible subsets of the terms (4). In this way the significance of each term can be ascertained. Once all relevant physiochemical properties have been defined, an optimal chemical structure can be proposed. This semiempirical approach, however, does not characterize the biological limitations imposed by the membrane, such as the significance of parallel aqueous pore pathways or limiting diffusional layers.

The permeability coefficients (P_T) of 12 β-blocking agents through excised rabbit corneas mounted in a perfusion chamber at pH 7.65 were determined in the previous paper (5). Through multiple regression analyses (excluding one outlier), log P_T could be related to partitioning factors by:

$$\log P_T = 0.6228 \log DC - 0.1081(\log DC)^2 - 5.03$$
$$r = 0.9756 \quad p < 0.00009 \quad n = 11 \qquad \text{(Eq. 1)}$$

where DC represents the octanol–buffer (pH 7.65) distribution coefficient. Neither a log molecular weight term nor a log degree of ionization term significantly improved the correlation. The parabolic equation represented in Eq. 1 predicted optimal penetrability at a log DC value of 2.88, the apex of the parabola. However, the experimental data (log P_T *versus* log DC) was curvilinear, leveling off to a plateau such that the asymptotic transport model of Ho *et al.* (6) could be applied. It is the purpose of this study to determine the limiting biological factors governing the steady-state flux of β-blocking agents across the multilayered excised rabbit cornea.

[a] Standard deviation in parentheses. [b] Apparent permeability coefficient (10^{-6} cm/sec); n = 4–8 for each determination. [c] Hydration level (percent of water in excised cornea following permeation experiment).

oxyprenolol hydrochloride[5], penbutolol sulfate[7], propranolol hydrochloride[8], sotalol hydrochloride[9], and timolol maleate[10]. The distribution coefficients used in this study, as well as the general procedure for determining the coefficients, were described in the previous paper (5).

Excised Cornea Procedure—Male New Zealand White rabbits[11], weighing 1.6–2.0 kg each, were sacrificed by injecting a bolus of air into the marginal ear vein. The experimental procedure for excising and mounting the corneas in the perfusion chamber were described previously (5). Four different corneal preparations were used in the permeability experiments: the intact cornea, stroma, epithelium–stroma, and endothelium–stroma.

The epithelium and/or endothelium was removed before mounting in the perfusion chamber. The entire epithelium was removed immediately after enucleation by scraping with the blunt end of a scalpel blade. The endothelium was removed after excising the cornea and attaching it to the corneal ring, but just prior to mounting in the perfusion chamber. It was removed by carefully and gently rubbing the endothelial surface with a cotton-tipped applicator (7, 8). The removal of endothelium could be detected with the aid of a dissecting microscope. Whenever a particular corneal layer was removed, the remaining layers were left undisturbed. Solutions used during the permeability experiments as well as sampling procedure, assay methodology, and permeability coefficient calculations were described in the previous paper (5).

Corneal Thickness—Following each permeability experiment, the corneal preparations were weighed and dried in an oven at 103° for 8–12 hr. The dried corneal mass was weighed so that the hydration level of the cornea during steady state could be determined. For a 2-kg rabbit the thickness of the cornea can be determined by:

$$q(\text{cm}) = \frac{0.42 + \text{H}}{100} \qquad \text{(Eq. 2)}$$

where H represents mg of water/mg of dry tissue (9).

The rabbit cornea can be divided into three distinct diffusional layers. The outer (epithelium), consisting of 6–10 cellular layers, is the most lipophilic. The inner layer, which is also lipophilic, consists of a single layer of endothelial cells. The middle layer (stroma) is a hydrophilic layer which accounts for 90% of the corneal thickness. The epithelium and endothelium control hydration and therefore normal thickness; however, when the cornea swells it is the stromal layer only which collects fluid and swells. Consequently, for a 2-kg rabbit the epithelial and endothelial thicknesses remain constant at 0.00385 and 0.0005 cm, respectively (10). From these values and from the experimentally determined hydration levels, Eq. 2 was used to correct for differences in stromal thickness for all corneal preparations. One particular result of stromal swelling is that its thickness but not its diameter increases, which is the reason for the linear form of Eq. 2.

Calculation of Corneal Layer Resistances—The total diffusional resistance, R_{app}, through the multilayered cornea is represented by (11):

$$R_{app} = \frac{1}{P_{app}} = \sum_{i=1}^{n} R_i = \sum \frac{h_i}{D_i A (\text{PC})_i} \qquad \text{(Eq. 3)}$$

where P_{app} is the experimentally measured permeability coefficient, i is the designation for each homogeneous barrier in a series of n barriers, h is the barrier thickness, A its surface area, D represents the effective diffusion coefficient, and PC represents the effective partition coefficient between the barrier and its adjacent phase.

The calculated permeability coefficients were converted to their reciprocals and expressed as resistances. Including the aqueous diffusional barrier, the apparent resistance of the excised cornea can be represented as a sum of barriers in a series:

$$R_{app} = R_T + R_{aq} \qquad \text{(Eq. 4)}$$

and

$$R_T = R_{epi} + R_{str} + R_{endo} \qquad \text{(Eq. 5)}$$

where R_{aq} is the sum of the aqueous diffusional resistances on each side of the cornea in the perfusion chamber and R_T is the sum of resistances of the significant layers of the cornea (epithelium, stroma, and endothelium).

The resistance of the aqueous diffusional layer in the perfusion chamber was 3.7×10^3 sec/cm using O_2–CO_2 gas (5:95) to induce stirring. R_{aq} was determined for atenolol by comparing the permeability coefficient of the drug at different stirring rates using a modified perfusion chamber equipped with a stainless steel stirrer (5); R_{aq} was then deducted from the apparent resistances to obtain the intrinsic resistance for intact cornea, stroma, epithelium–stroma, and stroma–endothelium for all compounds.

The thicknesses varied for each corneal preparation depending on whether the cornea was intact or the epithelium and/or endothelium was removed. To apply Eq. 5, resistances were corrected for experimentally induced differences in thicknesses. Since resistance is directly proportional to barrier thickness, the resistances could be corrected to the normal stromal thickness as existing in the intact cornea ($R_{str,int}$) by:

$$R_{str,int} = R_{str,swl}\left(\frac{h_{int}}{h_{swl}}\right) \qquad \text{(Eq. 6)}$$

Table II—Calculated Log Distribution Coefficients and Log Permeability Coefficients [a] for Epithelium, Stroma, Endothelium, and Intact Cornea

β-Blocking Agent	Log P_{epi}	Log P_{str}	Log P_{endo}	Log P_T [b]	Log DC [c]

[a] Determined from epithelium–stroma, stroma–endothelium, and stroma corneal preparations (n = 4–8). [b] Determined from intact corneas (n = 4–8).

where h is the stromal thickness and the subscripts int and swl represent intact cornea and swollen stroma, respectively. Equation 6 was also used for another purpose: R_{epi} could be calculated by subtracting $R_{str,swl}$ from $R_{epi/str}$. Although the stroma was swollen in both preparations, their thicknesses were not exactly equal; therefore, the $R_{str,swl}$ value was first adjusted to the same stromal thickness as occurred for $R_{epi/str}$. This was done using the hydration levels and Eqs. 2 and 6. By the same procedure R_{endo} was calculated from the resistance value experimentally determined for the stroma–endothelium corneal preparation.

RESULTS AND DISCUSSION

The permeability coefficients were obtained by linear regression of the quantity of drug penetrating the corneal preparation over time after steady state had been reached. Table I lists the averaged permeability coefficient of each β-blocking agent for intact cornea, stroma, epithelium–stroma, and stroma–endothelium; Table I also lists the hydration levels obtained for each corneal preparation. Excised intact cornea maintained its transparency and rarely exceeded a hydration level of 80% after 4 hr of permeation. If the drug concentration was above a certain level (which varied for each drug), swelling occurred and consequently the hydration level increased. This was a result of cationic drug interaction with the cornea. For each drug a concentration was used that did not induce intact corneal swelling. For stroma, epithelium–stroma, and stroma–endothelium, swelling could not be avoided since the removal of the epithelium and/or endothelium caused the swelling and not the drug. It was determined in preliminary experiments that swelling, and hence stromal thickness, gradually increased over time reaching 95% of maximum in 0.45, 1.0, and 0.30 hr for stroma, epithelium–stroma, and stroma–endothelium corneal preparations, respectively.

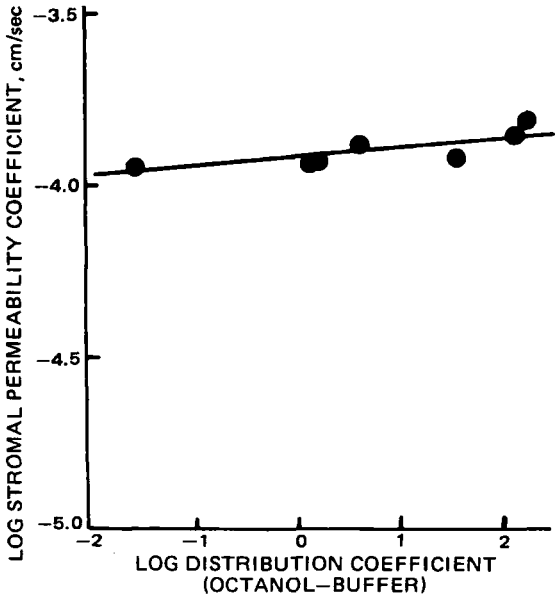

Figure 1—*Log–log plot of permeability coefficient through stroma (P_{str}) corrected to intact corneal thickness* versus *distribution coefficient (octanol–Sorenson's buffer, pH 7.65) for seven β-blocking agents. Linear regression: slope = 0.0292, intercept = −3.9098, and r = 0.8062.*

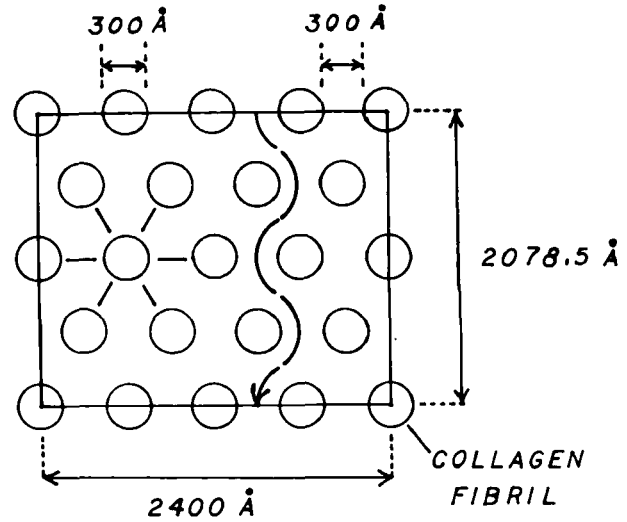

Figure 2—*Arrangement of collagen fibrils geometrically interspersed in the stroma as proposed to calculate the ratio of tortuosity to porosity (= 1.56) from stromal diffusion. The curved arrow between the fibrils represents the diffusional pathway of least resistance.*

Table II lists the calculated log values of R_{str}, R_{epi}, and R_{endo}. R_{str} was determined from $R_{str,swl}$ by correcting for thickness differences (Eq. 6) to the resistance expected in a normal cornea with a hydration level of 78.7%, the average obtained for all determinations of intact cornea (n = 43). Table III shows a comparison between the resistances of excised intact corneas, each determined from separate experiments, and that of the sum of three composite layers (Eq. 5) estimated from the various corneal preparations. Good agreement (106 ± 4%) exists for the seven β-blocking agents for which complete data were generated. These results indicate that the penetration of β-blocking agents through the excised rabbit cornea could be treated as three barriers in series.

Stromal Diffusion—Figure 1 represents a plot of log P_{str} *versus* log DC for the seven drugs for which complete permeability data were calculated. The plot shows a good linear relationship with a slope near zero (slope = 0.0292, intercept = 3.91, r = 0.778) indicating P_{str} is generally independent of DC. This is not surprising since the stroma contains 76–80% water. The remainder is composed mostly of collagen fibers and mucopolysaccharide, the latter of which is hydrophilic and responsible for the high water content of the stroma (10). Considering the large range of lipophilic/hydrophilic character covered by the seven drugs (over four log units), the results strongly suggest that drug is diffusing through the aqueous mucopolysaccharide medium of the stroma which is interspersed by a matrix of collagen fibers. The collagen fibrils, 300 Å in diameter, are arranged nearly parallel to one another with a fairly regular open spacing of ~300 Å between fibrils (10). The fibrils probably provide a high resistance to penetration and increase the diffusional path length as opposed to free diffusion through the aqueous stromal medium. Mathematically, resistance through the stroma can be defined by[12]:

$$R_{str} = \frac{h_{str}}{D_{str}(PC)} \qquad \text{(Eq. 7)}$$

where D_{str}, the effective diffusion coefficient in the stroma, can be expanded to (11):

$$D_{str} = \frac{D_{aq}\epsilon}{\tau} \qquad \text{(Eq. 8)}$$

In this equation, ϵ is the porosity (dimensionless) or volume fraction of the stroma, D_{aq} is the aqueous diffusion coefficient, and τ is the tortuosity (dimensionless) imposed by the geometrical arrangement of the stromal matrix. By combining Eqs. 7 and 8 and assuming PC as unity, stromal resistance can be defined by:

$$R_{str} = \frac{h_{str}\tau}{D_{aq}\epsilon} \qquad \text{(Eq. 9)}$$

[12] Equation 7 does not contain the A term in the denominator as shown in Eq. 3 because it is incorporated into the calculation of R_{str}; A = 1.087 cm² for 2-kg rabbits.

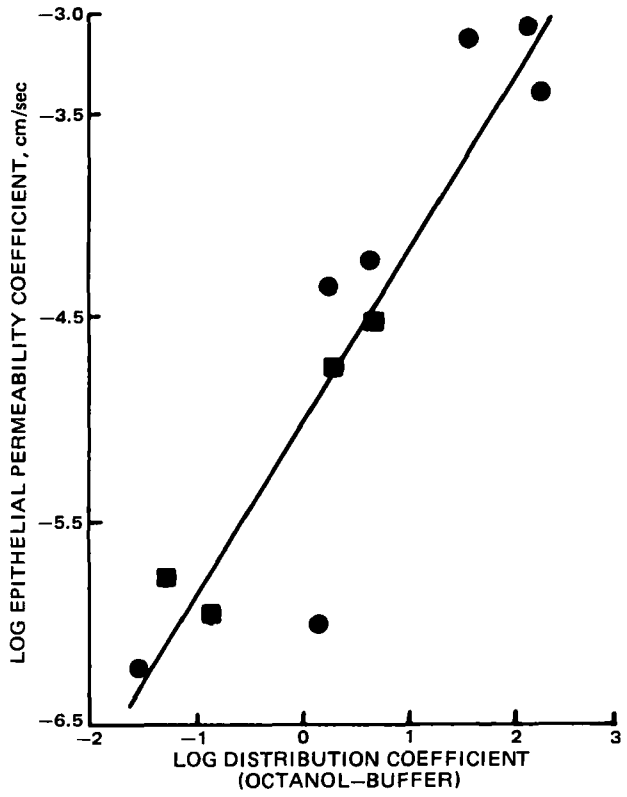

Figure 3—*Log–log plot of permeability coefficient through epithelium (P_{epi}) versus distribution coefficient (octanol–Sorensen's buffer, pH 7.65) for 11 β-blocking agents. Key: (●) determined from various corneal preparations, (■) calculated by difference using Eq. 5, regression results from Fig. 1, and permeability coefficient for intact cornea (penbutolol not shown). Linear regression: slope = 0.8505, intercept = −5.033 and* r = *0.9207.*

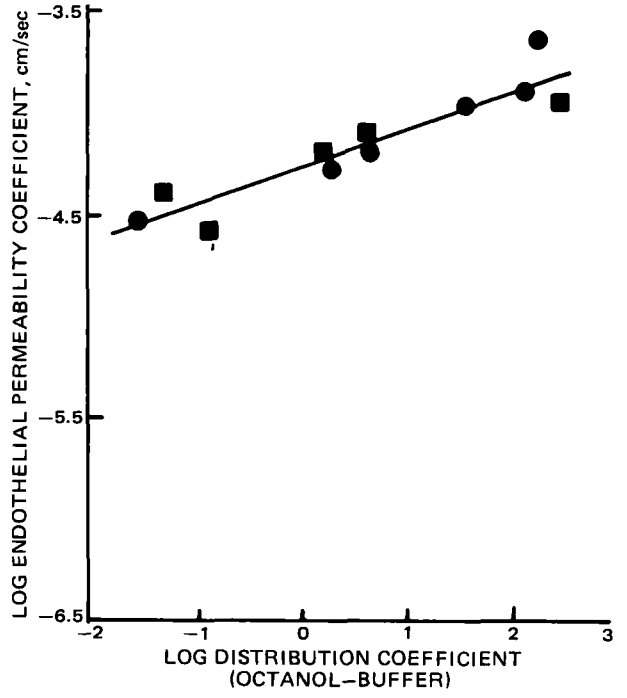

Figure 4—*Log–log plot of permeability coefficient through endothelium (P_{endo}) versus distribution coefficient (octanol–Sorensen's buffer, pH 7.65) for 11 β-blocking agents. Key: (●) determined from various corneal preparations (acebutolol not shown), (■) calculated by difference using Fig. 1 and permeability coefficient for intact cornea. Linear regression: slope = 0.1843, intercept = −4.2724, and* r = *0.9283.*

The collagen structure of the stroma can be depicted as in Fig. 2. Assuming that the average diffusional path of least resistance is midway between the geometrically arranged collagen fibrils, the porosity and tortuosity can be estimated as 0.773 and 1.21, respectively, resulting in a τ/ϵ ratio of 1.56.

In Eq. 9 both R_{str} and h_{str} are known from the experimental data. The averaged resistance for a normal stromal thickness of 0.03725 cm (78.7% hydration) is 7.83×10^3 sec/cm. To estimate D_{aq} for Eq. 9, the Sutherland–Einstein equation[13] and the well-established aqueous diffusion coefficient for benzoic acid (MW = 122), 1.1×10^5 cm²/sec at 25° (11), were used. After correcting for molecular weight, the β-blocking agents yielded an average diffusion coefficient of 7.5×10^{-6} cm²/sec in water. Temperature and viscosity differences between water and stromal medium were not included in the correction, although they should compensate for one another. These estimations yielded a τ/ϵ value of 1.58 for normal stroma. Therefore, good agreement exists between the τ/ϵ value for stroma predicted from geometrical considerations of collagen in Fig. 2, neglecting the mucopolysaccharide contribution to viscosity or structure.

Maurice (12) described a factor referred to as an obstruction of the stroma to diffusion or more specifically, as "how many times diffusion in tissue is slower than diffusion in saline at the same temperature." This factor is similar to the τ/ϵ ratio in Eqs. 7–9. Values for ^{134}Cs, ^{82}Br, and ^{24}Na ranged from 1.9 to 2.7, which agree fairly well with our value of 1.58 considering that the molecules studied and the methods used are quite different.

[13] The Sutherland-Einstein equation is:

$$D = \frac{RT}{6T\eta N}\left(\frac{4N}{3M\upsilon}\right)^{1/3}$$

where D is the diffusion coefficient, R is the gas constant, T is the temperature, N is Avogadro's number, M is the molecular weight, υ is the partial specific volume, and η is viscosity of the solvent. Assuming D is proportional to $(1/M)^{1/3}$ and that all other parameters remain unchanged, then the value D_{aq} for β-blocking agents with an average molecular weight of 288 is: $D_{aq} = (1.1 \times 10^{-5})(122/288)^{1/3} = 7.5 \times 10^{-6}$ cm²/sec.

Epithelial Diffusion—Figure 3 represents a linear plot of log P_{epi} *versus* log DC. Five drugs (penbutolol, levbunolol, timolol, nadolol, and sotalol) lack the permeability data for stroma and epithelium–stroma preparations so that individual resistances could not be directly calculated for all layers. However, because of the excellent fit between permeability and partitioning for seven of the drugs shown in Fig. 1, predictions for R_{str} could be obtained from the known DC value. Using the experimentally determined permeability data for intact cornea, R_T was calculated. Consequently R_{epi} could be determined from Eq. 5 by difference for the five drugs lacking the appropriate experimental data. The R_{epi} value for penbutolol was over one log unit from the least-squares fitted line (slope = 0.8505, intercept = −5.033, and r = 0.9207). Its deviation could be a consequence of the very small percentage contribution of the P_{epi} value estimated for penbutolol and, therefore, the large potential for error when taking its reciprocal. It is interesting to note that the slope in Fig. 3 is only slightly <1, suggesting that the lipophilic character of the epithelium is only slightly lower than octanol (a slope of 1 would indicate identical partitioning behavior).

Endothelial Diffusion—Figure 4 represents a plot of log P_{endo} *versus* log DC for all of the drugs except acebutolol, which had an outlying value. The R_{endo} value of acebutolol was small compared to R_{epi} and may have been subject to a relatively large error. The linear regression analysis

Table IV—Percent Contribution of the Resistance of Individual Corneal Layers to the Total Corneal Resistance

β-Blocking Agent	R_{epi}/R_T, %	R_{str}/R_T, %	R_{endo}/R_T, %	Log DC[a]
Penbutolol	1.0	46.0	53.0	2.53
Bufuralol	18.0	50.0	32.0	2.31
Bevantolol	7.0	44.0	49.0	2.19
Propranolol	7.0	45.0	48.0	1.62
Levbunolol	58.0	15.0	27.0	0.72
Oxprenolol	45.0	21.0	34.0	0.69
Timolol	68.0	9.0	23.0	0.34
Metoprolol	48.0	18.0	34.0	0.28
Acebutolol	91.0	1.0	8.0	0.20
Nadolol	95.0	1.0	4.0	−0.82
Sotalol	95.0	1.0	4.0	−1.25
Atenolol	97.5	0.5	2.0	−1.52

[a] The distribution coefficient is between octanol and Sorensen's buffer at pH 7.65, which is also the pH of the permeability experiments.

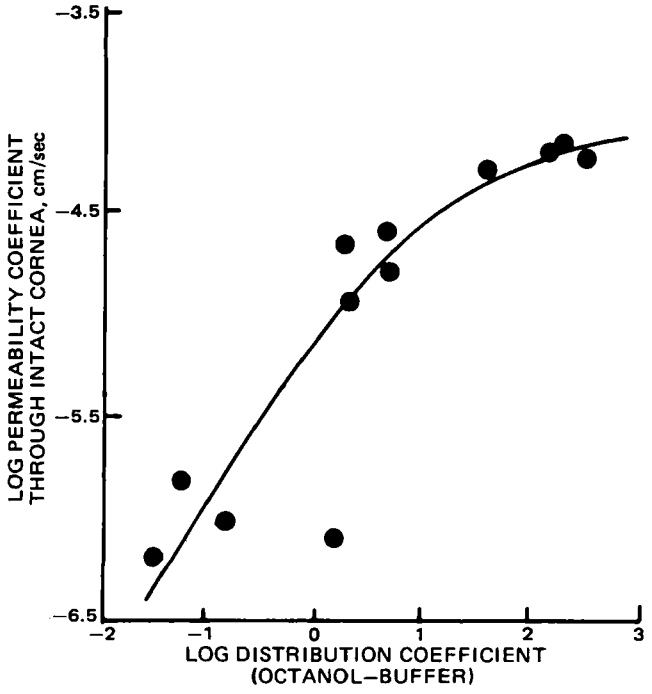

Figure 5—*Log–log plot of theoretical curve fitted to experimentally determined permeability coefficients through intact cornea (●) versus distribution coefficient (octanol–Sorensen's buffer, pH 7.65) for 12 β-blocking agents; computer-generated curve represents the sum of three composite corneal layers according to Eq. 20.*

produced a line with a slope and intercept intermediate between epithelial and stromal data (slope = 0.1843, intercept = −4.272, and r = 0.9282).

The intercepts from the linear regression in Figs. 2–4 represent the log P_T value for a compound with a log DC of zero. The permeability coefficients, in units of 10^{-6} cm/sec, are 9.27, 53.46, and 123.03, respectively, for epithelium, endothelium, and stroma for a compound whose DC equals 1. For a compound with this partitioning behavior, the epithelium is the rate-determining barrier. A β-blocking agent must be considerably more lipophilic before another layer becomes rate determining.

Relative Layer Contributions—Table IV shows the percent contribution of the resistances from each corneal layer to the total corneal resistance according to Eq. 5. The percent contribution of epithelial resistance increases as the drug lipophilicity decreases. Conversely, resistance decreases for stroma and endothelium as the lipophilicity of the drug decreases. Stroma is hydrophilic and expected to behave in this manner. However, the endothelium is considered lipophilic due to its cellular composition. Because the endothelium is only one cell thick and therefore does not present the tortuosity of the multilayered epithelium, it is possible that intercellular (pore) transport becomes significant for the more hydrophilic compounds.

For the most lipophilic compounds (penbutolol, bufuralol, bevantolol and propranolol), the stroma and endothelium offer the greater resistance. For the other more hydrophilic compounds, the epithelium is the most significant barrier to penetration.

Diffusional Model Relating DC to P_T—The total diffusional resistance, R_T, through the three-layer corneal membrane was generalized in Eq. 3, but can be expanded according to Eq. 5 to:

$$P_T = \frac{1}{R_T} = \frac{1}{\frac{h_1}{D_1(\mathrm{PC})_1} + \frac{h_2}{D_2(\mathrm{PC})_2} + \frac{h_3}{D_3(\mathrm{PC})_3}} \qquad \text{(Eq. 10)}$$

where all terms have been previously defined; for simplicity, the numerical subscripts 1, 2, and 3 are used for the epithelial, stromal, and endothelial layers, respectively. An attempt was made to determine if each corneal layer, with its own effective partition coefficient (PC), could be related to the distribution coefficient of an octanol–buffer (pH 7.65) system according to:

$$(\mathrm{PC})_i = \gamma_i(\mathrm{DC})^a \qquad \text{(Eq. 11)}$$

where γ is a proportionality constant and a represents a measure of the sensitivity of the biological partition coefficient (PC) of layer i to the *in vitro* distribution coefficient (DC).

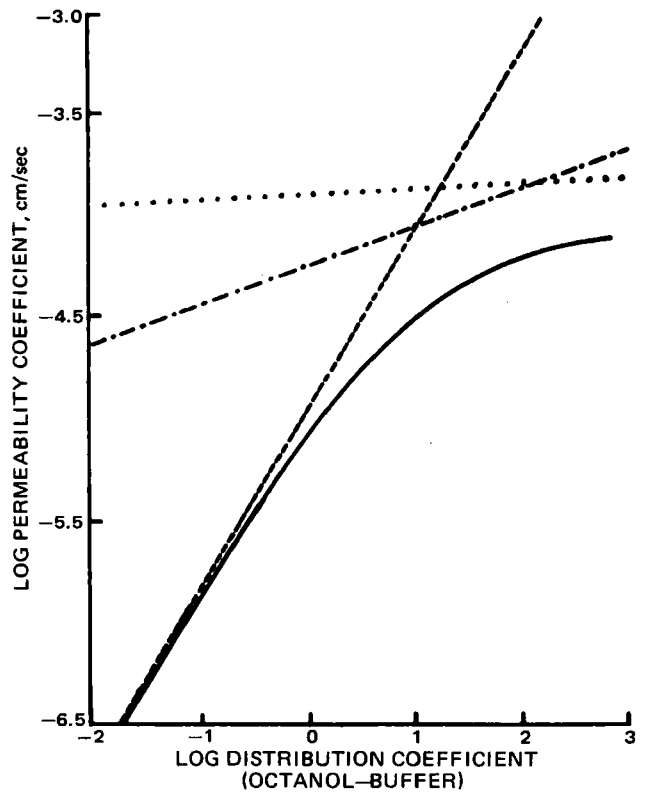

Figure 6—*Computer-generated log–log plots of permeability coefficient for intact cornea and three separate corneal layers* versus *distribution coefficient (octanol–Sorensen's buffer, pH 7.65). Key: (- - -) epithelium, (· · ·) stroma, (— · —) endothelium, (——) intact cornea generated from Eq. 20.*

The basis for use of Eq. 11 comes from the work of Collander (13), who studied the partition of organic compounds between higher alcohols and water. He found that there was a linear relationship among the log partition coefficients in two different solvent systems:

$$\log \mathrm{PC}_{S2} = a \cdot \log(\mathrm{PC}_{S1}) + b \qquad \text{(Eq. 12)}$$

where S1 and S2 represent two different solvent systems each containing water as the polar phase, but with different nonpolar phases. The octanol–water system has been used as a reference system for correlation to *in vivo* responses (14, 15). When other systems are used, conversion to the octanol–water system can be achieved through Eq. 12. Equation 11 can be converted to a form identical to Eq. 12, where S1 in Eq. 11 represents octanol–buffer (pH 7.65) and S2 represents a membrane–water system. Equation 11 can be substituted into Eq. 10 to give:

$$P_T = \frac{1}{\frac{h_1}{D_1\gamma_1(\mathrm{DC})^{a_1}} + \frac{h_2}{D_2\gamma_2(DC)^{a_2}} + \frac{h_3}{D_3\gamma_3(DC)^{a_3}}} \qquad \text{(Eq. 13)}$$

Combining fractions and rearranging gives:

$$P_T = \frac{(D_1\gamma_1/h_1)(\mathrm{DC})^{a_1}}{1 + (h_2D_1\gamma_1/h_1D_2\gamma_2)(\mathrm{DC})^{a_1-a_2} + (h_3D_1\gamma_1/h_1D_3\gamma_3)(\mathrm{DC})^{a_1-a_3}} \qquad \text{(Eq. 14)}$$

and combining constants leads to:

$$P_T = \frac{dx^e}{1 + fx^g + ix^j} \qquad \text{(Eq. 15)}$$

where x = DC, $d = D_1\gamma_1/h_1$, $e = a_1$, $f = h_2D_1\gamma_1/h_1D_2\gamma_2$, $g = a_1 - a_2$, $i = h_3D_1\gamma_1/h_1D_3\gamma_3$, and $j = a_1 - a_3$. For a single epithelial layer, $h_2 = h_3 = 0$ and Eq. 13 becomes:

$$P_{epi} = \frac{1}{R_{epi}} = \frac{D_1\gamma_1(\mathrm{DC})^{a_1}}{h_1} \qquad \text{(Eq. 16)}$$

Similarly:

$$P_{str} = \frac{1}{R_{str}} = \frac{D_2\gamma_2(\mathrm{DC})^{a_2}}{h_2} \qquad \text{(Eq. 17)}$$

Table V—Nonlinear Least-Squares Best Fit of the Relationship Between Permeability Coefficient and Distribution Coefficient (Octanol–Buffer) [a]

Corneal Layer	f_hP_h 10^{-6} cm/sec	$f_lD\gamma/h$, 10^{-6} cm/sec	a	Weight	RMS[b]	r[c]	DF[d]

	0.60[e]	25.290	0.6152	$(1/P)^{0.50}$	2007.7	0.101	9

[a] Results apply to three barriers in series with parallel pathways assigned to epithelium and endothelium only; see Eq. 23 for an explanation of the symbols. [b] Residual mean square calculated by dividing residual sum of squares by degrees of freedom. [c] Correlation coefficient. [d] Degrees of freedom. [e] A fixed value for computer fitting represents the permeability coefficient from the most hydrophilic drug, atenolol.

and

$$P_{endo} = \frac{1}{R_{endo}} = \frac{D_3\gamma_3(DC)^{a3}}{h_3} \qquad \text{(Eq. 18)}$$

Equations 16–18 can be linearly rearranged to yield:

$$\log P_i = a_i \log (DC) + \log \frac{D_i\gamma_i}{n_i} \qquad \text{(Eq. 19)}$$

Equation 19 indicates that for a single corneal layer, the plot of log P_i *versus* log DC will show a linear relationship with a slope a_i and an intercept equal to log $D_i\gamma_i/h_i$. This requires that all drugs used in the plot have the same diffusion coefficient within layer i.

By substituting the intercepts and slopes from the log P_i *versus* log DC plots of the three corneal layers into Eq. 15, the following equation was obtained:

$$P_T = \frac{(9.27 \times 10^{-6})(DC)^{0.8505}}{1 + 0.0753(DC)^{0.8216} + 0.1734(DC)^{0.6662}} \qquad \text{(Eq. 20)}$$

Equation 20 is exactly the same form as Eq. 15. Figure 5 shows that the experimental data corresponding to the log P_T *versus* log DC plot for intact corneal permeability fits the curve represented by Eq. 20. The excellent fit further justifies our theoretical basis regarding corneal penetration through three composite layers acting as a sum of barriers in series.

Figure 6 is a combination of all the log P_i *versus* log DC curves for permeation through intact cornea, epithelium, stroma, and endothelium. It clearly shows that the permeabilities are rate determined by the epithelium for the four hydrophilic compounds (atenolol, sotalol, nadolol, and acebutolol). There are four intermediate lipophilic compounds (*i.e.*, metoprolol, timolol, oxyprenolol, and levbunolol) whose permeabilities are controlled by epithelium, endothelium, and stroma, in that order. The most lipophilic compounds fall on the plateau range, with their permeabilities controlled by endothelium and stroma; these compounds include propranolol, bufuralol, bevantolol, and penbutolol. It is interesting to note that linear processes (Fig. 6) can be added to produce curvilinear results. This occurs because of the small slope values (a in Eq. 19) of stroma and endothelium; therefore, a plateau is reached for the most lipophilic compounds.

The only outlier in Fig. 5 is acebutolol, for which the experimental permeability coefficient falls significantly below the theoretical curve represented by Eq. 20. By applying the Sutherland–Einstein equation to correct for the difference in molecular weight between acebutolol (336.4) and the remaining 11 β-blocking agents (289.6), the diffusion coefficient of acebutolol was found to be only 5% lower than the average. When the 5% correction is applied, the permeability coefficient is still significantly below the computer-generated line of best fit. Figures 3 and 4 indicate that log P_{epi} and log P_{endo} for acebutolol deviate from the observed trend, shown by their respective plots against log DC. This suggests that the decreased permeability coefficients of acebutolol through epithelium and endothelium, and not the stroma, account for the deviation of the experimental data from the curve. It was thought that acebutolol might cause a physiological or structural change in the epithelial or endothelial layers such that the permeation decreases. However, the experimental hydration level obtained following intact corneal permeability was within the normal range, suggesting that the corneal layers had not been altered in permeability. Still another possibility for the deviation for acebutolol may lie in its partitioning behavior. From a structural point of view, acebutolol may show exceptional hydrogen bonding ability compared to the other 11 β-blocking agents. The fact that the acebutolol structure contains acetyl, amide, and tertiary amine groups indicates that significantly more hydrogen bonding could occur compared with the other compounds, possibly leading to the deviation of acebutolol in Fig. 5.

Intercellular (or Aqueous Pore) Pathways in the Epithelial and Endothelial Layers—When two or more independent diffusional pathways exist in a given diffusional medium, the total permeability coefficient at steady state is (11):

$$P_T = f_1P_1 + f_2P_2 + \ldots + f_nP_n \qquad \text{(Eq. 21)}$$

where $f_1, f_2, \ldots f_n$ define the fractional areas of each route and $P_1, P_2, \ldots P_n$ are the individual permeability coefficients through each pathway. It has been suggested that there are two parallel pathways occurring for the diffusion of drugs across biological membranes (6, 16). One pathway is represented by hydrophilic channels that consist of pores or intercellular spaces, whereas the other pathway is represented by lipophilic transport across lipoid-like cell membranes. Hydrophilic molecules with low lipophilic partitioning behavior (low DC) are logically thought to diffuse through the hydrophilic channels, the path of least resistance. Applying these concepts to either the epithelium or endothelium, Eq. 21 becomes:

$$P_i = f_hP_h + f_lP_l \qquad \text{(Eq. 22)}$$

where subscripts h and l refer to hydrophilic and lipophilic transport, respectively. Since the hydrophilic channels are mostly filled with water, the diffusion coefficients for the β-blocking agents should approximate the diffusion coefficient in water for an average molecular weight of 288. The DC value for each drug can be assumed equal to 1. P_h becomes a

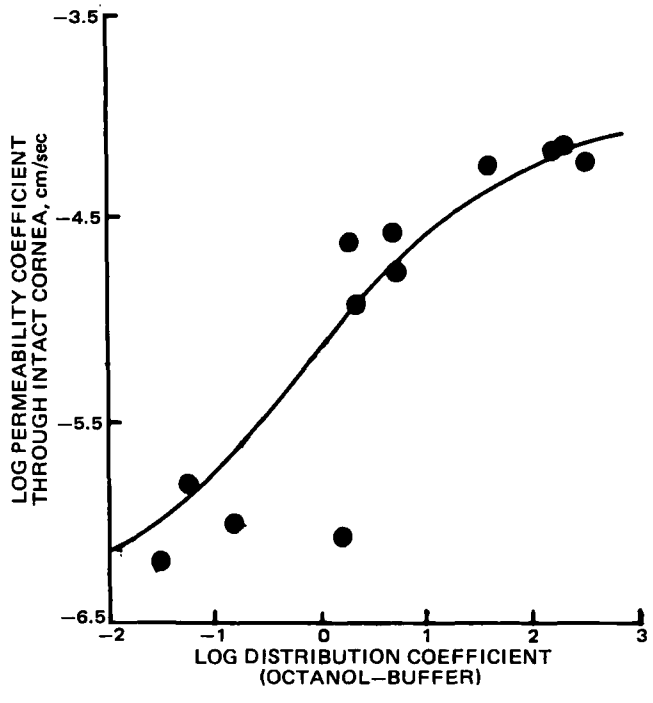

Figure 7—*Log–log plot of permeability coefficient* versus *distribution coefficient (octanol–Sorensen's buffer, pH 7.65). Key: (●) intact corneal permeability data, (—) computer-generated sigmoidal curve representing parallel pathways according to Eq. 24.*

[14] Nonlinear regression was performed using the BMDP3R program on an IBM370 computer.

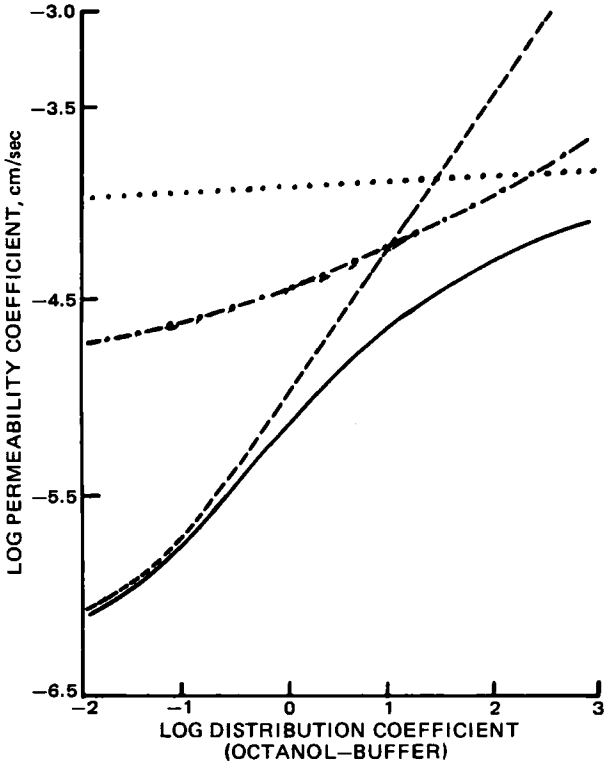

Figure 8—*Computer-generated log–log plots of permeability coefficient for intact cornea and three separate corneal layers* versus *distribution coefficient using (octanol–Sorensen's buffer, pH 7.65). The model includes intra- and intercellular pathways for epithelium and endothelium. Key: (- - -) epithelium, (· · ·) stroma, (-·-) endothelium, (—) intact cornea generated from Eq. 24.*

constant, but P_l is dependent on DC; thus, by combining Eqs. 3, 11, and 22 for either epithelial or endothelial transport:

$$P_i = f_h P_h + \frac{f_l D \gamma_i (\mathrm{DC})^{a_i}}{h_i} \qquad \text{(Eq. 23)}$$

Equation 23 can be fit by nonlinear regression[14] to either P_{epi} or P_{endo} *versus* DC to obtain estimates of $f_h P_h$ and $f_l D\gamma_i/h_i$.

Parallel Endothelial Pathways—Electron micrographs show that the boundries of adjoining endothelial cells are separated by ~200 Å (10). Based on an average endothelial thickness of 4.5 μm, as well as an experimentally determined P_{endo} of 2×10^{-5} cm/sec and a diffusion coefficient of 1.7×10^{-5} cm²/sec for ^{24}Na, Maurice (10, 17) estimated f_h in the endothelium to be 1/1720. Setting P_h equal to $D(\mathrm{PC})/h$ and assuming that PC = 1, h = 4.5 μm, and $D = 7.5 \times 10^{-6}$ cm²/sec[13], P_h becomes 1.7×10^{-2} cm/sec and $f_h P_h$ becomes 9.7×10^{-6} cm/sec. Therefore, 9.7×10^{-6} cm/sec was used as an initial estimate for the nonlinear fit to Eq. 23 for P_{endo} *versus* DC. Since f_l is nearly unity, the initial estimates for $D\gamma/h$ and a were obtained from the linear fit of log P_{endo} *versus* log DC (Fig. 4).

Weighting factors were used in the nonlinear fitting procedure since $f_h P_h$ is more likely determined by the hydrophilic compounds, which have much lower permeability and distribution coefficients than those of the lipophilic compounds. Table V shows the results of the computer fit for the endothelium. Using the weights of $(1/P_3)^{0.85}$ or $(1/P_3)^{0.5}$ the final estimates of $f_h P_h$ are reasonably close to the theoretically derived initial estimate. However, if the endothelial permeability coefficient for acebutolol, which is extremely low, is again taken as an outlier and discarded for the computer fitting, then $f_h P_h$ decreases to ~0. Consequently, a strict interpretation of the results is tenuous based on the variability of the data. The intercellular pathway for the endothelium cannot be confirmed from our nonlinear regression analysis unless a greater number of data points in the hydrophilic range are used.

Parallel Epithelial Pathways—Since the epithelium has 5–10 cellular layers, its intercellular pathway should have a large tortuosity and small area fraction. The epithelial permeability coefficient for the most hydrophilic drug, atenolol, is only 0.6×10^{-6} cm/sec. Assuming atenolol traversed the epithelium predominately through pores, the value of 0.6×10^{-6} cm/sec was assigned as an initial estimate for $f_h P_h$ for the nonlinear regression of epithelial permeation. The initial estimates for $D\gamma/h$ and a were obtained from the linear fit of log P_{epi} *versus* log DC (Fig. 3).

Despite the uncertainty defining the intercellular pathway, the computer fitting using Eq. 23 provides useful information for both epithelial and endothelial layers. As pointed out previously, the a-value indicates the sensitivity of the respective corneal layer to the change in the lipophilicity/hydrophilicity character of the penetrating drug. As shown in Table V, the slope values (a) are <0.35 for the endothelium. In contrast, the epithelium has a-values 2 times as high as that calculated for the endothelium. The results indicate that compared with endothelium, the epithelium is more sensitive to the lipophilicity of permeating compounds. These conclusions are consistent with the results of the linear regression fits of log P_i *versus* log DC.

The hydrophilic stroma contains very low cell counts and, therefore, the intercellular pathway model did not apply. The log P_{str} *versus* log DC data was fitted by linear regression. The parameter values from the line of best fit as well as those from the P_i *versus* DC nonlinear curve-fitting procedure were used to construct the following:

$$P_T = \frac{1}{\dfrac{10^6}{0.6 + 9.346 \cdot (\mathrm{DC})^{0.7885}} + \dfrac{10^6}{123.03 \cdot (\mathrm{DC})^{0.0289}} + \dfrac{10^6}{15.19 + 21.38 \cdot (\mathrm{DC})^{0.3298}}} \qquad \text{(Eq. 24)}$$

where the three terms in the denominator on the right-hand side represent the permeability coefficient through epithelium, stroma, and endothelium, respectively. According to Eq. 24, the computer-generated curve of log P_T *versus* log DC (Fig. 7) describes the experimental permeability coefficients through intact cornea. The lower limit of the curve represents the intercellular pathway while the plateau is controlled by the endothelium and stroma, overall resulting in a sigmoidal curve. Figure 8 shows the computer-fitted curves for stroma, endothelium, epithelium, and intact cornea. Unlike the linear log P_{str} *versus* log DC plot for stroma, the curves for epithelium and endothelium in Fig. 8 approach a minimum in the hydrophilic range.

Because of the variability in the log P_i values for the hydrophilic compounds, Figs. 7 and 8 do not describe the data any better than Figs. 5 and 6. Nevertheless, the sigmoidal curve obtained in Figs. 7 and 8 resemble the intestinal absorption profile proposed by Ho *et al.* (6) for similar data. These authors showed that a sigmoidal relationship existed between the rates of absorption and lipophilicity. Diffusion through the aqueous pore pathway in the intestine accounted for the lower limiting value represented by the most hydrophilic compounds, whereas at high lipophilicity, the absorption rate reached a plateau controlled by the aqueous boundary layer adjacent to the intestinal absorptive cell membrane. Corneal penetration rate, on the other hand, is limited for lipophilic β-blocking agents by the stroma, which is primarily an aqueous barrier on the cornea; however, the hydrophilic stromal barrier is a physiologically real and permanent barrier located within the cornea. Both Figs. 5 and 7 show that stroma and endothelium control the corneal permeation of lipophilic compounds in the absence of an aqueous diffusional (or boundary) layer.

Corneal Penetration Behavior of β-Blocking Agents III: *In Vitro–In Vivo* Correlations

HONG-SHIAN HUANG *, RONALD D. SCHOENWALD ˣ, and JOHN L. LACH

Received July 26, 1982, from the *Pharmaceutics Division, College of Pharmacy, University of Iowa, Iowa City, IA 52242.* Accepted for publication September 4, 1982. *Present address: National Defense Medical Center, P.O. Box 8244-14, Taipei, Taiwan 107, ROC.

Abstract □ Aqueous humor levels were determined over time after the topical administration to rabbit eyes of 1% isotonic buffered (pH 7.3) solutions of three β-blocking agents, acebutolol hydrochloride, timolol maleate, and bufuralol hydrochloride (arranged in order of increasing lipophilicity). Corneal permeability coefficients, determined from a previous *in vitro* study, were inversely related to the observed time to peak for the three drugs, as expected. Two of the drugs, bufuralol and timolol, did not give the expected rank order for C_{max} and AUC, which could result from differences in distribution and/or elimination processes. Aqueous boundary layers were postulated for *in vivo* corneal permeability which suggested that bufuralol and timolol may have nearly identical effective permeability coefficients *in vivo*.

Keyphrases □ Permeability—acebutolol, timolol, bufuralol, excised rabbit corneas, pharmacokinetics, *in vitro–in vivo* correlations □ Acebutolol—corneal permeability in rabbits, pharmacokinetics, *in vitro–in vivo* correlations □ Timolol—corneal permeability in rabbits, pharmacokinetics, *in vitro–in vivo* correlations □ Bufuralol—corneal permeability in rabbits, pharmacokinetics, *in vitro–in vivo* correlations

In a previous report (1) the penetration behavior of 12 β-blocking agents measured across excised rabbit corneas was correlated with partitioning, which varied over a fourfold logarithmic range. Optimal penetration (log permeability coefficient) reached a maximum at a log distribution coefficient (octanol–buffer, pH 7.65) of ~2–3. Subsequent results (2) showed that a plateau was reached because the stroma, and to a lesser extent the endothelium, became the rate-controlling barrier for the most lipophilic compounds, while the epithelium acted as a rate-determining barrier for the hydrophilic compounds.

The purpose of this study was to determine if the corneal permeability coefficients of three compounds ranging widely in lipophilicity could be correlated with parameters obtained from the aqueous humor–time profile. The three drugs (in descending lipophilic order: bufuralol, timolol, and acebutolol) were administered as 1% isotonic, buffered (pH 7.3) solutions.

EXPERIMENTAL

Reagents and Materials—Isotonic, buffered (pH 7.3), 1% w/v solutions of acebutolol hydrochloride, timolol maleate, and bufuralol hydrochloride were prepared separately[1]. The reagents used for aqueous humor extraction and subsequent high-performance liquid chromatographic (HPL) assay were reagent- or UV spectrophotometry-grade chemicals. New Zealand White rabbits, 2 months of age and of either sex, weighing 1.6–2.0 kg were used for the experiments.

Topical Administration and Aqueous Humor Sampling—The rabbits were administered drug with their heads in an upright position while resting in a restraining box. The rabbits were returned to their cages when the sampling interval was >1 hr. A 50-μl volume was instilled onto the cornea of each eye while the lower lid was gently pulled away from the eye globe to form a pocket. The lower eyelid was held against the upper lid for 20 sec after instillation. Second and third instillations were given 2 and 4 min after the first application. The multiple-dose regimen was designed to give aqueous humor concentrations above the sensitivity of the assay. This especially applies to acebutolol hydrochloride, since its permeability was found to be the lowest.

At various postinstillation times, rabbits were sacrificed by a rapid injection of ~25 ml of air into the marginal ear vein. Each cornea was then quickly rinsed with 1 ml of normal saline solution to get rid of residual drug. The aqueous humor samples were withdrawn by puncture with a 26-gauge 0.95-cm needle attached to a 0.5-ml disposable syringe[2] through the corneal–scleral junction into the anterior chamber. The same syringe was used for the opposite eye of each rabbit in order to pool the aqueous humor of both eyes.

The sampling times for each drug are listed in Table I; each value represents an average of 4–12 rabbit eyes. The aqueous humor samples were left in the syringes and were assayed within a few hours. Although rabbit aqueous humor sample volumes varied from animal to animal (ranging from 0.25 to 0.35 ml), a constant volume of sample was used in the assay for each drug.

Extraction and Analyses—A mixer[3] was used to facilitate the mixing and extraction. In 10-ml, glass centrifuge tubes, aqueous humor samples of 0.25 ml were mixed with 0.1 ml of 0.5 *N* NaOH, extracted with 2.0 ml of methylene chloride, and centrifuged. After discarding the aqueous layer, the organic phase was extracted with 1.0 ml of 0.05 *N* sulfuric acid. The acidic aqueous phase was used for HPLC assay of acebutolol.

A 0.30-ml volume of aqueous humor sample was mixed with 0.1 ml of 1 *N* NaOH and extracted with 5 ml of heptane containing 4% isoamyl alcohol in a 10-ml glass centrifuge tube. No centrifugation was necessary

[1] 1% Acebutolol (as hydrochloride salt) contained the following vehicle ingredients: 0.184 g of $NaH_2PO_4 \cdot H_2O$, 0.758 g of Na_2HPO_4, and 0.288 g of NaCl/100 ml of solution. 1% Timolol (as maleate salt) contained the following vehicle ingredients: 0.947 g of Na_2HPO_4, 0.265 g of NaOH, and 0.332 g of NaCl/100 ml of solution. 1% Bufuralol (as hydrochloride salt) contained the following vehicle ingredients: 0.184 g of $NaH_2PO_4 \cdot H_2O$, 0.758 g of Na_2HPO_4, and 0.242 g of NaCl (1.0 g bufuralol hydrochloride)/100 ml of solution.

as the two layers separated completely. A 4-ml volume of the heptane layer was transferred to 1.0 ml of 0.1 *N* HCl in another 10-ml glass tube and mixed. The acidic aqueous layer was then assayed for timolol by HPLC.

Aqueous humor samples of 0.25 ml from bufuralol-treated rabbits were placed into a 10-ml glass centrifuge tube, alkalinized with 0.1 ml of 0.5 *N* NaOH, and extracted with 0.5 ml of heptane containing 1.5% isoamyl alcohol. After centrifugation, 0.4 ml of the heptane layer was transferred to a 4-ml glass vial, extracted with 0.5 ml of 0.1 *N* HCl; and then assayed by HPLC for bufuralol concentration.

Aqueous humor blanks obtained from control rabbits were spiked with various quantities of each drug and extracted by the methods described above. The slopes of the calibration curves were used for calculation of drug concentrations in the unknown aqueous humor samples.

The HPLC system[4] was equipped with an injector[5] consisting of different-sized loops ranging from 50 to 200 μl, which enabled the injection of an accurate sample volume. Each sample was divided so that two injections could be made and the results averaged. The mobile phase for

[a] 50 μl of a 1%, isotonic, buffered (p 7.3) solution was topically administered to rabbit eyes at 0, 2, and 4 min. [b] Time to peak (t_p) and peak concentration (C_{max}). [c] Area under the curve up to last sampling point (180 min). [d] Intrinsic corneal permeability coefficient obtained from *in vitro* permeability experiments (1, 2). [e] Log distribution coefficient between octanol and buffer (pH 7.65) (1, 2).

acebutolol and bufuralol consisted of methanol and 1.5% acetic acid in deaerated, deionized water adjusted to pH 4 with sodium hydroxide (3:7 and 7:18, respectively). For timolol the mobile phase contained 42% methanol and 58% 0.005 *M* heptanesulfonic acid in 1% acetic acid solution adjusted to pH 4. For all three drugs the flow rate was 2.0 ml/min (1). The assay sensitivity for acebutolol and bufuralol was 25 ng/ml; the assay sensitivity for timolol was 50 ng/ml.

Permeability and Distribution Coefficients—The procedures for determining these coefficients, as well as the reported values for each drug used in this study, were reported in the previous papers (1, 2). Both coefficients were determined at pH 7.65.

RESULTS AND DISCUSSION

Following the topical administration of 50 μl of isotonic, buffered (pH 7.3) 1% drug solutions to rabbit eyes at 0, 2, and 4 min; the aqueous humor concentrations at various times were measured. Table I and Fig. 1 list the results obtained for acebutolol, timolol, and bufuralol.

Table II lists the peak concentration (C_{max}), time to peak (t_p), the area under the aqueous humor–time curve through 180 min (AUC), excised corneal permeability coefficient (P_T), and the log distribution coefficient (log DC). A correlation exists between t_p and P_T (and DC). Excluding elimination considerations, the more slowly the drug penetrates, the greater t_p becomes; theoretically, this will occur as the lipophilicity of

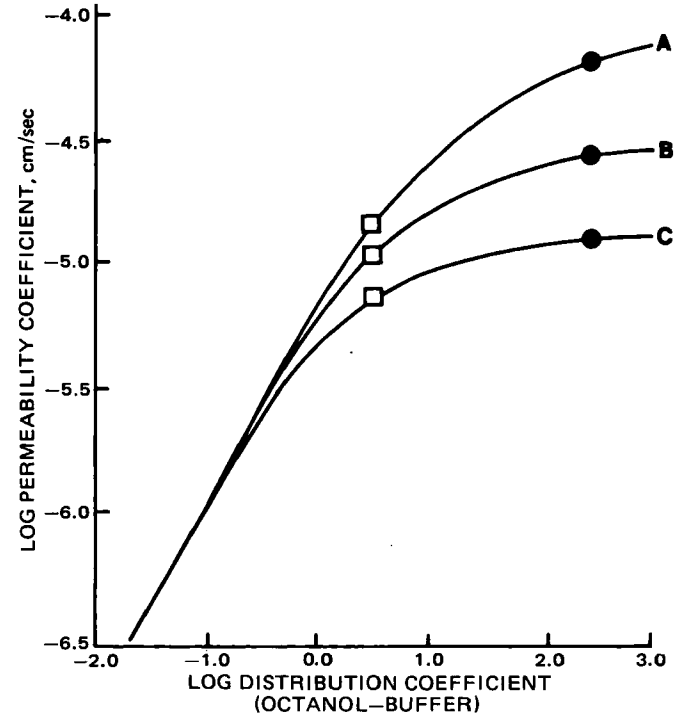

Figure 2—*Simulated curves for the log–log plot of permeability coefficient* versus *distribution coefficient (octanol–buffer, pH 7.65) for intact cornea in the presence of various postulated thicknesses of aqueous humor diffusional layers. Key: (A) none, (B) 0.15 cm, (C) 0.45 cm; (●) bufuralol; (□) timolol.*

the drug decreases. Acebutolol has the lowest cornea permeability coefficient and, thus, has the longest t_p (85 min). Bufuralol has the shortest t_p (10 min), whereas timolol has an intermediate t_p of 25 min. Acebutolol has the lowest C_{max} and AUC; these results are expected for a hydrophilic drug which does not rapidly penetrate the cornea. Although bufuralol is much more lipophilic than timolol, its C_{max} and AUC are actually less than the values reported for timolol (Table II).

These drugs differ structurally and therefore could vary not only in penetration, but also in distribution, metabolism, and excretion processes. Consequently, C_{max}, t_p, and AUC may not necessarily correlate perfectly to the permeability coefficient. The t_p value is perhaps the parameter most likely to show a perfect correlation. This is reasoned from the work of Makoid and Robinson (3), who determined the ophthalmic pharmacokinetics of pilocarpine topically applied to the rabbit eye. From their work an equation was developed for t_p:

$$t_p = \frac{\ln \frac{k_{10}}{k_{23}}}{k_{10} - k_{23}} \qquad \text{(Eq. 1)}$$

where k_{10} is the precorneal loss rate constant and k_{23} is the loss rate constant from cornea to aqueous humor. The permeability coefficient would be directly related to k_{23}. Equation 1 assumes that k_{10} is much larger than uptake into the epithelium of the cornea from the precorneal area. This assumption applies to most, if not all, ophthalmic drugs, since k_{10} is a function of scleral absorption as well as drainage rate, the latter being relatively large for aqueous solutions. The drainage rate would be expected to be the same for each β-blocking agent at the same pH and osmolarity.

Both C_{max} and AUC are a function of distribution to corneal tissue and elimination from the eye in addition to penetration. A smaller AUC or C_{max} may result from a larger volume of distribution within the eye and/or from a more rapid elimination from the aqueous humor. For drugs with large differences in P_T, such that this factor predominates, perfect correlations between P_T and C_{max} or AUC may be more likely. However, if aqueous boundary layers are significant this may not be true. Aqueous boundary layers have been shown to play an important role in intestinal absorption. For high lipophilic compounds, the absorption rate assumes a plateau with a maximal rate; intestinal absorption is limited by the rate of diffusion through the aqueous diffusional barrier adjacent to the mucous membrane.

Aside from disposition considerations, drug permeation across the cornea *in vivo* may be significantly hindered by the diffusional layers on both sides of the cornea. The aqueous boundary layer adjacent to the endothelium and within the anterior chamber may be large. The physiological aqueous volume of the rabbit is 287 μl with a turnover rate of ~1%/min (4, 5). It is difficult to estimate the effective diffusional layer thickness in aqueous humor that would exist in the presence of this turnover rate. It is possible that a turnover rate of 1% would have a negligible mixing effect on the aqueous humor compared with the stirring in the modified perfusion chamber. For example purposes let us assume that the entire anterior chamber volume is a barrier. Since the aqueous diffusional layer represents the entire sampling volume for drug analysis, only half of the aqueous humor thickness can be used as the diffusional layer. As a result, the diffusional layer is estimated to be ~0.15 cm[6].

In the precorneal region the thickness of the tear film ($6–7 \times 10^{-4}$ cm) could also serve as an aqueous boundary layer (6). Although blinking of the eyelid mixes the drug with the tear film, it may also reduce the size of an aqueous boundary layer to below the thickness of the tear film. Regardless, it is probably small and not significant in size compared with the potential aqueous barrier in the anterior chamber.

To show the effect of a postulated *in vivo* aqueous boundary layer in addition to corneal layer resistances, curves were simulated for the log–log plot of permeability coefficient *versus* distribution coefficient. These curves[7] are shown in Fig. 2 for intact cornea in the presence of postulated aqueous boundary layers of 0, 0.15, and 0.45 cm. As the aqueous boundary layer increases, the plateau region in curves B and C occur at a lower distribution coefficient. Also, the maximum log permeability coefficient is greatly reduced. Therefore, if we consider these additional boundary resistances, which may exist *in vivo*, it is likely that the log P_T[8] *versus* log DC curve would form a plateau at lower log DC values than calculated from the *in vitro* experiments (1, 2). This suggests that timolol and bufuralol may have nearly identical effective permeability coefficients *in vivo*. Although the results shown in Fig. 2 may not explain the lack of a perfect correlation between the *in vitro* permeability and distribution coefficients for two of the drugs, it should be realized that another prodrug more lipophilic than timolol may not increase the penetration rate.

ACKNOWLEDGMENTS

This work was abstracted in part from a doctoral dissertation submitted by Hong-Shian Huang to the Graduate College, University of Iowa.

The study was supported in part by Allergan Pharmaceuticals, Irvine, Calif.

[6] The anterior chamber can be assumed crudely to represent a cylinder with a radius r, a height h, and a volume V equal to 287 μl or ~0.3 cm^3. Since $V = \pi r^2 h$, h is calculated to be 0.15 cm.

[7] The curves in Fig. 2 were generated from Eq. 20 in Ref. 2 with the additional consideration of an R_{aq} = 0.15 and 0.45. Equation 20 in Ref. 2 equates the permeability coefficient to the sum of the reciprocal of the resistances of each boundary layer.

[8] P_T represents the intrinsic permeability coefficient for excised corneas for which the *in vitro* R_{aq} was substracted.

Anti-inflammatory Agents III: Structure–Activity Relationships of Brusatol and Related Quassinoids

I. H. HALL ˣ, K. H. LEE, Y. IMAKURA, M. OKANO, and A. JOHNSON

Received June 14, 1982, from the *Division of Medicinal Chemistry, School of Pharmacy, University of North Carolina, Chapel Hill, NC 27514.* Accepted for publication September 21, 1982.

Abstract □ A series of quassinoids were observed to be potent inhibitors of induced inflammation and arthritis in rodents. Brusatol afforded the most potent activity followed by brucein-D. A 3-hydroxy-Δ^3-2-oxo moiety in brusatol or a 1-hydroxy-Δ^3-2-oxo moiety in brucein-D, as well as a C-15 ester-bearing δ-lactone ring in brusatol and C-11 and C-12 free hydroxyl groups are required in both quassinoids for potent anti-inflammatory activity. Preliminary studies indicate that one of the modes of action of quassinoids as anti-inflammatory agents is to stabilize lysosomal membranes, reducing the release of hydrolytic enzymes that cause damage to surrounding tissues.

Keyphrases □ Anti-inflammatory agents—potential, brusatol and related quassinoids, structure–activity relationships □ Brusatol—related quassinoids, anti-inflammatory potential, structure–activity relationships □ Structure–activity relationships—brusatol and related quassinoids, anti-inflammatory potential

Previously, a series of pseudoguaianolides and germacranolides were reported to possess potent anti-inflammatory and antiarthritic activity in rodents (1, 2). Common to all of these compounds is the inclusion within their structure of an α-methylene-γ-lactone moiety which is a γ-lactone enone system. Those compounds containing an α-methylene-γ-lactone were ~2–4 times more potent than indomethacin in rodent screens. Since quassinoids contain a cyclohexanone enone system within their structure in addition to a δ-lactone ring, a study was undertaken to investigate a series of quassinoids and their ester derivatives for anti-inflammatory activity. Furthermore, brusatol-producing *Brucea javanica* and other quassinoid-producing species, such as *Simaba cedron*, have been observed to have anti-inflammatory activity (3, 4).

Bruceantin is an antineoplastic agent used in clinical trials in humans. Previous studies have shown that brusatol (I) and bruceantin (II) suppress oxidative phosphorylation of P-388 lymphocytic leukemia cells (5) and inhibit lysosomal hydrolytic enzymatic activities, *e.g.*, cathepsin and ribonuclease (6). Aspirin-type anti-inflammatory agents uncouple oxidative phosphorylation, and corticosteroids stabilize lysosomal membranes. Thus, both modes of action are important to anti-inflammatory activity.

EXPERIMENTAL

Source of Compounds—Bruceoside-A (X), brucein-D (XIII), and brucein-E (XIV) were originally isolated from *B. javanica* (7). Brusatol (I) was obtained either by treating bruceoside-A (X) with 3 *N* H_2SO_4–methanol (1:1) to hydrolyze the glycosidic linkage (7, 8) or directly from the chloroform extract of *B. javanica*. Bruceantin (II) and bruceolide (III) were obtained from bruceoside-A by a synthetic procedure (9). The chemical synthesis, purification, and physical characteristics of a series

of brusatolyl and bisbrusatolyl esters (IV–VI) (10), two bisbruceantinyl esters (VII and VIII) (11) and tetrahydrobrusatol (IX) (10) have been reported previously by this laboratory. Bruceantinoside-A (XI) was isolated from *Brucea antidysenterica* by a published procedure (12), and bruceoside-A hexaacetate (XII) was synthesized from bruceoside-A (8).

Anti-inflammatory Screen—Sprague–Dawley male rats (~160 g) were administered test compounds at 0.25 and 1.0 mg/kg in 0.05% polysorbate 80–water at 3 hr and again at 30 min prior to injection of 0.2 ml of 1% carrageenan in saline into the plantar surface of the right hindfoot. Isotonic saline was injected into the left hindfoot, which served as a baseline. After 3 hr, both feet were excised at the tibiotarsal (ankle) joint according to a modified method (13), resulting in an average net weight increase of 0.655 g for the control animals. Indomethacin and phenylbutazone were used as standards.

Antiarthritic Screen—Male Sprague–Dawley rats (~160 g) were injected at the base of the tail with 0.2 ml of light mineral oil containing 1 mg of dried *Mycobacterium butyricum* and 0.4 mg of digitonin. The test drugs were administered on days 3–20 at 0.25 and 0.50 mg/kg/day ip. Animals were sacrificed on day 21, and the feet were excised and weighed (14). The control animals achieved an average net weight increase of 0.830 g.

Writhing Reflex—The writhing reflex also was utilized as an analgesic test. Mice were administered the test drugs at 0.25, 0.5, and 1.0 mg/kg ip 20 min prior to the administration of 0.5 ml of 0.6% acetic acid (15). After 5 min, the number of stretches, characterized by repeated contractures, was counted for 10 min. The control mice averaged 78 stretch reflexes/10 min.

Cell Preparation—Metabolic studies were conducted on CF_1 male mouse (~30 g) liver homogenates. Homogenates (10%) were prepared using a pestle in 0.25 *M* sucrose and 0.001 *M* EDTA (ethylenediaminetetraacetic acid) at pH 7.2.

Oxidative Phosphorylation Studies—Basal and adenosine diphosphate-stimulated respirations of the 10% liver homogenates of CF_1 male mice were measured using succinate or α-ketoglutarate as the substrate (16). The reaction vessel contained sucrose (55 μmoles), potassium chloride (22 μmoles), dibasic potassium phosphate (22 μmoles), sodium succinate (90 μmoles) or α-ketoglutarate (60 μmoles), and the test compounds (brusatol, bruceantin, and bruceoside-A) at 25, 50, and 100 μ*M* in 0.05% polysorbate 80–water in a total volume of 1.8 ml.

Oxygen consumption was measured using a Clark electrode connected to an oxygraph. After the basal metabolism (state 4) level was obtained, 0.257 μmole of adenosine diphosphate was added to obtain the adenosine diphosphate-stimulated respiration rate (state 3). The respiration rate was calculated in microliters of oxygen consumed per hour per milligram of wet weight of CF_1 mouse liver homogenate. *In vivo* oxidative phosphorylation studies were conducted on male mice and rats treated with

brusatol at 0.25 mg/kg/day for 3 days. Animals were sacrificed on day 4, and liver homogenates were prepared for the respiration studies.

Lysosomal Hydrolytic Enzymatic Activities—Free and total acid phosphatase activities were studied using 0.1 *M* β-glycerol phosphate in pH 5.0, 0.1 *M* acetate buffer incubated with CF_1 mouse liver homogenates for 30 min (17). The test drugs were incubated *in vitro* at 25, 50, and 100 μ*M* in 0.05% polysorbate 80–water. The total enzymatic activity was obtained by treating the liver homogenates with 0.02% alkylphenoxypolyethoxyethanol 100 to release the bound hydrolytic enzymes from the lysosomal membrane. The reaction was terminated with 10% trichloroacetic acid, and the mixture was centrifuged. Inorganic phosphate was determined by the method of Chen *et al.* (18). Free, total, and percent released acid phosphatase activities were calculated after correcting for the blank values.

Free and total cathepsin activities were determined in an analogous manner on mouse liver homogenates with 2% azocasein as the substrate in pH 5.0, 0.1 *M* acetate buffer (19). The supernatant was assayed for acid-soluble peptide fragments at 366 nm. Free, total, and percent released cathepsin activities were calculated after correcting for the blank values.

Prostaglandin Synthetase Activity—The incubation medium of Tomlinson *et al.* (20) was used to determine the [^{3}H]prostaglandin formation from [^{3}H]arachidonic acid (86.2 Ci/mmole) and 10 mg of purified commercial prostaglandin synthetase from bovine seminal vesicles. After 1 hr at 37°, the reaction was terminated with 1 *N* HCl, and the mixture was extracted with ether and evaporated. The residue was dissolved in ethyl acetate and spotted on silica gel TLC plates, which were eluted with chloroform–methanol–water–acetic acid (90:8:1:0.8) (21). The plates were dried and developed in iodine vapor; with the use of prostaglandin standards, the appropriate areas were scraped and counted for tritium content. Indomethacin was used as an internal standard at 10^{-4} and 10^{-6} *M*. Quassinoids were tested at 25, 50, and 100 μ*M* final concentrations.

RESULTS AND DISCUSSION

In Tables I–VI the values are presented as percent of control ± the standard deviation. The number of animals in each group was six.

The quassinoids demonstrated significant anti-inflammatory activity at 0.25 and 1 mg/kg in Sprague–Dawley rats (Table I). When tested at 1 mg/kg, all of the quassinoids showed at least 30% reduction of inflammation. Brusatol (I) was the most potent compound, demonstrating higher activity at 1 mg/kg than indomethacin at 10 mg/kg. The hydroxy enone ring-A system (as seen in I, II, and XIII) and an ester group attached to C-15 of the δ-lactone ring of I and II are required for potent anti-inflammatory activity, as either reduction of the ring-A enone olefinic bond or removal of the C-15 ester group (as in IX and III, respectively) led to decreased activity. Esterification of the hydroxyl groups at C-3, C-11, and C-12 or glucosidation of the hydroxyl group at C-2 gave rise to less active compounds (*e.g.*, IV, V–VIII, and X–XII). In addition, a reduction of the ring-A enone carbonyl group of XIII to an α-glycol (XIV) also caused a diminution in activity. Thus, the structural requirement for the potent anti-inflammatory activity of the foregoing brusatol-related quassinoids may include either a 3-hydroxy-Δ^3-2-oxo

moiety in ring-A for I or a 1-hydroxy-Δ^3-2-oxo moiety in ring-A of XIII, a C-15 ester bearing δ-lactone ring-D of I, and the free hydroxyl groups at C-11 and C-12.

Brusatol at 0.6 mg/kg appeared to be as potent as indomethacin at 10 mg/kg in reducing the writhing reflex in mice, which is a test for irritant or inflammation pain (Table II). After 3 weeks administration, brusatol effectively reduced induced chronic arthritis in rats at 0.25 and 0.50 mg/kg/day, which was comparable to the activity of indomethacin at 10 mg/kg/day (Table III).

Although an in-depth mode of action study was not carried out, preliminary data (Table IV) indicates that brusatol and bruceantin did not uncouple oxidative phosphorylation of liver mitochondria with succinate as substrate (which is a flavin adenine dinucleotide dehydrogenase) or with α-ketoglutarate (a nicotinic adenine dinucleotide-linked dehydrogenase) in both the *in vitro* and *in vivo* studies. It has been noted before that quassinoids uncouple oxidative phosphorylation of P-388 lymphocytic leukemia cells, but not liver cells (3). The quassinoids tested did not inhibit prostaglandin synthesis using an isolated enzyme system (Table V); however, indomethacin did effectively inhibit prostaglandin synthesis in this system. Brusatol and bruceantin reduced the release of hydrolytic enzymes from lysosomes of the liver (Table VI). Both acid phosphatase and cathepsin release was inhibited significantly. Brusatol and bruceantin inhibited acid phosphatase release 49 and 60%, respectively, at 100 μM. Cathepsin activity was inhibited 78% by brusatol at 25 μM and 30% by bruceantin at 100 μM. Elevated cathepsin activity has previously been related to the inflammation process, and suppression of the enzymatic activity has been linked to anti-inflammatory action (22). The margin of inhibition of free lysosomal enzyme release by the quassinoid is sufficient to account for the anti-inflammatory activity observed. Quassinoids have been observed to inhibit other lysosomal enzymes in P-388 cells (4).

Other studies have established that the antineoplastic activity of quassinoids is linked directly to their ability to suppress the elongation step of protein by blocking the peptidyl synthetase reaction of P-388 cells. The inhibition of protein synthesis may be important in the rapid proliferation of lymphocytes and polymorphonuclear neutrophils during the inflammation process. Therefore, this mode of action cannot be excluded as a mode for the anti-inflammatory action of quassinoids.

Plant Anticancer Agents XXVII: Antileukemic and Cytotoxic Constituents of *Dirca occidentalis* (Thymelaeaceae)

MOHAMMED M. BADAWI, SUKHDEV S. HANDA, A. DOUGLAS KINGHORN[x], GEOFFREY A. CORDELL, and NORMAN R. FARNSWORTH

Received August 12, 1982, from the *Department of Pharmacognosy and Pharmacology, College of Pharmacy, University of Illinois at the Medical Center, Chicago, IL 60612.* Accepted for publication September 7, 1982.

Abstract □ Two antileukemic daphnane esters, Pimelea factor P_2 (I) and the new compound dircin (II), were isolated from the twigs and flowers of *Dirca occidentalis* A. Gray (Thymelaeaceae). Three lignans, (−)-medioresinol (III), (+)-syringaresinol (IV), and (−)-lariciresinol (V), as well as the coumarin daphnoretin (VI), were found to be additional cytotoxic constitents of this taxon.

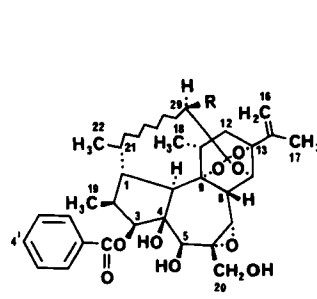
Keyphrases □ *Dirca occidentalis* (Thymelaeaceae)—isolation of antileukemic and cytotoxic constituents, daphnane esters and lignans, identification □ Daphnane esters—isolation from *Dirca occidentalis* (Thymelaeaceae), identification, antileukemic and cytotoxic potential □ Lignans—isolation from *Dirca occidentalis* (Thymelaeaceae), identification, antileukemic and cytotoxic potential □ Antileukemic agents—potential, daphnane esters and lignans isolated from *Dirca occidentalis* (Thymelaeaceae), cytotoxicity

Dirca occidentalis, one of two species representing a small genus in the family Thymelaeaceae indigenous to North America (1), is native to the Pacific States, where it is known by the colloquial name of western leatherwood (2). Although no laboratory studies appear to have been performed on either *D. occidentalis* or *Dirca palustris* L., the bark of *D. palustris* is highly vesicant to the skin and produces severe vomiting and purgation when ingested (3, 4).

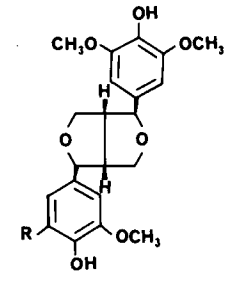
In a continuing search for anticancer agents of plant origin[1], our attention turned to *D. occidentalis* after a chloroform extract of a combined sample of the twigs and flowers was found to display significant *in vivo* and *in vitro* activity against the P-388 lymphocytic leukemia system[2] when tested according to standard protocols (6). In this paper, we report the isolation and identification of two antileukemic daphnane ester principles from this plant, Pimelea factor P_2 (I) and the novel compound dircin (II). In addition, four other cytotoxic constituents were isolated, namely, the lignans (−)-medioresinol (III), (+)-syringaresinol (IV), and (−)-lariciresinol (V) and the coumarin daphnoretin (VI).

DISCUSSION

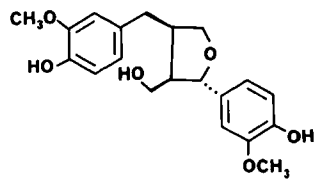
The molecular mass of dircin (II) was determined as 696 daltons by field-desorption mass spectrometry, a value consistent with a molecular formula of $C_{39}H_{52}O_{11}$. Comparison of the spectroscopic data (UV, IR, ^{1}H-NMR, MS) obtained for this isolate with those of Pimelea factor P_2 (I) and other 1α-alkyldaphnane derivatives (7–9), suggested that II is an acetoxy derivative of Pimelea factor P_2 (I). Thus, observations of



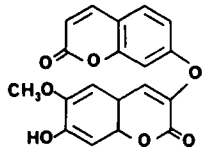
I: R = H
II: R = $OCOCH_3$



III: R = H
IV: R = OCH_3



V



VI

similar chemical shifts in the ^{1}H-NMR spectra of I and II permitted the assignment in the latter compound of methyl groups attached to C-2, C-11, and C-21; an isopropenyl group at C-13; a C-6α,C-7α-epoxide bridge; a C-9α,C-13α,C-14α-orthoester function; a 1α-alkyl chain; and a benzoate ester substituent at C-3. The remaining sites for possible esterification by an acetate group are at hydroxy groups attached to C-4, C-5, C-20, or at some other site in the molecule. The first of these alternatives was ruled out because esterification of this tertiary hydroxy group is unlikely, and no C-4-esterified tigliane or daphnane esters have been found as natural products to date (10). In addition, no resonance shifts in the ^{1}H-NMR spectrum of II relative to that of I for the protons adjacent to C-4 suggested such ester substitution. Likewise, a lack of esterification at either C-5 or C-20 in II was evident from the observation of resonances at δ 4.05 and 3.81 ppm, respectively (7–9). Since no signal assignable for a C-12 methine proton was present in the ^{1}H-NMR spectrum of II at ~δ 5.00 ppm (11, 12), such as that observed at δ 4.93 ppm in the ^{1}H-NMR spectrum of the positional isomer of II, linifolin a (12β-acetoxy-Pimelea factor P_2) (8), by a process of elimination the acetate group was placed in the alkyl chain of II. Similarities in the ^{1}H-NMR resonances assigned for the C-16 methylene protons in II(δ 4.88, 5.07 ppm) with those in the 29β-hydroxylated 1α-alkyldaphnane ester gnidimacrin (δ 4.85, 5.09) [a structure established by X-ray crystallography (9)] suggested the presence of a 29β-acetoxy function in II. In support of this the C-16 methylene protons in Pimelea factor P_2 (I), with no electronegative group substitution at C-29 on the alkyl chain, were found to resonate in a slightly upfield position at δ 4.85 and 4.96 ppm. The observation of the C-29 methine proton chemical shift at δ 5.28 ppm as a doublet in the ^{1}H-NMR spectrum of II suggested that coupling was apparent with only the *cis*-oriented C-28 methylene proton.

The structural assignment proposed here for dircin (II) is tentative, since the limited amounts of this isolate obtained in this investigation did not permit selective hydrolysis experiments to be performed to confirm the relative positions of ester substitution. However, support for our assignment of dircin as II may be gathered from the fact that all 3-esterified 1α-alkyldaphnane esters isolated to date from plants of the

[1] For the previous article in this series, see Ref. 5.

[2] Plant extracts, fractions, and isolates were tested under the auspices of the Drug Research and Development Program of the National Cancer Institute. A compound is considered active *in vivo* if it exhibits a prolongation of life in excess of 125% and is regarded as cytotoxic if the ED_{50} is ≤4 μg/ml. In *in vivo* testing, samples were administered intraperitoneally to six CD_2F_1 male tumor-bearing mice over a 10-day period. Evaluation was carried out by comparison of survival times with control tumor-bearing animal groups.

[a] Tested according to standard protocols (6). [b] NT = not tested.

Thymelaeaceae have been found to possess a benzoate group at C-3 (7–10). Dircin (II) is thus assigned as 29β-acetoxy-Pimelea factor P_2, being the 29β-acetate ester of the parent structure 1,2,6,7-tetrahydro-5,29-dihydroxy-21-methyl-6α,7α-epoxy-1α-nonylresiniferonol-30-oic acid (10).

Daphnane esters (8–14), lignans (15, 16), and coumarins (5, 15) have all been found previously as antileukemic and/or cytotoxic constituents of plants in the family Thymelaeaceae. It is pertinent to point out that while Pimelea factor P_2 (linifolin b) was determined in an earlier investigation to be devoid of activity against the P-388 lymphocytic leukemia system *in vivo* (8), this compound was shown to be active against this test system at the higher dose levels used in this study (Table I). Dircin (II), the most potent of the compounds isolated from *D. occidentalis* (Table I), exhibits somewhat less intense activity in the P-388 test system than demonstrated by the 1α-alkyldaphnane esters gnidimacrin and gnidimacrin 20-palmitate, which were isolated from *Gnidia subcordata* Meisn (9). However, the previously demonstrated skin-irritant and mouse skin tumor-promoting activities of Pimelea factor P_2 (I) and other daphnane esters (10) may very well act to restrict the development of I and II as clinically useful anticancer agents.

EXPERIMENTAL[3]

Plant Material—The twigs and flowers of *D. occidentalis* A. Gray (Thymelaeaceae) were collected in California in August 1977[4].

Extraction and Fractionation—The air-dried, milled plant material (12.5 kg) was defatted with petroleum ether (bp 60–80°), with the marc being extracted with methanol. On removal of solvent *in vacuo*, the residue was partitioned between water and chloroform. Biological activity was concentrated in both the petroleum ether extract, which was not examined further, and the chloroform extract, which was active against the P-388 lymphocytic leukemia test system both *in vivo* (T/C 144% at 1.87 mg/kg) and *in vitro* (ED_{50} 0.21 μg/ml).

A portion (90 g) of the dried chloroform extract was chromatographed on silica gel[5] (2 kg), with 2-liter fractions being collected and pooled on the basis of similar TLC profiles. Fraction F037 (17 g), obtained by elution with chloroform–methanol (9:1), exhibited an ED_{50} of 0.07 μg/ml in the P-388 cell culture system, while combined fractions F040–F042 (2.2 g), eluted with chloroform–methanol (19:1 and 17:3), were also found to be cytotoxic (P-388, ED_{50} 0.043, 0.18, 0.14 μg/ml, respectively).

Fraction F037 was rechromatographed on silica gel[5] (820 g), and eluted with chloroform and chloroform–methanol mixtures of increasing polarity, to afford 50 fractions (500 ml each). Crystals of daphnoretin (VI, 50 mg, 0.000092%), (−)-medioresinol (III, 6 mg, 0.000011%) and (+)-syringaresinol (IV, 18 mg, 0.000033%) were successively obtained during this separation on elution with chloroform–methanol (99:1). However, the more polar fractions F060–F064 (1.2 g) were highly cytotoxic (P-388, ED_{50} 1.9×10^{-4}–4.8×10^{-6} μg/ml), and were rechromatographed on silica gel[5] (40 g). Fractions eluted with chloroform–methanol (9:1) were pooled (0.9 g) and subjected to low-pressure column chromatography on octylsilyl silica gel contained in a prepacked column[6], using solvent systems composed of water–acetonitrile–methanol mixtures of decreasing polarity. Two daphnane esters were obtained as a result of this separation and were purified by preparative TLC on silica gel G plates[5], developed with benzene–ethyl acetate–hexane–ether (3:3:1:1), as follows: Pimelea factor P_2 (I, R_f 0.49, 3 mg, 0.000005%) and dircin (II, R_f 0.36, 4 mg). Further quantities of II were obtained by workup of other active fractions from the chloroform extract of *D. occidentalis*, in a manner similar to that described above, to produce a total of 32 mg (0.000059%) of this compound.

Fractions F040–F042 were similarly chromatographed on silica gel[5] eluted with chloroform–methanol mixtures. (−)-Lariciresinol (V, 10 mg, 0.000018%) was eluted with chloroform–methanol (19:1) and was purified by recrystallization from acetone–hexane (1:1).

Characterization of Biologically Active Isolates—The resinous Pimelea factor P_2 (I) exhibited the following spectral data. IR ν_{max} ($CHCl_3$): 3500, 1740, 1580, 1420, 1365, and 1235 cm^{-1}; UV λ_{max} (MeOH) (log ε): 229 (3.85) and 279 (3.10) nm; ^{1}H-NMR (60 MHz): δ 0.83 (d, 3, J = 6.4 Hz, 18-CH_3), 1.04 (d, 3, J = 6.5 Hz, 19-CH_3), 1.47 (d, 3, J = 3.5 Hz, 22-CH_3), 1.73 (bs, 3, 17-CH_3), 2.90 (d, 1, J = 2.7 Hz, 8-H), 3.11 (d, 1, J = 11.0 Hz, 10-H), 3.34 (s, 1, 7-H), 3.85 (bs, 2, 20-H_2), 4.10 (s, 1, H-5), 4.27 (d, 1, J = 2.7 Hz, 14-H), 4.85 and 4.96 (two bs, 1 each, 16-H_2), 5.09 (d, 1, J = 4.0 Hz, 3-H), and 7.45–8.05 ppm (m, 5, aromatic H); MS (20 eV): *m/z* 638 (M^+, 12%), 607 (11), 595 (24), 480 (11), 475 (13), 467 (16), 327 (11), 309 (10), 279 (13), 269 (15), 265 (10), 203 (11), 176 (19), 163 (16), 161 (41), 149 (22), 121 (16), and 105 (100). These data are in agreement with those reported for Pimelea factor P_2 (Daphnopsis factor R_1) (7) and linifolin b (8). Identity was established as Pimelea factor P_2 by direct comparison with an authentic sample[7] (^{1}H-NMR, MS, co-TLC).

The resinous isolate dircin (II), $[\alpha]_D^{25}$ + 9.0° (*c* 0.07, $CHCl_3$), exhibited the following spectral data. IR ν_{max} ($CHCl_3$): 3500, 1700, 1450, 1360, and 1270 cm^{-1}; UV λ_{max} (MeOH) (log ε): 228 (3.91) and 278 (3.10) nm; ^{1}H-NMR (400 MHz): δ 0.98 (d, 3, J = 7.5 Hz, 18-CH_3), 1.08 (d, 3, J = 7 Hz, 19-CH_3), 1.32 (d, 3, J = 7.5 Hz, 22-CH_3), 1.77 (bs, 3, 17-CH_3), 2.04 (s, 3, —OCOCH_3), 2.95 (d, 1, J = 12 Hz, 10-H), 2.96 (d, 1, J = 3 Hz, 8-H), 3.32 (s, 1, 7-H), 3.81 (ABq, 2, J_{AB} = 12 Hz, 20-H_2), 4.05 (s, 1, H-5), 4.19 (d, 1, J = 3 Hz, 14-H), 4.88 (d, 1, J = 6 Hz, H-3), 4.88 and 5.07 (two bs, 1 each, 16-H_2), 5.28 (d, 1, J = 8 Hz, 29-H), 7.50 (t, 2, J = 8 Hz, 3′- and 5′-H), 7.63 (t, 1, J = 7.5 Hz, 4′-H), and 8.06 ppm (dd, 2, J = 1.5 and 7.5 Hz, 2′- and 6′-H); MS (20 eV): *m/z* 696 (M^+, 2%), 678 (2), 647 (2), 592 (1), 561 (2), 556 (3), 533 (3), 467 (4), 403 (4), 368 (3), 363 (3), 345 (4), 327 (6), 309 (6), 299 (3), 297 (3), 281 (9), 205 (12), 203 (5), 189 (9), 188 (9), 177 (9), 176 (16), 161 (19), 148 (15), 147 (13), 133 (10), 123 (11), 122 (20), and 105 (100); field-desorption MS: MH^+ observed at *m/z* 697.

(−)-Medioresinol (III), mp 155–160°, $[\alpha]_D^{25}$−17.0° (*c* 0.14, $CHCl_3$) [lit. (17) (+)-medioresinol, mp 175–176°, $[\alpha]_D$ +57.4° ($CHCl_3$)], exhibited the following spectral data. IR ν_{max} (KBr): 3450, 3090, 1600, 1505, 1445, 1415, 1355, 1270, 1235, 1190, 1145, 1095, 1045, 945, and 780 cm^{-1}; UV λ_{max} (95% EtOH) (log ε): 220 sh (4.58), 232 (4.13), and 280 (3.58) nm; ^{1}H-NMR (60 MHz): δ 3.01–3.16 (m, 2, 8- and 8′-H), 3.88 (s, 9, 3 × —OCH_3), 3.76–3.98 and 4.13–4.30 (m, 4, 9- and 9′-H_2), 4.73 (dm, 2, J = 4.0 Hz, 7- and 7′-H), 5.48 (s, 1, phenolic OH), 5.59 (s, 1, phenolic OH), 6.58 (s, 2, 2- and 6-H), and 6.86 ppm (m, 3, 2′-, 5′-, and 6′-H); MS: *m/z* 388 (M^+, 100%), 358 (8), 235 (8), 210 (17), 206 (19), 193 (23), 182 (38), 181 (48), 180 (21), 167 (33), 163 (21), 161 (19), 154 (17), 151 (48), 137 (35), 124 (10), and 123 (10). These spectral data are in agreement with those published for (+)-medioresinol (17), and III exhibited identical TLC migration data to an authentic sample of (+)-medioresinol[8]. (−)-Medioresinol has not been isolated from a plant source previously.

[3] Melting points were determined by means of a Kofler hot-plate apparatus and are uncorrected. Specific rotations were measured on a Perkin-Elmer 241 polarimeter. The UV spectra were obtained with a Beckman DB-G spectrophotometer and IR spectra on a Beckman model 18-A spectrophotometer, with polystyrene calibration at 1601 cm^{-1}. ^{1}H-NMR spectra were recorded in $CDCl_3$ with a Varian T-60A instrument operating at 60 MHz, equipped with a Nicolet Model TT-7 attachment. Tetramethylsilane was used as an internal standard, and chemical shifts are reported in δ (ppm). Low-resolution mass spectra were obtained with a Varian MAT-112S double-focusing spectrometer, operating at 70 eV.

[4] Plant material was collected and identified by staff of the Economic Botany Laboratory, BARC-East, U.S.D.A., Science and Education Administration, Beltsville, Md. A voucher specimen representing this collection has been deposited in the Herbarium of the National Arboretum, Washington, D.C.

[5] E. Merck, Darmstadt, W. Germany.

[6] Lobar, size B, containing LiChoprep RP-8 (40–63 μm); manufactured by E. Merck, Darmstadt, W. Germany.

[7] An authentic sample of Pimelea factor P_2 and a copy of its ^{1}H-NMR spectrum were kindly supplied by Professor E. Hecker.

[8] Authentic samples of (+)-medioresinol and (±)-syringaresinol were kindly provided by Dr. H. Fujimoto.

(+)-Syringaresinol (IV), mp 173–175°, $[\alpha]_D^{25}$+12.8° (*c* 0.05, $CHCl_3$) [lit. (17) mp 171–173°, $[\alpha]_D$ +19.0° ($CHCl_3$)], exhibited the following spectral data. IR ν_{max} (KBr): 3450, 3080, 1600, 1510, 1445, 1415, 1370, 1190, 1100, 980, 840, and 730 cm^{-1}; UV λ_{max} (95% EtOH) (log ϵ): 220 sh (4.16), 239 (4.05), and 273 (3.27) nm; ^{1}H-NMR (60 MHz): δ 3.07 (m, 2, 8- and 8′-H), 3.89 (s, 12, 4 × —OCH_3), 3.80–3.99 and 4.16–4.42 (m, 4, 9- and 9′-H_2), 4.73 (d,2, J = 4.0 Hz, 7- and 7′-H), 5.54 (s, 2, 4- and 4′-H), and 6.58 ppm (s, 4, 2-, 6-, 2′-, and 6′-H); MS: *m/z* 418 (M^+, 100%), 403 (3), 358 (3), 280 (4), 251 (5), 235 (11), 210 (16), 193 (25), 182 (41), 181 (65), 167 (56), 161 (18), 154 (17), and 151 (19). These spectral data are in agreement with those reported for (+)- and (±)-syringaresinol (17, 18), and the identification of IV as (+)-syringaresinol was confirmed by direct comparison (MS, co-TLC) with an authentic sample of (±)-syringaresinol.

(−)-Lariciresinol (V), mp 160–162°, $[\alpha]_D^{25}$−17.8° (*c* 1.4, acetone), exhibited the following spectral properties. IR ν_{max} (KBr): 3320, 3090, 1510, 1460, 1420, 1230, 1035, and 845 cm^{-1}; UV λ_{max} (MeOH) (log ϵ): 232 (4.17) and 283 (4.02) nm; ^{1}H-NMR (60 MHz): δ 2.2–3.0 (m, 4, 7-H_2, 8- and 8′-H), 3.5–4.1 (m, 4, 9- and 9′-H_2), 3.70 (s, 3, —OCH_3), 3.82 (s, 3, —OCH_3), 4.78 (d, 1, J = 6.2 Hz, 7′-H), 5.61 (m, 2, phenolic OH), and 6.70–6.83 ppm (m, 6, aromatic H); MS: *m/z* 360 (M^+, 62%), 345 (4), 329 (1), 252 (8), 236 (11), 194 (22), 180 (12), 175 (10), 167 (11), 153 (31), 151 (47), 137 (100), and 122 (17). These spectral data are similar to those expressed previously for (+)-lariciresinol (19), and V was closely comparable to an authentic sample[9] of (+)-lariciresinol (MS, co-TLC). The (−)-enantiomer of this lignan does not appear to have been obtained previously from a plant source.

Daphnoretin (VI), mp 243–244°, exhibited the following spectral data. IR ν_{max} (KBr): 3400, 3080, 1722, 1715, 1618, 1585, 1565, 1280, 1245, 1085, 840, and 757 cm^{-1}; UV λ_{max} (MeOH) (log ϵ): 230 (4.13), 267 (3.80), 325 (4.17), and 343 (4.22) nm; ^{1}H-NMR (60 MHz, DMSO-d_6): δ 3.83 (s, 3, —OCH_3), 6.35 (d, 1, J = 9.5 Hz, 3′-H), 7.03–7.78 (m, 5, aromatic H), 7.85 (s, 1, 4-H), and 8.01 (d, 1, J = 9.5 Hz, 4′-H); MS: *m/z* 352 (M^+, 100%), 337 (4), 324 (5), 309 (11), 262 (5), 179 (25), 167 (20), and 89 (18). Compound VI was identified as daphnoretin on the basis of consistency of the above data with published spectral data for this compound (15, 20–22), and confirmation of this identity was made by direct comparison with an authentic sample[10].

Biological Activity of the Isolates—The activities of isolates I–VI from *D. occidentalis* against the P-388 lymphocytic leukemia test system, *in vivo* and *in vitro*, are shown in Table I.

[9] An authentic sample of (+)-lariciresinol was donated by Dr. S. F. Fonseca.

[10] Daphnoretin was isolated in our laboratory previously from *Peddia fischeri* (5).

Demethylation of Imipramine by Enteric Bacteria

ALICE M. CLARK *, ROBERT T. CLINTON *,
JOHN K. BAKER ‡, and CHARLES D. HUFFORD *x

Received March 19, 1982, from the *Department of Pharmacognosy and the ‡Department of Medicinal Chemistry, School of Pharmacy, University of Mississippi, University, MS 38677. Accepted for publication September 30, 1982.

Abstract □ The ability of a number of aerobic and anaerobic bacteria to *N*-demethylate imipramine (I) to desipramine (II) has been investigated. Of the bacteria investigated, almost half were known inhabitants of the human GI tract. More than half of the enteric bacteria studied were capable of *N*-demethylating imipramine (I) to desipramine (II) to some extent in at least one medium. It was found that the medium in which the organism was grown had a significant effect on the *N*-demethylase activity observed.

Keyphrases □ Imipramine—*N*-demethylation to desipramine, microbial transformation, enteric bacteria □ Microbial transformation—imipramine, *N*-demethylation to desipramine, enteric bacteria □ Desipramine—microbial *N*-demethylation of imipramine, enteric bacteria

Imipramine (I) is a widely used tricyclic antidepressant whose metabolism, distribution, and excretion has been studied in detail (1–5). Desipramine (II) is a biologically active metabolite of imipramine which is formed by hepatic as well as by extrahepatic metabolism (6). A major site of extrahepatic metabolism has been shown to be the GI contents (6). It has also been shown that demethylation of I does not occur during passage across the intestinal wall (7). The role of the GI microflora in drug metabolism has been reviewed and has been shown to be a significant factor with many drugs (8–11). The microbial metabolism of imipramine using a number of fungi has also been shown to parallel the mammalian metabolism of imipramine (12). This study examined the metabolism of imipramine by bacteria, many of which are known to be inhabitants of the human GI tract.

EXPERIMENTAL

Imipramine hydrochloride (I)[1] was shown to be free of desipramine (II) and iminodibenzyl (III), known contaminants of some commercial samples of imipramine (13), by high-performance liquid chromatographic (HPLC) and TLC analyses. Desipramine hydrochloride was also shown to be pure by HPLC and TLC analyses. All solvents used for HPLC analysis were reagent grade quality.

II: R = $(CH_2)_3NHCH_3$
III: R = H

Fermentation Screening Procedures for Aerobic Bacteria—Aerobic bacterial stock cultures were maintained on nutrient agar[2] and eugon agar[3] at 4° and transferred every 4–6 months. Screening for the demethylation of imipramine to desipramine was carried out in four different media. Three of the media used were complex media; the fourth was a defined medium. The media used were: eugon broth[3] (medium A); 5 g of dextrose, 2 g of corn steep liquor, 5 g of yeast extract, 1 g of peptone, and 1 liter of distilled water (medium B); 20 g of dextrose, 5 g of peptone, 5 g of tryptone, 2.5 g of $CaCO_3$, and 1 liter of distilled water (medium C); and 780 ml of basal salts solution (14) [containing 1.5 g of KH_2PO_4, 7.0 g of $(NH_4)_2HPO_4$, 0.5 g of $MgSO_4 \cdot 7H_2O$, 0.3 g of $CaCl_2 \cdot 2H_2O$, 0.04 g of $MnSO_4 \cdot 4H_2O$, 0.025 g of $FeSO_4 \cdot 7H_2O$, 0.002 g of ammonium molybdate, and 1 liter of distilled water], 100 ml of amino acid solution (containing 0.38 g of DL-alanine, 0.89 g of DL-aspartic acid, 0.30 g of L-arginine hydrochloride, 0.02 g of L-cystine, 0.140 g of L-glutamic acid, 0.17 g of glycine, 0.24 g of L-histidine hydrochloride, 0.76 g of DL-isoleucine, 0.57 g of L-leucine, 0.24 g of L-lysine hydrochloride, 0.06 g of DL-methionine, 0.11 g of L-proline, 0.12 g of DL-serine, 0.10 g of DL-threonine, 0.06 g of L-tyrosine, 0.15 g of DL-valine, and 100 ml of distilled water), 20 ml of vitamin solution (15) (containing 5.0 μg of biotin, 10.0 μg of folic acid, 0.5 mg of riboflavin, 2.5 mg of thiamine hydrochloride, 2.5 mg of pyridoxal hydrochloride, 2.5 mg of calcium pantothenate, 2.5 mg of nicotinic acid, and 100 ml of distilled water), and 100 ml of glucose solution (30%, w/v) (medium D).

A two-stage fermentation procedure was utilized as previously described (12). For screening in media A–C, the cultures were grown in 25 ml of medium held in 125-ml Erlenmeyer flasks. The cultures were incubated at 37° and 250 rpm. Imipramine hydrochloride was added to 24-hr-old stage II cultures as a 5% solution in dimethylformamide to give a final concentration of 200 μg/ml of medium. The cultures were incubated for 6 days and assayed for desipramine formation at 3 and 6 days after substrate addition. The samples were adjusted to pH 8 and extracted with three equal volumes of chloroform. The combined chloroform layers were dried and evaporated, and the residues were analyzed by TLC and HPLC.

For screening in medium D, the cultures were grown in 10 ml of medium held in 50-ml Erlenmeyer flasks, incubated at 250 rpm and 37°. Imipramine hydrochloride was added to sterile medium D prior to inoculation of stage II cultures. The substrate was added as a 1% dimethylformamide solution to give a final concentration of 100 μg/ml of medium. The stage II cultures, containing substrate, were incubated for 48 hr. Each whole culture was adjusted to pH 8 and extracted with an equal volume of dichloromethane, and the dichloromethane extracts were evaporated and analyzed by TLC and HPLC.

Fermentation Screening Procedures for Anaerobic Bacteria—Stock cultures of anaerobic bacteria were maintained in appropriate agar or broth media in disposable anaerobic systems[4]. Screening for desipramine production was carried out in 10 ml of either brain heart infusion broth[3] or medium E which consisted of 20 g of peptone, 10 g of yeast extract, 5 g of glucose, 5 g of maltose, 0.5 g of cysteine, 40 ml of salts solution, and 4 ml of a 0.025% aqueous solution of resazurin per liter of distilled water. The salts solution consisted of 0.1 g of K_2HPO_4, 0.1 g of KH_2PO_4, 1.0 g of $NaHCO_3$, 0.2 g of NaCl, 0.02 g of $CaCl_2$, 0.02 g of $MgSO_4$, trace amounts of ammonium molybdate and $CoCl_2 \cdot 6H_2O$, and 0.3 ml of 50% H_2SO_4 per 200 ml of distilled water. Each medium was dispersed into 16 × 125-mm screw-cap test tubes (10 ml/tube) and sterilized by autoclaving at 121° and 15 psi for 20 min. After sterilization each medium was supplemented with 100 μg of imipramine hydrochloride/ml of medium.

The sterile medium containing imipramine was inoculated from stock cultures of anaerobic bacteria (0.05 ml broth culture/10 ml sterile medium). The cultures were incubated at 37° under anaerobic conditions[4] for 7 days, at which time the whole cultures were extracted and analyzed as described for aerobic cultures grown in medium D.

Control Studies—Culture controls consisted of fermentation blanks in which each organism was grown under identical conditions as biotransformation cultures, but without substrate. The cultures were extracted and analyzed as described for the biotransformation cultures.

Substrate controls were necessary to establish the stability of the substrate to the fermentation conditions used. Therefore, substrate controls were obtained for each set of medium and incubation conditions used. Substrate controls for aerobic cultures grown in media A–C were

obtained by growing stage II cultures of two representative organisms (*Escherichia coli* 10536 and *Bacillus cereus* v. *fluorescens* 13024) in each medium for 7 days (250 rpm, 37°). The cultures were then sterilized by autoclaving. Imipramine hydrochloride (200 μg/ml of medium) was added to the sterilized cultures, which were incubated an additional 6 days at 37° and 250 rpm. The sterilized substrate control cultures were then extracted and analyzed as described for aerobic cultures grown in media A–C. Five cultures of *E. coli* 10536 and two cultures of *B. cereus* v. *fluorescens* 13824 were used to determine medium A control values. For medium B control values, five cultures of *E. coli* 10536 and three cultures of *B. cereus* v. *fluorescens* 13824 were used. For medium C five cultures of each organism were used. Three cultures of *B. cereus* v. *fluorescens* grown in medium A and two cultures grown in medium B became contaminated after sterilization and addition of imipramine, and therefore could not be used in calculating control values. In addition, substrate controls consisting of sterile media (A–C) containing imipramine (200 μg/ml) were prepared and incubated at 250 rpm and 37° for 6 days (five determinations/medium). Each substrate control was extracted and analyzed as described for growing cultures. In addition, substrate controls consisting of sterile medium D containing imipramine (100 μg/ml of medium) were prepared and incubated at 250 rpm and 37° for 48 hr (five determinations). Each substrate control was extracted and analyzed as described for aerobic cultures grown in medium D.

Substrate controls for anaerobic media were obtained by growing each of the seven anaerobic bacteria in media without imipramine for 7 days. The cultures were then sterilized by autoclaving. After cooling, imipramine hydrochloride was added (100 μg/ml of medium) and incubation under anaerobic conditions[4] (37°) was continued an additional 7 days. The substrate control cultures were then extracted and analyzed as described for aerobic cultures grown in medium D.

TLC Analyses—Culture extracts were redissolved in 100 μl of chloroform or dichloromethane, and 6-μl aliquots of the solutions were spotted on precoated silica gel G TLC plates[5]. The plates were developed in ethyl acetate–methanol–ammonium hydroxide (81:15:4) and visualized by UV light and by spraying with diazotized *p*-nitroaniline followed by spraying with concentrated hydrochloric acid. The R_f values and colors for imipramine and desipramine are 0.57 (blue) and 0.29 (blue), respectively.

HPLC Analyses—Quantitative analyses of the culture extracts were accomplished on a silica column[6] using an HPLC pump[7], a microsyringe-loaded loop injector[8], and a UV detector[9]. The mobile phase consisted of methanol–2 *N* ammonia–1 *N* ammonium nitrate (27:2:1) and was used at a flow rate of 1.0 ml/min. Culture extracts were redissolved in 400 μl of methanol, and 5-μl aliquots of the solutions were injected for HPLC. Quantitation of desipramine in culture extracts was accomplished by comparison of the peak heights in culture extracts with the peak heights of standard samples of desipramine at known concentrations.

For aerobic cultures grown in complex media (A–C), desipramine levels were considered significant if the level exceeded the sterilized control value plus four times the standard deviation for that medium. Thus, for medium A, levels <0.56% were not considered significant and for media B and C, levels <0.59% and 0.64%, respectively, were not considered significant. For aerobic cultures grown in medium D, a sterilized control value was established for each organism. In these cases, yields of desipramine that exceeded 3 times the control value were considered significant. The same criterion was used for determining significant *N*-demethylase activity among anaerobic bacteria.

RESULTS AND DISCUSSION

Imipramine (I) was subjected to biotransformation screening using 29 aerobic and 7 anaerobic bacteria. Of the aerobic bacteria, nine are known to be inhabitants of the human GI tract; these organisms were screened in three complex media (media A–C) and one defined medium (D). The remaining 20 aerobic bacteria were screened in the three complex media (A–C). All seven anaerobic bacteria were screened for their ability to *N*-demethylate imipramine in two complex media: brain heart infusion broth and medium E. Cultures grown in the presence of imipramine were extracted with either dichloromethane or chloroform, and the extracts were analyzed by TLC and HPLC. The results of these studies are summarized in Tables I–III.

[a] Yields are expressed as percent yield on a mole basis. [b] Considered as significant *N*-demethylase activity, based on a minimum value of the sterilized control value plus 4 times the standard deviation. [c] These cultures were not analyzed by HPLC since TLC analysis showed no desipramine. [d] Known inhabitants of the gut. [e] Sterilized control values are expressed as the average (±*SD*) of 7–10 determinations using sterilized cultures of two representative organisms, *E. coli* 10536 and *B. cereus* v. *fluorescens* 13824, grown in each of the three media. [f] Simple control values are expressed as the average (±*SD*) of five determinations in which imipramine was incubated in each of the sterile media for 6 days.

The quantitative results obtained from HPLC analyses of aerobic bacteria grown in complex media (A–C) containing imipramine are shown in Table I. The results obtained from HPLC analyses of aerobic gut bacteria grown in the defined medium (D) containing imipramine are shown in Table II. Twelve of the twenty-nine organisms screened were capable of *N*-demethylation in medium A. In media B and C, six of the bacteria screened could *N*-demethylate imipramine (Table I). In total, 16 of the 29 aerobic bacteria screened, including 5 of the 9 gut bacteria, were capable of *N*-demethylating imipramine to some extent in at least one of the complex media (Table I).

Two additional gut bacteria, which were incapable of *N*-methylation in the complex media, were shown to *N*-demethylate imipramine when grown in medium D (Table II). One organism, *Streptococcus faecalis* 6569 would not grow in medium D. Only two aerobic gut bacteria, *Klebsiella pneumoniae* 29016 and *Streptococcus faecium* 6056, were capable of *N*-demethylation in both complex (A) and defined media (D).

A number of anaerobic bacteria were also screened for their ability to *N*-demethylate imipramine (I). A total of seven anaerobes known to inhabit the GI tract of the human were screened for *N*-demethylase activity in two complex media. The results of these studies are shown in Table III. Only one anaerobe, *Fusobacterium fusiforme* 23726 showed signifi-

Table II—Yields of Desipramine by Aerobic Gut Bacteria in Defined Medium [a]

Bacterium (ATCC number)	Yields of Desipramine	
	Growing Cultures	Control Cultures[b]
Enterobacter aerogenes (13048)	0.72	0.60
Escherichia coli (27165)	2.02[c]	0.67
Klebsiella pneumoniae (27889)	2.19	1.23
K. pneumoniae (29016)	1.12[c]	0.22
Proteus vulgaris (27973)	1.77[c]	0.52
Pseudomonas aeruginosa (14205)	2.20	1.58
Staphylococcus aureus (14458)	0.55	0.19
Streptococcus faecalis (6569)	—[d]	—[d]
Streptococcus faecium (6056)	1.60[c]	0.52

[a] Yields are expressed as percent yield on a mole basis. [b] Simple substrate controls consisting of sterile medium containing imipramine showed an average percent yield of desipramine of 0.17 ± 0.05 after 48 hr of incubation. [c] Considered as significant *N*-demethylase activity, based on a minimum value of 3 times the control value. [d] No growth in this medium.

cant *N*-demethylase activity in medium E. However, in brain heart infusion medium, four of the seven anaerobes (*Bacteroides eggerthii* 27754, *Bifidobacterium longum* 15707, *Clostridium paraperfringens* 27640, and *Lactobacillus catenaforme* 25644) were capable of *N*-demethylation. It is interesting to note that *F. fusiforme* 23726 did not show *N*-demethylase activity in brain heart infusion medium. Therefore, as with the aerobic bacteria, it appears that the choice of medium is important in demonstrating *N*-demethylase activity in anaerobic bacteria.

Table III—Yields of Desipramine from Anaerobic Bacteria in Complex Media [a]

Bacterium (ATCC number)	Yield of Desipramine			
	Growing Cultures in Medium E	Control Cultures in Medium E	Growing Cultures in Brain Heart Infusion Medium	Control Cultures in Brain Heart Infusion Medium
Bacteroides eggerthii (27754)	0.58	0.55	1.28[b]	0.31
Bifidobacterium adolescentis (15703)	0.80	0.65	0.53	0.26
Bifidobacterium bifidum (15696)	0.66	0.34	0.68	0.47
Bifidobacterium longum (15707)	0.48	0.26	1.73[b]	0.45
Clostridium paraperfringens (27640)	0.52	0.42	0.78[b]	0.22
Fusobacterium fusiforme (23726)	0.78[b]	0.21	0.39	0.24
Lactobacillus catenaforme (25644)	0.60	0.42	0.81[b]	0.21

[a] Yields are expressed as percent yield on a mole basis. [b] Considered as significant *N*-demethylase activity, based on a minimum value of 3 times the control value.

Based on these studies, it appears that *N*-demethylase activity was common among bacteria. Of particular interest were the enteric bacteria, both aerobic and anaerobic. A high percentage of the gut bacteria screened were capable of *N*-demethylation of imipramine to desipramine. Among the anaerobic bacteria, five of seven were capable of *N*-demethylating imipramine to desipramine as were seven of nine aerobic gut bacteria. The medium in which the organism was grown appeared to have a significant influence on the *N*-demethylase activity. Since it is known that considerable variability exists in response to imipramine therapy, the variable *N*-demethylation of imipramine may be an important consideration (16). A similar situation occurs with digoxin in which the gut flora metabolizes the drug to biologically inactive metabolites in some patients, lowering their plasma levels of digoxin (17).

Microbial Transformations of Natural Antitumor Agents XXII: Conversion of Bouvardin to *O*-Desmethylbouvardin and Bouvardin Catechol

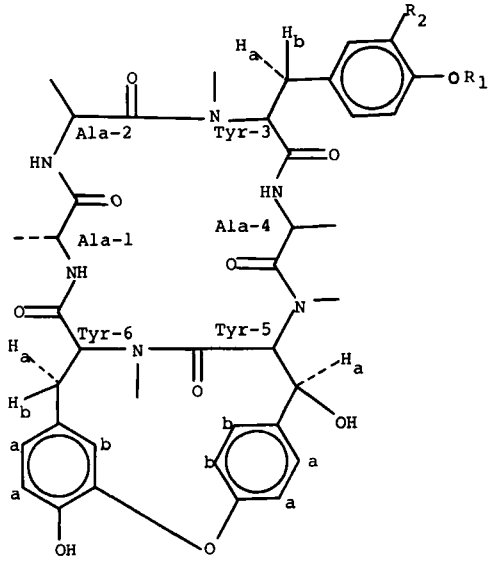
RICHARD J. PETROSKI *, ROBERT B. BATES ‡, GARY S. LINZ ‡, and JOHN P. ROSAZZA *x

Received July 19, 1982, from the **Division of Medicinal Chemistry and Natural Products, College of Pharmacy, The University of Iowa, Iowa City, IA 52242* and the ‡*Department of Chemistry, College of Liberal Arts, University of Arizona, Tucson, AZ 85721.* Accepted for publication September 9, 1982.

Abstract □ Bouvardin is a cyclic hexapeptide antitumor agent which undergoes two major microbial transformation reactions. Screening with 220 cultures revealed 17 different strains capable of producing *O*-desmethylbouvardin in good yield. *O*-Desmethylbouvardin was isolated and characterized from preparative scale incubations with *Streptomyces rutgersensis* NRRL B-1256. Four aspergilli and one streptomycete formed bouvardin catechol when *O*-desmethylbouvardin was used as substrate. Bouvardin catechol was isolated and characterized from a preparative scale incubation with *Aspergillus ochraceous* UI 398.

Keyphrases □ Bouvardin—conversion to *O*-desmethylbouvardin and bouvardin catechol, microbial transformation, *Streptomyces rutgersensis, Aspergillus ochraceous* □ Microbial transformation—bouvardin to *O*-desmethylbouvardin and bouvardin catechol, *Streptomyces rutgersensis, Aspergillus ochraceous* □ Metabolites—bouvardin, microbial transformation to *O*-desmethylbouvardin and bouvardin catechol, *Streptomyces rutgersensis, Aspergillus ochraceous*

Bouvardin (I), a novel cyclic hexapeptide antitumor agent isolated from the plant *Bouvardia ternifolia* (Rubiaceae) (1), has demonstrated antitumor activity against the P-388 lymphocytic leukemia test system and against B-16 melanoma (1). Modification of bouvardin by synthetic methods appeared to be difficult; thus, this material was deemed an excellent candidate for microbiological modification (2). This report describes microbial transformation experiments of bouvardin which afforded two major metabolites, *O*-desmethylbouvardin (II) and bouvardin catechol (III).



I: $R_1 = CH_3$, $R_2 = H$
II: $R_1 = R_2 = H$
III: $R_1 = H$, $R_2 = OH$

EXPERIMENTAL

Melting points were determined in open-ended capillary tubes and are corrected. UV spectra[1] were measured in ethanol solutions, and IR spectra[2] were determined in potassium bromide pellets. ^{1}H-NMR spectra[3] were obtained in $CDCl_3$ using tetramethylsilane as an internal standard. ^{13}C-NMR spectra were obtained in DMSO-d_6 at 90 MHz with an instrument operating at 22.635 MHz. Assignments for appropriate carbon signals were confirmed by use of off-resonance noise decoupling and delayed decoupling techniques to indicate multiplicities of carbons due to carbon-proton splittings. Low-resolution mass spectra[4] were obtained using a direct-inlet probe, and high-resolution and field-desorption mass spectra were provided through the mass spectral facility of the Massachusetts Institute of Technology, Cambridge, Mass.

Chromatography—TLC was performed on buffered 0.25-mm layers of silica gel GF_{254} on glass plates. Plates were prepared by spreading a slurry of 25 g of silica gel GF_{254} in 50 ml of 4% aqueous KH_2PO_4. After air drying, plates were uniformly deactivated by predevelopment with methyl ethyl ketone saturated with water. Plates were developed with methylene chloride–methanol–water (90:10:0.5 or 85:10:0.5), and developed chromatograms were visualized by fluorescence quenching under 254-nm UV light, or by spraying with Dragendorff's reagent (3) or with ceric ammonium sulfate reagent [1% $Ce(NH_4)_4(SO_4)_4$ in 50% H_3PO_4] and warming the sprayed plates with a heat gun.

Bouvardin (I)—Bouvardin was obtained[5] as a crystalline compound which possessed the following physical properties: mp 240–241°; UV (EtOH): 278 (ϵ 3780) and 284 nm (3370); IR: 3620 (OH phenolic), 1680 (amide C=O), and 1245 cm^{-1} (C—O—C); ^{1}H-NMR: see Table I; mass spectrum (field-desorption): m/z 772 for $C_{40}H_{48}N_6O_{10}$; high-resolution mass spectral fragments obtained by electron-impact spectroscopy: see Table II. ^{13}C-NMR spectral data was obtained on a DMSO-d_6 solution of bouvardin and was identical to that reported by Bates *et al.* (4).

Fermentation Procedure—All cultures are maintained in the University of Iowa, College of Pharmacy culture collection. Cultures were grown according to the usual two-stage fermentation procedure used in these laboratories (5) in a soybean meal–glucose medium of the following composition: 5 g of soybean meal; 20 g of glucose, 5 g of yeast extract, 5 g of sodium chloride, 5 g of dibasic potassium phosphate, and 1000 ml of distilled water; the pH was adjusted to 7.0 with 6 *N* HCl. Nutrient broth[6] was employed in the cultivation of bacterial strains. Media were sterilized in an autoclave at 121° for 15 min prior to use.

Fermentations were conducted on rotary shakers[7] operating at 250 rpm and describing a 2.5-cm orbital stroke at 27° in steel-capped Delong culture flasks containing one-fifth of their volumes of culture medium. Fermentations were initiated by suspending the surface growth from slants in 5 ml of sterile medium and by using the resulting suspension to inoculate stage I cultures. Thick 72-hr stage I cultures were used to inoculate stage II fermentations; the inoculum volume consisted of 10% of the volume of medium held in the stage II culture flasks. Bouvardin was added as substrate to 24-hr stage II cultures in a dimethylformamide solution, and the progress of microbial transformation reactions was monitored by TLC. For this, 4-ml samples were withdrawn at various time intervals, adjusted to pH 6.5 by the addition of 1 ml of 2 *M* pH 6.3

phosphate buffer, and extracted with 1 ml of ethyl acetate. Approximately 30 μl of the extracts were spotted onto TLC plates for analysis.

Small-scale fermentations were used to screen 220 microorganisms for their abilities to metabolize bouvardin. Screening experiments were conducted in 125-ml steel-capped Delong flasks in 25 ml of medium, and 10 mg of bouvardin was added to each culture. Initial screening results were confirmed in a second experiment with control cultures containing no substrate and with autoclaved cultures incubated with bouvardin.

Preparation of *O*-Desmethylbouvardin (II) from Bouvardin by *Streptomyces rutgersensis* (NRRL) B-1256)—*S. rutgersensis* was grown in 500- or 1000-ml culture flasks, and a total of 3.36 g of I in 22.4 ml of dimethylformamide was evenly dispensed to a final concentration of 0.6 mg of bouvardin/ml of culture medium in the 24-hr stage II cultures. Conversions of bouvardin to one major metabolite commenced within 24 hr and neared completion after 12 days of incubation (TLC). Cells were separated from the fermentation beer by filtration, and the combined filtrates were adjusted to pH 6.5 with 10% aqueous KOH. The filtrate (5.5 liters) was extracted exhaustively with ethyl acetate (2 × 2.5 liters) and then with ethyl acetate–2-propanol (9:1, 2 × 2 liters). The extracts were combined, dried over anhydrous sodium sulfate, filtered, and evaporated to a thick oily residue. This residue was triturated with water to remove the dimethylformamide, and the resulting suspension was filtered through a sintered glass funnel to collect the bouvardin-containing solids. The crude product (4.57 g) was purified by column chromatography on silica gel[8] (90 g, 3 × 35 cm) using a solvent system of methylene chloride–methanol–water (90:10:0.5) at a flow rate of 0.7 ml/min; 20-ml fractions were collected. Fractions 17–24 contained bouvardin (0.49 g), while fractions 25–42 provided *O*-desmethylbouvardin (II) (2.53 g, 79% yield). Recrystallization of the metabolite from ethyl acetate yielded the analytical sample (1.91 g): mp 224.5–227.0°; UV: 239.5 (6850), 278 (3540), and 280 nm (3560); IR: 3380 (OH phenolic), 1680 (amide C=O), and 1245 cm^{-1} (C—O—C); ^{1}H-NMR; see Table I; mass spectrum (field-desorption): *m/z* 797 ($M + K^+$), 781 ($M + Na^+$), 758 (M^+ for $C_{39}H_{46}N_6O_{10}$), and 740 ($M - H_2O$); electron-impact mass spectral data: see Table II.

Preparation of Bouvardin Catechol (III) from *O*-Desmethylbouvardin (II) by *Aspergillus ochraceous*—*A. ochraceous* (UI 398) was grown in 12, 1-liter Delong culture flasks for the stage II incubation. A total of 960 mg of II was dissolved in 9.6 ml of dimethylformamide and dispensed evenly among the cultures to give a final *O*-desmethylbouvardin concentration of 0.4 mg/ml in culture medium. Ascorbic acid (500 mg in 4 ml of H_2O) was added to each flask at 48 hr after addition of *O*-desmethylbouvardin, when TLC analyses first indicated the presence of III (6). After 96 hr, TLC estimation indicated an 80% conversion of II to III, and the fermentation was harvested.

Cells were separated from the medium by filtration through cheesecloth, and the cells were extracted with ethyl acetate (200 ml). This extract was later combined with culture filtrate extracts. The filtrate (2000 ml) was extracted with ethyl acetate (3 × 1 liter) and then with ethyl acetate–2-propanol (9:1, 1 liter). After drying the combined extracts over anhydrous sodium sulfate, evaporation yielded an oily residue (800 mg), which was dissolved in methylene chloride–methanol–water (90:10:0.5, 5 ml) and applied to silica gel column (90 g, 3 × 35 cm). The column was

[8] Baker 3405; J. T. Baker Chemical Co., Phillipsburg, N.J.

eluted at a flow rate of 0.7 ml/min while 20-ml fractions were collected. After 50 fractions, the solvent was changed to methylene chloride–methanol–water (90:20:0.5) for an additional 30 fractions. Fractions 14–24 contained unreacted *O*-desmethylbouvardin (II) (164 mg), fractions 25 and 26 contained a mixture of II and III (49 mg), and fractions 27–55 contained bouvardin catechol (III) (280 mg, 34.5% yield based on substrate utilized). The crude bouvardin catechol was dissolved in methyl ethyl ketone (10 ml), and 50 ml of hexane was added to precipitate 262 mg of the catechol (III) from solution. This material was collected by filtration and gave the following physical data: mp 221–223°; UV: 284 nm (2740); IR: 3350 (broad, OH phenolic), 1650 (amide C=O), and 1270 cm^{-1} (C—O—C); ^{1}H-NMR: see Table I; mass spectrum (field-desorption): *m/z* 797 ($M + Na^+$) and 774 (M^+ for $C_{39}H_{46}N_6O_{11}$); electron-impact spectrum: see Table II. The Arnow's test was positive, indicative of a catechol moiety in the structure of the metabolite (7).

RESULTS AND DISCUSSION

Compounds such as bouvardin whose structural complexity render total synthesis or chemical modification difficult are excellent substrates for microbiological modification (2). The present study was designed to provide metabolites of bouvardin in sufficient quantity for biological evaluation to extend the structure–activity relationships of the antitumor peptide. Small-scale screening experiments with 220 cultures resulted in the identification of 17 microorganisms which accumulated the same major metabolite (Table III). The metabolite was produced in consistently high yield (TLC) by *S. rutgersensis* (NRRL B-1256), and this organism was selected for preparative-scale fermentation to obtain sufficient amounts of the metabolite for structure elucidation and biological testing. The metabolite was obtained in 79% yield in the preparative-scale incubation, and ^{1}H-NMR and mass spectral measurements supported its structure as *O*-desmethylbouvardin (II).

The ^{1}H-NMR spectrum of the metabolite was identical to that of bouvardin, except for the absence of the signal for the methoxyl group protons of the tyrosine-3 residue (Table I) and the presence of a new hydroxyl signal at 4.48 ppm. Similarly, the signal for the methoxyl carbon atom of bouvardin, which resonates at 55.494 ppm, was absent in the ^{13}C-NMR spectrum of the metabolite. Field-desorption mass spectral measurement provided a molecular ion of *m/z* 758 for the metabolite *versus m/z* 772 for bouvardin. While the electron-impact mass spectrum failed to provide ions at higher mass, the base peak of the metabolite spectrum was at *m/z* 107.04833 for C_7H_7O (Table II). This peak is derived from the *N*-methyltyrosine-3 residue of the metabolite. In bouvardin, the base peak exists at *m/z* 121.06343 for C_8H_9O, the methoxylated aromatic ring derived from the tyrosine-3 amino acid residue. These data strongly support the structure of the major bouvardin metabolite as *O*-desmethylbouvardin (II).

Since II could be efficiently produced by microbial transformation of bouvardin, this metabolite was also utilized as a substrate in microbial transformation experiments. *O*-Desmethylbouvardin (II) was screened with 10 cultures known to accomplish aromatic hydroxylation. Of the cultures examined, *Aspergillus alliaceus* (NRRL 315), *A. ochraceous* (UI 398). *A. ochraceous* (NRRL 1008), and *Streptomyces griseus* (UI 1158) provided the same more polar (TLC) metabolite of II. *A. ochraceous* UI 398 gave the highest and most consistent yields of the new metabolite, and it was used in a preparative-scale incubation. In the preparative-scale fermentation, ascorbic acid was employed to prevent possible degradation of the phenolic starting material and the presumed catechol metabolite that was being formed. A similar approach was utilized in the microbial oxidation of *N*-blocked tyrosine residues to form *N*-blocked levodopa derivatives (6). Following solvent extraction and chromatography, the metabolite was obtained in 34.5% yield and was identified as bouvardin catechol by spectral and chemical methods.

A positive Arnow's test suggested that the metabolite possessed a catechol moiety in its structure (7). While the metabolite gave a positive test, *O*-desmethylbouvardin and bouvardin were negative. Field-desorption mass spectrometry indicated a molecular weight of 774 for the metabolite, consistent with the addition of a single oxygen atom to *O*-desmethylbouvardin. The base peak in the electron-impact spectrum (Table II) of the metabolite was at *m/z* 123.04461 for $C_7H_7O_2$, which would be expected if an oxygen atom had been introduced into the tyrosine-3 residue of *O*-desmethylbouvardin. This fragment is supported by the presence of a characteristic catechol fragment at *m/z* 110.03977 for $C_6H_6O_2$, which was intense in the spectrum of the metabolite but relatively insignificant in the spectrum of *O*-desmethylbouvardin or bouvardin (Table II).

A detailed analysis of the ^{1}H- and ^{13}C-NMR spectral properties of bouvardin has been made (4); this provided a useful tool in establishing the structure of the new bouvardin metabolite. The 250-MHz ^{1}H-NMR spectrum of the metabolite strongly supported its proposed structure as bouvardin catechol (III). All of the resonances of the metabolite were virtually identical for I, II, and III except for signals attributed to the aromatic protons of the tyrosine-3 moiety and for OH and NH absorptions which moved farther downfield in the spectrum of III due to concentration differences. The tyrosine-3 absorption changed in the expected ways for III. The aromatic absorption pattern for this metabolite resembled that of 4-methyl catechol (8) as a typical ABX system with protons for the Tyr-3δ [6.53 ppm (dd, J = 7.4 and 2.0 Hz) and 6.70 ppm (d, J = 2.0 Hz)] and Tyr-3ϵ [6.81 ppm (d, J = 7.4 Hz)] possessing the appropriate coupling constants. These data confirm the structure of the metabolite as that of bouvardin catechol (III).

Additional attempts were made to modify bouvardin by employing cultures known to form peptide antibiotics containing α,β-unsaturation or dehydro-amino acid moieties in their structural backbones. It was reasoned that formation of the dehydro-moieties could occur as late biosynthetic reactions in the formation of antibiotics such as mikamycin (9), subtilin (10), dehydro-*N*-benzyloxycarbonyl-L-tryptophan (11), glycocinnamoyl-spermidines (12), antibiotic A32390A (13), telomycin (14), stendomycin (15), trichostatin C (16), and ostreogrycin (17), and that the introduction of this type of functionality into bouvardin could result in enhanced or novel antitumor activity. Cultures were grown in nutrient broth with and without supplements of phenylalanine, alanine, or tyrosine as possible inducers of enzymes capable of dehydrogenating amino acids (11). None of the antibiotic-producing cultures formed novel derivatives of bouvardin. In these experiments, *Nocardia* species (NRRL 5646), *Streptomyces hygroscopicus* (ATCC 32431), and *Actinoplanes philippinensis* (NRRL 5462) formed *O*-desmethylbouvardin from bouvardin, albeit in lower yields than *S. rutgersensis*.

Bouvardin and its metabolites, *O*-desmethylbouvardin (II) and bouvardin catechol (III) were submitted to the National Cancer Institute for biological testing *versus* the P-388 leukemia test system. None of the metabolites were active, thus indicating that the *O*-desmethylation and further hydroxylation reactions are bioinactivation processes.

Prodrugs as Drug Delivery Systems XXV: Hydrolysis of Oxazolidines—A Potential New Prodrug Type

MARIANNE JOHANSEN and HANS BUNDGAARD ˣ

Received September 7, 1982, from the *Royal Danish School of Pharmacy, Departments of Pharmaceutics and Pharmaceutical Chemistry AD, DK-2100 Copenhagen, Denmark.* Accepted for publication September 30, 1982.

Abstract □ The hydrolysis kinetics of several oxazolidines derived from (−)-ephedrine and various aldehydes and ketones were studied to assess their suitability as prodrug forms for β-amino alcohols and/or carbonyl-containing compounds. The oxazolidines were found to undergo a facile and complete hydrolysis in the pH range of 1–11 at 37°. The hydrolysis rates were subject to general acid–base catalysis by buffer substances and depended strongly on pH. Most oxazolidines showed sigmoidal pH–rate profiles with maximum rates at pH > 7–7.5. At pH 7.40 and 37° the following half-lives of hydrolysis for the various ephedrine oxazolidines were found: 5 sec (formaldehyde), 18 sec (propionaldehyde), 5 min (benzaldehyde), 5 sec (salicylaldehyde), 30 min (pivalaldehyde), 4 min (acetone), and 6 min (cyclohexanone). The reaction rates in neutral and basic solutions were shown to decrease with increasing steric effects of the substituents derived from the carbonyl component and to decrease with increasing basicity of the oxazolidines. The oxazolidines are weaker bases (pK_a 5.2–6.9) than the parent β-amino alcohol and more lipophilic at physiological pH. It is suggested that oxazolidines can be considered as potentially useful prodrug candidates for drugs containing a β-amino alcohol moiety or carbonyl groups.

Keyphrases □ Ephedrine—oxazolidine derivatives, potential prodrugs for β-amino alcohols and carbonyl-containing compounds □ Oxazolidines—potential prodrugs for β-amino alcohols and carbonyl-containing compounds, ephedrine □ Prodrugs—potential, oxazolidine derivatives, for β-amino alcohols and carbonyl-containing compounds, ephedrine

Bioreversible derivatization of drug substances to produce prodrugs with altered physicochemical properties can improve substantially both drug efficacy and safety (1–3). As a part of current studies involving new chemical approaches (4, 5), an investigation was carried out to obtain prodrug candidates for the β-amino alcohol moiety and/or carbonyl groups (aldehydes and ketones). There are several drugs containing a β-amino alcohol moiety (*e.g.*, various sympathomimetic amines and β-blockers) which may exhibit delivery problems, *e.g.*, due to unfavorable solubility or lipophilicity characteristics. For this moiety no prodrug types have apparently been described, and likewise, only few bioreversible derivatives of carbonyl-containing drugs have been explored (6, 7). We recently suggested (8) that oxazolidines should be considered as potentially useful prodrug candidates for β-amino alcohols or drugs containing carbonyl groups. Oxazolidines (II and III) derived from (−)-ephedrine (I) and benzaldehyde or salicylaldehyde were found to undergo a facile and quantitative hydrolysis in the pH range of 1–11, the half-lives of hydrolysis at pH 7.4 and 37° being 5 min (II) and 5 sec (III). To further explore the potential of oxazolidines as prodrug types and to delineate some structure–activity relationships, this study has been extended to include oxazolidines derived from (−)-ephedrine and the ketones acetone and cyclohexanone, as well as the aliphatic aldehydes formaldehyde, propionaldehyde, and pivalaldehyde. In the present paper the kinetics of hydrolysis of these oxazolidines (IV–VIII) are described along with data for the lipophilicity of the compounds.

EXPERIMENTAL

Chemicals—The oxazolidines IV–VIII were prepared by treating (−)-ephedrine[1] with the appropriate aldehyde or ketone, according to previously described procedures (9–11), and these materials were purified by distillation *in vacuo*. The boiling or melting points observed agreed with those previously reported (9–11), and satisfactory elemental analysis data (C, H, and N) were obtained. Buffer substances and all chemicals or solvents were of reagent grade.

Kinetic Studies—All rate studies were performed in aqueous buffer solutions at 37.0 ± 0.2°. The buffers used were hydrochloric acid, formate, acetate, phosphate, borate, and carbonate solutions. A constant ionic strength (μ) of 0.5 was maintained for each buffer by adding a calculated amount of potassium chloride. The rates of hydrolysis were followed by one or more of three methods depending on the reaction rate.

Direct UV spectrophotometry—In this method the progress of decomposition of the oxazolidines was followed spectrophotometrically[2] by recording the decrease in absorbance at 220 nm. At this wavelength the absorption of substrate and products differed maximally. Reactions were performed in 2.5-ml aliquot portions of buffer solutions in a thermostated quartz cell and were initiated by adding 20 μl of a stock solution of the oxazolidines in acetonitrile to give a final concentration of ~5×10^{-4} *M*. Rate constants were calculated from the slopes of linear plots of log ($A_t - A_\infty$) against time, where A_t and A_∞ are the absorbance

Prodrugs as Drug Delivery Systems XXV: Hydrolysis of Oxazolidines—A Potential New Prodrug Type

MARIANNE JOHANSEN and HANS BUNDGAARD ˣ

Received September 7, 1982, from the *Royal Danish School of Pharmacy, Departments of Pharmaceutics and Pharmaceutical Chemistry AD, DK-2100 Copenhagen, Denmark.* Accepted for publication September 30, 1982.

Abstract □ The hydrolysis kinetics of several oxazolidines derived from (−)-ephedrine and various aldehydes and ketones were studied to assess their suitability as prodrug forms for β-amino alcohols and/or carbonyl-containing compounds. The oxazolidines were found to undergo a facile and complete hydrolysis in the pH range of 1–11 at 37°. The hydrolysis rates were subject to general acid–base catalysis by buffer substances and depended strongly on pH. Most oxazolidines showed sigmoidal pH–rate profiles with maximum rates at pH > 7–7.5. At pH 7.40 and 37° the following half-lives of hydrolysis for the various ephedrine oxazolidines were found: 5 sec (formaldehyde), 18 sec (propionaldehyde), 5 min (benzaldehyde), 5 sec (salicylaldehyde), 30 min (pivalaldehyde), 4 min (acetone), and 6 min (cyclohexanone). The reaction rates in neutral and basic solutions were shown to decrease with increasing steric effects of the substituents derived from the carbonyl component and to decrease with increasing basicity of the oxazolidines. The oxazolidines are weaker bases (pK_a 5.2–6.9) than the parent β-amino alcohol and more lipophilic at physiological pH. It is suggested that oxazolidines can be considered as potentially useful prodrug candidates for drugs containing a β-amino alcohol moiety or carbonyl groups.

Keyphrases □ Ephedrine—oxazolidine derivatives, potential prodrugs for β-amino alcohols and carbonyl-containing compounds □ Oxazolidines—potential prodrugs for β-amino alcohols and carbonyl-containing compounds, ephedrine □ Prodrugs—potential, oxazolidine derivatives, for β-amino alcohols and carbonyl-containing compounds, ephedrine

Bioreversible derivatization of drug substances to produce prodrugs with altered physicochemical properties can improve substantially both drug efficacy and safety (1–3). As a part of current studies involving new chemical approaches (4, 5), an investigation was carried out to obtain prodrug candidates for the β-amino alcohol moiety and/or carbonyl groups (aldehydes and ketones). There are several drugs containing a β-amino alcohol moiety (*e.g.*, various sympathomimetic amines and β-blockers) which may exhibit delivery problems, *e.g.*, due to unfavorable solubility or lipophilicity characteristics. For this moiety no prodrug types have apparently been described, and likewise, only few bioreversible derivatives of carbonyl-containing drugs have been explored (6, 7). We recently suggested (8) that oxazolidines should be considered as potentially useful prodrug candidates for β-amino alcohols or drugs containing carbonyl groups. Oxazolidines (II and III) derived from (−)-ephedrine (I) and benzaldehyde or salicylaldehyde were found to undergo a facile and quantitative hydrolysis in the pH range of 1–11, the half-lives of hydrolysis at pH 7.4 and 37° being 5 min (II) and 5 sec (III). To further explore the potential of oxazolidines as prodrug types and to delineate some structure–activity relationships, this study has been extended to include oxazolidines derived from (−)-ephedrine and the ketones acetone and cyclohexanone, as well as the aliphatic aldehydes formaldehyde, propionaldehyde, and pivalaldehyde. In the present paper the kinetics of hydrolysis of these oxazolidines (IV–VIII) are described along with data for the lipophilicity of the compounds.

EXPERIMENTAL

Chemicals—The oxazolidines IV–VIII were prepared by treating (−)-ephedrine[1] with the appropriate aldehyde or ketone, according to previously described procedures (9–11), and these materials were purified by distillation *in vacuo*. The boiling or melting points observed agreed with those previously reported (9–11), and satisfactory elemental analysis data (C, H, and N) were obtained. Buffer substances and all chemicals or solvents were of reagent grade.

Kinetic Studies—All rate studies were performed in aqueous buffer solutions at 37.0 ± 0.2°. The buffers used were hydrochloric acid, formate, acetate, phosphate, borate, and carbonate solutions. A constant ionic strength (μ) of 0.5 was maintained for each buffer by adding a calculated amount of potassium chloride. The rates of hydrolysis were followed by one or more of three methods depending on the reaction rate.

Direct UV spectrophotometry—In this method the progress of decomposition of the oxazolidines was followed spectrophotometrically[2] by recording the decrease in absorbance at 220 nm. At this wavelength the absorption of substrate and products differed maximally. Reactions were performed in 2.5-ml aliquot portions of buffer solutions in a thermostated quartz cell and were initiated by adding 20 μl of a stock solution of the oxazolidines in acetonitrile to give a final concentration of ~5×10^{-4} *M*. Rate constants were calculated from the slopes of linear plots of log ($A_t - A_\infty$) against time, where A_t and A_∞ are the absorbance

readings at time t and at infinity (*i.e.*, when no further changes in absorbance occurred), respectively.

Trapping of Carbonyl Product—The rates of hydrolysis of IV and VII were measured at some pH values (pH 3–6) by trapping the formaldehyde or cyclohexanone formed with semicarbazide and following the increase in absorbance of the semicarbazone at 235 nm (12, 13). Semicarbazide hydrochloride was included in the buffer solutions at a concentration of 5×10^{-3} *M*. The concentration of the trapping reagent (and pH range) was such that there was no induction period in the observed pseudo first-order rate plots, *i.e.*, trapping of carbonyl compound was fast relative to its formation. The semicarbazide had no significant influence on the reaction rate in the concentration used; at higher concentrations a slight catalytic effect was noted. The initial oxazolidine concentration was ~2×10^{-4} *M*, and the reactions were performed either directly in a thermostated cuvette or in flasks kept in a water bath. Pseudo first-order rate constants were determined from plots of log $(A_\infty - A_t)$ against time; in all cases stable end points (A_∞) were observed.

High-Performance Liquid Chromatography (HPLC)—Slower reactions were usually followed using an HPLC method. The apparatus[3] used was equipped with a variable-wavelength UV detector (8-μl, 1-cm flow cells), a 10-μl loop injection valve, and a reverse-phase column[4] (4.0 mm × 25 cm). The mobile phase consisted of methanol–0.04 *M* potassium dihydrogen phosphate (7:3 v/v). The flow rate was 1.6 ml/min, and the column effluent was monitored at 215 or 220 nm. Under these conditions the oxazolidines were separated from ephedrine and both could readily be determined (Fig. 1). Quantitation of the compounds was done from measurement of the peak heights in relation to those of standards chromatographed under the same conditions. In the kinetic runs, buffer solutions containing the oxazolidines at initial concentrations of ~0.5 mg/ml were kept at 37°, and aliquots were removed at suitable intervals and chromatographed. First-order rate constants for the hydrolysis were determined from the slopes of linear plots of the logarithm of residual oxazolidine against time.

Measurement of Partition Coefficients—The partition coefficients of the oxazolidine derivatives VI, VII, and VIII were determined in an octanol–phosphate buffer (0.05 *M*, pH 7.40) system as previously described (8). The solute concentration in the octanol phase was determined by the aforementioned HPLC method before and after partition, the equilibrium being obtained after mixing the two phases for only 3 min at 20° (for stability reasons). For each compound, determinations were carried out in triplicate, and the log P values thereby obtained were reproducible to within ±6%.

RESULTS AND DISCUSSION

Kinetics of Hydrolysis—The kinetics of decomposition of the oxazolidines IV–VII were studied in aqueous solution at 37° over the pH range of 0.5–11. At constant pH and temperature the hydrolysis displayed strict first-order kinetics for >3 half-lives, and in all kinetic runs followed by HPLC, ephedrine was found to be liberated in stoichiometric amounts. As described above, different experimental methods were used to follow the reactions. In several cases the rate of hydrolysis of oxazolidines at a given pH was determined using more than one of the methods and, as seen from the examples given in Table I, the values of the pseudo first-order rate constants (k_{obs}) derived were in favorable agreement.

The hydrolysis of the oxazolidines was found to be subject to significant buffer catalysis, as has previously been observed for II (8). The hydrolysis rates showed in all cases a linear dependence on buffer concentration, as illustrated in Fig. 2 for the degradation of oxazolidine VI in phosphate buffers.

The influence of pH on the hydrolysis rate is shown in Fig. 3, where the logarithms of the k_{obs} values at zero buffer concentration (k_0, obtained

by extrapolation of plots such as those in Fig. 2 to zero buffer concentration) are plotted against pH. The k_0 values at pH < 2.2 were obtained directly from runs in hydrochloric acid solution.

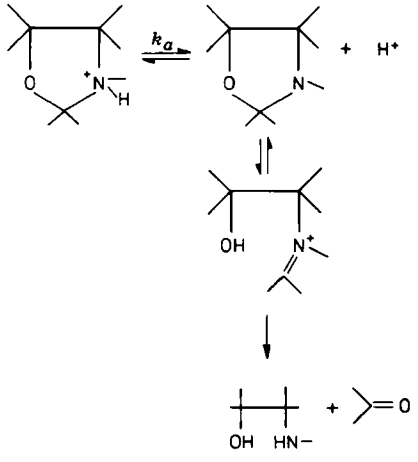
Previous studies (14–16) have shown that the hydrolysis occurs in two separate reaction stages: reversible ring opening to give a cationic Schiff base species followed by hydrolysis of this intermediate to give the β-amino alcohol and the carbonyl component (Scheme I). These studies involving various 2-(substituted phenyl)-3-ethyloxazolidines, 2-[4-(dimethylamino)styryl]-3-phenyloxazolidine, and 2-(4-methylphenyl)-2,3-dimethyloxazolidine led to the proposed reaction scheme in which the ring opening proceeding with C—O bond breaking is subject to hydrogen ion catalysis as well as a possible unimolecular C—O bond breaking or a water-catalyzed ring opening. The cationic Schiff base intermediate formed is in equilibrium with the oxazolidine and undergoes both spontaneous and hydroxide-ion-catalyzed hydrolysis.

A similar mechanism may be involved in the hydrolysis of the oxazolidines IV–VIII. For these derivatives, however, no build up of a Schiff base intermediate occurs. Using UV spectrophotometry no such intermediate could be detected in the pH range studied, and furthermore, no lag time was observed in the rate of appearance of ephedrine as determined by HPLC. Thus, if formed, the Schiff base intermediate must be present in small steady-state concentrations. A similar conclusion was also reached in case of hydrolysis of the benzaldehyde derivative II (8). The sigmoidal pH-rate profiles obtained for the oxazolidines studied indicate, on the other hand, that such an intermediate may be involved in the reaction pathway and that a change of the rate-determining step in the overall reaction with pH is taking place. In weakly acid to basic solution (pH > 5.5–6), the rate-determining step in the overall hydrolysis of the oxazolidines is suggested to involve a unimolecular or water-catalyzed breakdown of the free base form of the oxazolidines. Letting k_1 be the apparent first-order rate constant for this process and K_a the apparent ionization constant of the protonated oxazolidines, the expression for k_0 would be:

$$k_0 = \frac{k_1 K_a}{a_H + K_a} \qquad \text{(Eq. 1)}$$

where a_H is the hydrogen ion activity. In Fig. 3 the lines at pH > 5.5–6 were constructed from Eq. 1 and the rate constants and pK_a values given in Table I. It is seen that the experimental data obtained in this pH region fit very satisfactorily to Eq. 1. Further support for this interpretation of the kinetic data is provided by the identical pK_a values obtained kinetically and by potentiometric titration for the oxazolidines VI and VII (Table II). Due to their facile hydrolysis the pK_a values of IV and V could not be determined titrimetrically. It should be added, however, that other kinetically equivalent reactions, *e.g.*, hydroxide-ion-catalyzed hydrolysis of protonated oxazolidine, can equally account for the observed k_0–pH relationship in neutral and alkaline solutions.

As seen from Fig. 4 the oxazolidine derived from benzaldehyde (II) behaves quite differently from those from the aliphatic aldehydes (IV and V). The hydrolysis of this oxazolidine shows a bell-shaped pH–rate profile as previously reported (8). In contrast the pH–rate profile for the corresponding oxazolidine from salicylaldehyde (III) (8) is sigmoidal, as are those for IV, V, and VIII. The rate data for III at pH > 4 were analyzed in terms of Eq. 1, and the k_1 and pK_a values derived are included in Table I.



Scheme I

Table II—Rate Data for the Hydrolysis of Various Oxazolidines and pK_a Values[a]

Oxazolidine	k_1, min^{-1}	pK_a[b]	
II	—	—	(5.6)[c]
III	9.1	5.2	
IV	9.1	6.0	
V	2.4	5.9	
VI	0.21	6.9	(6.9)[c]
VII	0.13	6.9	(6.9)[c]
VIII	0.023	5.9	

[a] μ = 0.5; 37°. [b] Kinetically determined values; the values listed in parentheses were determined titrimetrically. [c] Values taken from Ref. 17.

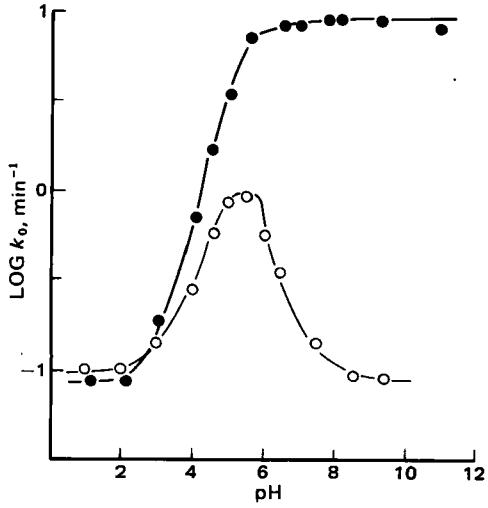


Figure 4—*The pH–rate profiles for the hydrolysis of the oxazolidines II (○) and III (●) at 37° (μ = 0.5). (Taken from Ref. 8.)*

The pK_a values derived for the oxazolidines are substantially smaller than the pK_a value (9.6) for ephedrine. The difference can most likely be attributed to the presence of the electronegative ring oxygen atom in the oxazolidines, *cf.*, the difference in the pK_a values for piperidine (11.1) and morpholine (8.3).

Lipophilicity of the Oxazolidines—The apparent partition coefficients ($P = C_{octanol}/C_{aqueous}$) for the oxazolidines VI–VIII were measured using an octanol–aqueous buffer system, using 0.05 *M* phosphate buffer, pH 7.40. The values found for log P were 0.92 (VI), 1.83 (VII), and 1.68 (VIII). The log P values for the free base forms of the compounds can be calculated from these values when correction is made for the degree of ionization at pH 7.4; the values thus obtained are 1.04 (VI), 1.94 (VII), and 1.69 (VIII). The log P value for the benzaldehyde derivative (II) was previously reported to be 1.58 at pH > 7. The log P value for ephedrine (pK_a 9.6) in a similar octanol–phosphate buffer (pH 7.4) system has been reported to be −1.35, with a log P value of 1.02 for the free base form (18). These results show that the oxazolidines prepared from acetone, cyclohexanone, or benzaldehyde are more lipophilic than the parent ephedrine, especially at physiological pH where the oxazolidines are largely in the free base form and ephedrine is largely protonated. Due to stability reasons the log P values for the oxazolidines III–V could not be experimentally determined, but could be estimated on the basis of hydrophobic substituent constants (19) and the values for derivatives described above.

Structural Effects on Reaction Rate—The rate data obtained show that the structure of the carbonyl component has a pronounced effect on the rate of oxazolidine hydrolysis in both acidic, neutral, and alkaline

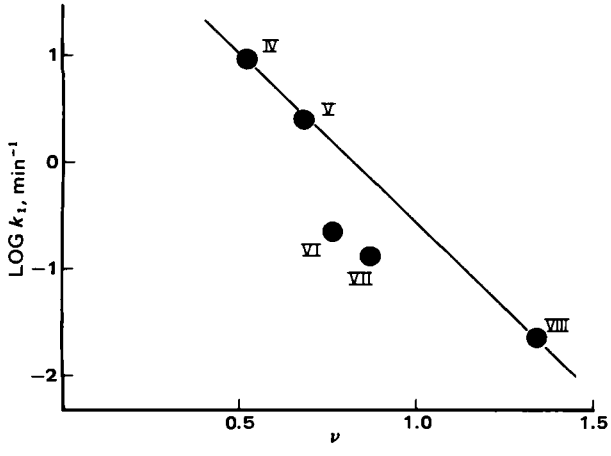

Figure 5—*Plot of log* k_1 *against the steric substituent parameter ν for various oxazolidines. The correlation plot was made for IV, V, and VIII possessing the same* pK_a *values. The ν values used refer to the moiety of the oxazolidines derived from the carbonyl compounds including the ring carbon atom in the oxazolidines, e.g., for IV and VI the ν values are those for methyl and isopropyl, respectively.*

Table III—Half-lives of Hydrolysis of Various Oxazolidines at pH 1 and 7.4 [a]

Oxazolidine	$t_{1/2}$, min	
	pH 1	pH 7.4
II[b]	7	5.0
III[b]	8	0.08
IV	96	0.08
V	70	0.3
VI	220	4.0
VII	230	5.9
VIII	—	30

[a] μ = 0.5; 37°. [b] The rate data are from a previous study (8).

solutions. Considering the rate constant k_1 and accordingly, the hydrolysis rate in weakly acidic to basic aqueous solutions, the structural effects appear to involve both electrical and steric effects. The oxazolidines derived from the three aliphatic aldehydes (IV, V, and VIII) possess almost the same pK_a values (Table II), and the variation of the rates of hydrolysis of these derivatives can be accounted for in terms of different steric properties of the aldehyde part. As seen in Fig. 5, an excellent linear correlation exists between log k_1 and the steric substituent parameter ν (20). The regression equation between log k_1 and ν for these oxazolidines is given by:

$$\log k_1 = -3.2\nu + 2.6 \quad (k_1 \text{ in } \text{min}^{-1};\ 37°) \qquad \text{(Eq. 2)}$$

This result implies that the reactivity of oxazolidines in neutral and basic solutions decreases with increasing steric effects within the carbonyl moiety. As seen from Fig. 5 such a correlation also appears to hold for oxazolidines derived from ketones, although only rate data for two derivatives have been obtained. The decreased reactivity of the ketone–oxazolidines as compared to the aldehyde–oxazolidines (Fig. 5) may most likely be due to differences in the pK_a values of the oxazolidines, *i.e.*, increased pK_a results in decreased reactivity. As previously suggested (8) the considerably greater reactivity of III compared with II may be attributed to some kind of intramolecular catalysis by the *ortho*-situated hydroxyl group in III. It is obvious, however, that the present data are insufficient to delineate the structural factors (steric and electrical), both within the aldehyde or ketone part and the amino alcohol moiety, that may influence the stability of oxazolidines.

Consideration of Oxazolidines as Prodrug Types—The results obtained extend the previous suggestion (8) that oxazolidines may have potential as prodrug forms for β-amino alcohols or carbonyl-containing compounds. The derivatives undergo a quantitative conversion to the parent compounds in aqueous solution with rates highly dependent on pH. As shown in Table III the decomposition of the oxazolidines at pH 7.4 and 37° is quite rapid, whereas a greater stability is achieved in acid solutions. These rates might not be expected to change much *in vivo*. The oxazolidines are much weaker bases than the parent β-amino alcohol, and this results in higher lipophilicity at physiological pH. Such increased lipophilicity may become advantageous in situations where delivery problems for β-amino alcohol-type drugs are due to low lipophilicity. Thus, by appropriate selection of the carbonyl moiety of oxazolidines it may be feasible to obtain prodrugs of β-amino alcohols with varying physicochemical properties, such as lipophilicity and rate of drug release, and hence to control and modify the delivery and overall activity characteristics of the parent drugs. In considering oxazolidines as prodrug candidates for carbonyl-containing substances, their weakly basic character may also be advantageous in that the transformation of such substances into oxazolidines introduces a readily ionizable moiety, which may allow the preparation of derivatives with increased aqueous solubilities at acidic pH values. For example, a potentially useful purpose of transforming a carbonyl-containing drug substance into a bioreversible oxazolidine derivative could be to enhance its dissolution behavior in an effort to improve the oral bioavailability.

Determinants of Bumetanide Response in the Dog: Effect of Indomethacin

DAVID E. SMITH ˣ and HENRY S. H. LAU

Received July 1, 1982, from the *College of Pharmacy, The University of Michigan, Ann Arbor, MI 48109.* Accepted for publication September 16, 1982.

Abstract □ Four male unanesthetized dogs each weighing 22.0–29.0 kg received 0.250 mg/kg iv of bumetanide before (treatment I) and after (treatment II) indomethacin pretreatment. Lactated Ringer's solution was administered intravenously throughout both treatments at a flow rate of 2 ml/min to avoid fluid and electrolyte depletion. Unchanged bumetanide and indomethacin concentrations were analyzed using high-performance liquid chromatography. Sodium was measured by flame photometry and creatinine by colorimetry. Indomethacin pretreatment did not significantly change the pharmacokinetics of bumetanide, affecting neither the total amount of drug nor time course of drug delivered into the urine. In contrast, indomethacin pretreatment resulted in a dramatic reduction in the 4-hr sodium excretion and urine volume. Therefore, a pharmacokinetic interaction may be eliminated as a possible mechanism for the attenuation, by indomethacin, of the natriuretic and diuretic response of bumetanide. Instead, it appears that indomethacin diminishes the response to bumetanide *via* prostaglandin inhibition.

Keyphrases □ Bumetanide—pharmacokinetics, sodium excretion, dogs, effect of indomethacin pretreatment □ Indomethacin—pretreatment, effect on sodium excretion, pharmacokinetics of bumetanide, dogs □ Pharmacokinetics—bumetanide, sodium excretion, pharmacokinetics in the dog, effect of indomethacin pretreatment

Bumetanide [3-(butylamino)-4-phenoxy-5-sulfamoylbenzoic acid] is a high-ceiling diuretic with pharmacological action similar to that of furosemide (1–3). The diuretic appears to act primarily at the medullary portion of the ascending limb of the loop of Henle, where it inhibits solute reabsorption, although inhibition of sodium transport in the proximal nephron also occurs (4–7). In addition, bumetanide induces intrarenal hemodynamic changes (8–12). Since bumetanide is highly bound to plasma proteins (13, 14), the drug gains access to the kidney lumen predominantly at the pars recta of the proximal tubule *via* the nonspecific organic acid secretory pathway (1, 13).

Indomethacin has been shown recently to attenuate the natriuretic and diuretic response to bumetanide in experimental animals (12), healthy volunteers (15, 16), and patients (17). These authors proposed that indomethacin, a potent inhibitor of prostaglandin synthetase, interferes with the prostaglandin-mediated effect of bumetanide. However, it is also possible that indomethacin may compete with bumetanide (both drugs are weak organic acids) for active secretion into the lumen of the kidney tubule, thereby modifying either the total amount of diuretic delivered to its active site or the time course of drug delivery. Since previous investigators (12, 15–17) did not measure concentrations and/or amounts of bumetanide in the plasma and urine, this alternative hypothesis (pharmacokinetic interaction) cannot be eliminated. Therefore, the present investigation was undertaken to clarify the mechanism by which indomethacin diminishes the pharmacodynamic response to bumetanide.

EXPERIMENTAL

Materials—An aqueous solution dosage form of bumetanide[1] was prepared using 0.4 *N* NaOH immediately prior to use. Indomethacin capsules[2] were obtained commercially. Indomethacin powder[3] was used as received. All other chemicals and solvents were reagent grade or better, as previously reported (18).

Methods—Four male, mongrel, conditioned, unanesthetized dogs weighing 22.0–29.0 kg received 0.250 mg/kg of bumetanide before (treatment I) and after (treatment II) pretreatment with indomethacin. Each dog was fasted the night before and throughout the entire study period. Bumetanide was administered intravenously over a 3-min infusion[4] period, with the beginning of the infusion being considered as time zero. A 100-mg dose of indomethacin (two 50-mg capsules) was ingested the night before (11:00 to 11:30 p.m.) and on the study day (60 min prior to bumetanide administration). An interval of at least 1 week elapsed between studies, and identical lots for each drug were used throughout.

Heparinized scalp vein needles[5] were placed in the forelegs of each dog:

Determinants of Bumetanide Response in the Dog: Effect of Indomethacin

DAVID E. SMITH ˣ and HENRY S. H. LAU

Received July 1, 1982, from the *College of Pharmacy, The University of Michigan, Ann Arbor, MI 48109.* Accepted for publication September 16, 1982.

Abstract □ Four male unanesthetized dogs each weighing 22.0–29.0 kg received 0.250 mg/kg iv of bumetanide before (treatment I) and after (treatment II) indomethacin pretreatment. Lactated Ringer's solution was administered intravenously throughout both treatments at a flow rate of 2 ml/min to avoid fluid and electrolyte depletion. Unchanged bumetanide and indomethacin concentrations were analyzed using high-performance liquid chromatography. Sodium was measured by flame photometry and creatinine by colorimetry. Indomethacin pretreatment did not significantly change the pharmacokinetics of bumetanide, affecting neither the total amount of drug nor time course of drug delivered into the urine. In contrast, indomethacin pretreatment resulted in a dramatic reduction in the 4-hr sodium excretion and urine volume. Therefore, a pharmacokinetic interaction may be eliminated as a possible mechanism for the attenuation, by indomethacin, of the natriuretic and diuretic response of bumetanide. Instead, it appears that indomethacin diminishes the response to bumetanide *via* prostaglandin inhibition.

Keyphrases □ Bumetanide—pharmacokinetics, sodium excretion, dogs, effect of indomethacin pretreatment □ Indomethacin—pretreatment, effect on sodium excretion, pharmacokinetics of bumetanide, dogs □ Pharmacokinetics—bumetanide, sodium excretion, pharmacokinetics in the dog, effect of indomethacin pretreatment

Bumetanide [3-(butylamino)-4-phenoxy-5-sulfamoylbenzoic acid] is a high-ceiling diuretic with pharmacological action similar to that of furosemide (1–3). The diuretic appears to act primarily at the medullary portion of the ascending limb of the loop of Henle, where it inhibits solute reabsorption, although inhibition of sodium transport in the proximal nephron also occurs (4–7). In addition, bumetanide induces intrarenal hemodynamic changes (8–12). Since bumetanide is highly bound to plasma proteins (13, 14), the drug gains access to the kidney lumen predominantly at the pars recta of the proximal tubule *via* the nonspecific organic acid secretory pathway (1, 13).

Indomethacin has been shown recently to attenuate the natriuretic and diuretic response to bumetanide in experimental animals (12), healthy volunteers (15, 16), and patients (17). These authors proposed that indomethacin, a potent inhibitor of prostaglandin synthetase, interferes with the prostaglandin-mediated effect of bumetanide. However, it is also possible that indomethacin may compete with bumetanide (both drugs are weak organic acids) for active secretion into the lumen of the kidney tubule, thereby modifying either the total amount of diuretic delivered to its active site or the time course of drug delivery. Since previous investigators (12, 15–17) did not measure concentrations and/or amounts of bumetanide in the plasma and urine, this alternative hypothesis (pharmacokinetic interaction) cannot be eliminated. Therefore, the present investigation was undertaken to clarify the mechanism by which indomethacin diminishes the pharmacodynamic response to bumetanide.

EXPERIMENTAL

Materials—An aqueous solution dosage form of bumetanide[1] was prepared using 0.4 *N* NaOH immediately prior to use. Indomethacin capsules[2] were obtained commercially. Indomethacin powder[3] was used as received. All other chemicals and solvents were reagent grade or better, as previously reported (18).

Methods—Four male, mongrel, conditioned, unanesthetized dogs weighing 22.0–29.0 kg received 0.250 mg/kg of bumetanide before (treatment I) and after (treatment II) pretreatment with indomethacin. Each dog was fasted the night before and throughout the entire study period. Bumetanide was administered intravenously over a 3-min infusion[4] period, with the beginning of the infusion being considered as time zero. A 100-mg dose of indomethacin (two 50-mg capsules) was ingested the night before (11:00 to 11:30 p.m.) and on the study day (60 min prior to bumetanide administration). An interval of at least 1 week elapsed between studies, and identical lots for each drug were used throughout.

Heparinized scalp vein needles[5] were placed in the forelegs of each dog:

0022-3549/83/1100-1298$01.00/0

one was used for administration of bumetanide and replacement fluids, the other for obtaining blood samples. Blood samples (3 ml) were collected just prior to bumetanide dose (blank) and at 3, 5, 10, 20, 30, 45, 60, 80, 100, 120, 150, 180, 210, and 240 min. Voided urine was collected *via* an indwelling bladder catheter[6] just prior to bumetanide dosing (blank) and at 20, 40, 80, 120, 180, and 240 min. The bladder was flushed with 2 × 5 ml of air at the end of each urine collection to ensure a complete catch. Lactated Ringer's solution ws administered intravenously throughout the entire study period of both treatments at a flow rate of 2 ml/min to avoid fluid and electrolyte depletion. All 4-hr plasma samples showed normal sodium concentrations.

Assays—Plasma and urine samples containing bumetanide, with and without indomethacin pretreatment, were analyzed by a high-performance liquid chromatographic (HPLC) method as described previously (18). Plasma samples (0.20 ml) containing indomethacin were prepared and analyzed in a similar fashion to that of bumetanide. A 50- μl aliquot of acetophenone (0.025 mg/ml) was used as the internal standard, and the solvent system (50% acetonitrile in 0.015 *M* phosphoric acid aqueous solution, adjusted to pH 5.0 with 4 *N* NaOH) was pumped isocratically at a flow rate of 2.0 ml/min at ambient temperature. Both indomethacin and acetophenone were measured using UV detection at 254 nm (0.01 AUFS). The voltage spans on the dual-pen recorder were set at 10 mV for indomethacin and at 50 mV for acetophenone. Using the mobile phase described above, indomethacin and acetophenone had retention times in plasma of 9.0 and 4.5 min, respectively (Fig. 1). A representative standard curve of indomethacin–acetophenone peak height ratio over the indomethacin plasma concentration range (0.25–5.00 μg/ml) resulted in the following linear least-squares regression equation: $y = 0.232x - 0.003$; $r^2 = 0.999$.

Plasma and urine samples were measured for sodium with a flame photometer[7]. Creatinine was determined colorimetrically using a commercial kit[8].

Calculations—Plasma concentration–time curves of bumetanide were fitted (equally weighted) to the general polyexponential equation for post constant-rate infusion data (19):

$$C_p = \sum_{i=1}^{n} Yi\, e^{-\lambda i t} \qquad \text{(Eq. 1)}$$

where C_p represents the plasma concentration at time t, Yi is the coefficient of the ith exponential term for post constant-rate intravenous infusion data, and λi is the exponent of the ith exponential term. The values of the coefficients and exponential terms in Eq. 1 were obtained using a nonlinear least-squares regression program[9] and a microcomputer[10]. Initial estimates were obtained using the RSTRIP[9] program. The number of exponents (n) needed for each data set were determined by the application of Akaike's information criterion (20).

Since:

$$Yi = \sum_{i=1}^{n} (1 - e^{\lambda i T}) Ci/(-\lambda i T) \qquad \text{(Eq. 2)}$$

and T is the constant-rate infusion time and Ci is the coefficient of the ith exponential term for bolus intravenous data, Eq. 1 can be rearranged (19) to:

$$C_p = \sum_{i=1}^{n} (1 - e^{\lambda i T})\, Ci\, e^{-\lambda i t}/(-\lambda i T) \qquad \text{(Eq. 3)}$$

Once the values of the coefficients and exponential terms in Eq. 1 are determined by computer fitting, the values of Ci in Eq. 3 can be calculated.

The following pharmacokinetic parameters were calculated using standard equations (19, 21):

$$V_1 = D/\sum_{i=1}^{n} Ci \qquad \text{(Eq. 4)}$$

$$Vd_{ss} = D \sum_{i=1}^{n} Ci/\lambda i^2 \Big/ \left(\sum_{i=1}^{n} Ci/\lambda i\right)^2 \qquad \text{(Eq. 5)}$$

$$Vd_{area} = D/\left(\lambda_1 \sum_{i=1}^{n} Ci/\lambda i\right) \qquad \text{(Eq. 6)}$$

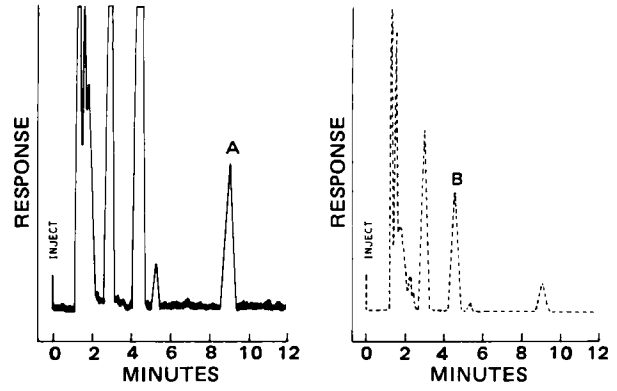

Figure 1—*Chromatograms for plasma spiked with indomethacin (A) and the internal standard (B), acetophenone, using UV detection (254 nm). Voltage spans on the dual-pen recorder were 10 mV (—) and 50 mV (- - - - -).*

$$CL_p = D/\sum_{i=1}^{n} Ci/\lambda i \qquad \text{(Eq. 7)}$$

$$CL_r = Ae^{\infty} \Big/ \sum_{i=1}^{n} Ci/\lambda i \qquad \text{(Eq. 8)}$$

$$CL_{nr} = CL_p - CL_r \qquad \text{(Eq. 9)}$$

$$t_{1/2} = 0.693/\lambda_1 \qquad \text{(Eq. 10)}$$

$$K_{10} = CL_p/V_1 \qquad \text{(Eq. 11)}$$

$$fe = Ae^{\infty}/D \qquad \text{(Eq. 12)}$$

In Eqs. 4–12, V_1 is the volume of the central compartment; Vd_{ss} is the volume of distribution at steady state; Vd_{area} is that volume which, when multiplied by C_p in the log-linear phase is equal to the amount of drug in the body; D is the intravenous dose (equal to the product of the zero-order infusion rate and the length of infusion); C_1 and λ_1 are the coefficient and exponent, respectively, such that λ_1 is the smallest of the λi values of the polyexponential equation; CL_p is the total plasma clearance; CL_r is the renal clearance; CL_{nr} is the nonrenal clearance; Ae^{∞} is the amount of unchanged drug recovered in the urine at time infinity; $t_{1/2}$ is the biological half-life; K_{10} is the first-order elimination rate constant from the central compartment; and fe is the fraction of the available dose excreted unchanged in the urine. Creatinine clearance (CL_{cr}) was calculated by dividing the urinary excretion rate of creatinine by its plasma concentration at the midpoint of the urine collection period.

Data throughout the study are expressed as mean ± *SD*, unless otherwise indicated. Statistical differences were determined by a paired t test. A p value of <0.05 was considered to be significant.

RESULTS

Plasma concentrations of bumetanide over 4 hr were fitted to a biexponential equation for six data sets and to a triexponential equation for two data sets (Table I). The goodness of the fit, as determined by R^2 and the correlation, was ≥0.991.

The pharmacokinetics of bumetanide before (treatment I) and after (treatment II) indomethacin pretreatment are presented in Table II. None of the pharmacokinetic parameters evaluated were statistically different between treatments. This is demonstrated by the virtually superimposable plasma concentration–time profiles (Fig. 2) and the urinary excretion rate–time profiles (Fig. 3) observed between treatments I and II. Mean plasma concentrations of indomethacin ranged from 0.62 to 4.36 μg/ml during the study period, well above the plasma concentrations of bumetanide (Fig. 2).

The effects of indomethacin on bumetanide-induced diuresis and natriuresis are presented in Table III. Pharmacodynamic data are reported as electrolyte excretion rate and cumulative excretion (as opposed to fractional excretion), since sodium concentrations and creatinine clearances did not differ between treatments (CL_{cr} = 2.49 ± 0.24 ml/min·kg for treatment I *versus* 2.33 ± 0.32 ml/min·kg for treatment II; $p > 0.50$). Indomethacin pretreatment results in a dramatic reduction in urine volume (1060 ± 77 ml/4 hr for treatment I *versus* 543 ± 115 ml/4 hr for treatment II; $p < 0.005$) as well as sodium excretion (121 ± 17 meq/4 hr for treatment I *versus* 62.4 ± 21.3 meq/4 hr for treatment II; $p < 0.005$). Analyses of the sodium excretion rate over time show that the

inhibiting effect of indomethacin was most pronounced during the initial 40–60 min (Fig. 4).

DISCUSSION

Several studies have shown that indomethacin decreases the cumulative response to bumetanide in experimental animals (12), healthy volunteers, (15, 16), and patients (17). Mechanisms consistent with this attenuated response include the inhibition, by indomethacin, of prostaglandin-induced changes in renal hemodynamics and direct tubular effects, as well as competition between bumetanide and indomethacin for active tubular transport into the kidney lumen. Previous investigators (12, 15–17) only considered the mechanism involving prostaglandin inhibition, since concentrations and/or amounts of bumetanide in the plasma and urine were not determined.

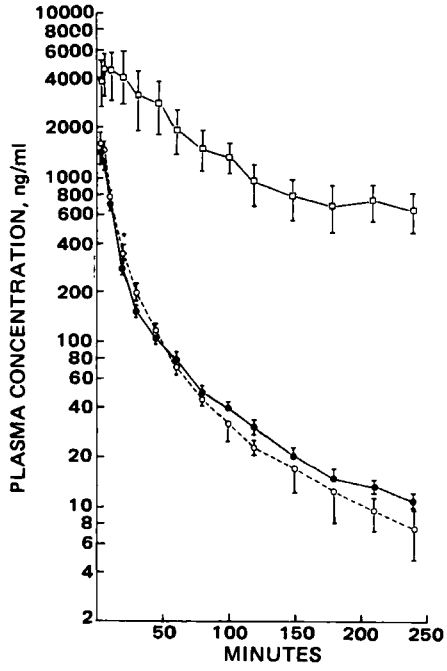

Figure 2—*Plasma concentration* versus *time plots of bumetanide alone (●), bumetanide after indomethacin pretreatment (○), and indomethacin (□). Data are expressed as the mean ± SEM (n = 4). Asterisks denote statistical differences between the treatments.*

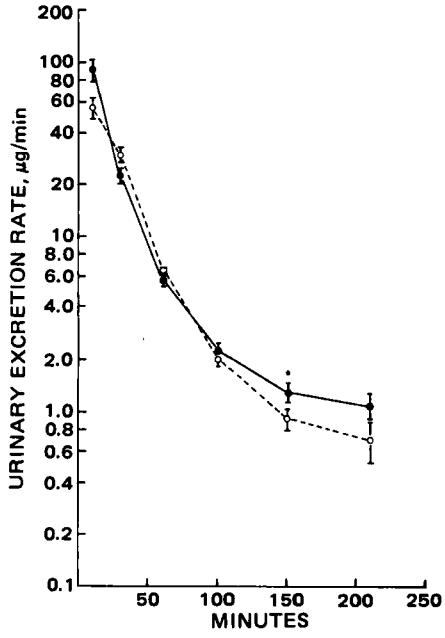

Figure 3—*Urinary excretion rate* versus *midpoint time plots of bumetanide alone (●) and bumetanide after indomethacin pretreatment (○). Data are expressed as the mean ± SEM (n = 4). Asterisks denote statistical differences between the treatments.*

In the present investigation, indomethacin pretreatment did not significantly change the pharmacokinetics of bumetanide (Table II), affecting neither the total amount of drug nor time course of drug delivered into the urine. Although *fe* was reduced ~25% in the presence of indomethacin, the extent of this change was minimal compared with the marked effect of indomethacin on bumetanide-induced natriuresis and diuresis (~50% reduction).

Figures 5 and 6 demonstrate the effect of indomethacin on the dose–response curves of bumetanide. Indomethacin decreased the maximal response (sodium excretion rate) to bumetanide when the dose was expressed as either plasma concentration (Fig. 5) or urinary excretion rate (Fig. 6). These effects are consistent with those of a noncompetitive inhibition, presumably that of prostaglandin synthesis. The effect of indomethacin on bumetanide-induced natriuresis and diuresis could not be explained by normalizing the response to creatinine clearance. This finding is in agreement with previous studies by Brater *et al.* (15) and Olsen (12). Brater *et al.* (15) reported that unlike furosemide, indomethacin decreased the increment in fractional sodium excretion due to bumetanide in healthy volunteers. Olsen (12) observed that absolute

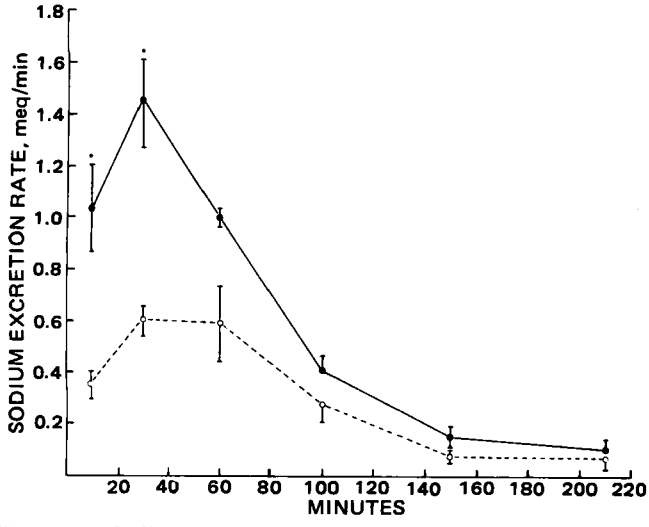

Figure 4—*Sodium excretion rate* versus *midpoint time plots of bumetanide alone (●) and bumetanide after indomethacin pretreatment (○). Data are expressed as the mean ± SEM (n = 4). Asterisks denote statistical differences between the treatments.*

and fractional sodium excretions after bumetanide were significantly lower in indomethacin-pretreated dogs compared with nonpretreated dogs at a time when neither renal blood flow nor glomerular filtration rate were significantly different.

The present study and that of previous investigators (12, 15) suggest that indomethacin affects the pharmacodynamic response to bumetanide by a mechanism other than prostaglandin-mediated changes in renal hemodynamics. Although speculative, renal prostaglandins may be involved in the regulation of medullary tonicity and solute excretion at a tubular level. This hypothesis is supported by an *in vitro* study in the isolated, perfused segments of rabbit nephrons (22), which demonstrated that dinoprostone inhibits net chloride transport across the medullary thick ascending limb of the loop of Henle, but had no effect on the cortical segment. This is consistent with the mechanism of action of bumetanide, which is inhibition of active chloride reabsorption in the ascending limb of the loop of Henle.

The present study demonstrated that indomethacin had no significant effect on the disposition of bumetanide. Therefore, a pharmacokinetic interaction may be eliminated as a possible mechanism for the attenuation, by indomethacin, of the natriuretic and diuretic response of bumetanide. Instead, it appears that indomethacin diminishes the response to bumetanide *via* prostaglandin inhibition, although the precise nature of this interaction remains unclear.

Contamination of Injectable Solutions with 2-Mercaptobenzothiazole Leached from Rubber Closures

JOHN C. REEPMEYER ˣ **and YVONNE H. JUHL**

Received June 18, 1982, from the *Food and Drug Administration, National Center for Drug Analysis, St. Louis, MO 63101.* Accepted for publication October 27, 1982.

Abstract □ An impurity, discovered in a sample of digoxin injectable solution commercially packaged in a syringe for single-dose delivery, was found to originate from the rubber closure of the syringe and was identified as 2-mercaptobenzothiazole, a common accelerator for rubber vulcanization. Several similarly packaged injectable solutions of a variety of drugs from various manufacturers were examined and over half contained 2-mercaptobenzothiazole. The compound was identified by UV spectrophotometry (including a pH-dependent shift in its absorbance maximum), by mass spectrometry, and by comparison with standard 2-mercaptobenzothiazole using silica gel and reverse-phase high-performance liquid chromatography (HPLC). The presence of this impurity in injectable solutions may have implications with regard to toxicity and may interfere with the assay of digoxin injectable solution by HPLC.

Keyphrases □ Injectable formulations—contamination by 2-mercaptobenzothiazole leached from rubber closures, single-dose syringes, syringe cartridges □ 2-Mercaptobenzothiazole—contaminant of injectable solutions, leached from rubber closures, single-dose syringes, syringe cartridges □ Drug packaging—injectable solutions, single-dose syringes, and syringe cartridges, contamination by 2-mercaptobenzothiazole leached from rubber closures

During the assay for digoxin in injectable solutions by reverse-phase high-performance liquid chromatography (HPLC) conducted according to the USP method (1), an impurity was discovered in a sample commercially packaged in a syringe for a single-dose delivery. The small variation in mobile phase compositions permitted by the method produced considerable differences in resolution of digoxin from its contaminant and differences in the digoxin assays. When the mobile phase composition was varied, a significant difference was observed between the change in retention time of digoxin and that of the impurity, which implied that the impurity was structurally unrelated to digoxin. The origin, identification, and significance of this impurity are discussed in this report.

EXPERIMENTAL

Reverse-Phase HPLC—For the analysis of digoxin injectable solutions, the HPLC system consisted of a liquid chromatograph[1], a variable-wavelength detector[2] set at 218 nm and 0.2 AUFS, a recorder–integrator[3] with a chart speed of 0.5 cm/min, and an automatic injector[4] set to inject 20 μl. A reverse-phase C18 column[5] and a mobile phase of 30% aqueous acetonitrile[6] were used; the flow rate was 2.0 ml/min. The digoxin injectable solution samples were used undiluted (0.25 mg/ml). To determine if the contaminant in the digoxin injectable solution was a cardiac glycoside related to digoxin, samples of digoxigenin mono- and bisdigitoxoside[7], digoxigenin[7], and diginatin[7] were chromatographed twice, with 26 and 30% acetonitrile as mobile phases, and were compared by retention time to the impurity.

Concomitant Use of HPLC and UV Spectrophotometry—To obtain a full UV spectrum of chromatographically pure compound, the column effluent was passed first through a detector[8], fixed at 254 nm and connected to a recorder[9] to produce a chromatogram and then through a 10-mm flow cell positioned in a rapid-scanning spectrophotometer[10] to produce the spectrum. As the mobile phase passed through the flow cell, UV spectra were recorded every 2 sec until the intensity of the signal reached a maximum, at which time the solvent flow from the column was diverted, locking the sample in the flow cell. This permitted repetitive scanning of the sample and produced a smooth spectrum of the com-

pound even at extremely low concentrations[11]. In this manner, a full spectrum of any or all compounds in a chromatogram could be generated. Samples were injected manually[12].

The UV spectrum of the impurity was obtained in this manner by injecting the digoxin injectable solution. Small variations seen in the absorbance maximum of the impurity seemed to coincide with slight variations in the mobile phase composition. To determine if this variation in the absorbance maximum was due to small changes in pH, a fraction of eluant containing the impurity was collected from the column into a microcell and treated with small aliquots of 2 *N* NaOH, 1 *N* HCl, and pH 8 buffer solution. The absorbance maximum was measured at various pH values.

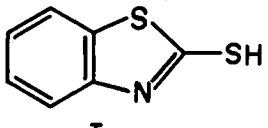
Extraction of Digoxin Injectable Solution—The contents of one 2-ml syringe of digoxin injectable solution was mixed with 2 ml of 1 *N* HCl and extracted with two 5-ml portions of chloroform. The aqueous acidic solution was made strongly basic with 2 *N* NaOH and extracted with two additional 5-ml portions of chloroform. A 400-μl aliquot from each of the four chloroform extracts was evaporated to dryness under a nitrogen stream; the residue from each was dissolved in 100 μl of 30% aqueous acetonitrile and analyzed by HPLC and UV spectroscopy using the method described above. Only the first chloroform extract contained the impurity. This solution was then extracted with 10 ml of 1 *N* NaOH. The aqueous solution was acidified with 2 *N* HCl to pH 1 and extracted with 5 ml of chloroform. The impurity was found only in this final chloroform extract.

Extraction of Container Parts—An empty digoxin injection container was separated into three parts: the rubber sheath which covered the needle, the glass barrel with its attached needle, and the rubber closure. Each part was submerged in a mixture of propylene glycol–ethanol–water (40:10:50), the solvent mixture used for the injection medium, and heated in an oil bath maintained at 60° for 2 weeks[13]. Extracts were examined for the presence of the impurity by HPLC.

Mass Spectroscopy—Since larger quantities of contaminant were available from the rubber parts of the injection container than from the injectable solution, the rubber sheath was selected as a source of a sample of the compound for mass spectroscopy. To avoid contamination of the compound with propylene glycol, one of the three solvents in the mixture originally used to extract the compound from the rubber sheath, other extraction solvents were sought: dilute NaOH solution was found to be suitable.

A 4-mm section of the rubber sheath was placed in 2 ml of 1 *N* NaOH in a tightly capped reaction vial and heated for 3 days in an oil bath maintained at 65°. The aqueous solution was extracted with two 3-ml portions of dichloromethane, acidified with 2 *N* HCl, and extracted with two 2.5-ml portions of dichloromethane. The latter two extracts were combined, and a 100-μl aliquot was analyzed by the aforementioned combination of HPLC and UV spectrophotometry. The solution contained a compound which appeared to be reasonably pure by HPLC and had a UV spectrum characteristic of the impurity. The dichloromethane solution was evaporated to dryness under a stream of dry nitrogen. Electron-impact mass spectra for this compound and for 2-mercaptobenzothiazole[14] (I), a compound suspected to be the impurity based on the prevailing evidence, were obtained by direct probe on a mass spectrometer[15].

Comparison of the Impurity to Standard I by HPLC and UV Spectrophotometry—A slice of rubber closure (55 mg) was placed in 5 ml of 0.5 *N* NaOH in a tightly stoppered container and heated at 50° for 24 hr. The solution was diluted with a mixture of CH_3CN–H_2O–HOAc (50:47:3), which produced a solution of pH 7, and injected onto the reverse-phase column. The rubber sheath (125 mg) was treated similarly. The extracted compound was compared to standard I by retention time and by the UV spectrum measured using the technique described above.



I

A mobile phase consisting of CH_3CN–H_2O–HOAc (260:740:0.03) provided an amount of acetic acid that was sufficiently high (the mobile phase was pH 4) to suppress ionization of the compound, but sufficiently low to prevent its interference in the UV spectrum of the compound.

A 100-μl portion of the digoxin injectable solution sample was mixed with 120 μl of the mobile phase, and a 200-μl aliquot was chromatographed. The impurity, which was separated from digoxin, was collected from the column and examined in both acid and base by UV spectrophotometry. Standard I was treated similarly, and its spectra were compared to those of the impurity.

Silica Gel HPLC and UV Spectrophotometry—Four different digoxin (0.25 mg/ml) and two sodium phenobarbital (65 and 130 mg/ml) injectable solution samples were extracted with organic solvents by the method described below to provide samples for silica gel chromatography. Because of its high concentration relative to the contaminant in the injectable solutions, it was necessary to eliminate most of the phenobarbital to avoid column overload and to allow resolution of the impurity from phenobarbital. Both phenobarbital and I are weakly acidic compounds, which eliminated simple base extraction as a means of separation. 1-Chlorobutane had the lowest reported distribution coefficient (K = 0.4) for phenobarbital (2), and therefore it was the solvent of choice for elimination of phenobarbital. Water (4 ml; 8 ml for sodium phenobarbital at 130 mg/ml), 1-chlorobutane (5 ml), the injectable solution (1–1.5 ml), and 0.5 *N* HCl (1 ml) were shaken in a 30-ml separatory funnel. The upper (chlorobutane) layer was separated, washed with four 5-ml portions of 0.5 *N* HCl, and evaporated to dryness. The residue was partitioned between 3 ml of 0.1 *N* NaOH and 3 ml of heptane. The aqueous base was acidified with 1 *N* HCl and extracted with 4 ml of CH_2Cl_2. The organic solvent was evaporated; the residue was dissolved in 200 μl of mobile solvent, and the entire amount was chromatographed. The contaminant was separated on a silica gel column[16] with a mobile phase consisting of heptane–isopropyl alcohol containing 1% water–acetic acid (990:10:0.3). The column effluent was passed through a rapid-scanning spectrophotometer, as previously described.

Examination of Various Injectable Drug Solutions—Samples from several manufacturers of injectable solutions of digoxin, sodium phenobarbital, epinephrine, lidocaine hydrochloride, mepivacaine hydrochloride, pilocarpine hydrochloride, and dexamethasone sodium phosphate, each packaged in a single-dose delivery syringe or syringe cartridge where the solution was in contact with a rubber closure, were examined for the presence of I by reverse-phase HPLC with a mobile phase of CH_3CN–H_2O–HOAc (260:740:0.3). Each injectable solution (200 μl), except for sodium phenobarbital, was used undiluted. With phenobarbital injectable solutions, I was not resolved from the drug during HPLC; therefore, it was necessary to perform a preliminary extraction by the procedure described above.

As each injectable solution was chromatographed, the fraction of eluate containing a compound with a retention time equal to that of standard I was collected in a microcell. The UV spectrum was recorded at pH 4 (the mobile phase pH) and again at pH 11 or 12 after the addition of 10–20 μl of 1 *N* NaOH. Spectra were normalized at their absorbance maxima (323 or 322 nm in acid; 311 or 310 nm in base) for direct comparison to the spectra of the standard.

Quantitation—Each of the various injectable drug solutions was quantitatively analyzed for I. The HPLC system was the same as that used in the analysis of digoxin injectable solution, except that the variable-wavelength detector was set to 323 nm and 0.04 AUFS and the mobile phase consisted of 30% acetonitrile and 1% acetic acid in water. Injectable solution samples were used directly without dilution. The standard solution was prepared by dissolving I in 50% ethanol to give a concentration of 4 or 8 μg/ml. The injection volume for samples and standard was 40 μl. Linearity for I was established. Repeatability was examined by making seven successive injections of I standard solution and measuring peak area. The relative standard deviation was 0.25%.

Interference with Digoxin Assay—Three samples of digoxin injectable solution known to contain I were assayed for digoxin by the HPLC method specified in the USP (1) with 31% CH_3CN, a mobile phase in which I coeluted with digoxin, and with 29% CH_3CN, a mobile phase in which I was separated from digoxin. The percent of the label claim was determined in each case.

RESULTS

Origin and Identity of the Contaminant—The chromatogram of the contaminated digoxin injectable solution is shown in Fig. 1; the mobile

[11] Good spectra were obtained at absorbance readings as low as 0.01 AUFS. At higher concentrations, smooth spectra were obtained with continuous flow through the flowcell.

Figure 1—*Chromatogram of a commercial sample of digoxin injectable solution showing the contaminant, 2-mercaptobenzothiazole (A), and digoxin (B). The mobile phase was 29% acetonitrile; the detector was set at 218 nm.*

phase was 29% acetonitrile. When a mobile phase of 26% acetonitrile was used to obtain the chromatograms of cardiac glycosides related to digoxin, the impurity had a retention time within 0.1 min of that of diginatin. However, in 30% acetonitrile, diginatin and the impurity were well separated with retention times of 5.30 and 7.70 min, respectively.

The UV spectrum of chromatographically purified contaminant had a λ_{max} that varied from 320 to 316 nm, corresponding to slight variations in the mobile phase composition. This implied that the impurity was devoid of an unsaturated butyrolactone chromophore and was unrelated

[a] Each injectable solution listed represents a different lot. Some samples were past their expiration date. [b] Unless otherwise noted, normalized spectra were practically superimposable with those of standard I. [c] Multiple values represent individual analyses of injectable solutions of the same lot but from different containers. [d] UV spectrum was distorted especially at shorter wavelengths due to interfering substances. [e] Three lots from this manufacturer were free of I.

to digoxin. When measured as a function of pH, the absorbance maximum shifted from 311 nm in base to 323 nm in acid, with the greatest shift occurring at pH ~6–7, indicating that the compound was ionic or ionizable. The impurity was partitioned from dilute hydrochloric acid into chloroform and from chloroform into aqueous base. This partitioning behavior, in conjunction with the observed pH profile, showed that the impurity was an acidic compound with an estimated pK_a of 6–7.

The rubber sheath and rubber closure extracts contained a compound with a retention time and a UV spectrum that matched those of the impurity in the digoxin injectable solution; the glass barrel extract did not. Thus, the impurity originated from the rubber parts of the syringe, and since the injection medium had limited, if any, contact with the rubber sheath which covered the needle, the contaminant was undoubtedly leached from the rubber closure.

2-Mercaptobenzothiazole (I), a compound commonly used as an accelerator in the vulcanization of rubber, contains a weakly acidic aromatic thiol group[17] and has an absorbance maximum at 320 nm (4), making it a prime candidate for the structure of the contaminant. The electron-impact mass spectrum for standard I and for the compound extracted from the rubber sheath matched very closely, each with a very strong molecular ion at m/z 167 (base peak). The impurity in the digoxin in-

[17] The acidic dissociation constant of I has been determined spectrophotometrically to be 6.93 in 40% aqueous ethanol at 27° (3).

jectable solution and the compounds extracted from the rubber sheath and rubber closure had the same retention time and the same UV spectrum as standard I. The UV spectra of the standard had absorbance maxima at 323 and 311 nm at pH 4 and pH 12, respectively (Fig. 2). These maxima were also oberved for the impurity when treated similarly.

Examination of Other Drug Injectable Solution Samples—Efforts to establish the source and identity of the impurity had been conducted on one digoxin injectable solution sample. Since the contaminant was found to originate from the rubber closure of the injection syringe, one would expect other drug samples packaged in this or a similar type of container to contain the contaminant also. Results of the qualitative and quantitative analysis of all drug injectable formulation samples examined are given in Table I. Fortunately, in most of the drug samples that were examined qualitatively by HPLC and by UV spectrophotometry, the injection ingredients did not interfere with the identification of I.

In some instances, the contaminant peak was not completely resolved from the tail or leading edge of the drug or excipient peaks, and some distortion was evident in the UV spectrum of the collected sample. This distortion occurred only in a few samples containing low levels of I (Table I) and, even in these cases, the distortion occurred generally in the shorter wavelengths of the spectrum; the peak at 323 nm (in acid) was unaffected, and the peak normally at 310 nm (in base) was sometimes shifted slightly toward shorter wavelengths. When there was no chromatographic interference, spectra of the isolated contaminant normalized at their absorbance maxima (323 nm in acid, 311 nm in base) were practically superimposable with those of the standard. In the case of sodium phenobarbital, I was completely submerged under one large phenobarbital absorption peak, necessitating removal of the drug by a preliminary extraction.

During quantitative analysis of the various drug samples when the detector was set to 323 nm, the only peak observed in the chromatogram, other than peaks occasionally seen at or near the solvent front, was the peak corresponding to I. 2-Mercaptobenzothiazole (I) was found in over half of the injectable solutions examined.

Silica Gel HPLC—Silica gel HPLC was performed on four digoxin and two sodium phenobarbital injectable solutions to complement the evidence provided by reverse-phase HPLC. Each sample contained a compound with a retention time between 6.10 and 6.22 min, which compared well with retention times of 6.09 and 6.19 min for duplicate injections of standard I. The spectrum of each sample and standard had an absorbance maximum at 327 nm, although the spectra of the impurity from phenobarbital samples were distorted by the presence of interfering compounds that were poorly resolved by HPLC.

Interference with Digoxin Assay—In reverse-phase HPLC, I was influenced less significantly by changes in the mobile phase than digoxin. Thus, in 29% CH_3CN I eluted before digoxin, in 31% CH_3CN the compounds coeluted, and in 34% CH_3CN digoxin eluted before I. Coelution of these two compounds during digoxin assay would give erroneously high assay values. Table II shows that the true assay results were raised by 10.6, 11.1, and 20.4% for three digoxin samples due to interference from I.

DISCUSSION

After the contaminant in the digoxin injectable formulation was identified, it was thought that this compound, being acidic, would be found at higher concentrations in injectable solutions of high pH, such as sodium phenobarbital; this proved not to be the case. The digoxin injectable solution medium consisted of 40% propylene glycol, 10% alcohol, and 50% water at neutral pH; sodium phenobarbital and dexamethasone sodium phosphate injectable solutions were weakly basic aqueous solutions; and epinephrine, lidocaine hydrochloride, and mepivacaine hydrochloride were weakly acidic aqueous solutions. A comparison of the amounts of I found in the injectable solutions (Table I) showed that the concentration of the impurity had no apparent dependence on the composition or pH of the solution medium and undoubtedly was more dependent on the level of the compound in the rubber closure. The concentration of I varied from lot to lot of a particular drug solution, and even from one container to the next within the same lot.

There are literature reports describing the extraction of I and related compounds from rubber materials. Various types of rubber were extracted with solvents simulating those found in food products, and all but chloroprene were found to contain I, its zinc salt, or 2,2-dithiobis-(benzothiazole), all apparently assayed as I by GC (5). The compound has also been extracted into water from rubber articles that come in contact with foods (6, 7). Two compounds related to I, 2-(methylmercapto)benzothiazole (8) and 2-(2-hydroxyethylmercapto)benzothiazole (9), have been extracted into aqueous media from the rubber closures of disposable syringes. The latter compound reportedly arose from a reaction between I and ethylene oxide, a compound used during the sterilization of the disposable syringes.

The official method of analysis for digoxin injectable solution (1) specifies reverse-phase HPLC with acetonitrile–water as the mobile phase. Unfortunately, if I were present in the digoxin solution, it might elute from the column together with digoxin and raise the apparent analytical result.

A literature survey was conducted for known toxicological properties of I. The compound was shown to be an allergen in rubber-induced skin sensitivity (10, 11). Mutagenic activity of I was observed in fruit flies (12), and slight mutagenic activity was produced in cultured cells from Chinese hamsters by a rubber extract containing I and other vulcanizing accelerators (7). One study revealed that the compound may produce neoplasms in mice (13), although the results of that study were inconclusive, and the amounts of the compound used in that study were much greater than the amounts found in the injectable solutions.

In conclusion, it appears that I is a common contaminant for a variety of injectable drug solutions packaged in single-dose injection syringes or syringe cartridges with rubber closures. It may pose problems as an analytical or toxicological contaminant.

Analysis of Folinic Acid in Human Serum Using High-Performance Liquid Chromatography with Amperometric Detection

B. K. BIRMINGHAM * and D. S. GREENE ‡x

Received April 22, 1982, from the **Department of Pharmacy, College of Pharmacy, University of Rhode Island, Kingston, RI 02881* and *‡Bio Research Laboratories, Ltd., Scientific Affairs Division, Senneville, Quebec H9X 3R3, Canada.* Accepted for publication September 23, 1982.

Abstract □ An assay for the separation and quantification of folinic acid in serum was developed using high-performance liquid chromatography with electrochemical detection. Folinic acid was extracted from serum using a C18 minicolumn treated with dibasic ammonium phosphate. The drug was eluted from this column with methanol, which was evaporated under a nitrogen stream at 50°. The mobile phase, pH 3.5 ammonium phosphate buffer–methanol–acetonitrile (93:4:3), was pumped at a flow rate of 3.0 ml/min. The recovery of folinic acid added to human serum was 101.11 ± 8.5% (mean ± *SD*). A plot of folinic acid peak height as a function of concentration was linear over the range of 2.5×10^{-7} to 2.5×10^{-6} *M*. Neither methotrexate nor other reduced folates interfered with the analysis of folinic acid. Sample preparation and analysis can be completed within 2 min of sample collection.

Keyphrases □ Folinic acid—analysis by high-performance liquid chromatography, amperometric detection, human serum □ High-performance liquid chromatography—amperometric detection, folinic acid and other folates, human serum

Folinic acid, *N*-[*p*-[[(2-amino-5-formyl-5,6,7,8-tetrahydro-4-hydroxy-6-pteridinyl)-methyl]amino]benzoyl]-L-glutamic acid, is a reduced folate used to prevent or reduce the toxicity associated with high-dose methotrexate therapy for the treatment of neoplastic disease (1). The optimization of folinic acid dosage regimens necessitates an understanding of its disposition; however, studies characterizing the pharmacokinetics of this compound have been hampered by the lack of a rapid, sensitive, and specific assay method. Previously reported methods for folinic acid quantification include microbiological assay (2), radiochemical assay (3), radioimmunology (4), and spectrophotometry (5). The application of these techniques to pharmacokinetic studies is somewhat limited since spectrophotometric methods are not sufficiently sensitive, differential microbiological assays are generally not precise, and radiochemical and radioimmunologic techniques may suffer from a lack of specificity.

A high-performance liquid chromatographic (HPLC) assay employing electrochemical detection, suitable for the routine analysis of folinic acid, has been designed and is free from interference from folic acid, dihydrofolic acid, 5-methyl tetrahydrofolic acid, and methotrexate. This assay has been applied to the quantification of folinic acid in human serum.

EXPERIMENTAL

Reagents—Folinic acid[1], 5-methyltetrahydrofolic acid[2], dibasic ammonium phosphate[3], methanol[4], acetonitrile[4], EDTA[5] (disodium ethylenediaminetetraacetic acid), and phosphoric acid[3] were used as received.

HPLC System—A liquid chromatograph consisting of a solvent delivery system[6], a fixed-loop injector[7] with a 100-μl loop, a microparticulate radially compressed reverse-phase column[8], an electronic noise filter[9], and an electrochemical detector with a 5-mm diameter glassy carbon electrode[10] was used. The temperature of the column was adjusted by placing the column in a constant-temperature oven[11]. Data were collected and analyzed using an electronic integrator/recorder[12].

The mobile phase consisted of 0.5 *M* ammonium phosphate buffer–methanol–acetonitrile (93:4:3) with pH adjusted to either 3.5 or 5.5. The pH of the mobile phase used for characterization of the system was 5.5; the pH was decreased to 3.5 when serum samples were analyzed, to increase resolution. EDTA (10 m*M*) was added to decrease background electrical noise. The mobile phase was prepared daily, filtered, and deaerated before use. Double-distilled, deionized water was used for the preparation of all solutions.

Electrochemical Characteristics of the Folate Analogues—The oxidation characteristics of folinic acid were evaluated using the mobile phase at a pH of 5.5 and a flow rate of 3.0 ml/min. The concentration of folinic acid was 1.0×10^{-6} *M*. Applied potentials were adjusted between +0.3 and +0.9 V. A 30-min equilibration period was necessary following each change in applied potential to reestablish a suitable baseline.

Extraction—Ascorbic acid (1 mg/ml) was added to all serum samples immediately after collection to prevent drug degradation. Folinic acid was extracted from serum using reverse-phase C18 disposable cartridges[13]. The cartridges were activated using 10 ml of methanol followed by 10 ml of 5 m*M* ammonium phosphate buffer, pH 5.5. One milliliter of serum was then pushed through the cartridge followed by 3 ml of 5 m*M* ammonium phosphate buffer, pH 5.5. The effluent was discarded. The outlet end of the cartridge was then connected to a vacuum and the cartridge was dried for 5 min, after which time the drug was eluted with 2 ml of methanol. The eluant was collected and evaporated at 50° under a nitrogen stream in a sample concentrator[14]. The evaporated samples were stored at −4°; samples were reconstituted in 500 μl of mobile phase before being assayed.

Recovery Studies—The recovery of folinic acid in serum was determined by comparison of peak heights of drug prepared in mobile phase to peak heights obtained after extraction from serum. A standard curve was constructed by plotting peak height as a function of concentration for extracted serum samples containing known amounts of folinic acid over the range of 2.5×10^{-7} to 2.5×10^{-6} *M*. The data were analyzed using a linear regression program on a programmable calculator. Concentrations of all samples were calculated using the resulting regression coefficients.

RESULTS AND DISCUSSION

Figure 1 is a plot of detector response (log peak height) as a function of applied potential for folinic acid. The threshold for the oxidation of this compound was +0.4 V. An increase in applied potential resulted in an increase in generated current until a plateau was reached at +0.7 V. It was not possible to characterize response at >+0.9 V due to an extremely high background current, presumably caused by the oxidation of components in the mobile phase.

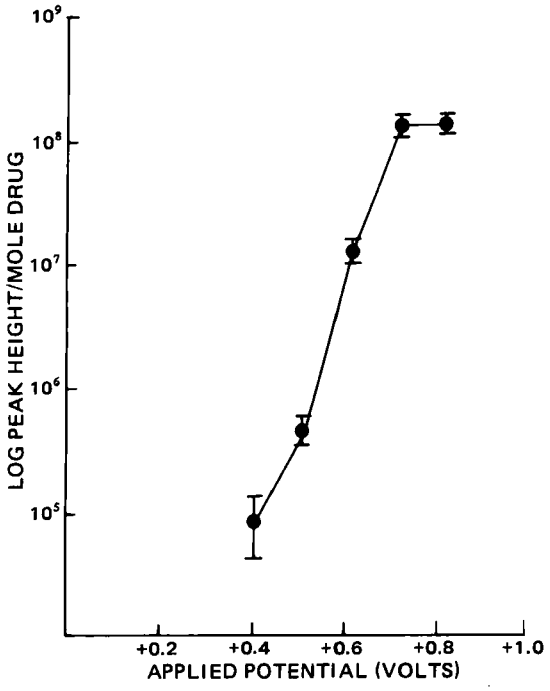

Figure 1—*Detector response as a function of applied potential for folinic acid.*

High electrolyte concentrations are necessary in mobile phases when electrochemical detection is used in order to reduce resistance and increase the current at the electrode surface. Varying concentrations of electrolyte may also affect the diffusion coefficient of the electroactive species, limiting the current at the electrode. The effect of varying ammonium phosphate concentrations, at a constant pH of 5.5, on detector response (Fig. 2) was determined for folinic acid. There was a constant increase in response with increasing salt concentration until a plateau was reached at 0.01 *M*.

The effect of buffer concentration on the retention of folinic acid was also characterized. Figure 3 describes the retention time for folinic acid as a function of ammonium phosphate concentration (pH 5.5). It is evident that as buffer concentration increases, there is a corresponding increase in retention time.

The general effect of mobile phase velocity on the diffusion layer thickness within the electrochemical cell and the resulting effect on current yield has been reported (6). The optimal flow rate, in terms of detector response, was determined by plotting response (measured as peak height) as a function of flow rate (Fig. 4) for folinic acid. It is apparent that the peak height decreases with increasing flow rate between 1.0 and 7.0 ml/min.

Investigation of the effect of flow rate on retention (Fig. 5) showed that significant deviations from linearity occur as flow rate increases. Both the capacity and selectivity of the radially compressed column decreased with increases in flow rate. A log–log transformation (Fig. 5 inset) of the data, however, was linear. These findings are in general agreement with studies of flow control in HPLC reported by Schrinker (7).

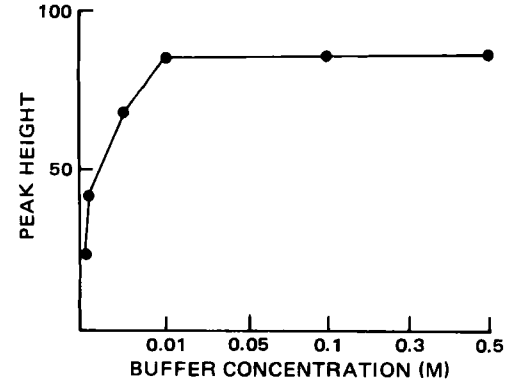

Figure 2—*Detector response as a function of mobile phase salt concentration (pH 5.5).*

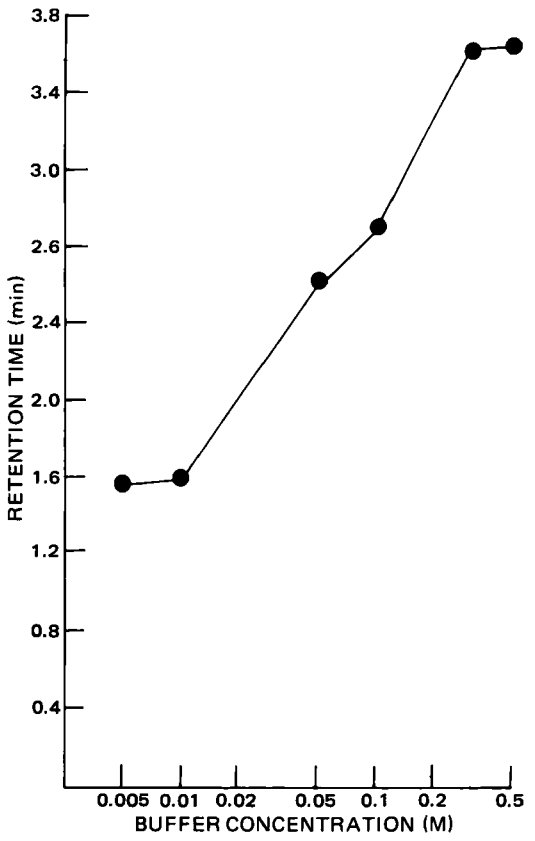

Figure 3—*Effect of buffer concentration on folinic acid retention.*

It has been reported by Gilpin and Sisco (8) that both normal and bonded phases may be affected by temperature, and that variations in capacity >25% have been reported with temperature changes of ≤1°. Because of the high efficiency and reactivity associated with radially compressed columns, the effect of temperature on the retention time of folinic acid was investigated. Table I reports the retention times for folinic acid over a range of temperatures between 20° and 50°. A decrease in retention time (capacity) with increasing temperature was observed; however, the resolution of the system actually improved at higher temperatures. This can best be explained by the decrease in folinic acid peak width.

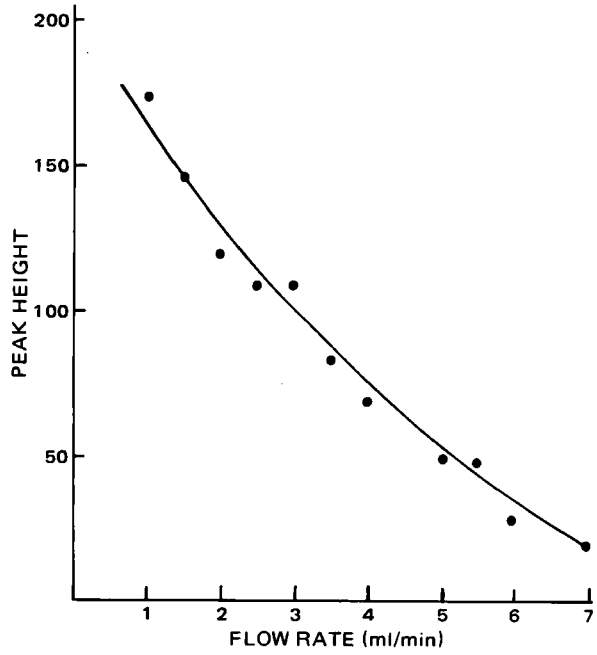

Figure 4—*Detector response to folinic acid as a function of mobile phase flow rate.*

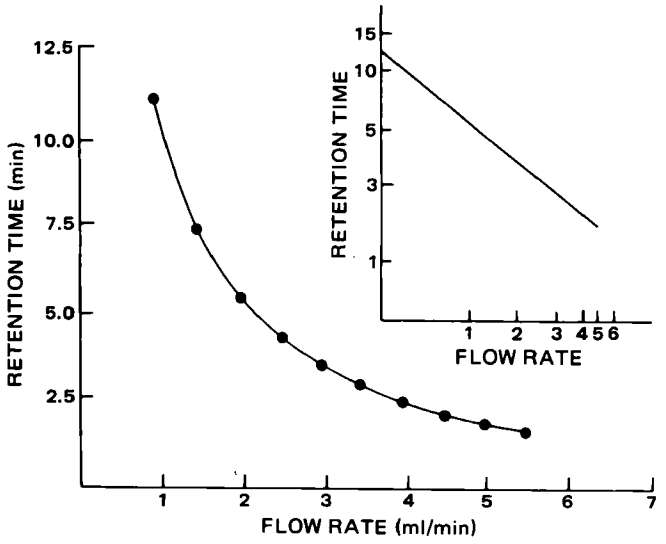

Figure 5—*Retention time as a function of flow rate for folinic acid. The inset is the log–log transformation of the graph.*

Temperature fluctuations were found to affect daily chromatographic results. Ambient temperatures varied as much as 10° during the course of the day, causing as much as 20% changes in observed retention times for folate compounds using the same mobile phase. The installation of a constant-temperature oven circumvented the effect of temperature changes on the system. Column temperatures were held constant at 40°, and the retention time was found to be reproducible within the 5% limits of the system.

Figure 6 is a plot of the retention of folinic acid as a function of pH. The mobile phase flow rate was 3.0 ml/min, and the ammonium phosphate concentration was 0.5 *M*. It was evident from examination of this figure that pH has a significant effect on folinic acid retention.

The extraction and recovery of folinic acid added to pooled human serum was virtually complete. The recovery of drug over the concentration range of 2.5×10^{-7} to 2.5×10^{-6} *M* ranged from 94 to 117% with a mean value of 101%. Folinic acid-spiked serum samples were found to be stable for 2 months when stored at −4°. However, after extraction, samples were only stable for 2 days. A plot of calculated folinic acid concentration as a function of actual concentration in spiked serum

Table I—Effect of Temperature on Folinic Acid Retention

Temperature	Retention Time, min
20°	4.60
30°	4.13
40°	3.50
50°	2.68

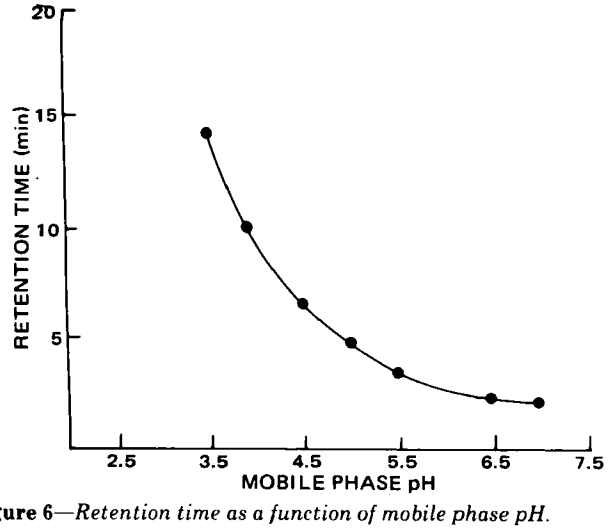

Figure 6—*Retention time as a function of mobile phase pH.*

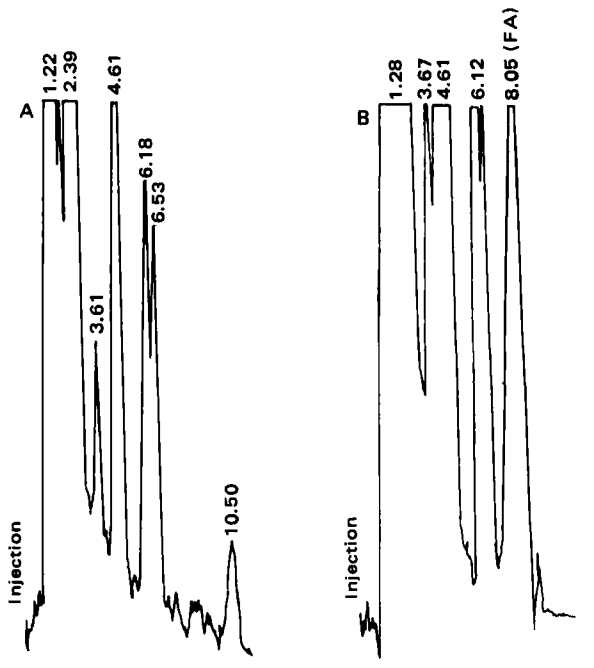

Figure 7—*Chromatograms from subject KB using chromatographic conditions described in the text. Numbers above peaks represent retention time in minutes. Key: (A) serum blank; (B) serum sample collected 5 min after intravenous injection of 10 mg of folinic acid; (FA) folinic acid (concentration 7.3×10^{-6} M).*

samples was linear ($r = 0.99$; slope = 1.02). The slope was not significantly different from 1.0 (Student's t test, $p > 0.05$) and the intercept was not significantly different from 0 (Student's t test, $p > 0.05$). To improve the resolution between folinic acid and other eluting components of the sample matrix, it was necessary to decrease the pH of the mobile phase from 5.5 to 3.5. The retention time for folinic acid under these conditions was 8.05 min. The compound was completely resolved from neighboring peaks at 6.53 and 10.50 min in all samples. The column capacity for folinic acid was 7.13; the efficiency of the column was calculated to be 530 plates. Figure 7A is a representative chromatogram of a drug-free serum sample; Fig. 7B shows a chromatogram obtained from a serum sample collected 5 min after the injection of 10 mg iv of folinic acid to the same 80-kg human volunteer.

Folic acid, dihydrofolic acid, and 5-methyltetrahydrofolic acid analyzed under these conditions had retention times of 4–6 min; therefore, these compounds did not interfere with folinic acid. Detection of methotrexate under these chromatographic conditions requires an applied potential of >+0.9 V. Therefore, the presence of methotrexate in serum samples obtained from patients receiving high-dose methotrexate therapy should not interfere with the analysis of folinic acid.

Figure 8 is a semilogarithmic plot of the data obtained following rapid

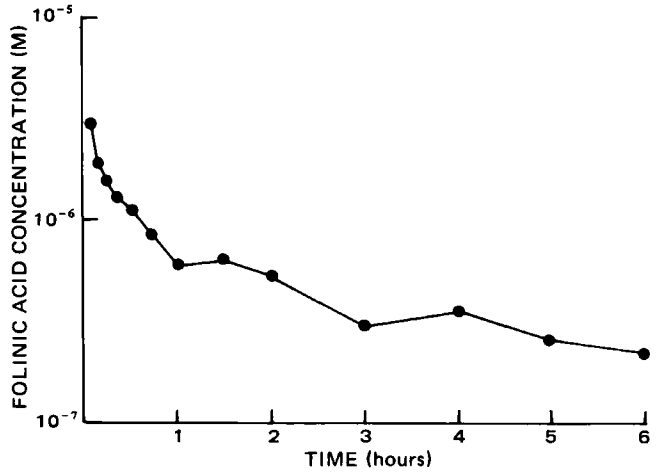

Figure 8—*Folinic acid concentration as a function of time following the intravenous administration of 10 mg of drug.*

intravenous administration of a 10-mg dose of folinic acid to a healthy 57-kg volunteer. These data are similar to those reported by Rothenberg *et al.* (3) following the administration of folinic acid to two healthy subjects. The disposition of folinic acid was characterized by a two-compartment open model. The peak plasma concentration was 3.5×10^{-6} *M*. The distribution and elimination half-lives were 0.27 and 3.7 hr, respectively. These half-lives are different from those obtained by Mehta *et al.* (2) using a microbiological assay, probably because the HPLC assay reported here and the assay of Rothenberg *et al.* (3) do not differentiate the stereoisomers, whereas the microbiological assay measures only the *l* isomer.

Plasmolysis, Red Blood Cell Partitioning, and Plasma Protein Binding of Etofibrate, Clofibrate, and Their Degradation Products

PAUL ALTMAYER and EDWARD R. GARRETT ˣ

Received May 24, 1982, from *The Beehive, College of Pharmacy, J. Hillis Miller Health Center, University of Florida, Gainesville, FL 32610.* Accepted for publication September 8, 1982.

Abstract □ Etofibrate (I), the ethylene glycol diester of clofibric and nicotinic acids, degrades almost equally through both half-esters with half-lives of ~10 and 1 min in fresh dog and human plasma, respectively. The nicotinate V degrades with half-lives of ~12 hr and 50 min in fresh dog and human plasma, respectively. Ester III and clofibrate VI degrade by saturable Michaelis–Menten kinetics in fresh human plasma, with similar maximum initial rates and respective terminal first-order half-lives of 12 and 26 min. Tetraethyl pyrophosphate at 100 μg/ml inhibited human plasma and red blood cell esterases permitting plasma protein binding and red blood cell partitioning studies. The red blood cell–plasma water partition coefficient was 5.4 for 0.2–80 μg/ml of I. Clofibrate (VI) showed a saturable erythrocyte partitioning that decreased from 7.8 (10 μg/ml) to 1 (50 μg/ml). The strong binding of I and VI to ultrafiltration membranes necessitated the determination of their plasma protein binding by the method of variable plasma concentrations of erythrocyte suspensions to give 96.6% (0.2–80 μg/ml) and 98.2% (13.6–108.4 μg/ml) binding, respectively. Methods for the determination of the parameters of saturable and nonsaturable plasma protein binding for unstable and membrane-binding drugs by the method of variable plasma concentrations in partitioning erythrocyte suspensions are presented.

Keyphrases □ Etofibrate—degradation products, plasmolysis, red blood cell partitioning, plasma protein binding □ Clofibrate—degradation products, plasmolysis, red blood cell partitioning, plasma protein binding □ Plasmolysis—etofibrate, clofibrate, degradation products □ Red blood cell partitioning—etofibrate, clofibrate, degradation products □ Plasma protein binding—etofibrate, clofibrate, degradation products

Clofibric acid derivatives and nicotinic acid are well established therapeutic agents for the treatment of hyperlipidemia, a major risk factor in coronary artery disease (1, 2). Etofibrate [2-nicotinoyloxyethyl 2-(4-chlorophenoxy)-2-methylpropionate, (I)], the ethylene glycol diester of clofibric and nicotinic acids, is effective in lowering triglycerides and cholesterol in controlled clinical trials (3, 4). The greater lipid-lowering effect of etofibrate in rats than simultaneously administered equimolar amounts of clofibric and nicotinic acids permitted the postulation that both etofibrate and/or its derived half-esters may have pharmacological activity (5). It was reported (6) that both half-esters were detectable after incubation of rat microsomes with etofibrate and that they appeared to be more stable in biological fluids than their etofibrate precursor.

The solution stabilities of etofibrate (I), clofibrate (VI), and derived monoesters were reported previously (7). The possible solvolytic routes are given in Schemes I and II. Conditions were established for optimal extractions and log k–pH profiles for solution solvolyses were constructed for various temperatures using specific high-performance liquid chromatographic (HPLC) assays. Preliminary studies in fresh dog plasma (7) indicated that a considerable fraction of etofibrate rapidly hydrolyzed in dog plasma to produce the ethylene glycol ester of clofibric acid (III), which also hydrolyzed rapidly. This is in contrast to other reported studies in diluted human blood (8).

This paper reports on the human red blood cell–plasma partitioning and human plasma protein binding of etofibrate (I), clofibrate (VI), and their degradation products using the esterase inhibitor, tetraethyl pyrophosphate. Improved HPLC assays of higher sensitivity were applied to complete studies of the human and dog plasmolytic routes and degradation rates. In addition, complete methods for the determination of the parameters of saturable and nonsaturable plasma protein binding for unstable and membrane-bound drugs by the method of variable plasma concentrations in partitioning erythrocyte suspensions are presented.

The greater lipid-lowering effect of etofibrate in rats than simultaneously administered equimolar amounts of clofibric and nicotinic acids permitted the postulation that both etofibrate and/or its derived half-esters may have pharmacological activity (5). It was reported (6) that both half-esters were detectable after incubation of rat microsomes with etofibrate and that they appeared to be more stable in biological fluids than their etofibrate precursor.

The solution stabilities of etofibrate (I), clofibrate (VI), and derived monoesters were reported previously (7). The possible solvolytic routes are given in Schemes I and II. Conditions were established for optimal extractions and log k–pH profiles for solution solvolyses were constructed for various temperatures using specific high-performance liquid chromatographic (HPLC) assays. Preliminary studies in fresh dog plasma (7) indicated that a considerable fraction of etofibrate rapidly hydrolyzed in dog plasma to produce the ethylene glycol ester of clofibric acid (III), which also hydrolyzed rapidly. This is in contrast to other reported studies in diluted human blood (8).

This paper reports on the human red blood cell–plasma partitioning and human plasma protein binding of etofibrate (I), clofibrate (VI), and their degradation products using the esterase inhibitor, tetraethyl pyrophosphate. Improved HPLC assays of higher sensitivity were applied to complete studies of the human and dog plasmolytic routes and degradation rates. In addition, complete methods for the determination of the parameters of saturable and nonsaturable plasma protein binding for unstable and membrane-bound drugs by the method of variable plasma concentrations in partitioning erythrocyte suspensions are presented.

EXPERIMENTAL

Methods—Acetic acid[1], sodium acetate[1], dibasic sodium phosphate[1], monobasic potassium phosphate[1], *tert*-butyl alcohol[2], sodium chloride[2],

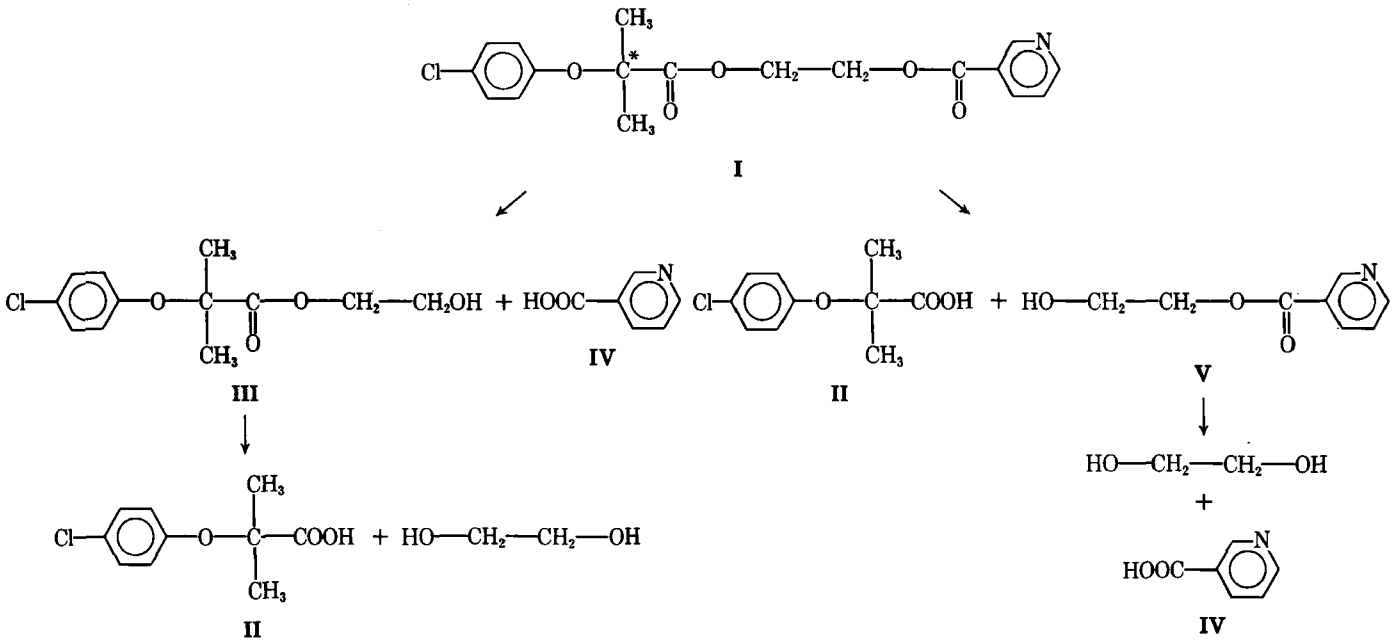
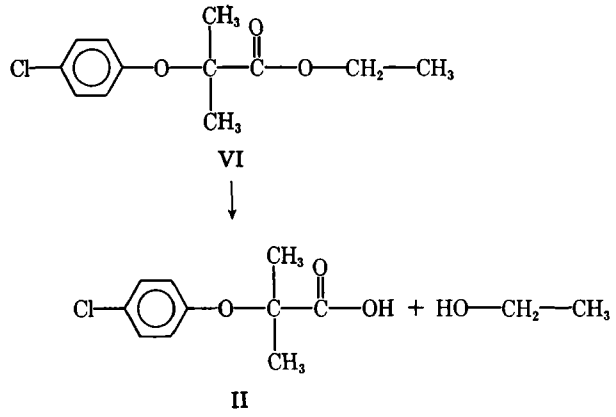


Scheme I—Pathways of etofibrate hydrolysis. (*) ^{14}C atom of radiolabeled etofibrate.



Scheme II—Pathway of clofibrate hydrolysis.

tetrabutylammonium phosphate[3], and volumetric concentrations of hydrochloric acid[4] were analytical grade. Chloroform[2], ethyl acetate[1], methanol[2], and acetonitrile[2] were HPLC or UV grade. The following also were used: sodium chloride injection USP[5], sodium heparin injection USP[6], and disposable syringes[7]. Tetraethyl pyrophosphate[8] was used as enzyme inhibitor. Thymol[2] and phenylurea[4] were internal standards for the HPLC systems. Etofibrate[9] (I), clofibric acid[9] (II), 2-hydroxyethyl 2-(4-chlorophenoxy)-2-methylpropionate[9] (III), nicotinic acid[9] (IV), 2-hydroxyethyl nicotinate[9] (V), and clofibrate[9] (VI) were used as received. For protein-binding studies, ultrafiltration cones[10], cone supports[11] and tubes[10], molecular filters[11], and a sample filtration assembly[11] were used.

Specifically ^{14}C-labeled etofibrate[9] (Scheme I) was used for plasma protein binding and red blood cell partition studies. A toluene-based scintillation[12] cocktail was used in the radioactive assay.

Apparatus—The HPLC system consisted of single pump[13], a radial compression module[14] equipped with a C_8 or C_{18} column[13] (8 mm i.d.), and an automatic injector[15]. The variable-wavelength UV detector[16] was set at 225 or 254 nm, with a strip chart recorder[17]. Radioactivity was assayed with a liquid scintillation counter[18]. A laboratory centrifuge was used[19].

HPLC Procedures—Three HPLC systems were used: System A for I, II, and III; System B for IV and V; and System C for VI.

System A—Prepared solutions of 0.05 *M* sodium acetate were adjusted to a measured pH 3.75 with 0.05 *M* acetic acid. The mobile phase was a mixture of this buffer and acetonitrile (50:50). The flow rate of 2 ml/min gave almost no back pressure (0–500 psi) on the C_8 column. The wavelength of the UV detector was 225 nm.

System B—The mobile phase was a mixture of an aqueous solution of 0.008 *M* tetrabutylammonium phosphate and methanol (25:75). The flow rate of 2 ml/min produced a back pressure of 400–700 psi with the C_{18} column. The wavelength of the UV detection was 254 nm.

System C—The mobile phase was a mixture of 0.05 *M* acetate buffer (pH 3.75) and acetonitrile (37:63). The flow rate of 2.2 ml/min gave a back-pressure of 1100 psi on the C_{18} column. The wavelength of the UV detector was 225 nm.

HPLC Analytical Methods in Plasma for I, II, and III—*Extraction Procedure (Method a)*—Aliquots (0.2 or 0.5 ml) of fresh, heparinized dog or human plasma were adjusted to pH 2.5 with 25 or 62.5 μl of 1 *N* HCl and extracted with 2 or 5 ml of chloroform for 10 min with slow shaking. Aliquots (1.6 or 4 ml) of the organic phase were evaporated to dryness under a nitrogen stream. The residue was reconstituted with mobile phase containing the internal standard (thymol), and 50 μl was injected into HPLC system A.

Acetonitrile Deproteinization (Method b)—An equal volume of acetonitrile containing the internal standard (thymol) was added to a plasma sample, vortexed at high speed for 30 sec, and centrifuged at 3000 rpm for 10 min. A 50-μl aliquot of the supernatant was injected into HPLC system A.

HPLC Analytical Methods in Plasma for IV and V—*Extraction Procedure (Method c)*—Fresh plasma (0.5 ml) was adjusted to pH 2 with 65 μl of 1 *N* HCl and extracted with 2 ml of an ethyl acetate–*tert*-butyl alcohol mixture (50:50) for 10 min with slow shaking. After centrifugation for 10 min at 3000 rpm, 1.8 ml of the organic phase was evaporated under a nitrogen stream. The residue was reconstituted with mobile phase containing phenylurea as an internal standard, and 50 μl was injected into HPLC system B.

Acetonitrile Deproteinization (Method d)—Acetonitrile (2 or 2.5 ml) was added to plasma (0.2 or 0.5 ml). The mixture was vortexed for 30 sec and centrifuged for 10 min at 3000 rpm. Aliquots of the clear supernatant

(1 or 2.5 ml) were evaporated to dryness under a nitrogen stream. The residue was reconstituted with mobile phase containing phenylurea as internal standard, and 50 μl was injected into HPLC system B.

HPLC Analytical Methods in Plasma for VI (Method e)—Appropriate volumes of acetonitrile containing the internal standard (etofibrate) were added to 0.2 or 0.5 ml of plasma. The mixture was vortexed and centrifuged at 3000 rpm for 10 min. Aliquots of the clear supernatant were injected into HPLC system C.

Purification of Radiolabeled Etofibrate—^{14}C-Labeled etofibrate (0.03 mg), of presumed specific activity 1.47×10^8 dpm/mg, was dissolved in 1 ml of acetonitrile. A 100-μl aliquot, mixed with 10 ml of scintillation fluid[12] was dark-adapted for 12 hr before liquid scintillation counting. The ^{14}C-labeled etofibrate in acetonitrile solution (100 μl) was injected into HPLC system A, monitored by the UV detector, and the eluant was collected in 30-sec intervals for 20 min. Scintillation fluid (10 ml) was added to each collection before counting. Approximately 20% of the counts of the injected sample lay outside the etofibrate fraction (retention time range: 8–13 min) identified by its UV peak. The ^{14}C-labeled etofibrate was purified by combining the collected etofibrate fractions obtained by repetitive injections of 100-μl aliquots into the chromatograph and extracting twice with chloroform. An aliquot (500 μl) of the aqueous phase was counted and showed no significant radioactivity (39 cpm), indicating complete extraction. The chloroform extract was evaporated under a nitrogen stream and the residue reconstituted in acetonitrile. A 50-μl aliquot of this purified ^{14}C-labeled etofibrate solution was injected into the chromatograph, and the 30-sec fractions of eluant (up to 20 min) were counted; 94.4% of the total injected radioactivity was in the etofibrate collection. The amount of etofibrate in the assayed sample was determined against a calibration curve prepared from unlabeled drug in the same system. Thus, the specific activity of the purified [^{14}C]etofibrate could be calculated (1.253×10^5 dpm/μg).

Plasmolysis Studies of I, III, V, and VI—Fresh human and dog plasma were used. The blood was centrifuged for 15 min at 3000 rpm immediately after blood withdrawal into a heparinized syringe. The plasma stability studies were performed in a water bath at 37.5° for human and 38.5° for dog plasma. The plasma was spiked with a known amount of III or V in phosphate buffer (pH 7.4) for the respective studies of their degradation. Since clofibrate (VI) had poor aqueous solubility, it was added to plasma in methanol solution (1–20 μl in 3 ml of plasma). Etofibrate in 0.05 *M* HCl was added to plasma. Aliquots (0.2 or 0.5 ml) of plasma were removed at intervals and added to tubes containing acetonitrile (methods b, d, and e) or extraction solvents (methods a and c) and immediately vortexed or shaken before assay.

The kinetics of plasmolysis were studied with and without the enzyme inhibitor tetraethyl pyrophosphate (usually 90–117 μg/ml of plasma or blood). The stability of etofibrate and clofibrate was also studied in fresh human whole blood inhibited by tetraethyl pyrophosphate. The solutions of tetraethyl pyrophosphate in phosphate buffer (pH 7.4) had to be prepared freshly before each study because of its instability. The plasma of spiked blood was assayed after separation from erythrocytes by centrifugation for 4 min at 5000 rpm.

Red Blood Cell–Buffer Partition Studies—Fresh human heparinized blood was centrifuged for 15 min at 3000 rpm and the plasma removed. Isoosmotic phosphate buffer (pH 7.4) was added to the packed red blood cells with gentle mixing. The slurry was centrifuged for 10 min at 2000 rpm, and the separated buffer was discarded; this procedure was repeated three times. A phosphate-buffered solution of tetraethyl pyrophosphate (11.7 mg/μl) was added to the packed red blood cells to give ~90 μg/ml of the inhibitor. Aliquots of this red blood cell suspension were added to previously assayed spiked phosphate buffer. The mixture was mixed carefully and allowed to equilibrate for 25 min. A hematocrit was taken, and the tube was centrifuged for 10 min at 2000 rpm. An aliquot (200 or 500 μl) of the supernatant buffer was removed for analysis. The red blood cell–phosphate buffer partition coefficients were determined as a function of drug concentration and time.

Binding to Ultrafiltration Membranes—The binding of I, VI, and their degradation products to three commonly used ultrafiltration membranes was studied[10,11]. Solutions of isoosmotic phosphate buffer (pH 7.4) were prepared with 10 μg/ml of I, VI, and their degradation products, separately and in mixture. An aliquot was taken for analysis, and 5 ml was filtered through the ultrafiltration assembly in 500-μl amounts. Aliquots (200 μl) of each sequential filtration were analyzed for drug.

Plasma Protein Binding—*Compounds II–V by the Ultrafiltration Method*—Appropriate volumes of stock solutions of II–V in acetonitrile were evaporated under a nitrogen stream to dryness. A phosphate buffer solution of tetraethyl pyrophosphate was added to 22 ml of fresh human heparinized plasma to give 95.7 μg/ml, and 8 ml of plasma was used to redissolve the compounds. Additional plasma was added to give five different drug concentrations, and the plasma samples were assayed. These plasma samples (4 ml) were filtered through pretreated ultrafiltration cones for 3 min at 3000 rpm. The first 0.8 ml of ultrafiltrate was discarded, and the next 0.5 ml was assayed. The filtration cones were pretreated by filtering 2 ml of phosphate buffer containing concentrations of drugs similar to those of the subsequently filtered plasma, *i.e.*, 5, 10, 20, 50, and 100 μg/ml with subsequent filtering of 4.0 ml of plain buffer on the premise that this latter filtration would remove the nonirreversibly bound material that would introduce error into the binding study.

Etofibrate (I) and Clofibrate (VI) by the Method of Variable Plasma Concentrations—Fresh heparinized human blood was centrifuged for 15 min at 3000 rpm. The plasma was transferred to a stoppered tube. The red blood cells were washed three times with isoosmotic phosphate buffer (pH 7.4), and the buffer phases were discarded.

The desired mixtures of acetonitrile and ^{14}C-labeled and unlabeled etofibrate in acetonitrile in a centrifuge tube were dried under a nitrogen stream. The residues were reconstituted in 40 μl of isotonic ethanol–buffer (50:50). Appropriate amounts of plasma (inhibited by 100 μg/ml of tetraethyl pyrophosphate) and isotonic phosphate buffer (pH 7.4) were mixed to give from 0 to 100% of etofibrate in each pseudoplasma. The pseudoplasma samples (1.0 ml of each) were added to the amounts of dried I needed to give concentrations of 0.2, 2.0, 8.0, 16.0, 40.0, and 80.0 μg/ml. An aliquot (200 μl) was mixed with 10 ml of scintillation fluid and counted. An aliquot (0.5 ml) of a red blood cell suspension containing 100 μg/ml of tetraethyl pyrophosphate was added to each pseudoplasma and gently mixed. Hematocrits were taken and the pseudoblood was allowed to equilibrate for 20 min. The pseudoblood samples were centrifuged for 10 min at 3000 rpm, and 200 μl of the pseudoplasma, mixed with 10 ml of a scintillation fluid, were counted by liquid scintillation.

The clofibrate protein binding was studied similarly with 20 μl of a methanolic solution containing 15, 30, 60, and 120 μg of VI added to separate 1.0-ml pseudoplasma samples before the addition of the red blood cells. The samples were analyzed by HPLC method e using mobile phase C.

RESULTS AND DISCUSSION

Reverse-Phase HPLC Assays—*Compounds I, II, and III*—HPLC system A with analytical method a using chloroform extraction, evaporation, and reconstitution provided a chromatogram (Fig. 1A) for analyses of I (retention time, 10.8 min), III (4.7 min), and II (3.4 min) in mixtures. The internal standard, thymol, had a retention time of 7.3 min. The average of the standard errors of estimate (65–185 ng/ml, $n = 8$), of the concentration of I was 99 ng/ml of plasma for the 0.4- to 20-μg/ml assay range. The average of standard errors of estimate for III (46–126 ng/ml, $n = 5$) was 102 ng/ml of plasma for the 0.4- to 10-μg/ml assay range. The average of standard errors of estimate for II (27–121 ng/ml, $n = 5$) was 72 ng/ml of plasma for the 0.4- to 10-μg/ml assay range. This HPLC system had advantages over those reported previously (1) in that mixtures of I, II, and III in plasma could be assayed simultaneously.

Compounds IV and V—The ion-pair methodology of HPLC system B with analytical method c using ethyl acetate–*tert*-butyl alcohol extraction, evaporation, and reconstitution provided chromatographic separation of V (retention time, 6.3 min) from IV (10 min) and from plasma interferences. The internal standard, phenylurea, had a retention time of 7.5 min (Fig. 1B). The average of standard errors of estimate for V (40–92 ng/ml, $n = 5$) was 67 ng/ml of plasma for the 0.4- to 10-μg/ml assay range, and for IV (49–172 ng/ml, $n = 5$) the average was 102 ng/ml of plasma for the same assay range. Specific assays for IV and V from plasma were not given previously (7), since plasma components interfered with their detection in the prior evaluated HPLC procedures.

Compound VI—HPLC system C with plasma deproteinization by analytical method e provided 225-nm UV detection of VI with a retention time of 6.1 min; the internal standard, I.S., had a retention time of 4.5 min (Fig. 1C). The standard error of estimate of VI in the 0.4- to 4-μg/ml plasma range was 51 ng/ml.

Plasmolysis of Etofibrate and Its Intermediate Solvolytic Products in Fresh Dog Plasma—Preliminary studies of the stability of etofibrate in fresh dog plasma (7) indicated apparent half-lives of 4.4–6.9 min at 37.5°: 4.4 min at an initial concentration of 3.6×10^{-5} *M*, 6.9 min at 5.9×10^{-5} *M*, and 5.7 min at 1.19×10^{-4} *M*. A repeat study in fresh dog plasma at 5.4×10^{-5} *M* (19.5 μg/ml) and 38.5° using the aforementioned HPLC assays showed a half-life of 10.6 min (Fig. 2A).

Another study (Fig. 2B) in fresh dog plasma at 3.6×10^{-5} *M* (13.3 μg/ml) showed a biphasic degradation of etofibrate at 38.5° that could

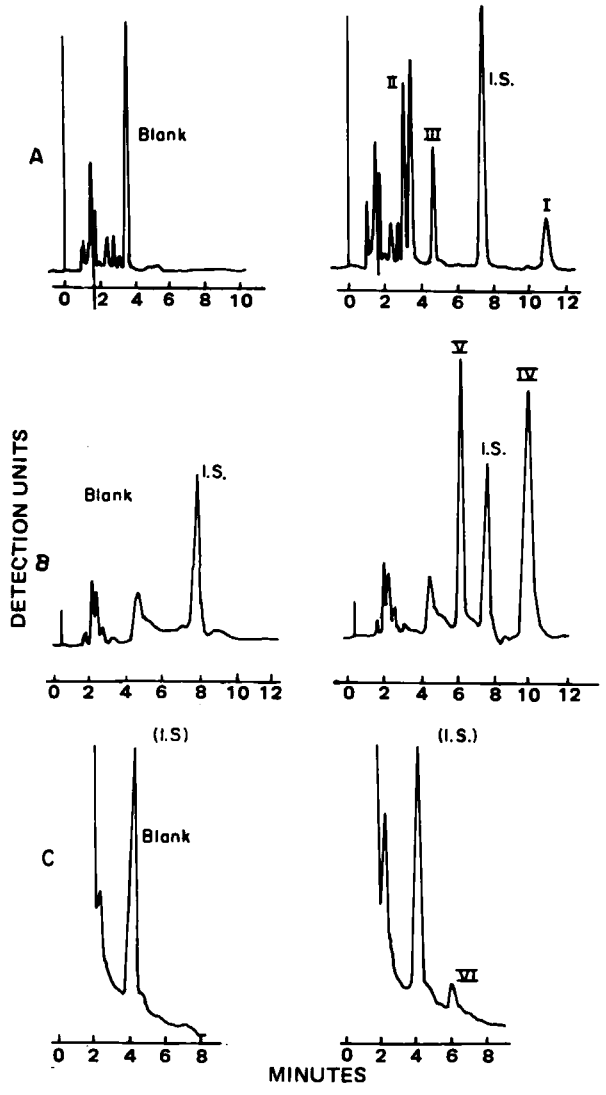

Figure 1—*Reverse-phase chromatograms of clofibric acid esters and their solvolytic products. Key: (A) Detection at 225 nm of plasma blank and plasma containing 2 μg/ml each of I, II, and III, extracted with chloroform (method a, system A). The injection volume was 50 μl; the internal standard was thymol (I.S.). (B) Detection at 254 nm of plasma blank and plasma containing 4.1 μg/ml of IV and V (method d, system B). The internal standard was phenylurea (I.S.); the injection volume was 50 μl. (C) Detection at 225 nm of plasma blank containing phenylurea as internal standard and plasma containing 0.8 μg/ml of VI (method c, system C) with 50 μl injected.*

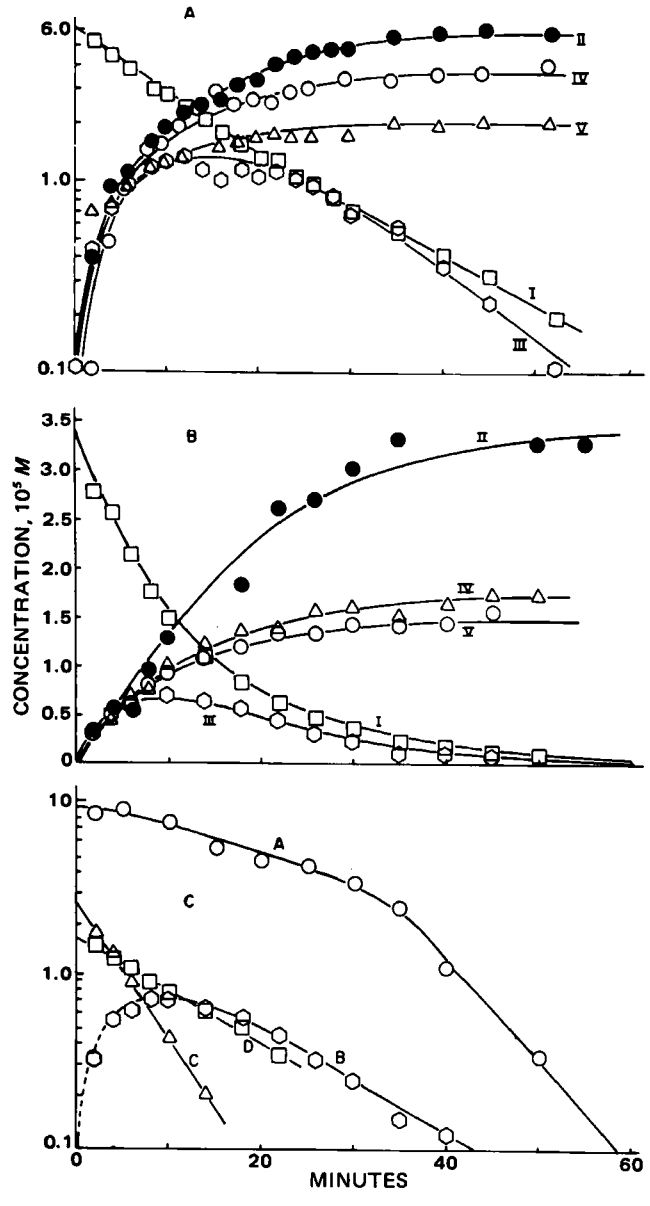

Figure 2—*(A) Semilogarithmic plots against time for 5.4 × 10^{-5} M (19.5 μg/ml) etofibrate (I) and its solvolytic products, II, III, IV, and V, in dog plasma at 38.5°. The apparent half-lives of I and III were 10.6 and 9.9 min, respectively. (B) Cartesian plots against time for 3.6 × 10^{-5} M I and its degradation products in dog plasma at 38.5°. The lines represent the predicted concentrations according to Eqs. 1 (I), 4 (V), 5 (III), 6 (IV), and 7 (II). The values used for the parameters were: f = 0.55, k_3 = 0.16616 min^{-1}, k_4 = 0.00096 min^{-1}, k = 0.07558 min^{-1}, and $[I]_0$ = 3.3 × 10^{-6} M. (C) Semilogarithmic plot against time of the III data resulting from I solvolysis in dog plasma (Fig. 2B). Curve B was calculated according to Eq. 5 with f = 0.55, k_3 = 0.166 min^{-1}, k = 0.0756 min^{-1}, $[I]_0$ = 3.3 × 10^{-6} M. Curve A shows a terminal half-life of 5.6 min for 8.08 × 10^{-5} M III in the same plasma. The appearing rate constant for III was calculated from the slope of the feathered line (curve C); the half-life of this process is 4.2 min. The appearing half-life of IV (12 min) was calculated from the slope of the sigma minus plot (curve D) of log ([IV]60 − [IV]) where $[IV]_{60}$ was the concentration of IV at 60 min.*

be fitted to $10^5 p = 14.5\, e^{-0.1438t} + 20.5\, e^{-0.058t}$ where p is in moles/liter and t is in min. The terminal half-life was 11.9 min; the apparent half-life of the first phase was 4.8 min, in the range of the half-life estimated previously (7) using assays of lower sensitivity.

The ester III previously showed apparent terminal half-lives of 11.2 min (initial etofibrate concentration of 5.9 × 10^{-5} *M*) and 5.8 min (initial etofibrate concentration of 1.19 × 10^{-4} *M*). Ester III, spiked at 4.23 × 10^{-5} *M* in fresh dog plasma had an apparent half-life of 11.5 min in the preliminary studies at 37.5° (7) and, in a present study at 8.08 × 10^{-5} *M*, of 5.6 min at 38.5° (curve A, Fig. 2C). This latter study used the greater analytical sensitivities given in this paper; the terminal phase was observed below 2.5 × 10^{-5} *M*, whereas in the preliminary study (7) the half-life was estimated from concentrations down to this value. The plasmolysis of III appears to be a saturable process (Fig. 2C). The terminal phase of the generated III in these present studies with 5.4 × 10^{-5} *M* (Fig. 2A) and 3.6 × 10^{-5} *M* (Fig. 2B and C) etofibrate in fresh dog plasma at 38.5° showed respective half-lives of 9.9, and 9.6 min. These values were well in excess of the aqueous solvolyses of these compounds, which were ~6 and 12 days at pH 7.4 and 40° for I and III, respectively.

The terminal half-lives (9.6–9.9 min) of III generated from etofibrate exceeded the terminal half-life of 5.6 min for spiked 8.08 × 10^{-5} *M* III in fresh dog plasma (Fig. 2C) and were close to the 10.6–11.9-min terminal half-lives for etofibrate. When the curve for III generated from etofibrate degradation was feathered, the resulting half-life for the appearance of III was determined as 4.2 min (curve C, Fig. 2C), close to the half-life for the loss of spiked III in plasma, indicating a probable "flip-flop."

The intermediary nicotinate (V), was more stable in fresh dog plasma than I and II (compare Figs. 2 and 3). The apparent half-life was 12.0 hr

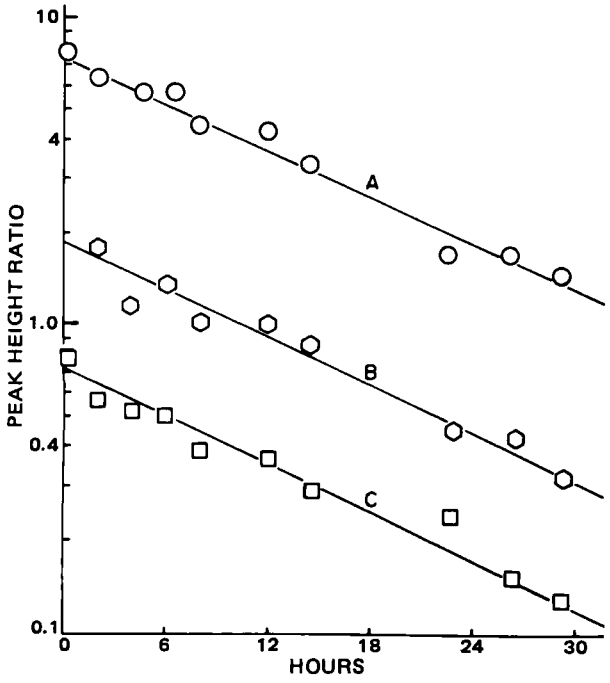

Figure 3—*Semilogarithmic plots of the peak height ratios (HPLC) of V with respect to phenylurea (internal standard) against time for the degradation in fresh dog plasma at 38.5°. Key: (A)* $C_0 = 99\ \mu g/ml$, $t_{1/2} = 12.1\ hr$; *(B)* $C_0 = 49.5\ \mu g/ml$, $t_{1/2} = 12.0\ hr$; *(C)* $C_0 = 12.4\ \mu g/ml$, $t_{1/2} = 11.9\ hr$.

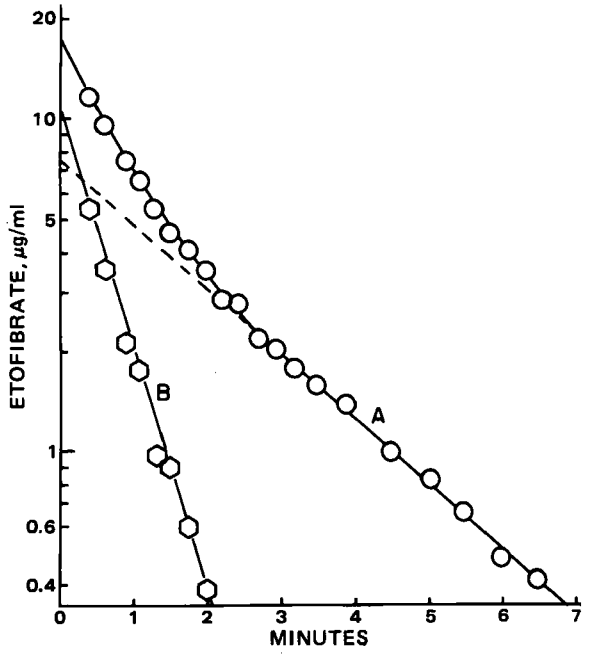

Figure 4—*Semilogarithmic plot (A) of the degradation of 18.09 μg/ml of I in heparinized human plasma at 37.5° which conforms to* C *(μg/ml)* $= 10.5\ e^{-1.59t} + 7.5\ e^{-0.444t}$ *where* t *is in minutes, and feathered curve (B) to characterize the first exponential.*

at 38.5° and was independent of the initial concentration (between 12.4 and 99 μg/ml).

The "flip-flop" phenomenon should not be, and was not, evident here, since the rate of generation of the nicotinate V is very much faster than its degradation. The slope of the semilogarithmic plot of amount of nicotinic acid not-yet-formed against time (sigma minus plot) gave an apparent half-life of ~12 min, equivalent to that for the disappearance of etofibrate and the assigned half-life for the appearance of ester III (estimated from the feathered curve of III against time).

To fit the solvolysis of etofibrate in plasma according to the model given in Scheme III, the concentration–time data from the plasmolysis of I could be reasonably approximated by a monoexponential function of the form:

$$[I] = [I]_0 \cdot e^{-kt} \qquad \text{(Eq. 1)}$$

If the products of etofibrate solvolysis were only V and II, and if no III were generated, the concentration of V could be calculated from the expression (9):

$$[V'] = [I]_0 \frac{k}{k_4 - k}\left[e^{-kt} - e^{-k_4 t}\right] \qquad \text{(Eq. 2)}$$

where $[I]_0$ is the initial concentration, [V'] is the nicotinic acid monoglycolate concentration on the presumption that I is only degrading through the V route, k is the first-order elimination rate constant for I degradation, and k_4 is the first-order rate constant for the plasmolysis of V. The ratio of experimentally observed [V] to calculated [V'] is:

$$f = [V]/[V'] \qquad \text{(Eq. 3)}$$

which was 0.55 for the studies given in Fig. 2B and C, and f is the fraction of I going through the V route. Thus the fraction of I going through the III route is $1 - f = 0.45$.

If the degradation of III can be approximated by a first-order rate constant k_3, the following set of equations describes the time course of all possible solvolysis products as a function of the initial etofibrate concentration $[I]_0$:

$$[V] = [I]_0 \cdot \frac{fk}{k_4 - k}\left[e^{-kt} - e^{-k_4 t}\right] \qquad \text{(Eq. 4)}$$

$$[III] = [I]_0 \cdot \frac{(1-f)k_3}{k - k_3}\left[e^{-k_3 t} - e^{-kt}\right] \qquad \text{(Eq. 5)}$$

$$[IV] = [I]_0 \cdot (1-f)(1 - e^{-kt}) + [I]_0 f\left[1 - \frac{1}{k - k_4}\left(ke^{-k_4 t} - k_4 e^{-kt}\right)\right] \qquad \text{(Eq. 6)}$$

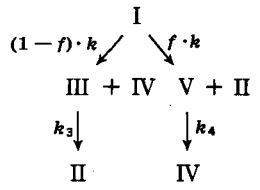
$$[II] = [I]_0 \cdot f(1 - e^{-kt}) + [I]_0 \cdot (1-f) \times \left[1 - \frac{1}{k_3 - k}\left(k_3 e^{-kt} - ke^{-k_3 t}\right)\right] \qquad \text{(Eq. 7)}$$

The lines through the experimental values in Fig. 2B and C were drawn on the basis of concentrations calculated from Eqs. 4–7 using the parameters given in the legend of the figures. The good agreement of the experimental data and calculated curves supports Scheme III and confirms the "flip-flop" phenomenon for the III curve.

Etofibrate Solvolysis in Human Plasma—A typical curve for the degradation of etofibrate in fresh heparinized human plasma is shown in Fig. 4 for 18.8 μg/ml and showed even more pronounced biphasic character than was observed in fresh dog plasma. The terminal half-life was 1.54 min at 37.5°; the half-life of the earlier phase, obtained by feathering, was 0.44 min. The nonlinearity of such semilogarithmic plots occurred with various other initial concentrations (8, 16, and 40 μg/ml) with similar terminal half-lives of 1.7 min at 38.5°. This indicated no dose dependency. An additional study at 18.7 μg of etofibrate/ml at 13° showed a biphasic curve also, with a terminal half-life of 7.7 min. The initial phase had a half-life of 0.4 min, and $10^5 p = 1.31\ e^{-1.67t} + 3.71\ e^{-0.096t}$ where p is in moles/liter and t is in min.

Since a possible explanation of this unexpected biphasic phenomenon could be the inhibition of an enzymatic process by formed solvolytic products, the solvolyses of 21.5 μg/ml of etofibrate were repeated in the same fresh human plasma in the absence and presence of 23.8 μg/ml of II, III, IV, or V added 20 sec before the addition of etofibrate. There were no significant differences in the etofibrate degradations, with terminal half-lives of 1.7 min in the same plasma with or without any of these added compounds. Thus, product inhibition or slowing of an enzymic process could not be concluded.

An alternative explanation could be the decay of enzymic activity with time or its irreversible inactivation by the substrate. If these were true, reinoculation of plasma with fresh substrate would give decreasing rates



Scheme III—Model of etofibrate plasmolysis.

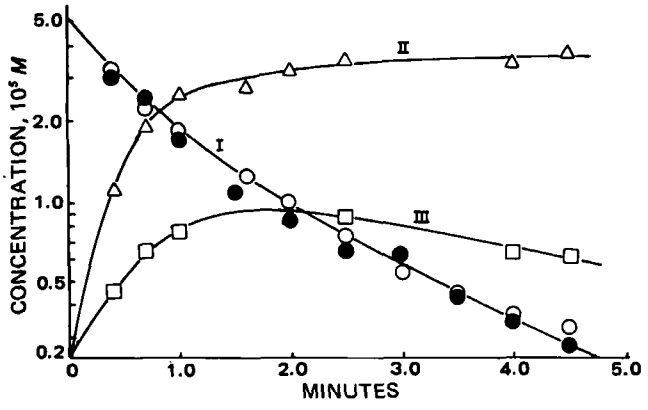


Figure 5—*Semilogarithmic plots of concentrations of I, II, and III with time. Ten minutes after the degradation of 19.77 μg/ml of I in the fresh human plasma at 37.5° (○), 20.17 μg/ml of I (●) was added and its time course monitored.*

or possibly eliminate the biphasic nature. Ten minutes after 19.77 μg/ml of etofibrate was added to fresh human plasma and subsequently degraded at 37.5°, 20.17 μg/ml of etofibrate was again added and its time course monitored (Fig. 5). There was no significant difference between the time courses of the sequential studies of etofibrate degradation in the same human plasma. Both showed terminal half-lives of 1.5 min in this plasma.

Etofibrate showed significantly shorter terminal half-lives of degradation (1.5–1.7 min) in fresh human plasma than in fresh dog plasma (5–10 min). In the several human plasma studies, 50 ± 5% of the degrading etofibrate produced the more stable nicotinate V and the remainder went through the route involving ester III.

2-Hydroxyethyl Nicotinate (V) Stability in Human Plasma—The ester, V, showed apparent first-order degradation in fresh human plasma with half-lives of 45–55 min, which were not significantly affected by concentration in the 2- to 21-μg/ml range (Fig. 6). These half-lives were more shorter than the 12-hr half-life observed in dog plasma (Fig. 3).

2-Hydroxyethyl 2-(4-chlorophenoxy)-2-methylpropionate (III) Stability in Human Plasma—The ester, III, did not degrade by first-order processes at all concentrations in fresh human plasma. Semilogarithmic plots of concentrations with time were not linear; they showed the decreasing convex curve typical of saturable processes (10).

Such saturable processes can be described by:

$$-dC/dt = \frac{\upsilon_{max} C}{K_m + C} \qquad \text{(Eq. 8)}$$

where preliminary estimates of υ_{max} can be made from the initial slope at high concentrations of linear plots of concentration against time (Fig. 7) and the υ_{max} and K_m values can be estimated from the terminal slopes

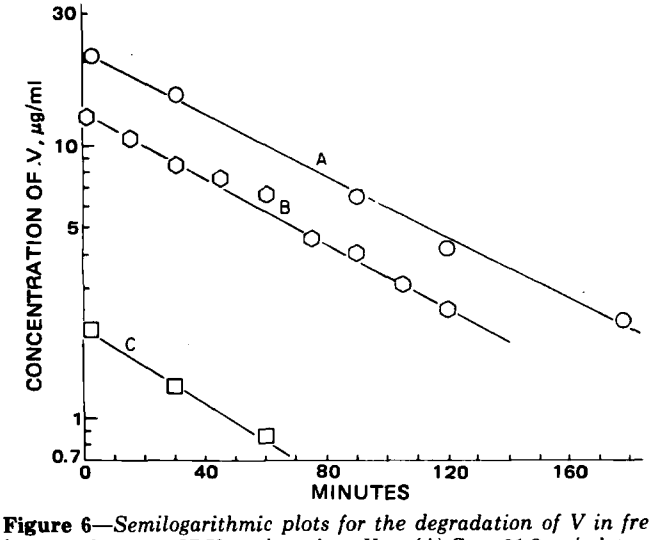

Figure 6—*Semilogarithmic plots for the degradation of V in fresh human plasma at 37.5° against time. Key: (A) C_0 = 21.3 μg/ml, $t_{1/2}$ = 54.5 min; (B) C_0 = 13.4 μg/ml, $t_{1/2}$ = 50.9 min; (C) C_0 = 2.1 μg/ml, $t_{1/2}$ = 45.4 min.*

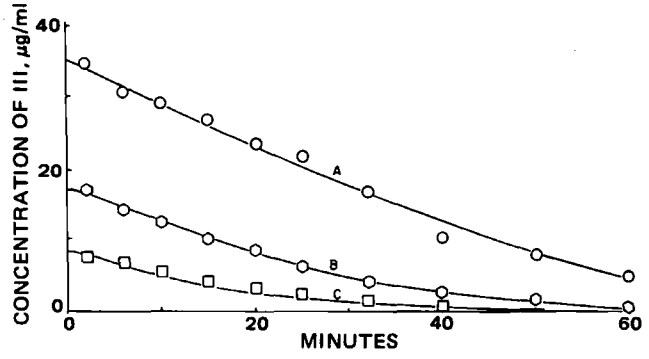

Figure 7—*Plots of concentrations of III with time in fresh human plasma at 37.5° fitted to the Michaelis–Menten equation $-dC/dt = v_{max}C/(K_m + C)$ with v_{max} = 0.77 μg/ml/min and K_m = 8 μg/ml. The initial concentrations of III were 35.2 (A), 17.5 (B), and 8.5 μg/ml (C).*

of ln C against time. The times for various concentrations (C) can be calculated from the integrated form of the Michaelis–Menten equation (Eq. 8):

$$-(K_m \ln C/C_0 + C - C_0)/\upsilon_{max} = t \qquad \text{(Eq. 9)}$$

where C_0 is the initial concentration and C the concentration at any time, t. All of the experimentally observed time courses for 8.5-, 17.5-, and 35.2-μg/ml initial concentrations of III in human plasma could be fitted by Eq. 9 with K_m = 8 μg/ml and υ_{max} = 0.77 μg/ml/min (Fig. 7) to demonstrate the validity of this equation and the postulation of saturable enzymic solvolysis for these initial concentrations. The apparent terminal half-life of III can be calculated from $0.693/(\upsilon_{max}/K_m)$ = 0.693/(0.77/8) = 7.2 min and was close to the half-life for the solvolysis of III in fresh dog plasma.

Clofibrate (VI) Stability in Human Plasma—Clofibrate demonstrated solvolysis in human plasma by a similar saturable enzymic process (Fig. 8), which agreed with the previously indicated saturable kinetics in dog plasma (7). The values of the parameters of Eqs. 8 and 9, υ_{max} = 0.77 μg/ml/min, K_m = 28 μg/ml, $t_{1/2} = 0.693K_m/\upsilon_{max}$ = 25.2 min, fitted the data for plasma level–time studies for initial clofibrate concentrations in human plasma of 125, 55.5, 12, and 6.1 μg/ml (Fig. 8). The identical υ_{max} of 0.77 μg/ml/min for clofibrate and ester III with the different K_m values could indicate solvolyses of these compounds by the same enzyme system, but with different affinities.

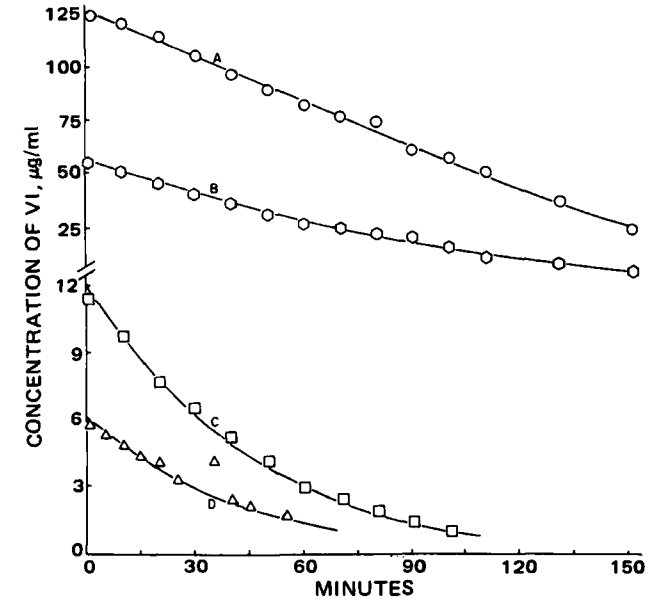

Figure 8—*Plots of VI concentrations with time in fresh human plasma at 37.5° fitted to the Michaelis–Menten equation $-dC/dt = v_{max}C/(K_m + C)$ with v_{max} = 0.77 μg/ml/min and K_m = 28 μg/ml. The initial concentrations were 125 (A), 55.5 (B), 12 (C), and 6.1 μg/ml (D). The apparent half-life of the apparent first-order terminal phase of curve C was 25.9 min.*

Table I—Red Blood Cell–Buffer Partitioning of Etofibrate (I), Clofibric Acid (II), 2-Hydroxyethyl 2-(4-Chlorophenoxy)-2-methylpropionate (III), Nicotinic Acid (IV), and 2-Hydroxyethyl Nicotinate (V)

[a] Capital letter designates the HPLC system; small letter designates the method of preparation for analysis as given in *Experimental*. [b] Concentration of tetraethyl pyrophosphate in the RBC suspension. [c] Drug concentration in buffer after equilibration with red blood cells. [d] Studies effected by simultaneous spiking with I, II, III, IV, and V. [e] Radiolabeled etofibrate was studied and assayed by liquid scintillation counting (LSC).

Inhibition of Clofibric Acid Ester Plasmolysis—The plasmolysis of heroin had been inhibited by the addition of 100 μg/ml of tetraethyl pyrophosphate, a compound that did not hemolyze red blood cells when added to blood nor denature proteins (11). This enzyme inhibitor was also used to inhibit the hydrolysis of clofibric acid esters in human blood and plasma (Fig. 9). The plasmolyses of etofibrate (I), (curves A and B), ester III, (curve C), and clofibrate (VI) (curves D and E) were suppressed for at least 1 hr by adding tetraethyl pyrophosphate to blood or plasma, in contrast with the ready solvolyses of these compounds in uninhibited human plasma (I, curve H; III, curve F; VI, curve G). The use of tetraethyl pyrophosphate as a plasmolysis inhibitor thus provided a method to ascertain the red blood cell partitioning and plasma protein binding of these highly unstable clofibric acid esters in human plasma.

Tetraethyl pyrophosphate showed different patterns in dog and human plasma. Tetraethyl pyrophosphate (137.5 μg/ml) in fresh dog plasma suppressed the solvolysis of I for only 10–12 min (Fig. 10, curves A, B, and E), in contrast with the inhibition in fresh human plasma for at least 130 min (Fig. 10, curve D). Increased (7.5×) tetraethyl pyrophosphate concentrations (963.3 μg/ml) did not even double the time of complete plasmolysis inhibition (Fig. 10, curve C). The solvolysis after 22 min increased to an apparent half-life of 58.2 min, similar to the half-life observed with 128.9 μg/ml of tetraethyl pyrophosphate.

Red Blood Cell–Buffer Partitioning—*Etofibrate and its Solvolytic Products*—The red blood cell–plasma partition coefficient of a drug (*D*), on the presumption that only unbound drug in the plasma can diffuse into the red blood cells, can be defined (12) as:

$$D = [A_{RBC}]/[A_p^u] = \{[A_B]/[A_p^u](1 - H) - [A_p^b]/[A_p^u] - 1\}(1 - H)/H \quad \text{(Eq. 10)}$$

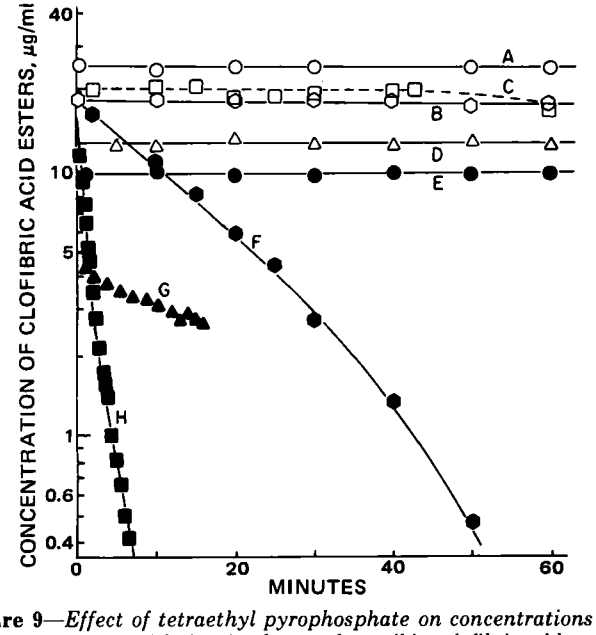

Figure 9—*Effect of tetraethyl pyrophosphate on concentrations of clofibric acid esters with time in plasma after spiking clofibric acid esters in fresh human blood or plasma. Key: (A) fresh human whole blood containing 102.4 μg/ml of tetraethyl pyrophosphate spiked with 18.24 μg/ml of I; (B) fresh human plasma containing 102.4 μg/ml of tetraethyl pyrophosphate spiked with 18.24 μg/ml of I; (C) fresh human plasma containing 47.2 μg/ml of tetraethyl pyrophosphate spiked with 19.84 μg/ml of III; (D) fresh human whole blood containing 99.5 μg/ml of tetraethyl pyrophosphate spiked with 12.65 μg/ml of VI; (E) fresh human plasma containing 101.4 μg/ml tetraethyl pyrophosphate spiked with 9.9 μg/ml of VI; (F) III degradation (C_0 = 16.5 μg/ml) in uninhibited human plasma; (G) VI degradation (C_0 = 4.5 μg/ml) in uninhibited human plasma; (H) I degradation (C_0 = 18.24 μg/ml) in uninhibited human plasma.*

[a] Tetraethyl pyrophosphate (95.7 μg/ml) was added to plasma before spiking with drug. [b] Drug concentration in plasma before filtration. [c] Drug concentration in ultrafiltrate (plasma water).

where $[A_{RBC}]$ is the total drug concentration in the red blood cells; $[A_p]$, $[A_p^u]$, and $[A_p^b]$ are the respective drug concentrations in plasma, plasma water (*i.e.*, unbound to plasma proteins), and bound to plasma proteins; $[A_B]$ is the total concentration of a drug in whole blood or red blood cell suspension; and H is the hematocrit. The value of $[A_p^b]$ is zero in red blood cell–buffer suspensions.

Etofibrate, clofibrate, and its solvolytic products showed rapid equilibration between buffer and human red blood cells. The apparent partition coefficients, D, did not change with time after the 3 min needed for mixing and subsequent centrifugation. There was no significant concentration dependency of the partition coefficient in the studied concentration ranges (Table I). There was no significant difference between the partition coefficients for the nonsolvolyzable clofibric and nicotinic acids with or without the presence of the enzyme inhibitor tetraethyl pyrophosphate, indicating the noninterference of this compound with the partitioning. The partition coefficients for etofibrate, clofibric acid, and ester III were much greater than unity (Table I), demonstrating specific binding to erythrocytes, greatly in excess of that which would be anticipated from simple volume partitioning.

Clofibrate—The red blood cell–buffer partition coefficient, D, for clofibrate was concentration dependent. It decreased with increasing clofibrate concentration, indicating saturable partitioning into the red blood cells, from 7.8 at 10 μg/ml to 1 at 50 μg/ml.

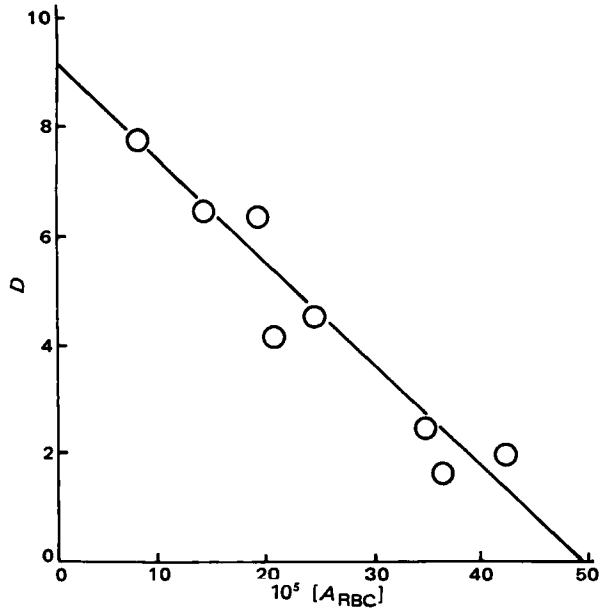

Figure 1—*Modified Scatchard plot for the presumed saturable binding or partitioning (D) of clofibrate to red blood cells from the buffer suspension against the clofibrate concentration in the buffer removed by binding to the red blood cells, [A_{RBC}]. The fitted line was calculated by least-square regression:* $D = 9.185 - 1.92 \times 10^4 [A_{RBC}]$.

The interaction between a ligand and a class of receptors can be formulated as (12):

$$n[A_p^u] + [R] \overset{K}{\rightleftharpoons} [A_nR] \qquad \text{(Eq. 11)}$$

where $[A_p^u]$ is the concentration of free or unbound drug in the buffer phase of the suspension, $[A_{RBC}] = [A_p] - [A_p^u]$ is the concentration of bound ligand to the receptor (erythrocyte) where $[A_p]$ would be the concentration of drug in the buffer phase if there were no binding to the receptor, K is the association constant for the binding of a molecule of drug to one of the equivalent n binding sites of the receptor, and $[R]$ is the concentration of the receptors.

The modified Scatchard equation can be derived on the premise of only one class of n equivalent binding sites (13):

$$D = \frac{[A_R]}{[A_p^u]} = nK[R] - K[A_{RBC}] \qquad \text{(Eq. 12)}$$

and shows that plots of the apparent partition coefficient (D) against the drug concentration in the continuous phase that had been removed to bind the receptors should be linear if there were only one class of n equivalent binding sites per receptor (red blood cell) so that saturable binding was manifested. Such a plot is given in Fig. 11 for a hematocrit of 0.24 at room temperature. The negative of the slope is $K = 1.92 \times 10^4$ M^{-1}. The intercept, $nK[R]$, is 9.185; the number of binding sites $n[R]$ on the postulation of a volume of a red blood cell of 90 μm^3 and 1.11×10^{10} cells/ml of packed red blood cells permits the calculation of the number of binding sites per red blood cell as 4.3×10^{-17} moles/single red blood cell.

Plasma Protein Binding by Ultrafiltration—When isotonic phosphate buffer, pH 7.4, containing 10 μg/ml of etofibrate, clofibrate, or their potential solvolytic products was ultrafiltered, nicotinate V and the clofibric and nicotinic acids showed no significant binding to the filter membranes. The concentration in the first and successive 0.5 ml of filtrate was the same as the initial concentration in the buffer to be filtered (Fig. 12). Etofibrate bound strongly to the membrane. Although the concentration in successive 0.5 ml filtrates of the 5-ml aliquot showed increasing concentrations, a maximum of only 39.8% of the filtered concentration could be recovered in the last 0.5 ml of ultrafiltrate (Fig. 12A). Although the ultrafiltrate showed increased concentrations of etofibrate if the membrane prefiltered 3 ml of 100 μg/ml etofibrate, the concentration recovery was still incomplete (Fig. 12B). Further attempts were made to saturate the membrane with prefiltration of larger concentrations and volumes of etofibrate solutions. However, the variability among successive filtrates and filtrations was too great. The cone filter[10] was chosen rather than the molecular filters[11] for the ultrafiltration studies because it showed the lowest binding for the investigated compounds, particularly for the ester III.

The percentages of drug bound to human plasma proteins by this ul-

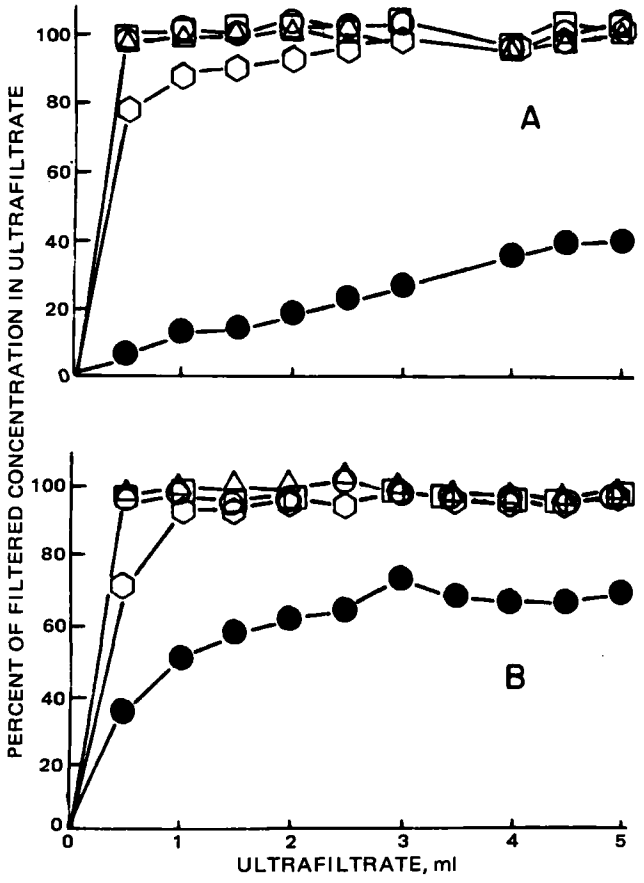

Figure 12—*Percent recovery of ultrafiltrate concentrations of I (●), II (□), III (○), IV (△), and V (○) in 5 ml of pH 7.4 isotonic phosphate buffer in each successive 0.5-ml filtrate. Key: (A) Each drug was filtered separately without membrane pretreatment. (B) The membranes were pretreated by prefiltering 2 ml of buffer containing 100 μg/ml of compound. The excess was rinsed with isotonic buffer.*

trafiltration technique for those compounds that do not show excessive binding to the ultrafiltration membranes are given in Table II. There was no apparent concentration dependence for the protein binding of clofibric acid (II) and ester III, with 97.2 ± 1.2 and 83.2 ± 1.7%, respectively. The results from protein binding studies of nicotinic acid (IV) and the nicotinate V had greater variability, 6.0 ± 6.3 and 12.6 ± 4.3%, respectively. If the study at the lower concentration of 5.9 μg/ml were omitted, the ester

[a] Total plasma concentration of drug before partitioning into red blood cells. [b] Slope of the plot of $f/(1-f)$ *versus* m. [c] $f = S/(1+S)$; *SEM* of $100f$ is $100\{|(S + SEM_S)/(1 + S + SEM_S)] - [(S - SEM_S)/(1 + S - SEM_S)]|/2$. [d] Radioactivity of labeled compound was assayed in red blood cell-equilibrated plasma. The tetraethyl pyrophosphate concentration was 89.5 μg/ml in the red blood cell suspension and 99.45 μg/ml in the plasma. [e] HPLC assay C-d of red blood cell-equilibrated plasma was used. The tetraethyl pyrophosphate concentration was 117 μg/ml in the red blood cell suspension and 115.84 μg/ml in the plasma.

V showed a possible concentration ratio dependence of protein binding.

Human Plasma Protein Binding of Etofibrate and Clofibrate by the Method of Variable Plasma Concentrations in Erythrocyte Suspensions—The high binding of etofibrate and clofibrate to ultrafiltration membranes prevented their use in the determination of plasma protein binding. The instability of these compounds in plasma 1 hr after enzyme inhibition of plasma with tetraethyl pyrophosphate prevented the use of such traditional methods as ultracentrifugation and equilibrium dialysis to determine plasma protein binding. Tetraethyl pyrophosphate undergoes degradation by solvolysis with time.

A method that uses the partitioning of plasma-unbound drug into erythrocytes with varying plasma concentrations to determine plasma protein binding was developed previously by Garrett and Hunt (14) and applied to the nonsaturable protein binding of tetrahydrocannabinol. The method was also applied to the determination of the plasma protein binding of papaverine (15) and methadone (16). In the latter case it was clearly shown that protein binding determined by this technique gave the same results (66% plasma protein binding) as the more conventional ultracentrifugation method. Synthetic blood samples are prepared with known hematocrit, varying fractions of plasma and plasma water (or pH 7.4 phosphate buffer), and known concentrations of drug. The drug-equilibrated erythrocytes are separated from the pseudoblood samples by centrifugation and the pseudoplasma samples are analyzed for their concentrations.

The total amount of drug, A_{tot}, added to pseudoplasma was confirmed by assay and washed red blood cells were added to give an hematocrit of H. From the assayed pseudoplasma concentrations $[A_p]$ of volume $V_p = V_{tot}(1 - H)$, centrifugally separated from a pseudoblood of hematocrit H and volume V_{tot}, the amount of drug partitioned into the red blood cells, A_{RBC}, was calculated:

$$A_{RBC} = A_{tot} - V_p[A_p] \qquad \text{(Eq. 13)}$$

where $[A_{RBC}] = A_{RBC}/V_{RBC}$ and $V_{RBC} = HV_{tot}$. Thus, the fraction (f) of drug in plasma that is unbound to plasma proteins can be calculated from the assayed, separated plasma concentration of drug, $[A_p]$, by:

$$f = 1 - \frac{[A_p^u]}{[A_p]} = 1 - \frac{[A_{RBC}]}{D[A_p]} = 1 - \frac{(A_{tot} - V_p[A_p])}{DHV_{tot}[A_p]} \qquad \text{(Eq. 14)}$$

where D is the partition coefficient for red blood cell–plasma water (or buffer) (Eq. 10). In the special case for clofibrate this partition coefficient was a function of the red blood cell concentration:

$$D = 9.185 - 1.92 \times 10^{-4}[A_{RBC}] \qquad \text{(Eq. 15)}$$

The method is extremely sensitive and particularly useful when both the plasma protein binding and red blood cell–plasma water partition coefficient are high.

In the cases of both etofibrate and clofibrate, plots of the fraction of drug bound to plasma protein, against the fraction of plasma, m, in

pseudoplasma were superimposable for all plasma and unbound drug in plasma concentrations [A_p^u]. Plots (Fig. 13) of $f/(1-f)$ against m are linear for all [A_p^u] and pass through the origin with slopes of S. The fraction of drug bound to 100% plasma when $m = 1$ can then be calculated (Table III). The human plasma protein binding of etofibrate is 96.89 ± 0.09% (*SD*) for plasma concentrations in the 0.2- to 80-μg/ml range. The human plasma protein binding of clofibrate is 98.23 ± 0.18% (*SD*) for plasma concentrations in the 14- to 108-μg/ml range.

Pharmacokinetic Model for Diazepam and its Major Metabolite Desmethyldiazepam Following Diazepam Administration

M. L. JACK and W. A. COLBURN ˣ

Received April 22, 1982, from the *Department of Pharmacokinetics and Biopharmaceutics, Hoffmann-La Roche Inc., Nutley, NJ 07110.* Accepted for publication September 29, 1982.

Abstract □ A five-compartment open model was used to simulate the blood concentration profiles of diazepam and its metabolite, desmethyldiazepam, following single- and multiple-dose administrations of diazepam. The parameter estimates for diazepam were previously reported literature values. The parameter estimates for the metabolite were calculated from literature values of blood concentrations of desmethyldiazepam following the administration of clorazepate. The five-compartment open model suggests that ~50% of the administered diazepam is biotransformed to desmethyldiazepam, and that the elimination profile of the metabolite is not altered by the presence of the drug. The model may also be readily adapted to predict the concentrations of diazepam and desmethyldiazepam in cerebrospinal fluid following the administration of diazepam by simply correcting the blood or plasma concentrations of the drug and metabolite for the degree of plasma protein binding.

Keyphrases □ Diazepam—desmethyldiazepam, pharmacokinetics, single- and multiple-dose administrations, five-compartment open model, blood, CSF □ Desmethyldiazepam—diazepam, pharmacokinetics, single- and multiple-dose administrations, five-compartment open model, blood, CSF □ Pharmacokinetics—diazepam, desmethyldiazepam, single- and multiple-dose administrations, five-compartment open model, blood, CSF

Diazepam (7-chloro-1,3-dihydro-1-methyl-5-phenyl-2*H*-1,4-benzodiazepin-2-one) is effective in the symptomatic relief of tension and anxiety, as well as for the relief of skeletal muscle spasms (1–5). Desmethyldiazepam, the major metabolite of diazepam, is the pharmacologically active metabolite of the prodrugs clorazepate and prazepam, which are also used as anxiolytic agents (6–8).

Diazepam pharmacokinetics have been described previously by a three-compartment model by Kaplan *et al.* (6) and Moolenaar *et al.* (9). Several investigators have described the pharmacokinetic profile of desmethyldiazepam following oral administration of the prodrug clorazepate in terms of a two-compartment open model (8, 10–12). The present report combines the three-compartment open model for diazepam and the two-compartment open model for desmethyldiazepam to define the pharmacokinetic profiles of diazepam and its metabolite following single- and multiple-dose administrations of the drug.

EXPERIMENTAL

Clinical Protocol—The data used in this study were previously reported by Kaplan *et al.* (study A) (6). Briefly, four healthy male volunteers, ages 25–43, each received single 10-mg doses of diazepam administered intravenously and orally 1 week apart. Commencing 1 week thereafter, each subject received a 10-mg oral dose of the drug every 24 hr for 15 days. The subjects were fasted for 7 hr prior to receiving the single-dose administrations, and food was withheld for 1 hr postadministration.

Blood specimens were obtained 1, 2.5, 5, 10, 20, 30, and 45 min and at 1, 1.5, 2, 3, 4, 6, 8, 12, 24, 30, and 48 hr following intravenous administration, and at 0.25, 0.5, 0.75, 1, 1.5, 2, 3, 4, 6, 8, 12, 24, 30, and 48 hr following the single-dose oral administration. Following chronic administration, blood samples were obtained 0 (predose), 0.5, 1, 2, 4, and 24 hr postadministration on day 1; 1, 2, and 24 hr postadministration on days 2–11; 1 and 2 hr postadministration on day 12 and at 0 (predose), 1, 2, 4, 6, 8, 12, 24, 30, 36, 48, 72, 96, 120, 144, 168, 192, and 216 hr postadministration on day 15.

Analytical Method—Blood specimens were analyzed for diazepam and desmethyldiazepam by the electron-capture GLC procedure of de Silva and Puglisi (13), with a sensitivity of 10 and 20 ng/ml, respectively, for each component using a 1-ml specimen.

Pharmacokinetic Model—The five-compartment open model used to describe the pharmacokinetic profiles of diazepam and its major me-

0022-3549/83/1100-1318$01.00/0

pseudoplasma were superimposable for all plasma and unbound drug in plasma concentrations [A_p^u]. Plots (Fig. 13) of $f/(1-f)$ against m are linear for all [A_p^u] and pass through the origin with slopes of S. The fraction of drug bound to 100% plasma when $m = 1$ can then be calculated (Table III). The human plasma protein binding of etofibrate is 96.89 ± 0.09% (*SD*) for plasma concentrations in the 0.2- to 80-μg/ml range. The human plasma protein binding of clofibrate is 98.23 ± 0.18% (*SD*) for plasma concentrations in the 14- to 108-μg/ml range.

Pharmacokinetic Model for Diazepam and its Major Metabolite Desmethyldiazepam Following Diazepam Administration

M. L. JACK and W. A. COLBURN ˣ

Received April 22, 1982, from the *Department of Pharmacokinetics and Biopharmaceutics, Hoffmann-La Roche Inc., Nutley, NJ 07110.* Accepted for publication September 29, 1982.

Abstract □ A five-compartment open model was used to simulate the blood concentration profiles of diazepam and its metabolite, desmethyldiazepam, following single- and multiple-dose administrations of diazepam. The parameter estimates for diazepam were previously reported literature values. The parameter estimates for the metabolite were calculated from literature values of blood concentrations of desmethyldiazepam following the administration of clorazepate. The five-compartment open model suggests that ~50% of the administered diazepam is biotransformed to desmethyldiazepam, and that the elimination profile of the metabolite is not altered by the presence of the drug. The model may also be readily adapted to predict the concentrations of diazepam and desmethyldiazepam in cerebrospinal fluid following the administration of diazepam by simply correcting the blood or plasma concentrations of the drug and metabolite for the degree of plasma protein binding.

Keyphrases □ Diazepam—desmethyldiazepam, pharmacokinetics, single- and multiple-dose administrations, five-compartment open model, blood, CSF □ Desmethyldiazepam—diazepam, pharmacokinetics, single- and multiple-dose administrations, five-compartment open model, blood, CSF □ Pharmacokinetics—diazepam, desmethyldiazepam, single- and multiple-dose administrations, five-compartment open model, blood, CSF

Diazepam (7-chloro-1,3-dihydro-1-methyl-5-phenyl-2*H*-1,4-benzodiazepin-2-one) is effective in the symptomatic relief of tension and anxiety, as well as for the relief of skeletal muscle spasms (1–5). Desmethyldiazepam, the major metabolite of diazepam, is the pharmacologically active metabolite of the prodrugs clorazepate and prazepam, which are also used as anxiolytic agents (6–8).

Diazepam pharmacokinetics have been described previously by a three-compartment model by Kaplan *et al.* (6) and Moolenaar *et al.* (9). Several investigators have described the pharmacokinetic profile of desmethyldiazepam following oral administration of the prodrug clorazepate in terms of a two-compartment open model (8, 10–12). The present report combines the three-compartment open model for diazepam and the two-compartment open model for desmethyldiazepam to define the pharmacokinetic profiles of diazepam and its metabolite following single- and multiple-dose administrations of the drug.

EXPERIMENTAL

Clinical Protocol—The data used in this study were previously reported by Kaplan *et al.* (study A) (6). Briefly, four healthy male volunteers, ages 25–43, each received single 10-mg doses of diazepam administered intravenously and orally 1 week apart. Commencing 1 week thereafter, each subject received a 10-mg oral dose of the drug every 24 hr for 15 days. The subjects were fasted for 7 hr prior to receiving the single-dose administrations, and food was withheld for 1 hr postadministration.

Blood specimens were obtained 1, 2.5, 5, 10, 20, 30, and 45 min and at 1, 1.5, 2, 3, 4, 6, 8, 12, 24, 30, and 48 hr following intravenous administration, and at 0.25, 0.5, 0.75, 1, 1.5, 2, 3, 4, 6, 8, 12, 24, 30, and 48 hr following the single-dose oral administration. Following chronic administration, blood samples were obtained 0 (predose), 0.5, 1, 2, 4, and 24 hr postadministration on day 1; 1, 2, and 24 hr postadministration on days 2–11; 1 and 2 hr postadministration on day 12 and at 0 (predose), 1, 2, 4, 6, 8, 12, 24, 30, 36, 48, 72, 96, 120, 144, 168, 192, and 216 hr postadministration on day 15.

Analytical Method—Blood specimens were analyzed for diazepam and desmethyldiazepam by the electron-capture GLC procedure of de Silva and Puglisi (13), with a sensitivity of 10 and 20 ng/ml, respectively, for each component using a 1-ml specimen.

tabolite, desmethyldiazepam, is presented in Fig. 1. Equations for the blood concentration–time profiles of drug and metabolite were derived by the method of Kaplan *et al.* (14). The pharmacokinetic parameters previously reported in study A were used as the estimates for diazepam (6). Desmethyldiazepam blood concentration–time data following administration of clorazepate, previously reported by Abruzzo *et al.* (study B) (7) and Brooks *et al.* (study C) (15) were fitted using NONLIN (16) to obtain parameter estimates for the metabolite disposition (Table I). The parameters K_{21} and K_{12} in Table I are identical to K_{54} and K_{45} in the present model.

Parameter estimates for K_{14}, the rate of formation of the metabolite following diazepam administration, had not been previously reported in the literature. Initial estimates of K_{14} were obtained based on the fraction (f_m) of diazepam metabolized to desmethyldiazepam calculated both following single-dose and chronic-dose administrations of the drug. To estimate the amount of diazepam biotransformed to desmethyldiazepam following single-dose intravenous and oral administrations, the mean area under the blood concentration–time curve from time 0 to infinity ($AUC_{0\to\infty}$ for desmethyldiazepam in four subjects (Study A) were calculated (Table II). The AUC were determined using the trapezoidal-rule for the blood concentration–time curve from 0 to 48 hr postadministration. The area from 48 hr to infinity was then calculated by dividing the last observed blood concentrations of the metabolite by the overall elimination rate constant (β) for desmethyldiazepam, which was determined following chronic administration of diazepam in the same subjects (6). The mean $AUC_{0\to\infty}$ for desmethyldiazepam following single-dose oral administration of 15 mg of clorazepate (studies B and C), which was used as a standard area representing 10 mg of systemically available metabolite are presented in Table II. The ratio of the desmethyldiazepam $AUC_{0\to\infty}$ for each subject in study A, divided by the mean $AUC_{0\to\infty}$ for the six subjects in studies B and C were used to estimate the fraction (f_m) of diazepam metabolized to desmethyldiazepam in study A. K_{14} is then calculated by multiplying the total elimination rate (K_{TOT}) of the drug by the estimated fraction (f_m) metabolized. K_{TOT} was previously reported as K_{el} in study A (6). K_{14} and the fraction (f_m) of diazepam metabolized to desmethyldiazepam for the four subjects in study A based on the single-dose administration of the drug are reported in Table II.

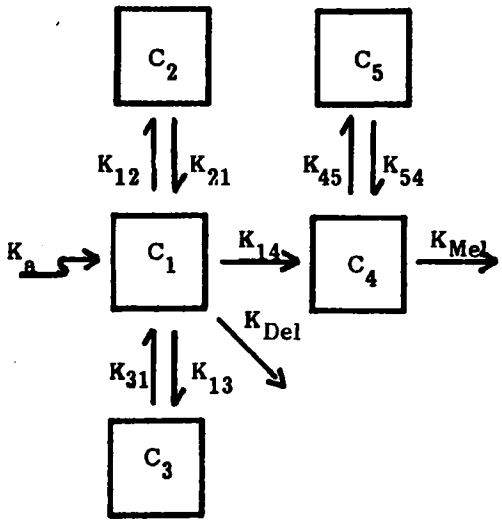

Figure 1—*Five-compartment open pharmacokinetic model used to describe the physiological disposition characteristics of diazepam and its metabolite, desmethyldiazepam.* C_1, C_2, *and* C_3 *are the concentrations of diazepam in the respective compartments;* C_4 *and* C_5 *are the concentrations of desmethyldiazepam in the respective compartments.* K_a *is the first-order absorption rate constant of diazepam;* K_{12}, K_{21}, K_{13}, K_{31}, K_{45}, *and* K_{54} *are the transfer coefficients between compartments;* K_{TOT} *is the total elimination rate of diazepam;* K_{14} *is the rate of metabolism of diazepam to desmethyldiazepam;* K_{Mel} *is the elimination rate of desmethyldiazepam; and* K_{Del} *is the rate of elimination of diazepam via pathways other than metabolism to desmethyldiazepam,* $K_{TOT} = (K_{14} + K_{Del})$.

The pharmacokinetic parameters for diazepam and its metabolite at steady state may also be used to estimate K_{14} and the fraction (f_m) of the drug metabolized to desmethyldiazepam. The differential equations describing the rate of change of desmethyldiazepam concentrations in the central (C_4) and peripheral (C_5) compartments, respectively, following the administration of diazepam based on Fig. 1 may be expressed as:

$$\frac{dC_4}{dt} = C_1K_{14} + K_{54}C_5 - (K_{45} + K_{Mel})C_4 \qquad \text{(Eq. 1)}$$

$$\frac{dC_5}{dt} = C_4K_{45} - C_5K_{54} \qquad \text{(Eq. 2)}$$

At steady state, both dC_4/dt and dC_5/dt equal zero and, based on Eq. 2, C_4K_{45} is equal to C_5K_{54}. Substituting for C_5K_{54} in Eq. 1, C_1K_{14} is then equal to $\overline{C}_4^{ss}K_{Mel}$ at steady state. The conversion of steady-state concentrations of diazepam and desmethyldiazepam to amounts is obtained by multiplying the concentrations by the volume of their respective compartments. Therefore, K_{14} may be expressed as:

$$K_{14} = \frac{\overline{C}_4^{ss} \cdot K_{Mel} \cdot V_{cDD}}{\overline{C}_1^{ss} \cdot V_{cD}} \qquad \text{(Eq. 3)}$$

where V_{cD} and V_{cDD} are the volumes of compartments 1 and 4, and $\overline{C}_4^{ss}$ and $\overline{C}_1^{ss}$ are the steady-state concentrations in compartments 1 and 4 respectively. V_{cD} was previously reported for each subject in study A, and the mean V_{cDD} and K_{Mel} for desmethyldiazepam (Table I) were used in Eq. 3. The average of the mean steady-state blood concentration ($\overline{C}_1^{ss}$) and $\overline{C}_4^{ss}$ from study A (for the drug and metabolite, respectively) following once daily chronic administration of diazepam are reported in Table III. The blood concentrations on days 8–12 and 15 were used to calculate the average of the mean $\overline{C}_1^{ss}$ for diazepam, and blood concentrations on days 11, 12, and 15 were used to determine the average of the mean $\overline{C}_4^{ss}$ for

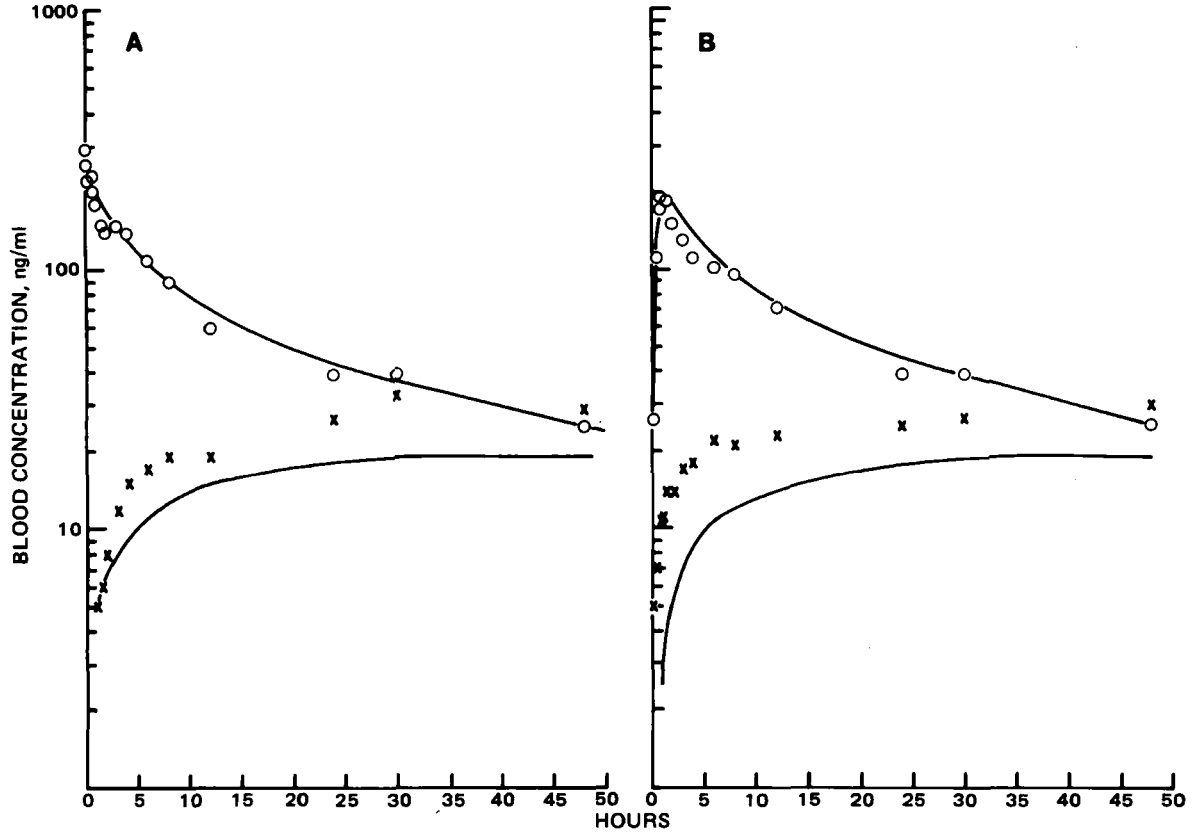

Figure 2—*Blood concentration–time profiles of diazepam (○) and desmethyldiazepam (×) following 10-mg intravenous (A) and oral (B) administrations of diazepam to a normal subject (solid lines represent simulated diazepam and desmethyldiazepam blood concentration–time profiles).*

desmethyldiazepam. The resulting K_{14} values calculated using Eq. 3 are reported in Table III. The fraction (f_m) is then calculated by:

$$f_m = \frac{K_{14}}{K_{TOT}} \qquad \text{(Eq. 4)}$$

where K_{TOT} was previously reported as K_{e1} in study A (6).

The mean K_{14} values from Tables II and III for each subject were used as initial parameter estimates for the pharmacokinetic model in Fig. 1. The blood concentration–time data for diazepam and desmethyldiazepam following single-dose intravenous and oral, and chronic oral administrations were then simulated using the initial parameter estimates previously described.

RESULTS AND DISCUSSION

Model for Blood Concentration–Time Data—The simulated and experimental blood concentration–time profiles of diazepam and desmethyldiazepam following single intravenous and oral doses in one subject are presented in Fig. 2. The corresponding simulated and experimental drug and metabolite blood concentrations following the chronic oral administration of diazepam are presented for the same subject in Fig. 3.

Support for the proposed model required coincidence of simulated and experimental blood concentration–time profiles for diazepam and its metabolite following single-dose intravenous and oral, and chronic oral administrations of the drug to normal subjects. Good agreement was observed between experimental data points and the simulated blood concentration of diazepam in the four subjects from study A. The desmethyldiazepam blood concentrations following chronic dosing were in good agreement with the simulated blood concentrations as shown in Fig. 3B. The simulated blood concentrations of the metabolite following single-dose administration of diazepam are lower than the observed blood concentrations. Such findings may reflect intersubject variability and/or residual amounts of desmethyldiazepam from a previous dose due to the 1-week washout period between doses and the half-life of the metabolite. These findings indicate that the five-compartment open model for diazepam and desmethyldiazepam adequately describe the pharmacokinetic profiles of the drug and its metabolite following diazepam administration. Since the same parameter estimates sufficiently described both the single-dose and chronic-dose blood–concentration time profiles of diazepam and desmethyldiazepam, it may be concluded that there was no enzyme induction or inhibition of the drug in this study.

The pharmacokinetic profiles of diazepam and its metabolite following administration of diazepam and profiles of desmethyldiazepam following administration of its prodrugs have been reported by numerous investigators. However, there are no studies in the literature comparing the pharmacokinetic profiles of desmethyldiazepam when formed as a metabolite of diazepam or as a metabolite of clorazepate in the same subjects. In determining the pharmacokinetic profile of the metabolite following clorazepate administration, it was assumed that clorazepate, at normal GI pH, is completely hydrolyzed to desmethyldiazepam, and that the resulting desmethyldiazepam was completely absorbed (10). Therefore,

Table III—Pharmacokinetic Parameters Resulting from the Five-Compartment Model in Four Subjects From Study A [a]

4	0.16	0.12	20.0	45.6	0.041	0.07	0.51

[a] Study A is from Ref. 6, Headings refer to the mean steady-state concentrations of diazepam ($\bar{C}_1^{ss}$) and desmethyldiazepam ($\bar{C}_4^{ss}$), volumes of compartments 1 (V_{cD}) and 4 (V_{cDD}), elimination rate of desmethyldiazepam (K_{Mel}, mean values from Table I), formation rate of desmethyldiazepam (K_{14}, calculated using Eq. 3), and the fraction (f_m, K_{14}/K_{TOT}) of diazepam metabolized to desmethyldiazepam.

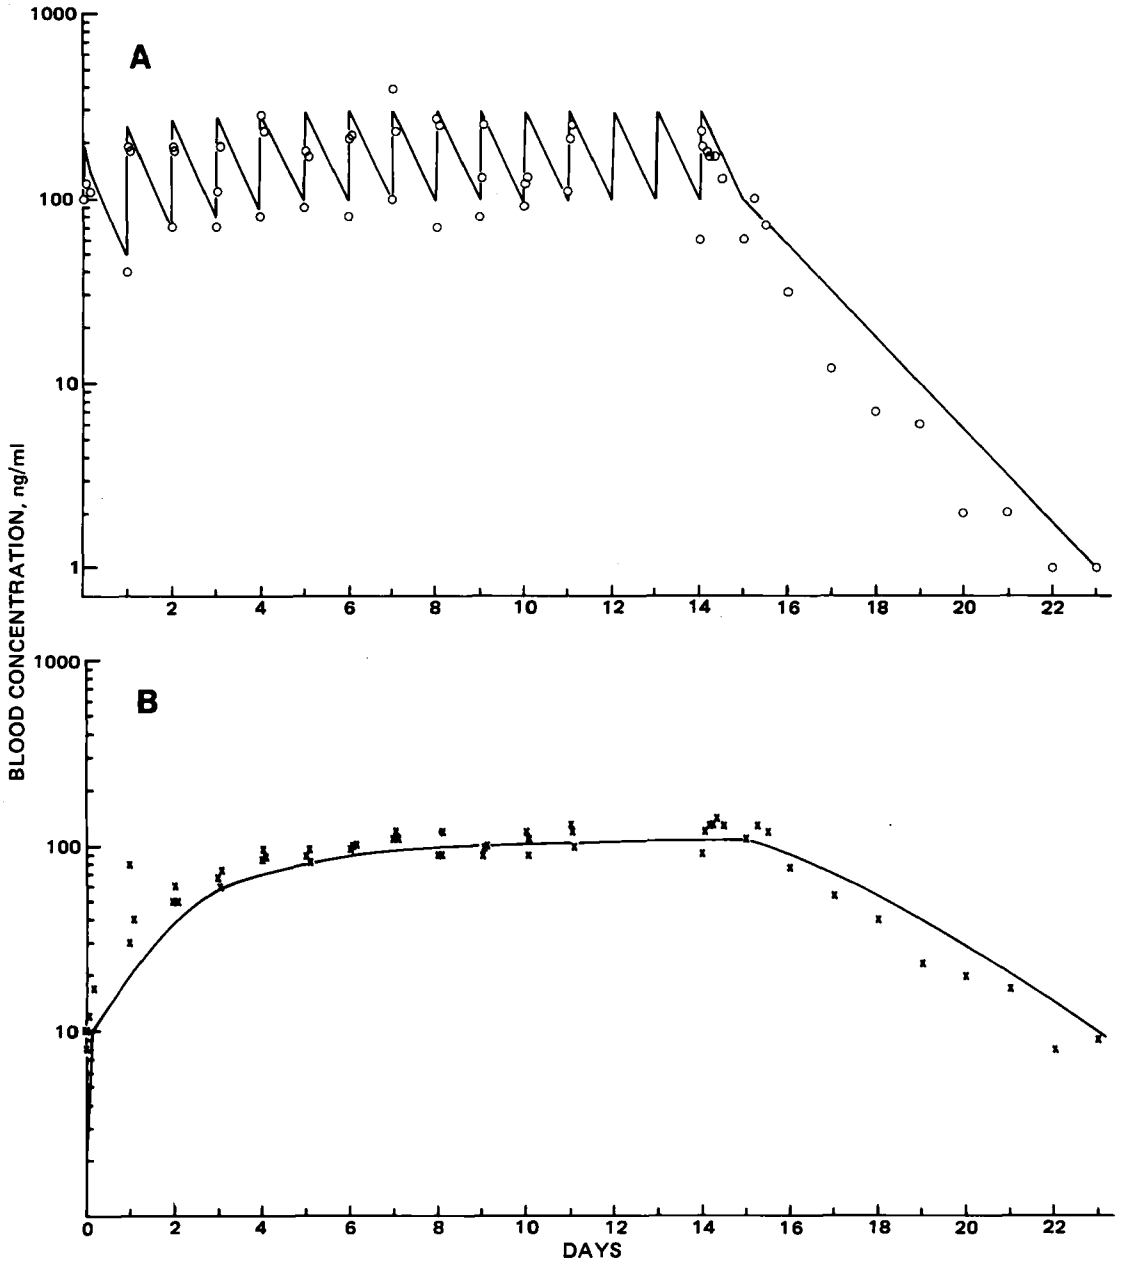

Figure 3—*Blood concentration–time profile of diazepam (A) and desmethyldiazepam (B) following once daily oral administration of 10 mg of diazepam for 15 days to a normal subject (solid lines represent simulated diazepam and desmethyldiazepam blood concentration–time profiles).*

the mean values of the desmethyldiazepam pharmacokinetic parameters following the administration of clorazepate to a normal subject population were used as parameter estimates.

Based on the initial estimates of the metabolite pharmacokinetic parameters, following clorazepate administration, the fraction (f_m) of diazepam metabolized to desmethyldiazepam was estimated to be ~0.5 by two different methods. Similar results were reported by Dasberg (17) following the chronic administration of 5 mg of diazepam and desmethyldiazepam to the same subjects in a double-blind, cross-over study. Similar results were also obtained in the cat following single-dose administration of both the drug and metabolite (18).

Model Adapted for Cerebrospinal Fluid Concentration–Time Data—This five-compartment open model may be readily adapted to predict the concentrations of diazepam and desmethyldiazepam in cerebrospinal fluid (CSF) following the administration of diazepam. Greenblatt *et al.* (19), Hallstrom *et al.* (20), Kanto *et al.* (21), and Hendel (22) have shown that the concentrations of the drug and its metabolite in CSF are in equilibrium with the unbound plasma concentrations of these compounds for the time course of the plasma concentration profile. Therefore by correcting the plasma concentrations of diazepam for protein binding, the CSF concentrations, which are presumed to reflect drug concentrations at the site of action, may be predicted.

Following single-dose administration, the concentrations of diazepam and desmethyldiazepam in CSF were simulated and are shown in Fig. 4. The model indicates that the concentration of the drug is greater than the concentration of the metabolite in CSF for the first 24 hr postadministration, suggesting that the clinical effects observed following a single-dose administration of diazepam must be attributed primarily to

Table IV—Observed and Calculated CSF Concentrations (ng/ml) of Diazepam and Desmethyldiazepam in Five Patients Following Long-Term Diazepam Therapy

Subject	Observed		Calculated
	Diazepam	Desmethyldiazepam	Desmethyldiazepam
1	22	56	55
2	30	49	75
3	14	39	35
4	21	42	50
5	28	68	70

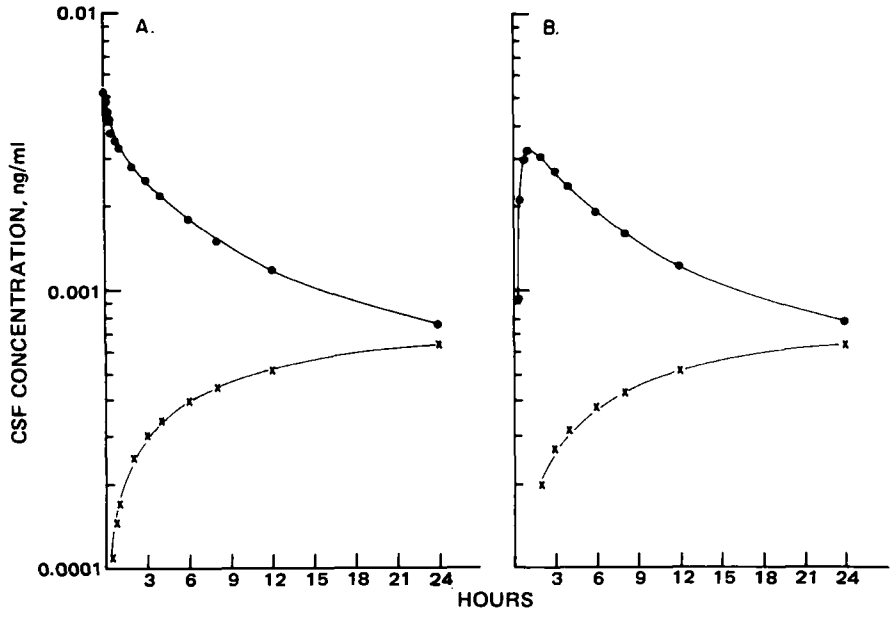

Figure 4—*Simulated CSF concentration–time profiles of diazepam (●) and desmethyldiazepam (×) following single-dose 10-mg intravenous (A) and oral (B) administrations of diazepam to a normal subject.*

diazepam and not desmethyldiazepam. Following chronic administration, the concentration of the metabolite in CSF at steady state will be equivalent to or greater than the concentration of the drug in CSF (Fig. 5). Therefore, at steady state the desmethyldiazepam will contribute significantly to the pharmacological activity observed following chronic administration of diazepam.

Hendel has reported that desmethyldiazepam accumulates in the CSF of patients treated with diazepam for several months (22). However, the metabolite CSF concentrations were calculated using the five-compartment model with the reported drug CSF concentrations in these patients corrected by the factor 2.52 (Table IV). This factor is the result of the product of 1.26 and 2; 1.26 is the relative accumulation factor for desmethyldiazepam with respect to diazepam in plasma at steady state as reported by Greenblatt *et al.* (23), and 2 is the difference in desmethyldiazepam free fraction compared with diazepam free fraction (24). The calculated CSF concentrations of metabolite at steady state are in good agreement with the observed CSF concentrations, suggesting that accumulation of this metabolite following chronic administration of diazepam is predictable.

CONCLUSION

A five-compartment open model describing the pharmacokinetic profile of diazepam and its metabolite, desmethyldiazepam, following the administration of diazepam has been developed. The pharmacokinetic parameters for desmethyldiazepam obtained following the oral administration of clorazepate adequately described the pharmacokinetics of this metabolite following diazepam administration. The parameter estimates and model simulations suggest that ~50% of the administered diazepam dose is metabolized to desmethyldiazepam. This finding suggests that the formation rate for the metabolite is approximately one-half of the total elimination rate for the drug; *i.e.*, $K_{14} = 0.06\ hr^{-1}$ whereas $K_{TOT} = 0.12\ hr^{-1}$. Overall, the single-dose pharmacokinetic parameters of diazepam following its administration and the single-dose

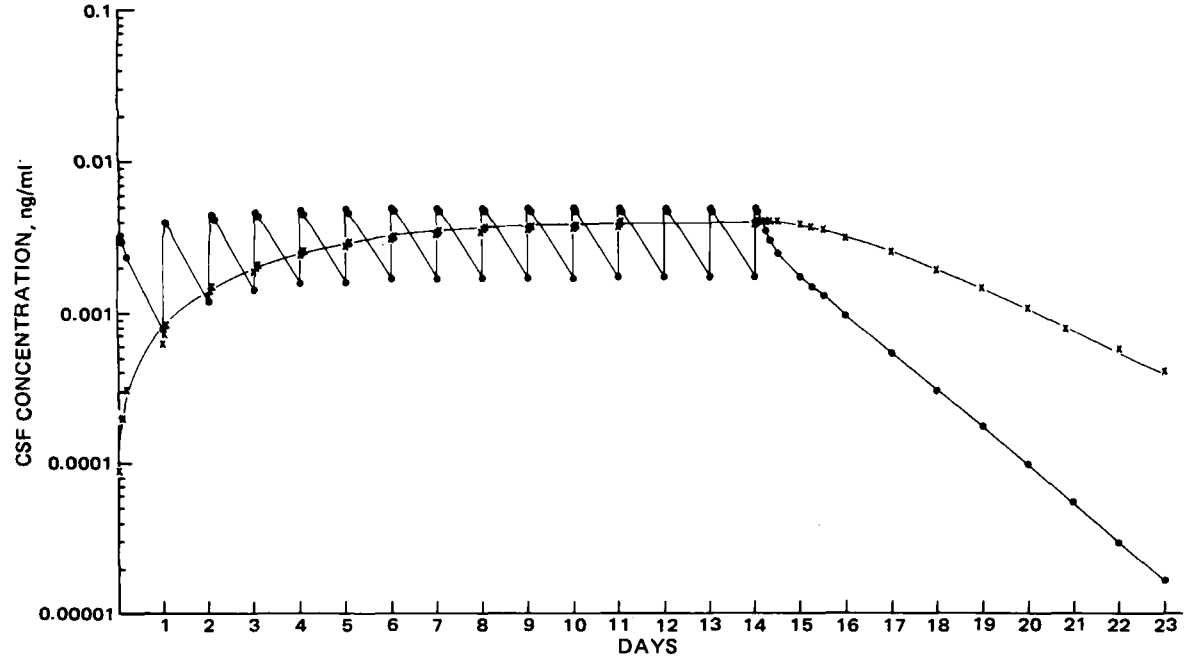

Figure 5—*Simulated CSF concentration–time profiles of diazepam (●) and desmethyldiazepam (×) following once daily chronic oral administration of 10 mg of diazepam for 15 days to a normal subject.*

pharmacokinetics of desmethyldiazepam following the administration of clorazepate can be used to describe the blood concentration–time profiles of diazepam and desmethyldiazepam following both single-dose and chronic administration of the drug, suggesting that there is no enzyme induction or inhibition of diazepam metabolism following multiple-dose administration. This model has also been adapted to predict the concentrations of diazepam and desmethyldiazepam in CSF following the administration of diazepam.

In Vivo Release of Norethindrone Coupled to a Biodegradable Poly(α-amino acid) Drug Delivery System

M. A. ZUPON *, S. M. FANG ˣ, J. M. CHRISTENSEN ‡, and R. V. PETERSEN

Received November 23, 1981, from the *Department of Pharmaceutics, College of Pharmacy, University of Utah, Salt Lake City, UT 84112.* Accepted for publication October 5, 1982. Present addresses: *Division of Product Development, Schering-Plough Corp., Bloomfield, NJ 07003 and ‡School of Pharmacy, Oregon State University, Corvallis, OR 97331.

Abstract □ The *in vivo* release of norethindrone from a biodegradable steroid–polymer conjugate was studied in rats. The drug–polymer conjugate, consisting of [^{3}H]norethindrone coupled *via* a 17-carbonate bond to poly-N^5-(3-hydroxypropyl)-L-glutamine was administered to female rats by subcutaneous injection. The *in vivo* release of steroid, determined by measuring the daily radioactivity output in urine and feces, was fairly constant though it showed a gradual decrease during the 9-month study period. The data indicate that this biodegradable norethindrone–polymer conjugate is a potential candidate for the controlled delivery of norethindrone to effect long-term contraception.

Keyphrases □ Norethindrone—sustained release, biodegradable steroid–polymer conjugate, *in vivo* release rate □ Delivery systems—sustained release of norethindrone, biodegradable steroid–polymer conjugate, *in vivo* release rate □ Contraceptives—norethindrone, sustained release, biodegradable steroid–polymer conjugate, *in vivo* release rate

Although controlled release of drugs at uniform predictable rates from various drug dosage forms has been an object of considerable research for many years, the use of synthetic polymeric materials in the design of controlled-release devices is of recent origin. Of major interest has been the incorporation of contraceptive progestins into various polymers to form controlled, sustained-release drug delivery systems. The use of monolithic devices of poly(dimethylsiloxane) with progestins has been the subject of numerous reports (1–8). These devices, however, have the disadvantage of requiring implantation and removal. Furthermore, significant foreign-body reactions were observed in tissues surrounding these implants, which may be the cause of difficulty in achieving prolonged, constant release of progestins from these devices. Alternatively, the "Uterine Progesterone System" has been the subject of several studies (9–11). The safety and effectiveness of this device has been well established (9, 10, 12). Hydrogel polymers, *e.g.*, poly(hydroxyethyl methacrylate), have also been used to prepare sustained-release devices for progestins (13, 14) with favorable results.

Recently, biodegradable polymers as carriers for controlled, sustained release of various drugs have been evaluated. These polymers are synthesized from monomers which are composed of normal body constituents or which exhibit good compatibility with the body physiology. Various biodegradable polymers have been prepared for the controlled release of contraceptive steroids (15–19). The materials employed for these studies are poly(lactic acid) (15, 16), glutamic acid–leucine copolymer (17), and polyesters of homo- or copolymers of glycolide, DL-lactide, ϵ-caprolactone, or DL-ϵ-decalactone (18). Studies on the *in vitro* and *in vivo* hydrolysis of homopolymers of δ-benzyl-L-glutamate have been reported (20, 21). The

0022-3549/83/1100-1323$01.00/0

pharmacokinetics of desmethyldiazepam following the administration of clorazepate can be used to describe the blood concentration–time profiles of diazepam and desmethyldiazepam following both single-dose and chronic administration of the drug, suggesting that there is no enzyme induction or inhibition of diazepam metabolism following multiple-dose administration. This model has also been adapted to predict the concentrations of diazepam and desmethyldiazepam in CSF following the administration of diazepam.

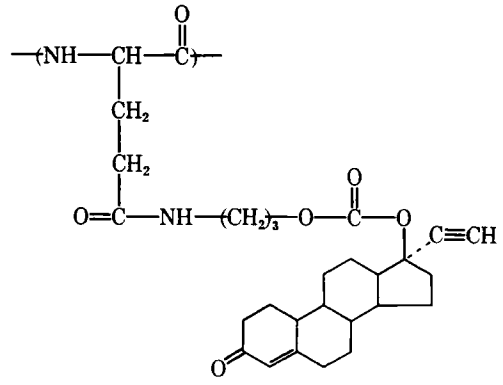
results indicated they could be favorable materials for the sustained release of contraceptive steroids.

In this laboratory, a drug delivery system consisting of norethindrone covalently coupled to poly-N^5-(3-hydroxypropyl)-L-glutamine was recently prepared (22). This drug delivery system should be ideally suited for the controlled release of norethindrone. The polymeric device is biogradable leaving no empty shell for removal at the end of the drug therapy. The hydrolytic product, L-glutamic acid, is a normal body constituent and should show compatibility with the body tissues. Furthermore, the steroid, which is covalently bonded to the biodegradable polymer by a labile bond, may be released in concert with the gradual erosion of the polymer backbone around the surface of the polymer particle. A sustained release of steroid may thus be achieved without the involvement of any diffusion process.

EXPERIMENTAL

Reagents—Tritium-labeled norethindrone and [^{14}C]testosterone obtained for a commercial source[1] were purified by TLC before use. The stability of the tritium atoms in [^{3}H]norethindrone was evaluated by repetitively placing the labeled drug in an ethanol–water (1:1) solution at 25° for 24 hr followed by vacuum distillation of the solution. The extent of exchange between the tritium atoms of the steroid and the hydrogen atoms of the medium was assessed by measuring the radioactivity associated with the distillates. The tritium atoms in [^{3}H]norethindrone were found to be quite stable. Only a negligible amount of radioactivity was found in the distillates: 0.15 and 0.012% in the first and second distillates, respectively.

Polymeric Drug Delivery System—The norethindrone–polymer conjugate consists of norethindrone covalently coupled to poly-N^5-(3-hydroxypropyl)-L-glutamine through the 17-carbonate bond (22):



Two batches of the compound (A and B) were obtained (Table I). Batch A was administered to two rats (A_1 and A_2) at doses of 4.9 and 10 mg, respectively, while 10 mg of batch B was administered to each of five rats.

Biological Half-Life of Norethindrone in Rats—Female Sprague–Dawley rats (200–240 g) were anesthetized with sodium pentobarbital (0.3 mg/g of body weight). An ~3-cm incision was made on the abdominal wall to expose the inferior vena cava. A catheter was placed into the inferior vena cava to inject and withdraw samples. Tritium-labeled norethindrone solution (1.88 μg/25 μCi/0.1 ml Ringer's solution) was injected into the vein, and 0.3 ml of blood was withdrawn at 30-min intervals with a syringe previously rinsed with heparin. Each 0.3-ml blood sample was replaced with 0.3 ml of Ringer's solution to restore blood volume. A portion (0.1 ml) of each 0.3-ml blood sample was pipetted into a conical centrifuge tube containing 5 μl each of nonlabeled norethindrone (1×10^{-3} *M*) and testosterone (1×10^{-3} *M*) and a known amount of [^{14}C]testosterone, which served as the internal standard. The blood sample was centrifuged, and the plasma was transferred to another tube. The cellular fraction was extracted four times with 0.3-ml portions of Ringer's solution, which was then combined with the plasma fraction. The above procedures were carried out quickly at 0–4° to prevent any metabolism of the internal standard. The combined plasma fraction was immediately extracted four times with 2-ml aliquots of methylene chloride. The methylene chloride fractions were pooled and evaporated to dryness under a nitrogen stream. The residue, after being dissolved in 100 μl of methanol, was spotted on a silica gel TLC plate. The plate was eluted with a benzene–ethyl acetate solution (4:1), and the spots corresponding to the parent drug and internal standard were isolated and placed into scintillation vials. To each fraction was added 12 ml of a scintillation fluor cocktail[2], and the radioactivity was measured in a scintillation counter[3]. The efficiency of recovery for norethindrone was normalized according to the amount of recovery of the internal standard, [^{14}C]testosterone, from the TLC plate.

The biological half-life of the total radioactivity, which represents the parent drug and all metabolites, was determined by measuring the radioactivity in 0.1-ml aliquots of the blood sample after treatment with 2 ml of a tissue solubilizer[4] and 0.5 ml of benzoyl peroxide solution (12% in toluene).

***In Vivo* Steroid Release Rate Determination**—The tritiated norethindrone–polymer conjugate (10 mg as a fine powder) was placed in 5 ml of sterile Ringer's solution and let stand overnight. The next day, the supernatant was decanted off, and the precipitate was rinsed several times with sterile Ringer's solution. A small amount of the resulting suspension was plated onto sheep's blood and trypticase soy-base agar plates and incubated for 48 hr at 37° for sterility testing. No colonies were found on the agar plates.

Mature female Sprague–Dawley rats, weighing 210–225 g, were each injected subcutaneously with 0.5 ml of the suspension into the dorsal side just below the neck. The rats were then placed in individual metabolism cages, and their feces and urine were collected at 24-hr intervals for at least 14 days following implantation. Thereafter, the biological samples were collected three times a week, 2 days apart.

The total volume of urine was measured, and a 1-ml aliquot of urine was sampled. To the urine sample, 0.6 ml of water and 12 ml of a scintillation fluor cocktail were added, and the radioactivity in each sample was counted in a scintillation counter. The total amount of fecal matter collected from each metabolism cage was weighed and put in an oven at 60° for ~12 hr until dry. The dry mass was then weighed and pulverized to an homogenous mixture of fine powders in a blender. Two aliquots of the dried fecal matter (0.2 g/sample) were accurately weighed and placed in separate glass scintillation vials. To each vial was added 0.3 ml of 70% perchloric acid and 0.6 ml of 30% hydrogen peroxide to effect complete digestion. The vials were then tightly sealed and incubated for 12 hr at 60° in a shaking water bath until all the fecal matter was completely solubilized. After the digestion, the vials were cooled for 30 min at room temperature before adding 12 ml of a scintillation fluor cocktail[5]. The vials were then kept in a dark place for at least 24 hr before they were counted in a scintillation counter. This procedure effectively minimized chemiluminescence. With this digestion procedure, no appreciable loss of radioactivity due to the processing was observed. These data were used to calculate the daily and cumulative output of radioactivity in the urine and feces.

RESULTS AND DISCUSSION

If the release of [^{3}H]norethindrone from the steroid–polymer conjugate approximates a zero-order kinetic process, the amount of total radioactivity in the body would gradually build up to an eventual steady-state value as shown in the following equation:

$$Q_b = (k_0/k_{el})(1 - e^{-k_{el}t}) \qquad \text{(Eq. 1)}$$

where Q_b is the amount of the total radioactivity in the body, k_0 is the

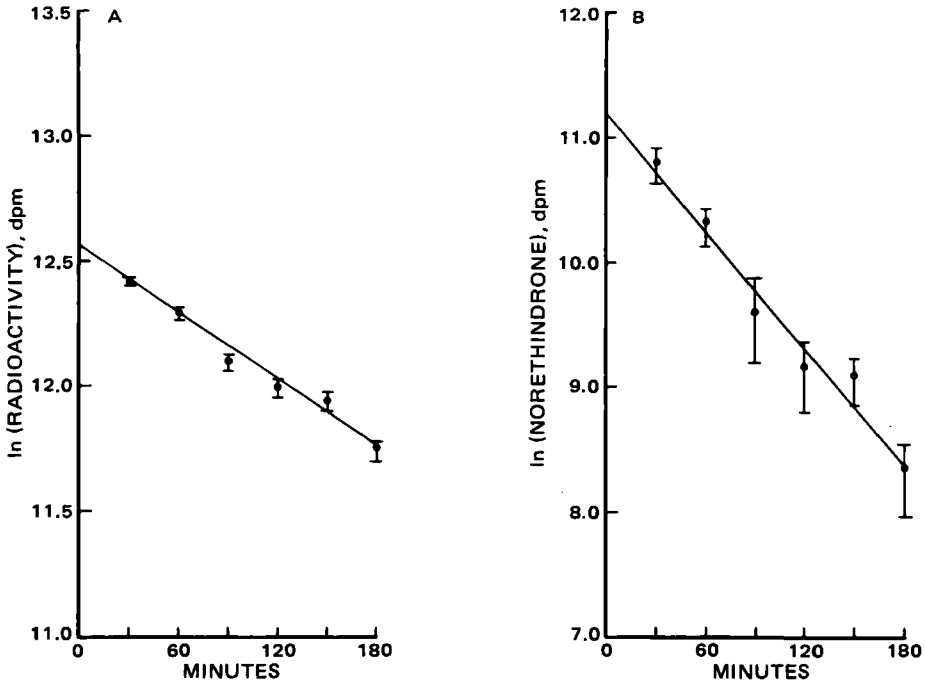

Figure 1—*Semilogarithmic plot of the elimination of total radioactivity (A) or [^{3}H]norethindrone (B) in female Sprague–Dawley rats. Values were determined after intravenous injection of [^{3}H]norethindrone (mean ± SD, n = 6).*

steroid release rate from the steroid–polymer conjugate, and k_{el} is the elimination rate of the total radioactivity. Since the amount of the total radioactivity excreted in the urine and feces (Q_{ex}) equals $k_{el} \cdot Q_b$, then:

$$Q_{ex} = k_0(1 - e^{-k_{el}t}) \qquad \text{(Eq. 2)}$$

and at steady state ($t \rightarrow \infty$):

$$Q_{ex} = k_0 \qquad \text{(Eq. 3)}$$

Equation 3 states that at steady state the amount of the total radioactivity excreted from the body is the same as that of the total radioactivity released from the steroid–polymer conjugate. The rate of the daily output of radioactivity in urine and feces at steady state is, therefore, a valid indication of the daily release rate of steroid from the biodegradable drug delivery system.

Since the above argument is valid only under steady-state conditions, it is necessary to know exactly when steady state is achieved in female rats. From Eq. 1, it can be shown that the time required to reach 95% of steady state is:

$$t_{0.95} = 4.3 \times t_{1/2} \qquad \text{(Eq. 4)}$$

The biological half-life of norethindrone in female rats was found to be 44 min (Fig. 1B), which agrees with that reported earlier by Back *et al.* (23). The elimination of the total radioactivity from rats after the intravenous injection of [^{3}H]norethindrone, however, was slower than that for parent [^{3}H]norethindrone. The half-life for the total radioactivity elimination was 161 min (Fig. 1A). This means that if the norethindrone–polymer conjugate releases norethindrone at a constant zero-order rate after its injection, it will take ~12 hr before the *in vivo* release rate in the urine and feces would reach a constant steady-state value.

Following intravenous and subcutaneous injection of [^{3}H]norethin-

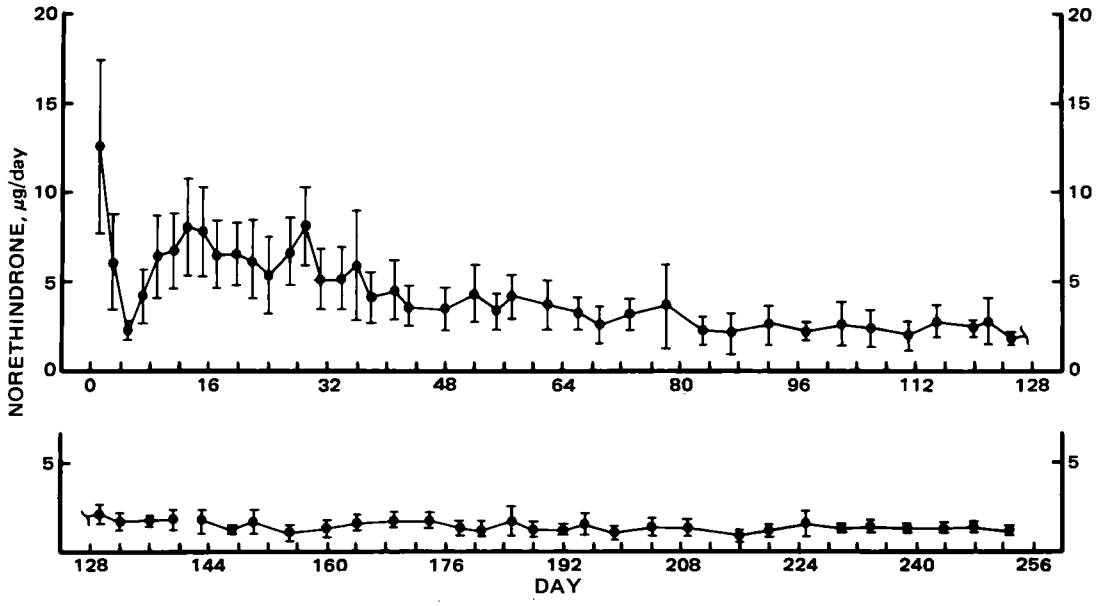

Figure 2—*Daily excretion of radioactivity in urine and feces. Norethindrone–polymer conjugate, batch B (10 mg), containing [^{3}H]norethindrone was injected subcutaneously into female Sprague–Dawley rats. The radioactivity excreted in the urine and feces was measured at various times after the administration (mean ± SD, n = 5).*

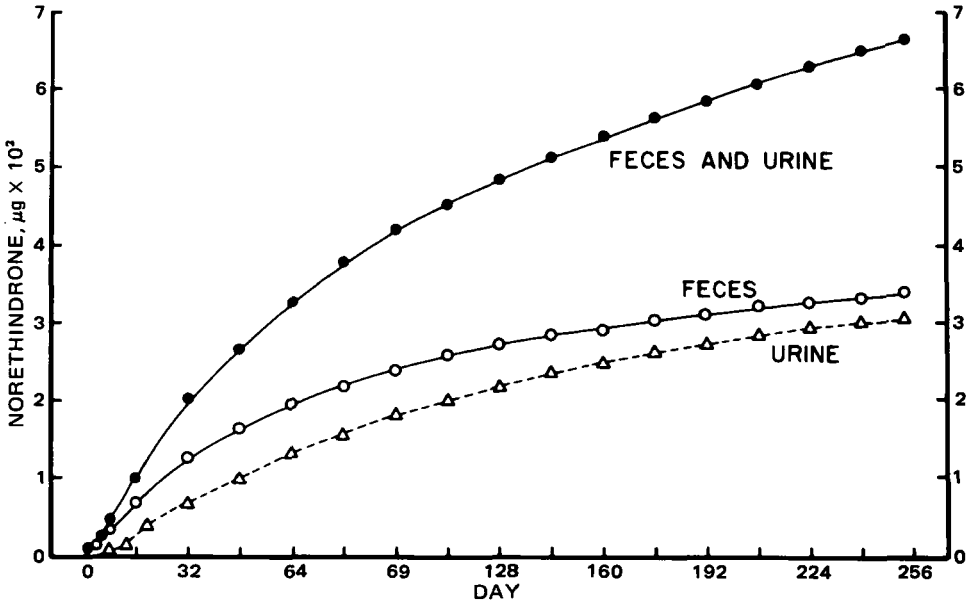

Figure 3—*Cumulative excretion of radioactivity in urine and feces. Norethindrone–polymer conjugate, batch B (10 mg), containing [³H]norethindrone was injected subcutaneously into female Sprague–Dawley rats. The total radioactivity excreted in the urine and feces at various times after the administration is presented (mean, n = 5).*

drone to female Sprague–Dawley rats, it was observed that ~50–60% of the total radioactivity was excreted in the feces. A similar pattern was observed in rats administered the norethindrone–polymer conjugate.

Figures 2 and 3 show the *in vivo* steroid release rate profile for batch B; similar results were observed with batch A. In all animals administered [³H]norethindrone–polymer conjugate (either batch A or B), the release rate profile was characterized by a slight burst of radioactivity release immediately after the injection, followed by a fairly constant release rate for a period up to 10 months. However, a gradual decrease in the rate of steroid release over this long period was evident.

The average *in vivo* release rate of steroid for batch B from day 17 through day 253 was 0.37 μg of norethindrone/mg of norethindrone–polymer conjugate/day. For batch A, the *in vivo* steroid release rate from day 22 through day 292, expressed as μg of norethindrone/mg of norethindrone–polymer conjugate/day, was 0.27 and 0.26 for rats A_1 and A_2, respectively. The daily steroid release from these two animals administered batch A at two different doses were essentially equivalent. The daily steroid release rates from the five animals administered batch B were also very similar, as evidenced from the relatively small standard deviation (Fig. 2). Additionally, both batches A and B appeared to show similar long-term steroid release profiles throughout the study period.

The work measured the *in vivo* release of norethindrone which was covalently coupled to a biodegradable polyglutamate polymer. The system showed a fairly constant release of steroid for a time period in excess of 9 months. A slight decrease in the amount of norethindrone release was evident, however, over this long period.

The data showed that the norethindrone–polymer conjugate is a potential candidate for the controlled delivery of norethindrone to effect long-term contraception. Variation of parameters (*e.g.*, molecular weight, particle size, degree of norethindrone coupling, and the length of spacer group of the steroid–polymer conjugate) may result in products capable of achieving a specified *in vivo* duration and rate of steroid release.

Comparative Study of Topological and Linear Free Energy-Related Parameters for the Prediction of GC Retention Indices

L. BUYDENS *, D. COOMANS *, M. VANBELLE *, D. L. MASSART *x, and R. VANDEN DRIESSCHE ‡

Received November 12, 1981, from the *Farmaceutisch Instituut and the ‡Laboratorium van Farmakologie, Vrije Universiteit Brussel, Laarbeeklaan 103, B-1090 Brussels, Belgium. Accepted for publication October 5, 1982.

Abstract □ The different molecular connectivity indices were considered as to their capacity for describing GC retention indices of a data set consisting of molecules of different chemical families. $^1\chi$ describes best the chromatographic behavior on nonpolar stationary phases, whereas $^3\chi_p$ in combination with an electronic parameter (σ) yields the best results when using the polar stationary phases.

Keyphrases □ Molecular connectivity—correlation to GC retention indices, polar and nonpolar stationary phases, topological and linear free-energy parameters □ GC retention indices—correlation to molecular connectivity, polar and nonpolar stationary phases, topological and linear free-energy parameters □ Topology—correlation of GC retention indices and molecular connectivity, linear free energy parameters, polar and nonpolar stationary phases

The pharmacological action of drugs results from the interaction of the molecules with receptor sites. These interactions are often described in terms of structural parameters (1–3). GC retention indices, which result from the interaction of the molecules with the stationary phase, have been shown (4–8) to be related to the various structural parameters used to describe drug–receptor interactions. Therefore, the GC behavior of the molecules can be used as a simple model for methodological studies of structure–activity relationships.

Relating GC behavior to structural parameters such as the molecular connectivity ($^1\chi$) or the combination of $^1\chi$ with physicochemical parameters such as σ and π (5, 7), leads to satisfactory results when one studies molecules of a single chemical family such as the alcohols, alkanes, or the methyl esters of fatty acids (5, 7). For molecules of different families, especially using more polar stationary phases, the results show that the parameters used do not satisfactorily describe the GC behavior (5). Therefore, use of additional parameters that describe the variance unexplained by the other variables is necessary.

This paper investigates to what extent the additional higher-order terms of the molecular connectivity permit better results. For this purpose the higher-order terms are included in a statistical treatment together with the previously used structural parameters (5).

THEORETICAL

The parameters used are the valence molecular connectivity indices (hereafter called connectivity indices) the Wiener number (W), Hosoya's index (Z), Hansch's constant (π), and Hammett's constant (σ). The full definitions and calculations for these parameters can be found elsewhere (1–3, 9, 10).

To calculate the connectivity parameters the molecule is displayed in skeletal form. To each of the i atoms a value, δ_i, is assigned according to the difference between the number of valence electrons and the number of hydrogen atoms suppressed. An example using 2-methyl-1-butanol (I) is given in Fig. 1.

The respective connectivity indices are calculated by means of the following equations. For the zero-order term ($^0\chi$):

$$^0\chi = \sum_1^i (\delta_i)^{-1/2} \qquad \text{(Eq. 1)}$$

where δ_i represent the δ-values of the i atoms. For the 2-methyl-1-butanol example, $^0\chi = (2/\sqrt{1}) + (2/\sqrt{2}) + (1/\sqrt{3}) + (1/\sqrt{5}) = 4.439$. For the first-order term ($^1\chi$):

$$^1\chi = \sum_i^N (\delta_i\delta_j)^{-1/2} \qquad \text{(Eq. 2)}$$

where $\delta_{i,j}$ are the δ-values of the adjacent atoms i and j, and N is the number of bonds in the molecule. Using 2-methyl-1-butanol, $^1\chi = (1/\sqrt{1\times2})\ (2/\sqrt{2\times3}) + (1/\sqrt{1\times3}) + (1/\sqrt{2\times5}) = 2.417$. For the second-order term ($^2\chi$):

$$^2\chi = \sum^M (\delta_i\delta_j\delta_k)^{-1/2} \qquad \text{(Eq. 3)}$$

where $\delta_{i,j,k}$ are the δ-values of the atoms of two adjacent bonds, and M is the number of adjacent bonds pairs in the molecule. For the 2-methyl-1-butanol example, $^2\chi = (1/\sqrt{1\times2\times3}) + (1/\sqrt{2\times3\times1}) + (1/\sqrt{1\times3\times2}) + (1/\sqrt{3\times2\times5}) + (1/\sqrt{2\times2\times3}) = 1.696$. For the third-order path term ($^3\chi_p$):

$$^3\chi_p = \sum^P (\delta_i\delta_j\delta_k\delta_l)^{-1/2} \qquad \text{(Eq. 4)}$$

where $\delta_{i,j,k,l}$ are the δ-values for the atoms of three adjacent bonds forming the butane skeleton (C—C—C—C) and p is the number of three adjacent bonds forming the butane skeleton in the molecule. Using 2-methyl-1-butanol, $^3\chi_p = (1/\sqrt{1\times2\times3\times1}) + (1/\sqrt{1\times2\times3\times2}) + (1/\sqrt{2\times3\times2\times5}) + (1/\sqrt{1\times3\times2\times5}) = 1.009$. For the third-order cluster term ($^3\chi_c$):

$$^3\chi_c = \sum^Q (\delta_i\delta_j\delta_k\delta_l)^{-1/2} \qquad \text{(Eq. 5)}$$

where $\delta_{i,j,k,l}$ are the δ-values for the atoms of three adjacent bonds forming the isobutane skeleton, and Q is the number of isobutane groups in the molecule. For 2-methyl-1-butanol: $^3\chi_c = (1/\sqrt{2\times3\times2\times1}) = 0.289$.

The Wiener number (W) and Hosoya's index (Z) are also topological parameters. Formulas for their calculation can be found elsewhere (3, 11). Because the molecules considered herein are all aliphatic molecules the σ scale, derived from the hydrolysis of aliphatic acid esters was used (1, 2, 10).

EXPERIMENTAL

The different parameters were calculated for ~100 compounds[1] belonging to different families (alkanes, alkenes, alcohols, aldehydes, ketones, and esters). Retention indices (12) on four stationary phases of different polarity were used: squalane and SE-30 were used as the nonpolar phases, while ethylene glycol was of intermediate polarity and di-

ethylene glycol succinate was used as the polar phase. The molecular connectivity indices were calculated with a microcomputer[2] using a program developed in-house.

Multiple regressions were calculated following a stepwise regression procedure using the SPSS program (13). The independent variables were introduced in the multiple regression equation only if they met certain statistical criteria. The variable that accounts for the largest amount of variance in the dependent variable (with the highest correlation coefficient) was used first in the regression equation. The variable that explains the greatest amount of variance not accounted for by the variables already in the equation entered the regression equation in the following step. Correlation studies between the different connectivity indices were also carried out using the SPSS program (13).

RESULTS AND DISCUSSION

To find the relationship between the different connectivity indices, correlation coefficients between these indices were calculated. The different structural features necessary to calculate all the connectivity indices are not present in all molecules. Therefore, some of the indices are not different from zero for all the molecules of the basic set. The correlation coefficients are calculated only for the molecules with a non-zero value for the indices. A subset was chosen to compare the different indices such that the indices compared are all different from zero for all the molecules of the subset. The resulting correlation matrix is shown in Table I.

The results show that the parameters W and Z correlate best with the zero- and first-order terms of the molecular connectivity. The parameter σ, as expected, is completely different from the other variables, since its correlation coefficient with the other variables is nearly zero. The correlation between the connectivity indices decreases for the higher-order terms. $^3\chi_c$ does not correlate with the path connectivity term. These results, in agreement with those of Kier and Hall (3), suggest that the higher-order terms of the molecular connectivity contain different information which can indeed improve the regression equation.

Regression equations were calculated for the retention indices on the four stationary phases using these parameters. The equations are of the general form:

$$(RI)_i = a + bx_{1i} + cx_{2i} + dx_{3i} + \ldots + e_i \qquad \text{(Eq. 6)}$$

where RI is the retention index and $x_{1i}, \ldots, x_{3i}$ are the values for the different structural parameters for compound i. The results are given in Table II; the multiple correlation (MR) and the simple correlation (SR) coefficients are given. The multiple correlation coefficient is the correlation coefficient of the regression equation with all variables entered up to the considered step.

	$^2\chi$	0.95	0.29

[a] $N = 48$. [b] $N = 45$. [c] $N = 44$.

For the nonpolar stationary phases, the topological parameter $^1\chi$ describes best the behavior; this is in agreement with earlier results (5). For the more polar stationary phases, the most important parameter in the earlier study was σ, describing electronic effects (5). In the present study σ also appeared first (Table II). This is not surprising, since the interaction with the more polar stationary phases are much more specific. The second most important parameter was the $^3\chi_p$ term. This means that once the electronic effects are filtered out of the total variance, $^3\chi_p$ describes best the residual steric influences on the chromatographic behavior of the more polar stationary phases.

As stated above, the higher-order terms of the molecular connectivity parameters cannot be computed for all 100 substances in the original data set. To derive the effect of the inclusion of $^3\chi_p$ in the set variables, the multiple regression was carried out with and without $^3\chi_p$ [*i.e.*, with the variables of our earlier study (5)]. It is clear that $^3\chi_p$ does indeed improve the correlation coefficient, since the correlation coefficient obtained with the two first variables introduced in the regression equation increased from 0.57 (without $^3\chi_p$) to 0.68 (with $^3\chi_p$) for diethylene glycol succinate. The results for the polar phases are improved by including the higher-order term $^3\chi_p$. They are, however, still worse than those for the nonpolar stationary phases.

To see which effects are not explained by the parameters included in the regression equation, the molecules whose chromatographic behavior is not well described with the regression equation, *i.e.*, the molecules which have a large residual (e in Eq. 6), can be examined. The greatest residuals are found for molecules that contain more than one functional group, such as an hydroxyl and a keto group or two keto groups. The results of the regression equations without these outliers are shown in Table III. For the nonpolar stationary phases, the results are satisfactory. For the most polar stationary phase (diethylene glycol succinate), the most important parameter is still the electronic parameter σ, followed by $^3\chi_p$. For the mediumly polar polyethylene glycol, the first parameter entered is now $^3\chi_p$, followed by σ. In both cases the results are improved by omitting the outliers.

$^1\chi$ is entered as the first topological parameter in the regression equation for the apolar stationary phases, while $^3\chi_p$ is used for the polar stationary phases. More information about the intercorrelation between the parameters and the retention indices can be obtained by factor analysis. Factor analysis reduces the total amount of variables to a few fundamental variables (factors or latent variables) which are a linear combination of the original variables. These new variables are chosen so that as much of the total variance as possible is explained. Up to this point, the retention indices were considered as dependent variables and π, σ, and the topological parameters as independent variables. This means that the retention indices were predicted or explained by means of the structural parameters. However, both the retention indices and the structural parameters can be thought of as variables containing information about the structural aspects and, therefore, about possible interactions of the molecules. Factor analysis can show which variables (structural parameters and retention indices) contain analogous information (*i.e.*, are related to each other).

Factor analysis of the data set, without the outliers, resulted in the extraction of three important factors, explaining respectively 55, 20, and 13% of the total variance. Figure 2A shows that the topological parameters form a cluster near the cluster of the nonpolar stationary phases in the two-dimensional space of the first two factors. This cluster is rather distant from the cluster of the two polar stationary phases. The only parameter in the neighborhood of the polar phases is σ. These results are analogous to those of an earlier study (5). The topological parameters best describe the chromatographic behavior on the nonpolar stationary phases. In the plane of the first and third factor (Fig. 2B), however, the topological parameter $^3\chi_p$ is situated near the polar phases, which means that in the three-dimensional space the parameters σ and $^3\chi_p$ are most closely related to the polar stationary phases. The other topological parameters are still best related to the nonpolar phases. This shows that the steric effects determining the GC behavior are different for polar and nonpolar stationary phases. For the nonpolar phases, the lower-order connectivity terms are sufficient to account for these effects. For the more polar stationary phases, a better description of the molecules is necessary to describe the chromatographic behavior; this can be provided by means of the higher-order term $^3\chi_p$. It is, however, not the $^3\chi_c$ term that improves the regression equation. A reason for this could be the fact that $^3\chi_c$ describes only part of the molecule, while $^3\chi_p$ gives a more general idea of the whole molecule.

From these results it can be concluded that the GC behavior of molecules from different chemical families can be described satisfactorily by means of a general topological parameter on nonpolar stationary phases, since these interactions are quite nonspecific. For the more polar phases a higher-order term of the molecular connectivity, $^3\chi_p$, and an electronic parameter, σ, are required, since these interactions are quite specific (dipole–dipole interactions, hydrogen bonding, *etc.*). It should, however, be pointed out that these results are obtained for molecules containing only one functional group. The interpretation of the chromatographic behavior of molecules with more than one functional group is more difficult. A reason for this could be that the resultant electronic effect of two functional groups is not described sufficiently by σ. Electronic parameters, such as the dipole moment, could possibly improve these results. It is also known that two functional groups influence the partition coefficient of the molecules in a different way than each functional group separately (2, 14).

Stability-Indicating High-Performance Liquid Chromatographic Assay for Oxazepam Tablets and Capsules

VAN D. REIF ˣ **and NICHOLAS J. DEANGELIS**

Received July 23, 1982, from the *Analytical Research and Development Subdivision, Wyeth Laboratories, Inc., Philadelphia, PA 19101.* Accepted for publication September 17, 1982.

Abstract □ A stability-indicating high-performance liquid chromatographic (HPLC) assay for oxazepam in capsules and tablets was developed. The material was extracted with 2% aqueous methanol and chromatographed on a C18 reverse-phase column, which was eluted with methanol–water–acetic acid (60:40:1). A wavelength of 254 was used for detection. This assay separated oxazepam from all degradation products mentioned in the literature or observed in stress-degraded samples. Degradation products could be detected at the 0.1% level. Degradation of oxazepam to 6-chloro-4-phenyl-2-quinazolinecarboxaldehyde and 2-amino-5-chlorobenzophenone was observed after either acid or base treatment. Acidic conditions also afforded 2′-benzoyl-4′-chloroglyoxanilide and 6-chloro-4-phenyl-2(1*H*)-quinazolinone.

Keyphrases □ Oxazepam—analysis, high-performance liquid chromatography, stability, tablets, capsules □ High-performance liquid chromatography—oxazepam capsules and tablets, stability-indicating analysis □ Sedatives—oxazepam, high-performance liquid chromatographic analysis, tablets, capsules, stability indicating

Various methods have been described for the determination of oxazepam (I), a 1,4-benzodiazepine tranquilizer. The current official method (1) employs UV spectrophotometric determination after extraction with ethanol. Increased selectivity was observed using polarographic detection (2, 3), which is dependent on reduction of the intact 4,5-azomethine bond. During GLC analysis, oxazepam decomposes to 6-chloro-4-phenyl-2-quinazolinecarboxaldehyde, II (4, 5). GLC methods, therefore, have been based on measurement of either II or 2-amino-5-chlorobenzophenone (III), which is formed by prior hydrolysis of oxazepam (6). High-performance liquid chromatographic (HPLC) methods have been described for detection and quantitation of I in biological fluids (7–11) and in mixtures of benzodiazepines (12–15). However, a selective chromatographic method for dosage forms in the presence of degradation products has not been published. This report describes the development of a specific and precise HPLC method for oxazepam tablets and capsules. Degradation products were isolated and identified to validate method specificity.

The hydrolysis of I to a benzophenone (III) was reported in 1964 (16). Formation of the aldehyde (II) after heat treatment (4, 5) and under acidic conditions (17) has been described, along with proposed mechanisms. Han *et al.* (18) reported the tentative identification of two intermediates of oxazepam hydrolysis. The interpretation of kinetic data obtained by UV measurements was, in part, substantiated by the isolation of these components. One, a prominent acid degradation product (IV) was designated as the initial product of 4,5-azomethine hydrolysis. The other (V) was predominant in base, but formed also in acid, and was designated as the product of 1,2-amide bond hydrolysis. However, neither degradation product when isolated, gave a mass spectral parent peak that corresponded to the mass of the assigned structure.

Two potential degradation products, 7-chloro-5-phenyl-4,5-dihydro-2*H*-benzodiazepine-2,3-(1*H*)-dione (VI) and 6-chloro-3,4-dihydro-4-phenyl-2-quinazolinecarboxylic acid (VII), were prepared from I by treatment with strong base (19). Two other potential degradation products, 2′-benzoyl-4′-chloroglyoxanilide (VIII) and 6-chloro-4-phenyl-2(1*H*)-quinazolinone (IX), have been reported as metabolites (20).

EXPERIMENTAL

Materials—The following reference compounds were synthesized according to literature procedures: II (17); VI and VII (19); and (IX) (21). Compounds VIII[1] and X[2] were obtained in-house. The mass spectra for X gave the predicted monochlorinated parent peaks at *m/z* 270 and 272, and the melting point was the same as reported (22). The melting point and IR spectra for VIII corresponded to reported data (23). Compounds I[3] and III[4] were obtained commercially.

[a] Assay system, Chromegabond C18, E. S. Industries. [b] Chloroform–toluene–methanol (52:45:7); silica gel GF, visualization by shortwave UV. [c] Distinguished by blue fluorescence under long wavelength UV. [d] Distinguished by yellow spot with visible light.

Oxazepam Degradation—Hydrolysis conditions and TLC procedures were similar to those reported previously (18). The following 0.1 *M* buffers at 80° were used: hydrochloric acid, pH 5.5 phosphate, pH 3.2 acetate, and sodium hydroxide. Aliquots of hydrolyzed solutions were also withdrawn and analyzed directly by HPLC. TLC spots were extracted with methanol and were analyzed by HPLC and mass spectra for further identification.

Assay—The chromatograph[5] was equipped with a UV detector[6] set at 254 nm. A fixed-loop septumless injector[7] with a 10-μl loop was used in conjunction with 10-μm microparticulate reverse-phase columns[8], 25–30 cm × 4.6-mm i.d. The mobile phase consisted of methanol–water–acetic acid (60:40:1) with a 2-ml/min flow rate. An electronic integrator[9] was used for area determinations; peak heights were determined manually.

The system suitability was tested by dissolving ~10 mg of oxazepam and 15 mg of II in 250 ml of methanol; 10 μl of this solution was chromatographed using the assay conditions. The resolution factor (24) between oxazepam and II is ≥5.0. Unsuitable resolution can often be improved by a slight reduction of the mobile phase methanol concentration.

The standard was prepared by dissolving a quantity of oxazepam standard[10] in methanol–water (49:1) to give a known concentration of ~0.1 mg/ml. Samples were prepared by emptying ≥20 capsules and determining the average weight, or by weighing ≥20 finely powdered tablets. An accurately weighed portion of the powder containing ~25 mg of oxazepam was transferred to a 250-ml volumetric flask, 5 ml of water was added, and the flask was swirled to wet the powder. Approximately 200 ml of methanol was added, the solution was sonicated[11] for 5 min, stirred for 30 min, and diluted to volume with methanol. A portion was centrifuged to provide a clear solution for injection into the chromatograph.

Degradation Determination—Degradation was determined in the dosage forms with a 0.1% limit of detection. Methanol (10 ml) was added to a portion of capsule or tablet powder containing ~25 mg of oxazepam. The suspension was sonicated for 10 min and then centrifuged. Using the above HPLC conditions, 10 μl of the supernatant was injected into the chromatograph within 30 min after preparation. (After 1 hr, 0.1% of II, due to degradation of I in the methanol solution, may be detected.) The detector sensitivity was adjusted to give standard peak heights of ≥10 mm. Standards were prepared in methanol at a concentration of ~5 μg/ml.

RESULTS AND DISCUSSION

Oxazepam Degradation—With the use of similar hydrolysis and TLC conditions, three degradation products, comparable to those originally reported by Han *et al.* (18), were observed. The pH conditions necessary for their formation and the TLC R_f values matched the original data. As reported, the ultimate hydrolysis product, the benzophenone (III), was observed after either acid or base treatment. Consistent with the original results, a second degradation product, which formed with ease in acid, had a mass spectral parent peak at *m/z* 287. However, this substance was identified by TLC R_f as the glyoxanilide (VIII) and not as the initial hydrolysis product, IV, as originally stated. When eluted from the TLC plate, this acid degradation product also had the same HPLC retention time as VIII reference material (Table I), and its mass spectrum was the same as a metabolite previously identified (20) as VIII. The third degradation product, predominant in base, was identified as the aldehyde (II) by comparison of mass spectra and chromatographic retention with reference material (Table I). No degradation products were observed that could be identified as IV or V.

A yellow TLC band at R_f 0.93, identified as the Schiff-base dimer of II and III, was also observed in chloroform extracts of both acidic and basic hydrolyses solutions. A mass spectrum of the extracted TLC band gave peaks at *m/z* 231, 268, and 481, corresponding to parent peaks for

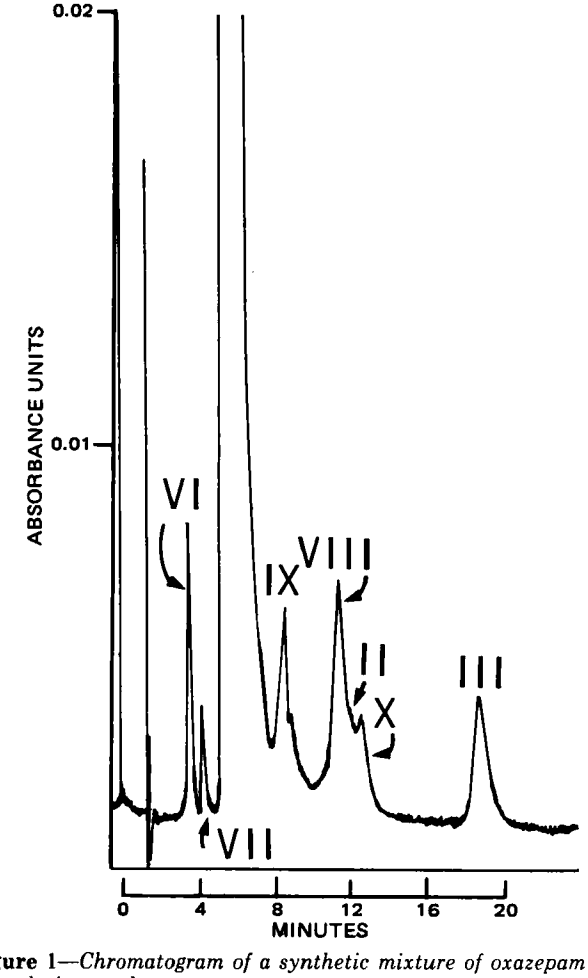

Figure 1—*Chromatogram of a synthetic mixture of oxazepam and degradation products.*

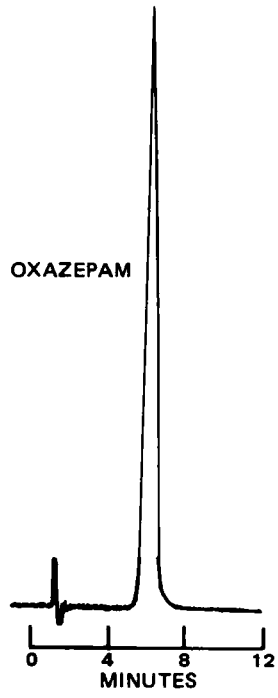

Figure 2—*Typical assay chromatogram.*

the benzophenone (III), the aldehyde (II), and the Schiff-base, respectively. Rechromatography of the extracted band gave, in addition to a spot at R_f 0.93, spots corresponding to II and III indicating that the dimer was not stable. HPLC gave only peaks corresponding to II and III. Further evidence for Schiff-base formation was the fact that the band at R_f 0.93 was obtained from chloroform standard solutions containing both II and III, but not from solutions containing II or III alone.

The quinazoline alcohol (X), the dione (VI), and the quinazolinecarboxylic acid (VII) were observed as relatively minor base-degradation products. The quinazolinone (IX) formed under either acidic or basic conditions. During method development, extraction of product composites with 0.1 *N* HCl–methanol (2:98) yielded low assays with rapid formation of IX.

The aldehyde, II, was the most prominent degradation product under stress conditions in the dosage forms. However, <0.5% was present in samples stored at room temperature for 5 years or at 45° for 6 months.

Assay—Precision data, obtained by replicate assays of commercial samples, and recovery data for synthetic mixtures of I and three combinations of commonly used excipients are reported in Table II. Placebo interference due to each mixture was <0.1% for the method. Linearity was checked by assaying solutions in the 0.06- to 0.12-mg/ml range. The chromatographic response was linear to the highest concentration tested.

The HPLC system separated I from all of the degradation products reported in the literature or observed in decomposed solutions (Table I). A separation of oxazepam from degradation products at levels of ~0.5% is shown in Fig. 1. Similar separations were achieved on the four different commercial columns tested, with the differences being minor variations in the resolution of individual impurities from each other. The columns tested passed the system suitability test. A typical assay chromatogram is shown in Fig. 2.

Complex Formation Between α-Cyclodextrin and 4-Substituted Phenols Studied by Potentiometric and Competitive Spectrophotometric Methods

SHU-FEN LIN and KENNETH A. CONNORS ˣ

Received February 11, 1982, from the *School of Pharmacy, University of Wisconsin, Madison, WI 53706.* Accepted for publication October 8, 1982.

Abstract □ Stability constants for complex formation between α-cyclodextrin and the conjugate acid and base forms of nine phenols were measured in aqueous solution at 25°. The potentiometric method, in which the apparent acid dissociation constant of the phenol is measured as a function of cyclodextrin concentration, was supplemented by a modified version of a competitive spectrophotometric methyl orange method. For all phenols, the 1:1 stability constant for the conjugate base form (K_{11b}) was larger than K_{11a} for the conjugate acid form. Finite K_{12b} values were found for phenols whose 4-substituents could tolerate a positive charge by electron delocalization. Complex stability, as measured by K_{11a} and K_{11b}, increases with electron density and polarizability at the 4-substituent. It is concluded that the 4-substituent is the sole or predominant site of binding for both the conjugate acid and base forms of the phenols. The general result that K_{11b} is greater than K_{11a} for any phenol is accounted for by relative delocalization of charge in the anion and neutral species.

Keyphrases □ α-Cyclodextrin—complex formation with 4-substituted phenols, stability constants, potentiometric and competitive spectrophotometric methods □ 4-Substituted phenols—complex formation with α-cyclodextrin, stability constants, potentiometric and competitive spectrophotometric methods □ Competitive spectrophotometry—with methyl orange, α-cyclodextrin–4-substituted phenol complexation, stability constants, comparison with potentiometric methods

In an earlier paper (1), the potentiometric method for studying cyclodextrin complexes was applied to a series of 4-substituted benzoic acids. This method has now been used to investigate the complexing of α-cyclodextrin with 4-substituted phenols.

THEORETICAL

Potentiometric Method—The theory of the method was described earlier (1); only a summary of the points pertinent to the present application is given here. The symbolism is identical with that used in the prior treatment (1).

The procedure is to measure the apparent dissociation constant (pK_a') of the phenol (substrate) at total concentration S_t in the presence of a total concentration L_t of α-cyclodextrin (the ligand), L_t being varied from zero up to nearly its solubility limit. The quantity $\Delta pK_a'$ is defined by:

$$\Delta pK_a' = pK_a' - pK_a \qquad \text{(Eq. 1)}$$

where pK_a is the dissociation constant when $L_t = 0$. The theory of the method (1), for a system that may contain 1:1 (SL) and 1:2 (SL_2) complexes of both the conjugate acid and base forms of the substrate, shows that $\Delta pK_a'$ is related to the complex stability constants by:

$$\Delta pK_a' = \log C = \log\left(\frac{1 + K_{11a}[L] + K_{11a}K_{12a}[L]^2}{1 + K_{11b}[L] + K_{11b}K_{12b}[L]^2}\right) \qquad \text{(Eq. 2)}$$

where K_{11a}, K_{12a}, K_{11b}, and K_{12b} are stepwise complex stability constants, the numerical subscripts indicating stoichiometry and the letters the conjugate acid–base form, and [L] is the equilibrium (unbound) concentration of ligand. For carboxylic acids it appears to be a general result that $\Delta pK_a'$ is a positive quantity (1–3); hence, C is greater than unity. For phenols, however, $\Delta pK_a'$ is negative, so C is smaller than one, and it becomes more convenient to work with its reciprocal C'. The basic relationship is then:

$$C' = \frac{1 + K_{11b}[L] + K_{11b}K_{12b}[L]^2}{1 + K_{11a}[L] + K_{11a}K_{12a}[L]^2} \qquad \text{(Eq. 3)}$$

All of the systems here can be described as special cases of Eq. 3. The particular case to which a system belongs is diagnosed by plotting C' against L_t; then, an appropriate linearized plotting form is applied to extract stability constant estimates. Since $L_t \neq [L]$, the free concentration [L] is calculated, and iterations are made until the stability constant estimates converge. The four special cases of Eq. 3, the linear plotting forms, and the equations for the calculation of [L] are:

Case I:

$$C' = \frac{1 + K_{11b}[L]}{1 + K_{11a}[L]} \qquad \text{(Eq. 4)}$$

$$\frac{C' - 1}{[L]} = K_{11b} - C'K_{11a} \qquad \text{(Eq. 5)}$$

$$[L] = L_t - \frac{S_t}{X + 1} \qquad \text{(Eq. 6)}$$

where:

$$X = \frac{(C' + 1)(R' - C')}{(C' - 1)(R' + C')} \qquad \text{(Eq. 7)}$$

and $R' = K_{11b}/K_{11a}$.

Case II:

$$C' = 1 + K_{11b}[L] \qquad \text{(Eq. 8)}$$

$$[L] = L_t - \frac{(C' - 1)}{2C'} S_t \qquad \text{(Eq. 9)}$$

Case III:

$$C' = 1 + K_{11b}[L] + K_{11b}K_{12b}[L]^2 \qquad \text{(Eq. 10)}$$

$$\frac{C' - 1}{[L]} = K_{11b} + K_{11b}K_{12b}[L] \qquad \text{(Eq. 11)}$$

$$[L] = \frac{2C'(L_t - S_t) + 2S_t}{2C' - S_tK_{11b}} \qquad \text{(Eq. 12)}$$

Case IV:

$$C' = \frac{1 + K_{11b}[L] + K_{11b}K_{12b}[L]^2}{1 + K_{11a}[L]} \qquad \text{(Eq. 13)}$$

$$\frac{C' - 1}{[L]} + C'K_{11a} = K_{11b} + K_{11b}K_{12b}[L] \qquad \text{(Eq. 14)}$$

$$K_{11a}[L]^2 + \left[1 + S_tK_{11a}\left(\frac{3}{2} - \frac{R'}{2C'}\right) - L_tK_{11a}\right][L] - \left[L_t - \frac{S_t(C' - 1)}{C'}\right] = 0 \qquad \text{(Eq. 15)}$$

To make the case IV linear plot according to Eq. 14, K_{11a} must be known. For case IV systems, K_{11a} was determined by a competitive spectrophotometric method as described in the following section.

Competitive Indicator Method—In 1953 Broser (4) showed that methyl orange and α-cyclodextrin form a complex in acidic solution, the complexed form of the indicator absorbing light much less intensely than the free form. If a third solute, capable of forming a cyclodextrin complex, is added to the solution, some of the complexed indicator will be competitively displaced, with a corresponding increase in the absorption intensity. This is the basis of the competitive methyl orange spectrophotometric method, which was used by Lautsch *et al.* (5) to study adrenalin–α-cyclodextrin complex formation. Casu and Ravà applied this method to measure K_{11a} values for many substituted benzoic acid substrates (6). The stability constants reported by these workers were, however, not in good agreement with those found potentiometrically in this laboratory (1). For this reason, the methyl orange method has been reexamined and modified as follows.

0022-3549/83/1100-1333$01.00/0

Let S represent the substrate of interest, L the cyclodextrin, and I the indicator. The competitive complexation equilibrium is shown in Scheme I:

$$IL + S \rightleftarrows SL + I$$

Scheme I

Mass balance equations on the substrate, ligand, and indicator are:

$$S_t = [S] + [SL] \quad \text{(Eq. 16)}$$

$$L_t = [L] + [SL] + [IL] \quad \text{(Eq. 17)}$$

$$I_t = [I] + [IL] \quad \text{(Eq. 18)}$$

(It is, in general, not permissible to neglect the [IL] term in Eq. 17.) Stability constants for the complexes SL and IL are defined, where 1:1 stoichiometry is assumed, as:

$$K_{11S} = \frac{[SL]}{[S][L]} \quad \text{(Eq. 20)}$$

$$K_{11I} = \frac{[IL]}{[I][L]} \quad \text{(Eq. 21)}$$

In the systems of present interest, where the substrate is the conjugate acid form of a phenol, K_{11S} is equivalent to K_{11a}.

Eqs. 16–21 are combined to give:

$$L_t = [L] + \frac{K_{11S}[L]S_t}{1 + K_{11S}[L]} + \frac{K_{11I}[L]I_t}{1 + K_{11I}[L]} \quad \text{(Eq. 22)}$$

Defining the indicator ratio $Q = [I]/[IL]$ allows Eq. 21 to be written as $K_{11I} = 1/Q[L]$, which, substituted into Eq. 22, gives:

$$L_t = \frac{1}{QK_{11I}} + \frac{S_tK_{11S}}{QK_{11I} + K_{11S}} + \frac{I_t}{Q + 1} \quad \text{(Eq. 23)}$$

The quantity P is defined as:

$$P = L_t - \frac{1}{QK_{11I}} - \frac{I_t}{Q + 1} \quad \text{(Eq. 24)}$$

Therefore, Eq. 23 may be written:

$$P = \frac{S_tK_{11S}}{QK_{11I} + K_{11S}}$$

or

$$\frac{S_t}{P} = \frac{K_{11I}}{K_{11S}}Q + 1 \quad \text{(Eq. 25)}$$

The indicator ratio Q can be measured by means of:

$$Q = \frac{\epsilon - \epsilon_{IL}}{\epsilon_I - \epsilon} \quad \text{(Eq. 26)}$$

where ϵ_I and ϵ_{IL} are the molar absorptivities of free and complexed indicator, respectively, and ϵ is the apparent molar absorptivity in any solvent containing both forms. If the total indicator concentration is constant in all solutions, the absorptivities can be replaced by absorbances.

K_{11I} can be obtained by independent measurements on solutions of indicator and ligand by the conventional spectrophotometric method. Eq. 25 therefore provides a graphical approach to determining K_{11S} by plotting S_t/P against Q, where P is obtained using Eq. 24.

The possible formation of a substrate–indicator complex (SI) has been analyzed (7) for its effect on the determination of K_{11S}. It was found that such an effect can be minimized if S_t and [I] are small; [I] is small when Q is small, when I_t is small, or when L_t is large. Another complicating factor is self-association of the indicator. DeVylder and DeKeukeleire (8) observed self-association of methyl orange in pH 2.2 aqueous solutions at indicator concentrations $>10^{-4}$ M. In the present work I_t was 1.67×10^{-5} M; hence, self-association could be neglected.

According to Eq. 25, the best estimate of K_{11S} should be possible if K_{11I} is approximately equal to K_{11S}, for then the slope will be approximately one. The method may therefore be useful for a wide range of substrates if indicators are identified with appropriate K_{11I} values.

EXPERIMENTAL

Materials—α-Cyclodextrin[1] was dried at 95° for 48 hr. Methyl orange[2] was recrystallized from water, then washed with ethanol followed by ether (9); its molar absorptivity in 0.08 M HCl at 508 nm was 4.82×10^4. Solid phenols[3] were recrystallized until their melting points agreed with literature values. 4-Methoxyphenol was distilled under reduced pressure; bp 111°/2 mm Hg, mp 55°. Water was redistilled from alkaline permanganate.

Potentiometric Studies—A stock solution of the phenol was prepared such that its final diluted total concentration (S_t) would be 0.003–0.004 M, and the phenol was half-neutralized with 0.10 M NaOH. The solution was brought to the mark with 0.10 M NaCl.

α-Cyclodextrin was weighed into 5-ml volumetric flasks in amounts that covered its full solubility range. Portions (4.0 ml) of the phenol stock solution were pipetted into each flask, and the solutions were brought to volume with 0.10 M NaCl. They were equilibrated at 25.0; to ensure adequate mixing, a 10-mm stirring bar was added and was driven by a submerged water-driven magnetic stirrer. The solution was transferred to a 5-ml test tube, and the combination pH electrode was lowered into the solution, which was protected from contact with the atmosphere. The pH was measured[4], and pK_a' was calculated using:

$$pK_a' = pH - \log \frac{b + [H^+] - [OH^-]}{S_t - (b + [H^+] - [OH^-])} \quad \text{(Eq. 27)}$$

where b is the added concentration of sodium hydroxide; in these studies $b = S_t/2$. Reproducibility on duplicate solutions was 0.003 pH unit or better. All studies were at 25.0° and ionic strength 0.10 M.

Competitive Methyl Orange Spectrophotometric Method—Portions (4.0 ml) of a stock solution containing 4.185×10^{-5} M methyl orange in 0.20 M HCl were pipetted into 10.0-ml volumetric flasks containing 2.0 ml of 0.01 M α-cyclodextrin aqueous solution. Substrate (phenol) solutions at variable concentrations such that the final substrate concentrations (S_t) were from 2.0×10^{-3} M to 1.38×10^{-2} M were added to the flasks, and the solutions were brought to volume. The reference solution was prepared with the same concentration of α-cyclodextrin in 0.08 M HCl. The final solutions were equilibrated at 25.0°, and absorbances were read[5] at 508 nm in 1-cm cells. For calculating Q by Eq. 26, the molar absorptivities were measured in 0.08 M HCl at 508 nm, giving $\epsilon_I = 4.82 \times 10^4$ and $\epsilon_{IL} = 8.72 \times 10^2$. The stability constant K_{11I} for the 1:1 complex of methyl orange with α-cyclodextrin at 25.0° in 0.08 M HCl was determined by the conventional Benesi–Hildebrand spectrophotometric method (10); K_{11I} was found to be 672.9 M^{-1} (standard deviation 5.0 M^{-1}).

RESULTS

Nine phenols were studied by the potentiometric method. 4-Cyanophenol and 4-nitrophenol could be described as case I systems; Fig. 1 shows the plot of C' against L_t for the 4-cyanophenol–α-cyclodextrin system, and Fig. 2 is the corresponding plot according to Eq. 5. Phenol, 4-methylphenol, and 4-fluorophenol were case II systems, as indicated for 4-methylphenol in Fig. 3. The C' *versus* L_t plot for 4-methoxyphenol (Fig. 4) shows that it is a case III system; Fig. 5 is the linearized plot according to Eq. 11 for this system. 4-Iodophenol, 4-bromophenol, and 4-chlorophenol showed case IV behavior, as seen in Fig. 6 for 4-chlorophenol.

For case IV systems, an independent study is necessary to determine K_{11a} for use in Eq. 14. The UV absorption spectra of these compounds were not significantly altered by the presence of α-cyclodextrin, so simple UV spectrophotometry did not provide a method for measuring K_{11a}. The competitive methyl orange spectrophotometric method was therefore used. Since the potentiometric data showed that these were case IV systems, evidently $K_{12a} = 0$, and only 1:1 stoichiometry need be considered for the conjugate acid forms of the substrates. The studies were made at constant L_t and varying S_t. Figure 7 is the plot according to Eq. 25 for the 4-chlorophenol–methyl orange–α-cyclodextrin system. Figure 8 shows the linear plot of Eq. 14 for 4-chlorophenol, in which the K_{11a} value determined from Fig. 7 has been used to construct the ordinate values.

The validity of the assignments of case I systems was tested by treating them according to case IV equation (Eq. 14), which should give a slope of zero for a case I system. Similarly, case II assignments were tested by plotting according to the case III equation. The stability constants are listed in Table I. The K_{12b} values for the methoxy, iodo, bromo, and chloro compounds are clearly significant; these are the case III and IV systems. The K_{12b} values evaluated for the case I and II systems are not significantly different from zero, except for phenol. However, the corre-

lation coefficient was 0.998 for the case II linear plot, whereas it was 0.553 for treatment as a case III system; hence, phenol is better described as a case II system, with K_{12b} equal to zero.

DISCUSSION

Competitive Indicator Method—To test the competitive methyl orange spectrophotometric method, it was applied to the determination of K_{11a} for 4-nitrophenol, which can be measured by several techniques. Table II lists stability constants for the 4-nitrophenol–α-cyclodextrin

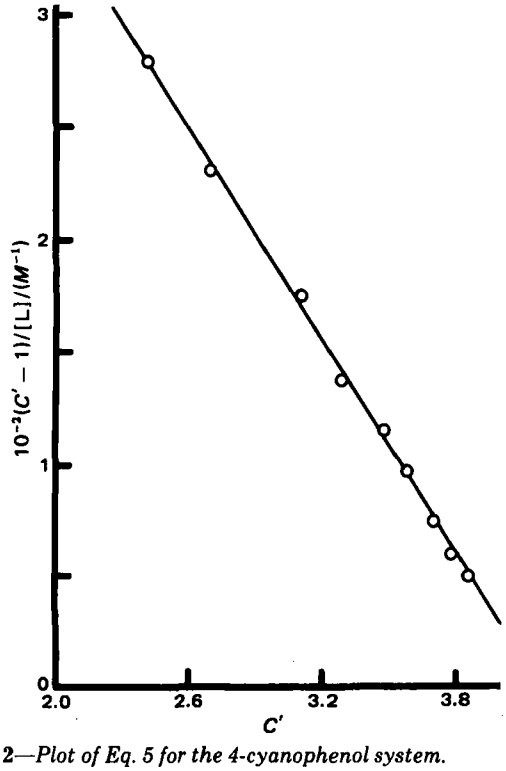

Figure 2—*Plot of Eq. 5 for the 4-cyanophenol system.*

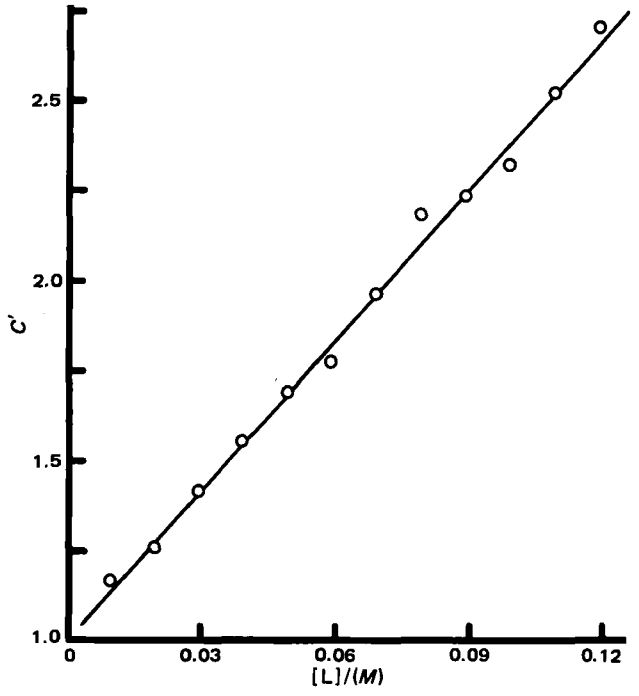

Figure 3—*Plot of Eq. 8 for the 4-methylphenol system.*

system determined in this work and as reported by other investigators. It is clear that the methyl orange method gives a result consistent with other methods. The methyl orange method was also applied to the benzoic acid–α-cyclodextrin system, yielding K_{11a} = 810 M^{-1}. This is significantly lower than the value 1050 M^{-1} reported by Casu and Ravà (6) for this system studied by their version of the competitive methyl orange method (which neglects the [IL] term in Eq. 17), but is consistent with recent values determined by other methods (1).

The method as described, using methyl orange as the indicator, is applicable only in an acidic solution, but with other indicators it may be useful under other conditions. The plot according to Eq. 25 should yield an intercept of unity, and this was verified in the present applications. When K_{11I} is approximately equal to K_{11S}, competition to displace the

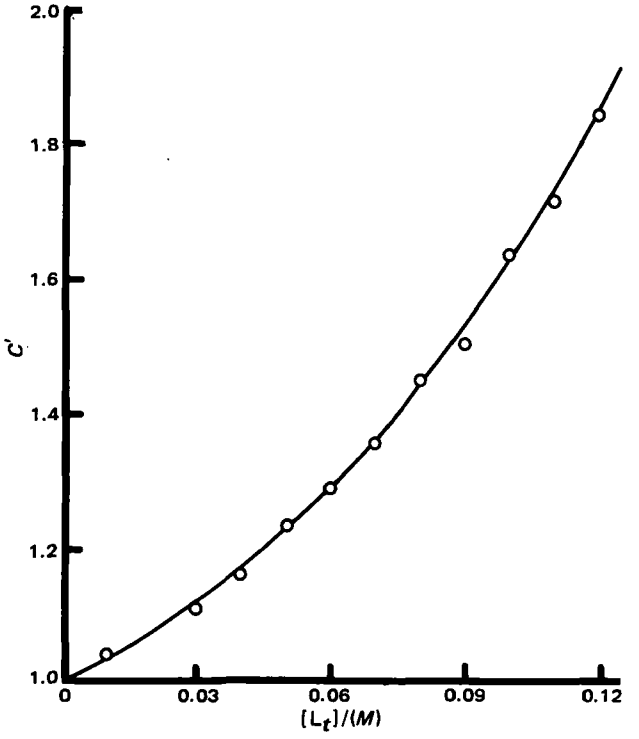

Figure 4—*Plot of C′ against L_t for 4-methoxyphenol, a case III system.*

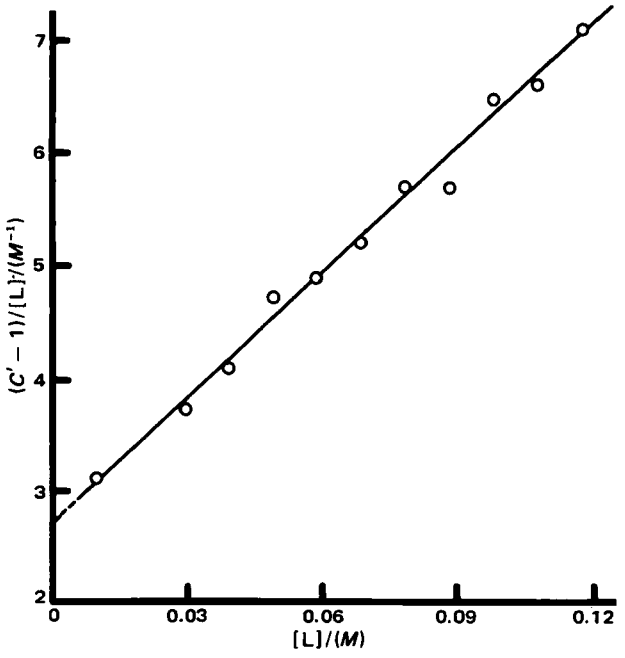

Figure 5—*Plot of Eq. 11 for the 4-methoxyphenol system.*

indicator requires that L_t and S_t be of comparable magnitude, although L_t can be much larger than I_t. If K_{11S} is much larger than K_{11I}, a smaller concentration of substrate would suffice to displace the indicator from its complex. Equation 25 can accommodate changes in both S_t and L_t in an experiment, but it was found convenient to hold L_t constant and to vary S_t.

Binding Sites and Complex Stability—These phenolic compounds can be viewed as substrates having two possible binding sites, namely the hydroxyl group and the 4-substituted moiety, that can interact with the cavity of the α-cyclodextrin. A model for such a system was described earlier (1, 18). For a two-binding site substrate that forms only 1:1 and 1:2 complexes, the experimental stability constants K_{11} and K_{12} are related to the binding site stability constants by:

$$K_{11} = K_X + K_Y \qquad \text{(Eq. 28)}$$

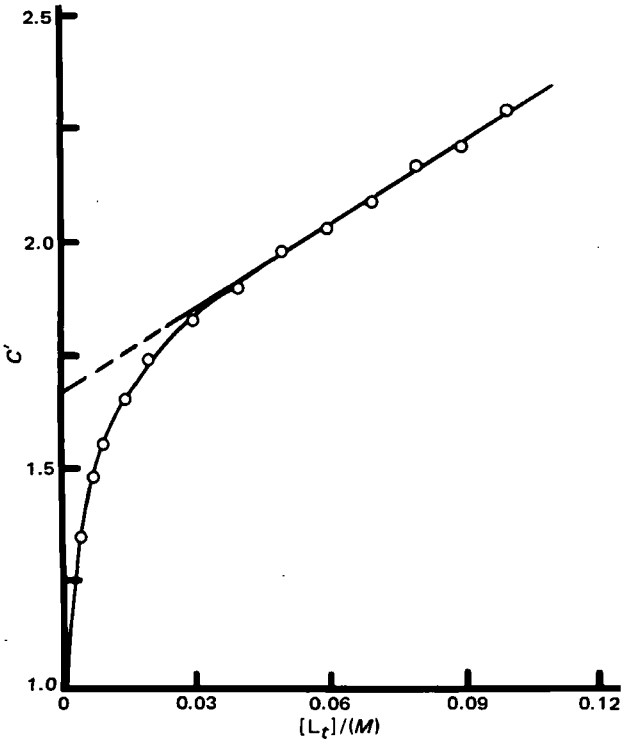

Figure 6—*Plot of C′ against L_t for 4-chlorophenol, a case IV system.*

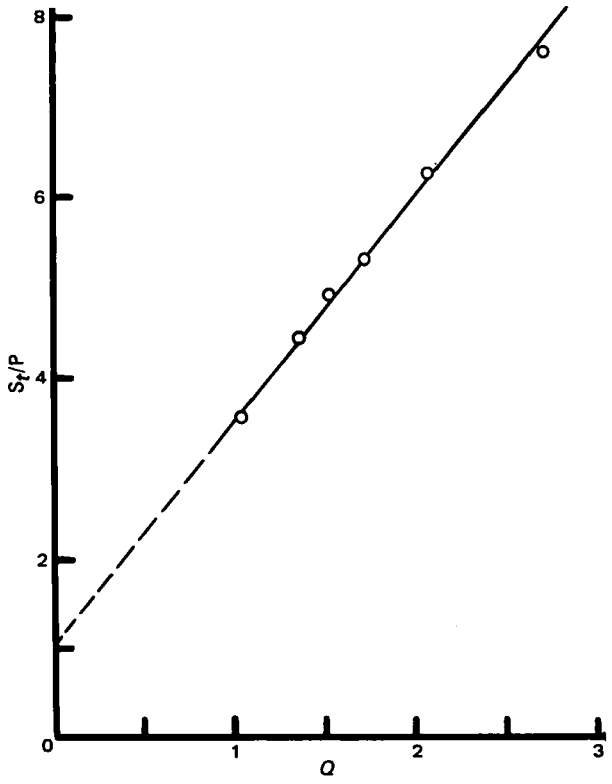

Figure 7—*Plot of Eq. 25 for the 4-chlorophenol–methyl orange–α-cyclodextrin system.*

$$K_{12} = \frac{aK_XK_Y}{K_{11}} \qquad \text{(Eq. 29)}$$

In these relationships K_X and K_Y are 1:1 stability constants for binding to sites X and Y, and a is a parameter that measures interaction between the two sites in a 1:2 complex. Such a two-site substrate is therefore capable of forming two isomeric 1:1 complexes and one 1:2 complex. This model leads to interpretations in terms of binding sites. The derivation

of Eq. 29 is given elsewhere (1), and the significance of a has also been discussed previously (1).

Whether a cyclodextrin interacts with a binding site is largely dependent on the size and shape of the site; but if the site can enter the cyclodextrin cavity to form an inclusion complex, the strength of the complex will be controlled mainly by the electron density, the polarizability, and the polarity of the binding site. Increases in site electron density and polarizability will tend to increase complex stability, whereas high polarity will decrease complex stability (in a polar solvent). In a series of closely related substrates, the trend of complex stabilities with these factors may therefore give information about the binding sites. In this way Hammett plots of K_{11a} and K_{11b} for 4-substituted benzoic acids (1) led to the conclusion that K_{11a} describes mainly binding to the carboxylic acid site, whereas K_{11b} describes binding solely at the 4-substituent site.

This approach will be used to discuss the data in Table I. It is postulated that complex stability in a series is primarily determined by site electron density, modified by polarizability and polarity. The substrates in Table I are arranged in order of increasing Hammett substituent constant σ for the 4-substituent; σ is a measure of the electron-attracting ability of the substituent. For both K_{11a} and K_{11b} the same rough trend is seen, namely an increase in complex stability with increasing electron density at the 4-substituent. These data therefore suggest that the primary binding site, for both the conjugate acid and the conjugate base forms of the substrates, is the 4-substituent end of the molecule.

The correlations of K_{11a} and K_{11b} with σ are obviously not closely followed, the halogens I and Br having complex-strengthening effects not accounted for by their σ values. But these substituents have high polarizabilities, which will tend to increase complex stability; K_{11a} and K_{11b} can be well correlated by:

$$\log K_{11a} = -0.96 + 0.12R_D - 0.10\mu \qquad \text{(Eq. 30)}$$

$$\log K_{11b} = -1.41 + 5.33\sigma + 0.15R_D - 0.81\mu \qquad \text{(Eq. 31)}$$

where R_D is the molar refraction of $X—C_6H_5$ and μ is the dipole moment of $X—C_6H_4—OH$[6]. These correlations have no theoretical significance, but they suggest that this interpretation is reasonable.

If K_{11b} and K_{11a} describe binding at the 4-substituent, then K_{12b} and K_{12a} describe binding at the hydroxyl site, because the 1:2 complex is formed by adding a second cyclodextrin to the 1:1 complex. But K_{12a} is zero for all systems, leading to the conclusion that no significant binding occurs at the phenolic hydroxyl site; this conclusion applies also to those phenolate substrates for which K_{12b} is zero. There exist, however, some finite K_{12b} values, and it is notable that in each of these substrates (the methoxy, iodo, chloro, and bromo compounds) the 4-substituent can tolerate a positive charge by electron release through resonance delocalization; this may sufficiently counter the electron release of the phenolate site to allow significant binding at that site.

K_{11a} for the phenol $^-OOC—C_6H_4—OH$ is evidently the same quantity as K_{11b} for the benzoic acid anion $HO—C_6H_4—COO^-$. When this was discussed as a benzoate (1), it was concluded that the carboxylate site binding was negligible, leaving binding at the phenolic site to account for the observed binding. On the other hand, it has been concluded here that binding at the hydroxyl site in phenols is probably negligible. This inconsistency suggests that it may not always be permissible to make a common assignment of binding mode to all of the members of a series. In this case, the negative charge on the carboxylate may oppose the usual electron release by the hydroxyl group, leaving the hydroxyl site susceptible to binding.

[6] The correlation coefficients are 0.99 for both equations. The standard deviations are 0.06 in log K_{11a} and 0.13 in log K_{11b}.

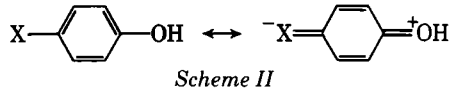
Effect of Phenol Ionization on Complex Stability—It is a general result that K_{11b} is greater than K_{11a} for the cyclodextrin complexes of phenols (Table I); that is, the anionic form of the substrate "partitions" into the relatively nonpolar cyclodextrin cavity more favorably than does the un-ionized form. This unexpected behavior (which is the reverse of the situation seen with carboxylic acid substrates) has been discussed for the particular case of 4-nitrophenol by several authors. Dunn and Bernhard (19) accounted for the greater stability of the 4-nitrophenoxide–α-cyclodextrin complex in terms of a stronger dispersion force field between the included nitrophenoxide and the interior of the cavity. These authors assumed that the nitro end of the substrate was inserted into the cavity. Bergeron and Channing (20) have shown that this is in fact the geometry of the complex. Benzoic acid, on the other hand, complexes with the carboxylic acid end of the molecule penetrating the cavity (1, 15, 21). Bergeron *et al.* (21) have called attention to this difference in substrate–ligand orientation and have related it to the corresponding difference in relative stabilities of the neutral and charged complexes. Their argument is that, if induced dipole–dipole interaction is primarily responsible for binding, the nitrophenolate will be more strongly bound than is the neutral phenol.

It is not necessary to specify the types of forces responsible for binding to account generally for the result that $K_{11b} > K_{11a}$. This result is surprising only if an ion is regarded as a point charge. But a phenolate ion is decidedly not a point charge on the molecular scale. The concept described in the preceding section, namely that complex stability is determined by *binding site* electron density, polarizability, and polarity, will be applied to the phenol and phenolate complexes with cyclodextrin.

Neutral phenols are highly dipolar species, especially those with electron-withdrawing 4-substituents, as revealed by their dipole moments, which can be accounted for by electron delocalization as shown in Scheme II.



Scheme II

Electron density is increased at the 4-substituent and is decreased at the hydroxyl group; moreover the polarizability of the hydroxyl group is decreased. Thus, complexing with the cyclodextrin cavity should occur at the 4-substituent site rather than at the hydroxyl site, and this is consistent with the trend of K_{11a} values as discussed above.

On ionization of the hydroxyl group, delocalization disperses the excess electronic charge as in Scheme III.

Scheme III

The electron density at the 4-substituent is greater in the anion than in the neutral form, hence the complex stability at this binding site is greater in the anion. As shown above, K_{11a} represents solely binding at the 4-substituent, and K_{11b} represents predominantly 4-substituent binding. (Those substrates with finite K_{12b} values include, in K_{11b}, a small contribution from binding at the hydroxyl site, according to Eq. 28.) Therefore, K_{11b} will be larger than K_{11a}. Moreover, the increased charge density on the oxygen in the phenolate species actually may lead to some binding at this site, which in the current context is actually less polar than the hydroxyl group in the neutral substrate. Localized negative charge

(as in carboxylic acid anions) may be destabilizing, positive charge (as in protonated amines) will always be destabilizing, but delocalized negative charge (as in phenol anions) may be stabilizing.

Improvement of the Oral Bioavailability of Digitalis Glycosides by Cyclodextrin Complexation

KANETO UEKAMA *x, TOSHIO FUJINAGA *, FUMITOSHI HIRAYAMA *, MASAKI OTAGIRI *, MASAKI YAMASAKI ‡, HAKARU SEO §, TSUYOSHI HASHIMOTO §, and MICHIO TSURUOKA §

Received January 6, 1982, from the **Faculty of Pharmaceutical Sciences, Kumamoto University, 5-1, Oe-honmachi, Kumamoto 862, Japan,* ‡*Department of Biochemistry, Medical School, Kumamoto University, 2-2-1, Honjo, Kumamoto 860, Japan,* and §*Department of Pharmacy, Miyazaki Medical College Hospital, 5200 Kiyotake-cho, Miyazaki-gun, Miyazaki 889-16, Japan.* Accepted for publication September 1, 1982.

Abstract □ Inclusion complexes of the digitalis glycosides digitoxin, digoxin, and methyl digoxin with three cyclodextrins (α-, β-, γ-homologues) in water and in the solid state were studied by a solubility method, IR and ^{1}H-NMR spectroscopy, and X-ray diffractometry. Solid complexes (in a molar ratio of 1:4) of the digitalis glycosides with γ-cyclodextrin were prepared and their *in vivo* absorption examined. The rapidly dissolving form of the γ-cyclodextrin complex significantly increased plasma levels of digoxin (~5.4-fold) after oral administration to dogs.

Keyphrases □ Bioavailability—oral, digoxin, digitoxin, methyl digoxin, complexation with cyclodextrins □ Digoxin—complexation with cyclodextrins, oral bioavailability, digitoxin, methyl digoxin □ Cyclodextrins—complexation with digitalis glycosides, oral bioavailability, digoxin, digitoxin, methyl digoxin

The bioavailability of the digitalis glycosides from commercial tablets varies significantly (1–3). The main cause of this variability appears to be related to such factors as low water solubility (4–6) and chemical instability in acidic media (7–9). Cyclodextrins have been used extensively to improve various physicochemical properties of drug molecules (10–12) by forming inclusion complexes in which the drug molecules are included in the relatively hydrophobic cavity of the cyclodextrins (13).

The present study describes the inclusion complexes of the digitalis glycosides digitoxin, digoxin, and methyl digoxin with the three cyclodextrins (α-, β-, γ-homologues). Complex formation in water and in the solid state was studied by a solubility method, IR and ^{1}H-NMR spectroscopy, and X-ray diffractometry. Plasma levels of digoxin were determined after the oral administration of the digoxin–γ-cyclodextrin complex to dogs.

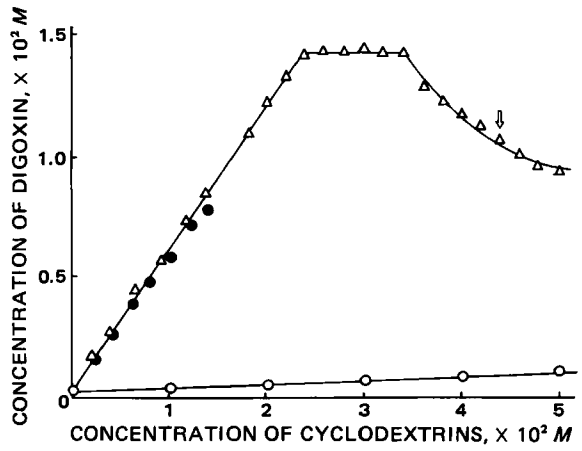

Figure 1—*Phase solubility diagrams of the digoxin–cyclodextrin systems in water at 25°. Key: (○) α-cyclodextrin; (●) β-cyclodextrin; and (△) γ-cyclodextrin. The arrow indicates the experimental conditions for the preparation of solid γ-cyclodextrin complexes (see* text*).*

EXPERIMENTAL

Materials—Digitoxin[1], digoxin[2], methyl digoxin[2], and the α-, β-, and γ-cyclodextrins[3] were used as supplied. All other materials and solvents were analytical reagent grade. Deionized double-distilled water was used.

Solubility Studies—Solubility measurements were carried out according to Higuchi and Lach (14). Excess amounts of digitalis glycosides were added to an aqueous solution containing various concentrations of cyclodextrins and were shaken at 25 ± 0.5°. After equilibrium was reached (~7 days), an aliquot was centrifuged and pipetted through a cotton filter. A 0.5-ml aliquot was diluted with ethanol–water (1:1, v/v) and analyzed spectrophotometrically[4]. An apparent stability constant, K', was calculated from the initial linear portion of the phase solubility diagram according to the following (15):

$$K' = \frac{\text{slope}}{\text{intercept} \cdot (1 - \text{slope})}$$

Preparation of Solid Complexes—The solid complexes were prepared by mixing appropriate amounts of the cyclodextrin and digitalis glycoside in water. Appropriate mixtures were chosen by examining the descending curvature of the B_s-type phase solubility diagram (see Fig. 1). For example, 3.25 g of digoxin and 14.3 g of γ-cyclodextrin were added to 250 ml of water, and the mixture was stirred at 25° for 7 days. The complex, which precipitated as a microcrystalline powder, was removed by filtration and dried under vacuum at 60° for 48 hr. This powder corresponded to a 1:4 digoxin–γ-cyclodextrin complex, which had a molecular weight of 5965.

Spectroscopic Studies—The IR spectra[5] were measured as potassium bromide pellets. ^{1}H-NMR spectra[6] were measured in D_2O using Fourier transform methodology (16). An average of 6000 accumulations with 8192 data points were made at a sweep width of 2000 Hz. The ^{1}H-chemical shifts were assigned values based on the external standard 3-(trimethylsilyl)propanesulfonic acid sodium salt with an accuracy of ±0.0012 ppm. The powder X-ray diffraction spectra[7] were obtained by scanning at 1°/min in terms of 2θ angle.

Dissolution Studies—The digoxin powder (150 mg, 100 mesh) was compressed into a cylindrical tablet (diameter 10 mm) at a pressure of ~200 kg/cm^2. The release of drug was measured using a rotating disk apparatus (17) in 0.05 M KCl–HCl solution (pH 1.52) at 37°. At appropriate intervals, 1-ml samples were removed, extracted with chloroform, and assayed by high-performance liquid chromatography (HPLC). The dissolution behavior of 1:4 digitalis glycoside–γ-cyclodextrin complexes (150 mg, 100 mesh) was examined in a similar manner.

HPLC Analysis—The chromatograph[8] was operated at a flow rate of 0.7 ml/min. The separation utilized a column[9] (40 mm × 25 cm) with methanol–water (58:42) as a mobile phase, and the eluant was monitored spectrophotometrically at 220 nm. Components were quantitated by measuring peak heights and comparing the height with an internal standard containing a known amount of prednisolone[2].

***In Vivo* Absorption Studies**—Six female beagle dogs, with an average weight of 11 kg, were used. A tablet was administered orally with 20 ml of water after an overnight fast at intervals of at least 1 week. The administration sequence was based on a crossover matrix designed to minimize any residual or cumulative effects of the preceding dose. The formulations of the tablets were as follows: 98–99% (w/w) lactose as a diluent, 1.0% (w/w) magnesium stearate as a lubricant, and 0.1% (w/w) digoxin or 0.76% (w/w) digoxin–γ-cyclodextrin complex. Plasma samples were obtained at timed intervals, and digoxin concentrations were determined by enzyme immunoassay[10] (18).

Table I—Apparent Stability Constants (M^{-1}) of Digitalis Glycoside–Cyclodextrin Complexes Determined by the Solubility Method in Water at 25°

Digitalis Glycoside	Cyclodextrin α	Cyclodextrin β	Cyclodextrin γ
Digoxin	180	11200	12200
Digitoxin	290	17000	63600
Methyl digoxin	400	11400	13600

RESULTS AND DISCUSSION

Solubility Study—The complexing behavior of digitalis glycosides with cyclodextrins in water was studied by a solubility method. The phase solubility diagrams obtained for digoxin with three cyclodextrins in water are shown in Fig. 1. In the case of α-cyclodextrin, the solubility of digoxin increased slightly in a linear fashion as a function of the α-cyclodextrin concentration, and the resulting solubility curve can be classified as type A_L (15). The solubility plot for the β-cyclodextrin system is qualitatively similar to that for α-cyclodextrin, where a large increase in digoxin solubility was obtained within the solubility limit of β-cyclodextrin (~1.6 × 10^{-2} M). On the other hand, γ-cyclodextrin showed a typical B_S-type solubility curve (15), where the initial ascending portion is followed by a plateau region and then a decrease in total digoxin solubility accompanied by precipitation of a microcrystalline complex. Although the shape of solubility curves in Fig. 1 cannot be completely explained in terms of a stoichiometric relationship (19), an apparent stability constant (K'), as a tentative measure of inclusion complexation, was estimated from the equation based on the assumption that a 1:1 complex is initially formed. Table I summarizes the K' values for digitalis glycoside–cyclodextrin systems calculated from the initial ascending portion of solubility diagrams. The cavity size dependencies of the present systems were clearly noted from the magnitude of K' values (γ- > β- > α-cyclodextrin).

Since the digitalis glycoside molecule is too large to be included within the cyclodextrin cavity, it is reasonable to assume that at least one complex with a stoichiometric host-to-guest molecular ratio greater than one may be formed, in particular for the higher concentrations of cyclodextrin. To gain insight into the stoichiometry of the γ-cyclodextrin system, the solid material that precipitated beyond the plateau region was analyzed (19). The analysis of the digoxin–γ-cyclodextrin system gave the following results for 10^2L_t (the total concentration of γ-cyclodextrin) and X_s (the mole fraction of digoxin in the solid): 3.6, 0.20; 4.0, 0.20; 4.2, 0.20; 4.4, 0.20; 4.8, 0.20; and 5.0, 0.20. These data indicate that 1:4 complex formation of digoxin with γ-cyclodextrin predominate beyond the plateau region, while the lower-order complexes (*i.e.*, 1:1, 1:2, and 1:3) may be formed around the initial increasing portion of the solubility diagram (Fig. 1). Similar results were obtained for γ-cyclodextrin with digitoxin and methyl digoxin. Since only the 1:4 solid complex was isolated from the descending curvature of the B_S-type solubility diagram (probably because of limited solubility), this form was used for further study.

NMR Study—^{1}H-NMR techniques (200 MHz) were employed to examine the inclusion mode in aqueous solution. Table II summarizes a typical example of the effects of cyclodextrins on some ^{1}H-chemical shifts (18-methyl and 19-methyl) of digoxin (20). Unfortunately, the other proton signals were too weak to be quantitatively analyzed under the experimental conditions used. In the presence of cyclodextrins, both

18-Methyl	0.772	0.038	0.055	0.040
19-Methyl	0.932	0.017	0.198	0.081

[a] Concentrations of digoxin and cyclodextrins were 1.0×10^{-4} *M* and 4.0×10^{-4} *M*, respectively. [b] Assigned according to Ref. 20. [c] The values are positive if any upfield shift of the resonance occurs.

signals moved downfield probably due to the steric perturbation through inclusion complexation (21). Interestingly, the downfield shift of the 19-methyl signal was apparently greater than that of the 18-methyl signal, particularly for β-cyclodextrin. This suggests that the A-ring moiety of the digoxin molecule may strongly interact with β-cyclodextrin. The magnitude of the downfield shifts of both methyl protons decreased in the order of β- > γ- > α-cyclodextrin. The effect of digoxin on ^{1}H-chemical shifts of cyclodextrins was also examined. All cyclodextrin protons located within or near the cavity (*e.g.*, H-3, H-5, or H-6) experienced a shielding effect, where the magnitude of the upfield shift decreased in the order of β- > γ- > α-cyclodextrin. These NMR data indicate that the digoxin molecule is located at the entrance of the α-cyclodextrin cavity, could penetrate further into the β-cyclodextrin cavity, and is loosely bound to γ-cyclodextrin.

Since β-cyclodextrin induced a chemical shift change that was the largest among the three cyclodextrins (Table II), ^{1}H-chemical shift displacements ($\Delta\delta$) of the 19-methyl signal of digoxin on addition of β-cyclodextrin were quantitatively examined. Figure 2 shows the plots of molar ratio of β-cyclodextrin–digoxin *versus* change in chemical shift (δ) of the 19-methyl signal. Above a molar ratio of 4 for β-cyclodextrin–digoxin, no further substantial changes of the chemical shifts occur. This suggests that the stoichiometric equivalence point is reached to form 1:4 complexes of digoxin with β-cyclodextrin. A similar stoichiometric relationship was expected for digoxin–γ-cyclodextrin, which is consistent with the result of the solubility study. Inspection of a space-filling molecular model[11] shows that four molecules of β- or γ-cyclodextrin are available for the complete inclusion of the digoxin; digoxin fits tightly into β-cyclodextrin channels and more loosely into the larger interior space of γ-cyclodextrin channels.

Evidences of Complex Formation in Solid State—To confirm the complexation of cyclodextrins with digitalis glycosides in the solid state, X-ray diffractometry and IR spectroscopy were employed and compared with the corresponding physical mixtures in the same molar ratio. Figure 3 shows the powder X-ray diffraction patterns of the digoxin–γ-cyclodextrin complex and their physical mixture. The diffraction pattern of the physical mixture was simply the superposition of each component, while that of γ-cyclodextrin complex was apparently different from each constituent and constituted a new solid phase. The γ-cyclodextrin complex gave a somewhat diffuse diffraction pattern, suggesting that it is less crystalline than the physical mixture. Figure 4 shows the IR spectra of the digoxin–γ-cyclodextrin complex in the carbonyl-stretching region of the C-23 carbonyl group in digoxin (22). In the case of the γ-cyclodextrin complex, the 1720 cm^{-1} band was found to shift to 1743 cm^{-1},

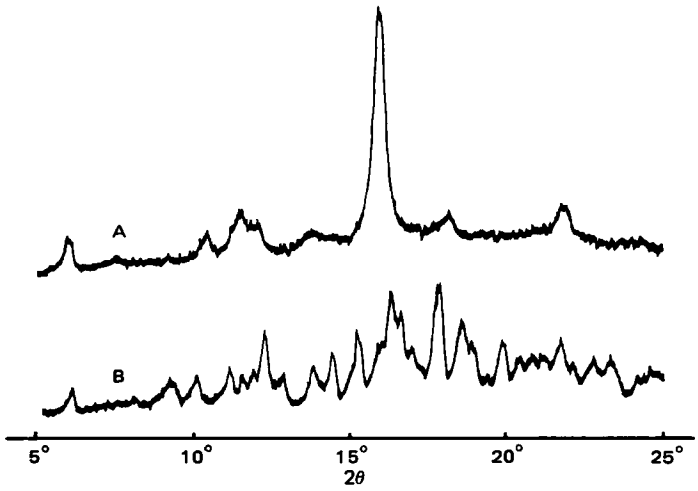

Figure 3—*Powder X-ray diffraction patterns of the digoxin–γ-cyclodextrin system. Key: (A) 1:4 complex of digoxin with γ-cyclodextrin; (B) physical mixture of digoxin and γ-cyclodextrin in 1:4 molar ratio.*

suggesting the dissociation of the intermolecular hydrogen bonds of digoxin through inclusion complexation. Similar results were obtained for other glycoside–γ-cyclodextrin systems. These data clearly indicate that the digitalis glycoside–γ-cyclodextrin complexes exist in the solid state.

Dissolution Behavior of Inclusion Complex—Figure 5 shows a typical example of the dissolution profiles of digoxin and 1:4 digoxin–γ-cyclodextrin complex from the rotating disk with constant surface area in acidic medium (pH 1.52) at 37°, where intact digoxin was quantitatively determined by HPLC. It is evident that the complexed form of digoxin dissolved much more rapidly (~100-fold) than digoxin itself. Similar results were obtained for other digitalis glycoside–γ-cyclodextrin systems. The observed increase in rate may be due to an increase in solubility and/or a decrease in crystallinity of the drug by inclusion complexation (23). It is interesting to note that the dissolution profile of the complex showed a negative curvature with time. This dissolution data may provide evidence for a complicated system, *i.e.*, decrease in concentration of intact digoxin due to acid hydrolysis or change in the tablet surface of the complexed digoxin during the dissolution process. This preliminary study revealed that γ-cyclodextrin significantly retarded the hydrolysis of digoxin in an acidic medium, which is described in detail in a separate paper (24). It seems most likely that the digoxin is precipitating on the surface of the tablet as it dissociates resulting in negative curvature of the dissolution curve, since the NMR data in Table II suggested that the inclusion of digoxin into the γ-cyclodextrin cavity is not tight. Although the complex appears to dissociate rather quickly after dissolution, the initial decrease in dissolution rate together with improved chemical stability in acidic medium suggests that the γ-cyclodextrin complexes of digitalis glycosides may have good oral bioavailability.

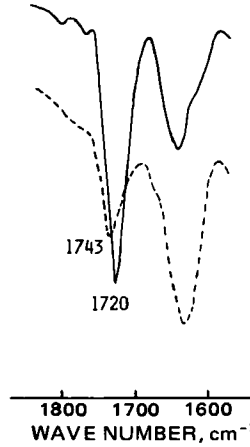

Figure 4—*IR spectra of the digoxin–γ-cyclodextrin system, measured by the potassium bromide disk method. Key: (- - - -) 1:4 complex of digoxin with γ-cyclodextrin; (—) physical mixture of digoxin and γ-cyclodextrin in 1:4 molar ratio.*

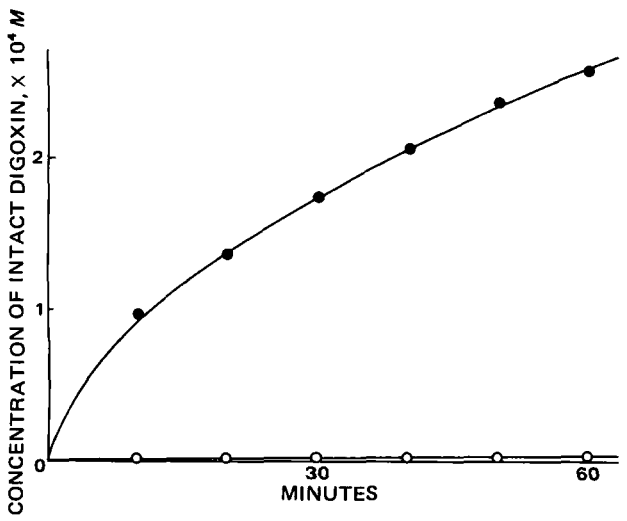

Figure 5—*Dissolution curves of digoxin and its γ-cyclodextrin complex in acidic medium (pH 1.52) at 37°, measured by the rotating disk method. Key: (○) digoxin; (●) 1:4 complex of digoxin with γ-cyclodextrin.*

Bioavailability of Digoxin–γ-Cyclodextrin Complex—The *in vivo* absorption study was undertaken to find out if the *in vitro* dissolution enhancement of digoxin from its γ-cyclodextrin complex increases the GI absorption of the drug. Finely powdered digoxin and its γ-cyclodextrin complex were compressed to tablets (average weight 50 mg) to give a final digoxin content of 0.1 or 0.05%. Figure 6 shows the mean plasma levels of digoxin following the oral administration of tablets to dogs, where the concentration of digoxin in the plasma sample was determined by enzyme immunoassay (18). When equivalent doses of digoxin (100 μg) were administered to dogs, the γ-cyclodextrin complex attained maximum plasma levels of 0.90 ± 0.14 mg/liter at 45 min, which was ~3 times higher than that of digoxin alone (25). The area under the plasma concentration–time curve (AUC) of the complex up to 24 hr was found to be 5.4 times as much as that of digoxin alone. Furthermore, the AUC of the γ-cyclodextrin complex containing 50 μg of digoxin was also found to be superior to that of 100 μg of digoxin alone. Therefore, the enhanced bioavailability of digoxin by γ-cyclodextrin complexation suggests that the complex offers a decrease in dose and fewer side effects in oral digitalis glycoside therapy. It should be noted also that the 1:4 complexation of digitalis glycosides with γ-cyclodextrin results in an ~8-fold increase in the molecular weight of the drug, which may facilitate the pharmaceutical preparation, particularly the content uniformity test.

Capillary GLC Assay for Carbinoxamine and Hydrocodone in Human Serum Using Nitrogen-Sensitive Detection

D. J. HOFFMAN ˣ, M. J. LEVEQUE, and T. THOMSON

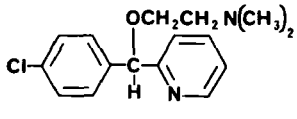
Received July 21, 1982, from the *Pharmaceutical Products Division, Abbott Laboratories, North Chicago, IL 60064.* Accepted for publication October 5, 1982

Abstract □ Capillary gas chromatography using an open tubular fused silica column and NP-FID was applied to the simultaneous analysis of the antihistamine, carbinoxamine, and the antitussive, hydrocodone, in human serum. Carbinoxamine and hydrocodone were extracted into methylene chloride–2-propanol (9:1) under alkaline conditions along with their respective internal standards, brompheniramine and *N*-ethylhydrocodone. The basic drugs were back-extracted into 0.1 *N* sulfuric acid and reextracted into benzene after making the aqueous phase alkaline with potassium hydroxide. The benzene extracts were evaporated to dryness and the residues were reconstituted with 40 μl of *n*-nonyl alcohol–methanol (19:1). Samples (1–2 μl) were injected onto the capillary column in the splitless mode (solvent effect) at 185° and the temperature programmed to 250°. Calibration curves using spiked serum standards were linear to at least 20 ng/ml for both drugs. Coefficients of variation averaged ±6.1% for carbinoxamine and ±5.0% for hydrocodone in the 2–15 ng/ml range. Sensitivity was estimated to be ~0.2 ng/ml for a 2-ml serum sample. Serum levels of carbinoxamine and hydrocodone were determined in a human volunteer administered these drugs.

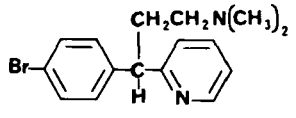
Keyphrases □ GLC assay—carbinoxamine and hydrocodone in human serum, nitrogen sensitive detection □ Carbinoxamine—GLC assay, nitrogen sensitive detection □ Hydrocodone—GLC assay, nitrogen sensitive detection □ Nitrogen sensitive detection—GLC assay for carbinoxamine and hydrocodone in human serum

Carbinoxamine, 2-[(4-chlorophenyl)-2-pyridinylmethoxy]-*N*,*N*-dimethylethanamine, is an antihistamine structurally related to chlorpheniramine. Quantitative methods for determining carbinoxamine in biological fluids have not been published. However, several methods have been published for chlorpheniramine. These methods include GLC–MS (1, 2), GLC–electron-capture detection (3), GLC–nitrogen-sensitive detection (4, 5) and high-performance liquid chromatography (HPLC) (6, 7).

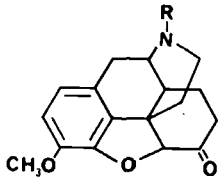
Hydrocodone, 4,5α-epoxy-3-methoxy-17-methylmorphinan-6-one, is a widely used antitussive agent. A method to determine hydrocodone in serum using GLC–electron-capture detection has been described by Barnhart and Caldwell (8) using the pentafluorophenylhydrazone derivative. The purpose of this investigation was to develop a specific and sensitive capillary GLC method for the simultaneous determination of carbinoxamine and hydrocodone in human serum.



CARBINOXAMINE



BROMPHENIRAMINE (INTERNAL STANDARD)



R = -CH_3 HYDROCODONE
R = -C_2H_5 N-ETHYLHYDROCODONE (INT.STD.)

EXPERIMENTAL

Chemicals—Carbinoxamine maleate, hydrocodone bitartrate, and brompheniramine maleate were USP reference standards. Reagent grade potassium hydroxide, sulfuric acid, hydrochloric acid, and 2-propanol were used without further purification[1]. Methylene chloride, benzene, and methanol were glass distilled[2]. *n*-Nonyl alcohol[3] was distilled in glass and the fraction boiling between 214°–215° was used.

Instrumentation—The GLC analyses were performed on a gas chromatograph[4] equipped with a capillary injection system[5] and a nitrogen-sensitive detector. Separations were performed on a 10–12 m × 0.25-mm i.d. fused silica open tubular column wall-coated with SE-30[6]. The film thickness was 0.25 μm. The flow rate of the helium carrier gas was adjusted to give partition ratios (k) of ~4.6 and 8 for carbinoxamine and hydrocodone, respectively, under the chromatographic conditions described below. Linear flow rates were in the 30–40-cm/sec range. The initial oven temperature was 185°. After 1.1 min at 185° it was programmed to increase at 25°/min for 0.9 min and then at 10°/min until it reached 250° where it was held for 1 min. The temperature of the nitrogen-specific detector was 300°, with hydrogen and air flow rates of 3.0 and 50 ml/min, respectively. The injection port temperature was 260°. A 8 cm × 2-mm i.d. fused silica splitless liner was used with a purge activation time of 0.9 min. The computing integrator had a slope sensitivity of 0.1 and an attenuation of 2^3 or 2^2.

Preparation of the Hydrocodone Internal Standard—The internal standard for hydrocodone, 4,5-epoxy-3-methoxy-17-ethylmorphinan-6-one, herein referred to as *N*-ethylhydrocodone, was synthesized from dihydronorcodeinone by the method of Clark and Woodbridge (9). Dihydronorcodeinone was synthesized from hydrocodone using the cyanogen bromide method of Clark *et al.* (10).

Preparation of Serum Standards—About 35 mg of carbinoxamine maleate and 37.5 mg of hydrocodone bitartrate reference standards were accurately weighed into a 50-ml volumetric flask and dissolved in water. A secondary aqueous standard was made in water to a final concentration of ~10 μg/ml as the free base. Working serum standards at 15, 10, 5, and 2 ng/ml were prepared by adding 75, 50, 25, and 10 μl of the secondary standard to a 50-ml volumetric flask and adjusting to volume with drug-free serum. The serum should be checked by the analytical procedure for interferences, since antihistamines are available in common nonprescription cold preparations. Internal standards, brompheniramine and *N*-ethylhydrocodone, were prepared in the same solution of 0.01 *N* HCl at 40 ng/ml.

Extraction Procedure—To a screw-cap test tube was added 2 ml of serum sample or standard, 1 ml of internal standard solution, 1 ml of 2 *N* KOH, and 6 ml of methylene chloride–2-propanol (9:1). The test tube

5	0.530 ± 0.032	4.87 ± 0.29	6.0
10	1.11 ± 0.038	10.2 ± 0.36	3.5
15	1.62 ± 0.050	14.9 ± 0.46	3.1

[a] Mean ± *SD*.

was capped and shaken at a moderate rate (150 cpm) on a reciprocal shaker[7] for 10 min. After centrifugation[8] at 2500 rpm for 5 min at 2–5°, the upper aqueous phase was discarded by aspiration. The organic phase was decanted into a clean test tube containing 2 ml of 0.1 *N* sulfuric acid and capped. After shaking and centrifuging the upper aqueous layer was transferred to a test tube containing 0.3 ml 2 *N* KOH and 2 ml of benzene. The sample was vigorously mixed[9] for 10 sec and centrifuged. Avoiding any aqueous phase, the benzene layer was transferred with a pipet freshly rinsed with absolute ethanol to a conical screw-cap test tube. The sample was evaporated to dryness at 35°–40° with a gentle stream of dry, filtered air. The residue was constituted with 40 μl of 5% methanol in *n*-nonyl alcohol and the entire test tube wall was rinsed with the solvent and centrifuged. A 2–3 μl aliquot was injected into the GLC using the splitless injection technique.

Injection Technique—Since injections were made in the splitless mode, using the solvent effect (11), the injection process was slow. The sample was loaded into a 10-μl syringe followed by air to the 1-μl mark. The purge flow was eliminated and the septum was pierced by the syringe needle. The needle was heated for 5–10 sec in the injection port and the sample injected at a rate of ~1 μl/sec. The syringe needle was left in the injection port for 5 sec after sample introduction.

Calculations—Calibration curves of peak area ratios (carbinoxamine–brompheniramine and hydrocodone–*N*-ethylhydrocodone) *versus* serum carbinoxamine or hydrocodone concentrations were linear to at least 20 ng/ml. Unknowns were calculated from a least-squares linear regression fit to known carbinoxamine and hydrocodone serum standards.

RESULTS AND DISCUSSION

Capillary GLC is inherently more sensitive than conventional GLC because of the higher amount of detectable substance passing through the detector per unit of time. Sensitivity is of particular importance in the analysis of drugs such as carbinoxamine and hydrocodone where peak serum concentrations are typically in the 5–15-ng/ml range.

Chromatographic peaks of carbinoxamine and hydrocodone were symmetrical and well resolved from serum coextractives, as shown in Fig. 1. It was necessary to use two internal standards because of the different extraction and chromatographic properties of carbinoxamine and hydrocodone. Brompheniramine was chosen as the internal standard for carbinoxamine because it eluted in a clean chromatographic region and was completely resolved from carbinoxamine. Chlorpheniramine, which elutes just prior to carbinoxamine, was not used because of its more common presence in pharmaceutical antihistamine preparations. This method could be used to determine serum chlorpheniramine levels. Either carbinoxamine or brompheniramine would suffice as an internal standard for a chlorpheniramine assay.

The precision of both assays is shown in Table I. In the concentration range of 2–15 ng/ml the coefficients of variation ranged from 4.1 to 9.6% for carbinoxamine and from 3.1 to 7.4% for hydrocodone. Extraction efficiencies averaged 71.2 ± 2.8% and 78.4 ± 2.5% for carbinoxamine and hydrocodone, respectively, at 10 ng/ml.

1.0	0.0736 ± .0075 (10.2%)	0.091 ± .0079 (8.7%)

[a] Mean ± *SD*; $n = 4$. [b] Coefficient of variation (%).

Calibration curves of peak area ratios *versus* concentration in serum were linear up to at least 20 ng/ml. Assay sensitivity or the minimum quantifiable concentration was evaluated by determining the assay precision in the 0.2–1.0-ng/ml range. By defining the sensitivity as that concentration of drug that has a ±25% *CV*, the sensitivity for both carbinoxamine and hydrocodone is ~0.2 ng/ml using a 2-ml sample volume (Table II).

To assess the validity of this analytical procedure, serum samples from a human volunteer were assayed. The serum carbinoxamine and hydrocodone concentrations from a human volunteer orally administered, under fasted conditions, a solution containing 4 mg of carbinoxamine maleate and 5 mg of hydrocodone bitartrate are shown in Table III. Typical chromatograms from a human volunteer are also shown in Fig. 1. This assay provides the precision and sensitivity to conduct pharmacokinetic and bioavailability studies in humans receiving a single oral dose of carbinoxamine maleate and hydrocodone bitartrate.

Hypolipidemic Activity of Phthalimide Derivatives IV: Further Chemical Modification and Investigation of the Hypolipidemic Activity of *N*-Substituted Imides

JAMES M. CHAPMAN, Jr., GEORGE H. COCOLAS, and I. H. HALL ˣ

Received June 14, 1982, from the *Division of Medicinal Chemistry, School of Pharmacy, University of North Carolina, Chapel Hill, NC 27154.* Accepted for publication September 24, 1982.

Abstract □ A further investigation of *N*-substituted derivatives of phthalimide for hypolipidemic activity has revealed that the chain length, as well as the type of substitution on the *N*-alkyl chain of phthalimide is critical for biological activity. In these studies the hypolipidemic activity was not improved by extending the chain length beyond five carbon atoms in the alkyl and alkanoic acid series. Imido nitrogen substituents, other than alkanoic acids, methyl ketones, and alkyl groups, caused a reduction in hypolipidemic activity, *e.g.*, hydroxy, amino, hydroxymethyl, or carbethoxy. Reduction of the keto group in the side chain to an alcohol, as well as forming derivatives of the keto group, did not improve the hypolipidemic activity with the exception of 1-*N*-phthalimidobutan-3-one semicarbazone. This compound demonstrated improved hypocholesterolemic activity over phthalimide and 1-*N*-phthalimidobutan-3-one. Substitution of the 3-position of the aromatic moiety of phthalimide with an amino or nitro group, as well as substituting a pyridine or cyclohexyl ring for the phenyl ring, led to the loss of hypolipidemic activity.

Keyphrases □ Phthalimide—*N*-substituted derivatives, synthesis, hypolipidemic activity, mice, structure–activity relationships □ Hypolipidemic agents—potential, *N*-substituted derivatives of phthalimide, structure–activity relationships, mice □ Structure–activity relationships—*N*-substituted phthalimide derivatives, hypolipidemic activity, mice

Previously, it was shown that phthalimide (I) is a potent hypolipidemic agent in rodents. Serum cholesterol levels were reduced 43% in mice after administration for 16 days at 20 mg/kg/day. Serum triglyceride levels were also reduced 56% after 14 days of administration in mice at the same dose. The phthalimide derivatives were more potent

Table II—Analysis of Spiked Serum Samples of Carbinoxamine and Hydrocodone at Low Concentration

Concentration, ng/ml	Peak Area Ratios[a]	
	Carbinoxamine/IS	Hydrocodone/IS
0.2	0.0065 ± .0018 (28.2%)[b]	0.0088 ± .002 (25.9%)
0.5	0.0206 ± .0042 (20.3%)	0.0423 ± .0061 (14.4%)
1.0	0.0736 ± .0075 (10.2%)	0.091 ± .0079 (8.7%)

[a] Mean ± *SD*; $n = 4$. [b] Coefficient of variation (%).

Calibration curves of peak area ratios *versus* concentration in serum were linear up to at least 20 ng/ml. Assay sensitivity or the minimum quantifiable concentration was evaluated by determining the assay precision in the 0.2–1.0-ng/ml range. By defining the sensitivity as that concentration of drug that has a ±25% *CV*, the sensitivity for both carbinoxamine and hydrocodone is ~0.2 ng/ml using a 2-ml sample volume (Table II).

To assess the validity of this analytical procedure, serum samples from a human volunteer were assayed. The serum carbinoxamine and hydrocodone concentrations from a human volunteer orally administered, under fasted conditions, a solution containing 4 mg of carbinoxamine maleate and 5 mg of hydrocodone bitartrate are shown in Table III. Typical chromatograms from a human volunteer are also shown in Fig. 1. This assay provides the precision and sensitivity to conduct pharmacokinetic and bioavailability studies in humans receiving a single oral dose of carbinoxamine maleate and hydrocodone bitartrate.

Table III—Serum Carbinoxamine and Hydrocodone Concentrations after Oral Administration of 4 mg of Carbinoxamine Maleate and 5 mg of Hydrocodone Bitartrate to a Human Volunteer

Hypolipidemic Activity of Phthalimide Derivatives IV: Further Chemical Modification and Investigation of the Hypolipidemic Activity of *N*-Substituted Imides

JAMES M. CHAPMAN, Jr., GEORGE H. COCOLAS, and I. H. HALL ˣ

Received June 14, 1982, from the *Division of Medicinal Chemistry, School of Pharmacy, University of North Carolina, Chapel Hill, NC 27154.* Accepted for publication September 24, 1982.

Abstract □ A further investigation of *N*-substituted derivatives of phthalimide for hypolipidemic activity has revealed that the chain length, as well as the type of substitution on the *N*-alkyl chain of phthalimide is critical for biological activity. In these studies the hypolipidemic activity was not improved by extending the chain length beyond five carbon atoms in the alkyl and alkanoic acid series. Imido nitrogen substituents, other than alkanoic acids, methyl ketones, and alkyl groups, caused a reduction in hypolipidemic activity, *e.g.*, hydroxy, amino, hydroxymethyl, or carbethoxy. Reduction of the keto group in the side chain to an alcohol, as well as forming derivatives of the keto group, did not improve the hypolipidemic activity with the exception of 1-*N*-phthalimidobutan-3-one semicarbazone. This compound demonstrated improved hypocholesterolemic activity over phthalimide and 1-*N*-phthalimidobutan-3-one. Substitution of the 3-position of the aromatic moiety of phthalimide with an amino or nitro group, as well as substituting a pyridine or cyclohexyl ring for the phenyl ring, led to the loss of hypolipidemic activity.

Keyphrases □ Phthalimide—*N*-substituted derivatives, synthesis, hypolipidemic activity, mice, structure–activity relationships □ Hypolipidemic agents—potential, *N*-substituted derivatives of phthalimide, structure–activity relationships, mice □ Structure–activity relationships—*N*-substituted phthalimide derivatives, hypolipidemic activity, mice

Previously, it was shown that phthalimide (I) is a potent hypolipidemic agent in rodents. Serum cholesterol levels were reduced 43% in mice after administration for 16 days at 20 mg/kg/day. Serum triglyceride levels were also reduced 56% after 14 days of administration in mice at the same dose. The phthalimide derivatives were more potent

than clofibrate, and preliminary experiments suggested they were nontoxic. Further investigation of SAR requirements for hypolipidemic activity of phthalimides was undertaken by substituting the nitrogen of the imide ring with a series of alkyl, methyl ketone, carboxylic acid, and acetate ester substituents of varying chain lengths (1).

The previous study revealed that alkyl substitutions of four carbon atoms or an oxygen atom substituted for one carbon atom afforded the best hypolipidemic activity in mice. Consequently, a number of other chemical modifications of phthalimides were undertaken. Many of these compounds were chemical probes to investigate the potential hypolipidemic activity and do not represent a full series of compounds for complete SAR analysis.

RESULTS AND DISCUSSION

Substitution of the phthalimido nitrogen with a hydroxyl group (II), a hydroxymethyl group (III), or an amino group (IV) resulted in compounds with decreased hypolipidemic activity compared with the parent molecule, phthalimide, in both the serum cholesterol and triglyceride screens. It may be noted that *N*-hydroxyphthalimide (II) reduced serum triglyceride levels 36%, whereas phthalimide reduced triglyceride levels 56%. Reduction of *N*-phthalimidopropan-2-one (V) and *N*-phthalimidobutan-2-one (VII) to the corresponding alkanols (VI and VIII) resulted in compounds which showed essentially no difference in hypolipidemic activity. However, reduction of 1-*N*-phthalimidobutan-3-one (IX) to 1-*N*-phthalimidobutan-3-ol (X) resulted in loss of hypolipidemic activity. Derivatization of the carbonyl group of the ketone moiety in 1-*N*-phthalimidobutan-3-one (IX) as in the ketoxime (XI), the ketoxime acetate (XII), and the semicarbazone of the ketone produced varied results in hypolipidemic activity. Compounds XI and XII did not significantly lower serum cholesterol and triglyceride levels in mice, but the semicarbazone (XIII) reduced serum cholesterol levels 47% and serum triglyceride levels 25%. This magnitude of reduction of serum cholesterol levels by the semicarbazone demonstrated that it was one of the more potent imide derivatives in the hypocholesterolemic screen in mice.

Substitution of an amino (XV) or nitro group (XVI) at the 3-position of the phenyl ring of *N*-*n*-butylphthalimide or substitution of the aromatic moiety of phthalimide by a pyridine (XVII) or cyclohexyl (XVIII) moiety resulted in no change in hypotriglyceridemic activity; however, there was a marked reduction in biological activity in the cholesterol screen. Elongation of the *N*-alkyl substitution on the imido nitrogen in the *N*-phthalimido alkanoic acid series led to a decrease in hypolipidemic activity. Previously, we have shown that *N*-substituted alkanoic acid series, from acetic to caproic, were potent as hypolipidemic agents in mice. Interestingly, the pharmacological data for these compounds demonstrated that the shorter the side chain, the higher the hypotriglyceridemic activity and the longer the side chain, the higher the hypocholesterolemic activity. However, the two acids tested in this present study were less active in both screens compared with those in the original series.

Random substitution of the side chain, *e.g.*, 1-*N*-phthalimido-3-phenyl-2-propene (XXI) and α-(*N*-phthalimido)ethylphenyl ketone (XXII), resulted in compounds which retained moderate (>25%) hypocholesterolemic activity, but only XXI demonstrated any hypotriglyceridemic activity (~23%). *N*-Carbethoxyphthalimide was essentially inactive in both screens.

We have previously synthesized a homologous series of *N*-*n*-alkylphthalimides, including the methyl through octyl derivatives. The butyl analogue showed the most potent activity with decreasing activity displayed by the pentyl through octyl derivatives. Further chain elongation, *e.g.*, *N*-*n*-octadecylphthalimide (XXIV), afforded a compound essentially devoid of hypolipidemic activity.

Substitution of a nitrogen for a methylene group of 1-*N*-phthalimidobutan-3-one (IX) resulted in XXV, which was active as a hypolipidemic agent lowering serum triglyceride levels 41% and serum cholesterol levels 30%. Isatin (XXVI), an isomer of phthalimide, demonstrated no hypotriglyceridemic activity and only moderate hypocholesterolemic activity (~23%).

Whereas the compounds presented here were generally no more potent than the ones previously reported in this series (1), they do demonstrate chemical modifications that will probably not result in the development of a potent hypolipidemic imide.

EXPERIMENTAL

Chemistry—Melting points were determined using a melting point apparatus[1] and are uncorrected. NMR data were obtained utilizing a 60-MHz spectrometer[2]. Compounds I, II, IV, XXIII, and XXVI were obtained from a commercial source[3] and were tested without further

1-*N*-Phthalimidobutan-2-one (VII) and 1-*N*-Phthalimidobutan-2-ol (VIII)—1-Amino-2-butanol (3.95 g, 0.044 mole), prepared from 1,2-epoxybutane by the procedure of de Montmollin and Achermann (6), was dissolved in 100 ml of toluene, and 6.5 g (0.044 mole) of phthalic anhydride was added. The mixture was refluxed for 2 hr, collecting the water formed in the reaction by azeotropic distillation. The toluene was removed *in vacuo*, and the residue was recrystallized from isopropyl alcohol to afford 4.0 g (41%) of 1-*N*-phthalimidobutan-2-ol (VIII), mp 71–71.5°. ^{1}H-NMR ($CDCl_3$): 7.72–8.10 (m, 4, aromatic), 3.76–4.00 (m, 3, CH_2CH(OH)—), 2.32–2.54 (br s, 1, OH), 1.38–1.88 (m, 2, —CH_2CH_3), and 1.05 (t, 3, CH_3).

Anal. Calc. for $C_{12}H_{13}NO_3$: C, 66.35; H, 5.10. Found: C, 66.58; H, 5.11.

1-*N*-Phthalimidobutan-2-ol (2.02 g, 0.009 mole) in 18 ml of CH_2Cl_2 was added to 2.98 g (0.014 mole) of pyridinium chlorochromate suspended in 20 ml of CH_2Cl_2. The mixture was stirred 2.5 hr, 50 ml of ether was added, and the supernatant was decanted and filtered. Evaporation of the filtrate and repeated recrystallization from water gave 0.27 g (14%) of 1-*N*-phthalimidobutan-2-one (VII), mp 107–108° [lit. (7) mp 107–108°].

Anal.—Calc. for $C_{13}H_{12}NO_3$: C, 66.74; H, 5.98. Found: C, 65.70; H, 5.98.

1-*N*-Phthalimidobutan-3-ol (X)—1-*N*-Phthalimidobutan-3-one (9.78 g, 0.045 mole) was added to a mixture of 32.31 g (0.158 mole) aluminum isopropoxide in 300 ml of isopropyl alcohol. The mixture was refluxed for 6 hr (at this time it gave a negative test for acetone with 2,4-dinitrophenylhydrazine). The isopropyl alcohol was removed *in vacuo*, 450 ml of 0.16 *N* HCl was added, and the mixture extracted with ethyl acetate. Evaporation of the organic phase *in vacuo* yielded a yellow oil which on distillation gave 5.6 g (49%) of 1-*N*-phthalimidobutan-3-ol, mp 58–60° [lit. (8) mp 48°].

Anal.—Calc. for $C_{12}H_{13}NO_8$: C, 65.74; H, 5.98. Found: C, 66.00; H, 5.92.

1-*N*-Phthalimidobutan-3-ketoxime (XI)—1-*N*-Phthalmidobutan-3-one (5.0 g, 0.023 mole) was suspended in 25 ml of ethanol, and 5.0 g of hydroxylamine hydrochloride was added, followed by 25 ml of pyridine. The mixture was refluxed 3 hr, the volatile material removed *in vacuo*, and the residue was recrystallized from ethanol to yield 0.62 g (12%) of 1-*N*-phthalimidobutan-3-ketoxime, mp 179° [lit. (9) mp 178°].

Anal.—Calc. for $C_{12}H_{12}N_2O_3$: C, 62.06; H, 5.20. Found: C, 62.31; H, 4.94.

1-*N*-Phthalimidobutan-3-ketoxime Acetate (XII)—1-*N*-Phthalimidobutan-3-ketoxime (1.0 g, 0.013 mole) was refluxed for 4 hr in 90 ml of acetic anhydride. The volatile material was removed *in vacuo*, and the residue was recrystallized from water to give 0.22 g (18%) of 1-*N*-phthalimidobutan-3-ketoxime acetate, mp 110–112°; ^{1}H-NMR (acetone-d_6): 7.98 (s, 4, aromatic), 4.02 (t, 2, N—CH_2), 2.73 (t, 2, CH_2C=N), 2.10 (s, 3, CH_3), and 2.02 ppm (s, 3, CH_3).

Anal.—Calc. for $C_{14}H_{14}N_2O_4$: C, 61.31; H, 5.15. Found: C, 61.50; H, 4.98.

1-*N*-Phthalimidobutan-3-semicarbazone (XIII)—1-*N*-Phthalimidobutan-3-one (4.0 g, 0.018 mole) was added to a solution of 4.0 g (0.035 mole) of semicarbazide hydrochloride and 6.0 g of sodium acetate in 40 ml of ethanol and 22 ml of water. The mixture was warmed until it became milky white and was then allowed to stand for 3 hr; 40 ml of water was added, and the precipitate was collected and recrystallized from methanol to give 1.98 g (40%) of 1-*N*-phthalimidobutan-3-semicarbazone, mp 221–223° [lit. (10) mp 202–203°].

Anal.—Calc. for $C_{13}H_{14}N_4O_3$: C, 56.93; H, 5.15. Found: C, 57.13; H, 5.07.

***N*-*n*-Butyl-3-aminophthalimide (XV)**—*N*-*n*-Butyl-3-nitrophthalimide (XVI) (12.4 g, 0.5 mole) was dissolved in 300 ml of ethanol, added to 4 g of 10% Pd-C, and shaken for 10 min under hydrogen in a low-pressure apparatus[4] (60 psig). The catalyst was removed by filtration, the solvent was evaporated *in vacuo*, and the residue was recrystallized from ethanol–water to give 8.05 g (73%) of *N*-*n*-butyl-3-aminophthalimide, mp 67–70°; ^{1}H-NMR ($CDCl_3$): 6.83–7.62 (m, 3, aromatic), 5.38 (s, 2, NH_2), 3.67 (t, 2, N—CH_2), and 0.75–1.95 ppm (m, 7, $CH_2CH_2CH_3$).

Anal.—Calc. for $C_{12}H_{14}N_2O_2$: C, 66.04; H. 6.47. Found: C, 66.00; H, 6.40.

1-*N*-Phthalimido-3-phenyl-2-propene (XXI)—This compound was prepared by refluxing equimolar amounts of potassium phthalimide and cinnamyl bromide in absolute ethanol for 12 hr. The solvent was removed under reduced pressure, and the residue was washed with water. The residual water-insoluble product was collected by filtration and then recrystallized from toluene to give XXI, in 65% yield, mp 160–161°.

Anal.—Calc. for $C_{17}H_{13}NO_2$: C, 77.55; H, 4.98; N, 5.32. Found: C, 77.78; H, 5.09; N, 5.39.

α-(*N*-Phthalimido)ethylphenyl Ketone (XXII)—An equimolar amount of potassium phthalimide and α-bromopropiophenone in ethyl alcohol were refluxed for 5 hr. The solvent was removed under reduced pressure, and the residue was washed with water and then recrystallized from toluene–petroleum ether to give XXII in 60% yield, mp 88–89°.

Anal.—Calc. for $C_{17}H_{13}NO_3$: C, 73.11; H, 4.69; N, 5.02. Found: C, 73.27; H, 4.72; N, 5.00.

***N*-(Phthalimidomethyl)acetamide (XXV)**—Utilizing the procedure of Buc (11), 8.85 g (0.05 mole) of *N*-hydroxymethylphthalimide and 3.5 ml (0.066 mole) of acetonitrile were added to 50 ml of concentrated sulfuric acid. The mixture was stirred for 22 hr, 250 ml of ice was added, and the precipitate was collected and recrystallized from ethanol to give 3.5 g (33%) of XXV, mp 224–227° [lit. (11) mp 213–214.5°].

Anal.—Calc. for $C_{11}H_{10}N_2O_3$: C, 60.57; H, 4.59. Found: C, 60.58; H, 4.59.

Biological Studies—All compounds were tested at 20 mg/kg/day and administered intraperitoneally to male mice at 11:00 a.m. On days 9 and 16, the blood was collected via the tail vein. The blood samples were collected between 8:00 and 9:30 a.m. in alkali-free nonheparinized microcapillary tubes, which were centrifuged for 3 min to obtain the serum (12). Duplicate 25-μl samples of nonhemolyzed serum were used to determine the milligram percent serum cholesterol levels by a modification of the Liebermann–Burchard reaction. Using a separate group of mice, which were bled on day 14, serum triglyceride levels (in dl/liter) were measured using duplicate samples of 50 μl[5].

High-Performance Liquid Chromatographic Stability-Indicating Assay for Naphazoline and Tetrahydrozoline in Ophthalmic Preparations

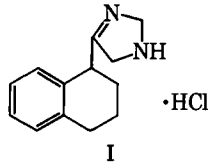
JOHN BAUER ˣ and SUZANNE KROGH

Received July 12, 1982, from the *Pharmaceutical Products Division, Abbott Laboratories, North Chicago, IL 60064.* Accepted for publication October 5, 1982.

Abstract □ A high-performance liquid chromatographic (HPLC) analysis for tetrahydrozoline and naphazoline in ophthalmic solutions is presented. The analysis allows a more reproducible, direct stability-indicating assay than the colorimetric methods generally employed. The HPLC system is so designed that a variety of ophthalmic solutions containing either naphazoline or tetrahydrozoline can be analyzed concomitantly.

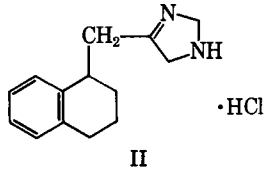
Keyphrases □ High-performance liquid chromatography—stability-indicating assay, ophthalmic preparation, naphazoline, tetrahydrozoline □ Naphazoline—high-performance liquid chromatographic stability-indicating assay, ophthalmic preparation □ Tetrahydrozoline—high-performance liquid chromatographic stability-indicating assay

Tetrahydrozoline (I) and naphazoline (II) are sympathomimetic agents used in the majority of commercially available occular decongestants. The current analytical methodologies are either colorimetric or ultraviolet. Tetrahydrozoline analysis involves color development with either sodium nitroprusside (1, 2) or bromophenol blue (2). Naphazoline is presently assayed by either UV-absorption spectroscopy (3) or colorimetry (1).



I

2-(1,2,3,4-Tetrahydro-1-naphthyl)-2-imidazoline, monohydrochloride



II

2(1-Naphthylmethyl)-2-imidazoline, monohydrochloride

These methods generally involve isolation steps as well as color development times and are subject to interferences. The high-performance liquid chromatographic (HPLC) procedure developed in our laboratory is a direct stability-indicating assay for tetrahydrozoline and naphazoline in ophthalmic solutions.

EXPERIMENTAL

Materials—Methanol[1], citric acid[2], sodium citrate[3], and perchloric acid[4] were used as received. Tetrahydrozoline and naphazoline were USP reference standards. A high-performance liquid chromatograph[5] and a UV visible spectrophotometer[6] were used. A microparticulate octadecylsilane column[7] was used. The temperature was ambient and the flow rate 2.0 ml/min. The analytical wavelength was 265 nm. Injection volume was 20 μl.

Mobile Phase—Six grams of sodium citrate dihydrate and 4 g of anhydrous citric acid were added to 700 ml of water and mixed until dissolved; 7 ml of perchloric acid was added and the pH determined. The pH was adjusted to 2.2 ± 0.2 by further addition of perchloric acid. A 300-ml volume of methanol was added, the solution mixed thoroughly, filtered through a 0.45-μm filter, and deaerated for ~10 min.

Tetrahydrozoline Internal Standard Solution—A solution containing ~150 mg of tetrahydrozoline hydrochloride was prepared by dissolving and diluting to volume with distilled water to 100 ml (~1.5 mg/ml).

Naphazoline Internal Standard Solution—A preparation of ~40 mg of naphazoline in 100 ml of water was prepared and diluted 1/10 with water for use as the internal standard solution (~0.04 mg/ml).

Naphazoline Standard—Approximately 120 mg of naphazoline hydrochloride was weighed accurately into a 100-ml volumetric flask and dissolved and diluted to volume with distilled water. A 5.0-ml volume of this solution was pipetted into a 50-ml volumetric flask and diluted to volume with distilled water (~0.12 mg/ml); 5.0 ml of this solution was pipetted into a 10-ml volumetric flask and diluted to volume with tetrahydrozoline internal standard solution.

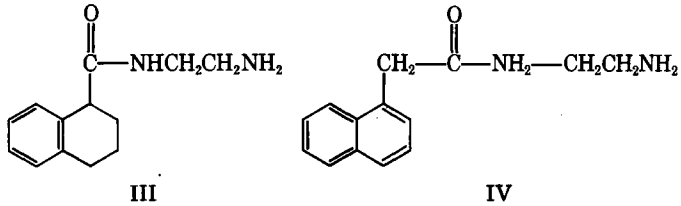
Sample Procedure—A 5.0-ml volume of the sample was pipetted into a 10-ml volumetric flask and diluted to volume with the appropriate internal standard solution.

RESULTS AND DISCUSSION

The HPLC analysis is, in the majority of cases, more reproducible than the sodium nitroprusside colorimetric methods for tetrahydrozoline and naphazoline (Tables I and II). In addition the use of naphazoline as the internal standard for tetrahydrozoline and tetrahydrozoline as the internal standard for naphazoline allows direct analysis of a variety of ophthalmic solutions using a single eluant system.

The precision data for the HPLC analysis (Table III) and the comparative study (Tables I and II) demonstrate that the HPLC analysis is better than the colorimetric techniques, which in our laboratories gave standard deviations of 1.5% for naphazoline and 2.8% for tetrahydrozoline.

A typical chormatogram is shown in Fig. 1. Both tetrahydrozoline and naphazoline can be separated from their respective degradation products, *N*-(2-aminoethyl)-1,2,3,4-tetrahydro-1-napthylamine (III) and *N*-(2-aminoethyl)-1-(1-napthyl)acetamide (IV) (Fig. 2). These components can be quantitated separately if desired, although appropriate corrections for extinction coefficient differences must be used.



III IV

Both compounds III and IV have been isolated from the HPLC system and identified spectroscopically. The response for both tetrahydrozoline and naphazoline is linear. The naphazoline response from 0.02 to 0.1 mg/ml gave a correlation coefficient of 0.9999, n = 1.0019 (4). Tetrahydrozoline response gave a correlation coefficient of 0.9999 between 0.1 and 0.5 mg/ml, n = 1.0029. The analysis is applicable to a variety of ophthalmic solutions[8].

The HPLC assay presented constitutes a direct, stability-indicating

[8] Clear Eyes, Naphcon, 20/20, Murine Plus, Visine, Visine AC, Soothe.

analysis for either of the two major sympathomimetic agents in use in topical ocular decongestants. The technique is more reproducible than the present colorimetric assay and does not suffer from the time restraints and interferences possible in colorimetric assays. The HPLC method presented can be easily automated and allows analysis of a variety of ophthalmic solutions on a single HPLC system.

Stability-Indicating Assay, Dissolution, and Content Uniformity of Sodium Levothyroxine in Tablets

STEVEN L. RICHHEIMER ˣ and TAHANI M. AMER

Received July 19, 1982, from the *Stability Laboratory, Pharmaceutical Basics, Inc., Denver, CO 80223.* Accepted for publication October 14, 1982.

Abstract □ A reverse-phase high-performance liquid chromatographic (HPLC) method for determining sodium levothyroxine in tablet formulations is described. The sodium levothyroxine was extracted from tablets using a mobile phase consisting of 60% acetonitrile and 40% aqueous buffer. After centrifugation 200 μl of the solution was chromatographed on a 10-μm C_{18} column. The method gave accurate results when tested against the USP method, by the standard additions method, and by the spiked-placebo method. The method can also be used to determine content uniformity and dissolution of sodium levothyroxine tablets.

Keyphrases □ Sodium levothyroxine—stability-indicating assay, dissolution, content uniformity, tablets □ Dissolution—sodium levothyroxine, stability-indicating assay, content uniformity, tablets □ Content uniformity—sodium levothyroxine, stability-indicating assay, dissolution, tablets □ Stability—assay of sodium levothyroxine in tablets, dissolution, content uniformity

Sodium levothyroxine (I) tablets are widely prescribed in thyroid replacement therapy, with a wide range of doses available (25–300 μg/tablet). The USP XX method of assay consists of a lengthy ignition and oxidation to iodate followed by titration of the liberated iodine (1). The method is neither stability indicating nor sensitive enough to be used for content uniformity and dissolution determinations.

A number of other assay procedures based on liquid chromatography have appeared in the literature (2–13). This report describes a new reverse-phase liquid chromatographic (HPLC) assay method that adequately separates I from degradation products and can be used for the identification, content uniformity analysis, and dissolution testing of I in tablets.

EXPERIMENTAL

Reagents and Materials—Sodium levothyroxine[1] (I) was assayed by the USP XX procedure (14); sodium liothyronine[1] and 3,5-diiodo-L-thyronine[2] were used as received. Reagents used were analytical reagent grade. The levothyroxine sodium tablets (USP) were obtained commercially from four sources[3–6].

Apparatus—The high-performance liquid chromatograph[7] was equipped with a variable-wavelength UV detector[8], a strip-chart recorder[9], an electronic integrator[10], and a 200-μl loop-type injector[11]. Commercial 10-μm C_{18} columns[12] (30 cm × 4 mm i.d.) were used at am-

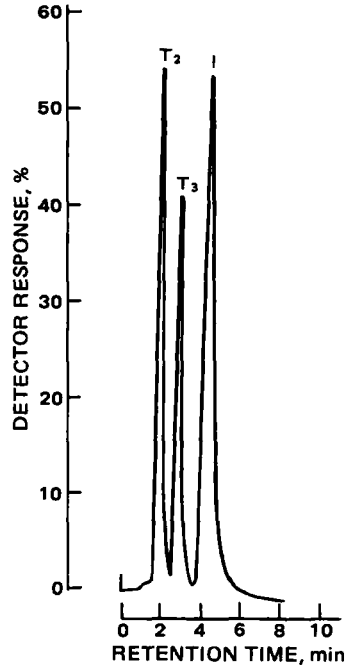

Figure 1—*Chromatogram of sodium levothyroxine (I, 20 μg/ml) with added sodium liothyronine (T_3, 10 μg/ml), and 3,5-diiodo-L-thyronine (T_2, 10 μg/ml).*

bient temperature. A stainless steel column (4 cm × 4 mm i.d.) packed with a 40-μm C_{18} pellicular material[13] was used both as a guard column and in place of the injection loop for dissolution studies. Dissolutions were performed on a commercial dissolution apparatus[14] using the USP-rotating-paddle method.

Chromatographic Conditions—The mobile phase was a mixture of 60% acetonitrile and 40% pH 3.0 aqueous buffer containing 0.005 *M* 1-octanesulfonic acid and 0.005 *M* tetramethylammonium chloride. The acetonitrile was reduced to 50% for columns with less retentive packing material[13]. Flow rate was 2 ml/min, and the detector was at 230 nm and 0.08 AUFS.

Standard Preparation—The levothyroxine reference standard[15] (19.5 mg) or I (20 mg) was dissolved in 100.0 ml of mobile phase. The stock solution could be stored for several months in darkness at 4°. Working standards were prepared daily from the stock solution by dilution with the mobile phase.

Sample Preparation—Twenty tablets were weighed and finely powdered. A portion of powder equivalent to 200 μg of I was transferred to a glass-stoppered centrifuge tube. Mobile phase (10.0 ml) was added, and the mixture was sonicated for 5 min and then centrifuged. The supernatant was then filtered through a 0.45-μm membrane filter[16] if it was not free of particulate matter. For content uniformity analyses, one tablet was placed in a centrifuge tube and enough mobile phase was added to make the final concentration 20 μg/ml (except 25- and 50-μg tablets, 5- and 10-μg/ml were acceptable). The tablet was sonicated until completely disintegrated, and the solution was analyzed using the composite assay, reducing the standard concentration where applicable.

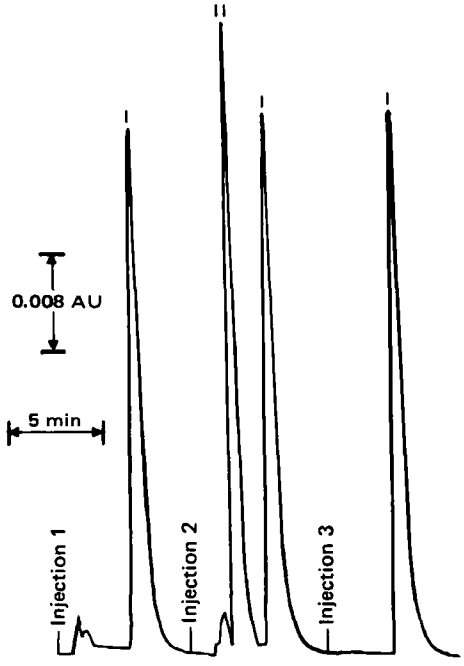

Figure 2—*Typical chromatograms for the assay of sodium levothyroxine. The mobile phase is 60% acetonitrile and 40% pH 3.0 buffer. Key: injection 1: 200-μg tablet from manufacturer B; injection 2: 100-μg tablet from manufacturer A (II is an excipient peak); and injection 3: standard, 20 μg/ml.*

[a] All samples stored at ambient humidity.

Assay Procedure—Standard and sample preparations (200 μl) were injected into the liquid chromatograph. Either peak areas or peak heights were measured. Compound I was quantitated by comparing the peak response of the sample to that of the standard.

Dissolution Procedure—Phosphate buffer (500 ml, pH 7.5, 0.05 *M*) at 37 ± 0.5° was used with the USP rotating-paddle method at 50 rpm. A 20-ml aliquot of the mixture was withdrawn after 30 min and filtered through a 0.45-μm membrane filter. A portion of the filtrate equivalent to 1 μg of I (0.25 μg for 25-μg tablets) was passed through a 4 cm × 4-mm guard column with C_{18} packing attached to the sampling valve. The column was rinsed with 1 ml of water and injected onto the liquid chromatograph under the same conditions specified for the assay. Similarly, 1.0 ml of a standard (1 μg/ml of I) in dissolution medium (0.25 μg/ml for 25-μg tablets) was injected. The amount of I dissolved was quantitated by comparing the peak areas obtained for the standard and sample chromatograms.

RESULTS AND DISCUSSION

Chromatography and Specificity—Various mobile phases were investigated; however, the equimolar combination of 1-octanesulfonate and tetramethylammonium chloride with acetonitrile was found to give the sharpest peak for I, as well as providing adequate separation of I from degradation products and tablet excipients. Figure 1 shows a typical chromatographic separation of I from liothyronine (T_3) and 3,5-diiodo-L-thyronine (T_2). Figure 2 shows typical chromatograms obtained in the assay of two brands of tablets and a standard. Extraction of I by the mobile phase was quantitative, as evidenced by recovery experiments using whole tablets and I in combination with individual tablet excipients. Incomplete extraction of I in the presence of magnesium stearate was observed using several other extracting solvents (100% acetonitrile, ammoniacal methanol, and 60:40 acetonitrile–water). It is possible that I forms an insoluble ion-pair complex with the stearate which is inhibited in the presence of 1-octanesulfonate and tetramethylammonium chloride but not other extracting solvents.

The specificity of the method was further tested by degrading samples of I (20–200 μg/ml) by irradiation, hydrolysis, oxidation, and heat and assaying the resulting solutions by the proposed method. Short-wavelength UV (24 hr) caused 100% degradation, while refluxing with 0.1 *N* HCl or 0.1 *N* NaOH (16 hr) caused 41.1 and 43.4% degradation, respectively. Oxidation with 0.01 *M* H_2O_2 and 0.01 *M* Fe^{2+} (16 hr) caused 97% degradation. Thermal degradation of I at 80° combined with tablet excipients was 17–87% in 24 hr depending on the formulation. In every case the unidentified degradation products eluted before the I peak and did not interfere with the analysis of I.

Comparison to the USP Method and Reproducibility—A new lot (<1 month since manufacture) of 100-μg tablets of I was assayed re-

Table III—Recovery of Sodium Levothyroxine (I) Added to Tablet Formulations

Manufacturer	Stated Potency, μg	Unspiked I/Tablet	Amt. of I Added, μg	Amt. of I Measured, μg	Recovery[a], %
A	25	24.0	12.5	35.6	97.5
A	300	281.0	150.1	429.4	99.6
B	25	22.2	12.5	33.6	96.9
B	200	195.7	100.9	297.9	100.4
C	100	89.5	50.4	140.8	100.6
D	200	196.7	100.9	297.6	100.0

[a] Percent Recovery = [measured I/(unspiked I + added I)] × 100.

peatedly by the USP XX method and by the proposed method. The results (Table I) indicate that the two methods are in close agreement for this lot and that reproducibility is good (*RSD* = 0.85%). However, samples stored at elevated temperatures (Table II) for even short periods of time gave higher assay results by the USP XX method than by HPLC due to degradation of I in the tablet formulations.

Recovery of I Added to Spiked Placebo Mixtures and Linearity—The effectiveness of the extraction step and accuracy of the method was tested by adding I in an amount corresponding to 50–125% of the label claim to several powdered placebo mixtures (25-, 100-, 200-, and 300-μg tablets). A plot of the amount of I added *versus* the amount recovered indicates that the slopes are unity within experimental error (1.000 ± 0.008), that the intercepts are near zero (0.40 ± 0.76), and that the correlation coefficients are unity (1.000). Recoveries for the 20 spiked samples tested (five for each potency) ranged from 98.1 to 100.6% (average: 100.0%; *RSD* = 0.53). In each case a placebo blank was also run which showed no interfering peaks. These data indicate that the method is linear and accurate between 50 and 125% for the tablet formulations tested. Both peak area and peak height gave equally accurate results.

The method was also tested by spiking several different commercially available tablets with additional I. Tablet potencies ranged from 25 to 300 μg, and in each case 50% of the label amount of I was added. The results (Table III) indicate that complete recovery was obtained for all formulations tested.

The linearity of the method was further tested by chromatographing a series of seven standard solutions ranging in concentration from 5 to 35 μg/ml. Plots of both peak area and peak height *versus* concentration were linear (correlation coefficients = 0.9999) and showed no bias (intercepts were 0.0 ± 0.75%). These results indicate that an external standard (equivalent to 20 μg/ml of I) can be used to analyze samples varying in concentration over a sevenfold range.

Content Uniformity and Dissolution Studies—The applicability of the method for content uniformity determinations was tested by assaying 10 individual 25-μg tablets from manufacturer A. The mean value of 95.9% agreed well with a composite assay for this lot of 96.0%, and the variation (2.60% high to 2.61% low) was close to the weight variation for the same 10 tablets (2.04–1.86%).

The accuracy of the dissolution method was tested by determining the recovery of varying amount of I added to dissolution medium (0.05 *M* phosphate buffer, pH 7.5) plus tablet excipients. The results (Table IV) indicate that recovery is quantitative in the range of 30–100% (0.3–1.0 μg); reproducibility using peak area was also good (*RSD* = 1.3%, $n = 8$). Retention of I on the guard column was complete, since washing with 10 times the normal amount of dissolution medium did not reduce the amount of I recovered (although the peak was broadened). Results using commercially available tablets (100 μg) varied from 36.2 to 68.4% dissolved using the method depending on manufacturer and were significantly lower with water (−39%) and 0.1 *N* HCl (−28%) as the dissolution media.

Several studies have shown differences in the potency and/or bioavailability of sodium levothyroxine preparations (15–17). Reported differences in bioavailability may be due to the use of subpotent tablets in the study, since several of the lots tested by the proposed HPLC method from more than one manufacturer were found to be well below the USP minimum of 90.0% of label claim. Since the stability of I in different formulations varies considerably, it is possible that the differences in potencies occur not at the time of manufacture but on aging. Unfortunately the USP method, which measures only total iodine, does not provide a specific or meaningful method for the determination of the stability of I in dosage forms. The proposed method is accurate, reproducible, and specific for I and adequately quantitates I in the presence of degradation products. In addition the method can be applied to identification, content uniformity, and dissolution of I in tablets. Official adoption of an HPLC method for the assay of sodium levothyroxine tablets will go a long way toward providing a better standardized and uniform product with a well-established shelf life.

Table IV—Sodium Levothyroxine (I) Dissolution–Recovery Study

Sample	Amount of I added, μg	Amount of I measured, μg[a]	Recovery, %
30	30.0	30.3	101.0
50	50.0	50.0	100.0
70	70.0	69.2	98.9
100	100.0	98.6	98.6

[a] 500 ml of dissolution medium was used and 5.0 ml passed through guard column prior to injection (0.3–1.0 μg injected).

In Vivo Evaluation of the Michaelis–Menten Constant For a Medium Extraction Ratio Drug: Application to Cinromide in the Rhesus Monkey

ELIZABETH A. LANE * **and RENÉ H. LEVY** ˣ

Received August 27, 1982, from the *University of Washington, Department of Pharmaceutics, Seattle, WA 98195.* Accepted for publication October 14, 1982. *Present address: Laboratory of Chemical Pharmacology, National Heart, Lung and Blood Institute, Bethesda, MD 20205.

Abstract □ The dose-dependent nonlinearity of the clearance of cinromide, a medium extraction ratio drug, has been established in two monkeys. Special problems encountered in evaluation of nonlinearity of such drugs were resolved by the experimental design: cinromide was infused to steady state *via* the portal vein. A linearized form of the Michaelis–Menten equation was used to determine v_{max} and K_m. In addition, cinromide was administered to one of the monkeys *via* a femoral vein to verify the overestimation of K_m by administration at a peripheral venous site.

Keyphrases □ Cinromide—*in vivo* evaluation of Michaelis–Menten constant, medium extraction ratio drug, application to the rhesus monkey □ Michaelis–Menten constant—*in vivo* evaluation, medium extraction ratio drug, application to cinromide in the rhesus monkey □ Medium extraction ratio drug—*in vivo* evaluation of Michaelis-Menten constant, application to cinromide in the rhesus monkey

The accurate determination of *in vivo* Michaelis–Menten parameters is dependent on a number of considerations. For any drug it is a function of the compartmental model to which the data are fitted (1). For drugs with medium or high extraction ratios, the relationship between site of administration and site of elimination is important (2). For example, it has been pointed out that an overestimation of the Michaelis–Menten constant (K_m) is theoretically expected for drugs with high hepatic extraction ratios administered by a peripheral venous site (3). Oral administration presents the advantage of an estimation of intrinsic clearance, but it allows no control over the rate of absorption. Furthermore, it requires an independent determination of fraction absorbed. A review of the literature indicates that the problems associated with the *in vivo* determination of Michaelis–Menten parameters for a medium or high extraction ratio drug have not yet been resolved.

An investigation of the pharmacokinetic characteristics of cinromide in the rhesus monkey established that this drug has a medium extraction ratio (4). Administration of this drug by intravenous (femoral vein) infusion at three zero-order rates for 5 hr suggested the presence of nonlinearity. At the highest infusion rate (~100 mg/hr) steady state was achieved within 5 hr (half-life = 0.92 ± 0.23 hr) in only two of the five monkeys, and the postinfusion half-life of cinromide was significantly longer after the highest infusion rate (4). The object of the present study was to establish the nonlinearity of cinromide and to attempt an *in vivo* determination of Michaelis–Menten parameters. The experimental design was based on the following considerations: (*a*) the problems of extraction ratio, site of administration, and fraction absorbed were resolved by placement of a catheter in the hepatoportal vein; (*b*) the bias of compartmental models was avoided, and the rate of presentation of the drug to the liver was controlled by selection of a steady-state approach.

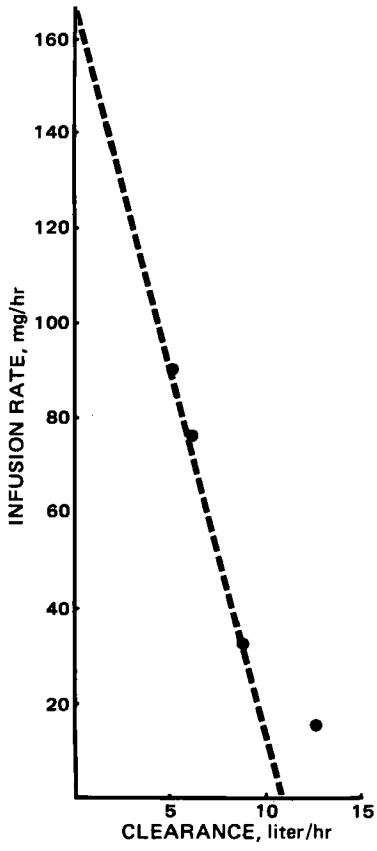

Figure 4—*Graphic evaluation of Michaelis–Menten constants for cinromide administered* via *a femoral vein (nonportal route) to monkey 307.*

EXPERIMENTAL

Two male rhesus monkeys [306 (5.7 kg) and 307 (7.9 kg)] were conditioned in primate chairs prior to the beginning of this study. Two catheters were surgically implanted in each monkey; one in the portal vein and one in the jugular vein. Patency of catheters was assured by infusion of saline (1 ml/hr). The monkeys were maintained on fresh fruit and monkey food.

Cinromide[1] was administered in 60% polyethylene glycol 400 solution by constant-rate infusion at 4 ml/hr *via* the portal vein. Four different concentrations of cinromide were infused to give dosage rates of ~10-, 30-, 70-, and 90-mg/hr. Infusions were aimed at achieving steady state and were maintained for at least 7 hr for the 10-, 30-, and 70-mg/hr doses, and at least 10 hr for the 90-mg/hr dose rate. Eleven blood samples were collected *via* the jugular vein catheter during each infusion. Blood samples were analyzed by high-performance liquid chromatography (HPLC) as previously described (4). To verify the effect of administration route on determination of the Michaelis–Menten constant, cinromide was administered to one monkey (307) *via* a femoral vein at the same four infusion rates.

RESULTS AND DISCUSSION

The concentrations achieved by four portal vein infusions to two monkeys are shown in Fig. 1. In every case, steady state appears to have been achieved. In both monkeys, the increase in steady-state concentration was more than proportional to the increase in infusion rate, illustrating the decrease in intrinsic clearance with increase in dose rate. A sevenfold increase in dosing rate corresponded to a 30-fold increase in steady-state concentration. The concentrations achieved by infusion of cinromide at the same rates *via* a femoral vein into monkey 307 are shown in Fig. 2. A sixfold increase in dosing rate corresponded to a 15-fold increase in steady-state concentration. Thus, the nonlinearity of cinromide was less pronounced when administered *via* the femoral vein than when administered *via* the portal vein. These results demonstrate the buffering effect of blood flow on systemic clearance.

Determination of parameters from the data of Figs. 1 and 2 was based on the following theoretical considerations. For a low extraction ratio drug, the dose-dependent clearance (CL) may be expressed as:

$$CL = \frac{R_0}{C^*} = \sum_{i=1}^{n} \frac{v_{\max_i}}{K_{m_i} + C^*} \qquad \text{(Eq. 1)}$$

where C^* is the steady-state total drug concentration, R_0 is the drug infusion rate, $v_{\max_i}$ is the maximum velocity of the reaction for the ith enzyme, and K_{m_i} is the Michaelis constant for the ith enzyme, uncorrected for blood protein binding. It is also assumed that the free fraction in blood is constant.

Most commonly a single $v_{\max}$ and K_m are evaluated as if a single enzyme is responsible for the elimination of the drug. If the drug is eliminated by more than one enzyme having similar values of K_m, they cannot be distinguished by this approach (5). A useful linear transformation of this relationship (Eq. 1) has been applied to phenytoin (6) and other drugs:

$$R_0 = v_{\max_1} - K_{m_1} \frac{R_0}{C^*} \qquad \text{(Eq. 2)}$$

For a medium to high extraction ratio drug eliminated only in the liver, it is appropriate to apply the above equations when drug is administered by a portal route. When drug is administered *via* a peripheral vein and the well-stirred model of the liver is assumed, the clearance is related to the Michaelis–Menten parameters by:

$$CL = \frac{R_0}{C^*} = \frac{Q_H \sum_{i=1}^{n} \frac{v_{\max_i}}{K_{m_i} + C^*}}{Q_H + \sum_{i=1}^{n} \frac{v_{\max_i}}{K_{m_i} + C^*}} \qquad \text{(Eq. 3)}$$

where Q_H is the liver blood flow. If drug is eliminated by a single enzyme, Eq. 3 may be rearranged to give:

$$R_0 = v_{\max_1} - \left(K_{m_1} + \frac{v_{\max_1}}{Q_H}\right) \frac{R_0}{C^*} \qquad \text{(Eq. 4)}$$

Comparison of Eqs. 2 and 4 demonstrates that the evaluation of K_m is dependent on administration route, while the determination of $v_{\max}$ is independent. When drug is administered by a peripheral venous site, K_m is overestimated by the value of $v_{\max}/Q_H$, as suggested by other authors (3).

The data from the portal vein infusions were plotted according to the

[1] Supplied by Burroughs Wellcome Co., Research Triangle Park, N.C.

linearized form of the Michaelis–Menten equation (Eq. 2). These data appeared to be nonlinear for both monkeys (Fig. 3). This nonlinearity is of the type observed in cases involving two saturable pathways with different values of K_m (5). Nonlinear least-squares fitting of data to acquire the best estimates of parameters requires at least one more datum point than the number of parameters to be estimated. In this case, there are only four data points to estimate four parameters; therefore, no estimates of the parameters for the pathway having the lower K_m were attempted. The v_{max} and K_m for the higher capacity pathway could be approximated by fitting the data from the three higher infusion rates to a straight line. The values of v_{max} and K_m were 120 mg/hr and 3.35 mg/liter for monkey 306 and 114 mg/hr and 4.43 mg/liter for monkey 307. A plot of data from the femoral vein infusions according to the linearized form of the Michaelis–Menten equation shows nonlinearity similar to that of the portal vein data (Fig. 4). The estimated values of v_{max} and K_m are 170 mg/hr and 15.6 mg/liter, respectively.

These values of v_{max} and K_m for femoral vein administration may be compared with those obtained for the same monkey dosed *via* the portal vein. The observed difference in v_{max} was not expected. It may be a result of the metabolism of cinromide by more than one enzyme, as indicated by the nonlinearity of the data from all four infusions. Also, the clearance values obtained from the three higher infusion rates into the femoral vein span a narrow range (5.1 to 9.3 liter/hr), which can result in uncertainty in the intercept. According to theory (Eqs. 2 and 4) the value of K_m obtained by femoral vein administration (15.6 mg/liter) should exceed that obtained by portal vein administration (4.4 mg/liter) by the ratio v_{max}/Q_H. This ratio can be roughly estimated if the hepatic blood flow in monkey 307 is calculated using the portal and femoral infusion data and the equation of Wilkinson and Shand (7). Although this equation was developed for a dose-independent intrinsic clearance, it can be applied in the dose-dependent case, provided that the steady-state concentration of drug at the enzyme is equal for the two routes of administration. This is accomplished by the administration of drug by the femoral and portal routes at equal rates. The average value obtained from the four pairs of infusions was 21.0 ± 2.8 liter/hr. Division of the two values of v_{max} from monkey 307 by this value of blood flow yields 5.4 and 8.4 mg/liter, within 50–70% of the difference between the two values of K_m (11.2 mg/liter). This calculation is compatible with the theoretical prediction. Equality between these two estimates of the difference in K_m arising from route of administration is not expected, since the determination of K_m, v_{max}, and Q_H involve error. In fact, the degree of compatibility suggests that the well-stirred model of the liver can be used to explain the effects of administration route on the disposition of cinromide.

The dose-dependent nonlinearity of cinromide, a medium extraction ratio drug, has been demonstrated. Catheterization of the portal vein for chronic drug administration provided a means of evaluating the intrinsic clearance of cinromide independently of hepatic blood flow and, thereby, a means of examining the dose dependence of cinromide. Comparison of values obtained for the whole body Michaelis–Menten constant for the peripheral and portal routes of administration confirmed the theoretically predicted effects of flow limitation on clearance.

Tick Repellents II: *N*-Substituted Azacyclopentanones and Azacyclopentenones

W. A. SKINNER ˣ, U. ROSENTRETER*, and T. ELWARD

Received May 10, 1982, from *Life Sciences Division, SRI International, Menlo Park, CA 94025.* Accepted for publication September 3, 1982. *Present address: Waldstrasse 11, 5600 Wuppertal 1, West Germany.

Abstract □ Several *N*-substituted azacyclopentanones and azacyclopentenones were synthesized and evaluated as repellents for the brown dog tick *Rhipicephalus sanguineus*. Several of these compounds were more effective in our test system than were the standard repellents, *N,N*-diethyl-*m*-toluamide and butopyranoxyl.

Keyphrases □ *N*-Substituted azacyclopentanones—synthesis, structure–activity relationships, evaluation as tick repellents □ *N*-Substituted azacyclopentenones—synthesis, structure–activity relationships, evaluation as tick repellents □ Tick repellents—potential, *N*-substituted azacyclopentanones and azacyclopentenones, synthesis

Tick-borne diseases still represent a problem and the need for a safe means of controlling ticks exists. Compounds useful for repelling mosquitoes are not necessarily those that are the most effective for ticks. Screening of repellents for ticks required the development of a rapid, simple assay system, which has been completed in our laboratories. This method, which was described previously (1), involved the use of a plastic vial containing the ticks with a filter paper cap impregnated with the test substance. The common behavior of ticks to travel upward is used to compare the control behavior with that in a vial treated at the top with repellent.

Most repellents reported for ticks have been amides or esters (2). We decided to explore azacyclopentanones and azacyclopentenones as a group of cyclic amides for their ability to repel the brown dog tick, *Rhipicephalus sanguineus*.

Compounds reported in Tables I–III were prepared by the methods described in *Experimental* for selected compounds.

linearized form of the Michaelis–Menten equation (Eq. 2). These data appeared to be nonlinear for both monkeys (Fig. 3). This nonlinearity is of the type observed in cases involving two saturable pathways with different values of K_m (5). Nonlinear least-squares fitting of data to acquire the best estimates of parameters requires at least one more datum point than the number of parameters to be estimated. In this case, there are only four data points to estimate four parameters; therefore, no estimates of the parameters for the pathway having the lower K_m were attempted. The v_{max} and K_m for the higher capacity pathway could be approximated by fitting the data from the three higher infusion rates to a straight line. The values of v_{max} and K_m were 120 mg/hr and 3.35 mg/liter for monkey 306 and 114 mg/hr and 4.43 mg/liter for monkey 307. A plot of data from the femoral vein infusions according to the linearized form of the Michaelis–Menten equation shows nonlinearity similar to that of the portal vein data (Fig. 4). The estimated values of v_{max} and K_m are 170 mg/hr and 15.6 mg/liter, respectively.

These values of v_{max} and K_m for femoral vein administration may be compared with those obtained for the same monkey dosed *via* the portal vein. The observed difference in v_{max} was not expected. It may be a result of the metabolism of cinromide by more than one enzyme, as indicated by the nonlinearity of the data from all four infusions. Also, the clearance values obtained from the three higher infusion rates into the femoral vein span a narrow range (5.1 to 9.3 liter/hr), which can result in uncertainty in the intercept. According to theory (Eqs. 2 and 4) the value of K_m obtained by femoral vein administration (15.6 mg/liter) should exceed that obtained by portal vein administration (4.4 mg/liter) by the ratio v_{max}/Q_H. This ratio can be roughly estimated if the hepatic blood flow in monkey 307 is calculated using the portal and femoral infusion data and the equation of Wilkinson and Shand (7). Although this equation was developed for a dose-independent intrinsic clearance, it can be applied in the dose-dependent case, provided that the steady-state concentration of drug at the enzyme is equal for the two routes of administration. This is accomplished by the administration of drug by the femoral and portal routes at equal rates. The average value obtained from the four pairs of infusions was 21.0 ± 2.8 liter/hr. Division of the two values of v_{max} from monkey 307 by this value of blood flow yields 5.4 and 8.4 mg/liter, within 50–70% of the difference between the two values of K_m (11.2 mg/liter). This calculation is compatible with the theoretical prediction. Equality between these two estimates of the difference in K_m arising from route of administration is not expected, since the determination of K_m, v_{max}, and Q_H involve error. In fact, the degree of compatibility suggests that the well-stirred model of the liver can be used to explain the effects of administration route on the disposition of cinromide.

The dose-dependent nonlinearity of cinromide, a medium extraction ratio drug, has been demonstrated. Catheterization of the portal vein for chronic drug administration provided a means of evaluating the intrinsic clearance of cinromide independently of hepatic blood flow and, thereby, a means of examining the dose dependence of cinromide. Comparison of values obtained for the whole body Michaelis–Menten constant for the peripheral and portal routes of administration confirmed the theoretically predicted effects of flow limitation on clearance.

Tick Repellents II: *N*-Substituted Azacyclopentanones and Azacyclopentenones

W. A. SKINNER ˣ, U. ROSENTRETER*, and T. ELWARD

Received May 10, 1982, from *Life Sciences Division, SRI International, Menlo Park, CA 94025.* Accepted for publication September 3, 1982. *Present address: Waldstrasse 11, 5600 Wuppertal 1, West Germany.

Abstract □ Several *N*-substituted azacyclopentanones and azacyclopentenones were synthesized and evaluated as repellents for the brown dog tick *Rhipicephalus sanguineus*. Several of these compounds were more effective in our test system than were the standard repellents, *N,N*-diethyl-*m*-toluamide and butopyranoxyl.

Keyphrases □ *N*-Substituted azacyclopentanones—synthesis, structure–activity relationships, evaluation as tick repellents □ *N*-Substituted azacyclopentenones—synthesis, structure–activity relationships, evaluation as tick repellents □ Tick repellents—potential, *N*-substituted azacyclopentanones and azacyclopentenones, synthesis

Tick-borne diseases still represent a problem and the need for a safe means of controlling ticks exists. Compounds useful for repelling mosquitoes are not necessarily those that are the most effective for ticks. Screening of repellents for ticks required the development of a rapid, simple assay system, which has been completed in our laboratories. This method, which was described previously (1), involved the use of a plastic vial containing the ticks with a filter paper cap impregnated with the test substance. The common behavior of ticks to travel upward is used to compare the control behavior with that in a vial treated at the top with repellent.

Most repellents reported for ticks have been amides or esters (2). We decided to explore azacyclopentanones and azacyclopentenones as a group of cyclic amides for their ability to repel the brown dog tick, *Rhipicephalus sanguineus*.

Compounds reported in Tables I–III were prepared by the methods described in *Experimental* for selected compounds.

and 11.2 g (0.1 mole) of potassium *tert*-butoxide was stirred in 100 ml of anhydrous dimethyl sulfoxide for 1 hr. The dimethyl sulfoxide was removed under reduced pressure, the residue dissolved in 100 ml of ether, and washed with water (2 times). After drying the organic phase with anhydrous magnesium sulfate and removing the solvent under reduced pressure, the oily residue was distilled *in vacuo*. The first fraction, (bp 140–147°/1.2 mm Hg), was discarded. The second fraction gave 17.4 g of product, bp 148°/1.2 mm Hg.

1-Ethyl-5-octyl-azacyclopent-4-ene-2-one (IIe)—A solution of octylmagnesium bromide was prepared by adding in a dropwise manner, 34.2 g (0.177 mole) of 1-bromooctane in 10 ml of ether to 6.5 g (0.268 g-atom) of magnesium in 10 ml of ether and then heating at reflux for 3 hr. The Grignard reagent was added over a 2-hr period to a solution of 15 g (0.118 mole) of *N*-ethyl-succinimide in 50 ml of anhydrous tetrahydrofuran. The mixture was allowed to stand at room temperature for 2 days, and then was poured into a mixture of ice and 10% sulfuric acid. After separation of the organic layer, the aqueous phase was extracted twice with 50 ml of ether. The combined organic phases were washed with saturated sodium hydrogen carbonate and dried over anhydrous sodium sulfate. The solvent was removed under reduced pressure, and the residue was evaporatively distilled to give 10 g of a yellow oil, 120° air bath temperature/0.9 mm Hg. A second fractional distillation using a Vigreux column yielded 6.6 g of product, bp 130°/1.0 mm Hg.

1-Ethyl-5-octyl-azacyclopentane-2-one (IIIb)—1-Ethyl-5-octyl-azacyclopent-4-ene-2-one, (5.3 g, 0.0238 mole) in 25 ml of ethanol was hydrogenated under atmospheric pressure with 0.5 g of 10% Pd-C. After the uptake of hydrogen was completed, the catalyst was removed by filtration, the solvent evaporated, and the residue distilled to give 5 g of product, bp 130°/0.9 mm Hg.

The tick repellency assay was as previously described (1).

RESULTS AND DISCUSSION

A comparison of the tick repellency of the azacyclopentanones with *N,N*-diethyl-*m*-toluamide and butopyranoxyl at 0.44 mg/cm² shows that a number of these substances are considerably more repellent than the standard compounds (Tables I–III). In the 1-alkyl-azacyclopentane-2-one series, the *n*-octyl derivative is outstanding. The boiling point of 110°/0.5 mm Hg corresponds closely to that of *N,N*-diethyl-*m*-toluamide, whereas the *n*-decyl and dodecyl compounds are considerably higher boiling derivatives and are probably too nonvolatile for optimum repellency.

In the 1-ethyl-5-alkyl-azacyclopentane-4-ene-2-one series, the *n*-pentyl, -hexyl, -heptyl, -octyl, and -decyl derivatives are all outstanding as tick repellents. The maximum activity is reached with the *n*-hexyl derivative (bp 110°/0.5 mm Hg). However, a comparison of the *n*-hexyl derivative with the *n*-octyl derivative in the 1-alkyl-azacyclopentane-2-one series, where the boiling points are identical, reveals that the unsaturation in the ring leads to enhanced repellency.

In the last series explored, 1-ethyl-5-alkyl-azacyclopentane-2-ones, the *n*-octyl and *n*-decyl derivatives have improved repellency over *N,N*-diethyl-*m*-toluamide with the *n*-octyl derivative, boiling point of 120°/0.5 mm Hg, being the best. Comparison of this series with the aza-

Synthesis and Antileukemic Activity of 2-(2-Methylthio-2-aminovinyl)-1-methylquinolinium Iodides

WILLIAM O. FOYE ˣ, YOUNG HO KIM *, and JOEL M. KAUFFMAN ‡

Received July 19, 1982, from the *Samuel M. Best Research Laboratory, Massachusetts College of Pharmacy and Allied Health Sciences, Boston, MA 02115.* Accepted for publication October 13, 1982. Present address: *U.E.C. Co., Ltd., Hanyang Building, Chung-ku, Seoul, Korea and ‡Department of Chemistry, Philadelphia College of Pharmacy and Science, Philadelphia, PA 19104.

Abstract □ Reaction of 2-bis(2-methylthio)vinyl-1-methylquinolinium iodide with several heterocyclic aliphatic amines at 30–70° resulted in replacement of one methylthio group to give the title compounds. Reaction with pyrrolidine gave an unidentified product lacking sulfur. Antileukemic screening against P-388 lymphocytic leukemia showed positive activity only with the 6-methyl-morpholino derivative, whereas the 6-unsubstituted morpholino derivative was inactive. This result is in contrast to previous testing results with the 2-bis(2-methylthio)vinyl compounds where both 6-substituted and 6-unsubstituted derivatives showed activity.

Keyphrases □ 2-(2-Methyl-2-aminovinyl)-1-methylquinolinium iodides—synthesis, antileukemic activity in mice □ Synthesis—2-(2-methyl-2-aminovinyl)-1-methylquinolinium iodides, antileukemic activity in mice □ Antileukemia agents—potential, 2-(2-methyl-2-aminovinyl)-1-methylquinolinium iodides, synthesis, P-388 screen in mice

A series of 6-substituted-1-methylquinolinium-2-dithioacetic acid zwitterions (I) (1, 2) has shown appreciable antileukemic activity against P-388 lymphocytic leukemia in mice. An attempt to find compounds having better solubilities, in both water and organic solvents, led to the synthesis of the derived 2-bis(2-methylthio)vinyl-1-methylquinolinium iodides (II) (3). The latter compounds had comparable antileukemic activity, but at lower dose levels than found for the zwitterions. The 6-unsubstituted derivative, however, had activity equal to or better than that of the 6-substituted compounds. Compounds with electron-attracting and electron-releasing 6-substituents were equally active in this series.

Another type of derivative of the dithioacetic acid zwitterion structure (I), which should show improved solubility properties, is the 2-methylthio-2-aminovinyl compound (III) (3). Accordingly, a series of these compounds, using several heterocyclic amines, was prepared for anticancer screening. With the exception of the previously prepared morpholino derivative where a 6-methyl substituent was included, the 6-position was left unsubstituted.

Leukemia cell culture studies were carried out with the 6-methyl derivative of II, but no effects on cell cycle traverse were observed (4). This indicated that a metabolic conversion of the bis(methylthio)vinyl compounds, and most likely their dithioacetic acid precursors as well, is required for antileukemic activity. A study of DNA-binding specificity and RNA polymerase-inhibitory activity showed that the bis(methylthio)vinyl compounds (II), as well as the 2-methylthio-2-morpholinovinyl derivative (III, R = CH_3), had DNA-binding ability involving

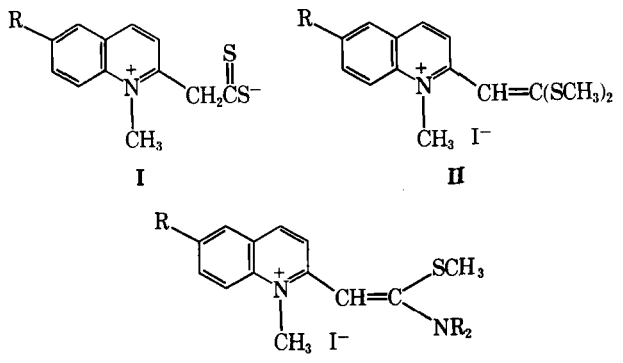
Another type of derivative of the dithioacetic acid zwitterion structure (I), which should show improved solubility properties, is the 2-methylthio-2-aminovinyl compound (III) (3). Accordingly, a series of these compounds, using several heterocyclic amines, was prepared for anticancer screening. With the exception of the previously prepared morpholino derivative where a 6-methyl substituent was included, the 6-position was left unsubstituted.

Leukemia cell culture studies were carried out with the 6-methyl derivative of II, but no effects on cell cycle traverse were observed (4). This indicated that a metabolic conversion of the bis(methylthio)vinyl compounds, and most likely their dithioacetic acid precursors as well, is required for antileukemic activity. A study of DNA-binding specificity and RNA polymerase-inhibitory activity showed that the bis(methylthio)vinyl compounds (II), as well as the 2-methylthio-2-morpholinovinyl derivative (III, R = CH_3), had DNA-binding ability involving

0022-3549/83/1100-1356$01.00/0

one binding function and inhibited RNA polymerase to a somewhat lower degree than was shown by chloroquine (5). It was believed that the function responsible for binding to DNA is the active methylene (V) resulting from loss of the bis(methylthio)methinyl moiety (4).

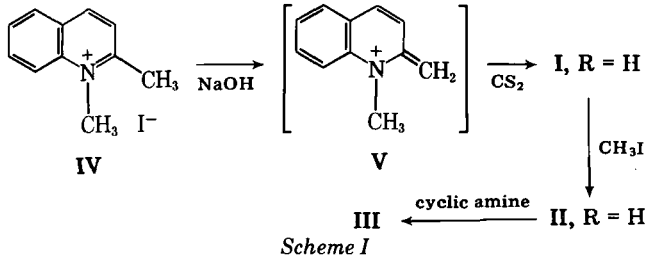


I II III

DISCUSSION

Chemistry—The 2-methylthio-2-aminovinyl-1-methylquinolinium iodides (III) were prepared from the 2-bis(2-methylthio)vinyl-1-methylquinolinium iodides (II) by reaction with the appropriate amine at 30–70°, according to the previous procedure (3). The bis(methylthio)vinyl compounds were obtained from the reaction of the dithioacetic acid zwitterions (I) by reaction with methyl iodide (6, 7); the monomethyl esters of the dithioacetic acids were never isolated in these reactions. In actual practice, preparing a solution of the methylene base (V) in dry toluene, followed by reaction with carbon disulfide in toluene, and treatment with iodomethane in dimethyl formamide, was found to be superior to isolating the intermediate zwitterion (I). The synthetic route is indicated in Scheme I.

The reaction mixtures were examined for by-products, but only the original methiodide (IV) was found. Since the method of preparation precludes the carrying along of the methiodide because it is insoluble in toluene, and there was no chromatographic or other evidence that the products contained any of the active antileukemic compound II (R = H), any antileukemic activity found should be due to structure III.



IV V

Scheme I

The NMR spectra of III generally agreed with the spectrum of the morpholino derivative already described (3). The *S*-methyl protons appeared as a singlet at δ 2.6 ppm, and the *N*-methyl peak appeared as a singlet at δ 4.1 ppm. The vinyl proton, at δ 5.5–5.6 ppm, was shielded to a considerable extent, compared with its position at δ 6.76 ppm in the bis(methylthio) compound.

It has already been pointed out (3) that this shielding provided an indication for a *trans* arrangement of the amino function, with partial involvement of charge on the morpholino nitrogen. Calculations by the Tobey–Simon Rule (8) agreed with a *trans* structure.

The reduced heterocyclic amines employed in this synthesis gave variable yields of crystalline products. In the case of 2-methylpiperazine, only a 14% yield was realized, probably due to steric hindrance of the methyl. It is assumed that the nitrogen at the greater distance from the methyl was involved in replacing *S*-methyl, since less steric hindrance would result in the product. Reaction with pyrrolidine gave a product having no sulfur whose structure was not that of a nucleophilic replacement of the bis(methylthio)methinyl moiety by pyrrole. Nucleophilic replacement of the bis(methylthio)methinyl moiety by amines has been observed by Mizuyama *et al.* (9).

[a] CD_2F_1 mice were inoculated with P-388 lymphocytic leukemia cells. [b] Drugs were administered intraperitoneally on days 1, 5, and 9. [c] Test group minus control group. [d] A T/C% value of ≥125 is considered a positive result.

Antileukemia Test Results—Antileukemia testing was performed at the National Cancer Institute using P-388 lymphocytic leukemia in mice according to their protocol (10). Details regarding dose and survival time are listed in Table I.

Positive activity was shown in this series only by the *N*-morpholino-6-methyl derivative (3). The *N*-morpholino derivative lacking the 6-methyl was inactive. This result is in contrast with testing data for the dithioacetic acid zwitterions (2) and the bis(methylthio)vinyl derivatives (3) where activity was found with both the 6-substituted and 6-unsubstituted derivatives. It is possible that in this (methylthioamino)vinyl series, the antileukemic activity does not depend on the formation of the active methylene compound (V) but on binding to nucleic acid or other macromolecules involving the morpholine moiety. Equilibrium binding constants to calf thymus DNA for several of the bis(methylthio)vinyl derivatives were lower than for the *N*-morpholino-6-methyl compound (5). Also, the (methylthioamino)vinyl group, a tautomeric form of a thioamide, should be more stable to hydrolysis than the ketene thioacetals.

EXPERIMENTAL[1]

1-Methyl-2-[2-methylthio-2-(1-morpholino)vinyl]-quinolinium Iodide—To a suspension of 2-bis(2-methylthio)vinyl-1-methylquinolinium iodide (2.70 g, 0.007 mole) (2), in 50 ml of dimethylformamide was added an equimolar amount of morpholine (0.61 g, 0.007 mole). The mixture was stirred at 70° for 2 hr and then at 50° for 17 hr. The reaction was monitored by TLC (chloroform–methanol, 95:5). After it was cooled, the mixture was diluted with toluene (300 ml) and stored at 0°.

The precipitate was collected and dissolved in acetone, treated twice with charcoal, and the solvent was evaporated. The orange crystalline product was recrystallized from absolute ethanol to give 1.8 g (60%), m.p. 198–200°. ^{1}H-NMR: δ 2.60 (s, 3, SCH_3), 3.70 (s, br, 8, morpholino), 4.09 (s, 3, NCH_3), 5.59 (s, 1, vinyl), and 7.6–8.2 ppm (m, 6, aromatic).

Anal.—Calc. for $C_{17}H_{21}IN_2OS$: C, 47.67; H, 4.94; N, 6.54; S, 7.48. Found: C, 47.52; H, 5.07; N, 6.43; S, 7.59.

1-Methyl-2-[2-methylthio-2-(4-thiomorpholino)vinyl]-quinolinium Iodide—To a suspension of II (R = H) (2.72 g, 0.007 mole) in 50 ml of dimethylformamide was added freshly distilled thiomorpholine (1.33 g, 0.013 mole), and the mixture was stirred at 35° for 4 days. The reaction was monitored by TLC (chloroform–methanol 9:1). It was diluted with anhydrous ether (200 ml) and stored at 0° for 2 hr.

The precipitate was collected and recrystallized twice from 1-propanol using charcoal, giving 2.0 g (69%) of orange crystals, m.p. 203–205°.

[1] Melting points were determined in capillaries with a Mel-Temp block and are uncorrected. ^{1}H-NMR spectra were obtained with a Varian T-60 spectrometer using DMSO-d_6 as solvent and tetramethylsilane as internal standard. IR spectra were obtained with a Perkin–Elmer model 457A grating spectrophotometer using KBr pellets. Elemental analyses were done by F. B. Strauss, Oxford, England. TLC was carried out using silica gel plates, and products were detected by exposure to iodine vapor. Organic reagents were supplied by Aldrich Chemical Co. or Eastman Organic Chemicals.

^{1}H-NMR: δ 2.60 (s, 3), 2.9 (d, br, 4), 4.0 (d, br, 4), 4.10 (s, 3), 5.60 (s, 1), and 7.6–8.2 ppm (m, 6).

Anal.—Calc. for $C_{17}H_{21}IN_2S_2$: C, 45.94; H, 4.76; N, 6.30. Found: C, 45.59; H, 4.79; N, 6.32.

1-Methyl-2 - [2-methylthio-2-(1-piperidino)vinyl] - quinolinium Iodide—To a suspension of II (R = H) (2.72 g, 0.007 mole) in 25 ml of dimethyl sulfoxide was added freshly distilled piperidine (1.0 g, 0.012 mole), and the mixture was stirred at 30° for 5 days. It was treated as in the previous procedure, and the crude precipitate was dissolved in 1-propanol (300 ml), treated with charcoal, and filtered while hot. This procedure was repeated three times, and the combined filtrates were evaporated to dryness under reduced pressure. The residue was recrystallized from 2-propanol to give 2.70 g (90%) of orange crystals, m.p. 195–196°. ^{1}H-NMR: δ 1.75 (s, 6), 2.63 (s, br, 3), 3.81 (s, br, 4), 4.10 (s, 3), 5.55 (s, 1), and 7.6–8.2 ppm (m, 6).

Quantitative Analysis of Ethchlorvynol in a Capsule Dosage Form by NMR Spectroscopy

KAREN B. FEKETY ˣ **and THOMAS MEDWICK**

Received July 19, 1982, from the *College of Pharmacy, Rutgers University, Piscataway, NJ 08854.* Accepted for publication October 14, 1982.

Abstract □ A quantitative ^{1}H-NMR procedure is described for measuring ethchlorvynol in capsules. Deuterochloroform is used as the solvent, and hexamethylenetetramine as the internal standard; the analysis is based on the comparison of the area of the AB peak system of ethchlorvynol with the area of the hexamethylenetetramine singlet. The ^{1}H-NMR method yields results that are precise to within 1% and agree well with results of the more cumbersome and less specific USP titrimetric procedure.

Keyphrases □ Ethchlorvynol—NMR quantitative analysis, capsule dosage form □ NMR quantitative analysis—ethchlorvynol, capsule dosage form

Ethchlorvynol (I), a nonbarbiturate hypnotic, is a tertiary acetylenic carbinol (1-chloro-3-ethyl-1-penten-4-yn-3-ol). The official USP XX procedure for the analytical determination of this drug substance, both alone and in its pharmaceutical dosage form, is based on the reaction of I with excess silver nitrate, producing the silver acetylide and nitric acid (1, 2). The resultant acid is immediately titrated with ~0.05 *N* NaOH; however, end point determination with the methyl red–methylene blue indicator is hampered by the precipitation of the silver acetylide. According to the official procedure, capsules must be weighed, carefully opened, emptied, and reweighed, with the difference taken as the capsule contents. The difficult end point and sample manipulations often lead to poor results.

Although there are several procedures published for the determination of I in biological fluids (3–8), there are only two other published methods for its determination in the pharmaceutical dosage form. Davidson (9), proposed a GLC analysis, accepted by the AOAC (10), and that uses 1,3-dichloro-2-propanol as an internal standard; a standard deviation range of 1.3–2.9% on assays of known solutions and the 500-mg capsule dosage form is reported. Drawbacks inherent in this procedure include the need for column preparation and overnight conditioning and the necessity of injecting a I standard (purified by vacuum distillation and quantified by the USP XX titrimetric procedure) along with the unknown solutions. Rizk and associates (11) proposed a colorimetric method for the determination of certain monosubstituted acetylenic hypnotic drugs, including I. In this procedure, silver acetylide

Quantitative Analysis of Ethchlorvynol in a Capsule Dosage Form by NMR Spectroscopy

KAREN B. FEKETY ˣ **and THOMAS MEDWICK**

Received July 19, 1982, from the *College of Pharmacy, Rutgers University, Piscataway, NJ 08854.* Accepted for publication October 14, 1982.

Abstract □ A quantitative ^{1}H-NMR procedure is described for measuring ethchlorvynol in capsules. Deuterochloroform is used as the solvent, and hexamethylenetetramine as the internal standard; the analysis is based on the comparison of the area of the AB peak system of ethchlorvynol with the area of the hexamethylenetetramine singlet. The ^{1}H-NMR method yields results that are precise to within 1% and agree well with results of the more cumbersome and less specific USP titrimetric procedure.

Keyphrases □ Ethchlorvynol—NMR quantitative analysis, capsule dosage form □ NMR quantitative analysis—ethchlorvynol, capsule dosage form

Ethchlorvynol (I), a nonbarbiturate hypnotic, is a tertiary acetylenic carbinol (1-chloro-3-ethyl-1-penten-4-yn-3-ol). The official USP XX procedure for the analytical determination of this drug substance, both alone and in its pharmaceutical dosage form, is based on the reaction of I with excess silver nitrate, producing the silver acetylide and nitric acid (1, 2). The resultant acid is immediately titrated with ~0.05 *N* NaOH; however, end point determination with the methyl red–methylene blue indicator is hampered by the precipitation of the silver acetylide. According to the official procedure, capsules must be weighed, carefully opened, emptied, and reweighed, with the difference taken as the capsule contents. The difficult end point and sample manipulations often lead to poor results.

Although there are several procedures published for the determination of I in biological fluids (3–8), there are only two other published methods for its determination in the pharmaceutical dosage form. Davidson (9), proposed a GLC analysis, accepted by the AOAC (10), and that uses 1,3-dichloro-2-propanol as an internal standard; a standard deviation range of 1.3–2.9% on assays of known solutions and the 500-mg capsule dosage form is reported. Drawbacks inherent in this procedure include the need for column preparation and overnight conditioning and the necessity of injecting a I standard (purified by vacuum distillation and quantified by the USP XX titrimetric procedure) along with the unknown solutions. Rizk and associates (11) proposed a colorimetric method for the determination of certain monosubstituted acetylenic hypnotic drugs, including I. In this procedure, silver acetylide

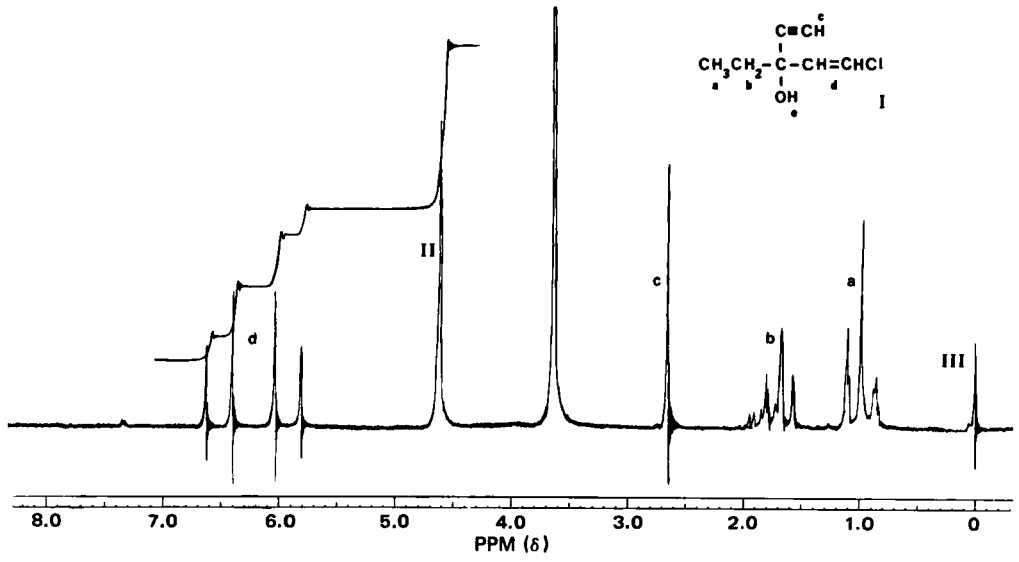

Figure 1—*^{1}H-NMR spectrum of ethchlorvynol in deuterochloroform. Key: (II) hexamethylenetetramine (internal standard); (III) tetramethylsilane.*

is formed and extracted into 4-methyl-2-pentanone, and after acidification, an equivalent amount of silver ions is liberated and assayed colorimetrically as silver dithizonate (λ_{max} = 472 nm). Although the method claims a standard deviation of 1.5–2.9%, it is complicated by the need for a calibration curve for silver nitrate and an involved extraction procedure.

The procedure proposed in this study utilizes quantitative ^{1}H-NMR. Rucker and Natarajan (12) used NMR spectroscopy to quantitatively determine nine sedatives (including I) in mixtures using calibration curves obtained from the responses of standard solutions. However, this study describes the use of an internal standard, which results in a simple, rapid, specific, precise, and accurate analytical method.

EXPERIMENTAL

Materials—The following were used: internal standard, hexamethylenetetramine (methenamine USP), 100.05%, 30 mesh (II)[1]; reference standard, tetramethylsilane (III)[2]; solvent, deuterochloroform, 99.8% D[3] (IV). Ethchlorvynol capsules, 500 mg and 750 mg, were obtained from commercial sources.

Procedure—An individual capsule of I was placed into a suitable glass-stoppered vessel for cutting (*e.g.*, a weighing bottle). With a dissecting scalpel, the capsule was cut cleanly in half, and the blade was rinsed with a few drops of IV to ensure recovery of the entire capsule contents. The appropriate amount of accurately weighed II (~80 mg for a 500-mg capsule and 120 mg for a 750-mg capsule) was added to the container, followed by ~3 ml of IV. The container was stoppered and shaken to ensure complete dissolution of II. The solution was transferred to a glass syringe fitted with a filter apparatus[4], and ~0.5 ml was filtered directly into a standard 5-mm analytical NMR tube. A drop of III was added as needed to reference the peak field positions to 0 ppm on the δ scale. The tube was placed into an NMR spectrometer[5], and the spectrum was obtained adjusting the spin rate so that no spinning side bands interfered with the peaks of interest. The peaks were integrated at 5.81, 6.05, 6.40, and 6.62 ppm and the singlet at 4.65 ppm, not fewer than five times, taking care to avoid saturation.

[1] Merck and Co., Rahway, N.J.
[2] Aldrich Chemical Co., Milwaukee, Wis.
[3] Sci-Graphics, Wayne, N.J.
[4] A Millipore HA filter type 0.45 μm and a 2-ml B-D Yale Luerlok glass syringe.
[5] A Varian A-60 NMR spectrometer, equipped with a V-6031 variable temperature probe having a six-turn insert was used. All spectra were scanned at a probe temperature of 42°.

The amount of I per capsule was calculated as follows:

$$\text{mg of I/capsule} = \text{mg of II} \times (\text{Au/As}) \times (\text{Eu/Es})$$

where Au is the integral value representing I (5.81, 6.05, 6.40, and 6.62 ppm), As is the integral representing II (4.65 ppm), Eu is the proton equivalent weight of I (FW/2 = 72.305), and Es is the proton equivalent weight of II (FW/12 = 11.683).

RESULTS AND DISCUSSION

The solubility of ethchlorvynol (I) and hexamethylenetetramine (II) in deuterochloroform (IV) and the insolubility of the capsule shell makes this solvent a good choice for this ^{1}H-NMR procedure. Although the actual formulation of the dosage form is unknown to the authors, the only peak not ascribable to I occurs at 3.60 ppm and does not interfere with the spectrum of I. Filtration of the solution removes undissolved material, since the unfiltered samples leave difficult-to-remove beadlets in the NMR tube. Filtering the sample does not affect the analytical results, as evidenced by studies of samples before and after filtration.

The ^{1}H-NMR spectrum for I with the addition of II is seen in Fig. 1. The assignments made in this work are in agreement with the limited assignments made by Rucker and Natarajan (12) for the ^{1}H-NMR spectrum of I. For I, the resonances, characteristic of an AB system (d) at δ 5.81, 6.06, 6.40, and 6.62 ppm, correspond to the olefinic protons in the molecule. The methylene protons (b) are not chemically equivalent because of the adjacent asymmetric carbon atom, and therefore are split into 2 quartets (band center δ 1.67 ppm) by the methyl protons; the methyl protons (a) are seen as a triplet centered at δ 1.00 ppm. The acetylenic hydrogen (c) resonates as a singlet at δ 2.62 ppm. The broad based peak at δ 3.60 ppm appears to be a consequence of the formulation and may be a polar material that exchanges with the hydroxyl proton (e) of I. Compound II exhibits only one resonance signal at δ 4.65 ppm, since all 12 of its protons are equivalent. Finally, a very small peak from an impurity in IV is seen at δ 7.32 ppm. All chemical shifts are measured with respect to III at 0 ppm.

The quantitative analysis of I is based on the integration of the area of the AB system quartet which is compared with the area arising from the singlet for II. Summaries of the analyses of a series of both the 500- and 750-mg commercial capsules appear in Tables I and II, respectively. As the results indicate, the ^{1}H-NMR method is both precise, with a relative standard deviation of ~1%, and accurate, as evidenced by the good agreement of the ^{1}H-NMR results in comparison with samples analyzed by the official USP procedure.

The potential value of the proposed ^{1}H-NMR procedure in the analysis of dosage forms of I is established by these measurements, with no evidence of interference from other capsule components or the capsule shell. Blank systems including only the solvent and the capsule shell, with and without the internal standard, showed that no signals are derived from the capsule shell ingredients. This analytical measurement by quantitative ^{1}H-NMR circumvents the lengthy manipulations inherent in the

2,3-Dihydro-4*H*-1-benzopyran-4-one *O*-Carbamoyloximes, a Series of Gastric Antisecretory Agents

GEORGE C. WRIGHT ˣ, THOMAS J. SCHWAN, MARVIN M. GOLDENBERG, and RONALD E. WHITE

Received May 28, 1982, from the *Division of Biological and Chemical Research, Research and Development, Norwich Eaton Pharmaceuticals, Inc., Norwich, NY 13815.* Accepted for publication September 3, 1982.

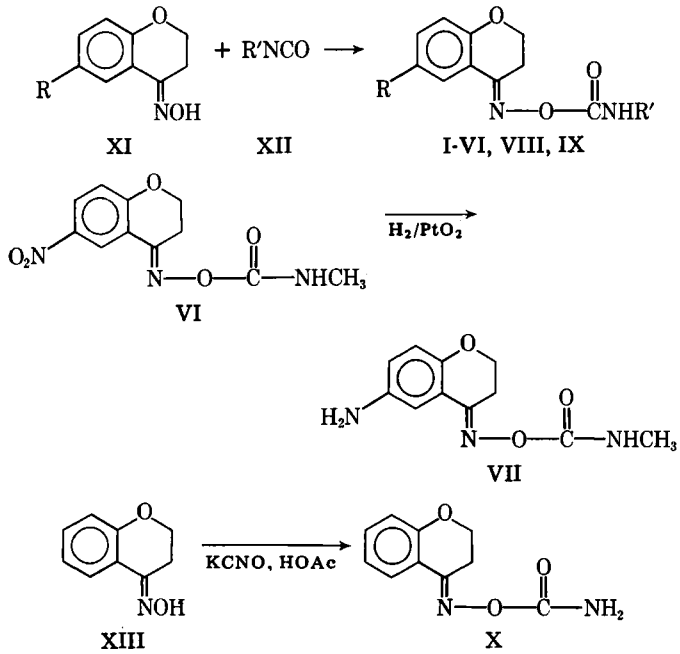
Abstract □ A series of 2,3-dihydro-4*H*-1-benzopyran-4-one *O*-carbamoyloximes were synthesized and evaluated for gastric antisecretory activity in a pylorus-ligated rat model. Various substituents in the 6-position did not afford any compounds more active than I.

Keyphrases □ 2,3-Dihydro-4*H*-1-benzopyran-4-one *O*-carbamoyloximes—synthesis, antisecretory activity, pylorus-ligated rats □ Antisecretory agents, gastric—potential, 2,3-dihydro-4*H*-1-benzopyran-4-one *O*-carbamoyloxime series, synthesis, evaluation in pylorus-ligated rats □ Synthesis—2,3-dihydro-4*H*-1-benzopyran-4-one *O*-carbamoyloxime series, gastric antisecretory activity, pylorus-ligated rats

To identify novel agents acting on the GI tract, 10 members of a series of 2,3-dihydro-4*H*-1-benzopyran-4-one *O*-carbamoyloximes were synthesized and evaluated for gastric antisecretory activity (1).

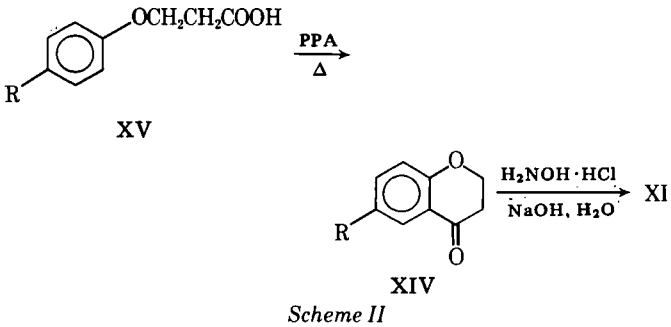
RESULTS AND DISCUSSION

Chemistry—Eight compounds (I–VI, VIII, and IX; Table I) were prepared by the reaction of the appropriate oxime XI with the isocyanate XII (Scheme I). The amine VII (Table I) was obtained by catalytic hydrogenation of the corresponding nitro compound VI (Table I, Scheme I), while acid-catalyzed reaction of XIII with potassium cyanate gave X (Scheme I).



Scheme I

The intermediate oximes XIa–d (Table II) were prepared from the corresponding 2,3-dihydro-4*H*-benzopyran-4-ones (XIV) (Scheme II), which were synthesized by ring closure of the corresponding 3-phenoxypropanoic acids (XV) with polyphosphoric acid, as described by Parham and Huestis (2).



Scheme II

Pharmacology—Compounds I–V and VII exhibited marked antagonism of total gastric acid output in pylorus-ligated rats. Compounds VIII–X showed moderate antagonism, while VI was inactive (Table III). Dose–response determinations of the 10 compounds revealed that I was most potent in inhibiting total gastric acid output as exemplified by a low ID_{50} value of 5.7 mg/kg p.o. Compounds II–V were also active in reducing gastric acid output with ID_{50} values of 22.1–22.7 mg/kg p.o. No evidence of toxicity was noted at their respective ID_{50} values.

EXPERIMENTAL[1]

Synthesis—*2,3-Dihydro-6-nitro-4*H*-1-benzopyran-4-one Oxime (XI d)*—To a solution of hydroxylamine hydrochloride (79 g, 1.14 moles) in water (770 ml) were added 10% NaOH (619 ml) and 2,3-dihydro-6-nitro-4*H*-benzopyran-4-one (150 g, 0.78 mole) (3, 4). Sufficient ethanol–ether (95:5) (750 ml) was added to give a solution at reflux. The mixture was refluxed for 25 min, cooled to 50° over 2 hr, and the resultant tan crystals were collected by filtration and washed with ethanol–ether (95:5) to give 60 g, mp 173–178°. Recrystallization from benzene gave material with a melting point of 185–186° in 27% yield.

*2,3-Dihydro-6-nitro-4*H*-1-benzopyran-4-one O-(Methylaminocarbonyl)oxime (VI)*—A mixture of XI d (19 g, 0.09 mole) and benzene was refluxed for 45 min in a flask equipped with a Dean Stark trap. Heating was discontinued and *N,N*-diethylethanamine (0.5 ml) was added, followed by a solution of methyl isocyanate (7.3 g, 0.10 mole) in benzene (30 ml). The mixture was refluxed for 3 hr and then stored at room temperature for 3 days. The material was collected by filtration, stirred in absolute ethanol (150 ml), and cooled overnight to give, after filtration, 16 g of VI.

An analytical sample was prepared by recrystallization from absolute ethanol (Table I); IR (mineral oil): 2.98 (NH) and 5.73 μm (C=O); ^{1}H-NMR: 2.80 (d, 3, CH_3, collapsed to singlet on exchange with D_2O), 3.10 and 4.45 (2 t, J = 6.4 Hz, 4, CH_2CH_2), 6.21 (d, J = 9.2 Hz, 1, aromatic), 7.27 (dd, $J_{5,7}$ = 2.7 Hz, $J_{7,8}$ = 9.2 Hz, 1, aromatic), 7.98 (d, J = 2.7 Hz, 1, aromatic), and 6.77 ppm (broad, 1, NH, exchanged with D_2O).

Similarly prepared were I–IV, VIII, and IX (Table I). In the case of V, filtration of the reaction mixture provided the product directly (Table I).

*6-Amino-2,3-dihydro-4*H*-1-benzopyran-4-one O-(Methylaminocarbonyl)oxime Hydrochloride (VII)*—A mixture of VI (4.0 g, 0.016 mole) and ethanol (400 ml) was shaken with hydrogen in the presence of platinum oxide (0.20 g) until the theoretical quantity of hydrogen was consumed (21 hr). The catalyst was removed by filtration, and the filtrate was cooled in an ice bath and treated with ethanolic hydrogen chloride.

[1] Melting points were determined on a Mel-Temp apparatus, and those below 230° were corrected. IR spectra were determined as Nujol mulls on a Perkin-Elmer 137B spectrophotometer, and NMR spectra were determined on a Varian A-60A spectrometer in dimethyl sulfoxide-d_6 with tetramethylsilane as an internal standard.

[a] For intermediate 6-chloro-2,3-dihydro-4*H*-1-benzopyran-4-one, see Ref. 3 and 4. [b] See Ref. 1.

The solution was concentrated to a volume of 70 ml and cooled. The product was removed by filtration. IR (mineral oil): 2.90 (NH_2) and 5.70 μm (C=O); ^{1}H-NMR: 2.73 (d, 3, CH_3, collapsed to singlet in D_2O), 3.00 and 4.30 (2 t, J = 6.4 Hz, 4, CH_2CH_2), 7.07 (d, J = 9.0 Hz, 1, aromatic), 7.48 (dd, $J_{5,7}$ = 2.7 Hz, $J_{7,8}$ = 8.8 Hz, 1, aromatic), 8.06 (d, J = 2.7 Hz, 1, aromatic), 7.7 (broad, 2, NH_2, exchanged with D_2O), and 6.82 ppm (broad, 2, NH and HCl).

*2,3-Dihydro-4*H*-1-benzopyran-4-one O-(Aminocarbonyl)oxime* (*X*)—To a solution of the oxime (XI a) (8.15 g, 0.05 mole) in glacial acetic acid (175 ml) at ambient temperature was added a solution of potassium cyanate (4.05 g, 0.05 mole) in water (20 ml). The solution was stirred at ambient temperature for 48 hr, diluted with 200 ml of water, and extracted with chloroform (2 × 150 ml). The combined extracts were dried (magnesium sulfate), concentrated to dryness *in vacuo*, and the residue was recrystallized from methylbenzene (40 ml) to give the product (Table I); IR (mineral oil): 2.83 and 2.90 (NH_2) and 5.67 μm (C=O); ^{1}H-NMR: 3.01 and 4.28 (2 t, J = 6.8 Hz, 4, CH_2CH_2), 7.27 (m, 4, aromatic and NH_2), and 8.22 ppm (d, J = 2.0 Hz, 2, aromatic).

Pharmacology—Male Sprague–Dawley rats, each weighing 180–210 g and previously fasted for 24 hr, were used in the modified, standard pylorus-ligated gastric secretory model. All compounds were given perorally, as suspensions in 0.5% methyl cellulose[2], 1 hr prior to pylorus

[2] Methocel.

X	3	100	2.22 ± 0.055	39	0.014 ± 0.091	23	50.4 (30.1–127.1)

[a] The control values were obtained by peroral administration of 0.50% methylcellulose solution to a group of rats at 1 ml/100 g % body weight. [b] Compared to control (nondrug-treated) reading 4 hr after pylorus-ligation of rat stomach. [c] The dose eliciting 50% inhibition of total gastric acid output; calculated from data obtained at doses of 10, 30, and 100 mg/kg p.o., by method of linear regression analysis (5) of the dose–response curve.

ligation. Under light ether anesthesia, the rat stomach was ligated at the pylorus region. The conscious rat was sacrificed by a chloroform overdose 4 hr after ligation. The stomach was carefully excised and its contents drained into a centrifuge tube. Samples were centrifuged to separate secretions from debris, and gastric fluid volume was read and recorded. Titration was performed on a sample aliquot of 1 ml diluted to a volume of 5 ml using distilled water. The titrant used was 0.1 *N* NaOH. Acid concentration in the stomach was determined by titration to pH 7. Total gastric acid output was calculated as the product of volume of gastric secretions and acid concentration for each compound tested.

Effect of Nutrient Depletion on the Sensitivity of *Pseudomonas cepacia* to Antimicrobial Agents

R. M. COZENS * **and M. R. W. BROWN** ˣ

Received June 28, 1982, from the *Microbiology Research Group, Department of Pharmacy, University of Aston in Birmingham, Birmingham B4 7ET, England.* Accepted for publication October 7, 1982.

* Present address: CIBA-GEIGY Ltd., Infectious Diseases Research, Basle, CH-4002 Switzerland.

Abstract □ *Pseudomonas cepacia* depleted of various nutrients showed marked variation in sensitivity to cetrimide, chlorhexidine, and benzalkonium chloride. In all cases cells depleted of magnesium were the most resistant. It is proposed that these observations may be due to alterations of the envelope of *P. cepacia* in response to changes in the growth environment. This may have profound implications for investigations of the resistance of this organism both *in vivo* and *in vitro*.

Keyphrases □ Nutrient depletion—effect of senstivity of *Pseudomonas cepacia* to antimicrobial agents □ Antimicrobial agents—effect of nutrient depletion on sensitivity of *Pseudomonas cepacia* □ *Pseudomonas cepacia*—effect of nutrient depletion on sensitivity to antimicrobial agents

Pseudomonas cepacia, previously considered as only a plant pathogen, has, in the last decade, been implicated in nosocomial infections with increasing frequency (1–3). The organism is more resistant to most useful antimicrobial agents than other Gram-negative bacteria. It is capable of survival and even multiplication in quaternary ammonium compounds (2, 4, 5) and will multiply in distilled or deionized water (6, 7).

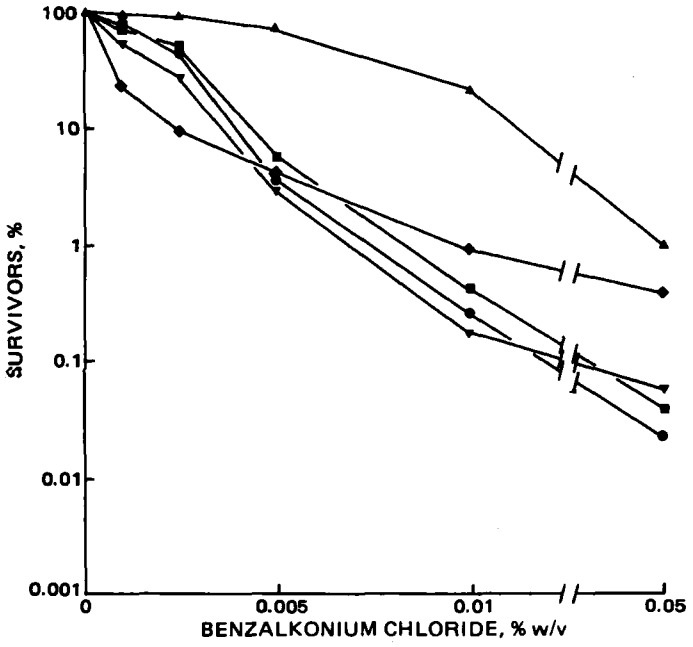

Figure 1—*The effect of benzalkonium chloride on cells of* P. cepacia *depleted of glucose (●), magnesium (▲), and ammonium (■), phosphate (◆), and ferrous ions (▼).*

The relationship between susceptibility to antimicrobial agents and the growth environment has been recognized for some time (8). Brown (9) has emphasized the need for the use of nutritionally defined cultures for the investigation of the response of bacteria to antimicrobial agents and host defense mechanisms. As *P. cepacia* in its natural environment or as a contaminant of disinfectant solutions is probably depleted of an essential nutrient (9), the use of cultures depleted in this way would possibly be more relevant in investigations of the extreme resistance of this organism. This paper describes the effect of nutrient depletion on the resistance of *P. cepacia* to some common antimicrobial agents.

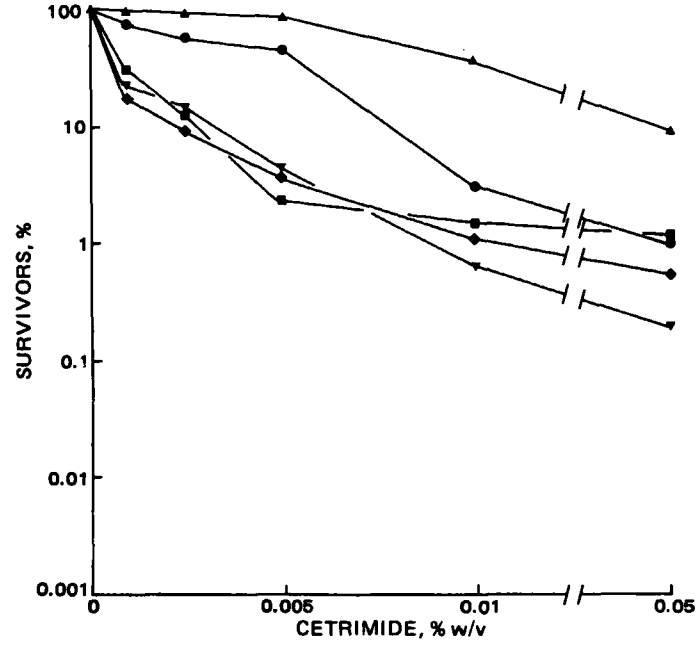

Figure 2—*The effect of cetrimide on cells of* P. cepacia *depleted of various nutrients (see Fig. 1 for key).*

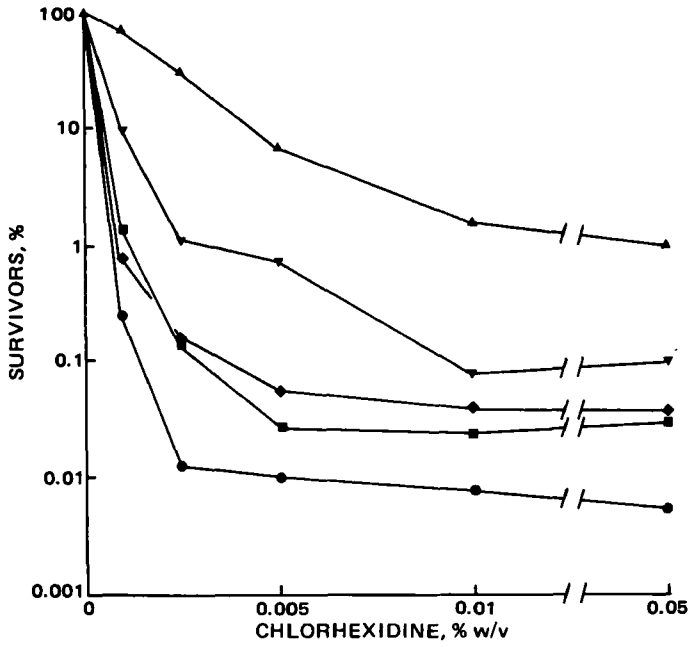

Figure 3—*The effect of chlorhexidine on cells of* P. cepacia *depleted of various nutrients (see Fig. 1 for key).*

EXPERIMENTAL

Organism—*Pseudomonas cepacia* NCTC 10661 was used throughout. Cultures were maintained by monthly subculture on nutrient agar slopes stored at 4°. The basic medium contained 20 m*M* of glucose, 12 m*M* of $(NH_4)_2SO_4$, 1.2 m*M* of K_2HPO_4, 3.2 m*M* of $MgSO_4 \cdot 7H_2O$, 0.02 m*M* of $FeSO_4 \cdot 7H_2O$, 3 m*M* of NaCl, 3 m*M* of KCl, and 50 m*M* of 3-(*N*-morpholino)propanesulfonic acid (I), pH 7.4. Chemicals[1] were of the purest grade available.

For nutrient depletion studies the concentrations were separately adjusted: 2.0 m*M* of glucose, 0.5 m*M* of $(NH_4)_2SO_4$, 0.1 m*M* of K_2HPO_4, 0.01 m*M* of $MgSO_4 \cdot 7H_2O$, and no added iron to give the respective depletions. These concentrations allowed the cultures to reach maximum exponential phase at A_{470} = 0.5. Cultures (25 ml) were grown in baffled 100-ml Erlenmeyer flasks at 37° in a reciprocal shaking water bath at 120 throws/min.

Resistance to Antibacterial Agents—Cells grown under various nutrient depletions, as described above, were harvested by centrifugation, washed twice in saline buffered with I (pH 7.4) and finally resuspended to a A_{470} = 1.0. Cell suspension (0.1 ml) was added to 9.9 ml of various concentrations of drug (cetrimide[1], benzalkonium chloride[2], chlorhexidine gluconate[3]) prepared in saline buffered with (I). After 15 min at 37° samples were removed, the drugs inactivated by dilution in lecithin–polysorbate 80 broth, and suitable dilutions were incorporated into pour plates of nutrient agar. The plates were incubated for 36 hr at 37° before counting the resulting colonies.

RESULTS AND DISCUSSION

Figures 1–3 show the variation in sensitivity to antibacterial agents when the depleting nutrient was altered. In all cases, cells depleted of magnesium showed the greatest resistance to the action of these agents. Of the other depletions examined, the resistances against benzalkonium chloride and cetrimide showed little variation. Chlorhexidine showed a wider spread of activity, with glucose-depleted cells being the most sensitive.

Al-Hiti and Gilbert (10) have shown that those organisms specified for use in the USP XIX test for the effectiveness of antimicrobial preservatives exhibited a changed sensitivity to chlorhexidine diacetate and benzalkonium chloride, when depleted of different nutrients. The results described here show that *P. cepacia* exhibits similar changes in sensitivity to antimicrobial agents caused by different nutrient depletions.

[1] BDH Chemicals, Poole, UK. Listed in The British Pharmacopoeia as mainly tetradecyltrimethylammonium bromide with smaller amounts of dodecyl- and hexadecyltrimethylammonium bromide.
[2] Sigma, Poole, UK.
[3] ICI Ltd., Macclesfield, UK.

The cell envelope, and particularly the outer membrane, of Gram-negative bacteria is known to change in response to changes in the growth environment (8, 11, 12). It is therefore likely that these changes in resistance may reflect changes in the cell envelope which either prevent access of the drug to the site of action or alter the site of action such that the drugs show decreased activity. Little is known about the cell envelope of *P. cepacia*. The lipopolysaccharide is atypical, not containing 2-keto-3-deoxyoctonate and with several quantitative differences in the sugar moieties (13). The cellular fatty acid compositions (mostly derived from the envelope phospholipids) of *P. cepacia* and *Pseudomonas aeruginosa* differ in that the former has proportionately more cyclopropane fatty acids than does the latter (14).

Mean Hepatic Transit Time in the Determination of Mean Absorption Time

Keyphrases □ Mean hepatic transit time—determination of mean absorption time, pharmacokinetics □ Mean absorption time—determination by mean hepatic transit time, pharmacokinetics □ Pharmacokinetics—mean hepatic transit time, mean absorption time, mean residence time

To the Editor:

In recent studies the statistical moment theory has been employed to estimate mean absorption time (MAT) of drugs (1–5). The MAT has been defined as the mean time of a molecule (1) or the mean residence time (MRT) of all molecules (2) from a dosage form (such as solution or tablet) spent at the input site (GI lumen in the case of oral administration) before being absorbed into the general circulation. The MAT after oral administration has been calculated based on the following equation (1–5):

$$MAT = MRT_{po} - MRT_{iv} \qquad \text{(Eq. 1)}$$

where MRT_{po} is the MRT of the orally absorbed drug molecules in the body, and MRT_{iv} is the MRT of intravenously (usually from a peripheral vein in the leg or arm) administered drug molecules in the body. Both plasma and urinary excretion data have been proposed to estimate the MRT_{po} and MRT_{iv}. When a solution dosage form is studied, the calculated MAT has been referred to as mean intrinsic absorption time (5). When both solution and solid dosage forms are evaluated, the difference in their MRT may be considered to equal the mean *in vivo* dissolution time (MDT) from the solid dosage form. This is based on the assumption that once released from the solid dosage form, it is subject to the same influence as the drug administered in solution (1–3).

The main purpose of this communication is to discuss a complication in using Eq. 1 to determine the MAT. Its potential significance in absorption rate calculations and hepatic clearance studies will also be briefly mentioned. In analogy to the above assumption requirement in the determination of MDT, use of Eq. 1 must also require that the orally absorbed drug is handled in the body exactly the same way as that administered intravenously. This demand apparently can not be met because the orally absorbed drug has to pass through the GI wall and then the liver before entering the heart, while the intravenously administered drug can be carried almost instantaneously from the injection site to the heart before being distributed to the rest of body. The mean time to pass through the GI wall and liver can be called mean GI wall transit time, MTT_{GI}, and mean hepatic transit time, MTT_h, respectively. The portal circulation between the GI wall and liver is extremely fast and can be ignored. Therefore, Eq. 1 can be modified to:

$$MAT = MRT_{po} - MRT_{iv} - MTT_{GI} - MTT_h \qquad \text{(Eq. 2)}$$

The MTT in a tissue or organ during a single passage can be determined directly by instantaneous injection of a compound into the affluent blood and monitoring of effluent blood concentration, C_{out}, under the single-pass nonrecirculating condition (6–8):

$$MTT = \frac{\int_0^\infty tC_{out}dt}{\int_0^\infty C_{out}dt} \qquad \text{(Eq. 3)}$$

0022-3549/83/1100-1365$01.00/0

The cell envelope, and particularly the outer membrane, of Gram-negative bacteria is known to change in response to changes in the growth environment (8, 11, 12). It is therefore likely that these changes in resistance may reflect changes in the cell envelope which either prevent access of the drug to the site of action or alter the site of action such that the drugs show decreased activity. Mean Hepatic Transit Time in the Determination of Mean Absorption Time

Keyphrases □ Mean hepatic transit time—determination of mean absorption time, pharmacokinetics □ Mean absorption time—determination by mean hepatic transit time, pharmacokinetics □ Pharmacokinetics—mean hepatic transit time, mean absorption time, mean residence time

To the Editor:

In recent studies the statistical moment theory has been employed to estimate mean absorption time (MAT) of drugs (1–5). The MAT has been defined as the mean time of a molecule (1) or the mean residence time (MRT) of all molecules (2) from a dosage form (such as solution or tablet) spent at the input site (GI lumen in the case of oral administration) before being absorbed into the general circulation. The MAT after oral administration has been calculated based on the following equation (1–5):

$$MAT = MRT_{po} - MRT_{iv} \qquad \text{(Eq. 1)}$$

where MRT_{po} is the MRT of the orally absorbed drug molecules in the body, and MRT_{iv} is the MRT of intravenously (usually from a peripheral vein in the leg or arm) administered drug molecules in the body. Both plasma and urinary excretion data have been proposed to estimate the MRT_{po} and MRT_{iv}. When a solution dosage form is studied, the calculated MAT has been referred to as mean intrinsic absorption time (5). When both solution and solid dosage forms are evaluated, the difference in their MRT may be considered to equal the mean *in vivo* dissolution time (MDT) from the solid dosage form. This is based on the assumption that once released from the solid dosage form, it is subject to the same influence as the drug administered in solution (1–3).

The main purpose of this communication is to discuss a complication in using Eq. 1 to determine the MAT. Its potential significance in absorption rate calculations and hepatic clearance studies will also be briefly mentioned. In analogy to the above assumption requirement in the determination of MDT, use of Eq. 1 must also require that the orally absorbed drug is handled in the body exactly the same way as that administered intravenously. This demand apparently can not be met because the orally absorbed drug has to pass through the GI wall and then the liver before entering the heart, while the intravenously administered drug can be carried almost instantaneously from the injection site to the heart before being distributed to the rest of body. The mean time to pass through the GI wall and liver can be called mean GI wall transit time, MTT_{GI}, and mean hepatic transit time, MTT_h, respectively. The portal circulation between the GI wall and liver is extremely fast and can be ignored. Therefore, Eq. 1 can be modified to:

$$MAT = MRT_{po} - MRT_{iv} - MTT_{GI} - MTT_h \qquad \text{(Eq. 2)}$$

The MTT in a tissue or organ during a single passage can be determined directly by instantaneous injection of a compound into the affluent blood and monitoring of effluent blood concentration, C_{out}, under the single-pass nonrecirculating condition (6–8):

$$MTT = \frac{\int_0^\infty tC_{out}dt}{\int_0^\infty C_{out}dt} \qquad \text{(Eq. 3)}$$

0022-3549/83/1100-1365$01.00/0

In linear pharmacokinetics it can also be estimated by (6–9):

$$MTT = V_{ss}/Q \qquad \text{(Eq. 4)}$$

where V_{ss} is the apparent (effective) steady-state volume of distribution of the tissue or organ for a given drug and Q is the blood flow rate through that tissue or organ. In view of the fast blood flow through the small section (with a limited tissue mass during each passage) of major GI absorption sites (usually in the small intestine) the MTT_{GI} may be expected to be relatively short or negligible for most drugs except those with extremely high binding property. Furthermore, the precise location and fraction absorbed at each location usually can not be ascertained. Therefore, under most circumstances the MTT_{GI} probably can be ignored.

The V_{ss} for the liver may be estimated by (10, 11):

$$V_{ss} = V_b + R_h V_h \qquad \text{(Eq. 5)}$$

where V_b is the volume of blood in the liver, R_h is the hepatic tissue–venous blood partition coefficient of drug, and V_h is the hepatic tissue volume (excluding blood). For a normal 70-kg human adult the V_b, V_h, and Q_h can be assumed to be 0.37, 1.5, and 1.58 liters/min, respectively (12, 13). Substitution of the above values into Eqs. 4 and 5 will result in the following equation for estimating the MTT_h for various drugs in human adults:

$$MTT_h \text{ in min} = (0.37 + 1.5R_h)/1.58 \qquad \text{(Eq. 6)}$$

The actual determination of R_h values in normal humans is extremely difficult or virtually impossible under practical circumstances. In view of the many reported successes in interspecies scaling in pharmacokinetic studies (11, 13–15) R_h values of several drugs in animals reported or estimated from the literature (15–18) will be used here for the purpose of illustration; as an approximation, the drug is also assumed to be instantaneously (19, 20) and evenly distributed in whole blood. The results of the calculation are summarized in Table I. The MTT_h obtained ranged from 0.52 min for tolbutamide to 977 min (16.3 hr) for chloroquine. The unusually long transit times estimated here for chloroquine and hydroxychloroquine (12.8 hr) during a single passage through the liver are somewhat of a surprise. These results indicate that for chloroquine and hydroxychloroquine it may take an average of more than 10 hr before they are transported from the liver by the blood stream or before they are metabolized by the liver following absorption. The MTT_h for the blood across the liver, on the other hand, can be estimated to be only 0.234 min (0.37/1.58) or 14 sec, which is only slightly higher than the values of 8.4 and 9.0 sec, reported earlier in the dog (7) and rat (21), respectively. It should be noted that the blood MTT across hepatic sinusoids, where diffusion of drug into hepatocytes for biotransformation and/or biliary excretion takes place, could be 36% shorter (7).

Table I—Mean Hepatic Transit Times (MTT_h) of Several Drugs in Humans Estimated Based on the Hepatic Tissue–Plasma Concentration Ratios (R_h) Obtained from Animal Studies

Drug[a]	Animal Species for R_h value	R_h	MTT_h (min)
Sulfobromophthalein (15)	Rat	7.0	6.9
Digoxin (15)	Dog	15.8	15.2
Dactinomycin (15)	Dog	32.2	30.8
Doxorubicin (15)	Rabbit	60.4	57.6[c]
Tolbutamide (16)	Rat	0.30	0.52
Chlorpheniramine (10, 17)[b]	Rabbit	31.4	30.0
Chloroquine (18)	Rat	1029.0	977.0[d]
Hydroxychloroquine (18)	Rat	811.0	770.0[d]

[a] Number in parentheses is reference number. [b] Correction was made for hepatic extraction ratio of 0.89 (17) based on ref. 11. [c] An actual value of 57 min was calculated for the rat based on the rat liver perfusion data (see text for detail). [d] These values might be considerably overestimated (see text for detail).

The possibility of a long MTT_h (57.6 min) for doxorubicin in humans (Table I) seems to be substantiated by results of analysis of rat (200–250 g of body weight) liver perfusion data recently reported by Skibba *et al.* (22). The plasma level (μg/ml) *versus* time (min) profile in the reservoir following a bolus dose of 2250 μg of doxorubicin could be approximated by the following biexponential equation, $1.2e^{-0.0711t} + 2.1e^{-0.0041t}$. The estimated V_{ss} based on the standard method (23) was 1003 ml. Since the reservoir had a volume of 150 ml the V_{ss} for the liver should be 853 ml. With that estimated V_{ss} and a Q of 15 ml/min used in their study, one could estimate the MTT_h (based on Eq. 4) to be 57 min.

The true MTT_h of chloroquine in humans might be considerably shorter than estimated here if its distribution between plasma and red blood cells could take place very rapidly, since its concentration in red blood cells has been shown to be much higher (~10 times) than that in plasma (24). The uptake of chloroquine by human red blood cells has been shown to follow saturable kinetics and not to be "instantaneous" (25). Therefore, it appears reasonable to assume that the estimated MTT_h for chloroquine shown in Table I might be either slightly or markedly overestimated. This probably was the case with hydroxychloroquine as well.

The above concepts and findings may be of importance in our study of MAT and the process of GI absorption. They indicate that the conventional method (Eq. 1) may significantly overestimate the true MAT. For digoxin, dactinomycin, doxorubicin, chlorpheniramine, and chloroquine, these overestimations might be 16, 32, 60, 30, and 977 min, respectively (Table I). In theory, the MRT_{po} should be always greater than the MRT_{iv}, even if all the drug is instantaneously absorbed through the GI tract. The degree of differences may vary tremendously with drugs that depends largely on their R_h values (Table I), although the size of the liver and the blood flow may also be important. In this regard it is of interest to point out that in patients with congestive heart failure, hepatic flow might be greatly reduced, and the volume of blood in the liver greatly increased [*i.e.*, up to one extra liter (26)]. Therefore, hepatic transit time for drugs or blood might be much longer than in normal subjects. It is likely that a drug with a larger steady-state volume of distribution in the body would tend to have a longer MTT_h.

It appears that in theory the MTT_h should also be a function of the hepatic extraction ratio, as shown for ethanol (27). For example, when the extraction ratio is unity, no drug molecules will be transported to the general circulation. Therefore, the calculated MTT_h will be zero.

When all drug molecules diffusing out of the hepatic sinusoids are eliminated through biotransformation and/or biliary excretion, the MTT_h for those remaining molecules will essentially equal that for blood. On the other hand, the MTT_h would become the longest for a given drug when the extraction ratio is zero (*i.e.*, no hepatic elimination). Under this condition, transit times for those molecules penetrating hepatic tissues deeply and/or binding strongly hepatic tissues will all be "counted" in the determination of MTT_h for all molecules. Therefore, the data presented in Table I probably represent average values with "normal" hepatic functions.

The MRT analysis has been regarded generally as being model independent. However, it has been shown recently that it might be subject to the influence of the blood-sampling site (28, 29). Although disposition kinetics in the whole body are best represented by systemic arterial data, use of venous data in the MDT analysis should be satisfactory as long as the same site is used for blood sampling throughout the study; this is also true with the MAT analysis shown in Eq. 1 or 2.

In the calculation of MRT_{iv} plasma-level data are most often described by polyexponential equations assuming that the injected drug is instantaneously and homogeneously (kinetically speaking) distributed to the plasma (central) compartment or initial volume of distribution. Such a concept has been questioned recently (29–33). Its potential effect on the determination of MRT_{iv} and MAT seems apparent.

The concept of hepatic first-pass transit times discussed in this communication may also be important in the evaluation of rates of oral absorption using conventional compartmental or deconvolution methods (34–38). This is consistent with an early study (39) which suggested that in the oral absorption rate calculation the calculated rate is based on the same reference sampling point (such as from an arm vein) between intravenous and oral studies. Since one is really only interested in the rate of absorption across the GI membrane, the conventional methods of calculation (34–38) may tend to underestimate the true rate of absorption due to the first "stop" or "trap" in the liver. The extensive trapping in and subsequent slow release from the liver apparently could account for the peculiar peripheral venous plasma level profile of doxorubicin following 30 min of constant intraarterial hepatic infusion to a patient (40). Plasma levels at 10 and 30 min after the beginning of peripheral intravenous infusion of the same dose 3 days later could be estimated (Fig. 1 of ref. 40) to be ~12 and 7 times higher than from the first infusion. The plasma level from intrahepatic infusion started to rise only 60 min after the end of infusion and was 3.3 times higher than from the intravenous infusion 90 min later. Using the 10-min data, the conventional methods would predict the rate of intraarterial infusion or absorption to be only one-twelfth the intravenous infusion. In other words, the infusion or absorption rate could be underestimated by about 92%. This phenomenon might also have occurred in the three dogs receiving portal venous dosing of propranolol in a previous study (41). The infusion rate was repeatedly reduced by ~two-thirds every 7.5 min for 45 min. Systemic arterial propranolol levels were the lowest at the end of the highest rate of infusion (Fig. 5 of ref. 41). One dog peaked at 30 min, another at 60 min, and a third dog plateaued between 20 and 40 min. On the other hand, the highest plasma concentrations were found in the other two dogs studied almost immediately after the same highest rate of infusion (41). The maximum difference at the end of the highest infusion among the five dogs studied could be estimated to be ~150-fold. This dramatic difference was probably primarily a result of the difference in hepatic transit time during the first passage since the plasma levels were quite similar during later periods. Unusually extensive uptake of propranolol by the liver following oral or hepatic portal administration (up to 10 mg/kg) to rats has also been reported (42, 43). The uptake has also been shown (42, 43) to be dependent on the route and dose of administration, thus further complicating the MAT calculation using Eq. 1 or 2.

The concepts of hepatic transit times discussed in this communication also may be useful in the design and evaluation of intrahepatic administration regimens and in the study of hepatic clearance of drugs. The importance of finite hepatic blood transit times and metabolite transfer times in metabolism has been extensively discussed recently (21, 44).

Errors in Estimating the Unbound Fraction of Drugs Due to the Volume Shift in Equilibrium Dialysis

Keyphrases □ Equilibrium dialysis—volume shift, unbound fraction of drug □ Unbound fraction of drugs—equilibrium dialysis, volume shift

To the Editor:

Equilibrium dialysis is commonly used to estimate serum protein binding of drugs. Consideration of the influence of the volume shift on the unbound fraction has, however, not been addressed until recently (1). The water flux from the buffer side to the serum side during dialysis causes binding protein dilution as well as an overestimation of the unbound fraction. The overestimation is dependent on the extent of the volume shift, the unbound fraction of drugs, and the concentration dependency of binding. Correction for the volume shift is important when the volume shift is substantial and when the unbound fraction of drugs is small.

The molarity of macromolecules in undiluted serum sample is ~1 m*M*, which gives 0.025 atm (263 mm H_2O) of osmotic pressure at 37°. The pressure causes water to migrate from the buffer side to the serum side (1) and expands the dialysis membrane. Because the serum sample is not completely restrained in the dialysis cells and the dialysis membrane, the hydrostatic pressure due to the volume shift is always less than the osmotic pressure. Osmotic equilibrium is actually never reached in this type of equilibrium dialysis. The extent of the volume shift depends on the time used for dialysis. Tozer *et al.* (1) reported an average volume shift of 31% in 16-hr dialysis. Using the same type of dialysis cells and dialysis membrane, we experienced an average volume shift of 10% in 4–6 hr of dialysis. Undue water flux can be avoided by a judicious choice of equilibration time.

Assuming that binding follows the law of mass action, the unbound fraction (f_u) of a drug that has multiple binding sites on a serum binding protein can be expressed as follows:

$$f_u = 1 \Big/ \left[1 + \mathrm{Pt} \sum_{i=1}^{n} 1/(C_u + K\mathrm{d}_i)\right] \qquad \text{(Eq. 1)}$$

where $K\mathrm{d}_i$ is the dissociation constant for binding site i, Pt is the total concentration of binding sites, and C_u is the measured unbound drug concentration. The extent of the volume shift can be defined as the ratio of serum volume before (V_s) and after ($V_{s'}$) dialysis and expressed as:

$$\mathrm{F} = V_s/V_{s'} = \mathrm{Pt}'/\mathrm{Pt} \qquad \text{(Eq. 2)}$$

where Pt′ is the concentration of binding sites after dialysis. In assessing the importance of the volume shift correction, the unbound fractions, with and without water flux correction, need to be compared. Assuming the unbound concentration to be the same with and without a water flux, the unbound fraction without correction for volume shift ($f_{u'}$) is related to the unbound fraction with volume shift correction by:

$$f_{u'} = f_u/[\mathrm{F} \cdot (1 - f_u) + f_u] \qquad \text{(Eq. 3)}$$

or

$$f_u = f_{u'} \cdot \mathrm{F}/(f_{u'} \cdot \mathrm{F} + 1 - f_{u'}) \qquad \text{(Eq. 4)}$$

(See *Appendix* for derivation.) Neglecting the volume shift, the fractional error [$\mathrm{E} = (f_{u'} - f_u)/f_u$] in calculating the unbound fraction is:

$$\mathrm{E} = (1 - \mathrm{F}) \cdot (1 - f_u)/[\mathrm{F} \cdot (1 - f_u) + f_u] \qquad \text{(Eq. 5)}$$

or

$$\mathrm{E} = (1 - \mathrm{F}) \cdot (1 - f_{u'})/\mathrm{F} \qquad \text{(Eq. 6)}$$

It is apparent from Eqs. 5 and 6 that when the volume shift is <10% (F > 0.9), the error introduced in neglecting volume shift is <11%, which is not critical in comparison with other errors in the protein binding determination. However, if the volume shift is >10% and the unbound fraction calculated without the volume shift correction is <0.9, the volume shift should always be considered in calculating the unbound fraction. Equation 4 can be used for the volume shift correction provided that the binding is not concentration dependent in the measured concentration range.

When equilibrium dialysis is used to determine the unbound fraction of a drug with concentration-dependent binding, the transfer of drug from the serum side to the buffer side causes a decrease in the drug concentration on the serum side with a subsequent decrease in the unbound fraction of the drug (1, 2). Errors in Estimating the Unbound Fraction of Drugs Due to the Volume Shift in Equilibrium Dialysis

Keyphrases □ Equilibrium dialysis—volume shift, unbound fraction of drug □ Unbound fraction of drugs—equilibrium dialysis, volume shift

To the Editor:

Equilibrium dialysis is commonly used to estimate serum protein binding of drugs. Consideration of the influence of the volume shift on the unbound fraction has, however, not been addressed until recently (1). The water flux from the buffer side to the serum side during dialysis causes binding protein dilution as well as an overestimation of the unbound fraction. The overestimation is dependent on the extent of the volume shift, the unbound fraction of drugs, and the concentration dependency of binding. Correction for the volume shift is important when the volume shift is substantial and when the unbound fraction of drugs is small.

The molarity of macromolecules in undiluted serum sample is ~1 m*M*, which gives 0.025 atm (263 mm H_2O) of osmotic pressure at 37°. The pressure causes water to migrate from the buffer side to the serum side (1) and expands the dialysis membrane. Because the serum sample is not completely restrained in the dialysis cells and the dialysis membrane, the hydrostatic pressure due to the volume shift is always less than the osmotic pressure. Osmotic equilibrium is actually never reached in this type of equilibrium dialysis. The extent of the volume shift depends on the time used for dialysis. Tozer *et al.* (1) reported an average volume shift of 31% in 16-hr dialysis. Using the same type of dialysis cells and dialysis membrane, we experienced an average volume shift of 10% in 4–6 hr of dialysis. Undue water flux can be avoided by a judicious choice of equilibration time.

Assuming that binding follows the law of mass action, the unbound fraction (f_u) of a drug that has multiple binding sites on a serum binding protein can be expressed as follows:

$$f_u = 1 \Big/ \left[1 + \mathrm{Pt} \sum_{i=1}^{n} 1/(C_u + K\mathrm{d}_i)\right] \qquad \text{(Eq. 1)}$$

where $K\mathrm{d}_i$ is the dissociation constant for binding site i, Pt is the total concentration of binding sites, and C_u is the measured unbound drug concentration. The extent of the volume shift can be defined as the ratio of serum volume before (V_s) and after ($V_{s'}$) dialysis and expressed as:

$$\mathrm{F} = V_s/V_{s'} = \mathrm{Pt}'/\mathrm{Pt} \qquad \text{(Eq. 2)}$$

where Pt′ is the concentration of binding sites after dialysis. In assessing the importance of the volume shift correction, the unbound fractions, with and without water flux correction, need to be compared. Assuming the unbound concentration to be the same with and without a water flux, the unbound fraction without correction for volume shift ($f_{u'}$) is related to the unbound fraction with volume shift correction by:

$$f_{u'} = f_u/[\mathrm{F} \cdot (1 - f_u) + f_u] \qquad \text{(Eq. 3)}$$

or

$$f_u = f_{u'} \cdot \mathrm{F}/(f_{u'} \cdot \mathrm{F} + 1 - f_{u'}) \qquad \text{(Eq. 4)}$$

(See *Appendix* for derivation.) Neglecting the volume shift, the fractional error [$\mathrm{E} = (f_{u'} - f_u)/f_u$] in calculating the unbound fraction is:

$$\mathrm{E} = (1 - \mathrm{F}) \cdot (1 - f_u)/[\mathrm{F} \cdot (1 - f_u) + f_u] \qquad \text{(Eq. 5)}$$

or

$$\mathrm{E} = (1 - \mathrm{F}) \cdot (1 - f_{u'})/\mathrm{F} \qquad \text{(Eq. 6)}$$

It is apparent from Eqs. 5 and 6 that when the volume shift is <10% (F > 0.9), the error introduced in neglecting volume shift is <11%, which is not critical in comparison with other errors in the protein binding determination. However, if the volume shift is >10% and the unbound fraction calculated without the volume shift correction is <0.9, the volume shift should always be considered in calculating the unbound fraction. Equation 4 can be used for the volume shift correction provided that the binding is not concentration dependent in the measured concentration range.

When equilibrium dialysis is used to determine the unbound fraction of a drug with concentration-dependent binding, the transfer of drug from the serum side to the buffer side causes a decrease in the drug concentration on the serum side with a subsequent decrease in the unbound fraction of the drug (1, 2). The complicated correction

0022-3549/83/1100-1368$01.00/0

method suggested by Tozer *et al.*, which corrects for both the volume shift and concentration-dependent binding, becomes necessary in calculating unbound fraction of a concentration-dependent binding drug such as prednisolone (1).

Although Eqs. 3 and 4 were derived under the assumption that drugs bind to a single-binding protein with multiple binding sites, the equations can be used as a good approximation to the correct unbound fractions for drugs that bind to two or more different binding proteins. For example, for a drug with two classes of binding sites, one having high capacity (600 μM) but low affinity (Kd = 100 μM), and the other having low capacity (20 μM) but high affinity (Kd = 1 μM), shows an unbound fraction of 0.04 at 0.1 μM drug concentration (Eq. 3A). A 30% volume shift gives a 40% error in unbound fraction ($f_{u'}$ = 0.056, Eq. 4A). Equation 4 can be used to convert $f_{u'}$ to f_u with good accuracy (f_u calculated = 0.04).

The extent of volume shift is usually determined by measuring the sample volume before and after equilibrium dialysis. Practically, it is not easy to determine the sample volume accurately after dialysis. It would be advisable instead to measure the binding protein concentration before and after dialysis and apply for correction calculations.

APPENDIX

The unbound fraction of a drug is by definition:

$$f_u = C_u \Big/ \left(C_u + \sum_{i=1}^{n} Cb_i\right) \qquad \text{(Eq. 1A)}$$

where $\sum_{i=1}^{n} Cb_i$ is the sum of concentrations of drugs bound to different binding sites. Based on the law of mass action, Cb_i can be expressed as:

$$Cb_i = C_u \cdot Pt_i/(Kd_i + C_u) \qquad \text{(Eq. 2A)}$$

and Eq. 1A can be written as:

$$f_u = 1 \Big/ \left[1 + \sum_{i=1}^{n} Pt_i/(Kd_i + C_u)\right] \qquad \text{(Eq. 3A)}$$

and

$$f_{u'} = 1 \Big/ \left[1 + \sum_{i=1}^{n} Pt_{i'}/(Kd_i + C_u)\right] \qquad \text{(Eq. 4A)}$$

Assuming a single binding protein with multiple binding sites, Eq. 3A can be simplified to be Eq. 1 and $f_{u'}$ is equal to:

$$f_{u'} = 1 \Big/ \left[1 + Pt' \sum_{i=1}^{n} 1/(C_u + Kd_i)\right] \qquad \text{(Eq. 5A)}$$

Letting

$$S = \sum_{i=1}^{n} 1/(C_u + Kd_i) \qquad \text{(Eq. 6A)}$$

Eq. 1 can be rearranged to:

$$S = (1 - f_u)/(f_u \cdot Pt) \qquad \text{(Eq. 7A)}$$

Substituting Eq. 7A into Eq. 5A, gives:

$$f_{u'} = 1/[1 + Pt' \cdot (1 - f_u)/(f_u \cdot Pt)] \qquad \text{(Eq. 8A)}$$

where Pt'/Pt is equal to F (Eq. 2). Substituting F into Eq. 8A gives Eq. 3. Similarly, Eq. 5A can be rearranged to:

$$S = (1 - f_{u'})/(f_{u'} \cdot Pt') \qquad \text{(Eq. 9A)}$$

Substituting Eqs. 2 and 9A into Eq. 1, Eq. 4 is derived.

Rate of Recovery from Fazadinium: Relationship to the Rate of Decline of its Plasma Concentration

Keyphrases □ Fazadinium—rate of recovery, relationship to plasma concentration, pharmacokinetics □ Pharmacokinetics—fazadinium, rate of recovery, relationship to plasma concentration

To the Editor:

Fazadinium bromide, introduced into anesthetic practice in 1972, is of clinical interest as a short-acting neuromuscular blocking agent. An approach is presented here which strongly suggests that the differences in the rate of recovery from the neuromuscular blocking effects of fazadinium are solely dependent on the pharmacokinetics of the relaxant. This approach is not new in that it was first presented on theoretical grounds more than a decade ago and utilized with recovery data for succinylcholine in both neonates and adults (1, 2).

If the claim (3) that fazadinium is eliminated by apparent first-order kinetics is true, and if it can be assumed that its metabolite(s) are inactive (4), then the duration (t) of the neuromuscular blocking action of fazadinium and the rate of decline (R) of the effect (paralysis) in the linear (20–80% or 25–75%) range can be related according to the following equations, as derived for succinylcholine (1, 2):

$$t = (2.3/k_{10})(\log A^0 - \log A_{min}) \qquad \text{(Eq. 1)}$$

$$R = m(k_{10}/2.3) \qquad \text{(Eq. 2)}$$

Table I—Pharmacokinetic Analysis of Recovery from the Neuromuscular Blocking Effects of Fazadinium [a]

Patient	Duration (t)[b], min	Rate of Decline (R)[c], % min^{-1}	$t \times R$, %	$k_{app\ 25\text{–}75}$[d], min^{-1}

method suggested by Tozer *et al.*, which corrects for both the volume shift and concentration-dependent binding, becomes necessary in calculating unbound fraction of a concentration-dependent binding drug such as prednisolone (1).

Although Eqs. 3 and 4 were derived under the assumption that drugs bind to a single-binding protein with multiple binding sites, the equations can be used as a good approximation to the correct unbound fractions for drugs that bind to two or more different binding proteins. For example, for a drug with two classes of binding sites, one having high capacity (600 μM) but low affinity (Kd = 100 μM), and the other having low capacity (20 μM) but high affinity (Kd = 1 μM), shows an unbound fraction of 0.04 at 0.1 μM drug concentration (Eq. 3A). A 30% volume shift gives a 40% error in unbound fraction ($f_{u'}$ = 0.056, Eq. 4A). Equation 4 can be used to convert $f_{u'}$ to f_u with good accuracy (f_u calculated = 0.04).

The extent of volume shift is usually determined by measuring the sample volume before and after equilibrium dialysis. Practically, it is not easy to determine the sample volume accurately after dialysis. It would be advisable instead to measure the binding protein concentration before and after dialysis and apply for correction calculations.

APPENDIX

The unbound fraction of a drug is by definition:

$$f_u = C_u \Big/ \left(C_u + \sum_{i=1}^{n} Cb_i\right) \qquad \text{(Eq. 1A)}$$

where $\sum_{i=1}^{n} Cb_i$ is the sum of concentrations of drugs bound to different binding sites. Based on the law of mass action, Cb_i can be expressed as:

$$Cb_i = C_u \cdot Pt_i/(Kd_i + C_u) \qquad \text{(Eq. 2A)}$$

and Eq. 1A can be written as:

$$f_u = 1 \Big/ \left[1 + \sum_{i=1}^{n} Pt_i/(Kd_i + C_u)\right] \qquad \text{(Eq. 3A)}$$

and

$$f_{u'} = 1 \Big/ \left[1 + \sum_{i=1}^{n} Pt_{i'}/(Kd_i + C_u)\right] \qquad \text{(Eq. 4A)}$$

Assuming a single binding protein with multiple binding sites, Eq. 3A can be simplified to be Eq. 1 and $f_{u'}$ is equal to:

$$f_{u'} = 1 \Big/ \left[1 + Pt' \sum_{i=1}^{n} 1/(C_u + Kd_i)\right] \qquad \text{(Eq. 5A)}$$

Letting

$$S = \sum_{i=1}^{n} 1/(C_u + Kd_i) \qquad \text{(Eq. 6A)}$$

Eq. 1 can be rearranged to:

$$S = (1 - f_u)/(f_u \cdot Pt) \qquad \text{(Eq. 7A)}$$

Substituting Eq. 7A into Eq. 5A, gives:

$$f_{u'} = 1/[1 + Pt' \cdot (1 - f_u)/(f_u \cdot Pt)] \qquad \text{(Eq. 8A)}$$

where Pt'/Pt is equal to F (Eq. 2). Substituting F into Eq. 8A gives Eq. 3. Similarly, Eq. 5A can be rearranged to:

$$S = (1 - f_{u'})/(f_{u'} \cdot Pt') \qquad \text{(Eq. 9A)}$$

Substituting Eqs. 2 and 9A into Eq. 1, Eq. 4 is derived.

Rate of Recovery from Fazadinium: Relationship to the Rate of Decline of its Plasma Concentration

Keyphrases □ Fazadinium—rate of recovery, relationship to plasma concentration, pharmacokinetics □ Pharmacokinetics—fazadinium, rate of recovery, relationship to plasma concentration

To the Editor:

Fazadinium bromide, introduced into anesthetic practice in 1972, is of clinical interest as a short-acting neuromuscular blocking agent. An approach is presented here which strongly suggests that the differences in the rate of recovery from the neuromuscular blocking effects of fazadinium are solely dependent on the pharmacokinetics of the relaxant. This approach is not new in that it was first presented on theoretical grounds more than a decade ago and utilized with recovery data for succinylcholine in both neonates and adults (1, 2).

If the claim (3) that fazadinium is eliminated by apparent first-order kinetics is true, and if it can be assumed that its metabolite(s) are inactive (4), then the duration (t) of the neuromuscular blocking action of fazadinium and the rate of decline (R) of the effect (paralysis) in the linear (20–80% or 25–75%) range can be related according to the following equations, as derived for succinylcholine (1, 2):

$$t = (2.3/k_{10})(\log A^0 - \log A_{min}) \qquad \text{(Eq. 1)}$$

$$R = m(k_{10}/2.3) \qquad \text{(Eq. 2)}$$

Table I—Pharmacokinetic Analysis of Recovery from the Neuromuscular Blocking Effects of Fazadinium [a]

Patient	Duration (t)[b], min	Rate of Decline (R)[c], % min^{-1}	$t \times R$, %	$k_{app\ 25\text{–}75}$[d], min^{-1}
3	14	3.57	49.98	−0.0382
4	22	2.27	49.94	−0.0286
5	24	2.08	49.92	−0.0210
1	26	1.92	49.92	−0.0251
2	27	1.85	49.95	−0.0219
6	34	1.47	49.98	−0.0149

[a] Based on data from ref. 3. [b] Time interval when the twitch height was depressed between 25 and 75% of its control value: between 75 and 25% muscle paralysis. [c] Rate of recovery in the 75–25% paralysis range. [d] $k_{app\ 25\text{–}75} = (\log C_{25} - \log C_{75}/t_{25} - t_{75})$ where C and t are the plasma concentrations and times respectively at 25 and 75% effect levels.

0022-3549/83/1100-1369$01.00/0

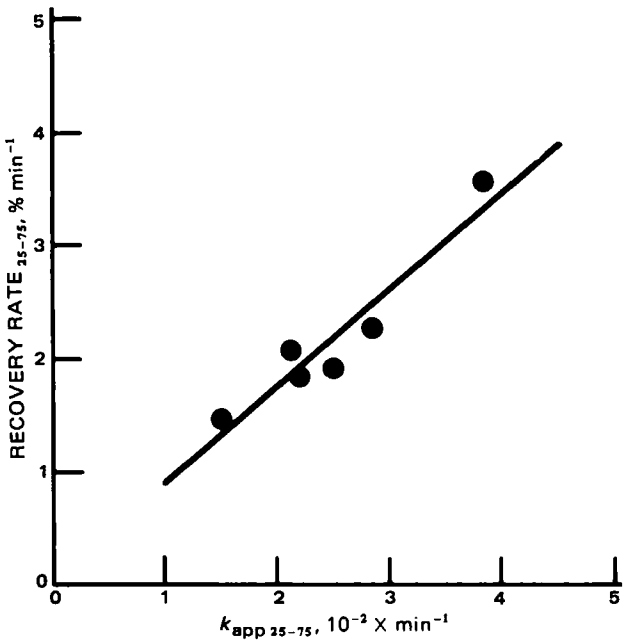

Figure 1—*Relationship between the rate of recovery from the neuromuscular blocking effects of fazadinium and the calculated* $k_{app\ 25-75}$. *Individual patient data are shown as solid circles while the solid line represents the linear regression line* ($r^2 = 0.897$, $p < 0.005$).

$$t \times R = m(\log A^0 - \log A_{min}) \qquad \text{(Eq. 3)}$$

where k_{10} is the apparent first-order rate constant for drug elimination from its site of action, A_{min} is the minimum effective dose, and m is the slope of the log dose (A^0) response relationship for the relaxant. Thus, according to the above three equations, four pharmacokinetic factors determine the duration and rate of decline of effect, with three of these terms (m, A^0, and A_{min}) appearing on the right side of Eq. 3, while k_{10} is implicit on the left-hand side but cancels out as such. Thus, in a group of patients given the same drug dose but showing different durations of effect, the product of duration (t) and rate of decline (R) of effect will yield a constant value if the differences in the observed time course of effect are solely the result of differences in k_{10}, the elimination rate constant. If, however, the values of $t \times R$ differ between the patients, then it must be concluded that these patients differ with respect to m and/or A_{min} and/or k_{10}.

The results obtained from the six patients in the study by D'Hollander *et al.* (3) are listed in Table I, with the numerical designations used by these authors but in order of increasing duration of effect. It can be seen that although the six patients differed in the duration (t) and the rate of decline (R) from the effects of fazadinium, the $t \times R$ values were identical for all the patients, implying that the differences in the rate of recovery from the neuromuscular effects of fazadinium in these six patients were solely due to a difference in the rate of elimination of the relaxant from the body. This claim is further supported by the finding that $k_{app\ 25-75}$, the apparent rate of decline of the (log) plasma concentration, which is a measure of the elimination rate of the relaxant during the linear (25–75%) phase of recovery, was different in each of the six patients and there was an excellent linear relationship between the *rate* of recovery from fazadinium and the calculated $k_{app\ 25-75}$ (Fig. 1).

BOOKS

REVIEWS

Pharmacokinetics, 2nd Ed. By MILO GIBALDI and DONALD PERRIER. Marcel Dekker, 270 Madison Avenue, New York, NY 11016. 1982. 494 pp. 16 × 23 cm. Price: $34.50 (20% higher outside the U.S. and Canada).

The second edition of this now classic text detailing the mathematical description of pharmacokinetics has been greatly expanded and updated over the previous edition. One of the most important new aspects to be presented is the comprehensive discussion of clearance concepts, flow models, and physiological modeling, which has given the new text a much broader scope while at the same time introduces the reader to new concepts presented over the last few years. In addition, an overview depicting the usefulness of statistical moments in pharmacokinetics is presented, a concept being explored extensively in the pharmacokinetic literature today which should prove useful to both the established researcher and the student. The new material added to the text is, in general, approached (as is the mark of these authors) in a detailed, step-by-step procedure that renders the work especially useful to novices and subsequently makes it an important teaching tool.

It is important to note that not only have new chapters and topics been added, but that the majority of the original text has undergone revision, expansion, and addition of new material. The majority of the equations have been generalized, thereby making them useful in a variety of models. Although the generalization makes the edition slightly less useful as a reference book for pharmacokinetic relationships, it is most illustrative for teaching purposes in demonstrating the generalities of kinetic models. Without too much effort, the generalized equations can readily be converted to relationships that can be applied in specific situations. The authors have also added a more philosophical overview to the various concepts that increase the understanding of many of the equations and relationships presented.

Other interesting additions to the second edition are the kinetics of irreversible pharmacological response, product inhibition aspects of nonlinear kinetics, and various aspects of protein binding in relation in pharmacokinetics. Although the discussion dealing with protein binding is often divergent from what this reviewer believes to be a rational development of the relationship between protein binding and pharmacokinetics, it is a valuable and instructive addition, especially in lieu of the paucity of such discussions.

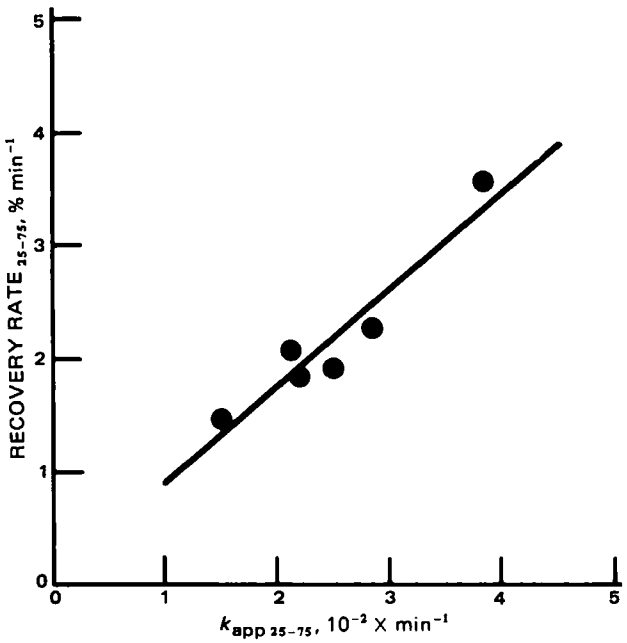

Figure 1—*Relationship between the rate of recovery from the neuromuscular blocking effects of fazadinium and the calculated* $k_{app\ 25-75}$. *Individual patient data are shown as solid circles while the solid line represents the linear regression line* ($r^2 = 0.897$, $p < 0.005$).

$$t \times R = m(\log A^0 - \log A_{min}) \qquad \text{(Eq. 3)}$$

where k_{10} is the apparent first-order rate constant for drug elimination from its site of action, A_{min} is the minimum effective dose, and m is the slope of the log dose (A^0) response relationship for the relaxant. Thus, according to the above three equations, four pharmacokinetic factors determine the duration and rate of decline of effect, with three of these terms (m, A^0, and A_{min}) appearing on the right side of Eq. 3, while k_{10} is implicit on the left-hand side but cancels out as such. Thus, in a group of patients given the same drug dose but showing different durations of effect, the product of duration (t) and rate of decline (R) of effect will yield a constant value if the differences in the observed time course of effect are solely the result of differences in k_{10}, the elimination rate constant. If, however, the values of $t \times R$ differ between the patients, then it must be concluded that these patients differ with respect to m and/or A_{min} and/or k_{10}.

The results obtained from the six patients in the study by D'Hollander *et al.* (3) are listed in Table I, with the numerical designations used by these authors but in order of increasing duration of effect. It can be seen that although the six patients differed in the duration (t) and the rate of decline (R) from the effects of fazadinium, the $t \times R$ values were identical for all the patients, implying that the differences in the rate of recovery from the neuromuscular effects of fazadinium in these six patients were solely due to a difference in the rate of elimination of the relaxant from the body. This claim is further supported by the finding that $k_{app\ 25-75}$, the apparent rate of decline of the (log) plasma concentration, which is a measure of the elimination rate of the relaxant during the linear (25–75%) phase of recovery, was different in each of the six patients and there was an excellent linear relationship between the *rate* of recovery from fazadinium and the calculated $k_{app\ 25-75}$ (Fig. 1).

It is important to note that not only have new chapters and topics been added, but that the majority of the original text has undergone revision, expansion, and addition of new material. The majority of the equations have been generalized, thereby making them useful in a variety of models. Although the generalization makes the edition slightly less useful as a reference book for pharmacokinetic relationships, it is most illustrative for teaching purposes in demonstrating the generalities of kinetic models. Without too much effort, the generalized equations can readily be converted to relationships that can be applied in specific situations. The authors have also added a more philosophical overview to the various concepts that increase the understanding of many of the equations and relationships presented.

Other interesting additions to the second edition are the kinetics of irreversible pharmacological response, product inhibition aspects of nonlinear kinetics, and various aspects of protein binding in relation in pharmacokinetics. Although the discussion dealing with protein binding is often divergent from what this reviewer believes to be a rational development of the relationship between protein binding and pharmacokinetics, it is a valuable and instructive addition, especially in lieu of the paucity of such discussions.

After extensive scrutinization this reviewer can find only a few areas that may be considered for changes in future editions: 1. The use of natural logarithms instead of log to the base of 10. This will remove the always difficult task by students of deciding when to use the correction factor 2.303. 2. The use of the current concept of clearance throughout the book, not just in segments; *i.e.*, treating clearance as a fundamental pharmacokinetic parameter throughout the book rather than being dependent on volume of distribution and fractional rates (*i.e.*, elimination rate constant).

In summary, this is a substantially expanded version of the first edition, and as a comprehensive and logically developed text, it will probably enjoy an even higher readership than its predecessor. A must for all pharmacokineticists.

Chromatography and Mass Spectrometry in Biomedical Sciences 2. (Analytical Chemistry Symposia Series 14). Edited by A. FRIGERIO. Elsevier/North Holland, 52 Vanderbilt Avenue, New York, N.Y. 10017. 1983. 506 pp. 16 × 24 cm. Price $106.50 (Dfl. 250).

This book contains the proceedings of the International Conference on Chromatography and Mass Spectrometry in Biomedical Sciences, held in Bordighera, Italy, in June 1982. There are five plenary lectures on five topics. Three of these lectures are on techniques such as combined gas chromatography–Fourier transform infrared spectroscopy, quantitative ion-exchange thin-layer chromatography, and tandem mass spectrometry (MS–MS). They represent the state of the art on each of the techniques and are well written. The other two plenary lectures are on "Recent Applications of Mass Spectrometry to Cannabinoid Studies" and "Chromatographic Techniques for Determination of Some Calcium Antagonist Drugs in Biological Fluids." Both of these presentations, as well as the previous three lectures, are worth reading. The rest of the papers presented or given as poster sessions at this meeting are widely varied, from drug studies to environmental analysis, where the techniques applied include the use of radioimmunoassay, high-performance liquid chromatography, thin-layer chromatography, gas chromatography, and combined techniques of gas chromatography–mass spectrometry. Like any other conference there are some good papers, some average in quality, and some which do not add anything new to the use of chromatography and mass spectrometry in the biomedical or environmental fields.

Since this book covers a very broad spectrum of techniques and subjects, it can not be recommended for anyone seeking an in-depth discussion on any particular subject. It certainly can be recommended for those who want an overview of the state of the art and current thinking of chromatography and mass spectrometry.

New Drug Parade: A Historical Minireview 1954–1982. By PAUL DE HAEN. Paul de Haen International, Inc., 2750 S. Shoshone Street, Englewood, CO 80110. 1983. 22 × 28 cm. Price $25.00.

New Drug Review: A Historical Minireview offers a statistical and descriptive tabulation of major new drug introductions in the United States from 1954 to present, including single chemical entities, duplicate single products, combination products, and new dosage forms. Major drugs introduced each year are listed by trade name, generic name, manufacturer, therapeutic use, chemical class, and foreign developer. The listed drugs have been selected on the basis of chemical innovation and therapeutic advantages.

In addition to the statistical and descriptive information, the publication includes brief comments for each year on such significant events as the state of research, trends in the pharmaceutical industry, and the relationship between the industry and governmental agencies. Also included are pertinent references to the original reports in *Drug and Cosmetic Industry* and secondary citations of the press comments, editorials, and reprint history. Following the individual information for each year is an overview of the entire period, including summary statistics.

Environmental Carcinogens—Selected Methods for Analysis, Vol. 5: Mycotoxins. (IARC Scientific Publications No. 44). Editor-in-Chief, H. EGAN. World Health Organization, 1211 Geneva 27, Switzerland. 1982. 455 pp. 19 × 25 cm. Price $30.00 (Sw. Fr. 60).

After extensive scrutinization this reviewer can find only a few areas that may be considered for changes in future editions: 1. The use of natural logarithms instead of log to the base of 10. This will remove the always difficult task by students of deciding when to use the correction factor 2.303. 2. The use of the current concept of clearance throughout the book, not just in segments; *i.e.*, treating clearance as a fundamental pharmacokinetic parameter throughout the book rather than being dependent on volume of distribution and fractional rates (*i.e.*, elimination rate constant).

In summary, this is a substantially expanded version of the first edition, and as a comprehensive and logically developed text, it will probably enjoy an even higher readership than its predecessor. A must for all pharmacokineticists.

Chromatography and Mass Spectrometry in Biomedical Sciences 2. (Analytical Chemistry Symposia Series 14). Edited by A. FRIGERIO. Elsevier/North Holland, 52 Vanderbilt Avenue, New York, N.Y. 10017. 1983. 506 pp. 16 × 24 cm. Price $106.50 (Dfl. 250).

This book contains the proceedings of the International Conference on Chromatography and Mass Spectrometry in Biomedical Sciences, held in Bordighera, Italy, in June 1982. There are five plenary lectures on five topics. Three of these lectures are on techniques such as combined gas chromatography–Fourier transform infrared spectroscopy, quantitative ion-exchange thin-layer chromatography, and tandem mass spectrometry (MS–MS). They represent the state of the art on each of the techniques and are well written. The other two plenary lectures are on "Recent Applications of Mass Spectrometry to Cannabinoid Studies" and "Chromatographic Techniques for Determination of Some Calcium Antagonist Drugs in Biological Fluids." Both of these presentations, as well as the previous three lectures, are worth reading. The rest of the papers presented or given as poster sessions at this meeting are widely varied, from drug studies to environmental analysis, where the techniques applied include the use of radioimmunoassay, high-performance liquid chromatography, thin-layer chromatography, gas chromatography, and combined techniques of gas chromatography–mass spectrometry. Like any other conference there are some good papers, some average in quality, and some which do not add anything new to the use of chromatography and mass spectrometry in the biomedical or environmental fields.

Since this book covers a very broad spectrum of techniques and subjects, it can not be recommended for anyone seeking an in-depth discussion on any particular subject. It certainly can be recommended for those who want an overview of the state of the art and current thinking of chromatography and mass spectrometry.

New Drug Parade: A Historical Minireview 1954–1982. By PAUL DE HAEN. Paul de Haen International, Inc., 2750 S. Shoshone Street, Englewood, CO 80110. 1983. 22 × 28 cm. Price $25.00.

New Drug Review: A Historical Minireview offers a statistical and descriptive tabulation of major new drug introductions in the United States from 1954 to present, including single chemical entities, duplicate single products, combination products, and new dosage forms. Major drugs introduced each year are listed by trade name, generic name, manufacturer, therapeutic use, chemical class, and foreign developer. The listed drugs have been selected on the basis of chemical innovation and therapeutic advantages.

In addition to the statistical and descriptive information, the publication includes brief comments for each year on such significant events as the state of research, trends in the pharmaceutical industry, and the relationship between the industry and governmental agencies. Also included are pertinent references to the original reports in *Drug and Cosmetic Industry* and secondary citations of the press comments, editorials, and reprint history. Following the individual information for each year is an overview of the entire period, including summary statistics.

Adverse Drug Reaction Reporting

After reading your comments in the June 10th issue of *Apharmacy Weekly*[1], regarding the adverse drug reaction reporting system, I felt that it was necessary to write you regarding this matter. Our company has been greatly concerned with this problem for many years. We have been constantly trying to find an effective system for reporting adverse drug reactions to the pharmacy department and participating in a national data collection program.

It has been our experience that the principal obstacle to the adverse drug reaction program is the physician. In the hospital setting, no physician wants to have an entry on a patient's chart stating that the patient experienced an adverse drug reaction. This is due to the fear of civil liability. In our efforts to have this information placed on the chart by a nurse, both pharmacy and nursing have been criticized for "diagnosing" or "practicing medicine."

I believe our experience is directly related to the surprising fact that Johnson and Johnson knew of nearly twice as many instances of adverse drug reactions from the prescription medication, Zomax, as the FDA had known. I would not be surprised to discover that this information, which the company had acquired, was verbal feedback from the physicians to the sales representatives, rather than a written report directly from the physicians. It appears that the fear of legal liability is having a very strong impact on the practice of medicine and our ADR reporting system problem is just one symptom of this.

Until this problem is resolved, it is my belief that it will be a continuing problem and present great difficulties in developing an effective reporting system. This situation will continue in spite of the efforts of JCAH surveyors, who constantly stress the necessity of accurate charting the patient's history and the response to therapy, and our own efforts in trying to have this information placed in the chart within the nursing notes, as a nursing diagnosis of a "suspected" adverse drug reaction. In addition to this, we are informing the medical staff through the pharmacy and therapeutics committee of their potential liability for failure to report adverse drug reactions in the patient's medical history and chart. This legal liability would result if the patient suffers a repeat adverse drug reaction with possible injury and mortality during subsequent hospitalization.

In summary, we continue to search for and would greatly enjoy your support in finding a system for reporting adverse drug reactions which could achieve the necessary physician support to ensure it's success.

Postscript:

Since I am in agreement with your concern with the problem of adverse drug reaction reporting, I am agreeable to using my letter in the "Open Forum Page" of the *Journal*. I hope it will stimulate more thought and discussion toward an effective method for reporting in our clinical settings. Hopefully, each pharmacy practitioner will begin to view themselves as members of the research and development process and communicate this attitude to physicians in such a manner that it becomes contagious within their ranks also.

JOURNAL OF PHARMACEUTICAL SCIENCES

A publication of the American Pharmaceutical Association

The *Journal of Pharmaceutical Sciences* (ISSN 0022-3549) is published monthly by the American Pharmaceutical Association (APhA) at 2215 Constitution Ave., N.W., Washington, DC 20037. Second-class postage paid at Washington, D.C. and at additional mailing office.

Offices—Editorial, Advertising, and Subscription: 2215 Constitution Ave., N.W., Washington, DC 20037. All Journal staff may be contacted at this address. Printing: 20th & Northampton Streets, Easton, PA 18042.

Annual Subscriptions—United States and foreign, industrial and government institutions $75; educational institutions $75; individuals *for personal use only* $40; single copies $10. APhA and SAPhA members may subscribe to *J. Pharm. Sci.* for $20.00 per year. All foreign subscriptions add $10 for postage. Subscription rates are subject to change without notice.

Claims—Missing numbers will not be supplied if dues or subscriptions are in arrears for more than 60 days or if claims are received more than 60 days after the date of the issue, or if loss was due to failure to give notice of change of address. APhA cannot accept responsibility for foreign delivery when its records indicate shipment was made.

Change of Address—Members and subscribers should notify at once both the Post Office and APhA of any change of address.

Microfilm—Available from University Microfilms International, 300 N. Zeeb Road, Ann Arbor, MI 48106.

New Era for Nonprescription Drugs

The law says that drugs must be "safe and effective" if they are to be legally on the market.

But it was not always so.

Specifically, less than 50 years ago, it was neither a legal requirement nor an actuality that drugs in the American marketplace were generally safe and effective.

The Federal Food, Drug, and Cosmetic Act of 1938 formally established safety as a condition of drug approval and marketing. The Drug Amendments of 1962 did likewise regarding drug effectiveness.

However, it takes more than just a vote in Congress and the signature of a President to transform the objective into the reality. Recognizing that the criteria of safety and effectiveness could be applied rather readily in evaluating *new* drugs as a condition of their approval by the federal Food and Drug Administration, it remained to develop some system for the review and evaluation of those drugs *already* on the market—particularly, for the effectiveness evaluation of pre-1962 drugs.

And so it was in the mid-1960's that the FDA—working along with the National Academy of Sciences/National Research Council—undertook the Drug Efficiency Study Implementation (DESI). This was a massive program over a 10-year period to evaluate the effectiveness of virtually all drug products marketed prior to 1962.

Very early in this project, it became evident that the complete task was impossible and certain limitations would need to be applied. The most fundamental of these adjustments was the decision to concentrate on the prescription drug products, of which there were almost 10,000, and to set aside the nonprescription drug products, which numbered over 300,000. In view of the fact that not only was a much smaller and manageable a universe involved, but also that the drugs were more important in the sense of being used to treat more serious health problems and conditions, this decision made a great deal of sense to all concerned.

And eventually, the DESI project ground to its inevitable conclusion, with many products forced off the market, others reformulated, and still others relabeled as to claims and conditions for use. Although the process was long and stressful, the general consensus appears to be that the net result has been beneficial to the public health and welfare, and that both consumers and health care professionals now can have a high level of confidence that prescription drug products will perform in accord with their claims.

But what about those several hundred thousand nonprescription drug products?

Under law, they must be just as safe and effective for their labeled purposes and claims as their prescription legend cousins. The only real difference between these two drug classes is that the former are judged to be suitable for use without professional supervision, while the latter—for one reason or another—are judged to necessitate such professional practitioner involvement.

As the DESI project was proceeding on track during the very late 60's and early 70's, the FDA concluded that the nonprescription drugs would require a different approach logistically. Instead of considering them on a product-by-product basis, the FDA decided to approach the project on a drug active ingredient basis. With active ingredients totaling less than a thousand, in contrast to the several hundred thousand products, this alternative was clearly more practical and manageable.

And so was conceived the FDA's "OTC Drug Review" which has now been in process for some 11 to 12 years, depending upon when one regards the starting date to have occurred. In contrast to the DESI project, in which the FDA contracted with the NAS-NRC to conduct the fact-finding aspect, the OTC Drug Review was organized and operated by FDA itself. A series of 17 advisory panels—composed of about 250 outside nongovernment drug experts—were established with each panel responsible for a particular therapeutic or pharmacologic class of drugs. The panels, which were staffed by FDA, reviewed 20,000 volumes of data, held 508 meetings over 1,047 days, and participated in innumerable phone conferences, exchanges of correspondence, and other activities relating to their deliberations.

On October 7 of this year, the FDA and its parent Department of Health and Human Services, proudly announced that a most important milestone had been reached in this monumental project. The 58th, and last, report of the advisory panels was publicly released.

Although agency officials pointed out that much work still remains to be done to convert the final panel recommendations into regulatory action, they emphasized that major strides had already been made "in improved products, greater safety, and reduced medical costs."

HHS Secretary Margaret M. Heckler concluded her statement with the comment that, "The review has begun to transform the nonprescription drug market." And the accompanying FDA summary cited ample statistics and examples to document her assessment.

What impact will this all have on pharmacy and the pharmaceutical sciences?

Nonprescription drugs and drug products have long had an image of being nothing more than harmless, ineffective nostrums at best, and potentially harmful quack remedies at worst.

But the FDA's OTC Drug Review has changed that. The products on the market now and in the future have been established as safe and effective. And professional organizations have been making great efforts to educate practitioners and the public in the proper selection and use of such products.

In particular, the American Pharmaceutical Association has contributed enormously in this regard through publication of its highly respected *Handbook of Nonprescription Drugs*, which is now in its 7th Edition. APhA has also been conducting a whole host of other efforts, including workshops and seminars, to support an active and effective role for the pharmacist with regard to self-medication by the public.

And in recent years the nonprescription drug industry has generally assumed a high sense of public responsibility for the products it produces as well as their proper use. Indeed, the Proprietary Association, which is the major trade organization of nonprescription drug manufacturers, currently is closely cooperating with APhA in efforts to produce a consumer version of APhA's *Handbook*.

Finally, the general public today is much more health conscious than ever before; it has a keen interest in knowing as much as possible about self-treatment; and it wants to feel confident that the therapeutic agents it uses are safe and reliable.

Consequently, the entire picture as to contemporary perceptions and attitudes regarding nonprescription drugs is dramatically different from that which prevailed just a few short years ago. And the resultant shift in emphasis will greatly affect not only pharmacy practitioners but also pharmaceutical educators and scientists as well.

LITERATURE SURVEY

Drug Delivery to Local Subcutaneous Structures Following Topical Administration

RICHARD H. GUY ˣ and HOWARD I. MAIBACH

Received October 26, 1982, from the *School of Pharmacy and Department of Dermatology, School of Medicine, University of California–San Francisco, San Francisco, CA 94143.*

Keyphrases □ Topical administration—drug delivery to local subcutaneous tissues, literature survey □ Drug delivery—local subcutaneous tissues *via* topical administration, literature survey

This article brings together a collection of results and observations which demonstrate the achievement of significant drug delivery to local subcutaneous structures following topical administration. It is probably no exaggeration to say that the concept of using the transdermal route to advantageously reach lower tissue, such as the muscle beneath the subcutaneous fat, goes directly against conventional thought. Indeed, the cutaneous microvasculature has long been offered as an excellent example of a classical "sink" phenomenon; that is, following penetration through the stratum corneum, epidermis, and upper dermis, it has been held that the permeating species will then pass into one of the small blood vessels forming the microcapillary network and hence be systemically diluted in the circulatory system. The argument seems totally reasonable: the stratum corneum is an excellent barrier to the passage into the body of many substances that contact with the skin. Thus, in the large majority of cases, drug arrival beneath the stratum corneum is slow such that the concentration of material at this point is invariably very much less than that present on the skin surface. These conditions are precisely those implicit in a "sink" situation and, coupled with the extensive dermal capillary matrix, it is not surprising that further penetration into the tissue has been considered unlikely.

On closer perusal of the literature, however, it becomes apparent that a small but significant number of reports exist which show that deeper penetration can take place and that subcutaneous drug levels can be achieved following topical application which cannot be reached after parenteral or oral administration of the active agent. This brief review gathers the results available in the (admittedly) diverse sources to reanalyze conventional thought and to stimulate inquiry into this important aspect of drug input *via* the skin.

SUBCUTANEOUS DRUG DELIVERY: EXPERIMENTAL OBSERVATIONS

Over the last 15 years, there have appeared several communications which address the question of local subcutaneous drug delivery following topical dosing. These encompass a diverse array of chemical substances such as dimethyl sulfoxide, a salicylate derivative, steroids, and commonly used organophosphorous pesticides. In almost all cases, the studies have involved animal models since excision of tissue and its analysis is possible. However, evidence has been found that the same deeper penetration from the skin surface occurs in humans; further, *a priori*, there is no reason to suggest that the animal experiments performed are not good qualitative predictors, at least of the behavior expected in humans. It is believed, therefore, that the following discussion provides tantalizing and somewhat novel information on the potential of the topical route for the delivery of chemotherapeutic agents.

In 1968, Gorog and Kovacs (1) studied the anti-inflammatory properties of dimethyl sulfoxide (DMSO) in rats. It was found that carrageenan-induced rat paw edema was improved by both oral and topical DMSO therapy. Furthermore, and of greater relevance, arthritis induced by Mycobacterium adjuvant was inhibited to a greater degree by topical, rather than oral, DMSO administration. In the same way, DMSO applied to the skin of rats had an inhibitory effect on arthritis produced experimentally by 6-sulfanilamidazole. These early data, therefore, argue strongly for local deep penetration of the solvent.

A more detailed investigation on the disposition of topically applied ^{3}H-labeled escin was performed in mice and rats by Lang (2). The radioactive compound was ap-

0022-3549/83/1200-1375$01.00/0

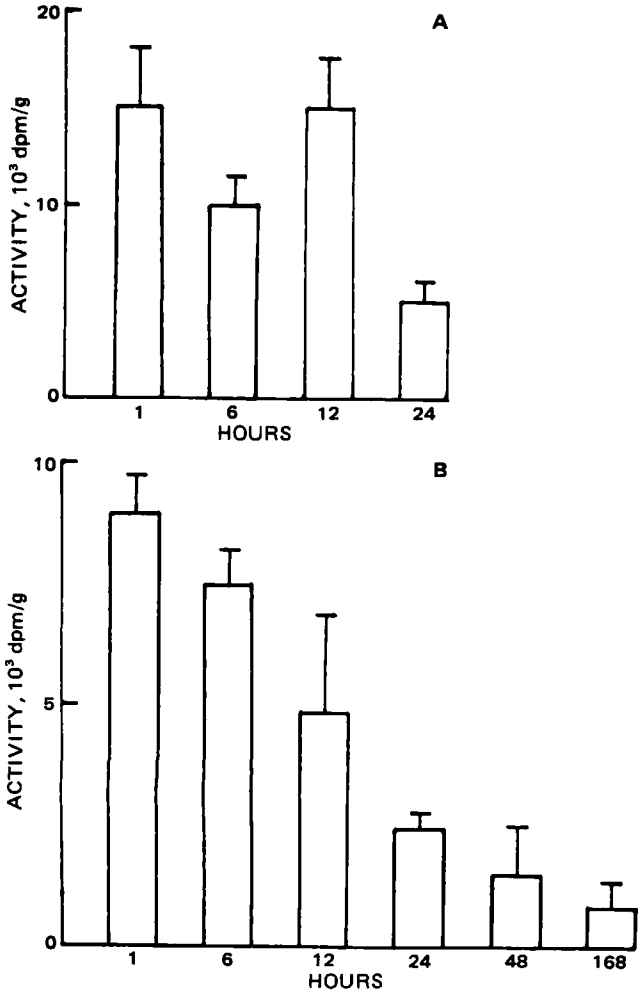

Figure 1—*Radioactivity in mouse (A) and rat (B) back muscles at various times after cutaneous application of [^{3}H]escin. (Data taken from Ref. 2.)*

plied to the backs of animals, and tissue distribution was subsequently evaluated at various times by organ dissection after sacrifice. The tissues monitored were the back muscles, blood, liver, kidney, heart, lungs, spleen, testes, brain, leg muscle, femur, and stomach lining. In the mouse the amount of activity detected in the back muscle beneath the skin application site exceeded by 20–100 times the amount detected in any of the other regions. A similar pattern of behavior, though less pronounced (10–30 times greater in the back muscle) was observed in the rat. The time course of disposition to the back muscle in the two species is shown in Fig. 1. It is apparent that significant levels of escin are present in the deeper local tissue over prolonged periods of time. A further observation reported in this paper (and elsewhere) also implies that all material penetrating the upper skin layers is not immediately subjected to a sink condition. Measurements were made of activity residing in the skin beneath the application site and in several skin strips 0.5 cm wide at distances of 1–5 cm from the center of the application zone. The data (Fig. 2) for the mouse clearly show that radial movement of drug within the skin is an additional transport pathway to the expected capillary uptake process. It should be pointed out that implied radial movement within the skin has been reported on other occasions. It is a common observation

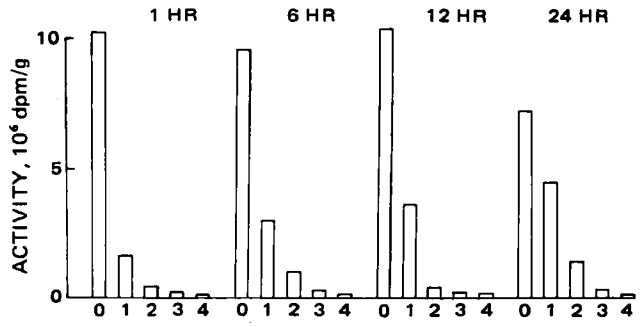

Figure 2—*Radioactivity located in several skin areas at various times after cutaneous application of [^{3}H]escin to the mouse. Column 0 corresponds to skin directly under the application site. Columns 1, 2, 3, and 4 refer to skin strips at 0.5-cm intervals away from the contact zone. (Data taken from Ref. 2.)*

that topical vasodilators capable of producing visible erythema induce a redness on the skin surface that expands with time beyond the region of application (3). As an example, the work by Fountain *et al.* (4) with the methyl ester of nicotinic acid may be cited (Fig. 3); recently, this line of investigation has been pursued in a more quantitative sense (5), and the radial transport of methyl nicotinate absorbed into the skin has been measured as a function of drug concentration and time (Table I). The rapidity of the outward movement implies that passive diffusion cannot be the mechanism involved, and it has been suggested that the cutaneous vasculature must participate. However, it is evident, whatever the mechanism, that the role of the microcirculation in this case is not merely depletive. It is also true that radial movement within the skin as assessed by visual detection of a pharmacological response is not limited to vasodilation, but has also been witnessed with the opposite effect produced by corticosteroids (6). Thus, the evidence for lateral transport prior to removal by dermal capillaries seems quite firm.

The most extensive study of local subcutaneous delivery of chemical substances was by Marty *et al.* (7–11) who

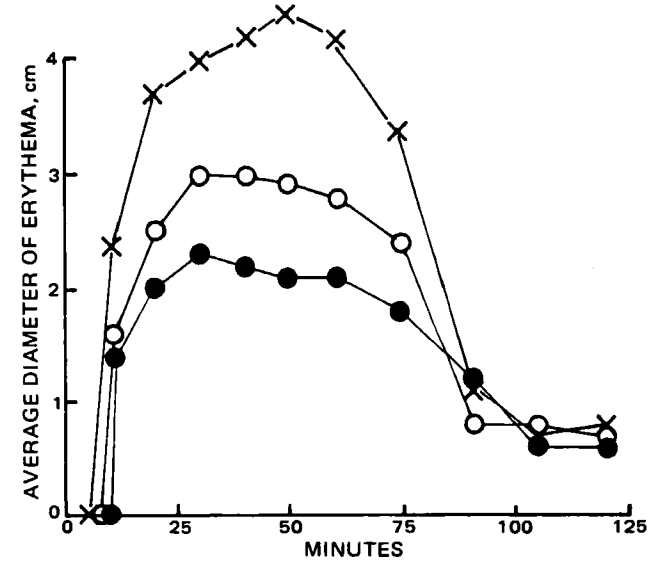

Figure 3—*Lateral movement of methyl nicotinate in the skin as assessed by erythematous area. The drug was applied in aqueous solution at ambient temperature (25°). Each data point is the average of five readings from various sites. Key: methyl nicotinate concentration (×) 1.0%; (○) 0.5%; (●) 0.25%. (Data from ref. 5.)*

attempted to explain the localized and deep therapeutic effect of certain dermatological preparations. These authors demonstrated, in each case, that percutaneous absorption was accompanied by diffusion and retention in the connective and muscle tissues located beneath the administration area. Alcoholic or propylene glycol solutions of radiolabeled thyroxine, triiodothyronine, estradiol, dexamethasone, and diisopropyl fluorophosphate were applied to the shorn abdomen or back of Sprague–Dawley rats, and the contact zones were protected and covered for periods of between 0.5 and 6 hr (7). At the end of the test the rat was killed and blood was drawn from the carotid artery. The site of skin application was dissected and fragments of subcutaneous tissue, muscle, and brown interscapular fat were removed from below the contact area. Samples of liver, kidneys, and part of the muscle from a rear paw were also collected and weighed.

Liquid scintillation counting was used to determine the radioactive concentrations in the various organs; the results were converted to amounts of drug present in nanograms per gram of tissue (Table II). For thyroxine, after 1 hr, the levels in plasma, liver, kidneys, and skeletal muscle were not significantly different. Beneath the application area, the radioactive concentration was 100 times greater in the subcutaneous tissue than in the plasma. The subjacent muscle showed the same phenomenon though of less intensity. The ratio (concentration in muscle below the application zone/concentration in paw muscle) increased substantially with time (4.2 at 30 min, 8.6 at 60 min, and 14.3 at 2 hr). Triiodothyronine gave similar results with considerable retention in the subcutaneous region and deeper muscle. Liver and kidney levels matched the plasma concentration. Estradiol showed the greatest retention in the subcutis and muscle below the application area (20 and 40 times the plasma level, respectively). The ratio of the skin muscle concentration to the paw muscle concentration was 17. Dexamethasone showed the lowest penetration rate, and enhanced drug delivery to the subjacent tissue was barely significant. Absorption of diisopropyl fluorophosphate was greatest, on the other hand, but resulted in little local muscle retention over that found elsewhere. In general, however, the authors showed accumulation in local skin muscle under the application zone.

It was suggested that this enhancement corresponded to molecular diffusion in the deep direction independent of the level of vascular perfusion (the latter being anatomically distinct for the regions of viable epidermis, dermis, and subjacent muscle). Further, the authors implied that, contrary to accepted concepts (12), the blood supply to the dermis is *not* capable of resorbing certain chemicals proportionately to their penetration through the epidermis. Thus, the substrate accumulates with time and is able to diffuse to deeper tissue. To support their hypothesis, Marty *et al.* (7) drew attention to the fact that both dexamethasone (a poorly absorbed substance with low solubility in water) and diisopropyl fluorophosphate (soluble in water and oil) show little accumulation, suggesting that the blood supply is able to transport these substances away in solution relatively efficiently. Conversely, the poorly water soluble thyroxine, triiodothyronine, and estradiol show much diminished resorption by the microvasculature and establish significant levels further into the tissue with increasing contact time.

In two subsequent reports (8, 9), the disposition of tritiated dexamethasone in mice and rats following topical application was compared with oral administration. Pro-

4	97 ± 30 [c]	29 ± 13 [d]	3.3 ± 1.0

[a] Data taken from Refs. 8 and 9. Dose applied = 19 μg/cm^2. [b] N = 5 at 1 hr; N = 6 at 2 and 4 hr. [c] Significance of difference between tissue and homogenized mouse, $p < 0.05$. [d] Significance of difference between tissue and homogenized mouse, $p < 0.01$.

cedures similar to those described in the previous study (7) were used; Tables III and IV summarize the results. It is plain that observations consistent with those of the earlier work were found; for example, in mice, under the area of topical application, the levels of radioactivity in subcutaneous tissue and in the lower muscle were 30 and 10 times higher, respectively, than in other tissues. Levels and distribution were quite different following oral administration; the plasma concentration was higher and large amounts were located in liver and kidney. Such a pattern of behavior (topical *versus* oral) was intimated to be of potential importance in terms of the metabolic inactivation of the administered chemical.

Further investigation into the fixation of topically applied materials in the superficial structures of the skin, and its importance in problems of decontamination and bioavailability, was then conducted (10, 11). The materials studied were diisopropyl fluorophosphate, malathion, parathion, estradiol, and progesterone. Comparable methodology was employed in the rat and mouse animal models (Tables V, VI, and VII). In the mouse, the amount of diisopropyl fluorophosphate found in the abdominal muscle under the application region and in the local vicinity represented ~28% (105 μg) of the total quantity absorbed; the remaining 72% was diluted in almost the entire animal. Malathion produced similar observations with 36% of the absorbed chemical being located in subcutaneous tissue at or near to the application zone. The subjacent tissue showed malathion levels of the order of 1000 μg/g compared with the animal carcass concentration

Table VII—Distribution of Diisopropyl Fluorophosphate, Malathion, and Parathion in Rat Tissues after Percutaneous Application [a]

Tissue	Tissue Concentration, μg/g: Diisopropyl Fluorophosphate	Malathion	Parathion
Subcutaneous tissue	130 ± 25 [b]	145 ± 20 [b]	155 ± 60 [b]

[a] Data taken from Ref. 10; 10 μl was applied over a surface area of 1 cm^2 for 1 hr. [b] N = 6 for diisopropyl fluorophosphate and parathion, N = 7 for malathion. [c] Significance of the difference between M_1 and M_2 (by the paired series method), $p < 0.001$. [d] Significance of the difference between M_1 and M_2 (by the paired series method), $p < 0.02$. [e] Significance of the difference between M_1 and M_2 (by the paired series method), $p < 0.05$.

Table VIII—Skin Absorption of Estradiol and Progesterone in the Mouse [a]

Steroid	Concentration, μg/g	Conc. in Tissue Under Application Zone, ng/g		Conc. in Whole Crushed Mouse, ng/g
		Subcutaneous	Muscle	
Estradiol	600	1695 ± 350	804 ± 191	43 ± 8
Progesterone	5000	43,600 ± 1100	9350 ± 2900	342 ± 52

[a] Data taken from Ref. 11.

Table IX—Local Concentrations of Steroids in Subcutaneous Tissue Beneath the Application Zone on the Skin after 2 hr [a]

Species	Steroid/Conc., %	Reference Conc.[b] (S), ng/g	Concentration Ratio (Tissue/S)	
			Subcutaneous	Muscle
Mouse	Estradiol/0.06	43 ± 8	39	19
Rat[c]	Estradiol/0.06	1.93 ± 0.18	75	11
Mouse	Progesterone/0.5	342 ± 52	125	27
Rat	Progesterone/0.5	15.1 ± 1.1	200	19

[a] Data taken from Ref. 11. [b] The reference concentration for the mouse is that in the whole crushed carcass after local excision; for the rat, the reference is plasma concentration. [c] After subcutaneous injection (10 μg/kg), S = 0.88 ± 0.05 and tissue/S = 2 (subcutaneous) and 0.75 (muscle).

of <5 μg/g. The data for parathion paralleled those for malathion quite closely. With the same substances in the rat, essentially the same pattern of behavior was found (Table VII). It is apparent, therefore, that the organophosphorous pesticides represent another class of compound for which subcutaneous fixation takes place.

For the steroids estradiol and progesterone (11) (Tables VIII and IX), accumulation was again found in the connective tissue of the abdominal muscle in the region under application. The effect was not seen after subcutaneous administration (Table IX). As before, the authors argued that the results demonstrate slow exchanges between blood and tissue such that the steroids are not removed efficiently as they diffuse in the intercellular fluids. Their observations were emphasized to be distinct from the classic "reservoir" effect noted for this class of compound (13–15), but it was suggested that the latter would mean that the likelihood of deeper penetration was increased. It was concluded that the data constitute pharmacokinetic proof contributing to the confirmation of local subcutaneous pharmacological effects of topically administered hormones.

Finally, in a recent paper (16) Rabinowitz *et al.* have studied the local, articular, and systemic absorption of oral and topical salicylates in dogs and humans using radioisotope techniques. Specifically, tissue disposition following oral [^{14}C]aspirin was compared with that after topical administration of triethanolamine [^{14}C]salicylate. In the canine model, one group of five beagles received per os a 500-mg capsule of [^{14}C]aspirin; a second group received 10 g of ^{14}C-labeled triethanolamine salicylate cream applied to the shaved right knee. Urine and blood samples were taken at 30 and 60 min, and the animals were then killed and tissue samples were analyzed. In the human model, six subjects with seropositive adult-onset rheumatoid arthritis and active knee synovitis were studied. Each subject was dosed, on separate occasions, orally with a [^{14}C]aspirin capsule and topically with 10 g of triethanolamine [^{14}C]salicylate cream to one knee; 2–6 weeks elapsed between the two administrations. Blood and urine samples were taken pretreatment and at 60 and 120 min postdose. At 120 min a synovial fluid aspiration was performed, taking care to avoid sample contamination from the application site. Patients were also asked to rate their subjective pain relief after the two medications.

Table X—[^{14}C]Salicylate Tissue Concentrations after Oral and Topical Salicylate Administration to Dogs [a]

Tissue	[^{14}C]Salicylate Concentration, μg/g	
	Oral	Topical
Blood		
30 min	34.80 ± 2.33	2.60 ± 0.02
60 min	30.60 ± 0.24	0.22 ± 0.02
Urine	12.57 ± 5.16	0.16 ± 0.09
Skin	0.64 ± 0.09	312.20 ± 40.80
Muscle	1.76 ± 0.16	38.20 ± 5.16
Fascia	1.04 ± 0.28	16.40 ± 1.96
Fat pad	1.00 ± 0.10	5.60 ± 1.20
Tendon	0.20 ± 0.03	3.00 ± 0.44
Ligament	0.50 ± 0.16	2.00 ± 0.20
Cartilage	0.43 ± 0.03	1.62 ± 0.49
Synovial fluid	1.00 ± 0.10	0.80 ± 0.12
Synovium	0.62 ± 0.10	0.74 ± 0.12

[a] Data taken from Ref. 16; all values are mean ± *SEM*.

Blood levels achieved in dogs after topical dosing were 10–100 times lower than those after oral administration of an equimolecular quantity of salicylate (Table X). However, the topical route resulted in higher local salicylate levels: the skin level was, expectedly, highest, but superior levels were seen in all local deeper tissues (ligament, tendon, cartilage, fascia, fat). The adjacent muscle showed 20 times more radioactivity after topical than oral administration.

Despite blood level differences spanning orders of magnitude (oral ≫ topical), topical dosing in humans produced 60% of the salicylate level in synovial fluid found after oral aspirin administration (Table XI). Subjective improvement was reported by two-thirds of the study group for both salicylate administration routes. Hence, once again, topical delivery is seen to produce high local subcutaneous levels of drug despite appreciably reduced blood concentrations. Direct deep penetration is thus the mechanism implicated. The authors of this study concluded that the lipid solubility of triethanolamine salicylate permits it to remain localized and to be slowly absorbed into the blood. This suggested a desirable feature for providing pain relief of local discomfort without systemic side effects. Parenthetically, a study[1] performed in the rabbit using two commercial preparations[2] of triethanolamine salicylate found as much salicylate in the muscle beneath the application site as in the same tissue

following oral dosing of aspirin. Also, a double-blind investigation carried out by Golden (17) using similar salicylate preparations[2] on 40 patients again indicated that equally effective subjective pain relief could be attained using topical triethanolamine salicylate as with oral aspirin. The topical delivery route was suggested to offer a superior alternative in the alleviation of certain rheumatic conditions.

CONCLUSIONS

The experimental work summarized in this survey leaves little doubt that the principle of subcutaneous delivery of topically applied substances is established. Together with the observations of lateral movement of penetrating materials within the dermis, it is apparent that the vascular supply of the skin is not always a perfect "sink." The limited data available is teasing and implies that deeper penetration may be a far more ubiquitous phenomenon than had ever been thought possible; in a sense, the behavior has rarely been seen (and hence assumed not to exist) because few have bothered to look for it. As with all research, additional studies will provide further clarification and delineation of these issues. For example, further kinetic information and, hence, the residence times of various penetrating species as a function of depth into the tissue, and the quantity of material present subcutaneously, await clearer assessment. More information is required about the amount of applied substance absorbed and what fraction of that amount is localized in the deeper tissues. In terms of a complete overview of percutaneous absorption as a drug delivery process, it is important that the aspects discussed here are not ignored. As for practical applications, the clinical one is self-evident and, even on the basis of the results reviewed here, has been repeatedly alluded to by the workers involved: deeper penetration can concentrate more active compound in local affected muscular tissue than can practical alternative administration routes. Better (or at least equivalent) therapy is possible, therefore, without systemic distribution of the drug, *i.e.*, significant blood levels, and possible side effects. The ramifications of this potential in terms of pharmacology and pharmacokinetics warrant further study.

ADDENDUM

Since the submission of this article two further examples of local deep penetration after topical administration have been brought to our attention. Areh (Ph.D. thesis, Massachusetts College of Pharmacy and Allied Health Science, 1982) prepared a number of salicylate derivatives and demonstrated, in rabbits, that therapeutic levels could be achieved in local muscle tissue after transdermal delivery. Wada *et al.* [*J. Pharm. Pharmacol.*, **34**, 467 (1982)] considered the percutaneous absorption and anti-inflammatory activity of indomethacin administered in a topical ointment to rats. They found that the drug concentration in the muscle of the treated paw was very high and ~10 times that in the tissue of any other paw and 7 times that in the blood.

Moisture Sorption Kinetics for Water-Soluble Substances I: Theoretical Considerations of Heat Transport Control

L. VAN CAMPEN *, G. L. AMIDON ‡, and G. ZOGRAFI ˣ

Received June 9, 1982, from the *School of Pharmacy, University of Wisconsin-Madison, Madison, WI 53706.* Accepted for publication October 22, 1982. Present addresses: *Boehringer Ingelheim Ltd., Ridgefield, CT 06877 and ‡College of Pharmacy, University of Michigan, Ann Arbor, MI 48104.

Abstract □ A model based on heat transport control was developed to describe the uptake of water on a deliquescent solid in an atmosphere of pure water vapor. The model assumes the presence of a saturated liquid film on the surface of the solid. The decrease in the vapor pressure of water over the surface, brought about by the colligative effect of solid dissolved in the liquid film, is effectively offset by the increase in temperature of the film (and the solid) caused by the heat released on condensation of the water vapor. The thermal transients die out quickly and a steady-state analysis is valid. At steady state the temperature of the liquid film (and solid) is that temperature at which the vapor pressure of water above the saturated solution is equal to the chamber pressure. Consequently, water uptake occurs at a rate that depends on the heat flux away from the surface. The water uptake rate, W'_h, is constant at a given relative humidity and is described by an equation of the form $W'_h = (C + F)\cdot\ln(RH_i/RH_o)$, where C and F are conductive and radiative coefficients, RH_i the chamber relative humidity, and RH_o the relative humidity at and above which continuous water uptake (deliquescence) occurs. The model contains no adjustable parameters and can thus be directly tested against experimental results.

Keyphrases □ Sorption—moisture, water-soluble substances, kinetics, heat transport control, theoretical model with water vapor atmosphere □ Kinetics—moisture sorption of water-soluble substances, heat transport control, theoretical model with water vapor atmosphere □ Deliquescence—water-soluble substances, sorption kinetics, heat transport control, theoretical model with water vapor atmosphere

The interaction of water with pharmaceutical materials plays a fundamental role in many aspects of drug product development, from synthetic design and dosage form selection to effective product packaging and drug bioavailability. The affinity that a substance has for sorbing water from its vapor state is generally referred to as hygroscopicity. Since adsorption or condensation is not an entropically favored process, the water–solid interaction must provide a sufficient enthalpic driving force if such sorption is to occur. Even the relatively weak binding of physisorption, for which the heat of adsorption is comparable to the heat of condensation, can provide this driving force over a large range in relative humidity. At higher relative humidities, multilayer adsorption can occur (1). For water-soluble substances, dissolution of the molecules at the solid surface can occur once such multilayer adsorption is established. Chikazawa, Kanazawa, and others have shown that as few as two layers of adsorbed water can effect hydrated ion formation at relative humidities 30–40% below that humidity associated with the equilibrium water vapor pressure over a saturated solution of the solid (2, 3). This critical relative humidity, or RH_o, characteristic of the solid is that point above which the adsorbed water assumes the character of bulk solution or condensate. Water activity of the condensate is depressed as a result of the solute present, and the phenomenon of deliquescence is thereby triggered.

Figure 1 shows a schematic representation of the deliquescent process for a soluble drug particle. Suppose that water vapor at a bulk atmosphere relative humidity, RH_i, adsorbs onto the solid surface of the particle. If this humidity is above the RH_o of the drug, further adsorption will occur spontaneously and the thickness of the condensate film will grow. Solid will continue to dissolve and saturate the film, maintaining the relative humidity at the surface at RH_o. To reach equilibrium with the atmosphere at RH_i, total dissolution and some degree of solution dilution must occur. To predict deliquescent behavior *a priori* requires an understanding of what fundamental factors, chemical and environmental, control the kinetics of the process. Despite the practical consequences of deliquescent hygroscopic behavior, only limited investigations of sorption kinetics above RH_o have appeared in the literature (4–8), all using an empirical expression to describe the phenomenon. The purpose of the present study, therefore, was to gain a more quantitative understanding of deliquescence.

BACKGROUND

Consider the overall picture of what processes are operating to control deliquescence in the presence of an inert atmosphere such as air, where adsorption of vapor onto any solid surface involves the simultaneous transport of both mass and heat (9–16). While there may exist additional heat effects, these two processes are at least coupled by the heat of water condensation released per unit mass transported from the vapor to the condensed phase. This is expressed by:

$$W' \cdot \Delta H = Q \qquad \text{(Eq. 1)}$$

where $W' = dW/dt$ = rate of mass transport (vapor condensation), W is the sample weight at time t, ΔH is the heat generated per unit mass condensed, and Q is the heat flux from the surface at which condensation occurs. The extent to which either process limits or controls the rate of condensation depends on the molecular diffusivities and thermal prop-

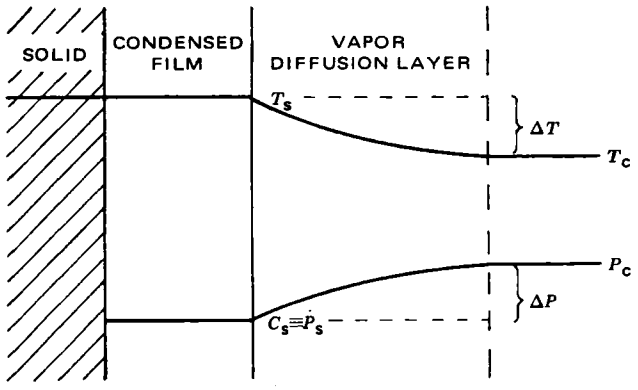

Figure 2—*Thermal and pressure gradients existing at a soluble solid surface covered with condensed water.*

erties of all phases in the condensing system. For hygroscopic moisture uptake by a solid exhibiting substantial water solubility, such as that illustrated in Fig. 1, this system consists of three phases: pure, undissolved solid; a liquid film of condensate in which solid has dissolved; and water vapor in an atmosphere of inert gas. It follows then that there exist two interfaces over which transport must occur: solid–liquid and liquid–vapor. A closer examination of this condensation system is given in Fig. 2, in which:

$$P_c = RH_i\left(\frac{P_0}{100}\right) \qquad \text{(Eq. 2)}$$

where P_c is equal to the bulk water vapor pressure in the atmosphere, and

$$P_s = RH_o\left(\frac{P_0}{100}\right) \qquad \text{(Eq. 3)}$$

where P_s is equal to the water vapor pressure in equilibrium over a saturated solution of the solid; P_0 represents the pressure of pure water vapor at bulk atmosphere temperature, T_c, and C_s and T_s represent the water vapor concentration and the temperature at the surface, respectively. Possible steady-state thermal and pressure gradients are indicated in Fig. 2. Steady-state sorption implies that the driving force for uptake, whether thermal or diffusive, has reached a constant value, *i.e.*, W' is constant.

The zero pressure (or concentration) gradient shown within the liquid film in Fig. 2 is consistent with the assumption that film saturation is maintained throughout steady-state moisture uptake. The likelihood of a zero gradient in temperature within the solid and liquid phases will be substantiated shortly in the discussion of non-steady-state heat transport.

The thermodynamic basis for hygroscopic uptake lies in the difference between P_s and P_c in the vicinity of the saturated film surface. Water vapor will condense progressively on the surface as long as $P_s < P_c$. Three general cases exist when sorption occurs, each implying a different extent to which heat or mass transport controls uptake.

Case *i*: Mass Transport Control (Isothermal), $\Delta T = 0$, $\Delta P = \Delta P_{max}$—Heat generated upon condensation is rapidly transported away from the liquid–vapor interface so as to render the system effectively isothermal throughout the course of steady-state uptake. The pressure difference, ΔP, is maximized since P_s at T_c is less than P_s at T_s for any $T_s > T_c$. The rate of uptake, W', is then proportional to ΔP and the surface area over which uptake occurs.

Case *ii*: Heat Transport Control (Isobaric), $\Delta T = \Delta T_{max}$, $\Delta P = 0$—Heat generated upon condensation is sufficient to maintain the liquid–vapor interface at a temperature T_s, elevated above that of the bulk atmosphere maintained externally at T_c. The temperature difference, $\Delta T = T_s - T_c$, is exactly that necessary to raise P_s at T_c to P_s at T_s such that P_s at T_s equals P_c at T_c. In this case, W' is proportional to ΔT by virtue of its explicit dependence on the heat flux as given in Eq. 1.

Case *iii*: Mass–Heat Transport in Balance, $0 < \Delta T < \Delta T_{max}$, $0 < \Delta P < \Delta P_{max}$—The gradients depicted in Fig. 2 exemplify this intermediate situation. Because neither ΔP nor ΔT is constrained to zero, there exists no unique ΔP–ΔT combination which can be predicted *a priori* to satisfy the requirements of steady-state condensation without knowledge of both the thermal and diffusive characteristics of the system.

In considering the three cases given above, it is apparent that for water uptake from an atmosphere of pure water vapor, diffusion barriers to transport in the vapor phase cannot exist. In the absence of a second gas component, resistance to transport can arise only from the collision of water molecules against one another, which in itself would not generate a measurable gradient in water vapor pressure, *i.e*, "nature abhors a vacuum." Consequently, the role of heat transport can be tested explicitly by deriving appropriate equations for case *ii* and testing the model with experimental studies using an atmosphere of pure water vapor. The present paper, therefore, reports a theoretical model for case *ii*; the second paper of this series (17) presents a test of this model with experimental studies, and the third paper describes water uptake in an inert atmosphere such as air (18).

THEORETICAL

The sample undergoing sorption is considered to be a compressed circular disk situated symmetrically near the hemispherical base of a cylindrical chamber, a configuration chosen for its experimental feasibility. Figure 3 illustrates the geometry that must be considered in discussing the transport of heat within this system. Regarding the development of a local temperature gradient within the sample disk itself, the disk may be considered to behave as a planar slab if its diameter far exceeds its thickness. With respect to any transport external to the sample or the surface of its developing film, a hollow-sphere geometry will be assumed, consistent with the radial nature of the transport occurring between the disk and the surrounding chamber. Here the sample is represented by a hypothetical inner sphere of radius $r = a$ such that it is equivalent in surface area to that of the sample itself; the chamber then behaves as an outer sphere of radius $r = b$ at which surface the temperature is maintained at T_c. Presuming the disk and chamber to behave as concentric spheres allows a more manageable mathematical treatment of transport occuring in the system. The more rigorous approach of using disk-to-sphere or disk-to-hemisphere transport geometries is unnecessarily complex for two reasons. First, the isotherm surfaces that exist during steady-state heat transport from a disk to a surrounding sphere take on spherical shape as distance from the disk increases, behaving much like a hollow-sphere system when the disk diameter is small relative to the outside sphere. Second, and more practically, the errors associated with predicting transport as if within a closed sphere should have a constant effect for any sample tested in this configuration. Thus, the legitimate theoretical comparison of the hygroscopic behavior of different materials can be made despite these approximations.

Upon condensation, heat is generated at the film surface by two primary sources (in the absence of auxiliary reactions, *e.g.*, hydration, *etc.*): heat of condensation, releasing $\Delta H_v = 0.58$ cal/mg of water condensed; and heat of dissolution, approximately equal to the product of the solubility, C_{sat}, and the heat of solution, ΔH_{soln}. For a number of nonhydrating alkali halide salts, $C_{sat} \cdot \Delta H_{soln}$ is unlikely to exceed an approximate value of 0.04 cal/mg of water; for such compounds the contribution of the heat of dissolution to the heat generated on condensation can be considered negligible, such that $\Delta H = -\Delta H_v$ in Eq. 1.

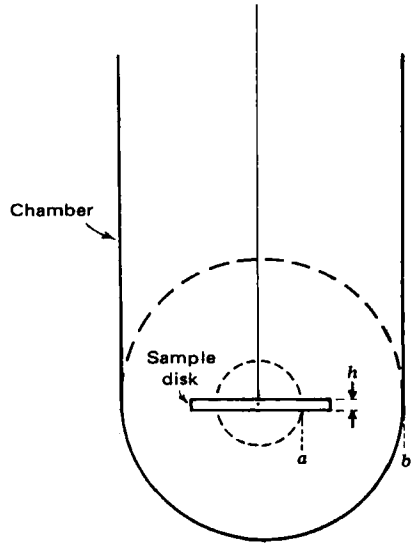

Figure 3—*Chamber and sample geometry; slab and hollow-sphere model.*

Table I—Physical Constants for the Transport Model in an Atmosphere of Pure Water Vapor

Symbols	Constants
a, cm	0.5[a]
b, cm	2.0[a]
M_w, mg/mole	1.8×10^4
k, cal/cm·sec·deg	4.26×10^{-5}
α, cm²/sec	4.13
ΔH, cal/mole	−10,500[b]
ΔH_v, cal/mole	10,500
R, cal/deg·mole	1.987
T_c, °K	298
σ, cal/cm²·sec·deg⁴	1.36×10^{-12}
e	0.95[c]

[a] Theoretically arbitrary in value; these particular values have been assigned in this case for their consistency with an available experimental apparatus. [b] The assumption is made here that the heat of condensation predominates over all other possible heat effects such that the latter are neglected. [c] Film surface emissivity approximated by value given for pure water (20).

Heat transport away from the surface limits the rate of condensation; thus, uptake depends on the thermal properties of the system. There exist two primary heat sinks in the system described in Fig. 3: the atmosphere surrounding the sample and the sample itself. Heat transport to and through these media can occur *via* three basic mechanisms: conduction inward through the sample or radially outward through the atmosphere; convection, a term used here (in the absence of forced convection) to designate the extra heat transport that occurs as a result of the radially inward bulk flow of water vapor that feeds the condensation process; and radiation from the hypothetical surface $r = a$ to surface $r = b$.

A general expression for heat flux, Q, reflecting the three mechanisms of heat transport (19) is:

$$Q = q_{cond} + q_{conv} + q_{rad} \quad \text{(Eq. 4)}$$

where

$$q_{cond} = -4\pi r^2 \cdot k \frac{dT}{dr} \quad \text{(Eq. 5)}$$

$$q_{conv} = W' C_p (T_s - T) \quad \text{(Eq. 6)}$$

$$q_{rad} = A\sigma e (T_s^4 - T_c^4) \quad \text{(Eq. 7)}$$

and k is the thermal conductivity of the medium, C_p is the specific heat capacity of the medium, A is the sample surface area $= 4\pi a^2$, σ is the Stefan–Boltzmann constant, and e is the emissivity of the sample surface. Table I contains the physical constants of interest.

Before discussing the quantitative implications of steady-state uptake for heat transport-controlled condensation, it is necessary to estimate the time required to establish steady-state thermal gradients within the system, *i.e.*, within both the solid disk and the surrounding atmosphere. In doing so the assumption is made that thermal conductivity, thermal diffusivity, and specific heat values are independent of water vapor concentration and temperature.

Non-Steady-State Heat Transport—*Sample Disk*—Only conduction need be considered for heat transport within the sample disk. The time-dependent temperature distribution for a slab of thickness, h, whose parallel surfaces are subjected to a sudden change in temperature has already been determined in the literature (21, 22). The sample disk can be assumed to behave according to this model if edge effects are neglected. Specifically, the disk region bounded by $-h/2 < z < +h/2$ is subjected to the boundary conditions that $T = T_c$ for all z at $t = 0$ and $T = T_s$ at $z = \pm h/2$ for $t > 0$. The temperature profile describing one-half of the (symmetrical) slab for $z = 0$ to $z = h/2$ is given by (21):

$$T = T_s + \frac{4}{h} \sum_{n=0}^{\infty} \exp[-\alpha(2n+1)^2\pi^2 t/h^2] \cos\frac{(2n+1)\pi z}{h} \cdot \left[\frac{h(-1)^{n+1}T_s}{(2n+1)\pi} + T_c \int_0^{h/2} \cos\frac{(2n+1)\pi z'}{h} dz'\right] \quad \text{(Eq. 8)}$$

where α is the thermal diffusivity of the solid slab. In dimensionless terms this can be written (21, 22):

$$T^* = 1 - \frac{4}{\pi} \sum_{n=0}^{\infty} \frac{(-1)^n}{2n+1} \cdot \exp[-(2n+1)^2\pi^2 t^*/4] \cos\frac{(2n+1)\pi z^*}{2} \quad \text{(Eq. 9)}$$

in which:

$$T^* = \frac{T - T_c}{T_s - T_c} \quad \text{(Eq. 10)}$$

$$z^* = \frac{z}{h/2} \quad \text{(Eq. 11)}$$

$$t^* = \frac{\alpha t}{(h/2)^2} \quad \text{(Eq. 12)}$$

From Eq. 9 it can be shown (21, 22) that the center ($z = 0$) of such a slab reaches 97% of its equilibrium value by dimensionless time, $t^* = 1.5$, from which real time can be calculated. For example, the center portion of a (relatively) thin solid disk of potassium chloride crystal of $\alpha = 0.056$ cm²/sec and a thickness $h = 0.06$ cm should attain ~97% of its final temperature change, ΔT, within 0.03 sec. Thus, one could predict that thermal equilibrium should be rapidly established within such materials as the alkali halide salts. Furthermore, the heat required to raise, for example, a 150-mg sample of potassium chloride ($C_p = 0.162$ cal/g·deg) by a $\Delta T = 5°$ is 0.12 cal. Since heat is released at the disk surface at the rate of 0.58 cal/mg of water vapor condensed, the role of such a disk as a significant heat sink over the course of substantial steady-state uptake can be considered negligible.

Atmosphere—The time required to establish a steady-state temperature gradient external to the disk surface depends on the non-steady-state component of heat transport radially outward from the sample. Such heat transport through the atmosphere can occur *via* all three mechanisms identified earlier, and indeed they all contribute to maintaining the steady-state gradient. If the water vapor atmosphere is considered transparent to radiation, however, only conduction and convection will contribute to the establishment of the gradient. Since the effect of convection on maintaining the steady state will be shown to be negligible in the following discussion, only conductive flux will be considered in the non-steady-state gradient development.

The solution for the time-dependent temperature distribution in the atmosphere is readily accessible from the non-steady-state mass and heat transport equations developed in Appendix I. In terms of dimensionless variables where T^* is defined in Eq. 10 and the analogous distance and time variables are defined as:

$$r^* = \frac{r - a}{b - a} \quad \text{(Eq. 13)}$$

and

$$t^* = \frac{\alpha t}{(b-a)^2} \quad \text{(Eq. 14)}$$

the expression for T^*, as taken from Eq. A8, becomes:

$$T^* = \left[\frac{1}{r^*(b/a - 1) + 1}\right] \cdot \left[1 - r^* - \frac{2}{\pi} \sum_{n=1}^{\infty} \frac{1}{n} \sin n\pi r^* \cdot \exp(-n^2\pi^2 t^*)\right] \quad \text{(Eq. 15)}$$

This function is described in Fig. 4 where $\Pi^* = T^*$. For condensation in vacuum (where $b - a = 1.5$ cm) the time required to reach $t^* = 0.5$ is only 0.28 sec. If air were present, steady-state gradients would essentially be attained within 5.6 sec given an estimated value of $\alpha = 0.214$ cm²/sec for humid air[1]. As apparent earlier for the disk, it can be concluded that a steady thermal state is rapidly established within the atmosphere relative to the time scale of extended uptake.

The time required for the conductive heat flux, and therefore uptake rate, to reach a steady-state level at surface $r = a$ can be calculated using Eq. A21. For the example above, these lag times equal (−)0.047 sec and (−)0.94 sec in vacuum and in air, respectively. These times are consistent with the development of the temperature gradients as established in Fig. 4. At surface $r = b$, lag times are calculated using Eq. A25, and for the vacuum and air systems equal 0.94 sec and 1.9 sec, respectively.

Steady-State Heat Transport—Steady-state moisture uptake requires a constant heat flux, by virtue of the coupling in Eq. 1; this, in turn, implies the maintenance of a constant ΔT. The ΔT necessary to raise P_s at T_c to P_s at T_s such that it equals P_c at T_c, as implied by heat transport control, can by first approximation be estimated by the Clausius–Cla-

[1] Since heat transfer will also contribute to sorption kinetics in air, and since the effect of air will be discussed in the third paper in this series (18), lag times in reaching steady state both in vacuum and air are included at this point for comparison purposes, as developed in Appendix I. This value for humid air was estimated using C_p values of water vapor and air weighted by mole fraction and thermal conductivity (k) values for water vapor and air, as taken from Table I and as calculated using the Lindsay and Bromley modification of the Wassiljewa equation (23), respectively.

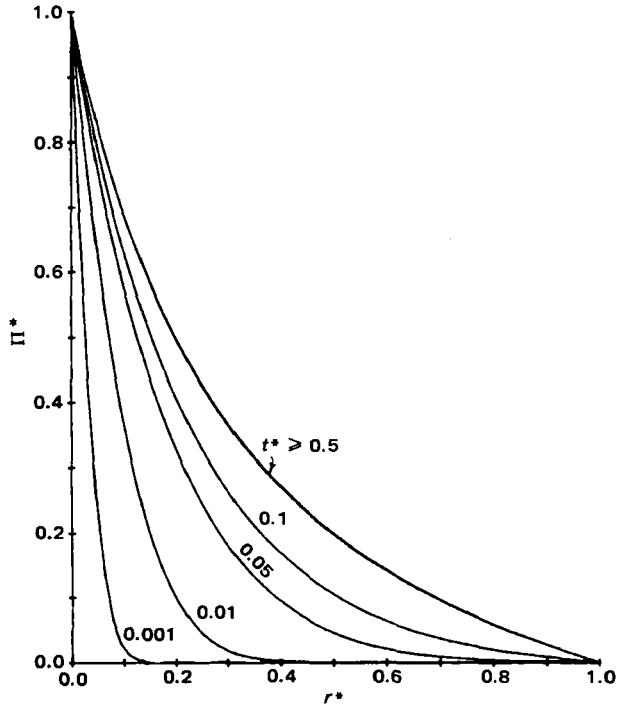

Figure 4—*Gradient in* Π* *at various* t* *values for a hollow sphere,* a < r < b, where b/a = 4.

peyron equation as developed below:

$$\ln \frac{P_s(T_s)}{P_s(T_c)} = \ln \frac{P_c(T_c)}{P_s(T_c)} \quad \text{(Eq. 16)}$$

$$= \ln \frac{RH_i}{RH_o} \quad \text{(Eq. 17)}$$

such that:

$$\ln \frac{RH_i}{RH_o} = \frac{\Delta H_v}{RT_sT_c}(T_s - T_c) \quad \text{(Eq. 18)}$$

where ΔH_v is the heat of vaporization and R is the gas constant. Solving for ΔT, one obtains:

$$T_s - T_c = \frac{RT_c^2 \ln \frac{RH_i}{RH_o}}{\Delta H_v - RT_c \ln \frac{RH_i}{RH_0}} \quad \text{(Eq. 19)}$$

For several nonhydrating alkali halide salts whose solubility and RH_o dependence on temperature are known (24, 25), ΔT as defined above is observed to vary from 0–15°, depending on the ratio of $RH_i(T_c)$ to $RH_o(T_c)$. Use of the Clausius–Clapeyron equation to estimate these ΔT values for saturated salt solutions is subject to two sources of error: the small temperature dependence of the heat of vaporization of pure water and, more significantly, the effect of the salt and its (temperature-dependent) solubility on water activity and the heat of vaporization. Despite these errors, Eq. 19 predicts ΔT values equal to 100–110% of those actually observed (24, 25) for saturated solutions of the alkali halides.

The evaluation of transient-state heat flux within and heat capacity of the sample disk suggests that the disk has a negligible effect on the maintenance of ΔT. Of primary importance, then, is the radial heat flow within the hollow-sphere system. From Eqs. 4–7 this steady-state flux can be expressed as:

$$Q = -4\pi r^2 \cdot k \frac{dT}{dr} + W'C_p(T_s - T) + A\sigma e(T_s^4 - T_c^4) \quad \text{(Eq. 20)}$$

During steady-state flux:

$$\frac{dQ}{dr} = 0 \quad \text{(Eq. 21)}$$

Therefore:

$$0 = 4\pi k \frac{d}{dr}\left(r^2 \frac{dT}{dr}\right) + W'C_p \frac{dT}{dr} \quad \text{(Eq. 22)}$$

where the derivative of the radiation term vanishes under the assumption that the atmosphere is transparent to radiative flux. Differentiating the product term and rearranging leads to:

$$\frac{d^2T}{dr^2} + \left(\frac{2}{r} + \frac{W'C_p}{4\pi kr^2}\right)\frac{dT}{dr} = 0 \quad \text{(Eq. 23)}$$

Solving the equation by reduction of order and then applying the boundary conditions, $T = T_s$ at $r = a$ and $T = T_c$ at $r = b$, one arrives at the expression:

$$T = \frac{T_s\left[\exp\left(\frac{W'C_p}{4\pi kr}\right) - \exp\left(\frac{W'C_p}{4\pi kb}\right)\right] - T_c\left[\exp\left(\frac{W'C_p}{4\pi kr}\right) - \exp\left(\frac{W'C_p}{4\pi ka}\right)\right]}{\left[\exp\left(\frac{W'C_p}{4\pi ka}\right) - \exp\left(\frac{W'C_p}{4\pi kb}\right)\right]} \quad \text{(Eq. 24)}$$

Expressed in terms of T^* as defined in Eq. 10:

$$T^* = \frac{1 - \exp\left[\frac{W'C_p}{4\pi k}\left(\frac{1}{r} - \frac{1}{b}\right)\right]}{1 - \exp\left[\frac{W'C_p}{4\pi k}\left(\frac{1}{a} - \frac{1}{b}\right)\right]} \quad \text{(Eq. 25)}$$

The above expressions describe the steady-state temperature gradient within the hollow sphere as maintained by both conduction and convection. Convection is used here to denote the heat transport that occurs in raising the temperature of the water vapor surrounding the sample to T_s just prior to its condensation. It will be shown that this convective component of the flux has essentially no effect on the temperature gradient given W' values of experimental magnitude. Neglecting the convective term, Eq. 22 becomes:

$$0 = 4\pi k \frac{d}{dr}\left(r^2 \frac{dT}{dr}\right) \quad \text{(Eq. 26)}$$

This leads to a second-order differential equation whose solution over the same boundary conditions is:

$$T = (T_s - T_c)\frac{a}{r}\left(\frac{b - r}{b - a}\right) \quad \text{(Eq. 27)}$$

or

$$T^* = \frac{a}{r}\left(\frac{b - r}{b - a}\right) \quad \text{(Eq. 28)}$$

As expected, this is the same gradient described by Eq. (A4) as $t \to \infty$. As the term $W'C_p/4\pi k$ increases, convection is more likely to influence the temperature profile. Yet even at a relatively high uptake rate of W' = 2 mg/min in the vacuum system, for which the value of $C_p/4\pi k$ = 837 cm·sec/g, the temperature gradient remains effectively indistinguishable from the steady-state profile exhibited in Fig. 4, in which convection was neglected. Consistent with this result, it has been shown (26) that convection contributes negligibly (<2%) to the overall steady-state heat flux from the surface $r = a$. This flux is then given by:

$$Q\Big|_{r=a} = -4\pi ka^2 \frac{dT}{dr}\Big|_{r=a} + q_{rad} \quad \text{(Eq. 29)}$$

$$= -4\pi ka^2(T_s - T_c)\frac{dT^*}{dr}\Big|_{r=a} + q_{rad} \quad \text{(Eq. 30)}$$

which on substituting Eqs. 7 and 28 yields:

$$Q\Big|_{r=a} = \frac{4\pi kab}{b - a}(T_s - T_c) + 4\pi a^2\sigma e(T_s^4 - T_c^4) \quad \text{(Eq. 31)}$$

Recalling Eq. 1, the uptake rate may easily be expressed in terms of T_s by utilizing the above equation. It is of greater interest, however, to determine the direct dependence of W', the dependent experimental variable, on RH_i, the independent variable. An expression relating ΔT to RH_i is given by Eq. 19. A comparable expression for $\Delta(T^4)$ is required for substitution into the radiation term. From Eq. 19 the solution for T_s can be raised to the fourth power and simplified by dropping all terms contributing <2% (for RH_i/RH_o ratios <2.7) to the resulting overall polynomial. This leads to an approximate expression for $\Delta(T^4)$ similar in form to that for ΔT:

$$T_s^4 - T_c^4 = \frac{4RT_c^5 \ln \frac{RH_i}{RH_o}}{\Delta H_v - 4RT_c \ln \frac{RH_i}{RH_o}} \quad \text{(Eq. 32)}$$

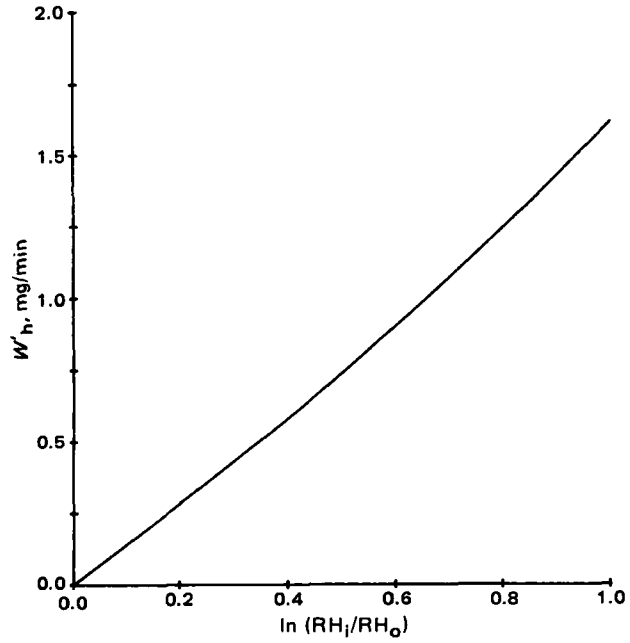

Figure 5—*Theoretical* W'_h versus *ln* (RH_i/RH_o) *as predicted by Eq. 33.*

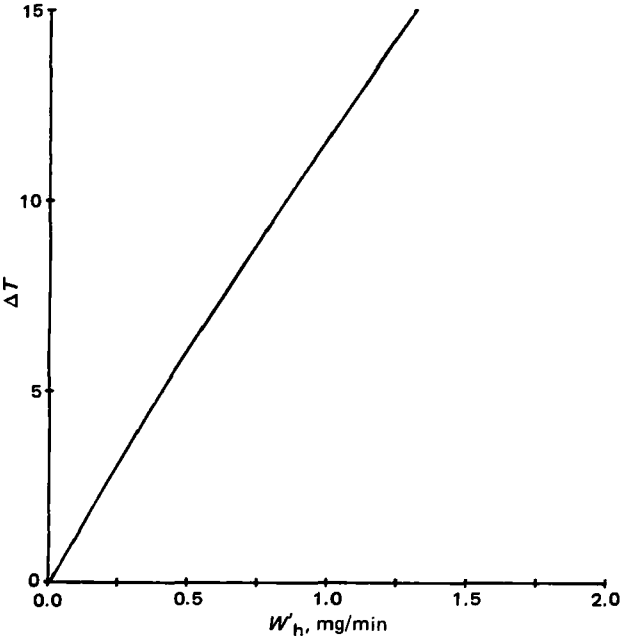

Figure 6—*Relationship between* ΔT *and* W'_h *for heat transport-controlled sorption (see Table I).*

Substituting Eqs. 19 and 32 into Eq. 31, then combining with Eq. 1, one arrives at a final equation for the dependence of W', or W'_h to indicate heat transport control, on RH_i:

$$W' = W'_h = \left[\frac{60M_w \cdot 4\pi kab}{\Delta H(b-a)}\left(\frac{RT_c^2}{\Delta H_v - RT_c \ln \frac{RH_i}{RH_o}}\right) + \frac{60M_w \cdot 4\pi a^2 \sigma e}{\Delta H}\left(\frac{4RT_c^5}{\Delta H_v - 4RT_c \ln \frac{RH_i}{RH_o}}\right)\right] \cdot \ln \frac{RH_i}{RH_o} \quad \text{(Eq. 33)}$$

where the factor $60M_w$ simply converts W'_h from mole/sec to mg/min. More simply:

$$W'_h = (C + F) \ln \frac{RH_i}{RH_o} \quad \text{(Eq. 34)}$$

where C and F represent the conduction and radiative terms, respectively, in Eq. 33 and are themselves weakly dependent on ln (RH_i/RH_o). Interestingly, C and F, *i.e.*, conduction and radiation, contribute almost equally to heat transport in an atmosphere of pure water vapor.

Eq. 33 allows *a priori* prediction of heat transport-controlled uptake rates for condensation systems whose geometry is well defined and whose physical properties are known. Furthermore, the curve so predicted and shown in Fig. 5 represents a unique curve for W'_h as a function of ln (RH_i/RH_o) that should be common to all materials, regardless of their RH_o values, given the same sample and chamber geometry.

Since ΔT is a unique function of ln (RH_i/RH_o) by virtue of the Clausius–Clapeyron relation and W'_h is also a unique function of ln(RH_i/RH_o), ΔT and W'_h should be interdependent if condensation is indeed proceeding under thermal control. Again using the parameters listed in Table I, the predicted graph of ΔT *versus* W'_h is given in Fig. 6.

SUMMARY

A heat transport control model for water uptake by solids has been developed for the case of a water-soluble solid immersed in an atmosphere of pure water vapor. The model is based on the fact that the heat of condensation of water released during water uptake must be transported to the surroundings. In an atmosphere of pure water vapor, where diffusion does not occur, this heat flux limits the rate of condensation.

Development of a non-steady-state model indicates that the non-steady time period is very short. Thus, a steady-state model is appropriate for time periods of pharmaceutical interest. The equations for heat transport (conduction, convection, and radiation) when combined with the Clausius–Clapeyron equation lead to an equation which predicts the water uptake rate with no adjustable parameters (Eq. 33). The results of the analysis indicate that the convection term is of minor importance and that conduction and radiation control heat flux to comparable degrees.

APPENDIX I: NON-STEADY STATE

The non-steady-state solution referred to previously is developed herein. Since non-steady-state considerations are of interest both here and in subsequent papers, which include mass transport considerations, a general solution is developed for both heat and mass transport. Because of the analogous behavior of mass diffusion and (conductive) heat flow, the general parameter, Π, will be used to represent either concentration (C) or temperature (T). Similarly, the symbol, τ, will be used to represent a general diffusivity in place of D or α.

The general equation for radial diffusion with a constant diffusion coefficient is:

$$\frac{\partial \Pi}{\partial t} = \tau \left[\frac{1}{r^2}\frac{\partial}{\partial r}\left(r^2 \frac{\partial \Pi}{\partial r}\right)\right] \quad \text{(Eq. A1)}$$

The solution to this equation describes the time dependence of either the concentration distribution for mass diffusion or the temperature distribution for conductive heat flux in which all velocity gradients associated with convection and viscous dissipation have been assumed to be equal to zero (27). For the hollow-sphere system in which $a < r < b$, subjected to the boundary conditions $\Pi = \Pi_c$ for all r at $t = 0$, $\Pi = \Pi_s$ at $r = a$, and $\Pi = \Pi_c$ at $r = b$ for $t > 0$, Π is described by the function (28):

$$\Pi = \frac{a\Pi_s}{r} + \frac{(b\Pi_c - a\Pi_s)(r-a)}{r(b-a)} + \frac{2}{\pi r}\sum_{n=1}^{\infty}\left\{\frac{b\Pi_c\cos n\pi - a\Pi_s}{n} \cdot \sin\frac{n\pi(r-a)}{b-a}\cdot\exp[-\tau n^2\pi^2 t/(b-a)^2]\right\} + \frac{2\Pi_c}{r(b-a)}\sum_{n=1}^{\infty}\left\{\sin\frac{n\pi(r-a)}{b-a}\cdot\exp[-\tau n^2\pi^2 t/(b-a)^2] \cdot\int_a^b r'\sin\frac{n\pi(r'-a)}{b-a}\,dr'\right\} \quad \text{(Eq. A2)}$$

Given that Π^* is defined as:

$$\Pi^* = \frac{\Pi - \Pi_c}{\Pi_s - \Pi_c} \quad \text{(Eq. A3)}$$

it can be shown that the nature of Eq. A1 does not change if expressed in dimensionless terms, *i.e.*, Π^* can be substituted for Π in Eq. A1. Thus, the solution expressed by Eq. A2 for Π is readily adapted to a solution for Π^* according to Eq. A3. Because the boundary conditions are redefined as $\Pi^* = 1$ at $r = a$ ($\Pi = \Pi_s$) and $\Pi^* = 0$ at $r = b$ ($\Pi = \Pi_c$), however, the solution for Π^* simplifies to:

$$\Pi^* = \frac{a}{r} + \frac{(-a)(r-a)}{r(b-a)} + \frac{2}{\pi r}\sum_{n=1}^{\infty}\left\{\frac{-a}{n}\sin\frac{n\pi(r-a)}{b-a}\cdot\exp[-\tau n^2\pi^2 t/(b-a)^2]\right\} \quad \text{(Eq. A4)}$$

where the fourth term vanishes when expressed in dimensionless form. Then, allowing:

$$t^* = \frac{\tau t}{(b-a)^2} \quad \text{(Eq. A5)}$$

and

$$r^* = \frac{r-a}{b-a} \quad \text{(Eq. A6)}$$

where then

$$\frac{a}{r} = \frac{1}{r^*(b/a-1)+1} \quad \text{(Eq. A7)}$$

and substituting these new variables into Eq. A4, the expression for Π^* further simplifies to:

$$\Pi^* = \left[\frac{1}{r^*(b/a-1)+1}\right]\left[1 - r^* - \frac{2}{\pi}\sum_{n=1}^{\infty}\frac{1}{n}\sin n\pi r^* \cdot\exp(-n^2\pi^2 t^*)\right] \quad \text{(Eq. A8)}$$

The time course to developing a steady-state Π^* gradient over r^* can then be plotted for various t^* values at a given ratio of b/a. Figure 4 presents such a plot for $b/a = 4$, where the incremented value of n was truncated at $n = 20$. Discontinuities observed in the $t^* = 0.001$ plot at $\Pi^* \sim 0$ would not have appeared if n were to have been truncated at an even higher value. It is clear from Fig. 4 that the gradient at $t^* = 0.5$ is virtually indistinguishable from the $t^* = \infty$ curve.

To determine the time required for the actual flux, and hence uptake rate, to reach a steady-state level, the time dependence of the flux must be evaluated. Total mass flux from the surface $r = a$ over time t is given by:

$$W_t\Big|_{r=a} = \int_0^t -D\frac{\partial C}{\partial r}\Big|_{r=a}\,dt' \quad \text{(Eq. A9)}$$

The term ρC_p must be introduced into the analoguos expression for heat flux:

$$Q_t\Big|_{r=a} = \int_0^t -\rho C_p\cdot\alpha\frac{\partial T}{\partial r}\Big|_{r=a}\,dt' \quad \text{(Eq. A10)}$$

or

$$Q_t\Big|_{r=a} = \int_0^t -k\frac{\partial T}{\partial r}\Big|_{r=a}\,dt' \quad \text{(Eq. A11)}$$

where k is the thermal conductivity of the medium in the hollow sphere. Because of the introduction of the additional parameter k and the potential confusion of its appearance with α in the solution to Eq. A11, the flux associated with heat conduction, rather than mass diffusion, will be solved for in the following development.

In terms of T^*, r, and t, where T^* is defined by Eq. 10 and is consistent with the definition of Π^*:

$$Q_t\Big|_{r=a} = -k(T_s - T_c)\int_0^t\frac{\partial T^*}{\partial r}\Big|_{r=a}\,dt' \quad \text{(Eq. A12)}$$

Allowing S to represent the summation term in Eq. A8 in which $\Pi^* = T^*$,

$$\frac{\partial T^*}{\partial r}\Big|_{r=a} = -\frac{1}{a} - \frac{1}{b-a} + \frac{\partial S}{\partial r}\Big|_{r=a} \quad \text{(Eq. A13)}$$

where:

$$\frac{\partial S}{\partial r}\Big|_{r=a} = -\frac{2a}{\pi r}\Big|_{r=a}\frac{\partial}{\partial r}\sum_{n=1}^{\infty}\left\{\frac{1}{n}\sin\frac{n\pi(r-a)}{b-a}\cdot\exp[-\alpha n^2\pi^2 t/(b-a)^2]\right\}\Big|_{r=a} + \frac{2a}{\pi r^2}\sum_{n=1}^{\infty}\left\{\frac{1}{n}\sin\frac{n\pi(r-a)}{b-a}\cdot\exp[-\alpha n^2\pi^2 t/(b-a)^2]\right\}\Big|_{r=a} \quad \text{(Eq. A14)}$$

$$= -\frac{2}{b-a}\sum_{n=1}^{\infty}\exp[-\alpha n^2\pi^2 t/(b-a)^2] \quad \text{(Eq. A15)}$$

Then:

$$\int_0^t\frac{\partial T^*}{\partial r}\Big|_{r=a}\,dt' = -\frac{bt}{a(b-a)} - \frac{2}{b-a}\cdot\int_0^t\sum_{n=1}^{\infty}\exp[-\alpha n^2\pi^2 t'/(b-a)^2]\,dt' \quad \text{(Eq. A16)}$$

$$= -\frac{bt}{a(b-a)} - \frac{2(b-a)}{\alpha\pi^2}\left\{\sum_{n=1}^{\infty}\frac{1}{n^2} - \sum_{n=1}^{\infty}\frac{1}{n^2}\cdot\exp[-\alpha n^2\pi^2 t/(b-a)^2]\right\}\Big| \quad \text{(Eq. A17)}$$

Since:

$$\sum_{n=1}^{\infty}\frac{1}{n^2} = \frac{\pi^2}{6} \quad \text{(Eq. A18)}$$

then

$$Q_t\Big|_{r=a} = k(T_s - T_c)\left\{\frac{bt}{a(b-a)} + \frac{b-a}{3\alpha} - \frac{2(b-a)}{\alpha\pi^2} \cdot \sum_{n=1}^{\infty}\frac{1}{n^2}\cdot\exp[-\alpha n^2\pi^2 t/(b-a)^2]\right\} \quad \text{(Eq. A19)}$$

As $t \to \infty$, the total conductive flux from surface $r = a$ becomes:

$$Q_{t\infty}\Big|_{r=a} = k(T_s - T_c)\left[\frac{b}{a(b-a)}\right]\left[t + \frac{a(b-a)^2}{3\alpha b}\right] \quad \text{(Eq. A20)}$$

revealing a lag time to steady-state flux of:

$$t_{\text{lag},r=a} = -\frac{a(b-a)^2}{3\alpha b} \quad \text{(Eq. A21)}$$

The total heat flux at the surface $r = b$ over time t can be similarly evaluated. In this case:

$$\frac{\partial T^*}{\partial r}\Big|_{r=b} = -\frac{a}{b(b-a)} + \frac{\partial S}{\partial r}\Big|_{r=b} \quad \text{(Eq. A22)}$$

which leads to:

$$Q_t\Big|_{r=b} = k(T_s - T_c)\left\{\frac{at}{b(b-a)} - \frac{a(b-a)}{6\alpha b} - \frac{2a(b-a)}{b\alpha\pi^2} \cdot \sum_{n=1}^{\infty}\frac{(-1)^n}{n^2}\cdot\exp[-\alpha n^2\pi^2 t/(b-a)^2]\right\} \quad \text{(Eq. A23)}$$

As $t \to \infty$, the total conductive flux to surface $r = b$ becomes:

$$Q_{t\infty}\Big|_{r=b} = k(T_s - T_c)\left[\frac{a}{b(b-a)}\right]\left[t - \frac{(b-a)^2}{6\alpha}\right] \quad \text{(Eq. A24)}$$

revealing a lag time to steady-state flux at the outside surface of:

$$t_{\text{lag},r=b} = \frac{(b-a)^2}{6\alpha} \quad \text{(Eq. A25)}$$

Note that the final equations given above for total heat flux and the lag times to steady state at either surface $r = a$ or $r = b$ (Eqs. A19, A21, A23, and A25) can be readily converted to the analogous expressions in time-dependent mass flux by replacing Q_t and T by W_t and C, respectively, and by replacing both α and k by D.

APPENDIX II: GLOSSARY

- a effective sample radius, radius of hypothetical inner sphere
- A surface area
- b chamber radius
- c subscript, chamber
- C concentration
- C conduction term
- C_p heat capacity
- C_s surface concentration
- C_{sat} saturation solubility
- D (vapor) diffusion coefficient
- e emissivity
- F radiation term
- h thickness of sample disk
- ΔH heat generated or consumed per unit moisture condensed
- ΔH_{soln} heat of solution
- ΔH_v heat of vaporization
- k thermal conductivity
- M_w molecular weight of water
- P water vapor pressure
- P_c pressure in atmosphere (chamber)
- P_0 pressure of pure water vapor at given temperature
- P_s pressure at sample surface
- ΔP pressure difference
- ΔP_{max} maximum pressure difference, taken as $P_c - P_s$
- q_{cond} conductive heat flux
- q_{conv} convective heat flux
- q_{rad} radiative heat flux
- Q heat flux
- Q_t quantity of heat flow in time t
- r radius
- r^* dimensionless radius
- R gas constant
- RH_i relative humidity in atmosphere
- RH_o critical relative humidity of a substance associated with the relative humidity in equilibrium over a saturated solution of the substance
- s subscript, at the sample surface
- S series term
- t time
- t^* dimensionless time variable
- $t_{lag,r=a}$ lag time to steady-state flux at surface $r = a$
- T temperature
- T_c temperature in chamber, *i.e.*, at temperature-controlled wall of chamber
- T_s temperature at sample surface
- T^* dimensionless temperature variable
- ΔT temperature difference
- ΔT_{max} maximum temperature difference, taken as $T_s - T_c$
- W sample weight
- W' sorption rate
- W'_h sorption rate associated with heat transport control
- z slab thickness
- z^* dimensionless slab thickness
- α thermal diffusivity
- Π general mass or heat quantity, non-steady state
- Π^* dimensionless non-steady-state general mass on heat quantity variable
- σ Stefan–Boltzmann constant
- τ diffusivity

Received June 9, 1982, from the *School of Pharmacy, University of Wisconsin–Madison, Madison, WI 53706.* Accepted for publication October 22, 1982. Present Addresses: * Boehringer Ingelheim Ltd., Ridgefield, CT 06877 and ‡ College of Pharmacy, University of Michigan, Ann Arbor, MI 48104.

Abstract □ The rates of water sorption as a function of relative humidity for water-soluble substances exhibiting deliquescence have been measured in an atmosphere of pure water vapor. The substances studied included a series of alkali halides, choline halides, and sugars. The results were compared with a theoretical model, previously described, which relates the rate of water uptake to the transport of heat produced during the process away from the surface. Taking into account the heat of water vapor condensation, heat of solution, and heat of hydration, when hydration occurs, the model allows excellent *a priori* prediction of water uptake rates as a function of relative humidity.

Keyphrases □ Sorption—kinetics, alkali halides, choline halides, and sugars in a water vapor atmosphere, application of theoretical model □ Kinetics—moisture sorption, alkali halides, choline halides, and sugars in a water vapor atmosphere, application of theoretical model □ Deliquescence—sorption kinetics, alkali halides, choline halides, and sugars in a water vapor atmosphere, application of theoretical model

A quantitative treatment for the kinetics of water vapor sorption onto water-soluble solids which exhibit deliquescence has been developed in the preceding paper (1). The treatment was confined to situations where the rate is determined solely by the kinetics of heat transfer away from the surface to the atmosphere surrounding the solid. It was assumed that the resultant film of aqueous solution is saturated with respect to the dissolved solid throughout the process.

The model essentially says that heat generated upon condensation of water vapor, and any other heat change occurring during sorption, maintains the liquid–vapor interface at a temperature, T_s, elevated above that of the bulk atmosphere, externally maintained at T_c. The water vapor pressure over the saturated film, therefore, rises with temperature until the pressure difference between surface and atmosphere becomes infinitesimal, and remains so during steady-state uptake. The ability of the system to transfer heat away from the surface is assumed to limit the sorption rate. This sorption rate, W_h', was shown to depend on the relative humidity of the atmosphere, RH_i, and that in equilibrium with the saturated aqueous film around the solid, RH_o, as described by the equation:

$$W_h' = \left[\frac{60M_w \cdot 4\pi kab}{\Delta H(b-a)}\left(\frac{RT_c^2}{\Delta H_v - RT_c \ln \frac{RH_i}{RH_o}}\right) + \frac{60M_w \cdot 4\pi a^2 \sigma e}{\Delta H} \times \left(\frac{4RT_c^5}{\Delta H_v - 4RT_c \ln \frac{RH_i}{RH_o}}\right)\right] \cdot \ln \frac{RH_i}{RH_o} \quad \text{(Eq. 1)}$$

Moisture Sorption Kinetics for Water-Soluble Substances II: Experimental Verification of Heat Transport Control

L. VAN CAMPEN*, G. L. AMIDON‡, and G. ZOGRAFI×

Received June 9, 1982, from the *School of Pharmacy, University of Wisconsin–Madison, Madison, WI 53706.* Accepted for publication October 22, 1982. Present Addresses: * Boehringer Ingelheim Ltd., Ridgefield, CT 06877 and ‡ College of Pharmacy, University of Michigan, Ann Arbor, MI 48104.

Abstract □ The rates of water sorption as a function of relative humidity for water-soluble substances exhibiting deliquescence have been measured in an atmosphere of pure water vapor. The substances studied included a series of alkali halides, choline halides, and sugars. The results were compared with a theoretical model, previously described, which relates the rate of water uptake to the transport of heat produced during the process away from the surface. Taking into account the heat of water vapor condensation, heat of solution, and heat of hydration, when hydration occurs, the model allows excellent *a priori* prediction of water uptake rates as a function of relative humidity.

Keyphrases □ Sorption—kinetics, alkali halides, choline halides, and sugars in a water vapor atmosphere, application of theoretical model □ Kinetics—moisture sorption, alkali halides, choline halides, and sugars in a water vapor atmosphere, application of theoretical model □ Deliquescence—sorption kinetics, alkali halides, choline halides, and sugars in a water vapor atmosphere, application of theoretical model

A quantitative treatment for the kinetics of water vapor sorption onto water-soluble solids which exhibit deliquescence has been developed in the preceding paper (1). The treatment was confined to situations where the rate is determined solely by the kinetics of heat transfer away from the surface to the atmosphere surrounding the solid. It was assumed that the resultant film of aqueous solution is saturated with respect to the dissolved solid throughout the process.

The model essentially says that heat generated upon condensation of water vapor, and any other heat change occurring during sorption, maintains the liquid–vapor interface at a temperature, T_s, elevated above that of the bulk atmosphere, externally maintained at T_c. The water vapor pressure over the saturated film, therefore, rises with temperature until the pressure difference between surface and atmosphere becomes infinitesimal, and remains so during steady-state uptake. The ability of the system to transfer heat away from the surface is assumed to limit the sorption rate. This sorption rate, W_h', was shown to depend on the relative humidity of the atmosphere, RH_i, and that in equilibrium with the saturated aqueous film around the solid, RH_o, as described by the equation:

$$W_h' = \left[\frac{60M_w \cdot 4\pi kab}{\Delta H(b-a)}\left(\frac{RT_c^2}{\Delta H_v - RT_c \ln \frac{RH_i}{RH_o}}\right) + \frac{60M_w \cdot 4\pi a^2 \sigma e}{\Delta H} \times \left(\frac{4RT_c^5}{\Delta H_v - 4RT_c \ln \frac{RH_i}{RH_o}}\right)\right] \cdot \ln \frac{RH_i}{RH_o} \quad \text{(Eq. 1)}$$

0022-3549/83/1200-1388$01.00/0

where the various symbols represent parameters defined in the preceding paper (1).

Since all of these parameters are either available in the literature or experimentally determinable, it is possible to use Eq. 1 to predict the value of W_h' for various values of RH_i and for solids of varying RH_o. In this paper we present experimental studies of water sorption kinetics under vacuum conditions, where diffusion of water vapor is not a consideration and where heat transport control would be expected to predominate.

EXPERIMENTAL

Materials—Potassium chloride[1], potassium bromide[2], potassium iodide[3], sodium chloride[4], anhydrous sodium bromide[1], choline chloride[5], choline bromide[5], choline iodide[5], tetrabutylammonium bromide[6], sucrose[7], fructose[5], D-glucose monohydrate[1], and anhydrous D-glucose[3] were all reagent grade and were used as received. The dihydrate of sodium bromide was prepared by dissolving a maximum amount of the anhydrous form in boiling distilled water, filtering the hot solution, and cooling to room temperature. The crystals were collected and dried on filter paper. Loss on drying indicated that the crystals contained 100.6% of the theoretical water content. All samples of the dihydrate were stored over their own saturated solution since it would effloresce at any relative humidity <57.7%. Manipulation of the more hygroscopic compounds, such as choline chloride, was performed within a plastic inflatible glove bag[8] in which a relative humidity of <15% could be maintained under nitrogen. Such compounds were stored in partially evacuated desiccators over anhydrous calcium sulfate[9].

Equipment and Procedures—The apparatus, consisting of an electrobalance associated with a vacuum system, and the general procedures used to measure sorption kinetics have been described in considerable detail elsewhere (2). In the studies reported here, silicone diffusion pump oil[10] was used as the oil manometer fluid because of its low vapor pressure (2.3×10^{-6} torr) and suitable viscosity (42 cps) at 25°. A chromel–alumel thermocouple, calibrated to 0.1° in vacuum against an external reference thermocouple kept at 25.0 ± 0.05°, was installed within the sample chamber and positioned in the vicinity of the solid sample surface. A vacuum of 10^{-2} torr was maintained and various relative humidities were provided from chambers containing different saturated inorganic salt solutions (2). Temperature of the sample chamber atmosphere was maintained at 25 ± 0.05° by a thermostated water jacket.

All studies were carried out using solid samples compressed into disks since the well-defined geometry could be expressed in terms of the hollow-sphere geometry used in the development of the theoretical model (1). These disks were prepared by compressing 300 mg of powder on a hydraulic press at 66 kN over a 1-min interval between two 1.91 cm flat-faced punches. The disks were generally cut in half with a razor blade to provide two samples per disk. The alkali halides were oven dried at temperatures >150° and ground to a fine powder before compression. The choline halides and sugars were not subjected to elevated temperatures, but were powdered by grinding under sub-RH_o conditions at 25°–27°.

Solubility and Heat of Solution—The molal solubilities at 25° for all compounds studied are listed in Table I. Because of their extremely high solubilities, values for the three choline halides, not previously reported, were determined in this study by a visual method. Known quantities of distilled water and choline halide were added in various proportions of 2-ml glass ampules which were then sealed with plastic film and equilibrated at constant temperature. After equilibration, the molal solubility was estimated by bracketing the point of saturation.

The heats of solution for the various compounds are also listed in Table I. All values were taken from the references cited or were determined as part of this study from the temperature coefficient of solubility and the application of the van't Hoff equation or by solution calorimetry. A value of 3.26 kcal/mole from the literature for choline chloride (3) is in reasonably close agreement with an estimate of 2.6 kcal/mole from solubility considering the difficulty of handling the extremely hygroscopic choline chloride samples, its high solubility, and the method used to determine solubility. The general direction and magnitude of change in going from choline chloride to choline bromide is very similar to that seen for the chloride and bromide salts of a related quaternary ammonium ion reported in the literature (3).

Table I—Aqueous Solubility and Heats of Solution for Various Deliquescent Solids at 25°

Compound	C_{sat}, m (Ref. No.)	ΔH_{soln}, kcal/mole
Potassium chloride	4.81 (4)	4.115 (5)
Potassium bromide	5.65 (4)	4.750 (5)

RESULTS

Rate of Moisture Sorption—The rate of moisture sorption was estimated from the slope of the earliest portion of the water uptake *versus* time curve exhibiting extended linearity under stable RH_i conditions (2). In all cases, the time required to reach steady state was consistent with theoretical estimates (1). For the alkali halides (except sodium bromide), choline chloride, and sucrose, linear uptake of the disks was observed over very long time intervals (*i.e.*, hours) and appeared independent of percent weight gained until sufficient moisture had been sorbed so as to cause distortion of the disk and drop formation on the bottom surface of the disk. For these materials, multiple data points could be collected for the same sample by subjecting it to successive increments (or decrements) in RH_i. For the other compounds a fresh sample was used for each RH_i.

Normalization of Disk Surface Area—Most disk samples were halved for testing as indicated in *Experimental*. Because the semicircular disks were not exact halves owing to slight crumbling or asymmetric cutting, there existed differences in surface areas between sample disks. Since the facial surface area-to-weight ratio of a partial disk is theoretically equal to the known facial surface area-to-weight ratio of the whole disk, the facial surface area of the sample could be normalized to that of a perfect semicircular disk by comparing its weight with one half that of the whole disk from which it was prepared. Edge effects on the resulting normalization factor are negligible. Since the uptake rate is approximately proportional to disk surface area over the small changes in area corrected for in this normalization, the weight ratio factor could then be directly applied to the observed sorption rate data. Thus the normalized rate, W_n', for a half disk, is calculated by:

$$W_n' = W_{obs}' \cdot \frac{0.5\ (W_0, \text{whole disk})}{(W_0, \text{half disk})} \qquad \text{(Eq. 2)}$$

In Fig. 1 rates of sorption, W', are plotted *versus* relative humidity before and after normalization for potassium bromide disks intentionally cut to ⅓ and ⅔ sizes. In all cases normalization puts points closer to a straight line[11] going through RH_o for potassium bromide.

Effect of Varying Compression Pressure—Disks of potassium bromide (300 mg) compressed at 66, 44, 22, and 6.6 kN force were compared for their sorption characteristics. The disks were halved for testing.

[11] While theoretically incorrect (1), the linear plot is a reasonable approximation for the W' function at the high RH_i and small ΔRH_i values that pertain to potassium bromide and, thus, serves adequately to illustrate the success of normalization.

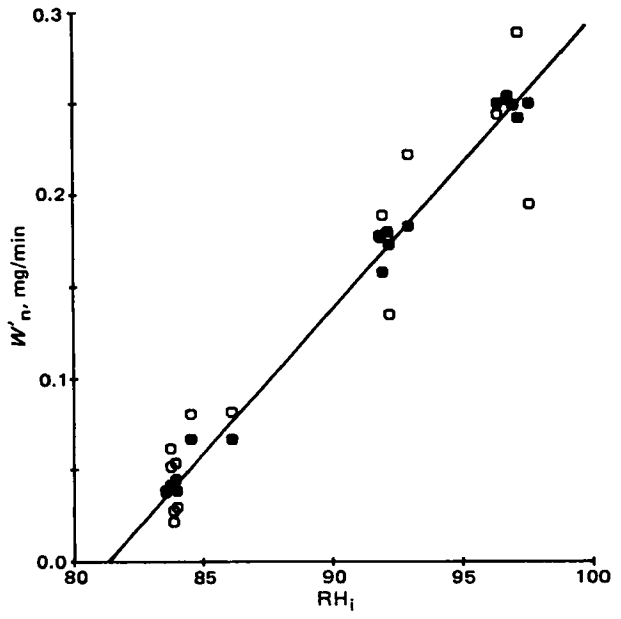

Figure 1—*Effect of normalization on treating observed W′ data for potassium bromide disks of varying size. Key: (○) observed W′; (●) W_n'.*

On the basis of weight, disk dimensions, and the density of pure potassium bromide, porosity of the disks ranged from ~4% (at 66 kN) to 25% (at 6.6 kN). Each sample was subjected to successive RH_i levels. The results are given in Fig. 2. It is clear from this plot that sorption rate did not depend significantly on disk porosity. It could, therefore, be inferred that lack of *density uniformity* in the disk is of no consequence to sorption, other than its potential effect on the normalization factor. The apparent reason porosity plays no role in sorption is that a film of (saturated) solution builds immediately during initial uptake, providing a smooth surface for continued sorption regardless of the internal porous structure of the disk.

Effect of Varying Disk Size—Heat transport-controlled sorption governed by Eq. 1 has a complex dependence on the effective disk (inner sphere) radius a. For a whole disk of real diameter 1.905 cm and average thickness 0.6 mm, $A = 4\pi a^2 = 2\pi(1.905/2)^2 + \pi(1.905)\,(0.06) = 6.06\ cm^2$, or $a = 0.69$ cm. As the disk is cut, the value of radius a does not fall by simple proportion. Accordingly, W' should not be expected to fall proportionally with decreasing disk size. From the expression given for W_h' by Eq. 1, one can write that:

$$W_h' = C' \cdot \frac{ab}{(b-a)} + F' \cdot a^2 \qquad \text{(Eq. 3)}$$

where C′ and F′ are conduction and radiation coefficients defined to reflect the dependence of W_h' on the characteristic disk dimension, a, pertaining to the hollow-sphere geometry of the system. If conduction and radiation contribute equally to heat transfer (1), then C′ = F′, and:

$$W_h' = C'\left(\frac{a}{1-a/b} + a^2\right) \qquad \text{(Eq. 4)}$$

The theoretical dependence of W_h' on disk W size is calculated according to Eq. 4, the results of which are summarized in Table II. A value of b = 2.05 cm was used for these calculations and for all subsequent calculations using Eq. 1 and related equations where b appears.

Table II—Predicted Sorption Rate Dependence on Disk Size

Disk Size	a[a] cm	W_h' (Eq. 4)	W_h'/W_h' at ½ disk
Whole	0.694	1.53 C′	1.72
⅔	0.567	1.10 C′	1.24
½	0.491	0.89 C′	1.00
⅓	0.401	0.66 C′	0.74

[a] Calculated neglecting edge effects for partial disks.

The sorption rates plotted for partial disks of potassium bromide in Fig. 1 to illustrate the normalization method are plotted again in Fig. 3, this time normalized to their appropriate facial surface area fraction, *e.g.*, ⅓, ⅔. Linear curves[11] for uptake by a whole disk, ⅔ disk, and ⅓ disk are drawn in Fig. 3 with appropriate theoretical slopes relative to the half disk, according to Table II. Excellent agreement is obtained between these curves and the observed (normalized) sorption rates, substantiating the appropriateness of the heat transport model expressed by Eq. 1, in general, and the relation between W' and disk size expressed by Eq. 4, specifically.

Effect of Varying the Initial Weight, W_0—Unless the heat capacity of the sample plays a significant role in the control of the sorption process, varying W_0 for a given disk size should have little or no effect on uptake rates. Again, W' should be expected to depend more on overall disk surface area than volume or weight of solid. Sorption by whole disks and half disks of potassium bromide of differing W_0 is compared in Fig. 4. The half-disk data have been normalized as usual according to Eq. 2. From the results in this plot[11], it can be concluded that W' is indeed relatively independent of W_0. Based on all of the preceding results, the sample preparation chosen for characterizing the sorption characteristics of

various compounds in vacuum was that of a halved disk of W_{00} = 150 mg placed directly on the open wire stirrup.

Temperatures Changes at the Surface—Simultaneous measurement of temperature in the vicinity of the solid surface using the thermocouple allowed the estimation of ΔT, the temperature difference between the atmosphere (25°) and the point near the surface where the thermocouple was positioned. Since a substantial gradient in temperature is predicted to exist at the surface by the heat transport model, direct measurement of such gradients would provide some additional support for such a model. Consequently, the bimetallic junction of the thermocouple installed in the sample chamber was adjusted to hang over the sample disk within 0.5 mm of the top surface. Measurements of temperature taken at varying heights above the sample, >0.5 mm, allowed some definition of the temperature gradients created during the process of water sorption. Although exact fit to theory was not expected because the thermocouple could not be positioned exactly at the disk surface

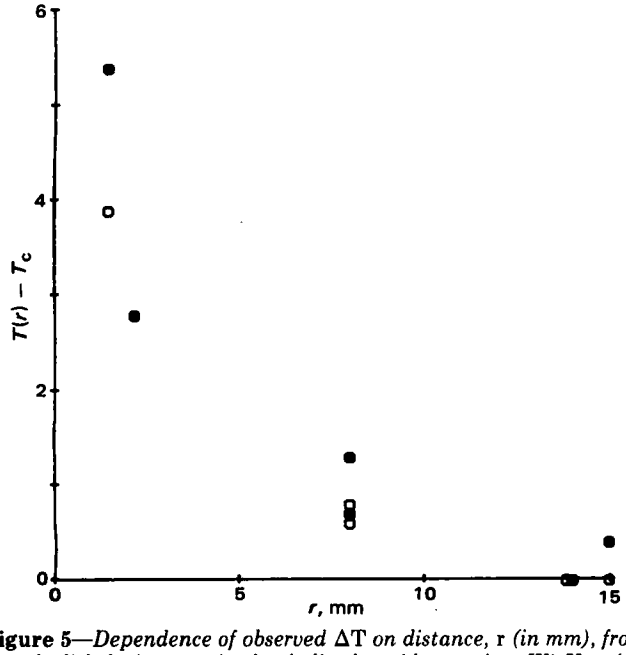

Figure 5—*Dependence of observed* ΔT *on distance,* r *(in mm), from sample disk during sorption by choline bromide at a given* W'. *Key: (●)* W' *~1.3 mg/min (*RH_i *~75); (○)* W' *~0.9 mg/min (*RH_i *~64).*

Table III—Values of ΔH and RH_o Used in Calculating Rates of Water Sorption from Eq. 1

Compound	ΔH kcal/mole	RH_o
Potassium chloride	−10.140	84.3
Potassium bromide	−10.020	80.7
Potassium iodide	−9.725	68.3
Sodium chloride	−10.400	75.3
Sodium bromide		
Anhydrous	−10.520	57.7
Dihydrate	−9.414	57.7
Choline iodide	−8.003	72.5
Choline bromide	−8.260	40.6
Choline chloride	−8.609	23.0
Tetrabutylammonium bromide	−11.475	61.0
Sucrose	−10.350	84.3
Glucose

Anhydrous	−10.260	81.3
Fructose	−9.759	64.0

where the temperature gradient is steepest in its decline, it was possible to show that ΔT exists, and that it falls off at increasing distance from the surface. This is seen in Fig. 5 for choline bromide at two rates of sorption, *i.e.*, two values of RH_i. Figure 6 also shows the distance-dependent temperature difference for choline bromide and potassium iodide and also shows that an increase in uptake rate at any position of the thermocouple is generally associated with an increasing temperature difference. Similar observations were made with the other compounds studied.

Prediction of Water Uptake Rates—To test Eq. 1 quantitatively, steady-state uptake rates were determined at various values of RH_o. Table III lists the values of RH_o and ΔH used to obtain theoretical plots from Eq. 1. Other constants were as described in the preceding paper (1). The value of ΔH, unless otherwise specified, was calculated using the heat of condensation of water vapor (ΔH_c, which is −10.5 kcal/mole), the heat of solution (ΔH_{soln}), and the aqueous molal solubility (C_{sat}) as follows:

$$\Delta H = \Delta H_c + (C_{sat} \cdot \Delta H_{soln})/55.5 \qquad \text{(Eq. 5)}$$

where C_{sat} has units of moles of solute/1000 g of water, and ΔH_{soln} is in kilocalories per mole. The number 55.5 converts values into appropriate units. In the case of anhydrous potassium bromide and anhydrous glucose, the value of RH_o used was that of the hydrated form and ΔH was estimated by including the heat of hydration along with the heat of

condensation and heat of solution, using Eq. 5. Figures 7–10 present theoretical graphs with experimental data for the heat transport-controlled W' (W_h') *versus* RH_i.

DISCUSSION

The results of experimental studies on water uptake rates of deliquescent substances in an atmosphere of pure water vapor, with the exception of tetrabutylammonium bromide and anhydrous glucose, provide excellent confirmation of the heat transport model described in the preceding paper (1). Thus, it appears possible to predict rates of uptake in a vacuum for most solids *a priori*, knowing their RH_0, solubility in water, and heat of solution, all experimentally determinable parameters. If crystalline hydrates can form, as in the case of sodium bromide, anhydrous glucose, and perhaps tetrabutylammonium bromide, the contribution of heat changes, attributable to hydration, however, must also be considered.

Fit of the model to solids varying very greatly in rates of water uptake, having also a broad range of solubilities and values of RH_0 and ΔH_{soln}, supports the important assumption that mass transport in the aqueous film surrounding the solid does not become rate limiting in determining the concentration of material dissolved in the film. In this regard, it is interesting to note that for systems having saturated solutions with viscosities 15–200 times that of water, agreement between theory and experiment for sorption rates was excellent. Analysis of the results using anhydrous sodium bromide and its dihydrate suggests the following picture. Below the value of RH_0 for the hydrate, water vapor can be taken up by the anhydrous form to form the hydrate. When RH_0 for the hydrate is exceeded, the hydrate layer dissolves in the liquid film to begin the

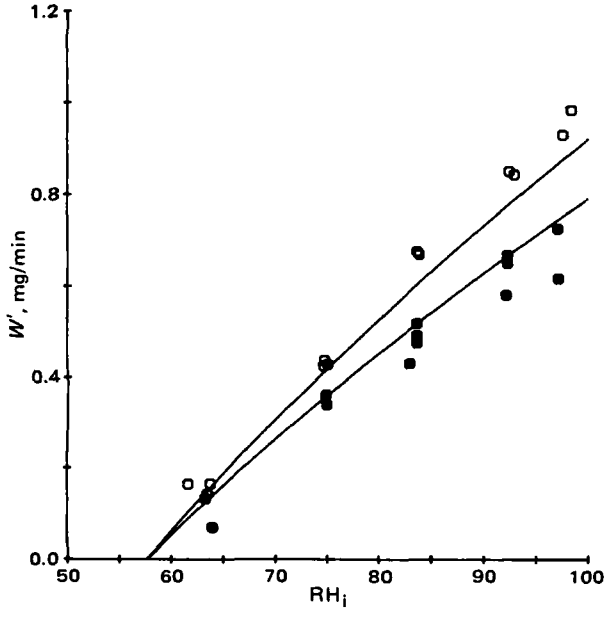

Figure 8—*Sorption rates for disks of the anhydrous (●) and dihydrate (○) forms of sodium bromide as a function of RH_i. The lines are the theoretical sorption curves plotted for W′ according to Eq. 1.*

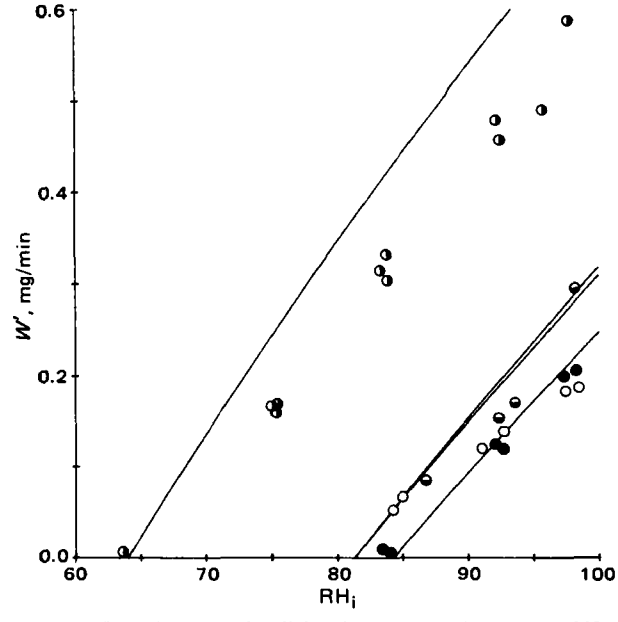

Figure 10—*Sorption rates for disks of sugars as a function of RH_i. The lines are the theoretical sorption curves plotted for W′ according to Eq. 1, where higher and lower curves intercepting RH_i = 81.3 represent W′ for the monhydrate and anhydrous forms of glucose, respectively. Key: (◒) fructose; (●) glucose · H_2O; (◐) glucose; (○) sucrose.*

process of deliquescence. This exposes more anhydrous crystal surface which quickly forms the hydrate. The heat released by hydrate formation increases the overall heat released, and this slows down the rate of water uptake relative to that observed with the hydrated crystal (see Fig. 8). The key to this picture is the rapid formation of the crystalline hydrate at the solid–liquid interface relative to the rate of heat transport and water uptake.

The significant lack of fit to the theoretical plot >84% RH_i for anhydrous glucose (Fig. 10) as opposed to the excellent fit for the monohydrate form of glucose, suggests strongly that the simple picture of rapid crystalline hydrate formation is not applicable. Rather, it appears that at higher RH_i values other kinetic processes, yet to be determined, are assuming greater significance. That the situation can be more complicated in some cases is seen with tetrabutylammonium bromide (Fig. 9) where the values predicted using only the heat of condensation of water and the reported heat of solution (7) are very different than those experimentally observed. In the case of tetrabutylammonium halide, the large cation has the tendency to exist in unusual states of hydration both in aqueous solution and in the crystalline form. In solution, tetrabutylammonium ions exhibit significant amounts of water structuring, leading to what has been termed "caging" of water around the cationic group (10, 11); this degree of structuring will decrease with increasing temperature. This strong tendency for hydration is also reflected in the formation by tetrabutylammonium salts of well-defined crystalline hydrates, having hydration numbers of 32 (12, 13). These hydrates are assumed to be of the clathrate type, similar in character to gas hydrates. Here, the cation acts as a guest in a host cavity created by water molecules and the anion. Evidence for polymorphism in these crystalline systems has also been reported (14).

Considering what takes place during the deliquescent process, any number of processes of structure formation or breaking in this system can contribute to ΔT and the net heat which must be transported away from the surface. If crystalline hydrate formation, as described for sodium bromide and glucose, predominates, we might expect a much slower rate than is actually observed. However, if water structuring in solution was being broken down, for example, as the temperature in the film increased, the net heat released would be much less than predicted from the heat of solution and this would lead to faster rates. In such a complex process involving higher degrees of ordering, there is also the possibility that simple equilibrium conditions are not reached and that incomplete hydration or slow rates of change during rapid water uptake affect the final rate of heat released and hence water uptake. It is interesting to note in this regard that the data obtained with tetrabutylammonium bromide can be fitted excellently if we assume a ΔH_{soln} of ~4.0 kcal/mole, which is close to the values of ΔH_{soln} for choline chloride and choline bromide, both of which have molal solubilities close to that of tetrabutylammonium bromide. This suggests the possibility that the part of the equilibrium heat of solution attributable to the unusual hydration properties of this ion is not making a contribution to the overall kinetic process. This certainly points out the importance of knowing as much as possible about the molecular nature of such complex water vapor–solid interactions when attempting to interpret the overall mechanisms of hygroscopicity. Fortunately, the behavior of many water-soluble species of pharmaceutical interest, exemplified by all of the other compounds studied, are much less complicated than tetrabutylammonium bromide.

CONCLUSIONS

A theoretical model for heat transport-controlled water uptake by deliquescent solids has been experimentally tested in an environment of pure water vapor (vacuum) where resistance to mass transport in the vapor phase would not be expected to be a factor. Studies with alkali halide salts, sugars, and choline salts provide excellent agreement with theory. As long as all heat-producing or -consuming processes are taken into account, knowing only solubility, various heat changes, and RH_0, it is possible to predict *a priori* the rate of water uptake for deliquescent substances as a function of RH_i, the chamber relative humidity.

Moisture Sorption Kinetics for Water-Soluble Substances III: Theoretical and Experimental Studies in Air

L. VAN CAMPEN *, G. L. AMIDON ‡, and G. ZOGRAFI ˣ

Received June 9, 1982, from the *School of Pharmacy, University of Wisconsin-Madison, Madison, WI 53706.* Accepted for publication October 22, 1982. Present addresses: *Boehringer Ingelheim Ltd., Ridgefield, CT 06877 and ‡College of Pharmacy, University of Michigan, Ann Arbor, MI 48104.

Abstract □ As an extension of the model of heat transport control developed for the kinetics of water sorption by water-soluble substances from an atmosphere of pure water vapor, equations have been developed to account for limitations of diffusion on mass transport of water vapor when air is present. Although the inability to determine the vapor diffusion layer thickness prevents using these equations to predict sorption behavior *a priori*, minimum water sorption rates can be calculated by assuming a diffusion layer thickness equal to the sample chamber radius. Combining heat transport and mass transport produces equations which describe very well the observed sorption by three water-soluble salts in one atmosphere of air. As in the absence of air, sorption rates are predicted and observed to be constant at a given atmospheric relative humidity.

Keyphrases □ Sorption—moisture, water-soluble substances, kinetics, theoretical model with air atmosphere, application to potassium bromide, potassium iodide, and choline iodide □ Kinetics—moisture sorption by water-soluble substances, theoretical model with air atmosphere, application to potassium bromide, potassium iodide, and choline iodide □ Deliquescence—kinetics of water sorption, theoretical model with air atmosphere, application to potassium bromide, potassium iodide, and choline iodide

In the first paper in this series (1) a theoretical model for the kinetics of water sorption by water-soluble solids exhibiting deliquescence was developed based on a heat transport control model. This model was tested successfully for water sorption from an atmosphere of pure water vapor over wide ranges of relative humidity in the second paper (2). In the present paper, this work is extended to include water sorption kinetics from an atmosphere containing air at approximately 1 atm of pressure. In such a case, one would expect the effects of diffusion through air on the mass transport of water vapor to influence the overall process. A model for water sorption in air is developed herein, first by assuming that only mass transport occurs and then by combining this with the heat transport model previously developed (1). Within the constraints of applying a mass transport model *a priori*, several water sorption experiments in an atmosphere of air have been performed to illustrate the potential importance of mass and heat transport in such a process.

THEORETICAL

Mass Transport Model (Isothermal)—As described in detail in the first paper (1) the thermodynamic basis for water uptake by water-soluble solids lies in the difference between equilibrium water vapor pressure, P_s, over the saturated solution of the solid and that in the atmosphere surrounding the solid, P_c. As seen in Fig. 1, when the heat sinks surrounding the liquid–vapor interface are sufficient in efficiency and capacity so as to maintain the system isothermal at T_c ($\Delta T = 0$), the rate of steady-state uptake is directly proportional to the constant water vapor pressure difference, $\Delta P = P_c - P_s$, over the vapor diffusion layer adjacent to the liquid–vapor interface. Expressed in terms of relative humidity, this difference becomes:

$$(100)\frac{\Delta P}{P_0} = RH_i - RH_o \qquad \text{(Eq. 1)}$$

where RH_i is the independent variable in a moisture-uptake experiment.

The radial diffusive flux of water vapor through a nondiffusing gas can be described by the following expression:

$$W'_{sp} = x_w W'_{sp} - M_w c D \frac{dx_w}{dr} \qquad \text{(Eq. 2)}$$

where W'_{sp} is the mass of water vapor transported in the z-direction per unit time per unit area, x_w is the mole fraction of water vapor in the atmosphere, M_w is the molecular weight of water, c is the total molar concentration in the atmosphere, and D is the binary diffusion coefficient of water vapor in the atmosphere. The first term in the right-hand side of Eq. 2 pertains to the mass flux of water vapor resulting from bulk fluid motion (where that of the inert gas is considered negligble) and the second term results from the diffusive mass flux of vapor superimposed on the bulk flow. Solving for W'_{sp} and expressing x_w in terms of pressure P, assuming gas ideality such that:

$$x_w = P/(P + P_i) \qquad \text{(Eq. 3)}$$

where P_i is inert gas pressure, one obtains:

$$W'_{sp} = -\frac{M_w c D}{P_T - P}\frac{dP}{dr} \qquad \text{(Eq. 4)}$$

where P_T represents the total (water vapor and inert gas) pressure. Here it is assumed that the temperature dependence of relative humidity is independent of the partial pressure of any inert gas present (3), and that the diffusion coefficient is independent of water vapor concentration and temperature.

Steady-state radial diffusion requires that:

$$\frac{d}{dr}(r^2 W'_{sp}) = 0 \qquad \text{(Eq. 5)}$$

Substitution of the expression for mass flux, W'_{sp}, from Eq. 4 then gives:

$$\frac{d}{dr}\left(r^2 \frac{M_w c D}{P_T - P}\frac{dP}{dr}\right) = 0 \qquad \text{(Eq. 6)}$$

When this expression is integrated over the boundary conditions for a hollow sphere[1], given as $P = P_s$ at $r = a$ and $P = P_c$ at $r = a'$, where $a' - a = \delta$ = effective thickness of the vapor diffusion layer, the following

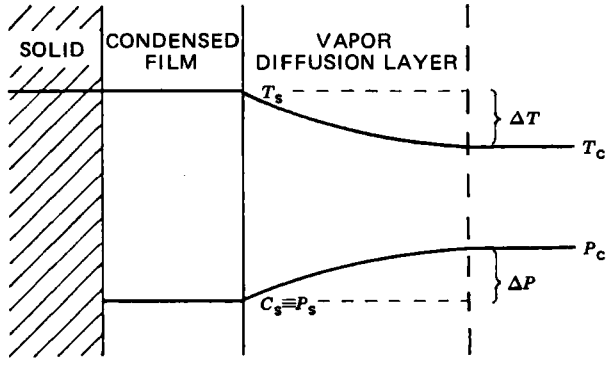

Figure 1—*Thermal and pressure gradients existing at a soluble solid surface covered with condensed water.*

[1] A hollow-sphere geometry was chosen earlier (1) for the development of the heat transport control model, and hence, it will also be carried through in this series of derivations.

0022-3549/83/1200-1394$01.00/0

relation is obtained:

$$\ln (P_T - P) = \left(\frac{\frac{1}{r} - \frac{1}{a}}{\frac{1}{a'} - \frac{1}{a}}\right) \ln \left(\frac{P_T - P_c}{P_T - P_s}\right) + \ln (P_T - P_s) \quad \text{(Eq. 7)}$$

From Eq. 4, the mass flux at surface $r = a$ is given as:

$$W'_{sp}\Big|_{r=a} = M_w c D \left.\frac{d \ln (P_T - P)}{dr}\right|_{r=a} \quad \text{(Eq. 8)}$$

for which the derivative is evaluated on the basis of Eq. 7 to yield:

$$W'_{sp}\Big|_{r=a} = -M_w c D \left(\frac{1}{\frac{a^2}{a'} - a}\right) \ln \left(\frac{P_T - P_c}{P_T - P_s}\right) \quad \text{(Eq. 9)}$$

Since mass is conserved, the mass flux across any spherical surface in the system is:

$$W' = 4\pi a^2 W'_{sp}\Big|_{r=a} \quad \text{(Eq. 10)}$$

$$= \left(\frac{4\pi M_w c D}{\frac{1}{a} - \frac{1}{a'}}\right) \ln \left(\frac{P_T - P_c}{P_T - P_s}\right) \quad \text{(Eq. 11)}$$

or, rearranged and expressed in terms of relative humidity:

$$W' = W'_m = -\left(\frac{60 \cdot 4\pi M_w c D}{\frac{1}{a} - \frac{1}{a'}}\right) \ln \left(\frac{100(P_T/P_0) - RH_o}{100(P_T/P_0) - RH_i}\right) \quad \text{(Eq. 12)}$$

where a factor of 60 has been included to convert W' (or W'_m to indicate mass transport control) to units of mg/min, given that M_w has units of mg/mole, c has units of mole/cm^3, and D has units of cm^2/sec. This equation is then the solution for steady-state radial mass diffusion in a hollow sphere. The negative sign for W' in Eq. 12 when $RH_o < RH_i$ reflects water vapor diffusion in the negative r-direction, consistent with the condensation process.

In the case where $P \ll P_T$, integration of Eq. 4 over the same boundary conditions followed by the evaluation of dP/dr at $r = a$ in the same manner given above, leads to the analogous expression for W'_m:

$$W'_m = -\frac{60 \cdot 4\pi M_w c D P_0}{100 P_T \left(\frac{1}{a} - \frac{1}{a'}\right)} (RH_i - RH_o) \quad \text{(Eq. 13)}$$

In addressing the question of the time required to reach steady state, the solution for the time-dependent radial pressure gradient in the atmosphere is readily obtained from the non-steady-state mass transport equations developed in Appendix I of the first paper in this series (1). From this, the time required for the steady-state diffusion expressed by Eq. 13 to establish itself can be determined. In terms of dimensionless concentration, pressure, or relative humidity (at a given constant temperature), this solution comes directly from Eq. A8 in Appendix I of Ref. 1:

$$C^* = P^* = RH^* = \left[\frac{1}{r^*(a'/a - 1) + 1}\right] \times \left[1 - r^* - \frac{2}{\pi} \sum_{n=1}^{\infty} \frac{1}{n} \sin n\pi r^* \cdot \exp(-n^2\pi^2 t^*)\right] \quad \text{(Eq. 14)}$$

where C^*, P^*, and RH^* are all defined analogously with the definition of Π^*, and where:

$$t^* = \frac{Dt}{(a' - a)^2} \quad \text{(Eq. 15)}$$

and

$$r^* = \frac{r - a}{a' - a} \quad \text{(Eq. 16)}$$

This function is described in Fig. 6 of Ref. 1 where $\Pi^* = C^*$ and $a' = b$. Since the time to steady state increases as $a' \to b$, allowing $a' = b$ should result in a conservative estimate of the time required for the pressure gradient to establish itself. In 1 atm of air, the time then required to reach $t^* = 0.5$ is only 4.3 sec using the constants given in Table I. Thus, even at the likely maximum diffusion layer thickness of 2 cm, pressure gradients within the system should be rapidly established relative to the time scale of extended uptake.

Table I—Physical Constants for the Transport Model in 1 atm of Air

Symbols	Constants
a, cm	0.5[a]
b, cm	2.05
P_0, atm	3.12×10^{-4}
P_T, atm	1
M_w, mg/mole	1.8×10^4
D, cm^2/sec	0.258[b]
c, moles/cm^3	4.09×10^{-5}
k, cal/cm · sec · deg	6.22×10^{-5} [c]
α, cm^2/sec	0.214[d]
ΔH_v, cal/mole	10500
R, cal/deg · mole	1.987
T_c, °K	298
σ, cal/cm^2·sec·deg^4	1.36×10^{-12}
e	0.95[e]

[a] Characteristic disk thickness unique to each compound examined; range = 0.492–0.512 cm. [b] Calculated according to Ref. 5 for water vapor in the presence of a nonpolar inert gas. [c] Calculated using the Lindsay and Bromley modification of the Wassiljewa equation (6). [d] Used in calculations were C_p values weighted by mole fraction and k as indicated above. [e] Film surface emissivity approximated by value given for pure water (7).

The time required for the mass flux to reach a steady-state level can be calculated from the lag time at surface $r = a$ whose solution is given by the analogous form of Eq. A21 (*cf.* Ref. 1) for mass diffusion:

$$t_{lag,r=a} = -\frac{a(a' - a)^2}{3Da'} \quad \text{(Eq. 17)}$$

For the example above, this lag time equals (−)0.72 sec, where again the value of a' is taken to its extreme value of $b = 2$ cm. At surface $r = b$, a lag time of 1.4 sec is calculated using the analogous form of Eq. A25 (*cf.* Ref. 1) for $a' = b$:

$$t_{lag,r=b} = \frac{(b - a)^2}{6D} \quad \text{(Eq. 18)}$$

It is clear from these results that in the system containing air, the measurement of steady-state uptake rates should not be precluded by the transient effects associated with the establishment of the steady-state pressure gradient driving the uptake.

Combined Mass–Heat Transport Model—The uptake rate W' in air is explicitly dependent on the difference in relative humidity, $RH_i - RH_o$, as described by Eq. 13 when condensation is limited by water vapor diffusion to the sample. When the process is limited by heat transport, however, W' exhibits only an implicit dependence on this difference as given below in Eq. 19, developed earlier (1):

$$W'_h = \left[\frac{60 M_w \cdot 4\pi k a b}{\Delta H (b - a)} \left(\frac{R T_c^2}{\Delta H_v - R T_c \ln \frac{RH_i}{RH_o}}\right) + \frac{60 M_w \cdot 4\pi a^2 \sigma e}{\Delta H} \left(\frac{4 R T_c^5}{\Delta H_v - 4 R T_c \ln \frac{RH_i}{RH_o}}\right)\right] \cdot \ln \frac{RH_i}{RH_o} \quad \text{(Eq. 19)}$$

When heat and mass transport are in balance, these equations must be solved simultaneously, since in this case neither the humidity difference (now $< RH_i - RH_o$) which drives mass transport, nor ΔT (now $< \Delta T_{max}$ as estimated by the Clausius–Clapeyron relation in Eq. 20 below) which drives heat transport, can be predicted *a priori*. As before (1):

$$\Delta T_{max} = \frac{R T_c^2 \ln \frac{RH_i}{RH_o}}{\Delta H_v - R T_c \ln \frac{RH_i}{RH_o}} \quad \text{(Eq. 20)}$$

Scheme I illustrates the interrelationship between the effective difference in relative humidity, $\Delta RH = RH_i - RH_s$, where RH_s is the effective relative humidity (relative to P_0 at 25°) at the sample surface, and

the experimentally controlled $\Delta RH = RH_i - RH_o$. The Clausius–Clapeyron equation now relates RH_o to RH_s, where the analogous form of Eq. 20 becomes:

$$\begin{array}{ccccc} & \text{Clausius–Clapeyron Equation} & & & \\ P_s^{(T_c)} & \longrightarrow & P_s^{(T_s)} & < & P_c^{(T_c)} \\ \| & & \| & & \| \\ RH_o & < & RH_s & < & RH_i \end{array}$$

Scheme I

$$\Delta T = T_s - T_c = \frac{RT_c^2 \ln \frac{RH_s}{RH_o}}{\Delta H_v - RT_c \ln \frac{RH_s}{RH_o}} \quad \text{(Eq. 21)}$$

Accounting for Eq. 21 in deriving an equation for the dependence of W' on ΔT as in Eq. 19, one obtains:

$$W' = \left[\frac{60M_w \cdot 4\pi kab}{\Delta H(b-a)}\left(\frac{RT_c^2}{\Delta H_v - RT_c \ln \frac{RH_s}{RH_o}}\right) + \frac{60M_w \cdot 4\pi a^2 \sigma e}{\Delta H}\left(\frac{4RT_c^5}{\Delta H_v - 4RT_c \ln \frac{RH_s}{RH_o}}\right)\right] \cdot \ln \frac{RH_s}{RH_o} \quad \text{(Eq. 22)}$$

The analogous transformation for mass transport (when $P \ll P_T$) as given by Eq. 13 becomes:

$$W' = -\frac{60 \cdot 4\pi M_w c D P_0}{100 P_T \left(\frac{1}{a} - \frac{1}{a'}\right)}(RH_i - RH_s) \quad \text{(Eq. 23)}$$

$$= -k_m A(RH_i - RH_s) \quad \text{(Eq. 24)}$$

where k_m, is a mass transport coefficient for diffusive flux over area $A = 4\pi a^2$, is given by:

$$k_m = \frac{60M_w c D P_0}{100 P_T \left(a - \frac{a^2}{a'}\right)} \quad \text{(Eq. 25)}$$

Since neither T_s nor RH_s is known in Eqs. 21–23, however, the above expressions for W' are not useful in their present form. Furthermore, because of the complex logarithmic dependence of W' on RH_s in Eq. 22 and linear dependence in Eq. 23, RH_s cannot be eliminated analytically from their simultaneous solution. For predictive purposes, therefore, it becomes worthwhile to introduce two approximations.

The first useful approximation entails linearizing the relationship between temperature and relative humidity in Eq. 21. This can be accomplished by establishing an empirical relation based on P_0-values covering an experimentally appropriate range in T_s and T_c. Consider moisture sorption by common alkali halide salts: according to the above model, heat transport-controlled sorption is predicted to occur over a $\Delta T < 10°$ at $T_c = 298°K$. Assuming that the water vapor pressure over a salt solution has the same temperature dependence as that over pure water, the variation of P_0 between 298°K and 303°K on conversion to relative humidity yields the following predictive equation for RH_s as a function of T_s:

$$RH_s - RH_o = 0.0679 \cdot RH_o(T_s - T_c) \quad \text{(Eq. 26)}$$

For sodium chloride this relation overestimates the reported value for RH_s at $T_s = 302.4°K$ (4) by only 0.5%.

The second useful approximation addresses the dependence of the radiation term on $\Delta(T^4)$. Allowing:

$$T_s^4 - T_c^4 = 4T_c^3(T_s - T_c) \quad \text{(Eq. 27)}$$

where $T_c = 298°K$ and $T_s = 313°K$, this approximation underestimates the value of $\Delta(T^4)$ by <7.5% even at an extreme ΔT of 15°.

The combination of Eqs. 1 and 31 from Ref. 1 with Eq. 27 (above), *including the units* conversion factor of $60M_w$, leads to a simpler expression for the dependence of W' on ΔT:

$$W' = \left[\frac{60M_w \cdot 4\pi kab}{\Delta H(b-a)} + \frac{4T_c^3 \cdot 60M_w \cdot 4\pi a^2 \sigma e}{\Delta H}\right] \cdot \Delta T \quad \text{(Eq. 28)}$$

Substituting for ΔT from Eq. 26 gives:

$$W' = k_h A(RH_s - RH_o) \quad \text{(Eq. 29)}$$

where k_h is a heat transport coefficient for heat flux over the surface of area $A = 4\pi a^2$, and is given by:

$$k_h = -\frac{14.72}{RH_o}\left[\frac{60M_w kb}{a\Delta H(b-a)} + \frac{4T_c^3 \cdot 60M_w \sigma e}{\Delta H}\right] \quad \text{(Eq. 30)}$$

Solving for RH_s in Eq. 29 and substituting the result into Eq. 24, one obtains:

$$W' = -k_m A(RH_i - RH_o + W'/k_h A) \quad \text{(Eq. 31)}$$

On rearranging, a final equation for W' is obtained in which the effects of both heat and mass transport (for systems in which $P \ll P_T$) are accounted for:

$$W' = W'_{mh} = -\frac{k_m k_h}{k_m + k_h} A(RH_i - RH_o) \quad \text{(Eq. 32)}$$

or

$$W'_{mh} = -\frac{60M_w \cdot 4\pi c D P_0(RH_i - RH_o)}{100P_T\left(\frac{1}{a} - \frac{1}{a'}\right) - \frac{cDP_0 \cdot \Delta H(b-a)RH_o}{14.72[kab + 4T_c^3 a^2 \sigma e(b-a)]}} \quad \text{(Eq. 33)}$$

The contribution of the mass–heat transport coupling is reflected by the demoninator of this equation: as the second term vanishes, as for a system with $k = \infty$ where $\Delta T \to 0$, the mass transport control relation of Eq. 13 remains. Conversely, as the vapor diffusion layer becomes infinitesimal as $a' \to a$, Eq. 33 reduces to an expression similar in form to Eq. 28 wherein the logarithmic dependence of ΔT on RH_i has been effectively linearized.

EXPERIMENTAL

Materials—The sources and treatment of potassium iodide, potassium bromide, and choline iodide have been presented in the preceding paper (2).

Methods—The preparation of disks, the apparatus used, and the method of treating data were described in the preceding paper (2), with one important change instituted in the present study. The very slow diffusion of water vapor from the relative humidity chambers to the sample through an atmosphere of air precluded use of the chambers as described previously. Therefore, a small volume of saturated salt solution, containing an excess of salt, whose RH_o equalled the desired RH_i, was placed directly into the sample tube. The tube was capped and shaken for several minutes prior to use to accelerate humidity equilibrium. The chamber was then rapidly set in place around the loaded sample, with air thus present at a pressure of approximately 1 atm.

To assure that the value of RH_i in the chamber containing air was known and constant during a run, an electronic humidity sensor[2] was installed within the sample chamber. This consisted of a thin rectangular block of cross-linked polystyrene copolymer. The impedance changes caused by sorption and desorption of water were measured by an AC bridge circuit, capable of measuring a maximum value of 1.1 MΩ. Calibration was carried out by exposing the sensor, placed in the sample chamber at atmospheric air pressure, to known relative humidities. The temperature change, ΔT, near the sample surface was also monitored with a thermocouple, as previously described (2).

RESULTS

Since the diffusion layer thickness, δ, is unknown, neither Eq. 13 nor Eq. 33 can be used to predict *a priori* uptake rates for a given system. In the case where a' approaches the radius of the sample tube, b, and hence where $\delta = b - a$, the diffusional barrier would be maximized such that the rate of water sorption would be at a minimum value of W'. Using appropriate values of the various parameters needed to apply Eqs. 13 (for W'_m) and 33 (for W'_{mh}) found in Table I, and also using parameters in Table I needed to apply Eq. 19 for W'_h for the heat transport model in an atmosphere of air, three theoretical plots can be produced to describe

water sorption rates as a function of RH_i. Figures 2–4 present comparisons of these theoretical curves with experimental results for potassium iodide, potassium bromide, and choline iodide, respectively. For the sake of further comparison, the corresponding theoretical plots as shown in the preceding paper (2) for water sorption in the absence of any inert gas, where heat transport strictly controls uptake, are also included in each case.

From the theoretical plots, it is clear that mass transport over a vapor diffusion layer of finite thickness is expected to limit the rates of water uptake relative to the case where only heat transport control is operating. It can be seen also that in the absence of resistance to mass transport, heat transport is sufficiently faster in air than in vacuum so that it alone would allow much higher rates of sorption. Hence any observed reduction in sorption rates in air relative to a vacuum must be a consequence of the mass transport component.

It is interesting to note that in all three cases shown in Figs. 1–4, the observed data are best described by the combined mass–heat transport model expressed by Eq. 33 when the vapor diffusion layer is assumed to be equal to the chamber dimension. Furthermore, measured ΔT values associated with sorption in air were observed to be depressed as much as 30–50% relative to values obtained at the same RH_i under an atmosphere of pure water vapor. This result is consistent with the lower ΔT value predicted for sorption controlled by both mass and heat transport.

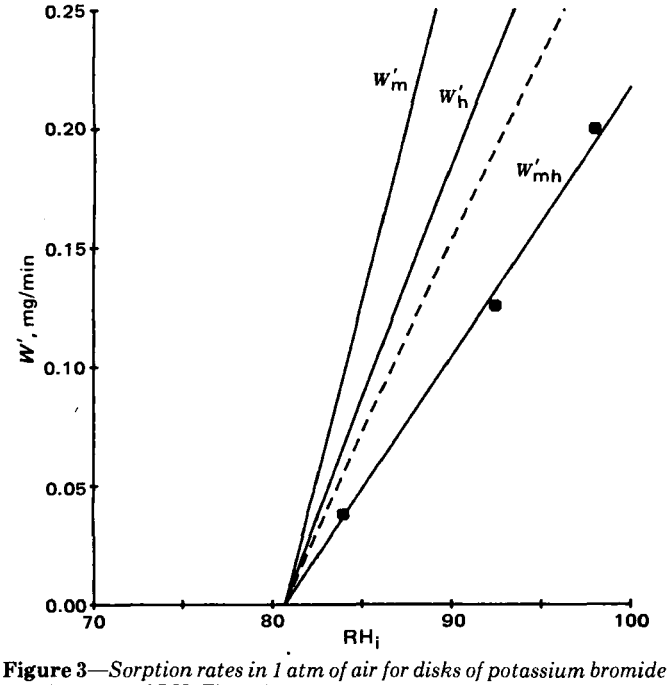

Figure 3—*Sorption rates in 1 atm of air for disks of potassium bromide as a function of RH. The solid lines are theoretical sorption curves for* W'_m, W'_h *(air), and* W'_{mh} *plotted according to Eqs. 13, 19 and 33, respectively. The dashed line presents the corresponding theoretical curve for heat transport-controlled sorption in the absence of inert gas.*

DISCUSSION

The results of studies in air, and previous work in an atmosphere of pure water vapor (1, 2), clearly indicate the importance of heat transport and mass transport as underlying mechanisms in the process of water sorption by water-soluble substances. The study of sorption in a vacuum provides a convenient approach for carrying out fundamental studies which demonstrate the importance of heat transport in these systems. Since convective flow of water vapor in the absence of an inert gas is rapid, constant pressure is immediately established throughout the chamber, making uncontrolled geometrical factors arising from equipment design relatively unimportant. In contrast, diffusional resistance to water vapor flow in air, from source to sample, retards the establishment of steady-state sorption and renders the system highly sensitive to the geometry of the sample chamber. To overcome this problem requires equipment design which emphasizes better control of vapor delivery to the solid surface. Even though our experimental results agree well with the combined heat–mass transport model, assuming minimum uptake at $\delta = b - a$, the present apparatus does not allow for flexibility in varying geometric factors.

Given the constraints of undetermined geometric factors which control mass transport of vapor, equations derived to include both heat and mass transport mechanisms are very successful in accounting for observations made when water sorption takes place in an atmosphere consisting of air and water vapor. The importance of heat transport, not previously discussed in the context of water uptake by deliquescent substances, seems

firmly established from both previous studies of sorption in the absence of air (1, 2) as well as the present study in which the moderating effects of diffusion are evident.

APPENDIX: GLOSSARY[3]

a' radius of sphere bounded by outside radius of vapor diffusion layer
c molar gas concentration; also subscript denoting "chamber"
C^* dimensionless concentration variable
k_h mass transport coefficient associated with heat transport-controlled aspect of sorption
k_m mass transport coefficient associated with mass transport-controlled aspect of sorption
P_i pressure of inert gas
P_T total pressure
P^* dimensionless pressure variable
RH_s unknown relative humidity at the sample surface associated with conditions of balanced heat and mass transport in which the two processes control sorption to a similar degree
RH^* dimensionless relative humidity variable
W_{sp} sorption rate per unit surface area
W_m sorption rate associated with mass transport control
W_{mh} sorption rate associated with the combined control of both heat and mass transport
x_w mole fraction water vapor
δ vapor diffusion layer thickness

Quantitative Determination of Benzoyl Peroxide by High-Performance Liquid Chromatography and Comparison to the Iodometric Method

NEHRU GADDIPATI ˣ, FRANK VOLPE, and G. ANTHONY

Received June 14, 1982, from the *Quality Services Department, R&D Division, Revlon Health Care Group, Tuckahoe, NY 10707.* Accepted for publication October 14, 1982.

Abstract □ A selective high-performance liquid chromatographic (HPLC) procedure for the quantitative determination of benzoyl peroxide in pharmaceutical dosage forms is described. Benzoyl peroxide was dissolved or extracted in the presence of an internal standard, acenaphthylene. The specificity of the stability-indicating HPLC and iodometric procedures are presented for benzoyl peroxide.

Keyphrases □ Benzoyl peroxide—degradation products, stability-indicating high-performance liquid chromatography, comparison with iodometric procedures □ High-performance liquid chromatography—stability indicating, benzoyl peroxide and its degradation products, commercial formulations, comparison with iodometric procedures □ Degradation products—benzoyl peroxide, stability-indicating high-performance liquid chromatography in commercial formulations.

Benzoyl peroxide (dibenzoyl peroxide), active against acne-causing bacteria, is widely used in pharmaceutical preparations as an antibacterial and keratolytic agent (1). Analytical methods currently available include spectrophotometry (2), polarography (2), TLC (3), titrimetry (4), and high-performance liquid chromatography (HPLC) (5, 6).

BACKGROUND

Benzoyl peroxide is a chemically reactive molecule which readily decomposes in various solvents (7) to give compounds such as biphenyl, phenyl benzoate, benzoic acid, benzene, 4-biphenylcarboxylic acid, homophthalic acid, homoterephthalic acid, and carbon dioxide (8). Daley *et al.* reported a selective titrimetric procedure (9), modifying the conventionally utilized iodometric method. They proposed the addition of phenyl sulfide prior to the titration to eliminate potential interferences caused by the presence of hydroperoxide impurities such as perbenzoic acid. This iodometric procedure has been accepted as the USP method for analysis of benzoyl peroxide lotion (10). Oliveri-Vigh and Hainsworth proposed an HPLC procedure that is selective in the presence of benzoic acid and benzaldehyde (5). Burton *et al.* proposed a similar HPLC procedure specific for analysis of benzoyl peroxide in gels and lotions in the presence of benzoic acid and perbenzoic acid (6); this procedure has been adopted as the USP method for analysis of benzoyl peroxide gel (11).

Analyses of benzoyl peroxide using Burton *et al.*'s procedure or the compendial HPLC procedure (6, 11) may give less accurate results, because this method depends on the use of an homogeneous reference standard. The aforementioned analytical procedures utilize aqueous benzoyl peroxide as the reference material to prepare the standard solutions. Aqueous benzoyl peroxide (70% benzoyl peroxide) is a heterogenous mixture which is nonuniform in its water content, typically varying

firmly established from both previous studies of sorption in the absence of air (1, 2) as well as the present study in which the moderating effects of diffusion are evident.

APPENDIX: GLOSSARY[3]

a' radius of sphere bounded by outside radius of vapor diffusion layer
c molar gas concentration; also subscript denoting "chamber"
C^* dimensionless concentration variable
k_h mass transport coefficient associated with heat transport-controlled aspect of sorption
k_m mass transport coefficient associated with mass transport-controlled aspect of sorption
P_i pressure of inert gas
P_T total pressure
P^* dimensionless pressure variable
RH_s unknown relative humidity at the sample surface associated with conditions of balanced heat and mass transport in which the two processes control sorption to a similar degree
RH^* dimensionless relative humidity variable
W_{sp} sorption rate per unit surface area
W_m sorption rate associated with mass transport control
W_{mh} sorption rate associated with the combined control of both heat and mass transport
x_w mole fraction water vapor
δ vapor diffusion layer thickness

Quantitative Determination of Benzoyl Peroxide by High-Performance Liquid Chromatography and Comparison to the Iodometric Method

NEHRU GADDIPATI ˣ, FRANK VOLPE, and G. ANTHONY

Received June 14, 1982, from the *Quality Services Department, R&D Division, Revlon Health Care Group, Tuckahoe, NY 10707.* Accepted for publication October 14, 1982.

Abstract □ A selective high-performance liquid chromatographic (HPLC) procedure for the quantitative determination of benzoyl peroxide in pharmaceutical dosage forms is described. Benzoyl peroxide was dissolved or extracted in the presence of an internal standard, acenaphthylene. The specificity of the stability-indicating HPLC and iodometric procedures are presented for benzoyl peroxide.

Keyphrases □ Benzoyl peroxide—degradation products, stability-indicating high-performance liquid chromatography, comparison with iodometric procedures □ High-performance liquid chromatography—stability indicating, benzoyl peroxide and its degradation products, commercial formulations, comparison with iodometric procedures □ Degradation products—benzoyl peroxide, stability-indicating high-performance liquid chromatography in commercial formulations.

Benzoyl peroxide (dibenzoyl peroxide), active against acne-causing bacteria, is widely used in pharmaceutical preparations as an antibacterial and keratolytic agent (1). Analytical methods currently available include spectrophotometry (2), polarography (2), TLC (3), titrimetry (4), and high-performance liquid chromatography (HPLC) (5, 6).

BACKGROUND

Benzoyl peroxide is a chemically reactive molecule which readily decomposes in various solvents (7) to give compounds such as biphenyl, phenyl benzoate, benzoic acid, benzene, 4-biphenylcarboxylic acid, homophthalic acid, homoterephthalic acid, and carbon dioxide (8). Daley *et al.* reported a selective titrimetric procedure (9), modifying the conventionally utilized iodometric method. They proposed the addition of phenyl sulfide prior to the titration to eliminate potential interferences caused by the presence of hydroperoxide impurities such as perbenzoic acid. This iodometric procedure has been accepted as the USP method for analysis of benzoyl peroxide lotion (10). Oliveri-Vigh and Hainsworth proposed an HPLC procedure that is selective in the presence of benzoic acid and benzaldehyde (5). Burton *et al.* proposed a similar HPLC procedure specific for analysis of benzoyl peroxide in gels and lotions in the presence of benzoic acid and perbenzoic acid (6); this procedure has been adopted as the USP method for analysis of benzoyl peroxide gel (11).

Analyses of benzoyl peroxide using Burton *et al.*'s procedure or the compendial HPLC procedure (6, 11) may give less accurate results, because this method depends on the use of an homogeneous reference standard. The aforementioned analytical procedures utilize aqueous benzoyl peroxide as the reference material to prepare the standard solutions. Aqueous benzoyl peroxide (70% benzoyl peroxide) is a heterogenous mixture which is nonuniform in its water content, typically varying

0022-3549/83/1200-1398$01.00/0

by a few percent from sample to sample. The specification in the pharmacopeia for aqueous benzoyl peroxide provides a range of not less than 65% and not more than 82% of $C_{14}H_{10}O_4$ (12).

Standard preparation in the proposed HPLC procedure has been designed to eliminate the inaccuracies associated with the use of a nonhomogeneous reference material like aqueous benzoyl peroxide. The HPLC procedure described in this paper is specific, provides the direct and accurate determination needed to evaluate the stability of pharmaceutical products containing benzoyl peroxide, and has the added advantages of detecting and quantifying degradation products.

EXPERIMENTAL

Apparatus and Reagents—A high-performance liquid chromatograph[1] equipped with an automatic sampler system[2], a reverse-phase column[3], and a variable-wavelength spectrophotometric detector[4] interfaced to an electronic integrator[5] was used. Aqueous benzoyl peroxide[6], acenaphthylene[7], homophthalic acid[7], 4-biphenylcarboxylic acid[7], benzaldehyde[7], phenyl benzoate[7], biphenyl[7], *o*-terphenyl[7], *p*-terphenyl[7], benzoic acid[8], benzene[8], acetone[8], UV-grade methanol and acetonitrile[9], reagent-grade potassium iodide and sodium thiosulfate[10], and phenyl sulfide[11] were used as received.

HPLC Assay—*Chromatographic Conditions*—The mobile phase consisted of methanol–water (75:25, v/v) filtered through a 0.45-μm membrane filter[12]. The flow rate of the mobile phase was set at 1.0 ml/min. The injection volume for the standard and sample preparations was maintained at 20 μl, and the column effluent was monitored by UV absorption at 238 nm (maximum absorbance for benzoyl peroxide).

Procedure—A stock solution of internal standard was prepared by dissolving acenaphthylene in acetonitrile at a concentration of 2.0 mg/ml. A reference standard stock solution was prepared by dissolving ~360 mg of aqueous benzoyl peroxide in 100 ml of acetonitrile. The potency of the reference standard stock solution was determined by pipetting a 10.0-ml aliquot and measuring the amount of benzoyl peroxide by the compendial iodometric procedure described under the monograph of benzoyl peroxide lotion (12), except that acetonitrile was substituted for acetone. A 20.0-ml aliquot of the reference standard stock solution was diluted to 100 ml with acetonitrile for the HPLC standard stock solution. A standard pair solution of benzoyl peroxide (0.05 mg/ml) and acenaphthylene (0.20 mg/ml) was prepared by mixing 10.0 ml of the internal standard stock solution and 10.0 ml of the HPLC standard stock solution, and diluting to 100 ml with acetonitrile.

Sample solutions were made by accurately weighing a sample equivalent to 50 mg of benzoyl peroxide into a 100-ml volumetric flask, sonicating for 15 min in 70 ml of acetonitrile, and then diluting to volume with acetonitrile. Sample pair solutions were prepared by mixing 10.0 ml of the internal standard solution and 10.0 ml of the sample solution in a 100 ml-volumetric flask and diluting this to volume with acetonitrile. All solutions were filtered through 0.45-μm membrane filter[13].

Compendial Titrimetric Assay—A reference standard stock solution was prepared by dissolving 250 mg of benzoyl peroxide in 100.0 ml of acetone. Aliquots (10.0 ml) of the reference standard stock solution were assayed in the presence of postulated degradation compounds for specificity evaluation, and in the presence of placebo ingredients for synthetic recovery studies for the lotion and wash formulations of benzoyl peroxide. Reference standard solutions and benzoyl peroxide formulations (cream, lotion, gel, and wash) were assayed by the pharmacopeial procedure described under the monograph for benzoyl peroxide lotion.

RESULTS AND DISCUSSIONS

Assay Selectivity—*HPLC Procedure*—A stability-indicating method must be able to discriminate between degradation products and the active ingredient. Preferably, a stability-indicating procedure should also quantitatively demonstrate the inverse relationship between the decrease in the active ingredient and increase in the degradation products. To show that a method is stability-indicating, routes of degradation products may be postulated and tested in the assay system for interference. The specificity of the HPLC system has been demonstrated (Fig. 1), and the retention times of the postulated degradation compounds are listed in Table I. Analyses of the synthetic placebos for benzoyl peroxide lotion and wash formulations by the proposed HPLC method showed no chromatographic peaks at the retention times of benzoyl peroxide and acenaphthylene (internal standard). A typical chromatogram of the standard pair mixture is shown in Fig. 2.

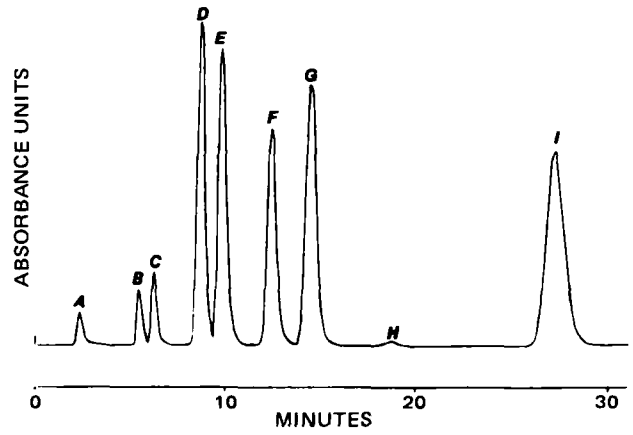

Figure 1—*High-performance liquid chromatogram of benzoyl peroxide and its decomposition products. Key: (A,B) degradation products of benzoyl peroxide in methanol; (C) benzene; (D) phenyl benzoate; (E) benzoyl peroxide; (F) acenaphthylene (internal standard); (G) biphenyl; (H) impurity from acenaphthylene; (I) o-terphenyl.*

Compendial Titrimetric Procedure—The compendial iodometric procedure involves a sodium thiosulfate titration of liberated iodine, resulting from the oxidation of potassium iodide by benzoyl peroxide. Phenyl sulfide is added prior to the introduction of potassium iodide to prevent the liberation of free iodine by the reduction of hydroperoxide impurities such as perbenzoic acid. To determine the influence of adding phenyl sulfide, benzoyl peroxide solution was tested with varying quantities of phenyl sulfide, and a linear relationship was observed between the decrease in recovery and amount of phenyl sulfide added. The regression equation (n = 7) for the volume of titrant consumed (y) for 18 mg of benzoyl peroxide and the amount of phenyl sulfide added (x, expressed in milliliters) was $y = 21.3867 + (-0.9134)(x)$. The coefficient of determination was 0.995, $CV = 0.25\%$, and at the 95% confidence interval the slope and intercept were -0.9134 ± 0.074 and 21.387 ± 0.078, respectively. To challenge the specificity of this method, benzoyl peroxide samples were analyzed in the presence of postulated degradation products; the data (Table II) demonstrate specificity of the iodometric procedure.

Statistical Evaluation—*HPLC Procedure*—Quantitation was based on the benzoyl peroxide–internal standard peak ratio. With these ratios, the linearity between detector response at 238 nm and the amount of active ingredient injected was established for concentrations between 13.5 and 76.4 μg of benzoyl peroxide. The regression equation (n = 9) for the benzoyl peroxide–internal standard peak area ratio (y) and the

p-Terphenyl	4.7	26.2	101.2

[a] Each aliquot contained 25.9 mg. [b] Equivalent to ~20% decomposition assuming a 1:1 stoichiometry.

amount of benzoyl peroxide injected (x, expressed as μg/ml) was $y = (1.104 \times 10^{-3}) + (1.953 \times 10^{-2})(x)$. The coefficient of determination was 0.9999, $CV = 0.74\%$, and at the 95% confidence interval the slope and intercept were 0.0195 ± 0.0002 and 0.0011 ± 0.0072, respectively. The response factor ratios, defined as the area ratio (acenaphthylene/benzoyl peroxide) times the concentration ratio (benzoyl peroxide/acenaphthalene) were quite constant for all concentrations. Precision was demonstrated by a relative standard deviation of 0.4% for 16 replicate injections. The results of the analyses of mixtures consisting of the addition of active ingredient to wash and lotion placebo mixtures demonstrate the accuracy of the proposed method with average recoveries of 99.5 and 99.7%, respectively.

Compendial Titrimetric Procedure—Linearity was obtained by the iodometric procedure between 2.0 and 81.4 mg of benzoyl peroxide. The regression equation ($n = 11$) for the volume of titrant consumed (y) and the amount of benzoyl peroxide (x, expressed in milligrams) were $y = (9.151 \times 10^{-2}) + 0.8107x$. The coefficient of determination was 0.9999, $CV = 0.73\%$, and at the 95% confidence interval the slope and intercept were 0.8107 ± 0.0055 and 0.915 ± 0.2422, respectively. Precision of this USP titration method was demonstrated by a relative standard deviation of 0.3% for seven replicate analyses. The analytical results of active and placebo mixtures for wash and lotion formulations demonstrate the accuracy of the iodometric procedure with average recoveries of 99.8 and 100.2%, respectively.

Gel	50	54.8	54.7

CONCLUSIONS

In five determinations of aqueous benzoyl peroxide using the USP iodometric determination, the benzoyl peroxide ranged from 66.9 to 73.5% ($CV = 4.25\%$) indicating the nonhomogenous distribution of water in the benzoyl peroxide raw material. Therefore, the utilization of aqueous benzoyl peroxide as the reference standard in HPLC analysis affects the analytical performance based on the homogeneity of the material. Standard preparation in the aforementioned HPLC procedure has been designed to compensate for the variability of water content in aqueous benzoyl peroxide.

The experimental data shown in Table III were obtained on randomly selected samples of benzoyl peroxide lotion, wash, cream, and gel formulations. Each sample was analyzed by the HPLC and the USP iodometric procedures. The results from both methods are comparable, and the procedures are precise, accurate, and specific for determination of benzoyl peroxide in commercial formulations. The HPLC procedure presented in this paper is stability indicating, capable of detecting and quantifying the decomposition products of benzoyl peroxide, and adopts a new technique for the standard preparation to improve the precision, accuracy, and reproducibility of the analysis for benzoyl peroxide formulations.

Effects of Preservatives, Steroids, and Ethylenediaminetetraacetate on the Antimicrobial Activity of Sulfacetamide

R. D. HOULSBY, M. GHAJAR ˣ, and L. CHAVEZ

Received August 13, 1982, from the *Microbiology Department, CooperVision Pharmaceuticals, Inc., Mountain View, CA 94043.* Accepted for publication October 14, 1983.

Abstract □ The effect of EDTA (ethylenediaminetetraacetate), steroids, and preservatives on the antimicrobial activity of 10% sodium sulfacetamide solutions was evaluated in this study by kill rate and minimum inhibitory concentration (MIC) using five representative microorganisms. The results indicate that thimerosal-preserved sulfacetamide solutions containing EDTA are more effective against *Pseudomonas aeruginosa*, *Serratia marcescens*, *Staphylococcus epidermidis*, and *Candida albicans* than similar paraben-preserved solutions. Furthermore, the addition of EDTA improves the kill rate, but not the MIC, for the *Pseudomonas*, *Serratia*, and *Candida* species regardless of the preservative. The combination of a steroid with sulfacetamide does not affect its antimicrobial activity.

Keyphrases □ Ophthalmic solutions—sulfacetamide, antimicrobial activity, effects of EDTA, steroids, preservatives □ Sulfacetamide—ophthalmic solutions, antimicrobial activity, effects of EDTA, steroids, preservatives □ Antimicrobial activity—of sulfacetamide in ophthalmic solutions, effects of EDTA, steroids, preservatives

Sodium sulfacetamide is an antimicrobial agent which prevents the growth and division of bacteria by interfering with the uptake of *p*-aminobenzoic acid. *p*-Aminobenzoic acid is required for folic acid synthesis which, in turn, is required for synthesis of purines and the pyrimidine, thymine, the building blocks of DNA. The competitive inhibition of *p*-aminobenzoic acid by sulfacetamide is reduced by some local anesthetics, such as tetracaine, that are derivatives of *p*-aminobenzoic acid (1). It has also been reported that the presence of sodium metabisulfite inhibits the antimicrobial activity of sodium sulfacetamide (2).

Sulfacetamide is the least sensitizing member of the sulfonamide group of antibiotics (3). It has been widely used during the past 25 years to treat blepharitis (4), pustular acne, and seborrheic dermatitis (5), and has also been used prophylactically following cataract surgery (6). It is effective against streptococci (except enterococci), pneumococci, *Bacillus anthracis*, *Corynebacterium diphtheriae*, *Clamydia trachomatis*, and some strains of *Haemophilus influenzae*, *Yersinia*, *Nocardia*, and *Actinomyces*. Many strains of *Neisseria* and *Enterobacteriaceae* have acquired resistance to this drug.

Sodium sulfacetamide solutions for ophthalmic use usually contain preservatives. Richards and McBride (2) showed that the inclusion of preservative systems decreases the sterilization time of sulfacetamide solutions from 5 hr to <15 min when challenged with 10^6 colony-forming units/ml of *Pseudomonas aeruginosa* 6750. The preservative systems included either chlorhexidine and phenylethyl alcohol, phenylmercuric nitrate and phenylethyl alcohol, or chlorocresol and phenylethyl alcohol, with or without EDTA (ethylenediaminetetraacetate).

The purpose of the present study was to determine the effects of prednisolone sodium phosphate, EDTA, thimerosal, and methyl- and propylparaben on the *in vitro* antimicrobial activity of solutions containing sodium sulfacetamide. The antimicrobial activities of the solutions tested were determined by kill rate and minimum inhibitory concentration (MIC) techniques using five test microorganisms: *Pseudomonas aeruginosa*, *Serratia marcescens*, *Staphylococcus epidermidis*, *Candida albicans*, and spores of *Aspergillus fumigatus*.

EXPERIMENTAL

Commercially available 10% sodium sulfacetamide solutions were obtained from pharmaceutical distributors; two experimental formulations were prepared in-house. The ingredients of each solution are listed in Table I. Both standard strains and clinical isolates were used as test microorganisms. The standard strains included *P. aeruginosa* 15442[1], *S. marcescens* 14041[1], *St. epidermidis* 17917[1], *C. albicans* 10231[1], and *A. fumigatus* 10894[1]. The clinical isolates of *P. aeruginosa* were SUH-51278[2] and H-23778[2]. Microbiological growth media included trypticase soy agar[3], trypticase soy broth[3], D/E neutralizing agar[4], and Sabouraud dextrose agar[4]. Other chemicals used in this study included APHA phosphate buffer[3], polysorbate 80[5], and sodium chloride[6].

Microbial cultures were prepared by inoculating 10-ml aliquots of trypticase soy broth with stock bacterial and yeast cultures maintained on either trypticase soy agar or Sabouraud dextrose agar slants and incubated for 18–24 hr at 32–34°. The second 24-hr cultures were harvested by centrifugation, washed three times in phosphate-buffered saline (centrifuged between each wash), and resuspended in sterile distilled water. The suspension of cells was further diluted to give an optical density at 500 nm, corresponding to ~10^6 colony-forming units/ml of test sample. Fungal spores were harvested from Sabouraud dextrose agar plates, washed five times in distilled water (centrifuged between each wash), and diluted to ~10^6 colony-forming units/ml of test sample.

To determine the death rate kinetics, the experiment was initiated by the addition of 0.1 ml of the standardized cultures to 20 ml of each test solution. The microbes were recovered between 1 min and 6 hr, diluted, and cultured in pour plates of D/E medium. The recovery plates were incubated for a maximum of 5 days at 30–35° followed by 5 days at room temperature. The experiments were repeated if recovery times or sample dilutions were inappropriate for the test microbe. The kill rate was expressed as a D-value, the time in minutes required to reduce the number of viable microorganisms by 90% (one log). The D-values were calculated from the best-fitting straight lines determined by linear regression. Thus, a lower D-value indicates a more rapid kill. All recoveries were validated by standard procedures.

MIC values were evaluated using microtiter plates with four overlapping concentrations of each solution, run in duplicate. After incubating the plates for 48 hr at 32–34°, the wells were scored as true positive (turbid), true negative (no turbidity), or plus–minus (very slight turbidity). The MIC was determined by calculating the geometric mean ($\bar{G}$) of the highest concentration of test solution to give a true positive, the lowest concentration to give a true negative, and the two median concentrations to give a plus–minus:

$$\bar{G} = (\text{highest positive value} \times \text{two median plus–minus values} \times \text{lowest negative value})^{1/4}$$

If only one median plus–minus value is used, the cube root of the product is taken; if no plus–minus values are used, the square root of the product is taken.

RESULTS

The kill rates of *P. aeruginosa*, *S. marcescens*, *St. epidermidis*, *C. albicans*, and *A. fumigatus* (spores) exposed to two ophthalmic solutions each formulated with 10% sodium sulfacetamide are presented in Table II. The data indicate that the sulfacetamide products are most rapidly bactericidal against *Pseudomonas*, (D = 168 min), slightly bactericidal against *Serratia* (D = 1318 min) and *Candida* (D = 2972 min), and not bactericidal against *Staphylococcus* or fungicidal against spores of *Aspergillus*. The large standard error associated with the D-value for *Serratia* is due to the preservative effect, as seen in Table III. Sulfacetamide solutions preserved with thimerosal are more rapidly bactericidal against *Serratia* than those preserved with parabens (Table III), resulting in lower D-values (faster kill rates). Since ocular anti-infective agents are washed out of the eye by natural tearing, solutions with low D-values would be more effective in controlling infection than those with high D-values.

Table II—Average Kill Rate (D-value) for Two Ophthalmic Solutions[a] Each Formulated with 10% Sodium Sulfacetamide

Microorganism	Number of Determinations	Average D-value[b] for Solutions A and B, min

[a] Without EDTA. [b] With EDTA.

The same anti-infective solutions were compared by MIC values in Table IV. The MIC values represent the bacteriostatic effect of each solution expressed as the percent of product required to inhibit growth; the lower the MIC, the more the test solution can be diluted and still inhibit microbial proliferation. Sulfacetamide solutions preserved with thimerosal have MIC values ranging from 0.2 to 2.8 for the five test microorganisms. The solutions preserved with parabens exhibit slightly higher MIC values for *Pseudomonas*, *Serratia*, and spores of *Aspergillus* (1.5–6.5) and significantly higher MIC values for *Staphylococcus* and *Candida* (19.6 and 5.0, respectively).

The effect of steroids and EDTA on the antimicrobial efficacy of the solutions was evaluated using the kill rate and MIC methods. The kill rates appear to be unaffected by the presence of steroids (Table V). The MIC values agree with this observation (Table VI). However, the addition of 0.1% EDTA to the sulfacetamide solutions significantly reduced the D-value for *Pseudomonas*, *Serratia*, and *Candida* regardless of the preservative (Table VII). This increase in antimicrobial activity, as indicated by smaller D-values, is not reflected by significantly different MIC values (Table VIII).

DISCUSSION

The results of both kill rate and MIC methods used to evaluate ophthalmic anti-infective solutions provide a better understanding of the antimicrobial effects of sulfacetamide and the clinical use of products containing this drug. Both methods indicate greater antimicrobial activity when thimerosal is used as the solution preservative than that seen with parabens: the kill rate for *Serratia* is increased and the MIC values for *Staphylococcus*, *Candida*, and possibly *Aspergillus* are decreased. The results using both methods also indicate that the addition of steroids to sulfacetamide formulations does not affect kill rates or MIC values.

However, only one method could detect the effect of EDTA on the antimicrobial activity of sulfacetamide. The kill rate for *Pseudomonas*, *Serratia*, and possibly *Candida* increased with the addition of EDTA, yet no differences in MIC values were observed. Thus, evaluation of antimicrobial activity using just one technique may not be adequate in determining the efficacy of ocular anti-infective products. MIC values are routinely used to evaluate the microbial sensitivity of parenterally administered antibiotics, yet this method of evaluation may miss interactions of other agents important in ocular therapy. This study shows that sulfacetamide solutions containing EDTA and thimerosal as preservatives are more effective against the organisms tested than sulfacetamide solutions containing paraben preservatives *without* EDTA. The antipseudomonal activity of thimerosal-preserved sulfacetamide solutions is particularly interesting, since they are usually not considered effective against this microorganism.

High-Performance Liquid Chromatographic Analysis of Diflunisal in Plasma and Urine: Application to Pharmacokinetic Studies in Two Normal Volunteers

J. E. RAY ˣ and R. O. DAY

Received May 17, 1982, from the *Department of Clinical Pharmacology, St. Vincent's Hospital, Darlinghurst, New South Wales, 2010, Australia.* Accepted for publication October 19, 1982.

Abstract □ A high-performance liquid chromatographic (HPLC) assay with fluorescence detection has been developed for the determination of diflunisal in plasma and urine. The plasma or urine, containing naproxen as the internal standard, was extracted with ether–hexane (1:1). The samples were analyzed on a microparticulate column, and the compounds were eluted using a mobile phase of 0.05 *M* phosphate buffer (pH 3) and methanol. Plasma samples were analyzed from two healthy male subjects who received a 250- and 750-mg oral dose of diflunisal 3 weeks apart. The data were analyzed according to a two-compartment open model. There was a disproportionate increase in the area under the plasma concentration–time curves (AUC 750 mg/AUC 250 mg was 3.84 for subject A and 4.22 for subject B) and a reduction in plasma clearance after the 750-mg dose of diflunisal. These data suggest that the kinetics of diflunisal may be dose dependent.

Keyphrases □ Diflunisal—high-performance liquid chromatographic analysis, plasma and urine, application to pharmacokinetic studies □ High-performance liquid chromatography—analysis of diflunisal in plasma and urine, application to pharmacokinetic studies □ Pharmacokinetics—diflunisal, high-performance liquid chromatographic analysis, plasma and urine

Diflunisal, 2′,4′-difluoro-4-hydroxy-3-biphenylcarboxylic acid, a salicylic acid derivative with analgesic and anti-inflammatory activity (1, 2), has been assayed in biological fluids by a fluorescence method (3). This assay procedure lacks the specificity of GLC and high-performance liquid chromatography (HPLC) (4). The more tedious GLC method (3) has been superseded by HPLC assays (4–6), but these methods have thus far been relatively insensitive.

The pharmacokinetics of diflunisal have been investigated, but these studies have used either the nonspecific fluorescence assay to measure plasma concentrations (3, 7–9) or the relatively insensitive HPLC procedures (10) which necessitated the administration of high doses (750 mg) of diflunisal. This paper reports the development of a sensitive and specific HPLC assay for quantitating diflunisal in plasma or urine and its application to a preliminary study of the pharmacokinetics of diflunisal in humans.

EXPERIMENTAL

High-Performance Liquid Chromatographic Analysis of Diflunisal in Plasma and Urine: Application to Pharmacokinetic Studies in Two Normal Volunteers

J. E. RAY ˣ and R. O. DAY

Received May 17, 1982, from the *Department of Clinical Pharmacology, St. Vincent's Hospital, Darlinghurst, New South Wales, 2010, Australia.* Accepted for publication October 19, 1982.

Abstract □ A high-performance liquid chromatographic (HPLC) assay with fluorescence detection has been developed for the determination of diflunisal in plasma and urine. The plasma or urine, containing naproxen as the internal standard, was extracted with ether–hexane (1:1). The samples were analyzed on a microparticulate column, and the compounds were eluted using a mobile phase of 0.05 *M* phosphate buffer (pH 3) and methanol. Plasma samples were analyzed from two healthy male subjects who received a 250- and 750-mg oral dose of diflunisal 3 weeks apart. The data were analyzed according to a two-compartment open model. There was a disproportionate increase in the area under the plasma concentration–time curves (AUC 750 mg/AUC 250 mg was 3.84 for subject A and 4.22 for subject B) and a reduction in plasma clearance after the 750-mg dose of diflunisal. These data suggest that the kinetics of diflunisal may be dose dependent.

Keyphrases □ Diflunisal—high-performance liquid chromatographic analysis, plasma and urine, application to pharmacokinetic studies □ High-performance liquid chromatography—analysis of diflunisal in plasma and urine, application to pharmacokinetic studies □ Pharmacokinetics—diflunisal, high-performance liquid chromatographic analysis, plasma and urine

Diflunisal, 2′,4′-difluoro-4-hydroxy-3-biphenylcarboxylic acid, a salicylic acid derivative with analgesic and anti-inflammatory activity (1, 2), has been assayed in biological fluids by a fluorescence method (3). This assay procedure lacks the specificity of GLC and high-performance liquid chromatography (HPLC) (4). The more tedious GLC method (3) has been superseded by HPLC assays (4–6), but these methods have thus far been relatively insensitive.

The pharmacokinetics of diflunisal have been investigated, but these studies have used either the nonspecific fluorescence assay to measure plasma concentrations (3, 7–9) or the relatively insensitive HPLC procedures (10) which necessitated the administration of high doses (750 mg) of diflunisal. This paper reports the development of a sensitive and specific HPLC assay for quantitating diflunisal in plasma or urine and its application to a preliminary study of the pharmacokinetics of diflunisal in humans.

EXPERIMENTAL

Chemicals and Reagents—Diflunisal[1] and naproxen[2] were the reference and internal standards, respectively. Stock solutions of these

[1] Dolobid; Merck Sharp & Dohme, Sydney, Australia.
[2] Syntex, Sydney, Australia.

0022-3549/83/1200-1403$01.00/0

compounds were prepared daily by dissolving the drugs in acetone[3]. Chromatographic-grade hexane[4] and methanol[5] were used, while all other reagents were analytical grade. Ether[6] was distilled in glass.

Extraction Procedure—The plasma or urine containing the internal standard was extracted according to the method of Van Loenhout *et al.* (6) with the following modifications: (*a*) to achieve adequate recovery of diflunisal from urine, samples were extracted twice with 5 ml of ether–hexane (1:1), and (*b*) the residue remaining after evaporation of the ether–hexane was resuspended in the HPLC mobile phase.

Clinical Study—Single 250- and 750-mg doses of diflunisal were administered to two healthy male subjects. The doses were not randomized, and the same formulation was used in both studies. Subjects fasted overnight before the drug administration and continued fasting until 4 hr postdose. All doses were administered at 8:00 a.m. and the tablets were swallowed whole with 200 ml of water. Venous blood samples were drawn into potassium oxalate–sodium fluoride[7] tubes before drug administration and at 0.5, 1, 1.5, 2, 2.5, 4, 5, 6, 8, 10, 12, 18, 24, 30, 36, 42, 48, 60, and 72 hr after the drug was given.

Instrumentation—Assays were carried out using a constant-flow high-performance liquid chromatograph[8]. It consisted of a solvent delivery system[9], an autosampler injector[10] with a pneumatic-actuated injection valve fitted with a 20-μl sample loop[11], a microparticulate reverse-phase column[12] (5 μm; 25 cm × 4.6-mm i.d.), a guard column[13], and a spectrophotofluorometer[14] with the excitation monochromotor set at 315 nm and the fluorescence emission at 389 nm (cutoff filter).

Chromatography—The compounds in plasma were eluted with a mobile phase of 64% methanol in 0.05 *M* phosphate buffer (pH 3), prepared from monobasic sodium phosphate with the pH adjusted using sulfuric acid. The column temperature was 50° and the flow rate was 1 ml/min. The same conditions were used to analyze urine samples, but a linear gradient (10 min) from 60% methanol in 0.05 *M* phosphate buffer (pH 3) to 70% methanol in phosphate buffer was necessary to move the diflunisal and naproxen peaks from interfering peaks at the solvent front.

Pharmacokinetic Analysis—The data were analyzed assuming a two-compartment open model with delayed absorption (11) and were fitted to the appropriate triexponential equation using a nonlinear regression analysis program (12). The equation fitted was:

$$C_1 = Ae^{-\alpha(t-t_0)} + Be^{-\beta(t-t_0)} - Ce^{-k_a(t-t_0)}$$

where C_1 is the plasma concentration, t the time after the dose, t_0 the lag time, and k_a the apparent first-order absorption rate constant. A, B, α, and β are constants related to model parameters (11); A and B are also related to the dose (D) and the fraction of the dose that reaches the systemic circulation (f). Initial estimates of these parameters were obtained graphically using the method of residuals (11). The volume of distribution V_d (area), the total body clearance (CL), and area under the curve (AUC) were estimated as described by Wagner (11).

RESULTS AND DISCUSSION

Assay—Reverse-phase HPLC with fluorescence detection was an effective method of quantitating diflunisal in human plasma and urine. Typical chromatograms obtained from blank plasma, blank urine, plasma containing diflunisal and naproxen (internal standard), and urine containing diflunisal and naproxen are shown in Fig. 1. Interference by endogenous substances did not occur from either drug-free plasma or urine (Fig. 1).

The standard curve for diflunisal was linear over the concentration range of 0.05–100 μg/ml in both plasma and urine. The correlation coefficient for the standard curves over this concentration range was >0.999 (n = 4). The coefficient of variation was <5% for all concentrations measured (Table I), and the sensitivity of the method was 50 ng/ml. Under the assay conditions described, acetylsalicylic acid and salicylic acid had elution times of 2.9 and 3.1 min, respectively, and did not interfere with the diflunisal or naproxen peaks.

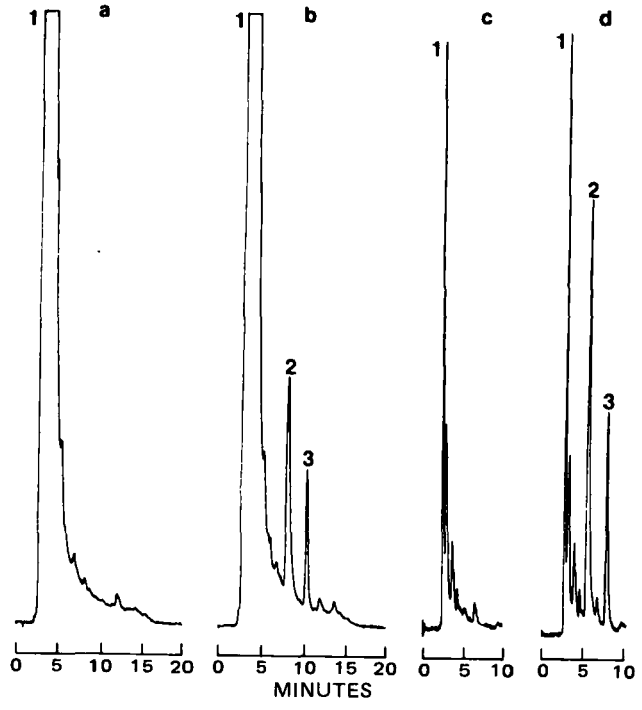

Figure 1—*Chromatograms of blank urine (a), spiked (200 ng/ml) urine (b), blank plasma (c), and spiked (200 ng/ml) plasma (d). Key: (1) solvent front; (2) diflunisal; (3) naproxen (internal standard).*

The method described was sufficiently sensitive to detect plasma concentrations of diflunisal for 80 hr after oral doses of 250 and 750 mg of the drug. The procedure has marked advantages over previous methods in both sensitivity (4–6) and specificity (3). The use of identical extraction and similar chromatographic conditions for the detection of diflunisal in plasma and urine makes the method simple and convenient for pharmacokinetic studies.

Pharmacokinetics—After the 250-mg dose of diflunisal, peak concentrations of 39.6 and 33.9 μg/ml were reached at 3.5 and 2.1 hr, respectively (Fig. 2). The pharmacokinetic data were analyzed according to a two-compartment open model although the elimination phase in subject B (250-mg dose) was not strictly linear. Agreement between the computer-generated curves and the experimental values was good. The various phramacokinetic parameters are shown in Table II. The half-lives of the initial α phase were 1.7 and 0.9 hr, while those of the β phase were 10.8 and 9.8 hr for the two subjects. The total body clearance was 8.6 and

k_a, hr^{-1}	0.5	1.7
$t_{1/2,\alpha}$, hr	1.7	0.9
$t_{1/2,\beta}$, hr	10.8	9.8
V_d (area), liters[a]	14.1	8.6
CL, ml/min	8.6	10.0
$AUC_{0-\infty}$, μg·hr/ml	482.2	415.5

[a] Calculation assumes $f = 1$ (7).

10.0 ml of plasma/min. The volume of distribution was 14.1 and 8.6 liters. These data are in good agreement with those previously obtained after a 500-mg oral dose (7). The volume of distribution and clearance of diflunisal are low, but similar to other nonsteroidal anti-inflammatory drugs (13). Pharmacokinetic parameters were not estimated after the 750-mg oral doses of diflunisal in the two subjects because the log plasma concentration–time curves suggested a nonlinear elimination phase.

It has been suggested that diflunisal exhibits dose-dependent kinetics (3, 7, 8). Tocco *et al.* showed that the AUC values for [^{14}C]diflunisal in plasma of healthy volunteers were ~18 times higher after a 500-mg dose when compared with a 50-mg dose of diflunisal (3). Further, these authors reported a shorter elimination half-life (6 hr) after a 50-mg oral dose, compared with an elimination half-life of 10.8 hr after a 500-mg oral dose. However, these data are difficult to interpret because the assays lacked specificity. Dresse *et al.* (8) administered 500 mg of diflunisal twice a day for 8 days to 10 male volunteers and suggested that the elimination of diflunisal might be nonlinear for plasma concentrations >10 μg/ml. A third study, in which a nonspecific fluorescence assay was used, reported that the plasma elimination half-life of diflunisal decreased with declining plasma concentration, again suggesting nonlinear elimination of the drug (7).

Table III—Plasma Pharmacokinetic Parameters in Two Normal Subjects After a 750-mg Oral Dose

Parameter	Subject A	Subject B
Peak time, hr	4.0	3.5
Peak concentration, μg/ml	99.0	99.3
CL, ml/min	6.74	7.13
$AUC_{0-\infty}$, μg·hr/ml	1855	1752
AUC 750 mg/AUC 250 mg	3.84[a]	4.22[b]

[a] This ratio is significantly different from 3.0 ($p < 0.05$), one-sample t test. The one-sample t test is used to find the probability that the mean of a single sample of a population is different than an hypothesized value (15). [b] This ratio is significantly different from 3.0 ($p < 0.01$), one-sample t test.

The pharmacokinetics of diflunisal after 250- and 750-mg oral doses of the drug are shown in Tables II and III. There was a disproportionate increase in the plasma concentration–time AUC (Table III) and a reduction in plasma clearance (Tables II and III) when comparing the 750-mg oral dose of diflunisal with the 250-mg oral dose. Visual inspection of the plasma–concentration time curve for subject A suggests nonlinear elimination of the drug following the 750-mg dose of diflunisal. However, this phenomenon is not apparent in subject B.

The elimination of diflunisal is almost exclusively dependent on glucuronidation of the parent compound to ether glucuronide (64%) and ester glucuronide (20%), which are excreted in the urine (3). Pharmacokinetic studies with sodium salicylate, a compound structurally similar to diflunisal, have demonstrated that humans have a limited capacity for salicyl phenolic glucuronide formation (14), while the salicyl acyl glucuronide formation follows a first-order process (14). Data in normal volunteers suggest that the diflunisal phenolic glucuronide formation may be capacity limited (3). The data obtained from our study suggest that the kinetics of diflunisal may be dose dependent, but further study is needed to confirm this.

Decomposition of Thimerosal in Aqueous Solution and its Determination by High-Performance Liquid Chromatography

M. J. READER ˣ **and C. B. LINES**

Received August 2, 1982, from the *Central Analytical Laboratories (Chemical), The Wellcome Foundation Limited, Temple Hill, Dartford, Kent, DA1 5AH, United Kingdom.* Accepted for publication October 14, 1982.

Abstract □ Studies on the decomposition of thimerosal in aqueous solution have confirmed that thiosalicylic acid and ethylmercuric hydroxide are the initial products. On prolonged reaction, thiosalicylic acid was oxidized to 2,2′-dithiosalicylic acid, while ethylmercuric hydroxide was reduced to elemental mercury. As a result, a specific, reverse-phase high-performance liquid chromatographic assay has been developed for thimerosal in the presence of its decomposition products. By comparison, an existing colorimetric assay procedure employing dithizone was shown to be not fully specific. The presence of sodium chloride in the solution accelerated the decomposition of thimerosal. There was evidence that thimerosal was sorbed onto plastic containers on storage.

Keyphrases □ Thimerosal—degradation products, aqueous solutions, effect of sodium chloride, high-performance liquid chromatography □ Ophthalmic solutions—thimerosal decomposition in aqueous solutions, effect of sodium chloride, high-performance liquid chromatography □ High-performance liquid chromatography—thimerosal and its degradation products, aqueous solutions, effect of sodium chloride

Thimerosal, ethyl (sodium *o*-mercaptobenzoato)mercury (I), is widely used in pharmaceutical preparations, such as eyedrops, as an antibacterial and antifungal preservative. However, it is known to be unstable in aqueous solution (1, 2). It has also been reported that the presence of halides can have an adverse influence on the stability of I (3–5), and that I can be lost from solutions stored in plastic containers (6). The object of this study was to identify the decomposition products of thimerosal in aqueous solution under various conditions and, hence, develop a specific analytical method for the intact preservative in stored test solutions.

The decomposition of I in aqueous solution has been studied previously (2), and it was shown that the major products were thiosalicylic acid (II) and ethylmercuric hydroxide (III). Compound II can also undergo irreversible oxidation to 2,2′-dithiosalicylic acid (IV) (7). Hydrolysis in the presence of halide ions gave ethylmercuric halide (V) rather than the hydroxide (4).

Chemical assay procedures previously reported for the analysis of I have included UV spectrophotometry (8), polarography (9, 10), and colorimetry (11–13). None of these methods were fully specific for I in the presence of decomposition products, particularly the colorimetric assay, which is sensitive to all mercury-containing species present in the solution. Therefore, it was decided to seek a high-performance liquid chromatographic (HPLC) method for the analysis of I. A previously reported anion exchange HPLC method (14) was considered to be unsuitable for the assay of I in pharmaceutical preparations due to poor peak shape, while another method (15) failed to provide adequate resolution of I from its decomposition products. A more recent method (16) using radial-compression HPLC gave imprecise assays and did not satisfactorily resolve the degradation products of I from each other. The HPLC method described here gave resolution of I from its major decomposition products and has been used to assay I in test solutions and pharmaceutical vehicles.

EXPERIMENTAL

Compounds and Reagents—The following compounds were obtained commercially and used without further purification: thimerosal[1], ethylmercuric chloride[2], thiosalicylic acid[3], and 2,2′-dithiosalicylic acid[4]. All other reagents and solvents were analytical reagent grade[1]. Ethylmercuric hydroxide was synthesized by a published method (17).

High-Performance Liquid Chromatography—*Equipment*—A constant-flow pump[5] was used to deliver the eluant to a stainless steel column packed with 10-μm silica particles bonded with octadecylsilane[6]. Injections were made with a rotary valve injector[7] equipped with a 25-μl loop. No attempt was made to control the column temperature. A variable-wavelength detector[8] set at 222 nm was employed at an attenuation of 0.5 AUFS for 0.01% (w/v) solutions of thimerosal and at 0.05 AUFS for 0.001% (w/v) solutions.

Chromatographic Conditions—The mobile phase consisted of a mixture of methanol–water–phosphoric acid in a ratio of 60:50:1.0. The pressure at a flow rate of 2.6 ml min^{-1} was 1800 psig. Separations were effected isocratically at ambient temperature, and quantification was carried out by comparison of the areas of peaks obtained from test solutions with the area of the peak obtained from a standard thimerosal solution (Fig. 1).

Thin-Layer Chromatography—TLC was carried out on prepared silica gel plates[9] (20 cm × 20 cm × 0.25 mm) with mixtures of chloroform–methanol (1:1) (system A) or butanone–ethanol–acetic acid (70:30:0.1) (system B) as the developing solvents; loadings of thimerosal were usually 50 or 100 μg. Components were detected by viewing under UV light at 254 nm and visualized by spraying with a 0.05% (w/v) solution of diphenylthiocarbazone (dithizone) in chloroform.

Dithizone Colorimetric Assay—A volume of the test solution equivalent to 0.1 mg of I was transferred by pipet to a separator containing 0.5 *M* sulfuric acid (20 ml) and glacial acetic acid (20 ml). Ten percent sodium hydroxide (30 ml) was added followed by toluene (15 ml) and dithizone solution (1 ml). The mixture was shaken and allowed to settle. Most of the aqueous (lower) phase was removed and discarded. Anhydrous sodium sulfate (1 g) was added to the remaining emulsion, which was then filtered through a phase separating paper[10]. The color of the clear solution was measured in a 1-cm cell at 475 nm against a reagent blank on a spectrophotometer[11]. This was compared with the color formed from an aliquot of a standard thimerosal solution (10 ml; 0.001% w/v) treated in an identical manner.

Preparation of Dithizone and Thimerosal Solutions—Dithizone (64 mg) was dissolved in chloroform (100 ml); 10 ml of this solution was diluted to 100 ml with chloroform. Thimerosal (100 mg) was dissolved in water (100 ml). Two successive dilutions of 10 ml to 100 ml were made to obtain the standard solution.

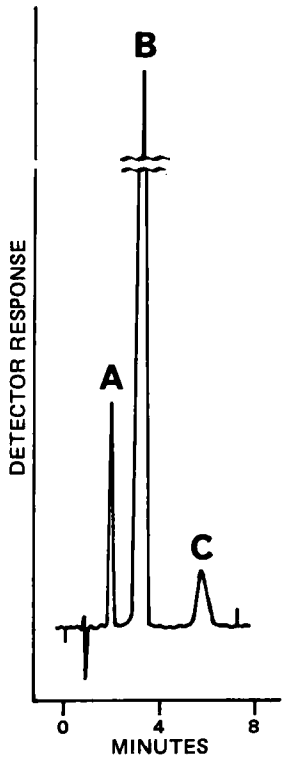

Figure 1—*Chromatogram of thiosalicylic acid (A), thimerosal (B), and 2,2′-dithiosalicylic acid (C).*

Hydrolysis of Thiomerosal in Aqueous Solution and in Saline—Solutions of thimerosal at a concentration of 0.5% in water and in 0.8% saline were heated under reflux and samples were removed at convenient intervals for TLC analysis. After 1 week, TLC (system B) showed one secondary spot at R_f 0.69 (nonabsorbing UV 254; yellow with dithizone) plus unreacted thimerosal (R_f 0.43). Neither solution contained any thimerosal after 3 weeks, but TLC now showed two major spots at R_f 0.23 and 0.30. The spot at R_f 0.69 was absent.

Both solutions were then cooled and acidified with hydrochloric acid to give white precipitates which were extracted into chloroform. The aqueous phases still contained insoluble materials which were filtered off, washed with water, and dried to give white solids, mp 283° (from the aqueous reaction) and 288° (from the saline reaction) identified as 2,2′-dithiosalicylic acid (IV) [lit. (2) mp 287–290°]. IR analysis gave an intense band at 1690 cm^{-1} due to the C=O stretching of an aromatic carboxylic acid. UV analysis showed two maxima at 252 and 313 nm in ethanol–0.1 *M* NaOH. TLC of the chloroform extracts showed two spots at R_f 0.23 and 0.30. Droplets of elemental mercury were also found in both solutions.

Stability in 0.8% Saline—*Thiosalicylic Acid*—A 0.2% solution of thiosalicylic acid in 0.8% saline was refluxed for 6 days. TLC (system B) showed complete conversion to IV (R_f 0.23); this was confirmed by UV analysis.

Ethylmercuric Chloride—A 0.2% solution/suspension of ethylmercuric chloride in 0.8% saline was refluxed for 6 days and monitored by TLC (system B). There was no indication of decomposition during this period and no visible formation of metallic mercury in the reaction vessel.

Interaction of Thiosalicylic Acid and Ethylmercuric Compounds in Aqueous Solution—Thiosalicylic acid (0.16 g, 1 mmole) and ethylmercuric chloride (0.27 g, 1 mmole) in water (20 ml) containing 1 *M* NaOH (1 ml) were refluxed for 1 week. TLC (system B) showed the formation of IV (R_f 0.23) and loss of ethylmercuric chloride (R_f 0.69). There was also deposition of metallic mercury. A parallel experiment with thiosalicylic acid (0.16 g, 1 mmole) and ethylmercuric hydroxide (0.25 g, 1 mmole) in 0.8% saline (20 ml) containing 1 *M* NaOH (1 ml) gave similar results.

RESULTS AND DISCUSSION

Decomposition Studies—The formation of II and III, or ethylmercuric chloride (V) in the presence of chloride ions, in the hydrolysis of I in water and 0.8% saline has been confirmed by TLC (Table I). No I and III (or V) remained after refluxing for 3 weeks, and the major products were shown to be II and IV by TLC and spectroscopic analysis. Mercury was also deposited from these solutions. The reaction shown in Scheme I represents the decomposition pathway of I under aqueous conditions. Compounds II and IV have been named and represented as the free carboxylic acids throughout, although in aqueous solution they will usually be present as their sodium salts.

Table I—R_f Values and Response to the Spray Reagent on TLC of I–V

Compound	R_f Values System A	R_f Values System B	Color with Dithizone
Thimerosal (I)	0.54	0.43	Yellow
Ethylmercuric chloride (V)	0.76	0.69	Lemon yellow
Ethylmercuric hydroxide (III)	0.70	0.65	Lemon yellow
Thiosalicylic acid (II)	0.40	0.29	Faint mauve[a]
2,2′-Dithiosalicylic acid (IV)	0.30	0.23	Faint mauve-pink[a]

[a] Color develops on standing.

It has been demonstrated that II oxidized to IV on heating in 0.8% saline. Compound V alone, when heated in 0.8% saline, failed to degrade to mercury. However equimolar mixtures of II and III, and of II and V, have been shown to interact when heated in aqueous solution. As II was oxidized to IV, the ethylmercuric compounds (III and V) were correspondingly reduced to metallic mercury.

Analytical Studies—During the development of a reverse-phase HPLC method various water–methanol mixtures were tried and the pH of the eluant was controlled using phosphoric acid to reduce the effect of peak tailing. The eluant allowed monitoring at 222 nm, the UV absorption maximum of thimerosal at this pH. The mobile phase chosen for the analysis gave the following k' values: thiosalicylic acid, 1.5; thimerosal, 3.0; 2,2′-dithiosalicylic acid, 6.0. The effect of decreasing the proportion of methanol relative to water in the mobile phase was to increase the retention of all three components resulting in a high overall analysis time, while an increase in the methanol–water ratio impaired the resolution of thimerosal and thiosalicylic acid.

A standard calibration curve for thimerosal was constructed using a stock solution of 102 μg/ml and three solutions of 61.2, 40.8, and 20.4 μg/ml prepared by dilution of the stock solution. The $y = mx + c$ linear regression equation gave a slope of 1844, and intercept of 1577, and was linear in the range of 20.4–102 μg/ml (the corresponding integrator response ranging from 38,741 to 189,527). The plot gave a Pearson's correlation coefficient of 0.99998 ($p < 0.01$).

It was considered that the good fit and linearity of the calibration plot (which also passed very close to the origin) together with the good reproducibility of the method (coefficient of variation, 0.7%) allowed analysis to be carried out using drug peak areas alone and obviated the need for an internal standard. The limits of detection when 25-μl injections of solutions were made with a detector attenuation of 0.05 AUFS were 0.2 μg/ml for thiosalicylic acid and 0.1 μg/ml for thimerosal.

The HPLC procedure was used to assay thimerosal in samples of 0.01% aqueous solutions after storage in various containers for 24 months at

[a] This figure represents the amount of thiosalicylic acid expected from the decomposition indicated by the HPLC assay of thimerosal. [b] A and B refer to assay values on two separate samples.

5°, 25°, 37°, and 50°. The containers included glass ampules, one-half of which were autoclaved at 120° for 20 min before the start of the storage test (the other half were not autoclaved) and three types of plastic containers. The results, together with those obtained colorimetrically using dithizone, are given in Table II.

After storage, the solutions in glass ampules that were not autoclaved showed HPLC assays lower than those obtained by the dithizone method. This trend was even more marked in those solutions which had been previously autoclaved. These figures are a reflection of the greater specificity of the HPLC method compared with the colorimetric assay.

The level of thimerosal after storage in plastic containers was found to be lower than that found in glass ampules especially at higher storage temperatures. There was, in general, fairly good agreement between the two assay methods for plastic containers. From the HPLC assay of solutions in plastic containers, it is clear that thimerosal is lost from solution by hydrolysis and by some form of sorption onto the containers; these effects increase with temperature. In plastic containers at 25° there was also less thiosalicylic acid detected than would have been anticipated from the thimerosal levels; this trend became more marked at 37° and 50°, providing a further indication of sorption of thimerosal onto the container. By comparison, in glass containers there was reasonably good mass balance between thimerosal decomposed and thiosalicylic acid formed up to 37°, less so at 50°. The sorption of organomercury compounds, including thimerosal, onto the surface of plastic containers has been noted previously (6, 18) and was shown to be dependent on storage temperature and time for a given plastic.

Table III—Results of the HPLC Assays of Thimerosal Solutions in Water and in Saline Stored for 15 days at 5°, 25°, and 50° in Glass Containers

[a] NA = not analyzed.

Since ophthalmic pharmaceutical formulations are commonly rendered isotonic with the fluids in the eye using sodium chloride, the effect of this salt on the stability of thimerosal in aqueous solution was investigated. Thimerosal was stored as 0.1, 0.01, and 0.001% solutions in water and 0.8% saline at 5°, 25°, and 50° for up to 15 days. HPLC analysis was carried out after 8 and 15 days (Table III).

In water, thimerosal was stable except when stored at 50° at the lowest concentration (0.001%), the assay dropping to 30–40%. This effect of the initial concentration of thimerosal became even more marked in saline. After 8 days at 0.001% initial concentration, there was no thimerosal remaining at 25° and 50° and only ~30% at 5°. These figures present a disturbing picture, since they mirror what could be expected in ophthalmic formulations where thimerosal is very often present at concentrations of 0.001% in the presence of 0.8% saline. At 0.01 and 0.1% initial concentrations, sodium chloride had a less dramatic effect on the assay, but decomposition of thimerosal was still much faster in its presence.

In view of these findings on the effect of sodium chloride on the stability of thimerosal, equivalent pharmaceutical vehicles containing thimerosal at an initial concentration of 0.001% and 0.8% sodium chloride were prepared and stored at 5° for 3 months. HPLC assay showed no thimerosal (<10%) remaining, while the dithizone method gave satisfactory assay values of 101.3 and 102.3% of the labelled strength for two such samples. These figures further reflect the specificity of the HPLC method compared with the colorimetric procedure.

It was reported (5) that there was only 30% thimerosal remaining after storage in 0.4% aqueous sodium chloride, and in an equivalent pharmaceutical vehicle containing sodium chloride, for 2 months at 70°. However these findings were based on the semispecific UV or colorimetric methods for the assay of thimerosal and would seem to be somewhat optimistic. If the data in Table III together with that obtained from an equivalent pharmaceutical vehicle are considered, a much more pessimistic picture is presented of the stability of thimerosal in saline solution and, thus, in pharmaceutical preparations containing sodium chloride.

The exact reasons for the marked effect of sodium chloride on the decomposition of thimerosal are not clear at present. It is well known that chloride and other halides have a marked affinity to coordinate with mercury(II) compounds, and this could be a contributory factor in the detrimental effect of sodium chloride on the stability of thimerosal in solution. There is some evidence to show that the decomposition of thimerosal in water to thiosalicylic acid and ethylmercuric hydroxide is a reversible reaction. The effect of chloride could be to disturb this equilibrium by reaction with the ethylmercuric hydroxide to give ethylmercuric chloride, which does not react nearly as readily with thiosalicylic acid in neutral solution to give thimerosal.

Further investigations will be needed to substantiate this mechanism of the action of chloride ions and other anionic species. What is evident

from these investigations is that the use of sodium chloride as an isotonic agent with thimerosal as preservative in ophthalmic preparations is open to question.

Bioavailability of Propylthiouracil in Humans

H. P. RINGHAND *, W. A. RITSCHEL *x, M. C. MEYER ‡, A. B. STRAUGHN ‡, and B. E. CABANA §

Received April 4, 1982, from the **College of Pharmacy, University of Cincinnati Medical Center, Cincinnati, OH 45267,* ‡*Department of Pharmaceutics, College of Pharmacy, University of Tennessee, Memphis, TN 38163,* and the §*Food and Drug Administration, Division of Biopharmaceutics, Rockville, MD 20852.* Accepted for publication October 6, 1982.

Abstract □ Single lots of five commercially available 50-mg propylthiouracil formulations were evaluated *in vitro* and *in vivo*. Each product met the USP XIX specifications for drug content, content uniformity, and disintegration time. However, major differences were noted among products in their rate and extent of dissolution. Statistically significant differences ($p < 0.05$) were observed *in vivo* among the drug formulations at all but one of the sampling times, as determined from crossover blood level studies in 12 healthy male volunteers. The differences among the areas under the plasma level–time curves for the various products were not statistically significant. No statistically significant correlations were found between the *in vitro* and *in vivo* parameters studied.

Keyphrases □ Propylthiouracil—human plasma levels *in vivo*, bioavailability, correlation with *in vitro* dissolution □ Bioavailability—propylthiouracil, human plasma, correlation with *in vitro* dissolution □ Dissolution, *in vitro*—propylthiouracil, correlation with *in vivo* bioavailability, humans

Propylthiouracil, a thyrostatic drug that inhibits the synthesis of hormones within the thyroid gland and reduces the conversion of thyroxine (T_4) to the more potent triiodothyronine, T_3, in the peripheral tissues (1), is prescribed for the chronic treatment of hyperthyroidism and the preparation of hyperthyroid patients for surgery. While differences in bioavailability among propylthiouracil formulations have not been documented, propylthiouracil has been included in several lists of drugs with potential or actual differences in bioavailability (2, 3). The present study involved a crossover comparison to assess the relative bioavailability of five currently marketed products.

EXPERIMENTAL

Product Selection—Five single lots of 50-mg propylthiouracil tablets from separate manufacturers were evaluated; the individual products are identified in Table I. The sixth formulation, a solution of propylthiouracil, was utilized as a reference and was prepared as follows.

A stock solution of sucrose–glycerin was prepared by combining 6.5 g of sucrose with 12.5 ml of glycerin, diluting to 500 ml with distilled water. The day before each study a sucrose–glycerin–citric acid solution was prepared by adding 2.0 ml of 0.5 *M* citric acid to 95.4 ml of the sucrose–glycerin stock solution. On the day of each study the propylthiouracil reference solution was freshly prepared using USP propylthiouracil powder[1]. A 150-mg quantity of the powdered propylthiouracil was accurately weighed and dissolved in 6 ml of 0.2 *M* NaOH. The resulting solution was then diluted immediately with 24 ml of the sucrose–glycerin–citric acid solution and administered to the subject.

Clinical Study Protocol—Twelve male volunteers[2] underwent urinalysis and hematological and blood chemistry[3] testing to ensure that they were in good health. Also included in the initial medical evaluation was a T_4 determination by radioimmunoassay, T_3 uptake, and free thyroxine blood study. As a precaution against possible side effects of the propylthiouracil, the white blood cell and differential count, as well as prothrombin time, were monitored at the midpoint of the 6-week study. The subjects ranged in age from 20 to 25 years, in height from 172 to 198 cm, and in weight from 72 to 93 kg; all were considered to be of normal weight for their height (4).

The sequence of dose administration was based on a crossover matrix, designed to minimize the influence of any residual or cumulative effects of the preceding doses (5). Each subject received three 50-mg tablets or reference solution equivalent to 150 mg of propylthiouracil once a week for 6 weeks. The propylthiouracil formulations were administered with 200 ml of water in the morning following an overnight fast[4]. No food and water were permitted for 4 hr after ingestion of the dose. The subjects were instructed to avoid any food high in fat content on days of testing to minimize analytical problems associated with excessive lipids in the plasma. While the subjects were not sequestered on the days of testing they were instructed to avoid undue exercise. Subjects were also cautioned to avoid any other medication during the 6-week period of the study.

Bioavailability of Propylthiouracil in Humans

H. P. RINGHAND *, W. A. RITSCHEL *x, M. C. MEYER ‡, A. B. STRAUGHN ‡, and B. E. CABANA §

Received April 4, 1982, from the **College of Pharmacy, University of Cincinnati Medical Center, Cincinnati, OH 45267,* ‡*Department of Pharmaceutics, College of Pharmacy, University of Tennessee, Memphis, TN 38163,* and the §*Food and Drug Administration, Division of Biopharmaceutics, Rockville, MD 20852.* Accepted for publication October 6, 1982.

Abstract □ Single lots of five commercially available 50-mg propylthiouracil formulations were evaluated *in vitro* and *in vivo*. Each product met the USP XIX specifications for drug content, content uniformity, and disintegration time. However, major differences were noted among products in their rate and extent of dissolution. Statistically significant differences ($p < 0.05$) were observed *in vivo* among the drug formulations at all but one of the sampling times, as determined from crossover blood level studies in 12 healthy male volunteers. The differences among the areas under the plasma level–time curves for the various products were not statistically significant. No statistically significant correlations were found between the *in vitro* and *in vivo* parameters studied.

Keyphrases □ Propylthiouracil—human plasma levels *in vivo*, bioavailability, correlation with *in vitro* dissolution □ Bioavailability—propylthiouracil, human plasma, correlation with *in vitro* dissolution □ Dissolution, *in vitro*—propylthiouracil, correlation with *in vivo* bioavailability, humans

Propylthiouracil, a thyrostatic drug that inhibits the synthesis of hormones within the thyroid gland and reduces the conversion of thyroxine (T_4) to the more potent triiodothyronine, T_3, in the peripheral tissues (1), is prescribed for the chronic treatment of hyperthyroidism and the preparation of hyperthyroid patients for surgery. While differences in bioavailability among propylthiouracil formulations have not been documented, propylthiouracil has been included in several lists of drugs with potential or actual differences in bioavailability (2, 3). The present study involved a crossover comparison to assess the relative bioavailability of five currently marketed products.

EXPERIMENTAL

Product Selection—Five single lots of 50-mg propylthiouracil tablets from separate manufacturers were evaluated; the individual products are identified in Table I. The sixth formulation, a solution of propylthiouracil, was utilized as a reference and was prepared as follows.

A stock solution of sucrose–glycerin was prepared by combining 6.5 g of sucrose with 12.5 ml of glycerin, diluting to 500 ml with distilled water. The day before each study a sucrose–glycerin–citric acid solution was prepared by adding 2.0 ml of 0.5 *M* citric acid to 95.4 ml of the sucrose–glycerin stock solution. On the day of each study the propylthiouracil reference solution was freshly prepared using USP propylthiouracil powder[1]. A 150-mg quantity of the powdered propylthiouracil was accurately weighed and dissolved in 6 ml of 0.2 *M* NaOH. The resulting solution was then diluted immediately with 24 ml of the sucrose–glycerin–citric acid solution and administered to the subject.

Clinical Study Protocol—Twelve male volunteers[2] underwent urinalysis and hematological and blood chemistry[3] testing to ensure that they were in good health. Also included in the initial medical evaluation was a T_4 determination by radioimmunoassay, T_3 uptake, and free thyroxine blood study. As a precaution against possible side effects of the propylthiouracil, the white blood cell and differential count, as well as prothrombin time, were monitored at the midpoint of the 6-week study. The subjects ranged in age from 20 to 25 years, in height from 172 to 198 cm, and in weight from 72 to 93 kg; all were considered to be of normal weight for their height (4).

The sequence of dose administration was based on a crossover matrix, designed to minimize the influence of any residual or cumulative effects of the preceding doses (5). Each subject received three 50-mg tablets or reference solution equivalent to 150 mg of propylthiouracil once a week for 6 weeks. The propylthiouracil formulations were administered with 200 ml of water in the morning following an overnight fast[4]. No food and water were permitted for 4 hr after ingestion of the dose. The subjects were instructed to avoid any food high in fat content on days of testing to minimize analytical problems associated with excessive lipids in the plasma. While the subjects were not sequestered on the days of testing they were instructed to avoid undue exercise. Subjects were also cautioned to avoid any other medication during the 6-week period of the study.

[a] See Table I for product information. [b] Values in parentheses represent the coefficient of variation, *i.e.*, *SD* × 100/mean.

Blood samples (7 ml) were collected in heparinized containers prior to ingestion of the dose and at 0.33, 0.66, 1, 1.5, 2, 3, 4, 6, and 8 hr post-administration. The blood samples were immediately centrifuged, and the plasma fractions were removed and frozen until assayed. All analyses were completed within 4 days from the time of sampling.

Assay of Plasma Samples—The determination of propylthiouracil concentrations was performed using a high-performance liquid chromatographic (HPLC) method developed by Ringhand and Ritschel (6). A 3.0-ml plasma sample was added to 0.5 g of ammonium sulfate and mixed vigorously for 1 min. The mixture was extracted for 10 min with 15.0 ml of chloroform. After centrifugation, a 10.0-ml aliquot of the chloroform layer was removed and mixed with 1.0 ml of a 1.75-μg/ml methylthiouracil internal standard solution and evaporated to dryness.

The residue was dissolved in 250 ml of mobile solvent, acetic acid–methanol–water (10:75:915), and 25 μl was injected into the chromatograph[5]. The chromatograph was equipped with a fixed-wavelength 280-nm detector and a stainless steel column, 25 cm × 3.1-mm i.d., packed with an octadecylsilane reverse-phase support[6]. A flow rate of 2.3 ml/min was used. Plasma propylthiouracil concentrations were determined from standard curves of propylthiouracil/methylthiouracil peak height ratio *versus* propylthiouracil concentration, prepared over a range of 0.1–5.0 μg/ml using pooled human plasma.

***In Vitro* Tests**—The USP XIX product assay, content uniformity, and tablet disintegration were performed on each product (7). Dissolution profiles were determined for each product on six individual tablets in two different media: water and 0.1 *N* HCl. Tests were performed using the USP Dissolution Apparatus 2 (8) maintained at 50 rpm and a temperature of 37 ± 0.5°[7]. Samples (10 ml) were taken at 5, 20, and 60 min. The liquid level was maintained by adding 10-ml aliquots of dissolution medium to replace the sample aliquots as they were taken.

Statistical Analysis—The relative bioavailability of the five propylthiouracil products was determined using the following parameters:

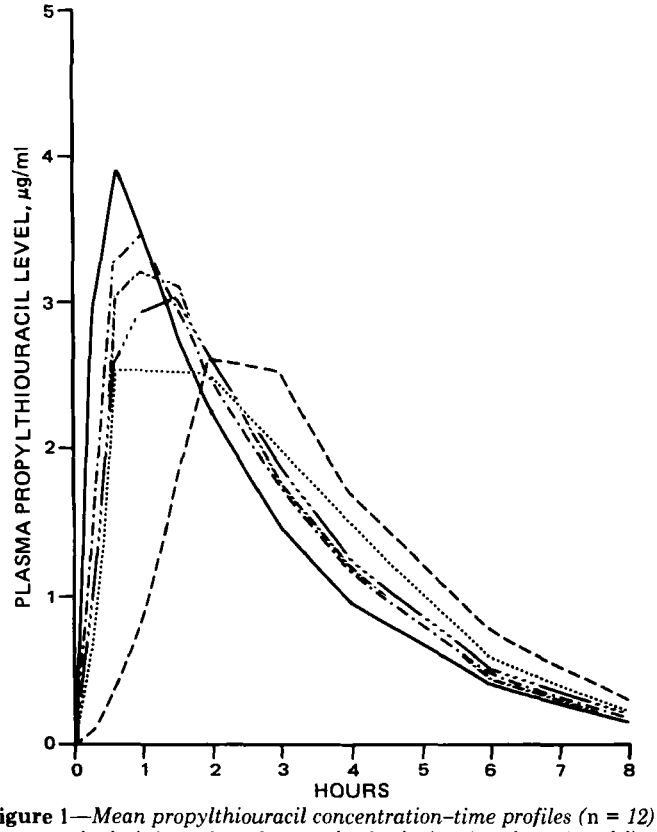

Figure 1—*Mean propylthiouracil concentration–time profiles (n = 12) on peroral administration of a standard solution (product 1) and five different commercially available propylthiouracil tablet preparations (products 2–6). plasma concentrations at each sampling time, time of peak plasma concentration, peak plasma concentration, and area under the plasma concentration–time curve (AUC). A three-way analysis of variance (9) and the Newman-Keuls *a posteriori* test (10) were used to analyze for differences among products, subjects, and weeks.

RESULTS AND DISCUSSION

Table I summarizes the results of the *in vitro* tests. Each of the five products met the USP XIX requirements for drug content, disintegration, and content uniformity. However, major differences were observed for the rate and extent of dissolution of the different drug products[8].

The average plasma concentrations for each product at each sampling time are summarized in Table II and illustrated graphically in Fig. 1. The statistical analyses of differences among subject groups, weeks, and test products at each sampling time are given in Tables III and IV. Significant differences ($p < 0.05$) in plasma levels were observed among the products at all sampling times except at 2 hr. The Newman-Keuls analysis found

[8] USP XIX does not include a dissolution requirement for propylthiouracil tablets.

	(21.9)	(51.2)	(15.0)	(15.7)

[a] Each value represents the mean of 12 subjects. *RSD* (*SD* × 100/mean) is given in parentheses. [b] See Table I for product information.

no significant differences among products 3–6 at any of the sampling times. All observed differences were due to products 1 and 2 being different from one or more of the other dosage forms.

The mean values of peak concentration, time to peak concentration, $AUC_{0-8\ hr}$ and $AUC_{0\rightarrow\infty}$ are summarized in Table V; the statistical analyses of differences among these parameters are given in Tables III and IV. There were no significant differences ($p < 0.05$) among products for either $AUC_{0-8\ hr}$ or $AUC_{0\rightarrow\infty}$. The ranges for both AUC values represented a difference of <7%.

The mean time (0.6 hr) for product 1, the reference solution, to reach peak concentration was significantly different from the 2.5 and 1.6 hr required to reach peak concentration for products 2 and 3, respectively. The mean time to reach peak concentration was significantly longer for product 2 than for all other products.

Since the products exhibited equal AUC values, products demonstrating the longest times to reach peak concentration would be expected to have lower peak concentrations. This was observed as product 1, the product exhibiting the shortest time to peak concentration had the greatest peak plasma concentration (4.23 μg/ml). In addition, product 2 (which demonstrated the longest time to peak concentration) had the lowest peak concentration (2.77 μg/ml).

It is evident that product 2 exhibited a significantly slower rate of absorption than the other four tablet products (products 3–6). As a result product 2 cannot be considered to be bioequivalent to those dosage forms. The clinical significance of this apparent slower absorption of product 2, or conversely the more rapid absorption of products 3–6, is not known.

To substantiate the ability of the study to detect significant differences among the parameters, a power analysis was applied to the data (Table VI). Because of the large variability obtained for the plasma levels of propylthiouracil at each sampling time, a subject population in excess of 30 would have been required for a 20% difference to be significant (p

Table VI—Power Analysis[a]

Parameter	Minimum Number of Subjects for 20% Differences	Minimum Detectable Difference, %
Plasma concentration		
20 min	>30	55.5
40 min	>30	41.8
1.0 hr	>30	41.1
1.5 hr	>30	34.4
2.0 hr	16–19	25.9
3.0 hr	10–11	18.6
4.0 hr	>30	35.6
6.0 hr	>30	41.2
8.0 hr	>30	39.1
Peak plasma concentration	16–19	23.7
Time to peak plasma concentration	>30	40.8
AUC		
0–8 hr	6–7	14.0
$0 \rightarrow \infty$	6–7	14.5

[a] $\alpha = 0.05$, $\beta = 0.2$.

< 0.05) at all but two of the sampling times. Nevertheless, significant differences were observed since actual differences exceeded 20%.

The relative standard deviation for the mean peak plasma concentration was <25%, and the number of subjects necessary to detect a 20% difference was 16–17. Statistically significant differences were observed for this parameter, since actual differences were >50%. Similarly, it would have taken >30 subjects to detect a 20% difference in time to reach peak plasma concentration. However, significant differences were observed because actual differences exceeded 200%. No significant differences were seen among the products for $AUC_{0-8\ hr}$ or $AUC_{0\to\infty}$, although the power of the study was adequate to detect differences of 14.5%.

There was a perfect rank-order correlation of the mean percent of drug dissolved at 5 min in both acid and water for products 2–6 and the propylthiouracil plasma concentration observed at 20 min. The best correlations were found between the mean percent dissolved in water at 5, 20, and 60 min and the plasma propylthiouracil concentration at 20 min, with correlation coefficients of 0.81, 0.86, and 0.89, respectively. Corresponding correlation coefficients of 0.82, 0.80, and 0.85 were found for dissolution data obtained in acid. Attempts to relate either peak plasma propylthiouracil concentration or time to peak concentration were less successful. Correlation coefficients describing peak concentration and any of the dissolution values were all <0.42. The best correlation with time to peak concentration was with the percent dissolved at 60 min in either water or acid ($r = 0.75$). It is apparent the results of the dissolution studies were not useful in providing generally applicable correlations with *in vivo* data. However product 2, which exhibited the longest time to achieve peak concentration, was somewhat more slowly dissolved in acid at each sampling time compared with the other more rapidly absorbed dosage forms.

Pharmacokinetic Profile of Intravenous Liposomal Triamcinolone Acetonide in the Rabbit

ISAAC ABRAHAM ˣ, JANE C. HILCHIE, and MICHAEL MEZEI

Received June 15, 1981, from the *College of Pharmacy, Dalhousie University, Halifax, Nova Scotia, Canada.* Accepted for publication October 8, 1982.

Abstract □ The pharmacokinetics of triamcinolone[2-^{14}C]acetonide, encapsulated in neutral multilamellar liposomes, and a control preparation of the steroid in a 3:1 solution of polyethylene glycol–water was investigated in the rabbit after single intravenous bolus injections. Blood samples were obtained at various times up to 7 hr postinjection and assayed for the drug by liquid scintillation counting. Blood drug concentration–time data showed biexponential decay and were analyzed by nonlinear, least-squares regression analysis to obtain the initial (time zero) drug concentration $[(C_b)_0]$ and the initial (fast, α) and terminal (slow, β) disposition rate constants. From these estimates the central compartment volume (V_c) and the respective half-lives $[(t_{1/2})_\alpha, (t_{1/2})_\beta]$ of the fast and slow disposition phases were calculated. The total body clearance (CL_T) and the apparent distribution volume (Vd) were obtained by nonparametric analysis. Significant differences were observed between the liposome-encapsulated dosage form and the solution of the steroid in β and Vd_β. While β for the liposomal form was smaller than that for the solution, the apparent Vd was larger with the liposome-encapsulated drug. There was no difference in the total body clearance of the drug in the two dosage forms. Results of the study suggest that when administered by the intravenous route, liposome-encapsulated drug may exhibit extensive tissue distribution and a prolonged half-life.

In recent years liposomes—artificial phospholipid vesicles—have gained increasing attention as a potential drug delivery system (1). A common objective for the choice of liposomes as drug carriers is the desire to ensure selective distribution or localization of therapeutic agents in specific organ tissues (2–4). By this means, high concentrations of an agent in an organ of interest can be attained while reducing potential toxicity to other organs, which can result from indiscriminate dispersion of the agent in the body. Notable successes have been reported with liposomal preparations in the treatment of arthritic joints (3, 5) and experimental leishmaniasis (6) and in the alleviation of respiratory distress syndrome in infants (7). However, reports on the formal pharmacokinetic analyses of liposome-encapsulated drugs are rather scanty.

Unlike many drug delivery systems that are designed to release the active component (drug) instantly *in vivo*, the liposome-encapsulated dosage form in circulation may remain as a single phospholipid vesicle for relatively long periods. In this instance the pharmacokinetic behavior of the encapsulated drug will largely be determined by the disposition characteristics of the liposomal entity. Several physical and chemical factors of the liposome can, therefore, potentially influence the disposition of liposome-entrapped drug. Such factors include vesicle size, surface charge, and lipid composition.

As interest in the clinical application of liposomes as drug carriers grows, there is need to gain more information about the pharmacokinetics of drugs and, hence, their

< 0.05) at all but two of the sampling times. Nevertheless, significant differences were observed since actual differences exceeded 20%.

The relative standard deviation for the mean peak plasma concentration was <25%, and the number of subjects necessary to detect a 20% difference was 16–17. Statistically significant differences were observed for this parameter, since actual differences were >50%. Similarly, it would have taken >30 subjects to detect a 20% difference in time to reach peak plasma concentration. However, significant differences were observed because actual differences exceeded 200%. No significant differences were seen among the products for $AUC_{0-8\ hr}$ or $AUC_{0\to\infty}$, although the power of the study was adequate to detect differences of 14.5%.

There was a perfect rank-order correlation of the mean percent of drug dissolved at 5 min in both acid and water for products 2–6 and the propylthiouracil plasma concentration observed at 20 min. The best correlations were found between the mean percent dissolved in water at 5, 20, and 60 min and the plasma propylthiouracil concentration at 20 min, with correlation coefficients of 0.81, 0.86, and 0.89, respectively. Corresponding correlation coefficients of 0.82, 0.80, and 0.85 were found for dissolution data obtained in acid. Attempts to relate either peak plasma propylthiouracil concentration or time to peak concentration were less successful. Correlation coefficients describing peak concentration and any of the dissolution values were all <0.42. The best correlation with time to peak concentration was with the percent dissolved at 60 min in either water or acid ($r = 0.75$). It is apparent the results of the dissolution studies were not useful in providing generally applicable correlations with *in vivo* data. However product 2, which exhibited the longest time to achieve peak concentration, was somewhat more slowly dissolved in acid at each sampling time compared with the other more rapidly absorbed dosage forms.

Pharmacokinetic Profile of Intravenous Liposomal Triamcinolone Acetonide in the Rabbit

ISAAC ABRAHAM ˣ, JANE C. HILCHIE, and MICHAEL MEZEI

Received June 15, 1981, from the *College of Pharmacy, Dalhousie University, Halifax, Nova Scotia, Canada.* Accepted for publication October 8, 1982.

Abstract □ The pharmacokinetics of triamcinolone[2-^{14}C]acetonide, encapsulated in neutral multilamellar liposomes, and a control preparation of the steroid in a 3:1 solution of polyethylene glycol–water was investigated in the rabbit after single intravenous bolus injections. Blood samples were obtained at various times up to 7 hr postinjection and assayed for the drug by liquid scintillation counting. Blood drug concentration–time data showed biexponential decay and were analyzed by nonlinear, least-squares regression analysis to obtain the initial (time zero) drug concentration $[(C_b)_0]$ and the initial (fast, α) and terminal (slow, β) disposition rate constants. From these estimates the central compartment volume (V_c) and the respective half-lives $[(t_{1/2})_\alpha, (t_{1/2})_\beta]$ of the fast and slow disposition phases were calculated. The total body clearance (CL_T) and the apparent distribution volume (Vd) were obtained by nonparametric analysis. Significant differences were observed between the liposome-encapsulated dosage form and the solution of the steroid in β and Vd_β. While β for the liposomal form was smaller than that for the solution, the apparent Vd was larger with the liposome-encapsulated drug. There was no difference in the total body clearance of the drug in the two dosage forms. Results of the study suggest that when administered by the intravenous route, liposome-encapsulated drug may exhibit extensive tissue distribution and a prolonged half-life.

In recent years liposomes—artificial phospholipid vesicles—have gained increasing attention as a potential drug delivery system (1). A common objective for the choice of liposomes as drug carriers is the desire to ensure selective distribution or localization of therapeutic agents in specific organ tissues (2–4). By this means, high concentrations of an agent in an organ of interest can be attained while reducing potential toxicity to other organs, which can result from indiscriminate dispersion of the agent in the body. Notable successes have been reported with liposomal preparations in the treatment of arthritic joints (3, 5) and experimental leishmaniasis (6) and in the alleviation of respiratory distress syndrome in infants (7). However, reports on the formal pharmacokinetic analyses of liposome-encapsulated drugs are rather scanty.

Unlike many drug delivery systems that are designed to release the active component (drug) instantly *in vivo*, the liposome-encapsulated dosage form in circulation may remain as a single phospholipid vesicle for relatively long periods. In this instance the pharmacokinetic behavior of the encapsulated drug will largely be determined by the disposition characteristics of the liposomal entity. Several physical and chemical factors of the liposome can, therefore, potentially influence the disposition of liposome-entrapped drug. Such factors include vesicle size, surface charge, and lipid composition.

As interest in the clinical application of liposomes as drug carriers grows, there is need to gain more information about the pharmacokinetics of drugs and, hence, their

0022-3549/83/1200-1412$01.00/0

therapeutic fate when entrapped in such phospholipid vesicles. The objective of the present study was to characterize the pharmacokinetics of a model compound, triamcinolone [2-^{14}C]acetonide, entrapped in neutral multilamellar liposomes after rapid intravenous injection in the rabbit.

EXPERIMENTAL

Liposomal Triamcinolone—Neutral, multilamellar liposomes containing triamcinolone[1], dipalmitoyl DL-α-phosphatidylcholine[2], and cholesterol[2] in the respective mole ratio of 0.5:1.1:0.5 were prepared as previously described (4). The volume of the final liposomal suspension was adjusted with the dispersion medium (8 m*M* $CaCl_2$) so that a 0.3-ml dose contained the desired radioactivity (12 μCi). Over 80% of the liposomes obtained by the procedure were shown by microscopic size distribution to have a mean diameter of 9 μm (range 7–11 μm) (8). Each batch of liposomes was used within 3 days of preparation, and daily microscopic examination of the liposomes showed no apparent lysis of the vesicles.

A control preparation of unencapsulated triamcinolone was prepared as a solution in polyethylene glycol 400–water (3:1) so that a 0.3-ml dose contained the desired radioactivity (12 μCi). The clear control solution of triamcinolone had approximately the same viscosity as the liposomal suspension as determined, visually, by their flow pattern.

Intravenous Administration of Liposomal and Control Triamcinolone Preparations—The hair on the ear lobes of male New Zealand White rabbits (3–4 kg) was removed with an animal hair clipper[3]. An infusion set[4] equipped with a 21-gauge (0.8-mm) hypodermic needle and a winged adapter was inserted into the central artery of one ear lobe to facilitate sampling of blood for drug analysis. The patency of the set was maintained by intermittent flushing with heparinized sodium chloride injection (100 IU/ml).

After removing 0.5 ml of arterial blood as a control sample, a single 0.3-ml dose of the triamcinolone preparation in a 1-ml tuberculin syringe[5] was administered by rapid intravenous injection *via* the marginal vein of the opposite ear lobe. Following administration of the dose, serial 0.5-ml blood samples were obtained over a 7-hr period *via* the catheterized ear artery. The blood samples were placed in glass tubes[6] containing 0.5 ml of citrated buffer solution as anticoagulant. The samples were frozen (−10°) until analyzed.

Quantitation of Triamcinolone in Whole Blood—Five milliliters of ethanol (95%) was added to the citrated blood (0.5 ml) in the stoppered collection tube. The mixture was vortexed at high speed for 2 min and centrifuged at 1000×*g* for 5 min at room temperature. The supernatant was decanted into a 50-ml Erlenmeyer flask, and the pellet was resuspended in another 5-ml aliquot of ethanol; the process was repeated four more times. The combined ethanolic extracts were evaporated to dryness over a boiling water bath. The residue was redissolved in 15 ml of methylene chloride and transferred to a 20-ml glass counting vial. The methylene chloride was allowed to evaporate to dryness overnight at room temperature. The residue was redissolved in 10 ml of Bray's solution[7], 0.5 ml of glacial acetic acid was added, and then the radioactivity was determined by liquid scintillation counting[8].

The blood triamcinolone concentration of each sample was calculated from the radioactivity and the specific activity of the administered preparation after correction for background values (determined using a blank). Over the triamcinolone concentration range of ~15–960 ng/ml, this extraction procedure resulted in ~80% recovery of equivalent radioactivity from whole blood spiked with the drug.

Data Analysis—Blood triamcinolone concentration (C_b) *versus* time (t) data after a single intravenous bolus injection were fitted to the following with the aid of the least-squares regression analysis program, NONLIN (9):

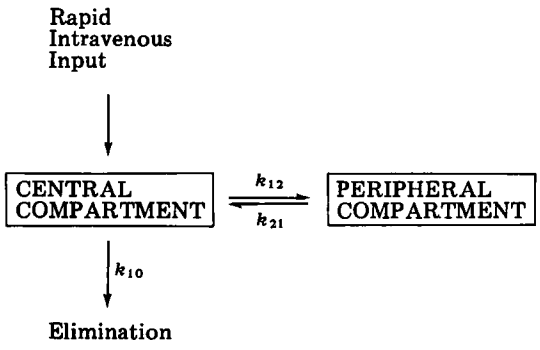

Figure 1—*A representation of the two-compartment open model system.*

$$C_b = Ae^{-\alpha t} + Be^{-\beta t} \quad \text{(Eq. 1)}$$

Initial estimates of A, B, α, and β were obtained with the CSTRIP program (10). In Eq. 1, α and β are first-order disposition rate constants, while A and B represent appropriate concentration constants. The two-compartment open model system with elimination from the central compartment (Fig. 1) was assumed.

The central compartment volume (V_c) was estimated by:

$$V_c = \text{Dose}/(C_b)_0 \quad \text{(Eq. 2)}$$

where $(C_b)_0 = (A + B)$. The intercompartmental transfer rate constants, k_{21} and k_{12}, and the elimination rate constant, k_{10}, were calculated from:

$$k_{21} = (A\beta + B\alpha)/(C_b)_0 \quad \text{(Eq. 3)}$$

$$k_{10} = \alpha\beta/k_{21} \quad \text{(Eq. 4)}$$

$$k_{12} = (\alpha + \beta) - (k_{21} + k_{10}) \quad \text{(Eq. 5)}$$

The total body clearance (CL_T) was calculated using:

$$CL_T = \frac{\text{Dose}}{\int_0^\infty C_b \cdot dt} \quad \text{(Eq. 6)}$$

where $\int_0^\infty C_b \cdot dt$ is the total area under the blood drug concentration–time curve and was estimated by the trapezoidal rule to obtain the area up to the last measured blood triamcinolone concentration (C_b^*). The area beyond C_b^* was computed by dividing C_b^* by β. The apparent volume of distribution (Vd_β) was determined by the relationship:

$$Vd_\beta = CL_T/\beta \quad \text{(Eq. 7)}$$

Half-life values for the fast disposition phase $(t_{1/2})_\alpha$ and terminal phase $(t_{1/2})_\beta$ were calculated using:

$$(t_{1/2})_\alpha = 0.693/\alpha \quad \text{(Eq. 8)}$$

$$(t_{1/2})_\beta = 0.693/\beta \quad \text{(Eq. 9)}$$

The unpaired, two-tailed Student's t test was used to assess the significance of the observed differences in the pharmacokinetic parameters between the control and liposomal triamcinolone preparations. A $p_{0.05}$ significance level was used.

RESULTS AND DISCUSSION

Figure 2 illustrates characteristic dose-normalized blood concentration–time curves for the control and liposomal triamcinolone dosage forms in two separate rabbits after single intravenous bolus injections. Relative to the control preparation, a characteristic feature of all liposomal curves was a more rapid initial disposition phase followed by a slower, more sustained terminal phase. A comparison of the mean pharmacokinetic constants (±*SEM*) for the control and liposomes is presented in Table I.

It has been reported (11) that triamcinolone hexacetonide administered orally to cats and dogs did not undergo significant deacetonization or de-esterification. Earlier in this laboratory it was determined that 90% of the intravenous dose of triamcinolone acetonide was excreted unchanged in the urine by rabbits (8). Recently we found that the total radioactivity of the ethanolic solution from whole blood obtained from

rabbits receiving intravenous triamcinolone was comparable with the radioactivity determined after the ethanolic solution was subjected to ethyl acetate extraction of the intact drug. These findings indicate that the ^{14}C-label on the ketal ring of triamcinolone acetonide is a stable tracer for disposition studies. They also suggest that the total radioactivity of the ethanolic solution from whole blood represented, essentially, the unchanged drug.

Compared with the control, the overall apparent distribution of triamcinolone in the liposomal form was more extensive. On the average, V_c increased by (1.8 − 0.7) liter/kg = 1.1 liter/kg (Table I), while Vd_β changed by (7.09 − 1.41) liter/kg = 5.68 liter/kg when the liposomal form of the drug was used. These volume increases suggest that, within both the central and peripheral compartments, liposome-entrapped drug reached organ tissues that were not normally accessible to the unencapsulated triamcinolone. It has been observed (12) that in plasma and other calcium-containing media, negatively charged liposomes aggregate to form larger particles; these particles are then rapidly removed from the circulatory system by the reticuloendothelial system (RES), of which the liver and spleen are major components. It has also been reported that subfractionation of livers of animals receiving liposomes showed that liposome-entrapped enzymes were localized chiefly in the lysosomal fraction (13). It is thus apparent that cells of the RES, particularly the Kupffer cells in the liver, play a major role in the removal of liposomes from the circulatory system, although electron microscopic evidence also indicates that hepatic parenchymal cells may be involved in liposomal clearance (14). A two-stage mechanism for liposomal removal from circulatory system has been proposed (15, 16) in which the Kupffer cells are thought to be responsible for the rapid phase of liposomal removal from the blood while the slower disappearance phase is attributable to the liver parenchymal cells. Therefore, it may be deduced that the liver and spleen could be regarded as part of the central compartment because of their high vascularity, ease of blood perfusion, and relatively high content of Kupffer cells. In addition, the liver parenchyma could be considered as part of the peripheral compartment.

The increase in the apparent volume of distribution with the liposomes and the concomitant increase in α and k_{12} relative to the control dosage form (Table I) suggest that liposomes potentially increase the rate and extent of entrapped drug distribution relative to the unencapsulated form of the drug. The relative constancy of the liposomal curve terminal slope (Fig. 2) suggests that any rapid initial accumulation of liposomes in the liver and other organs of the RES does not result in significant lysis of the vesicles. Since the liver does not metabolize triamcinolone as such (8, 11), any significant lysis of liposomes in the liver and subsequent release of drug would have resulted in a change in the slope of the terminal portion of the liposomal curve, which would then have declined in a fashion somewhat parallel to the terminal portion of the control curve. It is possible that the majority of liposomes (particularly the smaller vesicles) accumulating in the liver were held in the relatively open and fenestrated endothelium of the liver capillaries (1). It is not unlikely for small intact liposomes held in this type of hepatic vasculature architecture to reenter the circulatory system and sustain triamcinolone levels. Assuming that they do accumulate rapidly in the liver and are able to reenter the circulatory system liposomes could prove beneficial not only as drug carriers for targeting the liver and other organ tissues of the RES with therapeutic agents, but also as a potential intravascular depot system.

There was no significant difference in the mean clearances (0.73 ± 0.17 and 0.57 ± 0.06 liter/hr/kg, respectively) of triamcinolone from the liposomal and solution dosage forms. From the relationship between CL_T, Vd_β and β (Eq. 7), it is seen that an increase in Vd_β and a concurrent decrease in β tend to offset each other and thereby minimize potential changes in CL_T. However the apparent similarity of CL_T values observed in this study underlie the fact that there may not be a fundamental change in the clearance mechanisms of triamcinolone in the rabbit whether the steroid is administered in the liposomal or solution form. Similarities in the k_{10} (Table I) tend to support this view.

Due to technical difficulties it was not possible to administer equal amounts of triamcinolone in the two dosage forms. In the control studies, two of the doses employed were 263 and 803 µg. At these dose levels the respective areas under the blood drug concentration–time curves were 200 and 579 µg/hr/liter; CL_T values were 0.44 and 0.42 liter/hr/kg; and β values were 0.34 and 0.42 hr^{-1}, respectively. These etimates do not indicate that triamcinolone *per se* exhibits dose-dependent pharmacokinetics in the rabbit over the dose range employed in this study. It is, therefore, doubtful that the observed differences in the pharmacokinetics were due to differences in the dose administered in the two dosage forms.

Probably an ideal control dosage form in this study would have been a physical admixture of all the components in the liposomal dosage form, *i.e.* triamcinolone, phospholipids, cholesterol, and the dispersing liquid (8 m*M* aqueous calcium chloride). However, triamcinolone is insoluble in aqueous media; a control preparation which might contain triamcinolone crystals would be unsuitable for intravenous administration. Moreover, the presence of drug crystals in the control raises another

Table I—Mean Pharmacokinetic Parameters for Control and Liposomal Triamcinolone after Single Intravenous Injections in the Rabbit

objection in that the drug may not be presented in the same physical state, since in the liposomal triamcinolone is present as a molecular dispersion in lipid micelles (17). Under these circumstances the possibility of a dissolution-dependent disposition of triamcinolone in the control preparation would seriously affect the pharmacokinetic comparison of the two dosage forms. Finally, a physical admixture of drug, lipids, and calcium chloride solution could, potentially, promote the spontaneous formation of an undetermined number of liposomes when agitated. If this happened, the control would not be totally free of drug-containing liposomes. Thus, while the triamcinolone solution in polyethylene glycol–water used in this study may not be qualitatively similar to the liposomal dosage form, it was designed to present the model compound in an intravenous dosage form that was miscible with plasma water. The comparison of the pharmacokinetics of triamcinolone in liposomal and solution dosage forms is, thus, analogous to other comparative studies (*e.g.*, bioavailability) of a therapeutic agent in different formulations which may not (and often do not) contain the same excipients. If it is assumed that the presence in blood of exogenous lipids (used in the preparation of the liposomes) and polyethylene glycol in the concentrations used did not influence blood flow rate significantly, then the differences in β and Vd_β observed in this study are due probably to the favorable physicochemical properties (especially lipid solubility) of the liposomal entity.

Results of the present study indicate that liposome-encapsulated triamcinolone enhances tissue distribution of the drug in the rabbit. The results also suggest that, given by the intravenous route, neutral multilamellar liposomes could serve as carriers for chemotherapeutic agents whose efficacy depends on sustained blood levels and deep tissue distribution.

Acrylic Microspheres *In Vivo* IX: Blood Elimination Kinetics and Organ Distribution of Microparticles with Different Surface Characteristics

PER ARTURSON ‡, TIMO LAAKSO *, and PETER EDMAN *x

Received May 10, 1982, from the **Division of Pharmacy, Department of Drugs, National Board of Health and Welfare, S-751 25 Uppsala, Sweden* and ‡*Department of Pharmaceutical Biochemistry, Biomedical Center, University of Uppsala, S-751 23 Uppsala, Sweden.* Accepted for publication September 24, 1982.

Abstract □ The elimination of microparticles from blood after intravenous injection is dependent on the surface characteristics of the particles. The half-life in blood increases from 44 to 84 min after modification of surface-localized human serum albumin with polyethylene glycol. Irrespective of the surface properties, particles are localized in the reticuloendothelial system, mainly in the liver and spleen. In preimmunized mice, the distribution of particles is somewhat altered, *i.e.*, the liver and lung uptake is significantly higher in preimmunized animals than in untreated animals. The rate of phagocytosis of particles with different surface characteristics has also been studied *in vitro* with isolated mouse peritoneal macrophages. This technique gives a good correlation with the *in vivo* results; thus particles with a short half-life in mice are rapidly phagocytosed by the macrophages *in vitro*.

This project was supported by the Medical Research Council of Canada (Grant MA 6664).

The authors are particularly grateful to Dr. C. T. Ueda and Mrs. Jeannetta G. Nickols, University of Nebraska Medical Center, for the use of their computer facilities, Mrs. Anne Fenton of the Dalhousie University Animal Care Facility for her technical assistance, and Mrs. Annette Cook for her excellent secretarial work.

Acrylic Microspheres *In Vivo* IX: Blood Elimination Kinetics and Organ Distribution of Microparticles with Different Surface Characteristics

PER ARTURSON ‡, TIMO LAAKSO *, and PETER EDMAN *x

Received May 10, 1982, from the **Division of Pharmacy, Department of Drugs, National Board of Health and Welfare, S-751 25 Uppsala, Sweden* and ‡*Department of Pharmaceutical Biochemistry, Biomedical Center, University of Uppsala, S-751 23 Uppsala, Sweden.* Accepted for publication September 24, 1982.

Abstract □ The elimination of microparticles from blood after intravenous injection is dependent on the surface characteristics of the particles. The half-life in blood increases from 44 to 84 min after modification of surface-localized human serum albumin with polyethylene glycol. Irrespective of the surface properties, particles are localized in the reticuloendothelial system, mainly in the liver and spleen. In preimmunized mice, the distribution of particles is somewhat altered, *i.e.*, the liver and lung uptake is significantly higher in preimmunized animals than in untreated animals. The rate of phagocytosis of particles with different surface characteristics has also been studied *in vitro* with isolated mouse peritoneal macrophages. This technique gives a good correlation with the *in vivo* results; thus particles with a short half-life in mice are rapidly phagocytosed by the macrophages *in vitro*.

Keyphrases □ Microparticles—polyacrylamide, blood elimination kinetics, organ distribution, effect of surface characteristics, mice □ Elimination—polyacrylamide microparticles from blood, kinetics, organ distribution, effect of surface characteristics, mice □ Delivery systems—polyacrylamide microparticles, blood elimination, kinetics, organ distribution, mice

Immobilized systems in the form of small beads or particles have recently been introduced as carriers of enzymes *in vivo* (1). Some of these systems are characterized as biodegradable (*e.g.*, liposomes), while others are slowly metabolized (*e.g.*, acrylic particles). Irrespective of the type of particles, these systems show great promise as a tool for "active targeting" of enzymes and other macromolecules to specific cells or organs in the body. However, one of the

0022-3549/83/1200-1415$01.00/0

drawbacks of using such particles as a carrier system is the lack of "directability," because the reticuloendothelial system (RES), mainly the liver, spleen, and bone marrow, dominates the uptake of intravenously injected particles. It is well recognized that this uptake must be circumvented to realize the dream of "active targeting" using particulate carrier systems.

Within a few hours after intravenously injecting massive amounts of particles, none are left free in the circulatory system [*e.g.*, microparticles of polyacrylamide have a half-life of 40–60 min in blood (2)]. This efficacy in identifying the foreign nature of such particles in the presence of particles that are normal to blood must depend on surface characteristics. The present study investigates the possibility of changing the rate of phagocytosis of the microparticles in order to make them more suitable as carriers for enzymes.

EXPERIMENTAL

Materials—Human serum albumin[1], IgG[1], rabbit anti-(human serum albumin) globulin[2], L-asparaginase[3], polyethylene glycol monoethyl ether[4] (mol. wt. 1900), [^{14}C]salicylic acid[5], and [^{14}C]paraformaldehyde[5] were used without further purification. Acrylamide[6], *N,N'*-methylenebisacrylamide[6], *N,N,N',N'*-tetramethylethylenediamine[7], tris(hydroxymethyl)aminomethane[7], and other chemicals were analytical grade.

Preparation of Microparticles—Microparticles[8] were prepared and characterized using a reported method (1). A solution of acrylamide (6% w/v) and *N,N'*-methylenebisacrylamide (2% w/v) in 0.1 *M* KCl–0.005 *M* sodium phosphate buffer (pH 7.4), which also contained the protein to be immobilized, was homogenized in an organic phase consisting of toluene–chloroform (4:1 v/v). Ten milliliters of the aqueous phase was emulsified with an homogenizer in 200 ml of the organic phase with a detergent[9] immediately after the catalyst system, consisting of *N,N,N',N'*-tetramethylethylenediamine and ammonium persulfate, had been added to the monomer solution. For the experiments described, microparticles were prepared from human serum albumin, L-asparaginase, or polyethylene glycol-modified human serum albumin by dissolving 0.5–2 g, 96 mg, or 0.5 g of the substrate, respectively, in 10 ml of the monomer solution. After polymerization, the microparticles were freed from the organic phase by repeated washings with buffer and physiological saline. Prior to injection, the particles were carefully dispersed in physiological saline.

^{14}C-Labeled particles were prepared as described by Sjöholm and Edman (2). Radioactivity was measured by liquid scintillation counting. The counting efficiency was calculated with an external standard.

Functional Capacity of Immobilized Human Serum Albumin—The functional capacity of albumin in microparticles was determined as previously described (3). Microparticles with albumin were incubated with [^{14}C]salicylic acid. The amount of albumin binding with salicylic acid was calculated from the binding degree and from a standard curve derived by equilibrium dialysis with different albumin concentrations.

Preparation of Tissue Samples for the Determination of the Distribution of Microparticles—^{14}C-Labeled microparticles in physiological saline (0.2 ml) were injected intravenously or intraperitoneally in the mice. The dose corresponded to 0.5 mg of lyophilized microparticles. The different particles used are specified in Table I. After 6 hr, 24 hr, 1, and 2 weeks, five animals were killed by cervical dislocation. Five mice which were not given any microparticles were used as a control group. The organs were immediately removed, weighed, and prepared for radioactivity measurements. The whole spleen, both lungs, one kidney, and 0.2–0.3 g of the liver were each dissolved in 2 ml of a tissue solubilizer[10] in a counting vial. After treatment at 40° for 12 hr (yielding a clear solution), 2-propanol (0.4 ml) and 30% hydrogen peroxide (0.8 ml) were added to minimize color quenching. A scintillation cocktail[11] (10 ml) was then added, and the samples were counted after adapting to the dark and appropriate temperature.

Determination of the Disappearance Rate of Microparticles from the Circulatory System—Male mice[12] weighing 18–22 g were used. The microparticles (0.5 mg dry weight) were injected intravenously in the tail vein, in a total volume of 0.2 ml. The characteristics of the particles used are summarized in Tables I and II.

Blood samples (75 μl) were collected with a heparinized microtube from the orbital plexus 5, 10, 15, 20, 30, 45, 60, 90, 120, 240, and 300 min after dosing. Only two blood samples were drawn from each mouse; thus, the cumulative blood volume withdrawn never exceeded 10% of the total blood volume. Background values were obtained in the same manner from animals not given microparticles. The animals were unrestrained and had free access to food and water.

The whole blood was digested with 1 ml of a solution consisting of tissue solubilizer[10] and 2-propanol (1:1) in a counting vial. Hydrogen peroxide (30%, 0.5 ml,) was added and the vial was left at 40° for 15 min. A scintillation cocktail[11] was then added and after appropriate equilibration to darkness and temperature, the samples were counted in the liquid scintillation counter.

Assay of Native and Immobilized L-Asparaginase—L-Asparaginase activity was determined from the amount of ammonia produced by reaction with the substrate, L-asparagine, at 37° as earlier described (1). After addition of the ammonia color reagent, the absorbance was determined at 500 nm. Appropriate enzyme and substrate blanks were included in all assays. A standard curve was prepared with known amounts of ammonium sulfate. One unit of activity is defined as the amount of enzyme catalyzing the formation of 1.0 μmole of ammonia/min at 37°.

Autoradiography—Whole-body autoradiography was performed using the method of Ullberg (4). The ^{14}C-labeled microparticles in 0.2 ml of physiological saline were injected in the tail vein. After 24 hr the animals were anesthetized with ether and killed by immersion in hexane–solid carbon dioxide (−78°). With an aqueous gel of carboxymethylcellulose as the medium, the mice were mounted on a large microtome stage. Several 20- or 60-μm saggital sections were cut through the whole body and fixed on adhesive tape. The sections were cut at −15 to −20° and freeze-dried. The slices were pressed against photographic films, which were exposed for up to 6 months. After developing, the films were compared with the corresponding tissue sections.

Determination of Particle Size—The size of the particles was measured from photographs taken by scanning electron microscopy as described by Höglund and Morein (5). The particles were fixed at 4° with glutaric dialdehyde for ~20 hr. Postfixation was done in neutralized 1% osmium tetroxide for 1 hr. The samples were rinsed in saline and freeze-dried. The dehydrated specimens were coated with palladium–gold alloy in an evaporator and analyzed in a scanning electron microscope[13] at 30-keV accelerating voltage.

Immunization Procedures—The mice were injected with L-asparaginase (5 IU) in native form intramuscularly and/or subcutaneously. The enzyme was administered in Freund's complete or incomplete adjuvant. The animals received booster injections after 5, 10, 20, and 30 days. Blood was collected from the orbital plexus and centrifuged at 4° to obtain serum. Each mouse received a total dose of 20–25 IU of L-asparaginase during the study. The antibody titer was assayed by double immunodiffusion in agar gel as described by Ouchterlony (6).

Preparation of Polyethylene Glycol-Modified Human Serum Albumin—Covalent attachment of monomethoxy polyethylene glycol (mol. wt. 1900) to human serum albumin was effected using the procedure of Abuchowski *et al.* (7). Cyanuric chloride (5.5 g, 0.03 mmole) was dissolved in 400 ml of anhydrous toluene and monomethoxy polyethylene glycol (mol. wt. 1900) (19 g, 0.01 mmole) was added to the solution. The 2-*O*-methoxypolyethylene glycol-4,6-dichloro-*s*-triazine (activated polyethylene glycol) formed was precipitated several times with petroleum ether until it was free of cyanuric chloride. The activated polyethylene glycol was coupled to human serum albumin by dissolving the two reactants in sodium borate buffer (0.1 *M*, pH 9.2). The reaction was allowed to proceed for 2 hr at 4°. The fraction of modified primary amino groups was determined by the trinitrobenzenesulfonate method of Ha-

Table I—Characteristics of the Microparticles

Preparation	Protein Immobilized	mg of Protein Incorporated / mg of Dry Particles[a]	Size Distribution[b] <300 nm	301–750 nm	751–1050 nm	1051–1800 nm	Mean Particle Diameter, nm
I	None	—	30%	49%	11%	10%	520
II	None	—	9%	26%	36%	29%	860
III	Human serum albumin	0.05[c]	33%	64%	3%	—	290
IV	Human serum albumin	0.17[c]	not determined				
V	Polyethylene glycol-modified human serum albumin	0.13[d]	21%	70%	9%	—	370
VI	L-Asparaginase	0.02	not determined				

[a] The dry weight of the microparticles was determined after lyophilization. [b] Particle diameter. The size distribution was determined by scanning electron microscopy; 350–550 particles were counted from each preparation. [c] The values were obtained by determination of the functional capacity of albumin as described in the text. [d] The high degree of polyethylene glycol substitution changed the functional capacity of the albumin used. The amount of protein incorporated was therefore determined by amino acid analysis.

beeb (8). Protein concentrations were determined by the biuret method (9), since the method by Lowry *et al.* (10) gives erroneously high values with polyethylene glycol-modified albumin (7). A double immunodiffusion test was used (6) to study the interaction between polyethylene glycol-modified human serum albumin and rabbit anti-(human serum albumin).

Cultivation of Mouse Peritoneal Macrophages—Cells from the peritoneal cavity of unstimulated adult male mice were harvested with 3 ml of cold (4°) phosphate-buffered saline. The cells were further suspended in 10 ml of cold (4°) buffer and mildly spun down at 180×*g* for 10 min. The pellet was resuspended in a nutrient medium[14] containing 10 m*M* 4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid, pH 7.4. The medium was supplemented with benzylpenicillin (100 U/ml), streptomycin (10 μg/ml), and 20% fetal calf serum. The cells were seeded on 50-mm plastic petri dishes and cultured at 37° in 5% CO_2 in air at 85% humidity. After incubation for 45 min, nonadherent cells were removed by washing with buffer, and 5 ml of fresh medium was added. The cells were incubated for an additional 24 hr before use.

Measurement of Phagocytosis of Microparticles—^{14}C-Labeled microparticles (0.25 mg dry weight in 50 μl of phosphate-buffered saline) with a radioactivity of ~50,000 dpm were added to a petri dish containing 1–2 × 10^6 mouse peritoneal macrophages, and the phagocytosis was studied at 37° or 0°. After 2, 4, and 6 hr, the tissue culture medium was aspirated, and the tissue cultures were rinsed with saline (0.154 *M* NaCl) six times to remove unattached microparticles. The contents of the dried dishes were digested for 8 hr at room temperature in 1.5 ml of 0.5 *M* NaOH (11). A 100-μl portion of the digest was removed by aspiration for protein determination; the rest was quantitatively transferred to a liquid scintillation vial, and the radioactivity was determined.

Estimation of the Rate of Particle Aggregation—A light-scattering spectroscopy instrument[15] capable of estimating the size of particles, aggregates, or other particulate matter within the size range of 0.10–3 μm was used to measure the relative size of different microparticle batches and to follow the aggregation of microparticles in the presence of specific antisera. Microparticles and protein solutions were diluted in phosphate-buffered saline, which was passed through a membrane filter (pore size 0.22 μm) prior to use. In a typical experiment, particles of the same size containing human serum albumin, L-asparaginase, or no protein at all were diluted to the same absorption at 450 nm. The initial value for 450 μl of the sample was recorded by the instrument and 100 μl of a solution of antiserum [*i.e.*, rabbit anti-(human albumin serum) containing 3.6 mg of IgG/ml] or buffer was added with subsequent recording of the light scattering. All measurements were done in triplicate.

RESULTS

Blood Clearance of Microparticles with Different Surface Characteristics—When a protein is immobilized in microparticles, it will not only be localized within the gel structure but will also protrude from the matrix and, thus, will be partly localized on the surface of the microparticles (12). To investigate if surface-localized protein would influence the survival of microparticles in blood, four different preparations were made (Table I). After intravenous injection the blood life span of microparticles was followed with time (Fig. 1). In Table II some experimental values calculated from the curves in Fig. 1 are summarized. The experimental points obtained during the first 90 min were fitted to a straight line by linear regression (with time as the independent variable and the concentration in the circulatory system as the dependent variable). The 5-min values were omitted, since the initial mixing in the whole blood volume apparently was not complete at this time. From the slope of the line, k, the half life ($t_{1/2}$) was estimated from the expression:

Table II—Blood Elimination Parameters of the Microparticles[a]

Preparation	$t_{1/2}$, min	V_d, ml	CL, ml/min

Radioactivity is calculated in percent of the total dose (log scale) retained in 1 ml of blood. Key: (●) empty particles; (○) particles containing 0.17 mg of albumin/mg of particles; (□) particles containing 0.05 mg of albumin/mg of particles; and (■) particles containing polyethylene glycol-modified albumin.*

[14] F-10 medium, GIBCO BIO-CULT.
[15] Nanosizer, Coulter, England.

$$t_{1/2} = \frac{\log 2}{k} \quad \text{(Eq. 1)}$$

From the intercept on the y-axis (C_0^g) and the dose given, the apparent volume of distribution, V_d, was calculated:

$$V_d = \frac{\text{dose}}{C_0^g} \quad \text{(Eq. 2)}$$

From $t_{1/2}$ and V_d, the clearance from the blood was estimated according to:

$$CL = \frac{0.693 \times V_d}{t_{1/2}} \quad \text{(Eq. 3)}$$

Intravenously injected empty microparticles (I) were rapidly cleared from the circulatory system with a half-life of 61 min. Particles with immobilized human serum albumin (0.05 mg of protein/mg of lyophilized particles, III), were eliminated with a half-life of 44 min. The elimination rate was further accelerated when the protein content in the particles was increased; *e.g.*, particles with 0.17 mg of protein/mg of dry weight (IV) were eliminated from the circulatory system with a half-life of 33 min.

In an attempt to block the influence of the surface-localized proteins on the extraction rate of particles from the circulatory system, polyethylene glycol-modified human serum albumin was immobilized (V). Seventy percent of the primary amino groups of albumin were derivatized with activated polyethylene glycol. The antigenicity of the derivative was checked by double immunodiffusion. In accordance with the results of Abuchowski *et al.* (7), no precipitation occurred when ≥50% of the primary amino groups were modified. As a consequence, the survival time of these particles in blood was significantly prolonged ($t_{1/2}$ = 84 min) as compared with albumin-containing particles (33 min).

Distribution of Microparticles with Different Surface Characteristics—The distribution pattern of the microparticles was followed quantitatively in mice for 2 weeks after intravenous injection (Table III). The surface properties of the microparticles had no effect on the gross distribution pattern. The microparticles were concentrated in the spleen and liver, and initially also in the lungs. These results agree with those found earlier with empty polyacrylamide particles (2) except for the lung uptake. Earlier, only small amounts of radioactivity were found in the lungs after injection of massive doses (4.1 mg) of empty microparticles in mice. In this study, 4–30% of the radioactivity was found in the lungs 6 hr after injection. However, in 24 hr a redistribution could be seen, with elimination of radioactivity from the lungs and a corresponding uptake of radioactivity in the liver.

The differences in the results between this and the previous study (2) were thought to be an effect of the microparticle size, since larger particles were used in this study. In the earlier study, the mean particle size was estimated to 0.25 μm compared with mean values of 0.29–0.86 μm in this study (Table I). The effect of the particle size on the organ distribution was checked by comparing two preparations of empty microparticles with mean diameters of 0.52 and 0.86 μm (I and II, respectively). As expected, the batch with the larger particles was retained to a greater extent in the lungs than the batch with the smaller mean particle diameter. Thus, 6 hr after intravenous injection, 30% of II and 9% of I were found in the lungs. Two weeks after the injection of small microparticles (I), no radioactivity was detected in the lungs, while 10% of the large microparticles (II) still remained in the lungs.

Uptake of Microparticles by Mouse Peritoneal Macrophages—The dependence of the elimination rate of microparticles from blood in mice on the proteins immobilized in the microparticles was also studied *in vitro*. A system with mouse macrophages was designed, in which the phagocytosis of ^{14}C-labeled microparticles with different immobilized proteins was followed. A nontoxic dose (0.25 mg dry weight of particles) was added to a monolayer of the macrophages cultivated in a petri dish. The extent of phagocytosis was estimated from the radioactivity content in the macrophages after different time periods and related to the protein content, which represents a measure of viable cells. The dose chosen was the lowest found to give the maximal uptake in ~1–2 × 10^6 cells.

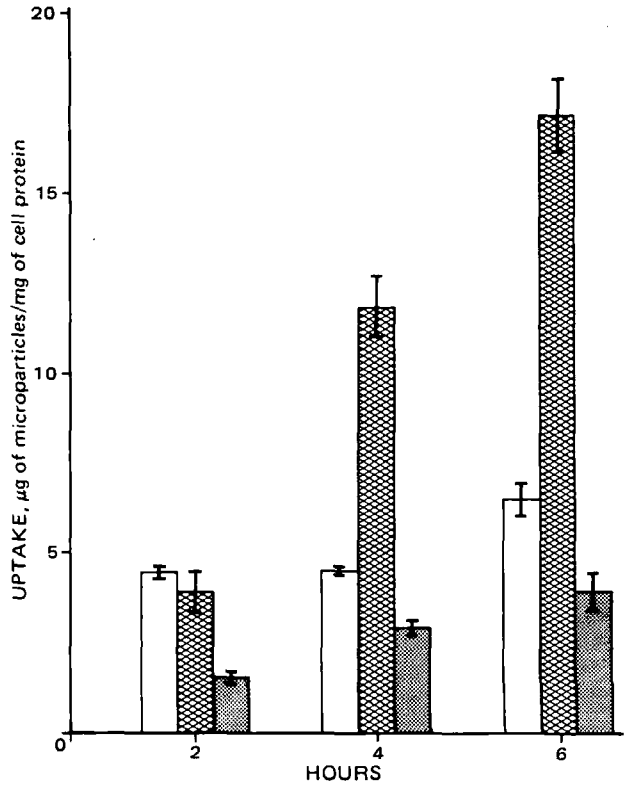

Figure 2—*Rates of uptake of microparticles with different surface characteristics by mouse peritoneal macrophages. All values represent the mean ± SEM of triplicate incubations, corrected for unspecific interaction between cells and particles. The uptake was calculated as the amount of microparticles (μg)/mg of cell protein. Key: (□) ^{14}C-Labeled empty microparticles (I); (▨) albumin-containing particles (IV); (■) particles with polyethylene glycol-modified albumin (V).*

The results from the cell studies are summarized in Fig. 2. The rate of uptake of empty microparticles was slower than that of particles containing human serum albumin, but faster than that of particles in which the amino groups of albumin had been chemically modified with polyethylene glycol. The unspecific adsorption of particles to the macrophages, as measured at 0°, was low and insignificant. As is apparent, the results correlate well with those found in the *in vivo* studies.

Disappearance Rate from Blood of Microparticles with L-Asparaginase in Preimmunized Mice—The mice were immunized with

[a] Distribution of ^{14}C-labeled microparticles containing L-asparaginase after intravenous injection in preimmunized and untreated mice. The figures show means ±*SEM* obtained from four or five animals.

soluble L-asparaginase as described above. The antibody titer, as detected by double immunodiffusion according to Ouchterlony (6), was 1:1 to 1:2. Only small doses of microparticles with L-asparaginase could be given. After intravenous injection of 0.5 mg of particles containing 1.2 IU of L-asparaginase, three of eight mice died within 15–20 min. After half the original dose (0.25 mg dry weight of microparticles) was administered, 3 of 18 mice died. The microparticles were very rapidly cleared from the circulatory system with a half-life of <10 min.

The quantitative distribution of the particles in surviving mice was followed in the liver, spleen, and lungs over a period of 2 weeks (Table IV). The values obtained from the lungs of preimmunized mice 6 hr postinjection showed that 12% of the injected dose was found in this organ compared with 6% in the controls (nonimmunized mice). The liver uptake of the injected dose was 8–11% greater for preimmunized animals during the entire study.

After intraperitoneal injection in preimmunized mice, the microparticles were localized in the lymph nodes draining the peritoneal cavity and the central lymphatic vessels, as shown by the autoradiogram (Fig. 3) taken 1 day after injection. The quantitative distribution of the L-asparaginase-containing particles in different organs was followed over a period of 1 week. The total recovery was low, 7% of the injected dose being found in the liver and spleen after 6 hr compared with 17% in the controls. After 1 week, 26 and 35% of the injected dose was recovered in these organs in preimmunized and nonimmunized animals, respectively.

The high lung uptake of L-asparaginase particles after intravenous injection in preimmunized mice is probably due to aggregate formation between the particles and circulating antibodies. To study the rate of formation of particle aggregates, an *in vitro* system was set up to simulate the interaction between specific antibodies and particles containing the corresponding antigen. In this study, anti-(human serum albumin) and albumin particles were used to simulate the *in vivo* condition and the particle size was followed with a light-scattering spectroscope (Fig. 4). As expected, incubation with the specific antibody gave a rapid increase in particle size. The apparent mean diameter increased from 0.6 to 2 μm after a 15-min incubation with the specific antibody and to >3 μm after 60 min. There was no interaction between anti-(human albumin globulin) and empty particles or with particles containing L-asparaginase under the conditions used. Furthermore, the interaction between the albumin particles and anti-albumin serum was inhibited by adding soluble human serum albumin to the solution.

Reticuloendothelial System (RES) Blockade—The capacity of the RES to phagocytose foreign particles from the circulation and an attempt to block such phagocytosis were investigated by repeated intravenous injections of empty polyacrylamide microparticles. In the first study, 0.5 mg of unlabeled empty particles was injected intravenously, and after 6 half-lives a second 0.5 mg dose of ^{14}C-labeled particles was injected. The second study was performed by injecting 2.5 mg (dry weight) particles, with the second dose (0.5 mg) given 16 hr later. This time point was chosen for two reasons. First, there are no particles in the blood after 16 hr. Second, it is known (13) that 24 hr after injection of particles there is an increasing number of phagocytosing cells in the RES, especially in the liver, signifying that the phagocytic capacity is increased. Considering these facts, we chose a time point between 6–24 hr, namely 16 hr.

Irrespective of the size of the first dose (0.5 or 2.5 mg), the RES retained its capacity to extract particles from the blood. Moreover, the blood clearance and organ uptake of microparticles in blockaded animals were almost the same as in normal animals. Thus, the liver and spleen uptake in blockaded animals corresponded to 60–70% of the injected dose, whereas the uptake in the lungs was increased to ~10–15% of the dose. The half-life ($t_{1/2}$) of the particles in blood was 50–60 min in the blockaded animals, the same as in untreated animals.

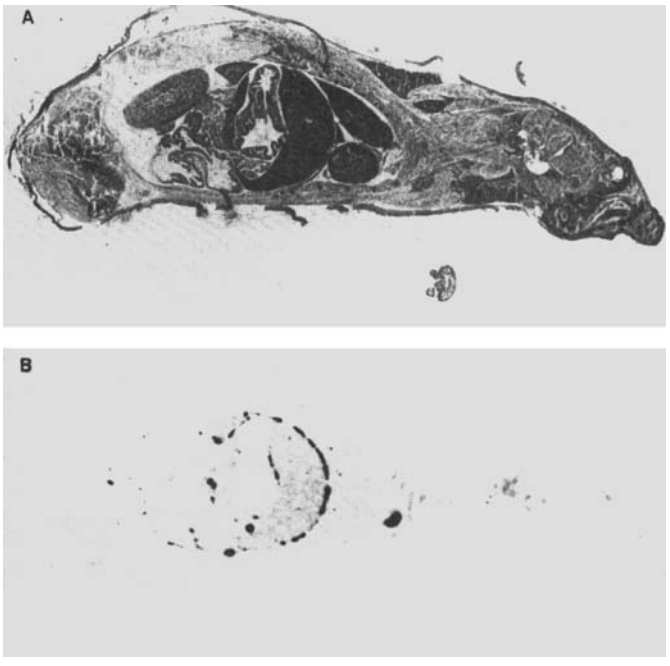

Figure 3—*Whole body autoradiogram (B) of a mouse 1 day after intraperitoneal injection of ^{14}C-labeled microparticles containing L-asparaginase (50,000 dpm in 0.5 mg). The mouse was immunized against L-asparaginase. (A) Corresponding tissue section, 20 μm.*

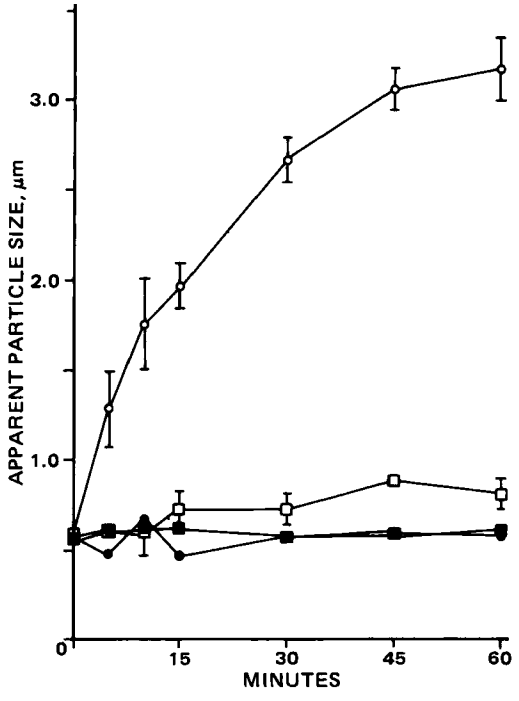

Figure 4—*Interaction between antialbumin globulin and particles with immobilized proteins. The immobilized proteins were albumin (○) and L-asparaginase (□); empty particles (●) were used as controls. In one study (■), albumin particles and antialbumin globulin were incubated in a solution containing free albumin (2×10^{-4} M). The interaction was measured as an increase in the apparent particle size. All values are mean ± SD from triplicate determinations.*

DISCUSSION

When immobilized in acrylic microparticles, proteins are partly entrapped within the polymeric network and partly fixed in the polymer threads forming the particles (12). As a consequence, a fraction of the immobilized macromolecules are localized on the surface and protrude from the particles. This phenomenon has been utilized to detect specific cell-surface receptors and for cell separation purposes after immobilization of appropriate cell-reactive agents in the microparticles (14).

Microparticles containing proteins are rapidly cleared from the circulatory system after intravenous injection. Furthermore, the rate of elimination from the incubation is significantly affected by the protein immobilized in the particles and depends on the amount of protein localized on the particle surface. The results indicate that the phagocytosis of the microparticles apparently is mediated by some receptor mechanism that makes it possible for the macrophages in the RES to discriminate between different surface characteristics and also to estimate the extent of the foreign nature of the particles. The data in Fig. 1, moreover, show that the "estrangement" of the microparticles mediated by the surface-localized proteins can be camouflaged by polyethylene glycol, manifested as an increased circulating lifetime. As a result of the modification with polyethylene glycol, the half-life of microparticles with human serum albumin in blood is increased from 33 to 84 min. This dramatic change may be due to different effects imparted by the modification of the surface properties: a decrease in the foreign nature, changed affinity for water, increased size, or a combination of these effects. The work of Abuchowski *et al.* (7) has shown that polyethylene glycol alters the immunological properties of bovine serum albumin and increases the circulating time of bovine catalase in mice. Polyethylene glycol has also been used in conjugates with antigen to suppress reaginic antibody response (15). It is thus evident that important determinants on the surface are quenched by the modification. However, the long half-life, which significantly exceeded that of microparticles containing no protein ($t_{1/2}$ = 61 min), indicates that other factors may also be involved, *e.g.*, physicochemical surface properties. In this case, the changed size distribution of the microparticles cannot be of any significance, as the size of the particles containing the modified albumin was approximately the same.

The survival time of microparticles in blood was drastically decreased in preimmunized mice, which in this case was a result of aggregation and a concomitant accelerated phagocytosis by the macrophages of the RES, especially the Kupffer cells. The liver uptake of the injected dose was 10% greater in immunized mice as compared with the controls. A plausible explanation to this difference is that Kupffer cells phagocytose larger particles in preference to smaller ones (16). *In vitro* experiments with particles containing albumin and anti-albumin globulin support such an interpretation. Thus, the apparent mean diameter of the particles increased from <1 μm to 3 μm within 15 min. A higher lung uptake in immunized animals gives further support to this hypothesis.

In the experiments presented only modest changes of the tissue distribution were observed, although a substantial change in the clearance rate of different particles was detected. This indicates that the RES, especially the liver and spleen, has an important and dominating role in particle clearance. It is likely that this phenomenon is representative for all particulate matter of submicron size.

Many papers describe attempts to block the RES (17, 18). These studies have shown that the capacity of the RES to eliminate foreign particles from the circulatory system is high. It was, moreover, necessary to inject massive and toxic doses of particles, ghost red blood cells, or liposomes to obtain a blockade. Pretreatment of mice with 0.5 mg of particles, which is the threshold dose required to produce morphological changes in the liver and spleen, did not affect the rate of elimination of subsequently injected particles. However, the practical use of an RES blockade is limited, because the treatment impairs the innate immunity of the recipient.

The results clearly demonstrate that alteration of the surface characteristics of the microparticles can lead to an increased circulation time *in vivo*. The finding is important because it constitutes a means of designing a carrier for macromolecular drugs in order to actively target drugs to specific cells in the vascular system *in vivo*.

Determination of Concentration-Dependent Water Diffusivity in a Keratinous Membrane

MAW-SHENG WU

Received July 6, 1982, from the *Personal Care Division, The Gillette Company, Boston, MA 02106.* Accepted for publication October 22, 1982.

Abstract □ A permeation method was developed to determine water diffusivity, $D(C)$, as a function of water concentration (C) in a keratinous membrane. The method involved the determination of a series of mean diffusivities ($\overline{D}$) and mean concentrations ($\overline{C}$) in the membrane. $\overline{D}$ was obtained from $\overline{D} = F\,H(C_o - C_h)$, where F was the flux at steady state, H was the membrane thickness, and C_o and C_h were the water concentrations in the membrane at the donor and receptor sides, respectively. The difference between C_o and C_h was kept small in each experiment. Therefore, as a first approximation, $\overline{C}$ was equal to $(C_o + C_h)/2$. After successive approximations, an empirical equation was found to provide the best fit to $\overline{D}$ *versus* $\overline{C}$ and to give the best convergence between the assumed and calculated $\overline{C}$; the equation was taken as $D(C)$. $D(C)$ for water in fetal hog periderm was found to be: $D(C) = 1.0 \times 10^{-18} + 9.70 \times 10^{-9}\,C^{0.69}$.

Keyphrases □ Diffusivity—water in keratinous membranes, determination using concentration, fetal hog periderm, topical formulations □ Topical formulations—determination of water diffusivity using concentration, keratinous membranes, fetal hog periderm □ Permeability—topically applied formulations, determination of diffusivity using concentration, keratinous membranes

Passive transport of matter through a biological membrane is usually governed by Fick's law. In most cases, a constant diffusion coefficient for transported material (penetrant) can adequately describe the diffusion process. However, on some occasions, especially when the penetrant is also a solvent or plasticizer for the membrane, the diffusion coefficient could be a function of the concentration of the penetrant (1).

Permeability of a topically applied drug sometimes is influenced by the hydration state of the stratum corneum (2). Therefore, knowing the water concentration profile in the stratum corneum would be helpful in studying the percutaneous absorption of the drug. *In vivo*, water is not evenly distributed across the thickness of the tissue: a concentration gradient exists. On the dermal side of the stratum corneum, the tissue is fully hydrated, whereas on the skin surface, the water concentration is much lower and is regulated by the ambient condition. Therefore, transpiration of water through the stratum corneum is inevitably due to the concentration gradient. From the rate of transpiration and Fick's diffusion equation, one may obtain the water concentration profile in the stratum corneum and thus, the amount of water at different sites within the tissue, if the diffusivity of water in the stratum corneum is known.

Methods have been developed to determine diffusivity as a function of concentration (3). The most commonly used sorption–desorption method, devised by Crank and Park (4), is based on the mass of the membrane as the frame of reference. To obtain a concentration profile across the thickness of a membrane, one may have to use the volume of the membrane as the frame of reference. However, if the change in the volume of mixing between the penetrant and the membrane varies with the concentration, as is the case with water in the stratum corneum (5), then converting a system based on the mass to one based on volume as the reference coordinate could be very difficult, if not impossible.

A method to determine the diffusivity of water in a keratinous membrane is reported here. The method considers the concentration variations of water in the membrane as well as concentration-dependent volume change of the membrane. Fetal hog periderm was chosen as the model tissue for the keratinous membrane as it is easy to obtain in large quantities and is free from the hair usually accompanying stratum corneum.

THEORETICAL

In diffusion-controlled transpiration, if the diffusion follows Fick's laws, then the rate of transpiration (flux) could be expressed by Fick's first law:

$$F = -D\frac{dC}{dx} \qquad \text{(Eq. 1)}$$

where F is the flux (*i.e.*, the rate of transpiration of water across any place in a keratinous membrane), C is the concentration of the diffusion substance (*e.g.*, water), x is the position along the direction of diffusion (position along the thickness of the membrane), and D is the diffusivity of the penetrant. Since D may be dependent on the concentration (C), D is rewritten as $D(C)$ to illustrate the relationship between these parameters. The flux, F, at steady state may be further expressed in an integrated form of Eq. 1 (6):

$$F = \frac{1}{H}\int_{C_h}^{C_o} D(C)dC \qquad \text{(Eq. 2)}$$

where H is the thickness of the membrane and C_h and C_o are the penetrant concentrations in the membrane at the receptor and donor sides, respectively.

The mean diffusivity $\overline{D}$, at the mean concentration $\overline{C}$, is defined as:

$$\overline{D} = \left[\int_{C_h}^{C_o} D(C)dC\right] \Big/ (C_o - C_h) \qquad \text{(Eq. 3)}$$

and by substituting Eq. 2 into Eq. 3, $\overline{D}$ becomes:

$$\overline{D} = FH/C_o - C_h) \qquad \text{(Eq. 4)}$$

$\overline{D}$ may be readily calculated from Eq. 4 using the measurements of F, H, C_o, and C_h. Furthermore, if the difference between C_o and C_h is small, then the mean concentration, $\overline{C}$, can be expressed as:

$$\overline{C} = (C_o + C_h)/2 \qquad \text{(Eq. 5)}$$

Therefore, as a first approximation to determine the empirical equation for $D(C)$, a series of permeation experiments in various concentration ranges can be conducted by keeping the difference of C_o and C_h small in each experiment. From the experimental results, a series of $\overline{D}$ and $\overline{C}$ can be calculated. Plotting $\overline{D}$ *versus* $\overline{C}$, an empirical equation for $D(C)$ which gives the best fit to the experimental data can be determined.

This equation is then inserted into Eq. 1, which can be integrated to give C as a function of x (or *vice versa*). The curve of C *versus* x, *i.e.*, the water distribution profile across the thickness of the membrane, is then integrated to obtain the area under the curve. This area, divided by the membrane thickness (H), yields the mean concentration ($\overline{C}$) of water in the membrane. These calculated values of $\overline{C}$ are then compared with the values of $\overline{C}$ used to obtain $D(C)$. If the assumed and calculated values

0022-3549/83/1200-1421$01.00/0

of $\overline{C}$ are not equal, then the assumed values are adjusted to obtain a new empirical equation for $D(C)$. The adjusted values are again compared with the calculated values. This process is repeated until the two sets of numbers are equal or converge. If more than one functional form for $D(C)$ is obtained from the first approximation, the functional form which results in the best convergence and provides the best fit to the experimental data will prevail in the iteration and is the best equation for $D(C)$.

In the previous calculation, the thickness of the membrane, H, is a known parameter. Its value lies between H_h and H_o (the membrane thickness when the water concentrations in the membrane are C_h and C_o, respectively). Although the relationship between H and C is not known, it may be assumed that:

$$H = (H_o + H_h)/2 \qquad \text{(Eq. 6)}$$

because the difference between C_o and C_h is small.

EXPERIMENTAL

Tissue Preparation—Fetal hog skin was obtained from a commercial source[1]. The periderm was prepared using a procedure reported for human stratum corneum (7). A whole fetal hog skin was immersed in a 60° water bath for ~1 min. The skin was then taken out of the bath, and the periderm was carefully peeled from the tissue.

Determination of Rate of Water Loss (F)—Measurement of the rate of water loss, *i.e.*, the flux (F), through the periderm was carried out using diffusion cells. The cell was half filled with a saturated salt solution to produce a constant relative humidity inside the cell and, hence, a constant water concentration (C_o) at the donor side of the membrane. The cell was placed in a desiccator filled with another saturated salt solution to produce a lower relative humidity outside of the cell and therefore, a constant water concentration (C_h) at the receptor side of the membrane. The desiccator was placed in a constant temperature room at 21°. The rate of water loss at steady state was obtained gravimetrically when the rate became constant. The experiments were carried out in small relative humidity ranges of 0–12%, 12–23%, 23–33%, 33–44%, 44–57%, 57–75%, 75–85%, 75–100%, and 85–100%. The salts used were phosphorous pentoxide, lithium chloride, potassium acetate, magnesium chloride, potassium carbonate, potassium bromide, sodium chloride, and potassium chloride for relative humidities of 0, 12, 23, 33, 44, 57, 75, and 85%, respectively.

Volume of the Membrane—Volumes of the membranes at various relative humidities were determined using air comparison pycnometry (8).

Determination of Water Concentration—Dry periderm was equilibrated in a desiccator at a constant humidity maintained by a saturated salt solution. After each tissue reached a constant weight, the weights of the tissues were taken and, from the weight gain and the volume of each tissue, the concentrations of water in the membranes at various relative humidities were determined.

Determination of Membrane Thickness—The thickness of the membrane at various humidities was obtained from the weight per area and the density of the tissue at each humidity. To do this, a sheet of periderm was placed on a sheet of aluminum foil. This was done by floating the tissue in water and carefully raising the aluminum foil beneath the tissue to bring the tissue out of the water. The tissue was free of wrinkles and could expand and contract freely. The tissue with the aluminum foil was then dried and put in a desiccator with a constant relative humidity. The desiccator and a microbalance were placed in a humidity chamber having the same relative humidity as the desiccator. After the tissue was equilibrated, a piece of the tissue–aluminum foil was cut and its weight was determined with the balance. The tissue was then removed from the aluminum foil, and the weight of the aluminum foil was determined. From the weight difference, the weight of the tissue was obtained; from the weight of the aluminum foil alone and a predetermined weight–area correlation curve for the aluminum, the area of the tissue was determined. Thus, the weight per unit area of periderm at each humidity could be determined.

RESULTS AND DISCUSSION

The rates of water loss (F) at various experimental conditions are listed in Table I. Table II shows the water concentration and the membrane thickness at the various relative humidities of interest. Large standard deviations were found in the rate of water loss and in the thickness measurements. These deviations are probably due to the large variation of the tissue sample used. The water concentration data are fairly consistent. Because each fetal hog provided <0.2 g of the dry periderm, at least 10 animals were required for each volume determination. Inherent variations in the tissues were probably balanced by the large sample size to produce the fairly consistent data in the water concentrations. The mean water diffusivityes, $\overline{D}$, obtained here (4×10^{-10} to 3.2×10^{-9} cm²/sec) are in the range of that for human stratum corneum (9).

From the plot of $\overline{D}$ *versus* $\overline{C}$, four functional forms can be found to provide a reasonable fit to the experimental data (Fig. 1). The four functional forms are $D(C) = D_o - Ae^{-BC}$, $D(C) = D_o + AC^B$, $D(C) = D_o + Ae^{BC}$, and $D(C) = D_o + AC/(1 + BC)$, where D_o, A, and B are constants.

Table I—Rate of Water Loss Through Fetal Hog Periderm at 21° and Various Relative Humidities

Experimental Condition (% RH_h − % RH_o)[a]	Rate of Water Loss, g/cm² sec × 10^8
0–12	0.95 ± 0.17 (6)[b]
12–23	1.69 ± 0.83 (7)
23–33	2.36 ± 1.08 (7)
33–44	3.88 ± 1.92 (9)
44–57	6.98 ± 1.92 (9)
57–75	10.73 ± 4.87 (11)
75–85	8.64 ± 0.55 (6)
75–100	20.54 ± 6.02 (6)
85–100	11.89 ± 4.43 (11)

[a] % RH_h and % RH_o were the relative humidity conditions under which C_h and C_o were determined. [b] Number of samples in parentheses.

Table II—Water Concentration and Thickness of Fetal Hog Periderm at Various Relative Humidities

Relative Humidity, %	Water Concentration, g/cm³	Membrane Thickness, cm × 10^4
0	0	10.1 ± 3.31
12	0.024	10.3 ± 4.92
23	0.043	10.5 ± 1.50
33	0.059	10.6 ± 3.31
44	0.084	10.9 ± 2.40
57	0.116	11.4 ± 2.32
75	0.173	11.8 ± 4.54
85	0.223	16.5 ± 5.95
100	0.290	24.3 ± 9.86

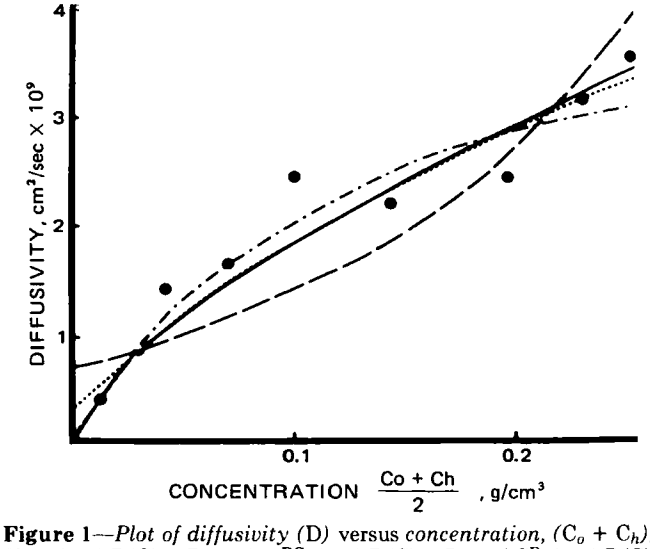

Figure 1—*Plot of diffusivity* (D) versus *concentration*, $(C_o + C_h)/2$. *Key:* (·····) $D(C) = D_o - Ae^{-BC}$; (——) $D(C) = D_o + AC^B$; (- - -) $D(C) = D_o + Ae^{BC}$; (-·-·-) $D(C) = D_o + AC/(1 + BC)$.

[1] Texas Biological Inc., Dallas, Tex.

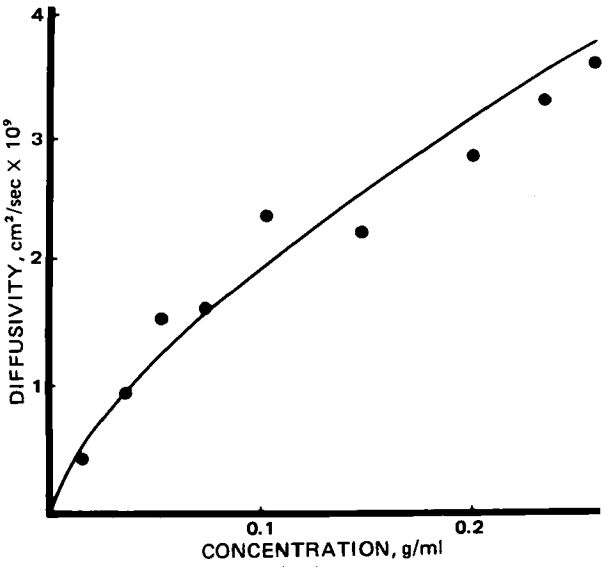

Figure 2—*Comparison of experimental data and the diffusivity equation. Key: (●) experimental data; (—)* $D(C) = 1.0 \times 10^{-18} + 9.70 \times 10^{-9} C^{0.69}$.

A computer was used to carry out the successive iterations. In the calculation, the equations were linearized. The value of D_o was determined by trial and error; values for B and A were obtained from the slope and the intercept of the linearized equation. In the iteration, the concentrations used were restricted between C_h and C_o. At the end of the iteration, $D(C) = D_o + AC^B$ was found to give the best convergence of the assumed and calculated mean concentrations and to provide the best fit to the experimental data (Fig. 2). The final equation for $D(C)$ is:

$$D(C) = 1.0 \times 10^{-18} + 9.70 \times 10^{-9} C^{0.69} \quad \text{(Eq. 7)}$$

The large standard deviation associated with the measured thickness, H (Table II), raised concern about the appropriateness of the approximation for H. Therefore, the iteration process was altered. The mean water concentration $\overline{C}$, was fixed as $(C_o + C_h)/2$ while the assumed values for H were adjusted in the iteration until they converged with the calculated values. The resulting equation is shown below:

$$D(C) = 1.0 \times 10^{-18} + 10.0 \times 10^{-9} C^{0.72} \quad \text{(Eq. 8)}$$

Comparison of Eq. 8 with Eq. 7 shows that they are not significantly different. Therefore, Eq. 7 is a reasonable representation for the diffusivity of water in fetal hog periderm.

The method developed here provides an alternative way to obtain the diffusivity as a function of the penetrant concentration. With the appropriate experimental designs and the data analyses mentioned herein, this method can circumvent some of the difficulties associated with the other methods of obtaining diffusivity.

High-Performance Liquid Chromatographic Assay for Etomidate in Human Plasma: Results of Preliminary Clinical Studies Using Etomidate for Hypnosis in Total Intravenous Anesthesia

MICHAEL J. AVRAM ˣ, ROBERT J. FRAGEN, HARRY W. LINDE

Received July 19, 1982, from *Northwestern University Medical School, Department of Anesthesia, Chicago, IL 60611.* Accepted for publication November 2, 1982.

Abstract □ A sensitive and specific high-performance liquid chromatographic assay was developed for the measurement of etomidate in human plasma following extraction of the drug and the internal standard. Using 0.5-ml aliquots of plasma, the assay was linear in the concentration range of 20–2000 ng of etomidate/ml of plasma. This method was used to evaluate a preliminary clinical study of an etomidate infusion regimen for hypnosis in a total intravenous anesthesia protocol in 23 patients. The average duration of the infusion was 30 min, and awakening and alertness occurred 20 and 36 min after the termination of the infusion, respectively, at the respective plasma concentrations of 297 and 214 ng/ml. These results and this assay will be used to design and evaluate an improved etomidate infusion regimen.

Key phrases □ Etomidate—high-performance liquid chromatography, human plasma, infusion, hypnosis in total intravenous anesthesia □ Hypnotic agents—etomidate, infusion, hypnosis in total intravenous anesthesia, high-performance liquid chromatography, human plasma □ High-performance liquid chromatography—etomidate, human plasma, infusion, hypnosis in total intravenous anesthesia

Etomidate, a carboxylated imidazole, is an hypnotic agent which rapidly produces sleep after intravenous administration (1) and has only a minimal and transient effect on respiration (2) and no effect on cardiovascular stability (3). Etomidate is primarily metabolized in the liver by ester hydrolysis to the inactive carboxylic acid (4, 5). Recovery of consciousness is rapid due to both redistribution and metabolism of the drug (6). These properties suggest that an etomidate infusion would be suitable for the maintenance of hypnosis in a totally intravenous anesthesia regimen.

Several methods for the measurement of etomidate in plasma have been reported, but these use instrumentation that may not be readily available and require the extraction of relatively large volumes of plasma. The method of Wynants *et al.* (7) uses GC with an alkali flame ionization detector (AFID) and is sensitive to 10 ng/ml but requires the extraction of 3 ml of plasma. Van Hamme *et al.* (8) reported a GC–MS assay that is sensitive to 1 ng/ml using extracts of 1–4 ml of plasma. Sensitivity to 5 ng/ml was achieved by De Boer *et al.* (9) using capillary GC with an nitrogen–phosphorus detector. A GC–AFID method was also developed by Haring *et al.* (10) which requires the extraction of only 1 ml of plasma, but is sensitive to only 30 ng/ml.

It was the purpose of the present study to develop a simple yet sensitive high-performance liquid chromatographic (HPLC) method for measuring plasma etomidate concentrations. This method was then used to measure the plasma etomidate concentrations in blood samples obtained during an infusion of etomidate for hypnosis in a totally intravenous anesthesia regimen and up to 6 hr postinfusion. The resulting plasma concentration *versus* time curves were then used to evaluate the infusion protocol and determine the plasma etomidate concentrations at awakening and alertness under the conditions of the anesthetic.

EXPERIMENTAL

Reagents—Etomidate sulfate [*R*-(+)-ethyl 1-(α-methylbenzyl)imidazole-5-carboxylate sulfate], propoxate hydrochloride [*R*-(+)-propyl 1-(α-methylbenzyl)imidazole-5-carboxylate hydrochloride], *R*-(+)-1-(α-methylbenzyl)imidazole-5-carboxylic acid, mandelic acid, and hippuric acid were used as received[1]. All organic solvents were LC[2] or analytical[3] grade. The sulfuric acid, ammonium hydroxide, sodium hydroxide, and sodium borate were analytical grade[4].

Instrumentation—Plasma etomidate concentrations were measured using a constant-flow HPLC system consisting of a solvent delivery system[5], a universal injector[6], a radial compression separation unit[7] liquid chromatography cartridge and cartridge insert packed with 10-μm CN resin[8], and a fixed-wavelength UV detector fitted with a 254-nm wavelength kit[9]. The chromatograms were recorded, the peaks were identified and integrated, and the concentrations were reported on the basis of the internal standard area ratio method by a reporting integrator[10].

Extraction—Five-milliliter blood samples were obtained by syringe through a 16-gauge polytef catheter, previously inserted in an arm vein in each patient, at appropriate time intervals (described below) and transferred to heparinized blood collection tubes[11]. The plasma samples were removed after centrifugation of the blood for 10 min at 2000 rpm and stored at −30° until extracted in duplicate according to a modification of the procedures of Wynants *et al.* (7) and Van Hamme *et al.* (8).

A 500-μl aliquot of plasma, 50 μl of a 3.423-μg/ml ethanolic solution of propoxate hydrochloride and 100 μl of 0.05 *M* borate buffer (pH 10) were added to a conical centrifuge tube and mixed. This mixture was extracted twice with 3.0 ml of hexane–ether (9:1, v/v) by mixing for 5 min on a slowly rotating mixer. The mixtures were centrifuged for 5 min at 2000 rpm, and the hexane–ether layers were transferred to a conical centrifuge tube containing 3.0 ml of 0.5 *M* H_2SO_4 and mixed for 5 min. The mixture was centrifuged for 5 min at 2000 rpm, and the hexane–ether layer was removed and discarded. The acidic aqueous extract was washed with 3.0 ml of hexane–ether for 5 min; the mixture was centrifuged for 5 min at 2000 rpm and the hexane–ether layer was removed and discarded. The acid extract was made basic by adding 1 ml of 3 *M* NH_4OH. This solution was extracted with 4 ml of methylene chloride, and then centrifuged for 5 min at 2000 rpm. The organic phase was evaporated to dryness under reduced pressure at 30° [12], and the residual material was reconstituted with 100 μl of methanol; 15 to 30 μl was injected into the HPLC. Recovery was evaluated by comparing the etomidate–propoxate area ratios for standards containing 2000, 200, and 20 ng of etomidate

(as the base)/ml of plasma in which the internal standard solution was added after the extraction to those in which it was added before the extraction.

Chromatography—The HPLC system was as described above; the mobile phase was methanol–water (54:46) delivered at 1.8 ml/min. The etomidate concentrations, in terms of free base, were determined by the internal standard area ratio method.

The linearity, accuracy, and precision of the assay were assessed by the measurement of the etomidate concentration of replicate plasma standards made by adding known amounts of etomidate from stock solutions to blank human plasma. These plasma standards contained 20, 50, 100, 200, 500, 1000, and 2000 ng/ml of etomidate as the base.

Clinical Study—Twenty-three women scheduled to have minor gynecologic surgery, but otherwise in good health, participated in this institutionally approved study after giving informed consent. The patients were premedicated with morphine sulfate (0.1 mg/kg im) 60–90 min prior to induction of anesthesia. An intravenous infusion of 5% dextrose in Ringer's lactate was started through a 20-gauge polytef catheter into a large vein of the arm opposite that used for blood sampling; drugs were administered intravenously through this tubing at the injection site closest to the catheter. Three to five minutes prior to the induction of anesthesia, fentanyl (100 μg iv) and droperidol (2.5 mg iv) were administered. Anesthesia was induced with 0.3 mg/kg of etomidate (a 2-mg/ml solution in propylene glycol) administered intravenously over 1 min. Maintenance of hypnosis was accomplished with a continuous intravenous infusion of 0.1% etomidate (1 ml of a 125-mg/ml etomidate solution in 10% ethyl alcohol diluted to 125 ml with 0.9% NaCl or 5% dextrose in water) by an infusion pump at a rate 0.1 mg/kg/min for the first 10 min then at 0.01 mg/kg/min for the remainder of the anesthesia. Further analgesia was provided, when necessary, using fentanyl (50 μg iv). Pancuronium was given, when necessary, to facilitate tracheal intubation and for muscle relaxation and was reversed at the end of the operation by pyridostigmine (10 mg iv) and glycopyrrolate (0.4 mg iv). Patients were ventilated with oxygen or oxygen-enriched air.

The times to awakening and alertness were determined as the time from discontinuing the etomidate infusion to the time the patients responded to verbal stimuli and the time the patients were oriented in time and place, respectively. Once they were alert, they were asked to attempt to arise and walk beside their bed every 15 min until they were able to walk unaided for a distance of ~2 m.

Blood samples were obtained 1, 2, 5, 10, 15, 30, and 45 min into the etomidate infusion and 5, 10, 15, 30, 45, 60, 75, 90, 120, 180, 240, and 360 min postinfusion. Plasma etomidate concentrations at awakening and alertness were determined, when necessary, by interpolation of the plasma concentration *versus* time curves for each patient. The elimination half-life was determined by a log-linear regression analysis of the plasma concentration *versus* time relationship during the elimination phase.

RESULTS AND DISCUSSION

Chromatographic Assay—Chromatograms of extracts of the 2000-ng/ml and the 20-ng/ml plasma etomidate standards are illustrated in Fig. 1. The carboxylic acid metabolities of etomidate eluted in <1.2 min, well before the esters etomidate and propoxate, and therefore did not interfere with the assay. None of the drugs administered concomitantly in the present protocol were found to interfere with the assay.

The accuracy and precision of the HPLC technique was evaluated by measuring the concentration of etomidate in spiked plasma standards six times each over the period of a week (Table I). A linear regression analysis of the standard etomidate concentrations from 20 to 2000 ng/ml *versus* etomidate–propoxate area ratios verified the linearity of the extracted standard curve ($r = 0.999$; $y = 267.9x + 3.5$). The average recoveries for four replicate samples at 2000, 200, and 20 ng/ml were 82.4, 82.6, and 82.4%, respectively.

Clinical Study—The average (±*SD*) age and weight of the patients were 35 (±10) years and 64 (±12) kg, respectively. No patient complained of pain on injection and no signs of venous irritation were observed. All patients fell asleep rapidly, remained asleep throughout the operation, and had no recall of operative events. Mild, almost imperceptible, myoclonia occurred at induction in two patients, but lasted less than 15 sec in each case. There were no clinically significant side effects during maintenance, and changes in blood pressure and heart rate occurred only in relation to the administration of other drugs and surgical stimulation. Awakening was complicated in six patients by the desire to turn to the lateral position, muscle twitching, restlessness, or hypertonus in the period between first awakening and complete alertness. Postoperative nausea or vomiting was observed in four patients.

[a] $n = 6$. [b] Mean ± *SD*.

A typical plasma etomidate concentration *versus* time curve during and after the infusion is shown in Fig. 2, and pertinent clinical results for the 23 patients are listed in Table II. The average length of anesthesia in these patients was 30 (±26) min, and they awoke at an average of 20 (±9) min after the end of the etomidate infusion. The mean plasma etomidate concentration on awakening was 297 (±74) ng/ml; Schüttler

[a] —Not determined.

et al. (11), using the analytical method of Wynants *et al.* (7), found the minimal plasma etomidate concentration producing an hypnotic effect to be ~300 ng/ml. The patients were alert an average of 36 (±15) min after the end of the etomidate infusion, and this was associated with an average plasma etomidate concentration of 214 (±50) ng/ml. The patients were able to walk unaided for ~2 m an average of 87 (±29) min following the termination of the infusion. The elimination half-life was 3.3 (±1.5) hr, which is longer than that of Schüttler *et al.* (11) but shorter than that of Van Hamme *et al.* (12). The patients generally remained drowsy for 4–6 hr after leaving the recovery room.

While these results demonstrate that anesthesia can be satisfactorily accomplished with an etomidate infusion and bolus injections of fentanyl, droperidol, and pancuronium, the present protocol is not optimal. An etomidate infusion regimen for hypnosis in totally intravenous anesthesia should be designed to maintain plasma concentrations above the awakening concentration while avoiding dose-related side effects and keeping awakening time under 10 min regardless of the duration of anesthesia. This could theoretically be accomplished using the plasma etomidate data of the present study and the etomidate pharmacokinetic data from the intravenous bolus study of Van Hamme *et al.* (12). The HPLC method reported here could then be easily used to evaluate such a designed infusion regimen.

Effect of Inorganic Additives on Solutions of Nonionic Surfactants V: Emulsion Stability

HANS SCHOTT ˣ and ALAN E. ROYCE

Received June 14, 1982 from the *School of Pharmacy, Temple University, Philadelphia, PA 19140.* Accepted for publication October 7, 1982.

Abstract □ Electrolytes often break emulsions to which they were added as active ingredients, adjuvants, or impurities. The stability of oil-in-water emulsions containing octoxynol 9 NF as the emulsifier and various added electrolytes was investigated by measuring droplet size, turbidity, and oil separation on storage at various temperatures and in a centrifugal field at 25°. Electrolytes were added to hexadecane emulsions after emulsification (direct addition); alternatively, hexadecane was emulsified in octoxynol 9–electrolyte mixtures (reverse addition). Xylene emulsions were prepared by direct addition only. Hexadecane emulsions containing 0.10% octoxynol 9 were considerably more stable than xylene emulsions containing 0.60% because the surfactant is practically insoluble in hexadecane, but miscible in all proportions with xylene. An emulsifier soluble in the disperse phase as well as the continuous phase evidently forms less stable interfacial films. The electrolytes investigated were sulfuric and hydrochloric acids, magnesium nitrate, and aluminum nitrate, which salt octoxynol 9 in by complexation between its ether groups and their cations; sodium thiocyanate, which salts the surfactant in by destructuring water; and sodium chloride and sodium sulfate, which salt octoxynol 9 out. The addition of these electrolytes at concentrations up to 2 or 3 *m* to hexadecane emulsions produced fast and extensive creaming, little or no flocculation, no coalescence, and only minor changes in droplet size or turbidity on storage at room temperature. The extent of coalescence during centrifugation was actually reduced by the additives. Such stability is unusual. Droplet size and turbidity depended mainly on octoxynol 9 concentration. The greatest decrease in the former and increase in the latter occurred when the concentration was increased from 0.10 to ~0.4%. All emulsions became slightly coarser on storage at 25°. Stability at 50° was impaired by aluminum nitrate and magnesium nitrate and to a lesser extent by sodium sulfate and sodium chloride. Reverse-addition emulsions differentiated better between the electrolytes than direct-addition emulsions. Electrolytes salting octoxynol 9 in, especially by complexation, generally produced the finest and most stable emulsions. Similarly, xylene emulsions were destabilized more by the electrolytes which salted the emulsifier out than by those salting it in. Centrifugation of hexadecane emulsions at 7800×*g* compressed the creamed emulsion layer into a plug of clear, transparent, isotropic gel from which coalesced hexadecane separated slowly on further centrifugation. These semisolid gels contained the hexadecane as discrete, uncoalesced droplets because, on immersion in water or octoxynol 9 solutions with or without electrolytes, they turned opaque, liquefied, and redispersed spontaneously into emulsions of nearly the same average droplet size as the original emulsions.

Keyphrases □ Hexadecane—emulsions with octoxynol 9, stability, effect of added electrolytes □ Xylene—emulsions with octoxynol 9, stability, effect of added electrolytes □ Stability—of hexadecane and xylene emulsions with octoxynol 9, effect of added electrolytes □ Emulsions—hexadecane with octoxynol 9, xylene with octoxynol 9, stability, effect of added electrolytes

The principal effect of electrolytes on aqueous solutions of polyoxyethylated nonionic surfactants consists of salting in or salting out, depending on whether the electrolyte increases or decreases the solubility of the surfactants, raising or lowering their cloud points. Electrolytes in the first category contain either cations capable of forming complexes with the ether groups of the polyoxyethylated moiety of the nonionic surfactants, or large and polarizable anions that break the hydrogen-bonded structure of water. All di- and trivalent cations, plus the hydronium and lithium cation, form complexes with model ethers and increase the solubility of polyoxyethylated surfactants by complexation (1, 2). Only salts of sodium, potassium, ammonium, tetramethylammonium, and cesium tend to salt out the surfactants (1–4) because these cations do not form complexes with the ether oxygen atoms.

Large anions that break the structure of water include iodide, thiocyanate (4, 5), and perchlorate (2) as well as the guanidinium cation (6). Depolymerization of water increases the hydration of the ether linkages of the surfactants through hydrogen bonding by disrupting the hydrogen bonds among the water molecules (1, 2). The salt effects of the anions are in agreement with the Hofmeister or lyotropic series (4).

Salts are frequently incorporated into emulsions for a variety of purposes or occur as impurities. The objective of the present work was to investigate how salting-in and salting-out electrolytes affect the stability of oil-in-water emulsions prepared with a nonionic polyoxyethylated emulsifier. The main variables to be investigated were surfactant concentration, nature and concentration of the electrolytes, temperature, and order of addition. The range of electrolyte concentrations was extended to the high values at which the surfactant is extensively salted in or out.

The surfactant, octoxynol 9, was selected because it is a monograph in the National Formulary and because its interactions with electrolytes have been investigated extensively with regard to cloud point (1–3, 5), micelle formation, and surface properties (7). Moreover, it is used commercially as an emulsifying and suspending agent and as a detergent for hard surfaces and skin.

EXPERIMENTAL

Materials—The surfactant, octoxynol 9 NF[1], is a branched octylphenol with an average of 9–10 ethylene oxide units. It is a viscous, anhydrous liquid with a hydrophilic–lipophilic balance (HLB) of 13.4 and a critical micelle concentration of 0.16 g/liter at 25°.

The oils used were hexadecane[2] and xylene[3]. The electrolytes were ACS reagent grade. The water was double distilled. Electrolyte concentrations are expressed as molality (*m*); the concentrations of oil and octoxynol 9 are expressed as percent (w/w) based on the weight of the water present in the solutions and emulsions as 100%. Thus, a 5.00% octoxynol 9 solution or emulsion contains 5.00 g of octoxynol 9 in 100 g of water.

Emulsification—In the direct-addition procedure, the electrolytes were added in the final stage. Preliminary coarse emulsions containing 50% oil were made in 100-g batches, as illustrated for a hexadecane emulsion with a 0.10% octoxynol 9 content: 1.40 g of a 5.00% octoxynol 9 solution, 65.29 g of water, and 33.31 g of hexadecane were added in this order to a tall-form 200-ml beaker. The octoxynol 9 solution was at least 2 days old to ensure full hydration. The mixture was stirred for 20 min at 30-V input with a mixer equipped with two counter-rotating propel-

lers[4]. The stirring conditions were selected because higher speeds and/or longer agitation caused foaming while lower speeds produced coarser droplets. The emulsion was further comminuted by passing it three times through a stainless steel hand-operated homogenizer[5], applying maximum tension to the spring. The second and third pass did not substantially reduce the mean droplet size, but improved the reproducibility.

The finished emulsion was prepared by mixing weighed amounts of a 5.00% aqueous octoxynol 9 solution, water, aqueous electrolyte solution, and homogenized emulsion to give the desired composition. The surfactant concentration was the same, for instance, 0.10%, in the preliminary and the finished emulsion. The oil content was 25% for most finished hexadecane and all finished xylene emulsions. Most hexadecane emulsions contained 0.10 or 0.20% octoxynol 9. Since the xylene emulsions were intrinsically less stable, their octoxynol 9 content was 0.60%. The preliminary coarse xylene emulsions made with the counter-rotating mixer contained, therefore, 8.37 g of a 5.00% octoxynol 9 solution, 58.43 g of water, and 33.20 g of xylene.

The reverse-addition procedure was used for hexadecane emulsions only. The order of mixing of the ingredients was as follows: 5.00% octoxynol 9 solution, water, and aqueous electrolyte solution to give a solution containing 0.10% octoxynol 9 and the desired electrolyte molality. This solution was stored at room temperature for at least 2 days prior to the addition of hexadecane and emulsification. The preliminary coarse emulsion was made in 100-g batches containing 25% hexadecane by stirring for 20 min at 30-V input with the counter-rotating mixer. The emulsification was completed by three passes through the hand-operated homogenizer.

Storage—To characterize the emulsions, various measurements were made on aliquots withdrawn at regular intervals. During the period of investigation, most emulsion samples were stored at 25 ± 0.5°. A few were stored at 50 ± 1°.

Visual Observation of Coalescence—Some xylene emulsions were so unstable that they separated visible amounts of clear oil at room temperature. For quantitative comparison, 55-g emulsion samples were stored in milk-test Babcock bottles; the volume of xylene separated after various storage times at 25° was calculated from its height in the neck.

Higher coalescence rates at elevated temperatures were measured for xylene or hexadecane emulsions by weighing 20- to 23-g emulsion samples into stoppered 25-ml graduated cylinders, immersing the cylinders into constant-temperature baths, and recording the volume of clear oil separated as a function of time. All emulsions used for measuring coalescence rates at elevated temperatures or in a centrifuge at room temperature, which contained 25% hexadecane or xylene, were prepared by direct addition.

Droplet Size Measurements—The method used for microscopic measurements of droplet size is described in a separate publication (8). Prior to the measurements, the emulsions were diluted ~600-fold, using either an octoxynol 9 solution of the same concentration as the emulsion, which was thickened with polyvinyl alcohol, or a warm gelatin solution, which gelled on cooling.

Turbidity Measurements—Emulsions containing 25% hexadecane were opaque. Transmittance was measured as a function of hexadecane concentration after diluting the emulsions to varying degrees. Dilutions, which usually ranged from 200- to 2000-fold, were made with octoxynol 9 solutions having the same surfactant concentration as the emulsions. Emulsions were diluted immediately before measuring their transmittance.

Transmittance measurements were made with a double-beam spectrophotometer[6] and 1-mm quartz cells. Even though the emulsions were "white," their transmittance varied with the wavelength. Unless otherwise specified, the wavelength used was 475 nm.

Centrifugation—The stability of hexadecane emulsions was studied by centrifugation at 25° and 10,000 rpm or 7800× the acceleration of gravity (g) for 65 min, using a thermostated centrifuge[7]. The glass tubes used had a capacity of 12 ml and an inside diameter of 12.5 mm. They were filled with an amount of emulsion containing 1.80 g of hexadecane, which ranged from 9 to 11 g.

Centrifugation separated the emulsions into four layers, which were (from bottom to top) a clear aqueous solution, a white opaque viscous layer of creamed emulsion a few millimeters thick, a clear gel layer with a thickness of up to 18 mm, and a layer of clear hexadecane a few millimeters thick. The tubes were stoppered and stored in a vertical position at 25°. On standing, the gel reverted gradually and almost completely to a white opaque cream over a 15-hr period, separating small amounts of clear hexadecane. The creamed emulsion layer continued to bleed additional small amounts of clear hexadecane for a few hours after the disappearance of the gel. When the oil separation was essentially complete, the clear hexadecane was aspirated quantitatively and weighed. Storage times after emulsification were, therefore, 17–24 hr for emulsions with 0.10% octoxynol 9 and 48 hr for emulsions with 0.20%. Results are expressed as percent hexadecane separated, based on the 1.80 g present in the emulsion samples placed in the centrifuge tubes.

Xylene emulsions, being less stable, were centrifuged at speeds of only 4000–5000 rpm for only 15–30 min to distinguish the effects of different additives. Even though only small amounts of clear gel formed, the centrifuged emulsions were stored for 24 hr at 25° prior to separating and weighing the coalesced xylene.

RESULTS

Droplet Size from Microscopic Measurements—Droplet sizes were measured in incremental intervals of 1 μm. The data were used to determine the droplet size distributions. The average droplet sizes were represented by the arithmetic mean diameter, D_a, and the mean volume–surface diameter, D_{vs}:

$$D_{vs} = \sum N_i D_i^3 \Big/ \sum N_i D_i^2 \qquad \text{(Eq. 1)}$$

where D_i is the diameter equal to the midpoint of the ith size interval and N_i the number of droplets in that interval.

The mean volume–surface diameter is inversely related to the specific surface area of the emulsion sample. For a given sample, it is larger than the arithmetic mean diameter because each droplet contributes to the latter only in proportion to the first power of its diameter. The mean volume–surface diameter is influenced to a greater extent by larger droplets and, hence, reflects more effectively increases in droplet size than the arithmetic mean diameter (9).

Table I lists the effects of various experimental variables on the mean droplet size of hexadecane emulsions in the absence of additives. The most influential variable was octoxynol 9 concentration. When it was increased from 0.10 to 0.30%, the D_a and D_{vs} values of freshly prepared emulsions decreased by 61 and 53%, respectively. Another approximately threefold increase in concentration, from 0.30 to 1.0% octoxynol 9, reduced the mean diameters by only 29 and 13%, respectively. Plots of average droplet size *versus* octoxynol 9 concentration level off at ~0.4% (Fig. 1).

Aging of the emulsions at room temperature or at 37° or 50° produced minor, but consistent, increases in droplet size (compare emulsions 1–5 and 7–10). The reverse-addition procedure resulted in smaller droplet sizes than direct addition. This fact is to be expected because, during the preliminary emulsification and the homogenization, the ratio of octoxynol 9 to hexadecane was twice as large in the reverse-addition procedure. Moreover, in the reverse addition, as opposed to direct addition, the entire volume of the emulsion was subjected to homogenization. Furthermore, all emulsions, regardless of the volume fraction of oil, were quite fluid: their relative viscosities were only ~2. Therefore, the shear stress during homogenization of the direct-addition emulsion, which at that point had twice the hexadecane concentration as the reverse-addition emulsion, was not substantially greater. A few hexadecane–water emulsions prepared by direct addition but containing 10% hexadecane had mean diameters comparable with standard 25% hexadecane emulsions prepared under identical conditions.

The purpose of this investigation was to compare the effect of various salting-in and salting-out electrolytes on emulsion stability. Therefore, electrolytes were employed at concentrations corresponding to comparable salting-in and salting-out efficiencies. When their solubilities permitted, the effect of salting-out electrolytes was compared at concentrations at which they lowered the cloud point of octoxynol 9 by 35° in the absence of hexadecane, *i.e.*, from 65° to 30°. Such a concentration is 0.40 *m* for sodium sulfate and 2.20 *m* for sodium chloride.

The effect of salting-in electrolytes was investigated mainly at concentrations at which they raised the cloud point of octoxynol 9 by 30° in the absence of hexadecane. These concentrations are 3.0 *m* for sulfuric and hydrochloric acids and 1.80 *m* for sodium thiocyanate (1). The corresponding magnesium nitrate concentration, 4.25 *m*, is too close to the solubility limit, so this salt was studied at 2.00 *m*. Higher and lower concentrations for all electrolytes were also investigated.

The effect of electrolytes is described first for emulsions stored at 25°. Comparison of the average diameters in Tables I and II illustrates two surprising facts. All hexadecane emulsions were remarkably stable towards electrolytes, even at 1–3 *m* concentrations. Neither salting-in nor salting-out electrolytes produced major changes in droplet size.

Since most emulsions became slightly but consistently coarser on aging, the average diameters were compared for emulsions of approximately the same age. When examining the effect of additives, emulsions were always compared at equal octoxynol 9 concentrations since this was the most important factor affecting droplet size.

For a few emulsions prepared by direct addition, electrolytes actually produced smaller droplets than blank emulsions without additives. For instance, emulsions 17–20 with added electrolytes have smaller D_a and D_{vs} values than emulsion 1 (blank). For most emulsions, the changes in droplet size produced by various additives were minor. The following emulsions have nearly identical values for D_a and D_{vs}, respectively: 6 (blank) and 23 and 24; 7 (blank) and 36, 39, 41, 44, 52, and 59; 8 (blank) and 27, 29, 34, 37, 45, 50, and 55; and 11 (blank) and 62 and 63.

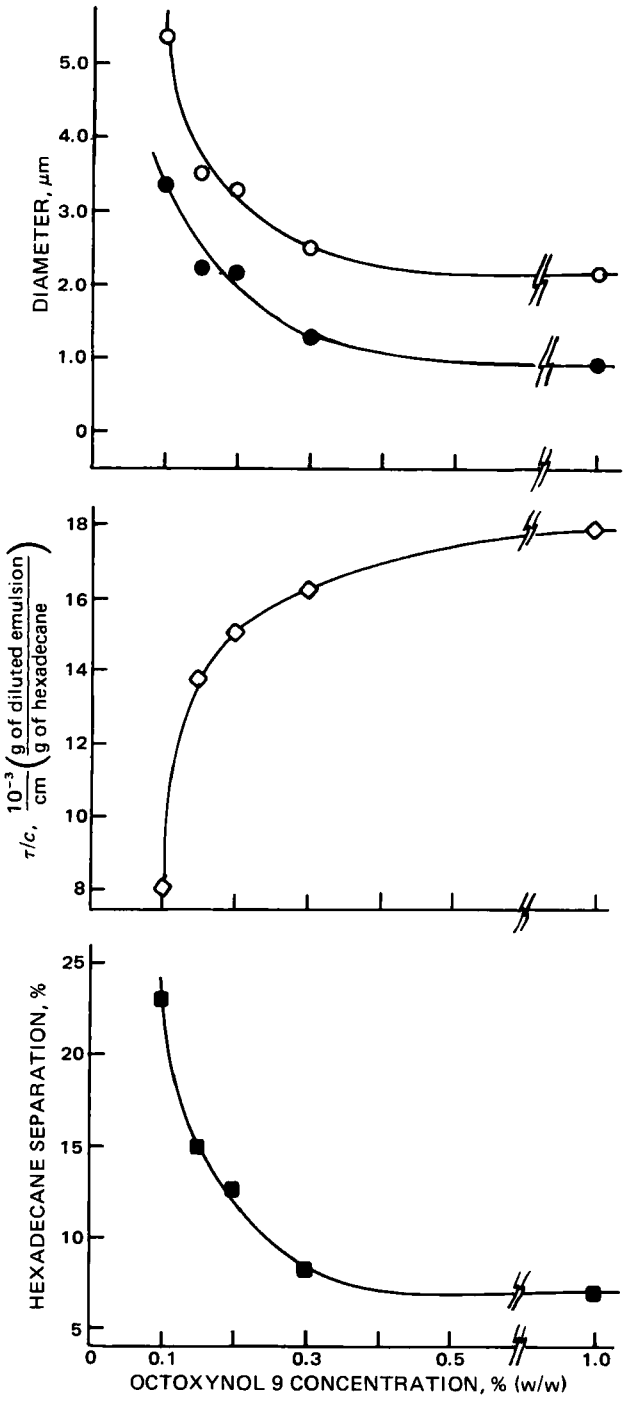

Figure 1—*Effect of octoxynol 9 concentration on mean volume–surface diameter, D_{vs}, arithmetic mean diameter, D_a, specific turbidity, τ/C, and hexadecane separation in the centrifuge. Key: (○) D_{vs}; (●) D_a; (◇) τ/C; (■) hexadecane separation.*

Where additives were investigated at several concentrations, no consistent trend of either increasing or decreasing average droplet sizes with increasing additive concentration are noticeable. This observation holds for the salting-in additives hydrochloric acid (compare emulsions 26, 28, 30, 33, and 36; 27, 29, 31, 34, and 37; and 32, 35, and 38), aluminum nitrate (compare emulsion 39 with 41 and 40 with 43), and magnesium nitrate (compare emulsion 44 with 47 and 46 with 48) as well as for the salting-out additives sodium chloride (compare emulsions 49, 52, and 54; also 51, 53, and 56) and sodium sulfate (compare emulsion 57 with 59).

The difference between the effect of salting-in and salting-out electrolytes on droplet size are clear-cut only in the case of emulsions prepared by reverse addition. Emulsions containing the salting-in complexing electrolytes sulfuric acid and magnesium nitrate had about the

same D_a and D_{vs} values, respectively, as emulsions without additives [compare emulsion 13 (blank) with 68, 69, and 71; and 14 (blank) with 70].

The two salting-out electrolytes sodium chloride and sodium sulfate produced coarser emulsions by reverse addition than the blanks [compare emulsions 13 (blank) with 74 and 76; and 14 (blank) with 75 and 77]. Sodium thiocyanate, which salts in octoxynol 9 by destructuring water, had an intermediate effect on droplet size (compare emulsions 13 with 72 and 14 with 73).

Emulsions stored above room temperature were gently inverted nearly once a day to redisperse the creamed layer throughout the entire volume. Mean droplet diameters are listed in Table III. As was observed for emulsions prepared by direct addition stored at 25°, both salting-in and salting-out additives produced only minor changes in droplet size [compare emulsions 2 and 4 (blanks) with 79 and 80; also 10 (blank) with 81–95]. Storage at 50° for 22 days (not listed in Table III) resulted in only slightly larger droplet sizes than storage for 7–9 days, with D_a increasing, on the average, 14% and D_{vs} 8%.

[a] Storage temperature in parentheses. [b] Arithmetic mean diameter. [c] Mean volume–surface diameter defined by Eq. 1. [d] Specific turbidity, derived from Eq. 2.

However, prolonged storage at 50° led to partial coalescence for all emulsions containing 0.20% octoxynol 9, ranging from <5% of the amount of emulsified hexadecane for emulsions without additives and those containing hydrochloric acid or sodium thiocyanate to 25–50% for emulsions containing aluminum nitrate within 250 days (see below).

Most xylene emulsions containing 0.60% octoxynol 9 underwent detectable coalescence within a few days at room temperature, separating at least traces of clear xylene. Moreover, they coalesced considerably on dilution with water. Therefore, xylene emulsions were not characterized by microscopic droplet size measurements.

Turbidity—To include any submicroscopic droplets that may have been present, microscopic droplet size measurements were supplemented by turbidity determinations. Turbidity, τ, is the inverse of the light path length, L, that reduces the intensity of a beam of light to $1/e$ of its original value by scattering or absorption (10):

$$\tau = \frac{\ln(I_0/I_{tr})}{L} \qquad \text{(Eq. 2)}$$

The light intensities I_0 and I_{tr} refer to the incident and transmitted beams, respectively. The turbidities of hexadecane–water emulsions were thus calculated from the measured transmittance values by dividing the natural logarithm of the reciprocal of the transmittance by the path length, which was 0.1 cm.

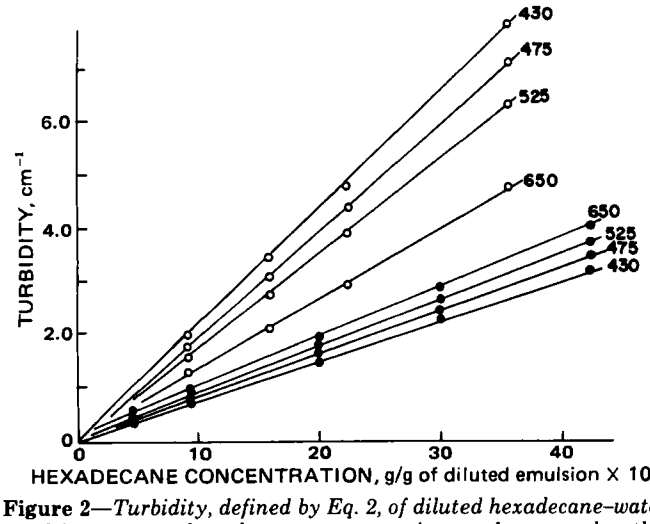

Figure 2—*Turbidity, defined by Eq. 2, of diluted hexadecane–water emulsions* versus *hexadecane concentration at four wavelengths. Numbers on lines designate wavelengths in nanometers. Key: (●) 0.10% octoxynol 9; (○) 1.00% octoxynol 9.*

Plots of turbidity *versus* hexadecane concentration, C, expressed as g of hexadecane/g of diluted emulsion, were straight lines going through the origin. Their slopes equal the specific turbidity, τ/C, expressed in units of (1/cm) (g of diluted emulsion/g of hexadecane). The specific turbidity is, thus, formally analogous to absorptivity, the difference being that the former includes light scattering and absorption whereas the latter, which refers to solutions, involves light absorption only (11).

Specific turbidities were generally calculated from transmittance values at five concentrations by linear regression as the slope of the straight line passing through the origin. Standard deviations of the slope (12) usually ranged from 0.4 to 3%.

At constant oil concentration, smaller droplet sizes result in more opaque emulsions. The specific turbidity is inversely proportional to the mean volume–surface droplet diameter (11, 13, 14) and can be used to assess the effect of additives on the latter.

Figure 2 contains plots of turbidity measured at four wavelengths *versus* hexadecane concentration for two 2-month-old emulsions without additives which were diluted immediately before the transmittance determinations. The upper set of curves represents an emulsion with 1.00% octoxynol 9 (D_{vs} = 2.21 μm) and the lower set represents an emulsion with 0.10% octoxynol 9 (D_{vs} = 5.28 μm). The slopes of the two sets of curves, representing specific turbidity, have the opposite wavelength dependence. The coarser emulsion scattered red light (650 nm) more strongly than violet (430 nm); the specific turbidities increased from violet to blue (475 nm) to green (525 nm) to red. The finer emulsion scattered violet light more strongly than red; the specific turbidities increased from red to green to blue to violet light.

Such a reversal of the wavelength dependence of turbidity is not uncommon. Plots of the total scattering coefficient (K) or of extinction *versus* the droplet size parameter ($\alpha = \pi nD/\lambda$) are sinusoidal (11, 13, 14). In that expression, n is the refractive index of the continuous phase and λ is the wavelength of the light. Hence, for some droplet size ranges, light scattering and turbidity increase as the wavelength increases (a descending branch of the K–α plot). For others, K increases with decreasing λ (an ascending branch).

The reason for selecting blue as the wavelength for subsequent transmittance measurements was that the ratio of the specific turbidities of the two additive-free emulsions containing 1.00 and 0.10% octoxynol 9, respectively, obtained with blue light approaches most closely the inverse ratio of their mean volume–surface diameters. The inverse D_{vs} ratio is 5.28/2.21 = 2.39. The specific turbidity ratios are 1.38, 1.96, 2.37, and 2.84 for red, green, blue, and violet light, respectively. The theoretical inverse D_{vs}–τ/C relationship in the range of droplet sizes encountered in the present work is, thus, most closely obeyed for turbidities measured with the blue light (λ = 475 nm).

It was not possible to measure the transmittance of xylene emulsions. Dilution with an octoxynol 9 solution having the same concentration as the emulsion, namely, 0.60%, reduced the size and number of droplets through micellar solubilization. This octoxynol 9 concentration exceeded the critical micelle concentration almost 40-fold and xylene, as opposed

to hexadecane, is solubilized extensively. Dilution of the xylene emulsions with water resulted in coalescence.

The conclusions derived from the turbidity measurements are similar to those from droplet size determinations, although the inverse proportionality between τ/C and D_{vs} was not always exactly obeyed. The exceptions were caused by changes in droplet size distribution, possibly involving submicroscopic droplets.

The most important factor determining specific turbidity was octoxynol 9 concentration. The major increase in τ/C with increasing surfactant concentration took place at <0.4% (Table I, Fig. 1). Aging produced small, but consistent, decreases in τ/C.

The addition of salting-in and salting-out electrolytes alike produced only minor changes in specific turbidity for emulsions prepared by direct addition. Major differences were observed for emulsions prepared by reverse addition, where emulsions without additives had the highest τ/C values. These values were considerably higher than the τ/C values of direct-addition emulsions without additives having the same 0.10% octoxynol 9 level; they were practically identical with those of direct-addition emulsions containing 0.20% octoxynol 9 (compare emulsion 13 with 1 and 7, and 14 with 2 and 8 in Table I). The near equality of the specific turbidities of the direct-addition blank emulsions containing 0.20% octoxynol 9 and the reverse-addition blank emulsions containing 0.10% octoxynol 9 is ascribed to the fact that both types had the same ratio of octoxynol 9 to hexadecane during the preliminary emulsification and homogenization.

Among the emulsions prepared by reverse addition, those without additives had the highest specific turbidities. Emulsions with sodium thiocyanate and magnesium nitrate (emulsions 69, 71, and 72) had intermediate values, while the remaining additives produced lower specific turbidities that were still larger than those of the corresponding emulsions prepared by direct addition.

Coalescence on Storage—Hexadecane emulsions prepared by direct addition containing 0.20% octoxynol 9 and all additives at the levels listed in Tables III–V were completely stable on storage for 8 months at 25°. Despite extensive creaming, resulting in the separation of concentrated emulsion layers above practically clear aqueous phases, no coalesced hexadecane could be detected. Gentle inversion of the containers readily redispersed the creamed layers, reconstituting intact and uniform emulsions.

Hexadecane emulsions stored at 50° separated cream layers that were viscous. In some samples, coalesced oil became evident after 42 days and more oil separated during the following 80–90 days. During an additional 120–130 days at 50°, the amount of coalesced oil increased only slightly except for emulsions containing aluminum nitrate, which already underwent extensive coalescence during the first 126-day period and which separated substantially more oil subsequently.

The emulsions are ranked below in order of increasing stability. Percentages in parentheses following the formula of the additive represent approximate volumes of coalesced hexadecane, expressed as percent of the total volume of hexadecane in the sample, observed after 126 ± 5 or 250 ± 5 days storage at 50°. When two percentages are listed, the first refers to hexadecane separated after 126 days, the second to separation after 250 days; single percentage values indicate that coalescence did not increase noticeably between 126 and 250 days. Absence of percentage values indicates that, while some hexadecane did coalesce in 126 and 250 days, it amounted to <5%. The ranking on storage at 50° is: 1.40 *m* $Al(NO_3)_3$ (30%, 50%) < 0.50 *m* $Al(NO_3)_3$ (20%, 25%) < 2.00 *m* $Mg(NO_3)_2$ (15%) < 0.50 *m* $Mg(NO_3)_2$ (12%) = 0.50 *m* NaCl (12%) < 0.40 *m* Na_2SO_4 (10%) < 0.20 *m* Na_2SO_4 (8%) < 1.20 *m* NaCl (<5%, 10%) < 2.20 *m* NaCl = blank = 0.10, 0.50, 1.00, 2.00, and 3.00 *m* HCl = 1.50 *m* NaSCN.

Hexadecane emulsions immersed in boiling water were unstable (Table IV). Those without additives, with hydrochloric acid, and with sodium thiocyanate coalesced more slowly than those containing sodium sulfate, aluminum nitrate, magnesium nitrate, and sodium chloride.

Xylene emulsions, despite their higher octoxynol 9 content, had considerably shorter shelf lives than hexadecane emulsions at comparable temperatures. The latter were more stable at 98° than the former at 50°. All four salting-in electrolytes investigated (hydrochloric acid, sodium thiocyanate, magnesium nitrate, and aluminum nitrate) destabilized the xylene emulsions only moderately compared with the blank while both salting-out electrolytes (sodium chloride and sodium sulfate) accelerated their coalescence considerably (Table IV).

Centrifugation Studies—The highest centrifugal speed that the glass tubes could withstand was 10,000 rpm or 7800×*g*. At that speed, 65 min provided optimum discrimination between the variables. Shorter periods, 30 or 45 min, separated smaller amounts of coalesced hexadecane and increased the coefficients of variation. Centrifugation periods of 2 or 4 hr increased the amounts of coalesced hexadecane without enhancing the differences between additives.

The separation of hexadecane did not follow zero-, first-, or second-order kinetics (15) nor the Vold–Mittal empirical equation (16). Therefore, the data presented in Table V are merely the amounts of hexadecane coalesced after 65 min centrifugation, expressed as percent of the total weight of hexadecane in the tube.

When the amount of emulsion containing 25% hexadecane (based on the weight of water) was increased from 7 to 8.5 and to 10 g in preliminary experiments, the percent coalesced hexadecane separated after 65 min centrifugation remained constant for blank emulsions and for emulsions containing each of the various additives. Despite this observation, the measurements presented in Table V were standardized by weighing into each centrifuge tube an amount of emulsion containing 1.80 g of hexadecane.

The driving force that promotes creaming of the emulsions, compression of most of the oil phase into a clear gel layer, and coalescence and separation of oil is directly proportional to the difference in density between the continuous aqueous phase and the oil droplets (10). Hence, at comparable acceleration, the centrifugal force is considerably greater when the aqueous phase is a concentrated and dense electrolyte solution than when no electrolytes were added to the water. To compensate for the increased buoyancy of the oil droplets in dense electrolyte solutions, the percent hexadecane separated (5th column of Table V) was multiplied by the factor $(d_{water} - d_{cetane})/(d_{salt} - d_{cetane})$, where d_{water}, d_{cetane}, and d_{salt} represent the 25° densities of water, of hexadecane (0.771), and of the aqueous electrolyte solutions, respectively. Neglecting the effect of octoxynol 9 on the densities changed the factor by <1%. The corrected hexadecane separation (last column of Table V) shows the intrinsic effects of electrolytes on emulsion stability. This correction generally magnified the trends produced by the various electrolytes shown in the 5th column.

Higher octoxynol 9 concentrations reduced the oil separation because they produced finer emulsions. At comparable octoxynol 9 concentrations, emulsions containing sodium sulfate separated somewhat less

[a] Stored at 25° unless marked by asterisk, indicating storage at 50°. [b] Weight of coalesced hexadecane, expressed as percent of the 1.80 g of hexadecane present per tube, ± SD. [c] Number of measurements. [d] See text for density correction.

hexadecane than emulsions without additives. The extent of hexadecane separation first decreased somewhat and then increased with progressively higher concentrations of sodium chloride at the 0.10% octoxynol 9 level. At the 0.20% level, no significant changes in hexadecane separation were observed beyond 0.50 *m* NaCl.

The salting-in electrolytes lowered the hexadecane separation significantly compared with emulsions without electrolytes of comparable octoxynol 9 concentration, especially those electrolytes which form complexes with octoxynol 9, namely, sulfuric and hydrochloric acids and magnesium and aluminum nitrates. Higher concentrations of these electrolytes resulted in considerably lower hexadecane separation. Only a few percent hexadecane was separated at the highest concentrations of these electrolytes (Table V): 5.00 *m* H_2SO_4, 2.00 *m* HCl only with 0.20% octoxynol 9, 1.50 or 2.00 *m* $Mg(NO_3)_2$, and 0.50 or 1.40 *m* $Al(NO_3)_3$ almost completely prevented coalescence of hexadecane at 7800×*g*. Sodium thiocyanate, which salts in octoxynol 9 by destructuring water, reduced coalescence only slightly.

Aging the emulsions at 25° prior to centrifugation caused small but significant increases in hexadecane separation. Aging at 50° generally produced more extensive separation.

Emulsions without added electrolytes prepared by direct addition separated more hexadecane on centrifugation than emulsions of comparable octoxynol content prepared by reverse addition, in keeping with their smaller droplet size. The presence of all electrolytes except sodium thiocyanate increased the separation of hexadecane during the centrifugation of emulsions prepared by reverse addition when compared with the corresponding emulsions without additives. The salting-out electrolytes sodium chloride and sodium sulfate increased the hexadecane

separation somewhat more for reverse-addition emulsions than for those prepared by direct addition. The major difference between the two types of emulsions occurred with the salting-in complexing electrolytes sulfuric acid and magnesium nitrate, which slightly increased the oil separation during centrifugation of the reverse-addition emulsions while strongly reducing the oil separation of the direct-addition emulsions.

The xylene emulsions employed in the low-speed centrifugation studies of Table VI contained 0.60% octoxynol 9 and were prepared by direct addition. After aging for 30 min at 25°, emulsion quantities containing 1.80 g of xylene were centrifuged for 30 min at 5000 rpm or 1960×*g*. Centrifugation of emulsions containing salting-in complexing electrolytes (hydrochloric acid, magnesium nitrate, and aluminum nitrate) produced a slight amount of clear gel, while the bulk of the emulsified droplets collected in an opaque creamed layer. The other emulsions produced no clear gel at all. Despite this observation, all centrifuged emulsions were stored for 24 hr at 25° prior to removing and weighing the coalesced xylene.

The differences between the effects of the various types of electrolytes during the centrifugation of xylene emulsions were pronounced. Sodium sulfate and sodium chloride, the salting-out electrolytes, caused extensive coalescence. Of the electrolytes which salt the surfactant in by complexation, magnesium nitrate and aluminum nitrate reduced the xylene coalescence even further than the already small extent observed for emulsions without additives, while hydrochloric acid increased it somewhat. Sodium thiocyanate, which salts octoxynol in by destructuring water, caused more extensive coalescence, but still considerably less than the salting-out electrolytes.

Freeze–Thaw Cycles—This technique was not well suited for studying the stability of emulsions containing high concentrations of electrolytes because they creamed rapidly before freezing and because the electrolytes lowered the freezing point of the aqueous phase considerably. Reproducible results were difficult to obtain even when agitating the emulsions while freezing them in a dry ice–acetone mixture. After one freeze–thaw cycle, thawed hexadecane emulsions containing only 0.10% octoxynol 9 were more opaque than emulsions also containing 0.40 *m* Na_2SO_4 or 3.00 *m* H_2SO_4, but the differences between the latter two were only minor. No significant amounts of coalesced hexadecane were observed in any of the thawed emulsions.

DISCUSSION

Shelf Stability—Emulsion stability can be defined in terms of three phenomena: creaming or clearing; flocculation or aggregation; and demulsification, coalescence, or breaking (17). Because of the high density of many of the aqueous electrolyte solutions employed, most emulsions used in this study creamed rapidly. The droplets in the concentrated cream layer preserved their identity, however, and gentle agitation redispersed them throughout the aqueous phase with no change in their size distribution.

Flocculation, another possible measure of instability, was moderate even in the presence of high electrolyte concentrations. By contrast, emulsions stabilized with ionic surfactants are prone to extensive flocculation even at comparatively low electrolyte concentrations, which may lead to coalescence. Instability, as used here, refers to the irreversible coalescence of small droplets into larger drops, resulting eventually in the separation of a clear layer of oil.

Nature of Oil Phase—Hexadecane emulsions prepared by direct addition with high concentrations of salting-in as well as salting-out electrolytes were unusually stable. The differences between the effects of the two types of electrolytes were only minor. Hexadecane emulsions prepared by reverse addition showed some discrimination between electrolytes. Salting-in electrolytes operating through complexation with the ether groups of octoxynol 9 generally increased the emulsion stability, salting-out electrolytes decreased it, while sodium thiocyanate, which salts octoxynol 9 in by destructuring water, was intermediate.

Xylene emulsions prepared by direct addition were considerably less stable than hexadecane emulsions even at a sixfold higher octoxynol 9 level. The electrolyte effects were more pronounced, but qualitatively similar to those observed with reverse-addition hexadecane emulsions.

The large difference in the stability of xylene and hexadecane emulsions based on octoxynol 9 is ascribed to the difference in solubility of the surfactant in the two hydrocarbons. Xylene and octoxynol 9 are miscible in all proportions. The solubility of octoxynol 9 in hexadecane at 25°, determined spectrophotometrically at 277 nm, was ~1.4% (w/v). This value is an upper limit because of the polydispersity of the surfactant and the likelihood that the species with the lowest degree of ethoxylation, *i.e.*, with the highest concentration of the absorbing phenyl group, have the highest solubility in hexadecane and were preferentially extracted from the bulk octoxynol 9.

The fact that octoxynol 9 is miscible in all proportions with the disperse phase as well as the continuous phase of xylene–water emulsions evidently reduced the stability of the interfacial octoxynol 9 films compared with those in hexadecane–water emulsions, where the surfactant is only slightly soluble in the disperse phase. This cause of emulsion instability is unusual because few surfactants are freely soluble in both water and oils.

In the case of xylene–water emulsions, salting-out electrolytes tend to displace octoxynol 9, including the octoxynol 9 forming the interfacial film surrounding the droplets, into the xylene phase. Thereby, these electrolytes were effective in breaking the emulsions. In the case of hexadecane–water emulsions, salting-out electrolytes can displace octoxynol 9 only as far as the hexadecane–water interface, thereby possibly increasing the thickness of the interfacial film. Such a stabilizing effect is probably offset, at least in part, by reduced hydration of the polyoxyethylene moiety of the adsorbed octoxynol 9 film, compressing that film and reducing its effectiveness as a barrier against coalescence. These considerations do not account for the effect of salting-in electrolytes on emulsion stability.

Stabilization Mechanisms and Salt Effects—Nonionic surfactants stabilize aqueous dispersions primarily by steric interactions (18) between the polyoxyethylene moieties of adsorbed surfactant molecules. Electrostatic repulsion plays, at best, a minor role even in the absence of electrolytes (19, 20). At the high and swamping electrolyte concentrations employed in this study, electrostatic forces are unlikely to make any contribution to emulsion stability. Therefore, surface, interfacial, and bulk properties of aqueous solutions of nonionic surfactants containing various electrolytes are examined below for an explanation of the differences between salting-in and salting-out electrolytes, which were especially noticeable in xylene emulsions and in hexadecane emulsions prepared by reverse addition.

The surface areas of polyoxyethylated surfactant molecules adsorbed at air–water or oil–water interfaces depend mainly on the cross-sectional areas of their randomly coiled polyoxyethylene moieties, which are immersed in the aqueous phase (21). Effects of electrolytes on the surface properties of octoxynol 9 and other nonionic surfactants were relatively small (22). In plots of surface tension *versus* the logarithm of concentration, the negative slopes in the region of saturation adsorption were rendered somewhat steeper by the addition of electrolytes at concentrations up to 3 *m*, corresponding to moderate reductions in the surface area per adsorbed surfactant molecule (7). The monolayers of adsorbed surfactant became more closely packed. Salting-in electrolytes produced somewhat larger decreases in surface area than salting-out electrolytes. The largest decreases, observed with cadmium nitrate and sulfuric acid, were 30% (7).

Salting-in electrolytes increased or decreased the plateau surface tensions above the critical micelle concentration by a few dyne/cm at most, and their effectiveness was unrelated to their capacity to raise cloud points (7). Sodium nitrate in concentrations up to 0.1 *M*, calcium nitrate up to 0.01 *M*, and aluminum nitrate up to 10^{-4} *M* produced only minor changes in the interfacial tension of the system chlorobenzene–water containing 1% or 10% of the homogeneous nonionic surfactant hexaoxyethylene glycol monohexadecyl ether (HLB = 10.4) (23).

These observations, which refer to monolayers of surfactants, do not adequately explain the differences between the effects of salting-in and

salting-out electrolytes on emulsion stability. On the other hand, an effect similar to the salt-induced contraction of the polyoxyethylene coils of octoxynol 9 molecules forming interfacial films was observed in bulk with aqueous solutions of high molecular weight polyethylene oxides. Their intrinsic viscosity was reduced by cloud-point-depressing electrolytes, indicating a contraction of their hydrodynamic volume[8] (24). Weaker cloud-point depressants produced smaller reductions in intrinsic viscosity (24), while salting-in electrolytes actually increased the intrinsic viscosity[8].

Another approach to interpreting the effects of electrolytes is in terms of steric stabilization. Steric stabilization of emulsions requires that the free energy change of the overlap interaction between the polyoxyethylene moieties of the surfactant molecules adsorbed on two approaching droplets be positive. The resulting repulsion may overcome the attraction due to London–van der Waals forces (18). The steric repulsion caused by interpenetration of the adsorbed surfactant layers can be ascribed to an entropic (volume restriction) effect due to a decrease in the conformational entropy of the polyoxyethylene chains and/or to a heat of mixing or osmotic effect (18).

It has been suggested that the increase in the heat of hydration and of mixing caused by salts such as sodium thiocyanate, which salt in nonionic surfactants by destructuring water, results in an increase in the enthalpic contribution to the steric barrier against coalescence (25). Electrolytes which salt in octoxynol 9 by complex formation between their cations and the ether groups are likely to cause an increase in the excess osmotic pressure arising from the overlap of the polyoxyethylene layers of two approaching droplets. An equivalent concept is that these electrolytes increase the positive value of the second virial coefficient of aqueous polyoxyethylene solutions, thereby increasing the repulsion between the polyoxyethylene layers surrounding the droplets (*cf.* Eq. 57 of Ref. 18).

The difference in the effects of salting-in and salting-out electrolytes on the stability of hexadecane emulsions prepared by direct and reverse addition indicates that the interfacial octoxynol 9 films were profoundly affected by the order of addition. This behavior, while not unusual in systems that are intrinsically unstable, is not readily explained by steric stabilization. If the interfacial octoxynol 9 film consisted of multilayers, the observed effects could be ascribed to the formation of a liquid crystalline phase at the hexadecane–water interface (26).

In this connection, it is of interest to estimate the thickness of the layer of octoxynol 9 adsorbed at the surface of the hexadecane droplets. The limiting cross-sectional area per octoxynol 9 molecule adsorbed at the isooctane–water interface is obtained from the bottom curve of Fig. 8 of Ref. 27, which is a plot of the interfacial tension, $\gamma_{O/W}$, *versus* the molar concentration, C_2, of octoxynol 9. The plot is linear from 10^{-5} M to the critical micelle concentration, indicating that saturation adsorption prevailed over that concentration range. The equation of the linear portion, obtained by regression analysis from the data points on the graph, is:

$$\gamma_{O/W} = -31.52 - 4.857 \ln C_2 \qquad \text{(Eq. 3)}$$

Using the value of the slope, $d\ \gamma_{O/W}/d \ln C_2 = -4.857$ in the Gibbs adsorption equation results in an area of 84.7 Å^2 per molecule of adsorbed octoxynol 9 at saturation adsorption, *i.e.*, in a close-packed monolayer.

The standard hexadecane emulsions contained 25 g of hexadecane per 100 g of water. Those with 0.10% octoxynol 9 had $D_{vs} = 5.28 \times 10^{-4}$ cm, which corresponds to an interfacial area of 367,000 cm^2. Assuming that all surfactant molecules in excess of the critical micelle concentration (0.016%) are adsorbed at the oil–water interface, 100 g of a 0.10% octoxynol 9 solution contains 0.084 g of surfactant available for adsorption. This amount covers 686,000 cm^2, *i.e.*, enough for 1.87× a monolayer, or nearly a bilayer of close-packed octoxynol 9 molecules.

The curves in Fig. 1 tend to level off at ~0.4% octoxynol 9, corresponding to $D_{vs} = 2.28$ μm. At that point, the amount of octoxynol 9 present exceeds that needed to cover the emulsion droplets with a close-packed monolayer by a factor of 3.7. This value is approximate because the area per octoxynol 9 molecule in an adsorbed multilayer is unlikely to be the same as that in a monolayer. The surfactant films surrounding the droplets, having a thickness of ~4 molecules, could well form a liquid crystalline interphase which, though birefringent, is too thin to be visible under the microscope between crossed polarizer and analyzer.

[8] Hans Schott, unpublished data.

Centrifugal Stability—The first stage in the centrifugation of common oil–water emulsions is the separation of an opaque creamed layer containing all of the oil droplets from a lower clear aqueous layer. Emulsions containing high electrolyte concentrations cream even on standing.

In high centrifugal fields, such as the 7800×g used here, the spherical oil droplets are probably pressed so close together in the cream layer that they become distorted into polyhedra similar to foams. The centrifugal force then squeezes liquid from the flattened aqueous lamellae separating the oil droplets, which drains through Plateau borders. Coalescence occurs on rupture of the interfacial octoxynol 9 films, resulting in the separation of a clear oil layer (28, 29).

In the course of centrifugation of the hexadecane emulsions, the opaque white cream layer changed within minutes almost completely into a new phase, namely, a transparent gel layer, which propagated from the bottom to the top. Coalescence of hexadecane droplets, resulting in the formation of a clear oil supernatant, occurred slowly from this transparent gel plug.

Despite extensive studies of ultracentrifugation of emulsions by Vold's group (15), Garrett (30), and Rehfeld (31), only brief mention is made (30) of a "translucent cream" above the opaque cream layer. The transparent gel observed in the present work apparently was not detected previously because it is as clear as the coalesced oil and, since it consists of almost pure oil, has almost the same refractive index. The boundary between gel and coalesced hexadecane is faint and becomes evident only to the touch, on separating the layers. Thus, it took a preparative rather than an analytical ultracentrifuge to detect the clear gel.

This gel, unlike the viscous opaque cream layers compacted by centrifugation, had a substantial yield value. Its plastic viscosity was low. Even though the gel consisted mainly of hexadecane, water was the continuous phase. When the centrifuge tubes containing hexadecane emulsions were stored after centrifugation, the clear gel plugs reverted to opaque cream layers as the aqueous phase diffused into them from below.

When pieces of gel were immersed in aqueous solutions, they slowly disintegrated to fluid emulsions. The hexadecane droplets preserved their identity and remained intact in these gels, as shown by the following set of experiments. Gels were prepared by centrifuging standard hexadecane emulsions containing 0.20% octoxynol 9 and either no electrolyte, or 2.00 m HCl, or 0.40 m Na_2SO_4. When these gels were redispersed in aqueous media of the same composition as those of the original emulsions, the mean volume–surface diameters of the reconstituted emulsions were 3.66 μm for the blank, 3.38 μm in 2.00 m HCl, and 4.75 μm in 0.40 m Na_2SO_4. These diameters are only 23, 5, and 49% larger, respectively, than the D_{vs} values of the original emulsions (Table II).

The gels were transparent and isotropic; they showed no birefringence when examined between crossed polarizer and analyzer. The individual oil droplets could not be distinguished under the microscope. These facts indicate that the thickness of the aqueous lamellae separating the distorted hexadecane droplets in the gels was considerably smaller than the wavelength of light. Thus, light passing through the clear gels underwent little or no refraction.

The chief driving force for the penetration of water or of aqueous solutions of octoxynol 9 and electrolytes into the gel plugs, transforming them back into cream layers and eventually redispersing them into dilute emulsions, is probably the osmotic or enthalpic component responsible for the steric stabilization of emulsions. Centrifugation of the cream layers squeezed the aqueous lamellae between distorted, polyhedral oil droplets down to a thickness of a few nanometers, causing compression or interpenetration of the polyoxyethylene moieties of the octoxynol 9 molecules adsorbed on adjacent droplets. The aqueous lamellae thus contained a high concentration of polyoxyethylene chains, *i.e.*, they were hypertonic compared with the bulk aqueous phase. Elastic retractive forces tending to expand the compressed polyoxyethylene chains and interfacial tension tending to restore the spherical droplet shape probably contributed somewhat to the penetration of aqueous media into the gel plugs.

In connection with the osmotic effect, it is significant that gels made from emulsions containing 0.20% octoxynol 9 plus 2.00 m HCl were somewhat more stable than gels formed from emulsions containing octoxynol 9 only, whereas gels from emulsions containing 0.20% octoxynol 9 plus 0.40 m Na_2SO_4 were less stable, separating some hexadecane on standing. The former gels probably had somewhat thicker lamellae than gels prepared from emulsions without electrolytes due to the presence of hydrochloric acid molecules bound to the ether groups of octoxynol 9 forming an oxonium compound. The latter gels probably had thinner aqueous lamellae owing to the salting-out effect of sodium sulfate.

The observation that stability measurements by centrifugation and

by the other methods were not in complete agreement is ascribed to the complex sequence of steps occurring during the former. The correlation between long-term shelf stability of emulsions and their resistance to high-speed centrifugation was not sufficiently good to make the latter a reliable technique for predicting the former (32, 33).

X-ray Structural Studies and Physicochemical Properties of Cimetidine Polymorphism

MEGUMI SHIBATA ˣ, HIROMASA KOKUBO, KAZUHIRO MORIMOTO, KATSUAKI MORISAKA, TOSHIMASA ISHIDA, and MASATOSHI INOUE

Received April 2, 1982, from the *Osaka College of Pharmacy, 2-10-65 Kawai, Matsubara-City, Osaka 580, Japan.* Accepted for publication October 7, 1982.

Abstract □ Four crystalline forms of cimetidine, three anhydrous (forms A, B, and D) and a monohydrate (form C), obtained by slow evaporation of aqueous solutions of varying concentrations were characterized by IR spectroscopy, X-ray powder patterns, dissolution rates in deionized water, and thermal analyses. Among the three anhydrous forms of cimetidine, form A was thermodynamically more stable than the others. The structural conversion of form C into form A on dehydration was confirmed by IR spectroscopy and X-ray powder patterns. The structures of forms C and D were determined using X-ray diffraction. Form D was of spirally curled conformation; it was linked in a head-to-tail arrangement with the neighboring molecules *via* intermolecular hydrogen bonds between the imidazole nitrogen and guanidine nitrogen atoms. Form C was characterized by its folded conformation due to the weak stacking interaction between the imidazole and guanidine moieties; there was stabilization by double hydrogen bond formation with neighboring molecules and *via* water molecules of crystallization. The dissolution rate constant in deionized water for form C was ~1.29, 1.70, and 1.90 times greater than those measured for forms A, D, and B, respectively. There was a similar relationship among the four forms with respect to the rates of inhibition of stress ulceration. Regarding the molecular conformations of the crystalline forms and the rates of inhibition of stress ulceration, the *gauche* orientation of the guanidine group relative to the imidazole ring would be the conformation necessary for effective binding to the histamine H_2-receptor. The compactly folded conformation of form C appears to be optimal for binding to the active site of the receptor and for clinical efficacy.

Cimetidine, *N″*-cyano-*N*-methyl-*N′*-[2-[[(5-methyl-1*H*-imidazol-4-yl)methyl]thio]ethyl]guanidine, a specific competitive histamine H_2-receptor antagonist, inhibits the secretion of histamine-stimulated gastric acid. Because of its minimal side effects, it is widely used in the treatment of human peptic ulcers (1). Cimetidine has different crystalline forms (polymorphism) when crystallized under various conditions (2, 3). Since the bioavailability of

0022-3549/83/1200-1436$01.00/0

pharmacologically active compounds is generally dependent on their crystalline forms (4), detection of the most active among the cimetidine crystalline forms is important for understanding the specific stereochemistry of the H_2-receptor and for the effective clinical use of the agent.

This paper reports the physicochemical properties of four cimetidine crystalline forms (A, B, C, and D) obtained from aqueous solutions at different sample concentrations. The different forms were characterized by determining melting points, IR spectra, X-ray powder patterns, thermal behavior, and dissolution rates. The crystal structures of forms C and D were determined by X-ray diffraction.

EXPERIMENTAL

Preparation of Cimetidine Crystalline Forms—The preparation of the crystalline forms of cimetidine has been reported previously (3); crystallization from organic solvents such as acetonitrile produced platelet crystals, and crystallization from aqueous solutions produced three crystalline forms. Four crystalline forms were obtained by slow evaporation of the aqueous solutions; these were platelet (form A), needle (form B), pyramidal (form C), and cubic (form D) crystals. The cimetidine concentrations used for the preparation of crystal forms A, B, C, and D were 80, 10–40, 150, and 2–10 mg/ml, respectively[1]. The solutions were placed inside covered beakers and allowed to evaporate slowly at room temperature (25°; forms A, B, and D) or at 4–6° (form C). After 3–4 weeks, well-formed crystals were obtained; the crystalline forms were confirmed to coincide with those reported previously (3) by comparison of their respective IR spectra.

IR Spectra and Thermal Analyses—IR spectra were measured by using potassium bromide disks[2]. Gravimetry and the calorimetric changes accompanying the thermal decomposition were measured by thermogravimetry (TG) and differential thermal analysis (DTA) instruments[3]. The TG and DTA profiles were measured using 20 mg of powdered samples; the heating rate was 5°/min.

X-ray Powder Patterns—X-ray powder patterns were measured by the permeance method, using a diffractometer[4] and copper Kα radiation. The powder pattern of each crystalline form was measured twice and averaged.

X-ray Data Collection of Crystalline Forms C and D—Preliminary oscillation and Weissenberg photographs showed both crystal systems to be monoclinic (Table I). The density of both crystals was measured by the flotation method in benzene–carbon tetrachloride. A single crystal (0.3 × 0.3 × 0.4 mm, form C; 0.5 × 0.4 × 0.3 mm, form D) was mounted on a computer-controlled four-circle diffractometer[5]. Intensity data on 2305 (form C) and 2138 (form D) independent reflections [$Fo \geq 3\sigma(Fo)$] were obtained using graphite-monochromated copper Kα radiation and the $\omega - 2\theta$ scanning technique ($\sin\theta/\lambda \leq 0.588$ Å^{-1}). The scan speed was 4°/min; the background was measured for 5 sec. The intensity of four standard reflections for the respective crystals, measured every 100 reflections, showed no structural deteriorations due to X-ray irradiation during the measurement of all reflections. Corrections were applied for the Lorentz and polarization factors, but not for the absorption effects.

Structure Determinations and Refinements—The structures of forms C and D were solved by the direct method using the MULTAN 78 program (5). An electron density map using the normalized structure factors (E), computed with the phase set having the highest figure of merit using 180 reflections with $|E| \geq 1.57$ (form C) or 170 reflections with $|E| \geq 1.73$ (form D), gave reasonable positions for all nonhydrogen atoms. The atomic coordinates were refined by the block-diagonal least-squares method with anisotropic temperature factors. The positional parameters of all hydrogen atoms could be determined from a difference Fourier map.

Refinement, including those parameters with isotropic temperature factors, was then continued. The quantity minimized was $\Sigma\omega(|Fo| - |Fc|)^2$; in the final refinement, the following weighting scheme was used: for form C, $w = 0.24$ for $Fo = 0.0$, $w = 1.0$ for $0 < Fo \leq 11.0$, and $w = 1.0/[1.0 + 0.112(Fo - 11.0)]$ for $Fo > 11.0$; for form D, $w = 1.0$ for $0 < Fo \leq 9.0$ and $w = 1.0/[1.0 + 0.235(Fo - 9.0)]$ for $Fo > 9.0$. The final R-value was 0.049 for form C and 0.039 for form D.

The final atomic positional and thermal parameters of form D are given in Tables II and III, respectively[6]. All numerical calculations were performed using the UNICS programs (6)[7]. Atomic scattering factors cited in the *International Tables for X-ray Crystallography* (7) were used.

Measurement of Dissolution Rates of the Four Crystalline Forms in Deionized Water—A schematic drawing of the dissolution apparatus is presented in Fig. 1. Deionized water (46 ml) was introduced into the dissolution chamber outside the cellulose dialysis membrane.[8] Each crystalline form (20 mg, 44–74 μm in diameter), suspended in 4 ml of

[a] The anisotropic temperature factors are expressed in the form: $\exp[-(B_{11}h^2 + B_{22}k^2 + B_{33}l^2 + B_{12}hk + B_{13}hl + B_{23}kl)]$. *SD* in parentheses.

deionized water, was introduced into the membrane. The test solution (550 ml) was placed into the reservoir; the total aqueous solution for measuring the dissolution rate constants was maintained at a volume of 600 ml, in order to retain the sink condition ($C \ll C_s$, where C is the concentration of the used sample and the C_s is the saturated sample).

The dissolution chamber was shaken at 200 strokes/min in an incubator at 37 ± 0.5°. The aqueous solution was circulated with a pump at a flow rate of 9.0 ml/min; the dissolved amount of the drug as a function of time was continuously monitored using a UV spectrophotometer (220 nm).

In addition to this method, the dissolution rate constants of forms A, B, and C were measured by the rotating disk method. These samples were tentatively measured using the compressed disks under several pressures: 454, 908, 1362, 1816, and 2270 kg/cm^2. As the rates of these forms were almost unchanged within the range of 454–2270 kg/cm^2, the experiment was carried out under the pressure that was suitable for making disks. The preparation of the disk samples did not affect the crystalline forms until a pressure of 4540 kg/cm^2 was reached, as verified by IR spectra.

All experiments were carried out under the following conditions. The compressed disk was attached to a holder of matched size in such a manner that only the bottom face of the disk was in contact with the deionized water; the other part of the disk was covered with paraffin. The holder (with disk) was attached to the shaft and set in a flask containing 1000 ml of deionized water; the flask was placed in a constant temperature bath (37 ± 0.5°). The rotating velocity of the disk was 100 rpm. The dissolved amount of the sample was monitored as noted above.

RESULTS AND DISCUSSION

Melting Points and IR Spectra of Four Crystalline Forms—The melting points of the four crystalline forms and their characteristic IR bands are summarized in Table IV. The IR spectra of crystalline forms A, B, C, and D corresponded to forms I, IV, II, and III reported by Pro-

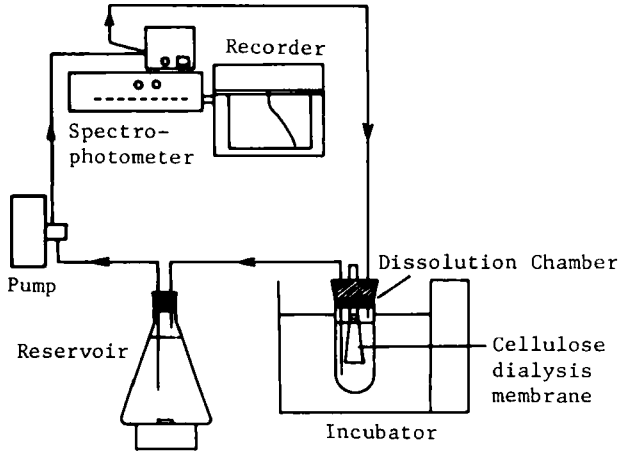

Figure 1—*Schematic drawing of the dissolution apparatus.*

Table IV—Melting Points and IR Spectra of the Four Crystalline Forms

Form	Crystal Form	Melting Point	Characteristic bands, cm^{-1}
A	plate	149–152°	1210 1160 1025 800 765 758 690 670 605 560 540
B	needle	152–154°	2850 1430 1420 1220 1190 1120 1040 650 630 590
C	pyramid	81–83°	3510 3400 3300 1180 1170 1130 1110 880 870 605 470
D	cube	146–147°	3400 3000 2920 2850 1470 1210 1190 1180 1160 1035 515 480

dic-Kojic *et al.* (3). Form C had the characteristic band at 3510 cm^{-1} corresponding to the hydroxyl group; its melting point was lower than that of the other forms, suggesting the presence of water of crystallization. The other crystalline forms, with melting points higher than form C, were anhydrous forms, indicative of the crystalline polymorphism of cimetidine. This point was also confirmed by measuring the X-ray powder patterns (Fig. 2).

DTA and TG Profiles—Figures 3 and 4 show the DTA and TG profiles of the four crystalline forms. In these profiles, the DTA and TG curves represent the thermal change and the percent of weight loss, respectively. In the DTA curves of forms B and D (Fig. 3), the endothermic peaks near 150° corresponded to the respective melting points. Exothermic reactions began near 185°. Although the thermal change behavior was similar, form D appears to be more loosely packed within the crystalline lattice because its endo- and exothermic peaks were smaller than those of form B. This idea is also supported by the difference of their densities [Dm = 1.351(2) g·cm^{-3} for form B and Dm = 1.310(1) g·cm^{-3} for form C].

In the DTA curve of form A (Fig. 4), the endothermic peak near 150° was larger than that of forms B and D. As is obvious from the TG curve below 150°, form A crystal is thermally quite stable; decomposition begins at a temperature >200°. These data suggest that the molecular packing mode of form A is thermodynamically more stable than that of forms B and D.

On the other hand, the DTA and TG curves of form C were very different; there were two endothermic peaks near 80° and 150° in the DTA curve. In the TG curve at 80°, which corresponds to the melting point of this form, the weight loss of one water molecular per cimetidine molecule was observed. Above 80°, the DTA and TG curves of form C were identical to those of form A, suggesting that the structural change of form C to form A was due to the release of water of crystallization. This point was also confirmed by measuring the IR spectra and the X-ray diffraction patterns.

bering. The equations of the least-squares planes for the imidazole ring, C(2)—C(5)—S, S—C(6)—C(7)—N(3), and the guanidine group, the displacement of individual atoms from these planes, and the dihedral angles between the planes are listed in Table V. A stereoscopic drawing of the molecule, projected onto the imidazole ring, is presented in Fig. 6.

Although the observed bond angles were in agreement with those of related histamine H_2-receptor antagonists within their estimated standard errors, the bond length of the thioether linkage in form D, C(5)—S (1.804 Å), was significantly shorter than that of form A (1.828 Å) (8), form

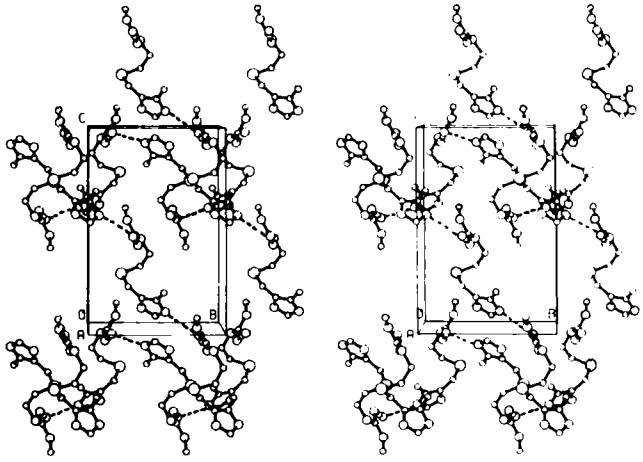

Figure 7—*Stereoscopic drawings of the molecular packing of form D, viewed along the* a*-axis. For the sake of clarity, the hydrogen atoms are omitted. The dotted lines represent the hydrogen bonds.*

C (1.825 Å), metiamide (1.828 Å) (9), and *N*-[2-[(imidazol-4-yl)methylthio]ethyl]-*N″*-methylthiourea (thiaburimamide) (1.829 Å) (9); the C(8)—N(5) bond length of the guanidine group (1.337 Å) is also shorter than that of form A (1.346 Å) and form C (1.343 Å). As in the related molecules, the imidazole ring of this crystal is planar with a maximum shift of 0.004 Å for the C(1) and the N(2) atoms; and C(4) and the C(5) atoms lie almost on this plane. The guanidine group is also planar with a maximum deviation of 0.006 Å for the C(8) atom; the C(7) atom lies essentially on the plane.

As is obvious from Fig. 6, the molecule can be characterized by its spiral-shaped conformation. The dihedral angle between the imidazole ring and the guanidine group is 54.1(1)°; both moieties are linked to each other by the C(5)—S—C(6)—C(7)—N(3) bond sequence manifesting the spirally curled arrangement with an ~360° rotation.

Crystal Packing of Crystalline Form D—The molecular packing viewed down the *a*-axis is shown in Fig. 7; the hydrogen bonding parameters and the short contacts <3.5 Å are listed in Table VI. The molecules are linked *via* intermolecular hydrogen bonds with the imidazole and guanidine nitrogen atoms of neighboring molecules, N(1)—H(N1)···N(6) = 2.988(2) Å and N(3)—H(N3)···N(6) = 2.959(2) Å, thereby forming head-to-tail molecular arrangements in the *b*- and *c*-directions. Many short contacts were observed between neighboring imidazole rings, between neighboring guanidine groups, and between the neighboring imidazole ring and guanidine group. These short contacts stabilize the molecular packing in the crystal.

Molecular and Crystal Structure of Form C—Since the present crystal determination showed the molecular and crystal structure of form C to be identical with that reported by Prodic-Kojic and Ruzic-Toros (10), the structural features observed in the crystal will be presented briefly. The molecular conformation in this crystal is characterized by the folded form resulting from the weak stacking interaction between the imidazole and guanidine moieties. The dihedral angle between both planes is 10.8(2)°; their mean interplanar spacing is 3.676 Å. This conformation is further stabilized by the hydrogen bond formed by the water of crystallization [N(1)···O = 2.383(7) Å, N(6)···O = 3.064(8) Å]. In the crystal packing, the water of crystallization is further hydrogen bonded to the N(2) atom of the neighboring imidazole ring [N(2)···O = 2.800 (7) Å]. The infinite double layers, found by these three hydrogen bonds by water of crystallization and a N(6)···N(3) hydrogen bond [3.034(8) Å], are arranged parallel to the *a*- and *b*-directions and are held together by van der Waals contacts in the *c*-direction.

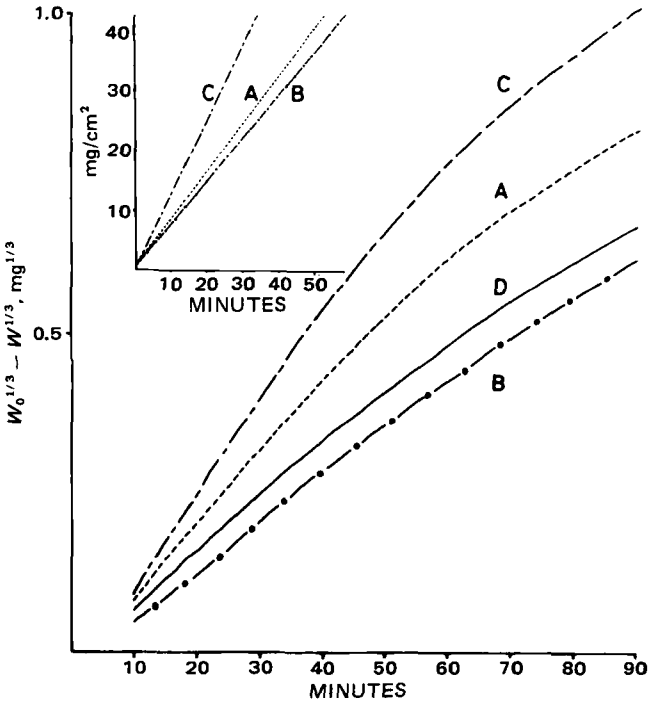

Figure 9—*Dissolution profiles of the four crystalline forms in particle systems and those of the three crystalline forms in disk systems (inset).*

prepared from aqueous solutions at different sample concentrations, the energetic stability of their molecular conformations (Fig. 8) appears to be the same. The conformations of forms A, C, and D are characterized by an intramolecular hydrogen bond formation, leading to the formation of a stable 10-member ring (form A), by a weak stacking interaction between the imidazole and guanidine moieties which is further stabilized by the hydrogen bond formation by water of crystallization (form C), and by a spiral conformation (form D).

Based on extended Hückel molecular orbital calculations of various related agonists, Kier (11) proposed that the conditions necessary for the H_2-receptor activity of histamine are: (*a*) distance between the N(2) atom of the imidazole ring and the nitrogen atom of the side chain is near 3.6 Å and (*b*) the orientation of the nitrogen atoms with respect to the imidazole ring is *gauche*. Durant *et al.* (12) reported that the introduction of an unchanged side chain such as the cyanoguanidine group into the imidazole ring is more effective for binding to the histamine H_2-receptor.

Table VIII lists the intramolecular distances between the N(2) atom of the imidazole ring and the N(3), N(4), or N(5) atom of the cyanoguanidine group, and the orientation between the two moieties in the cimetidine molecules. The *gauche* orientation of the guanidine group with respect to the imidazole ring is observed in forms A and C; their intramolecular N—N distances are in the range of 2.881–5.061 Å for form A and 3.836(7)–4.416(8) Å for form C. On the other hand, form D takes a *trans* orientation; the distance in this form ranges from 5.584(2) to 7.378(2) Å. According to the proposal of Kier (11), the molecular conformation of form A or C would probably be the conformation necessary for effective binding to the histamine H_2-receptor. The conformation of form C, which has an N—N distance of ~3.6 Å and *gauche* orientation, appears to be the most highly preferred conformation for binding to the active site of the receptor, although the energetically stable 10-member ring of form A, effected by an intramolecular hydrogen bond, was also found in the related H_2-receptor antagonists, metiamide (9) and *N*-[4-(imidazol-4-yl)butyl]-*N'*-methylthiourea (burimamide) (13).

Table IX—Effects of Four Crystalline Forms for Stress Ulceration in Rats

Dose, mg/kg	Mean Area of Ulcer, mm^2	Inhibition Rate, %
Control	22.3 ± 4.3	
Form A		
12.5	6.9 ± 2.1	69.3
25.0	5.9 ± 2.4	73.7
50.0	3.4 ± 2.3	84.4
Form B		
12.5	8.7 ± 4.8	60.8
25.0	3.2 ± 1.1	85.5
50.0	3.6 ± 2.2	84.0
Form C		
12.5	2.8 ± 1.7	87.4[a]
25.0	3.2 ± 1.1	85.8
50.0	2.2 ± 0.9	90.4
Form D		
12.5	8.0 ± 2.6	64.1

[a] $p < 0.05$ relative to the same dose of form A or B.

Dissolution Rates of the Four Crystal Forms and Their Efficacy in Preventing Stress Ulceration—The dissolution profiles measured by disk and particle methods are shown in Fig. 9. The rotating disk preparation was carried out under a pressure of 1362 kg/cm^2. The dissolution rate constants of forms A, B, and C were 0.81(6), 0.74(4), and 1.24(6) mg/cm^2/min, respectively; that of form C is ~1.53 and 1.68 times greater than those of forms A and B[9]. In the particle system, the dissolution rate can be expressed in terms of the Hixson–Crowell law (14), $W_0^{1/3} - W^{1/3} = Kt$, where W_0 is the initial weight of drug, W is the undissolved weight at time t, and K is the apparent dissolution rate constant. Up to 40 min, the profiles appear to be linear, suggesting that application of the Hixson–Crowell law is valid for measuring the dissolution rate of cimetidine. The dissolution rate constants of form A, B, C, and D during the 40-min period were 1.16(4), 0.79(1), 1.50(5), and 0.88(6) × 10^{-2} $mg^{1/3}$/min, respectively. The rate constant for form C is ~1.29, 1.70, and 1.90 times greater than those for forms A, D, and B, respectively. The results obtained by these two different methods show clearly that form C is more soluble in deionized water than the other forms. This relationship has also been observed in the difference of their solubilities [5.4(1), 4.7(1), 5.8(1), and 5.0(1) g/liter for forms A, B, C, and D, respectively, at 25°] and in gastric juice[10].

The effect of the four crystalline forms on rat gastric ulcers produced by restraint and water-immersion stress was also examined[11]. The animals received a peroral dose of 12.5, 25.0, or 50.0 mg/kg of the respective crystalline form before water immersion. The inhibition rate of the drug on the development of stress ulcers was calculated as follows:

$$\text{Inhibition rate (\%)} = 100 \times \frac{Mc - Mt}{Mc}$$

where Mc is the mean of the total ulcer area for rats in the control group (n = 12) and Mt is the mean of the total ulcer area in the test groups (n = 6/crystalline form). The Student's t test was used to determine the statistical significance of data obtained in this study. The results are given in Table IX; full details of this experiment will be reported elsewhere. Form C, especially at the lower dose which corresponds to that used clinically, exhibited significant inhibition of stress ulceration; results of the t test at the 12.5-mg/kg dose showed that form C was significantly more effective than forms A, B, and D.

Volume Shifts and Protein Binding Estimates using Equilibrium Dialysis: Application to Prednisolone Binding in Humans

THOMAS N. TOZER, JOHN G. GAMBERTOGLIO ˣ, DANIEL E. FURST, DENIS S. AVERY, and NICHOLAS H. G. HOLFORD

Received November 19, 1981, from the *Schools of Pharmacy and Medicine, University of California, San Francisco, CA 94143.* Accepted for publication October 21, 1982.

Abstract □ Sizable volume shifts can occur during equilibrium dialysis. This net movement of water, presumably caused by the osmotic effect of plasma proteins, reduces the concentration of binding proteins. In this paper the theory of protein binding estimation is extended, equations are developed for calculating the unbound and bound drug concentrations at dialysis equilibrium by correcting for the dilution of the proteins, and the equations are applied to a study of prednisolone. To demonstrate the importance of correcting for the volume shift, the parameters of a model in which prednisolone binds to corticosteroid-binding globulin, a protein with a limited capacity, and albumin were estimated. Unbound and bound concentrations were determined by correcting for both volume shifts (average 31%) and loss of drug to the buffer side, by correcting only for loss of drug to buffer side, and by making no correction at all (the usual method of treating equilibrium dialysis data). The error introduced by neglecting volume shifts was analyzed by comparing the parameter values obtained using the three methods. The results confirm the need to adjust for volume shifts and imply that reported binding constants obtained by equilibrium dialysis may be in error for many substances.

Keyphrases □ Equilibrium dialysis—measurement of protein binding, effect of volume shifts, theoretical model, application to prednisolone in humans □ Protein binding—determined by equilibrium dialysis, effect of volume shifts, theoretical model, application to prednisolone in humans □ Prednisolone—protein binding as determined by equilibrium dialysis, effect of volume shifts, application of theoretical model, humans

Binding of drugs to plasma proteins is important in pharmacokinetics and pharmacodynamics. Equilibrium dialysis is commonly employed for estimation of binding, but it has limitations. With the introduction of translucent cells, it has become evident that sizable volume shifts occur across the dialysis membrane. We have investigated the importance of these volume shifts in the estimation of plasma protein binding parameters and have developed a procedure to correct for them. The procedure is applied to a study of prednisolone in humans.

The binding of prednisolone in plasma is thought to involve two proteins, corticosteroid-binding globulin (transcortin) and albumin. In the range of concentrations associated with therapy (1), the plasma protein binding of prednisolone is concentration dependent largely because of saturable binding to sites on corticosteroid-binding globulin. It has been shown *in vitro* that glucocorticoid activity is a function of unbound concentration and that the activity can be altered by the addition or removal of the globulin (2). Definition of concentration–effect relationships for prednisolone, therefore, requires the ability to estimate unbound prednisolone concentrations. Estimates of unbound concentration *in vivo* can be obtained by measurement of total prednisolone concentration (bound plus unbound) and application of a suitable model for predicting the unbound concentration from the total concentration.

There are several complications in the use of equilibrium dialysis to estimate plasma protein binding. These include binding of drug to the dialysis cell or membrane, transfer of substantial amounts of drug from the plasma to the buffer side of the membrane, and osmotic volume shifts of fluid to the plasma side. Some of these problems have been discussed elsewhere (3). In this paper, a method is described for calculating the magnitude of osmotic volume shifts and for estimating the parameters that reflect binding *in vivo*.

THEORETICAL

Figure 1 is a schematic representation of equilibrium in a dialysis device containing plasma on one side and buffer solution on the other, with and without a volume shift. The volume of the plasma side is increased and the buffer side is decreased, because of a net osmotic transfer of water across the membrane. Osmotic equilibrium may or may not be reached at the time equilibrium is virtually achieved with respect to the drug. The derivations which follow assume conservation of the mass of prednisolone in the system and of the total volume of the two half-cells. Symbols and abbreviations are defined in Appendix I.

Conservation of Volume—The total volume of the cell is unchanged by dialysis; therefore:

$$\underset{\text{(before)}}{V_P + V_B} = \underset{\text{(after)}}{V'_P + V'_B} \qquad \text{(Eq. 1)}$$

Letting δ be the fractional increase in V_P due to osmotic water shift, then:

$$V'_P = V_P(1 + \delta) \qquad \text{(Eq. 2)}$$

and

Volume Shifts and Protein Binding Estimates using Equilibrium Dialysis: Application to Prednisolone Binding in Humans

THOMAS N. TOZER, JOHN G. GAMBERTOGLIO ˣ, DANIEL E. FURST, DENIS S. AVERY, and NICHOLAS H. G. HOLFORD

Received November 19, 1981, from the *Schools of Pharmacy and Medicine, University of California, San Francisco, CA 94143.* Accepted for publication October 21, 1982.

Abstract □ Sizable volume shifts can occur during equilibrium dialysis. This net movement of water, presumably caused by the osmotic effect of plasma proteins, reduces the concentration of binding proteins. In this paper the theory of protein binding estimation is extended, equations are developed for calculating the unbound and bound drug concentrations at dialysis equilibrium by correcting for the dilution of the proteins, and the equations are applied to a study of prednisolone. To demonstrate the importance of correcting for the volume shift, the parameters of a model in which prednisolone binds to corticosteroid-binding globulin, a protein with a limited capacity, and albumin were estimated. Unbound and bound concentrations were determined by correcting for both volume shifts (average 31%) and loss of drug to the buffer side, by correcting only for loss of drug to buffer side, and by making no correction at all (the usual method of treating equilibrium dialysis data). The error introduced by neglecting volume shifts was analyzed by comparing the parameter values obtained using the three methods. The results confirm the need to adjust for volume shifts and imply that reported binding constants obtained by equilibrium dialysis may be in error for many substances.

Keyphrases □ Equilibrium dialysis—measurement of protein binding, effect of volume shifts, theoretical model, application to prednisolone in humans □ Protein binding—determined by equilibrium dialysis, effect of volume shifts, theoretical model, application to prednisolone in humans □ Prednisolone—protein binding as determined by equilibrium dialysis, effect of volume shifts, application of theoretical model, humans

Binding of drugs to plasma proteins is important in pharmacokinetics and pharmacodynamics. Equilibrium dialysis is commonly employed for estimation of binding, but it has limitations. With the introduction of translucent cells, it has become evident that sizable volume shifts occur across the dialysis membrane. We have investigated the importance of these volume shifts in the estimation of plasma protein binding parameters and have developed a procedure to correct for them. The procedure is applied to a study of prednisolone in humans.

The binding of prednisolone in plasma is thought to involve two proteins, corticosteroid-binding globulin (transcortin) and albumin. In the range of concentrations associated with therapy (1), the plasma protein binding of prednisolone is concentration dependent largely because of saturable binding to sites on corticosteroid-binding globulin. It has been shown *in vitro* that glucocorticoid activity is a function of unbound concentration and that the activity can be altered by the addition or removal of the globulin (2). Definition of concentration–effect relationships for prednisolone, therefore, requires the ability to estimate unbound prednisolone concentrations. Estimates of unbound concentration *in vivo* can be obtained by measurement of total prednisolone concentration (bound plus unbound) and application of a suitable model for predicting the unbound concentration from the total concentration.

There are several complications in the use of equilibrium dialysis to estimate plasma protein binding. These include binding of drug to the dialysis cell or membrane, transfer of substantial amounts of drug from the plasma to the buffer side of the membrane, and osmotic volume shifts of fluid to the plasma side. Some of these problems have been discussed elsewhere (3). In this paper, a method is described for calculating the magnitude of osmotic volume shifts and for estimating the parameters that reflect binding *in vivo*.

THEORETICAL

Figure 1 is a schematic representation of equilibrium in a dialysis device containing plasma on one side and buffer solution on the other, with and without a volume shift. The volume of the plasma side is increased and the buffer side is decreased, because of a net osmotic transfer of water across the membrane. Osmotic equilibrium may or may not be reached at the time equilibrium is virtually achieved with respect to the drug. The derivations which follow assume conservation of the mass of prednisolone in the system and of the total volume of the two half-cells. Symbols and abbreviations are defined in Appendix I.

Conservation of Volume—The total volume of the cell is unchanged by dialysis; therefore:

$$\underset{\text{(before)}}{V_P + V_B} = \underset{\text{(after)}}{V'_P + V'_B} \qquad \text{(Eq. 1)}$$

Letting δ be the fractional increase in V_P due to osmotic water shift, then:

$$V'_P = V_P(1 + \delta) \qquad \text{(Eq. 2)}$$

and

0022-3549/83/1200-1442$01.00/0

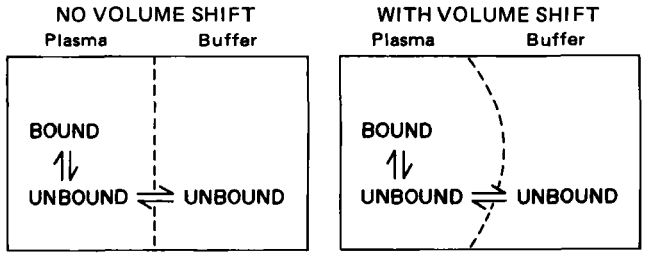

Figure 1—*Schematic diagram of a dialysis cell at equilibrium with respect to drug distribution. Whether there is a volume shift (on right) or not (on left), the unbound concentrations on both sides of the membrane (---) are identical. The amount bound on the plasma side is unchanged, but the bound concentration on the plasma side is decreased as the fluid shifts from the buffer side to the plasma side.*

$$V'_B = V_B - V_P \cdot \delta \qquad \text{(Eq. 3)}$$

Conservation of Mass—The total amount of drug is unchanged by dialysis; therefore $(C_P \cdot V_P + C^*_B \cdot V_B)$ (before) = $(C'_P \cdot V'_P + C'_B \cdot V'_B)$ (after), where C^*_B is the concentration of labeled drug added to the buffer before dialysis. Substituting for V'_P and V'_B using Eqs. 2 and 3 gives $C_P \cdot V_P + C^*_B \cdot V_B = C'_P \cdot V_P(1 + \delta) + C'_B(V_B - V_P \cdot \delta)$. Therefore:

$$C'_P = \frac{C_P \cdot V_P + C^*_B \cdot V_B}{V_P(1 + \delta) + \frac{C'_B}{C'_P}(V_B - V_P \cdot \delta)} \qquad \text{(Eq. 4)}$$

Conservation of Radiolabel—When radiolabeled drug is added to the buffer side before dialysis to produce a concentration of D_B disintegrations/min/ml, then the concentration of radioactivity on the plasma and buffer sides after dialysis are D'_P and D'_B, *i.e.*, $D_B \cdot V_B$ (before) = $(D'_P \cdot V'_P + D'_B \cdot V'_B)$ (after). Substituting for V'_P and V'_B using Eqs. 2 and 3 and solving for δ:

$$\delta = \frac{R \cdot (D_B - D'_B) - D'_P}{D'_P - D'_B} \qquad \text{(Eq. 5)}$$

where R is the ratio of V_B to V_P.

After dialysis, the ratio of unbound drug concentration to total drug concentration (C'_B/C'_P) is the same as the ratio of the radiolabel concentrations (D'_B/D'_P); therefore, Eq. 4 can be simplified by substituting Eq. 5 for δ and by replacing C'_B/C'_P with D'_B/D'_P, giving:

$$C'_P = \frac{(C_P + C^*_B \cdot R)}{R} \cdot \frac{D'_P}{D'_B} \qquad \text{(Eq. 6)}$$

and

$$C'_B = \frac{(C_P + C^*_B \cdot R)}{R} \cdot \frac{D'_B}{D_B} \qquad \text{(Eq. 7)}$$

The bound concentration on the plasma side, C'_{bnd}, is then obtained from the difference between C'_P and C'_B:

$$C'_{bnd} = \frac{(C_P + C^*_B \cdot R)}{R} \cdot \frac{(D'_P - D'_B)}{D_B} \qquad \text{(Eq. 8)}$$

Volume Shift Correction—The amount of drug bound to plasma proteins depends, among other factors, on the amount of binding proteins present and the unbound concentration. At dialysis equilibrium the shift in volume from the buffer side to the plasma side is simply the transfer of buffer solution, containing drug at the unbound concentration, from the buffer to the plasma side as shown in Fig. 1. This transfer does not change the unbound concentration, but the *bound* concentration on the plasma side is decreased by the transfer of fluid. The amount of binding protein is not influenced by the transfer nor is the unbound equilibrium concentration; therefore, the total *amount bound* is the same *with or without* a volume shift.

The theoretical basis of this conclusion has been previously reported (4) for the method of ultrafiltration. In ultrafiltration, plasma filtrate contains drug at the same concentration as that unbound in the plasma. Continued filtration concentrates the protein and the bound drug, but the amount of drug bound remains unchanged. In contrast to ultrafiltration, a volume shift in equilibrium dialysis produces a decrease in the protein and bound drug concentrations as a result of the net transfer of water and unbound drug to the plasma side. In both cases, the concentration of unbound drug remains the same.

Conservation of Amount Bound—The amount bound postdialysis is $C'_{bnd} \cdot V'_P$. From the argument in the previous paragraph, the amount bound if no volume shift had occurred would have been the same. Therefore:

$$C^0_{bnd} \cdot V_P = C'_{bnd} \cdot V'_P \qquad \text{(Eq. 9)}$$

where C^0_{bnd} is the bound drug concentration expected had no volume shift occurred. Substituting for V'_P from Eq. 2 and simplifying:

$$C^0_{bnd} = C'_{bnd}(1 + \delta) \qquad \text{(Eq. 10)}$$

Now substituting for C'_{bnd} from Eq. 8 and for δ from Eq. 5:

$$C^0_{bnd} = \frac{(C_P + C^*_B \cdot R) \cdot [R(D_B - D'_B) - D'_B]}{D_B \cdot R} \qquad \text{(Eq. 11)}$$

Nonlinear Binding—The sum of the estimates of the unbound (Eq. 7) and bound (Eq. 11) concentrations gives the expected total drug concentration in the plasma postdialysis had no volume shift occurred. This value is not the same as the drug concentration in plasma before dialysis, because some drug had been transferred to the buffer during dialysis. To predict the bound and unbound concentrations in the original plasma sample, an appropriate protein binding model, such as the one below (5), must be used:

$$C^0_{bnd} = \frac{CAP_1 \cdot C'_B}{K_{d1} + C'_B} + \frac{CAP_2 \cdot C'_B}{K_{d2} + C'_B} \qquad \text{(Eq. 12)}$$

where CAP_1 and CAP_2 are the binding capacities of two classes of binding protein sites with equilibrium dissociation constants K_{d1} and K_{d2}, respectively. If the concentrations of the binding proteins are measured, CAP_1 and CAP_2 can be expressed as $n_1 \cdot P_1$ and $n_2 \cdot P_2$, where P_1 and P_2 are the concentrations of the binding proteins ($P_1 = P_2$ if both classes of binding sites are on the same protein) and n_1 and n_2 are the numbers of the respective binding sites in each class. If the protein concentrations are not measured, the binding capacities are best expressed as CAP_1 and CAP_2.

If $K_d \gg C'_B$ (as is the case for prednisolone), the model expressed by Eq. 12 reduces to:

$$C^0_{bnd} = \frac{CAP_1 \cdot C'_B}{K_{d1} + C'_B} + S \cdot C'_B \qquad \text{(Eq. 13)}$$

where S is a constant (CAP_2/K_{d2}).

Once the parameters of a model such as Eq. 12 are estimated, the unbound (C_u) and bound (C_{bnd}) concentrations in the original plasma sample can be determined by simultaneous solution of Eq. 13 and the relationship, $C_P = C_{bnd} + C_u$. The unbound and bound concentrations are then:

$$C_u = \frac{C_P - L + \sqrt{(C_P - L)^2 + M \cdot C_P}}{N} \qquad \text{(Eq. 14)}$$

and

$$C_{bnd} = C_P - C_u \qquad \text{(Eq. 15)}$$

where $L = S \cdot K_{d1} + CAP_1 + K_{d1}$, $M = 4 \cdot K_{d1} \cdot (S + 1)$, and $N = 2 \cdot (S + 1)$.

Other Dialysis Systems—The expressions for the unbound (Eq. 7) and bound (Eq. 11) postdialysis concentrations corrected for volume shift are simplified if the initial plasma and buffer volumes are equal, as shown in Appendix II. The relationships for measurement of protein binding when no radiolabel is added are given in Appendix III. Appendix IV provides appropriate relationships for calculating the fraction unbound, a binding parameter commonly used in pharmacokinetics.

Error Introduced by not Recognizing Volume Shifts—The method described above (method I) accounts for volume shifts and for movement of drug from the plasma to the buffer side during dialysis. Behm and Wagner (3) proposed a method for calculating the value of C'_P with the assumption that no volume shift occurs, but accounting for movement of drug from plasma to buffer. On rearrangement and accounting for added radiolabel, their method (method II) becomes:

$$C'_P = \frac{(C_P + C^*_B \cdot R)}{1 + f_u' \cdot R} \qquad \text{(Eq. 16)}$$

where f_u' is the ratio of concentrations of drug (or radiolabel) in the buffer cell to the plasma cell after dialysis (C'_B/C'_P or D'_B/D'_P). Unbound (C'_B) and bound (C'_{bnd}) concentrations are:

$$C'_B = C'_P \cdot f_u' \qquad \text{(Eq. 17)}$$

$$C'_{bnd} = C'_P \cdot (1 - f_u') \qquad \text{(Eq. 18)}$$

A third method (method III) commonly used for protein binding measurements (6), ignores both the volume shift and the shift of drug from the plasma cell to the buffer cell. The unbound and bound concentrations are then given by:

$$C'_B = (C_P + C^*_B \cdot R) \cdot f_u' \quad \text{(Eq. 19)}$$

$$C'_{bnd} = (C_P + C^*_B \cdot R) \cdot (1 - f_u') \quad \text{(Eq. 20)}$$

EXPERIMENTAL

Nine patients who had received kidney transplants volunteered for a comparative bioavailability study of prednisone and prednisolone oral tablets *versus* intravenous prednisolone (1). Plasma samples obtained from this study were stored at −70° before analysis by high-performance liquid chromatography (HPLC) for total prednisolone concentration (7).

The protein binding of prednisolone was determined by equilibrium dialysis, using acrylic plastic equilibrium dialysis cells[1] with a 1-ml maximum capacity/cavity. The membrane employed[2] had a molecular weight cut-off of 12,000–14,000. One-half milliliter of plasma was equilibrated against 0.5 ml of Krebs–Ringer buffer, (pH 7.4, 0.153 *M*), containing 4.5 ng of [6,7-(*n*)-^{3}H]prednisolone (specific activity 43 Ci/mmole)[3]. Dialysis was continued for 16 hr in a shaking incubator[4] at a water temperature of 37°. One-tenth milliliter of dialyzed plasma and 0.1 ml of dialyzed buffer were then transferred to individual glass scintillation vials, to which was added 10 ml of scintillation fluid[5]. After shaking, the vials were counted in a scintillation counter[6]. The counting efficiency was determined by the channels-ratio method of quench correction. Additional correction was made for background counts. The purity (98%) of the radioactive prednisolone was confirmed by TLC and prednisolone was found to be stable in the dialysis cell during the equilibration period.

The bound and unbound concentrations after dialysis were computed after correction for volume shift (method I, Eqs. 7 and 11), by the method proposed by Behm and Wagner (3) (method II, Eqs. 17 and 18), and by the standard method (method III, Eqs. 19 and 20). The fractional increase in the plasma cell volume was calculated using Eq. 5. These calculations were performed using the PROPHET computer system (8). The binding parameters of Eq. 13 were estimated using MKMODEL (9) and unweighted nonlinear least-squares regression (10, 11).

RESULTS AND DISCUSSION

The distribution of volume shifts was estimated from 388 samples used in this study (Fig. 2). The mean volume shift was 0.31 ± 0.15 (mean ± *SD*). There was no correlation between volume shift and predialysis prednisolone concentration. On dialysis of the radiolabel in buffer against an equal volume of buffer, there was no volume shift and negligible binding (<2%) to cell walls or membrane. The binding parameters estimated in the samples from the intravenous and two oral studies by each of the three methods are shown and compared in Table I. The relatively large standard deviations mostly reflect interindividual differences.

Figure 3 shows the fit of the model (Eq. 13) to bound and unbound concentrations obtained by method I from an individual subject. Using average parameter values, graphs of bound against unbound concentrations were simulated (Fig. 4) using MKMODEL (7). In a similar fashion, the unbound concentrations predicted by the binding parameters from each method were plotted as a function of total concentration (Fig. 5). Finally, the unbound fraction was calculated for each method as a function of the total concentration (Fig. 6).

Measurement of drug (or radiolabel) on the plasma side after dialysis is not required when using the volume correction method. However, this measurement can be used to estimate the magnitude of the volume shift. A mean volume shift of 31% was estimated with the aforementioned dialysis conditions. The most likely cause of the shift is the osmotic effect of the impermeable plasma proteins; its magnitude is presumably controlled by the duration of dialysis, the concentration of protein, the area and thickness of the membrane, and other factors that determine the rate of osmotic equilibration.

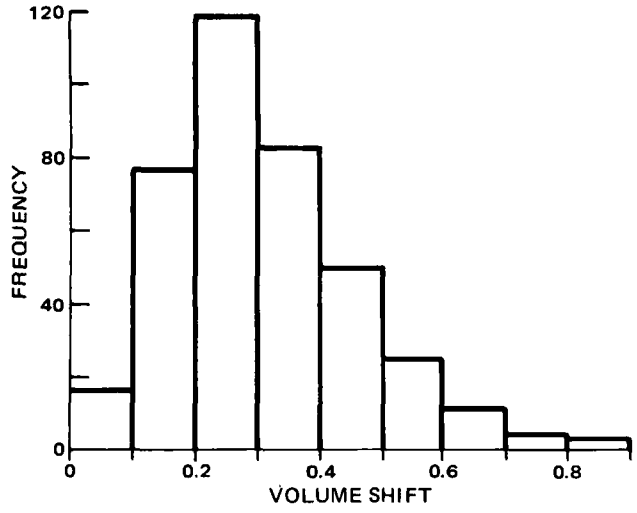

Figure 2—*Distribution of volume shifts (expressed by the fractional increase in V_p) calculated using Eq. 5 for 388 protein binding measurements. The statistics of the distribution are:* N = *388; mean* ± SD = *0.31* ± *0.15; median = 0.29; geometric mean = 0.27; range = 0.005–0.86; skewness = 0.91; kurtosis = 1.03.*

Failure to recognize and compensate for volume shifts in equilibrium dialysis can be a serious source of error. For example, if the volume shift determined in this study had been ignored, the pharmacokinetic parameters, clearance, and volume of distribution based on the unbound concentration, would have been underestimated by ~30%.

We contend that the proposed method (method I) for estimating the concentration of bound and unbound drug after equilibrium dialysis is superior to the other methods. This contention is based on the extension of the theoretical basis for equilibrium dialysis outlined in *Theoretical.*

It is clear from Table I that estimates of protein binding parameters are dependent on the method chosen for calculation of bound and unbound concentrations. The disparity between the predictions based on these parameter estimates, for bound as a function of unbound concentration and for unbound concentration or fraction unbound as a function of total drug concentration, are shown in Figs. 4–6. These differences are largely explained by the failure of methods II and III to account for the shift of fluid between the dialysis chambers.

The proposed method corrects for volume changes whether nonlinear binding is absent or present. The method is potentially required for any substance, drug or hormone, whose binding is estimated by equilibrium dialysis. Furthermore, the results of this study imply that all equilibrium dialysis binding data in the literature may be in error to the extent that volume shifts occurred and were ignored.

APPENDIX I: GLOSSARY OF TERMS

Volume Terms

V_P	Volume before dialysis on plasma side of dialysis cell
V'_P	Volume after dialysis on plasma side of dialysis cell
V_B	Volume before dialysis on buffer side of dialysis cell
V'_B	Volume after dialysis on buffer side of dialysis cell
R	Ratio of V_B to V_P
δ	Fractional increase in V_P due to volume change during dialysis

Concentration Terms

C_P	Total plasma drug concentration before dialysis, including radiolabeled drug if added to plasma
C'_P	Total drug concentration on plasma side after dialysis
C'_B	Drug concentration after dialysis on buffer side (unbound drug concentration on both sides at equilibrium)
C'_{bnd}	Bound drug concentration on plasma side after dialysis
C^0_{bnd}	Bound drug concentration that would have been observed after dialysis if no volume shift had occurred
C_{bnd}	Bound drug concentration in plasma before dialysis
C_u	Unbound drug concentration in plasma before dialysis
C^*_B	Concentration of radiolabelled drug in buffer before dialysis

Table I—Prednisolone Protein Binding Parameters

Method	Binding Capacity (CAP_1), ng/ml		Dissociation Constant (K_{d1}), ng/ml		Nonspecific Binding Constant (S)	
	iv[a]	po[b]	iv[a]	po[b]	iv[a]	po[b]
I	168 ± 52[c]	199 ± 154	18 ± 6	42 ± 73	2.1 ± 0.9	2.3 ± 1.9
II	202 ± 100	205 ± 146	31 ± 21	33 ± 26	1.2 ± 0.5	1.4 ± 1.2
III	241 ± 114	247 ± 183	40 ± 27	41 ± 32	1.3 ± 0.4	1.5 ± 1.2

[a] IV = intravenous prednisolone (N = 9). [b] PO = values for prednisolone following oral prednisone or oral prednisolone (N = 9 for both drugs). [c] Mean ± SD.

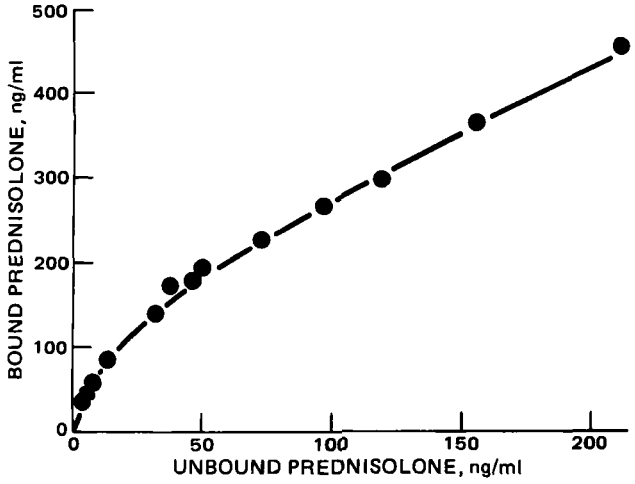

Figure 3—*Typical data of one individual for the determination of binding parameters. The bound concentration was determined by method I (see text) which corrects for volume shifts. The line was obtained by fitting the parameters of Eq. 13 to the data using unweighted nonlinear least-squares regression.*

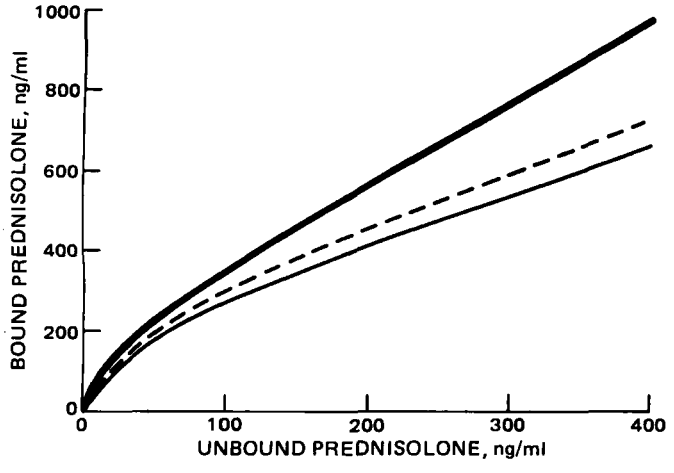

Figure 4—*Simulated relationships between bound and unbound prednisolone concentrations. Parameter values, from fits of individual data to Eq. 13 using the three methods, were averaged for the simulation. The average parameter values for CAP_1, K_{d1}, and S were: (—) method I, 168, 18, 2.1: (—) method II, 202, 31, 1.2; (------) method III, 241, 40, 1.3.*

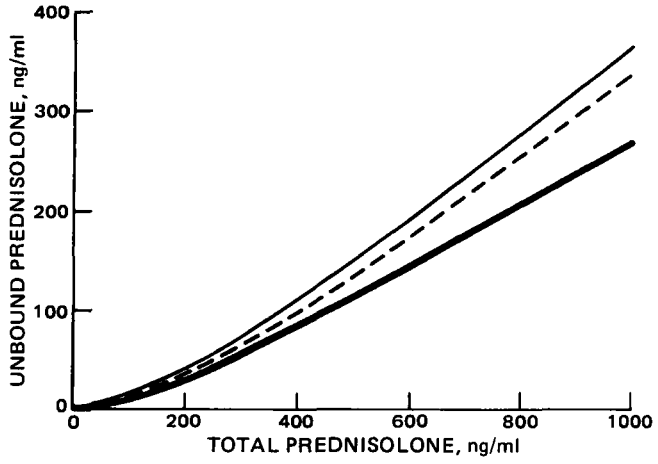

Figure 5—*Simulated relationship between unbound and total prednisolone concentrations using the three methods for determining prednisolone binding. The average parameter values are given in Fig. 4. Key: (—) method I; (—) method II; (---) method III.*

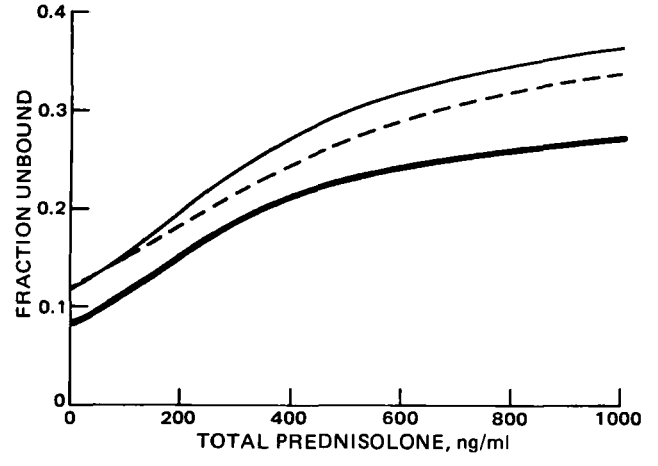

Figure 6—*Simulated relationship between the unbound fraction and the total prednisolone concentration using the three methods for determining prednisolone binding. The average parameter values are given in Fig. 4. Key: (—) method I; (—) method II; (---) method III.*

D_P Radiolabel concentration (dpm/ml) in plasma before dialysis (label added to plasma)

D'_P Radiolabel concentration (dpm/ml) on plasma side after dialysis

D_B Radiolabel concentration (dpm/ml) in buffer before dialysis

D'_B Radiolabel concentration (dpm/ml) on buffer side after dialysis

Binding Parameters

CAP_1, CAP_2 Binding capacities for drug to plasma proteins at two different sites

K_{d1}, K_{d2} Equilibrium dissociation constants for two different sites

S Ratio of CAP_2 to K_{d2}

f_u Ratio of C_u to C_P

f_u' Ratio of C'_B to C'_P

APPENDIX II: EQUAL PREDIALYSIS VOLUMES

In the derivations herein, the volume of the plasma and buffer cell contents are assumed to be unequal at the start of dialysis. It is common practice, as in these studies, to use equal volumes. This simplifies the expressions for unbound (Eq. 7) and bound (Eq. 11) concentrations incorporating the volume correction, that is:

$$C'_B = (C_P + C'_B)\frac{D'_B}{D_B} \qquad \text{(Eq. A1)}$$

$$C^0_{bnd} = C_P + C^*_B - 2 \cdot C'_B \quad \text{(Eq. A2)}$$

APPENDIX III: DIRECT DRUG MEASUREMENT

If concentration of drug (no radiolabel added) is measured, the volume-corrected bound concentration postdialysis is given by:

$$C^0_{bnd} = C_P - C'_B\,(R + 1) \quad \text{(Eq. A3)}$$

From mass balance, $V_P C_P = C'_P \cdot V'_P + C'_B \cdot V'_P$ and using Eqs. 2 and 3, the volume shift δ is:

$$\delta = \frac{C_P - C'_P - R \cdot C'_B}{(C_P - C'_B)} \quad \text{(Eq. A4)}$$

APPENDIX IV: THE FRACTION UNBOUND

Label Added to Buffer—The fraction unbound, f_u', after dialysis and corrected for volume shift, can be calculated from the concentrations of radioactivity in the buffer before and after dialysis. The relationship is:

$$f_u' = \frac{D'_B}{R(D_B - D'_B)} \quad \text{(Eq. A5)}$$

when radiolabel is initially added to the buffer. The relationship is obtained from Eqs. 7 and 11 and the definition of fraction unbound, $f_u' = C'_B/(C^0_{bnd} + C'_B)$. The fraction unbound after dialysis, when no radiolabel is added and drug is initially present in plasma, is:

$$f_u' = \frac{C'_B}{C_P - R \cdot C'_B} \quad \text{(Eq. A6)}$$

This relationship is obtained from Eqs. A3 and A4.

Label Added to Plasma Before Dialysis—Relationships similar to Eqs. 7, 11, and A5, can be derived for the situation in which radiolabel is added to the plasma before dialysis. These relationships, corrected for volume shift, are:

$$C'_B = C_P \cdot \frac{D'_B}{D_P} \quad \text{(Eq. A7)}$$

$$C^0_{bnd} = \frac{C_P \cdot [D_P - D'_B(R + 1)]}{D_P} \quad \text{(Eq. A8)}$$

$$f_u' = \frac{D'_B}{D_P - R \cdot D'_B} \quad \text{(Eq. A9)}$$

where C_P is the drug concentration, including radiolabel, and D_P is the disintegrations per min per ml in the plasma before dialysis.

Fraction Unbound When Nonlinear Binding Occurs—The fractions unbound calculated by Eqs. A5, A6, and A9 are the values expected at the postdialysis total plasma concentration; the fraction unbound in the plasma sample drawn from a subject or patient will be different, because of loss of drug to the buffer side. The fraction unbound in the original sample can then be determined from the unbound and bound concentrations as calculated in Eqs. 14 and 15 and from the definition of f_u, *i.e.*, $f_u = C_u/(C_u + C_{bnd})$.

Direct Determination of Avermectins in Plasma at Nanogram Levels by High-Performance Liquid Chromatography

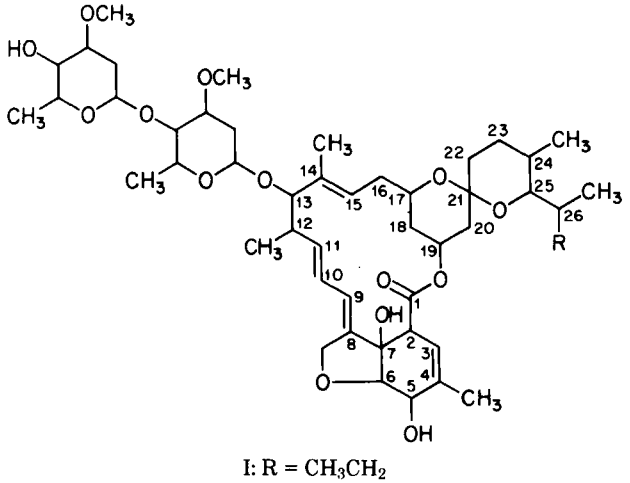
JAMES V. PIVNICHNY ˣ, JUNG-SOOK K. SHIM, and LAURIE A. ZIMMERMAN

Received June 16, 1982, from the *Merck Sharp and Dohme Research Laboratories, Rahway, NJ 07065.* Accepted for publication October 21, 1982.

Abstract □ 22,23-Dihydroavermectin B_{1a} (I) is determined in animal plasma over the concentration range 5–60 ng/ml by reverse-phase high-performance liquid chromatography (HPLC) with UV photometric detection. Prior to HPLC the sample is isolated by gravity-fed adsorption column chromatography on Florisil. The Δ^2 isomer of I (designated as compound III) is used as an internal standard, and the conversion of I to this isomer by base hydrolysis is described. An accuracy of 2 ng/ml (mean deviation) and a precision in the range of 1–3 ng/ml (standard deviation) were observed for the method. The limit of detection is 2 ng/ml based on the background observed for normal cattle plasma. The method is applicable to bioavailability studies of I at usual therapeutic concentrations.

Keyphrases □ Avermectins—direct determination in plasma at nanogram levels, high-performance liquid chromatography, isomerization by hydrolysis □ High-performance liquid chromatography—direct determination of avermectins in plasma at nanogram levels, isomerization by hydrolysis □ Isomerization—avermectins in plasma, hydrolysis, direct determination at nanogram levels, high-performance liquid chromatography

The avermectins are disaccharide derivatives of a structurally similar group of pentacyclic 16-membered lactones (1, 2) which function as broad-spectrum antiparasitic agents (3, 4). Studies in a variety of animals (5) have indicated that these compounds are exceptionally potent. Because of this, effective dosage levels are unusually low (typically 0.2 mg/kg), and the concentrations of this drug found in plasma samples from animals treated with such doses are correspondingly low (<100 ng/ml). The analytical procedure originally reported for determining the avermectins in animal plasma (6) is based on conversion of these compounds to fluorescent derivatives followed by high-performance liquid chromatography (HPLC) with fluorometric detection. The derivatization reaction, which involves dehydration using acetic anhydride–pyridine to form a six-membered aromatic ring in conjugation with a butadiene unit, is time consuming and sensitive to minor experimental variations. A recently reported modification of this method applied to cattle and sheep tissue (7) makes use of the catalyst 1-methylimidazole, as developed by Connors and coworkers for the acetylation of hydroxy compounds (8, 9), to decrease both the reaction time and variability.



I: R = CH_3CH_2
II: R = CH_3

This report describes a direct HPLC procedure with UV photometric detection for determining the avermectins in animal plasma. The particular avermectin component used, 22,23-dihydroavermectin B_{1a} (I), is one of major pharmaceutical interest. The method requires no derivatization and yet has a detection limit approaching that of the original fluorescence procedure.

EXPERIMENTAL

Instrumentation—A high-performance liquid chromatograph was used which consisted of a pump[1] operated at a constant flow rate of 0.8 ml/min, an automatic sample injector with the capability of handling 0.25-ml sample volumes[2], a prepacked microparticulate octadecylsilyl column[3], and a variable-wavelength photometric detector[4] set at 245 nm. The detector output (0.02 AUFS) was displayed on a strip chart recorder[5], and the column was completely enclosed in a water jacket maintained at 30° with a circulating constant-temperature bath[6].

Reagents—The production and isolation of the avermectins has been previously described (10, 11). The purity of the various lots of I used in this study, each of which contained <10% 22,23-dihydroavermectin B_{1b} (II), was established by HPLC. The conversion of I to its Δ^2 isomer (III) for use as an internal standard is described below. All solvents were either HPLC grade[7] or distilled in glass[8]. Distilled water was further purified by passing through an ultrapure water system[9]. The chromatographic eluant was acetonitrile–methanol–water (53:35:7).

22,23-Dihydroavermectin B_{1a} Δ^2 Isomer (III)—A solution of 20 mg/ml of I in methanol–water (9:1) was mixed with an equal volume of 0.1 *M* KOH in the same solvent. After 4 hr at room temperature, portions of the reaction mixture were injected into the HPLC system described above, and III was collected as a solution in the eluant as it emerged from the detector. A total amount of III in excess of 5 mg was collected from 10 separate 0.1-ml injections. After dilution with methanol, the concentration of III in this solution was determined by comparison of its HPLC peak area to that of I using the assumption that the molar absorptivities for the two compounds are equal at the detector wavelength.

Florisil Columns—Florisil[10], 100–200 mesh, was washed thoroughly with chloroform–ethyl acetate (3:1), dried, and then washed with water

and dried overnight at 120°. Glass columns (0.7-cm i.d. × 10 cm) were fabricated with conical funnel tops (6.5-cm diameter) and constricted bottoms. A small plug of silanized glass wool was inserted into each column followed by 0.40 g of Florisil. Each prepared column was rinsed with 10 ml of chloroform immediately before use.

Procedure—A plasma sample was combined with the internal standard by first evaporating 1.00 ml of a 140-ng/ml solution of III in an extraction vessel (50-ml centrifuge tube) at 50° under a stream of dry nitrogen and then adding 5.00 ml of the plasma. The sample was then extracted with three 15-ml portions of ethyl acetate, and the combined extracts were evaporated to dryness as above. The residue was dissolved in 1 ml of chloroform and placed on the Florisil column. Two chloroform rinses (1 ml each) and one additional 10-ml portion of chloroform were added to the column. Elution with 25 ml of chloroform–ethyl acetate (3:1) which had been saturated with water afforded the desired fraction. After evaporating to dryness at 50° with dry nitrogen, this was dissolved in 0.25 ml of methanol–water (19:1).

A 0.10-ml aliquot was injected into the chromatographic system. An analytical reference standard was processed as 1.0 ml of a chloroform solution containing 100 ng/ml of I and 140 ng/ml of III, starting with the Florisil chromatography. Quantitation was by peak height measurement with normalization using the internal standard.

RESULTS AND DISCUSSION

Characterization of the Analytical Method—The suitability of ethyl acetate for extracting the avermectins from animal plasma has previously been demonstrated using radiolabeled I in the original fluorescence HPLC procedure (6). The only modification employed here was the elimination of the initial treatment with ethanol. The Florisil column described in the original method was used here, but a total of 13 ml of chloroform was used to load the column instead of the 6 ml originally used. The additional chloroform removed more potential interfering material from the Florisil column before the desired material was eluted with water-saturated ethyl acetate–chloroform.

Typical chromatograms for a sample of normal cattle plasma supplemented with 40 ng/ml of I and the analytical reference standard are shown in Fig. 1. The sample (I) and the internal standard (III) elute with capacity factors (k') of 8.8 and 11.1, respectively, and are completely resolved from each other as well as from interfering endogenous substances. A small amount of the avermectin component II is apparent in the chromatogram of the analytical reference standard, but any of this which might be in the sample is obscured by extraneous plasma components.

No plasma components, however, interfere significantly with either the sample or the internal standard. This is shown in Fig. 2. Chromatogram A, which was obtained for a sample of drug-free cattle plasma, shows only a small peak eluting at the retention time of I. For this particular sample, the peak corresponds to an apparent drug concentration of 1.5 ng/ml. Chromatogram B was obtained from a plasma sample from an animal which had been dosed with I as described below. The sample was processed through the analytical procedure in the absence of internal standard; nothing can be seen eluting at the retention time of this compound. The peak and shoulder that are seen in this chromatogram eluting with retention times slightly less than that of III are due to extraneous plasma components which have been observed in varying amounts in the plasma of different animals. This case represents the maximum amount of these components encountered for any animal examined in this study, and, in fact, the components are completely absent in the other chromatograms illustrated here.

This analytical method is accurate and precise when applied to samples of cattle plasma containing I in the concentration range of 5–60 ng/ml. When normal cattle plasma was supplemented with I over this range, a mean deviation of 1.7 ng/ml from the expected concentration was observed. Linear least-squares analysis of these found *versus* expected results, which are listed in Table I, yield a coefficient of determination (r^2) of 0.979 with a slope of 0.936 and an intercept of 1.6 ng/ml. Replicate determinations at supplemented levels of 20, 30, 40, and 60 ng/ml indicate within-run precision values in the range of 1–3 ng/ml (standard deviation). Since the data of Table I are the combined results of five individual runs, an indication of between-run precision is given by the standard error of estimate for the least-squares fit. This value is 2.2 ng/ml. Analyses of samples from eight control animals showed an average apparent concentration of 1.1 ng/ml of I with a standard deviation of 0.9 ng/ml, demonstrating that the method is free of interferences at concentrations >5 ng/ml.

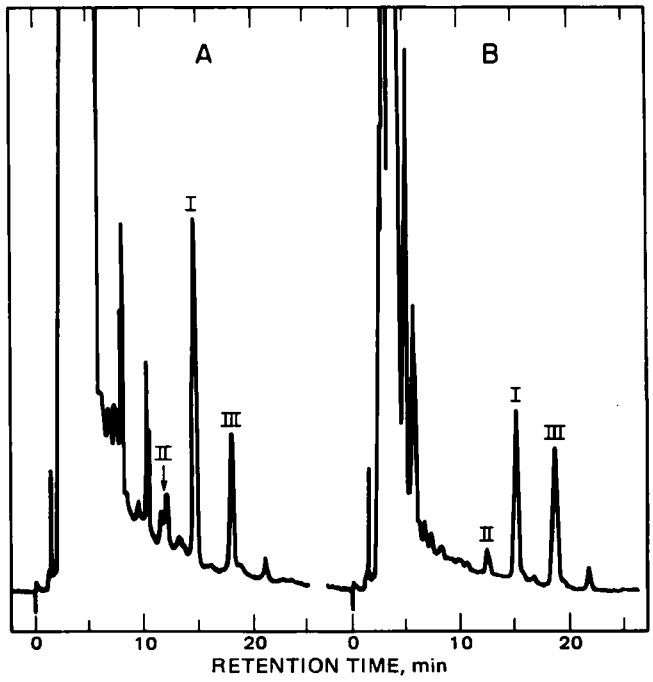

Figure 1—*Chromatograms obtained with this analytical procedure. Key: (A) normal cattle plasma supplemented with 40 ng/ml of I; (B) analytical reference standard corresponding to a sample containing 20 ng/ml of I carried through the procedure.*

The overall recoveries of both sample and internal standard carried through the analytical procedure were ~80%. This was determined by supplementing several 5-ml samples of normal cattle plasma with 100 ng of I and 140 ng of III, processing them through the entire procedure, and comparing the resultant chromatographic signals to those obtained for the same amounts of I and III chromatographed directly. These recovery values are essentially the same as that previously determined for I in the portion of the fluorescence procedure preceding the derivatization reaction (6).

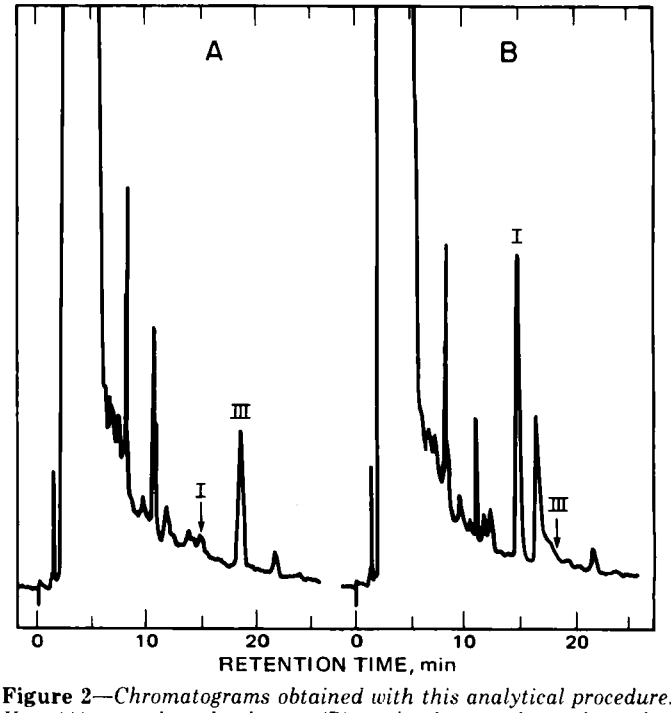

Figure 2—*Chromatograms obtained with this analytical procedure. Key: (A) normal cattle plasma; (B) cattle plasma taken 3 days after dosing with 0.2 mg/kg of I. The internal standard was omitted from the analytical procedure.*

Table I—Accuracy and Precision of the Method Applied to Normal Cattle Plasma Supplemented with Various Amounts of I

Concentration Added, ng/ml	Mean Concentration Determined, ng/ml	Number of Determinations	Standard Deviation ng/ml
5.0	6.0	1	—
15.0	14.4	1	—
20.0	21.5	5	1.0
25.0	25.9	1	—
30.0	30.1	8	0.8
35.0	31.6	1	—
40.0	37.4	8	2.5
45.0	45.8	1	—
55.0	54.9	1	—
60.0	58.1	7	2.8

Application—To further test this analytical procedure, it was applied to plasma samples obtained from an *in vivo* study involving an Angus steer. The animal was dosed subcutaneously with a solution of I at a dosage level of 0.2 mg/kg, and samples were collected over the period of 2 weeks. The observed concentration–time profile is shown in Fig. 3. A maximum concentration of ~70 ng/ml was reached in 1 day, and the elimination phase closely follows first-order decay kinetics as shown by the semilogarithmic insert in the figure. Least-squares fitting of the results covering 1–14 days gives the expression:

$$C = 80.6e^{-0.236t}$$

where C is the concentration in ng/ml and t is time in days. The coefficient of determination (r^2) is 0.993, and the half-life for elimination is 2.9 days.

The Δ^2 Isomer (III)—The avermectins react with hydroxide in methanol–water solutions to give a number of products as shown by the chromatograms of Fig. 4. Starting with I under the conditions chosen here, the predominant initial reaction is an epimerization of the hydrogen at C-2 to form IV. This compound has a slightly greater retention time than I in the chromatographic system, and the amount of IV increases as the amount of I decreases. The eventual result might be complete conversion of I to IV or the establishment of an equilibrium mixture of I and IV were it not for the fact that a third product forms by the shifting of a double bond from the C-3 position to C-2 to produce III.

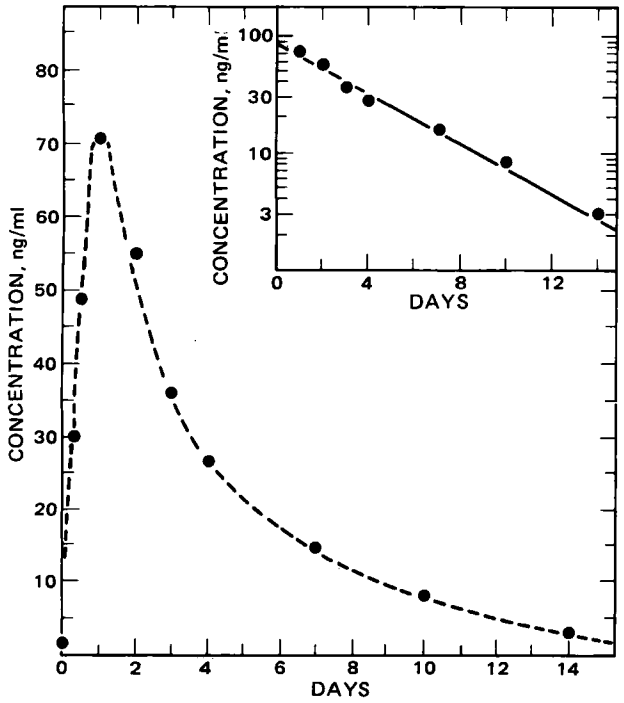

Figure 3—*Plasma concentration of I observed for an Angus steer dosed subcutaneously with I at a level of 0.2 mg/kg. The insert presents the elimination phase data on a logarithmic scale.*

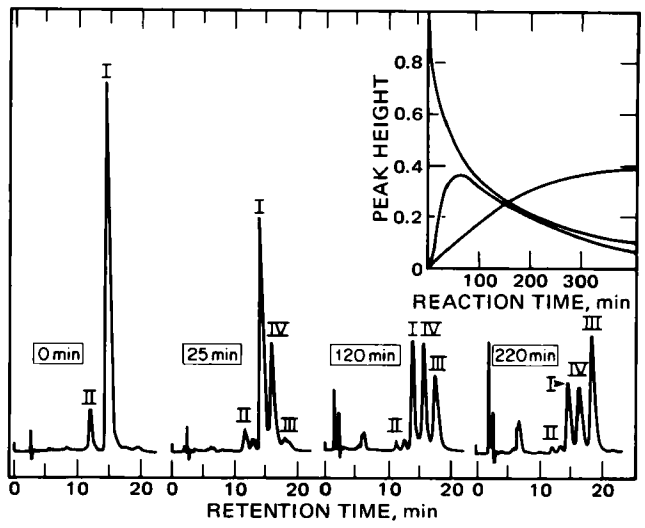

Figure 4—*Chromatograms showing the conversion of I to its 2-epimer and Δ^2 isomer by reaction with 0.05 M KOH in methanol–water (9:1). The inset shows the variation in chromatographic peak heights over the course of the reaction.*

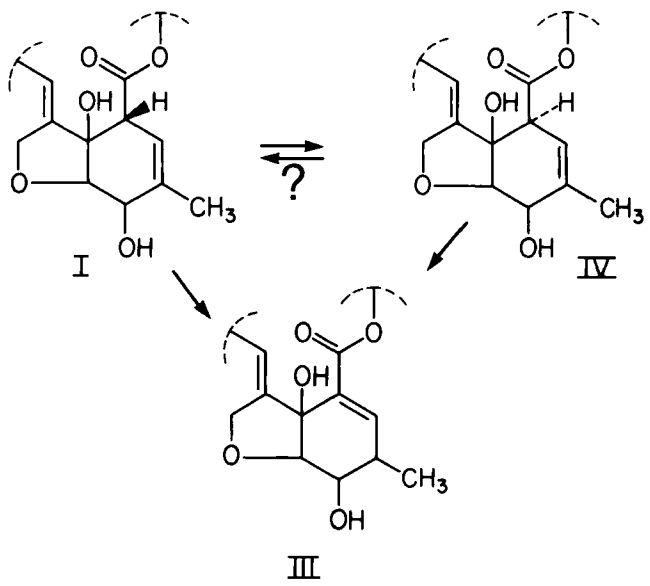

Scheme I

In the chromatographic system, III elutes after IV, and although its concentration increases more slowly than IV early in the reaction, it continues to increase even after IV begins to decrease. Eventually it becomes the predominant product, and at this point it is isolated by semipreparative HPLC. It is not known how stable III is in the basic reaction mixture, but after isolation it is completely stable in methanolic solution at 5° for at least several months. Also, it is not known whether the mechanism is strictly stepwise, that is, I goes to IV which then goes to III, or whether I and IV simultaneously are converted to III as indicated in Scheme I. Compound IV was identified by comparison of its HPLC retention time to that of an authentic sample which had been independently synthesized[11], and III was identified on the basis of its 300-MHz ^{1}H-NMR spectrum[12].

Using III as an internal standard is appropriate since its structure is very similar to that of the sample. That two such large molecules differing

[11] H. Mrozik, Merck Sharp and Dohme Research Laboratories, June 1979, personal communication.

[12] B. H. Arison, Merck Sharp and Dohme Research Laboratories, June 1979, personal communication.

only in the position of a double bond can be so well separated demonstrates that excellent efficiency and selectivity are provided by the chromatographic system. For all steps in the procedure other than HPLC, the two compounds behave identically. In addition, it is advantageous that the internal standard is easily prepared from the sample. The only problem in this situation is that the internal standard may also be a metabolite of the drug; but, this is not the case here. The plasma sample (Fig. 2B) which was analyzed with no internal standard was taken from an animal 3 days after dosing and 2 days after the highest drug concentration had been observed. No peak corresponding to III is present. Similarly, plasma samples taken at later times also show nothing eluting at this retention time.

CONCLUSION

The analytical procedure presented here is a substantial simplification of the original fluorescence derivatization HPLC method. At a typical therapeutic plasma concentration of 40 ng/ml, the observed mean deviation of 1.7 ng/ml corresponds to an accuracy of 4% mean relative error. Similarly, the standard deviation of 2 ng/ml typically observed corresponds to a precision of 5% relative standard deviation. These values are essentially the same as those observed for the fluorescence method. As one would expect, the fluorescence method has a definite advantage with a detection limit of one-tenth that of the direct method. However, the direct method is more rapid and reliable, and with a detection limit of 2 ng/ml, it is entirely suitable for quantitative determination of avermectins in plasma at normally effective dosage levels. Numerous bioavailability studies with both cattle and swine in which peak drug concentrations have ranged from 50 to 100 ng/ml have been successfully conducted in these laboratories using this analytical procedure.

Coil → Helix Transition in Polyadenylic Acid Induced by the Binding of Epinephrine, Norepinephrine, and Isoproterenol: Circular Dichroism Study

HANNA N. BORAZAN ˣ and SONA N. KOUMRIQIAN

Received October 21, 1981, from the *Department of Pharmaceutical Chemistry, College of Pharmacy, University of Baghdad, Baghdad, Republic of Iraq.* Accepted for publication October 19, 1982.

Abstract □ A circular dichroism spectropolarimetric study on the conformation of polyadenylic acid (poly A) in neutral solutions demonstrated a coil → helix transition induced by intercalative binding of critical amounts of epinephrine, norepinephrine, and isoproterenol relative to poly A. Theoretical treatment of the experimental data indicated a first-order kinetic transition in poly A. It was possible to measure transition rate constants of the epinephrine–poly A and norepinephrine–poly A systems and to calculate the activation energies. The results indicate a high level of temperature dependence of the rate constants. The effects can be reversed by increasing ionic strength, indicating the significance of the electrostatic interactions. The importance of the results is discussed in terms of the possible role of the catecholamines as control mechanisms for the poly A-regulated translation of the genetic code on mRNA.

Keyphrases □ Polyadenylic acid—coil → helix transition, intercalative binding of epinephrine, norepinephrine, and isoproterenol, circular dichroism □ Catecholamines—epinephrine, norepinephrine, isoproterenol, intercalative binding to polyadenylic acid, coil → helix transition, circular dichroism □ Coil → helix transition—of polyadenylic acid, induced by catecholamines, intercalative binding of epinephrine, norepinephrine, and isoproterenol, circular dichroism

Most mRNA molecules contain stretches of polyadenylic acid (poly A) at the 3′-end (1), with length of the poly A depending on the evolutionary level of the organism; the larger segments of poly A exist in highly differentiated cells (2). The exact function of this poly A segment is not yet known. Some researchers have proposed that the segments are responsible for increasing the stability of mRNA by inducing a circular structure, while others found that the translation of the genetic code becomes far more efficient in the presence of poly A, attributed to the greater stability of mRNA afforded by poly A (3).

In a continuing effort to study the diversity of the biological effects of adrenergic compounds at the molecular level, the investigation of the possibility that nucleic acids are the target molecules of these drugs was conducted in this laboratory. The present study deals with circular di-

chroism (CD) spectropolarimetric investigation of conformational changes in poly A, at pH 7, induced by epinephrine, norepinephrine, and isoproterenol.

EXPERIMENTAL

Polyadenylic acid[1], epinephrine hydrogen tartrate[2], EDTA (disodium ethylenediaminetetraacetate)[2], (+)-tartaric acid[2], norepinephrine[3], sodium cacodylate[3], isoproterenol sulfate dihydrate[4], and sodium chloride[5] were obtained from commercial sources. All chemicals were used without further purification, since they were of the highest commercially available purity.

The prepared solutions contained a fixed concentration of poly A (~5 × 10^{-5} *M*), with varying concentrations of the catecholamines (one-half to twice the concentration of poly A). A value of 10^4 was assumed for the molar absorptivity (ϵ) per nucleotide residue of poly A at 257 nm when preparing standard solutions. The norepinephrine hydrogen tartrate solution was prepared from an equimolar mixture of the acid and the base. The buffer system used was 1 m*M* sodium cacodylate, pH 7, containing 1 m*M* NaCl and 0.2 m*M* EDTA.

Spectroscopic measurements were performed on a spectrophotometer[6] and a circular dichroism spectropolarimeter[7]. All equations used were written on programs and executed on a programmable calculator[8].

The temperature of solutions in the cuvettes (quartz, with a 0.1-cm path length) was maintained constant throughout measurements by using a thermostated cell holder. When working at low temperatures, the spectra were recorded under dry conditions. The experiments were done in a room with subdued lighting to avoid undesired photooxidation of the catecholamines. Each experiment was replicated at least three times.

RESULTS AND DISCUSSION

It is known that poly A in neutral solutions exist in a single-stranded coil conformation (4). This conformation of poly A exhibits a charac-

teristic CD spectrum that is due to ordered base-stacked structures composed of two bands of nearly equal intensities: a positive band with a maximum located at 264 nm and a negative band at 247 nm, with a crossover at 254 nm (5–8).

In the present study, it was found that addition of epinephrine hydrogen tartrate or norepinephrine hydrogen tartrate to poly A at a concentration ratio (amine/poly A) of 0.5 caused a slight reduction of the intensities of the positive and negative bands of the CD spectrum of poly A without altering its shape. This pattern of change could indicate an intercalative binding of the aromatic nucleus between the stacked adenine bases (9, 10). When the concentration ratio was increased to 1.0, an increase in the positive band and a decrease in the negative band of the CD spectrum, as well as shifts in the λ_{max} and λ_{min} toward shorter wavelengths, were observed with time (Fig. 1). After the change was completed, the CD spectrum was composed of two bands, a positive band with a maximum at 263 nm and a negative band with a minimum at 242 nm; at 248 nm the CD signal had a zero value. This spectrum is considered to be identical to that of the double-stranded intertwined helical conformation of poly A existing in acidic solutions, pH 4.8, (5–7). These results indicate a coil → helix transition catalyzed by the binding of epinephrine and norepinephrine.

In order to have a basic understanding of the mechanism of this coil → helix transition, several kinetic models were tested. The best model that seems to be consistent with our experimental data is a first-order transition process in poly A. This led us to the following equation:

$$\ln (\theta_\infty - \theta) = \ln (\theta_\infty - \theta_0) - kt \qquad \text{(Eq. 1)}$$

where θ_0, θ, and θ_∞ represent the ellipticity of the CD signal at times 0, t, and ∞, respectively, and k is the rate constant of the transition. Thus, a plot of ln $(\theta_\infty - \theta)$ *versus* t should lead to a slope of $-k$.

Naturally, the activation energy of the coil → helix transition can be measured in principle according to the Arrhenius equation:

$$\ln k = -\frac{E_a}{RT} + \text{constant} \qquad \text{(Eq. 2)}$$

by plotting ln k *versus* $1/T$. In Eq. 2, E_a is the activation energy, R is the gas constant, and T is the absolute temperature in °K. Representative plots of Eqs. 1 and 2 are shown in Figs. 2 and 3, respectively; the data are summarized in Table I. To minimize errors, the slopes of the curves in Figs. 2 and 3 and those used to calculate the kinetic parameters presented in Table I were calculated by the method of least squares.

Isoproterenol can also induce the coil → helix transition, but this process is very slow. A 2:1 isoproterenol–poly A mixture can bring about the transition completion in >2 days at 25° (Fig. 1B). However, this transition is too slow to enable measurement of k or of the corresponding E_a.

It is evident from Fig. 2 that the transition is a first-order process in poly A when based on measurements of the positive band (264 → 263 nm) and the total peak-to-peak $\lambda_{max} - \lambda_{min}$ amplitude (λ_{min} shifts from 248 to 242 nm). The transition at 4° is a very slow process; it was therefore necessary to leave the solution overnight to bring the transition to completion and to measure θ_∞. Even though the transition occurring at 15° is faster than that at 4°, it was necessary to leave the solution overnight to achieve the most stable double-helical structure. θ_∞ was attained within 2 hr at 25° for both systems.

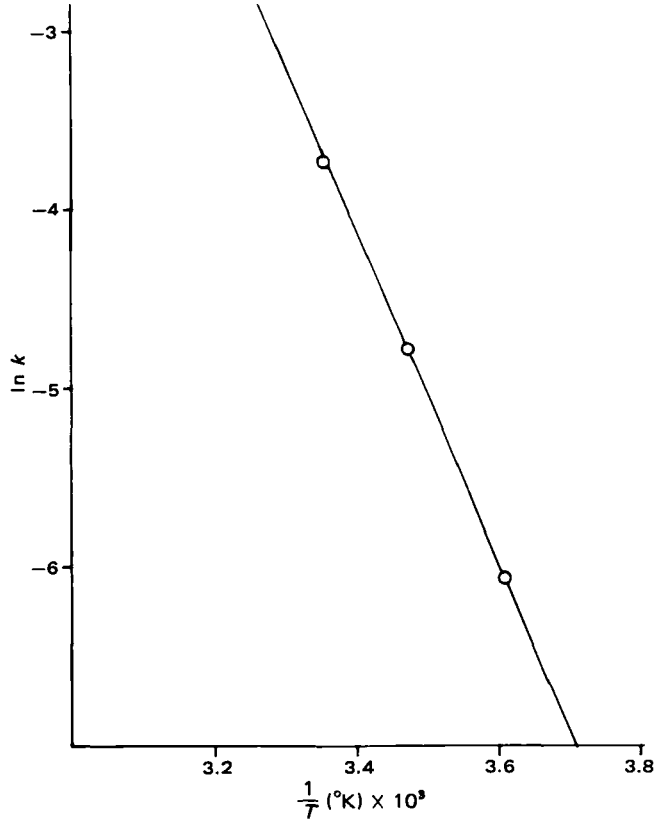

Figure 3—*Ln* k versus *1/*T *for the transition of poly A in the norepinephrine-poly A system based on measurements of the total peak-peak* $(\lambda_{max} - \lambda_{min})$ *amplitude.*

Table I—Rate Constants (k) and Coil → Helix Transition Activation Energies (E_a) of Poly A Based on CD Signals

Temperature ± 1°	Total Peak–Peak Amplitude k, min^{-1} × 10^3	Total Peak–Peak Amplitude E_a, kcal/mole	Positive Amplitude k, min^{-1} × 10^3	Positive Amplitude E_a, kcal/mole
	Epinephrine–Poly A			
4°	3.16		4.02	
15°	9.40	16.408	9.42	16.480
25°	25.50		33.22	
	Norepinephrine–Poly A			
4°	2.31		2.89	
15°	8.45	18.478	8.51	17.104
25°	24.16		25.59	

The positive CD band assumes the stable structure at a faster rate than that of the negative band (as reflected from measurements of the total amplitude) in the case of the epinephrine–poly A system (Table I). In the norepinephrine–poly A system, however, both bands of poly A attain their stable features at approximately the same rate. The activation energy calculated from the changes in the total amplitude and the positive band is very similar in the epinephrine–poly A system, while a slight difference appears to exist in the norepinephrine–poly A (Table I). In comparing both systems, one may observe the high temperature dependence of the rate constants; a change from 4° to 25° can bring about an 8- to 10-fold increase in the rate constant.

The significance of the contributions of electrostatic interactions to the total binding energy was verified by changing the ionic strength of the solutions. It was found that increasing the ionic strength to 0.2 *M* by the addition of sodium chloride had the effect of restoring almost entirely the initial CD spectra of poly A in the three systems (Fig. 1). This can be explained on the basis of competition occurring between sodium ions and the positively charged amino groups existing at pH 7 in the negatively charged phosphate residues. The contribution of other weaker forces to the intercalative binding cannot be neglected, however, since it has been demonstrated (11–13) that adenine can form charge transfer complexes with catechol, epinephrine, and isoproterenol.

The exact geometry of the complexes formed between the catecholamines and poly A in its single- and double-stranded conformations cannot be determined from the CD investigation alone. On the other hand, it should be emphasized that the conformational changes occurring in the poly A molecule cannot be attributed solely to the electrostatic interactions, due to the fact that isopropylamine does not change the CD spectrum of poly A (10). Finally, catecholamines may exert a control mechanism through induction of the coil → helix transition on the regulatory role in genetic code translation which has been hypothesized for the poly A segments present in most mRNA molecules.

Stability of Triamcinolone Acetonide Solutions as Determined by High-Performance Liquid Chromatography

V. DAS GUPTA

Received July 6, 1982, from the *Department of Pharmaceutics, University of Houston, Houston, TX 77030.* Accepted for publication October 14, 1982.

Abstract □ A stability-indicating assay method based on reverse-phase high-performance liquid chromatography has been developed for the quantitation of triamcinolone acetonide. The method was used to study the stability of triamcinolone acetonide in water–ethanol solutions of varying pH, buffer concentration, and ionic strength. The decomposition of triamcinolone followed pseudo-first-order law and was minimal at pH ~ 3.4. Above pH 5.5, the decomposition increased rapidly and was directly related to phosphate buffer concentration. The decomposition decreased with increasing ionic strength when the pH of the solution was >7. Two new peaks corresponding to decomposition products were noted in the chromatogram; their ratio varied significantly with the composition of the vehicle.

Keyphrases □ Triamcinolone acetonide—decomposition in solution, effect of pH, buffer concentration, and ionic strength, high-performance liquid chromatography □ High-performance liquid chromatography—stability indicating, triamcinolone acetonide and its decomposition products, effect of pH, buffer concentration, and ionic strength □ Stability—triamcinolone in solutions, effect of pH, buffer concentration, and ionic strength, high-performance liquid chromatography

Triamcinolone acetonide (I) is available in different dosage forms such as creams, ointments, and suspensions. Despite its extensive use, little is known about the stability of I in aqueous systems and water-washable ointment bases such as polyethylene glycol ointment base USP (1). In general, corticosteroid decomposition is first order (2) with two parallel routes of decomposition. One route (attack on ring A) produces neutral product(s) and the other (attack on the C-17 side chain) produces acidic product(s).

This study evaluates the stability of triamcinolone acetonide (*a*) in water–ethanol solutions of varying pH with different buffer concentrations and ionic strengths and (*b*) in polyethylene glycol ointment base USP (1) using a stability-indicating reverse-phase high-performance liquid chromatographic (HPLC) assay method developed in our laboratory.

EXPERIMENTAL

Reagents and Chemicals—All reagents and chemicals were either ACS, USP, or NF grade and were used without further purification. Triamcinolone acetonide[1] was used as received.

Chromatographic Conditions—Two columns (30 cm × 4-mm i.d.) were used. One contained a semipolar material[2], the other a nonpolar

[a] Each solution contained 25% v/v ethanol except solutions 20 and 21 (10%), 23 (50%), 24 (75%), and 25 (100%). [b] Adjusted with potassium chloride based on the pH of the buffer solutions. [c] The data at 50° are presented in Fig. 4. [d] It was not possible to estimate K_{obs} at 25° since these solutions did not decompose significantly in 8 weeks. [e] Not determined at this temperature. [f] Ionic strength not adjusted. [g] Solutions 20 and 26 contained 15% v/v and 25% v/v glycerin, respectively. Solutions 21 and 27 had 15% v/v and 25% v/v propylene glycol, respectively.

material[3]. The chromatograph[4] was connected to a multiple-wavelength detector[5], a recorder[6], and an integrator[7]. All pH values were determined using a pH meter[8]. Four mobile phases were used:

1. A 0.02 *M* aqueous solution of monobasic potassium phosphate containing 16% v/v of acetonitrile (pH ~4.2).
2. Same as 1 except that the buffering agent was 0.02 *M* ammonium acetate (pH ~7).
3. Same as 1 except that the pH was adjusted to ~2.5 with an 85% aqueous solution of phosphoric acid.
4. Same as 1 except that the acetonitrile concentration was 32% v/v (pH ~4.2).

The flow rate was 2.5 ml/min (3.0 ml/min with mobile phase 4), and the sensitivity was set at 0.04 AUFS (254 nm). The temperature was ambient, and the chart speed was 30.5 cm/hr.

Preparation of Samples—All solutions for stability studies were prepared as presented in Table I using a simple solution method. After the initial data was obtained (pH values and the assays), the solutions were stored at 50 ± 1° (some also at 25 ± 1°) in 60-ml amber-colored bottles[9].

Forty milligrams of I was thoroughly mixed with 19.96 g of polyethylene glycol ointment base USP (1) using the process of trituration. After the initial data was obtained (assay and the pH value of a 1% aqueous solution), the ointment was stored at 50 ± 1° in an opaque white ointment jar[9].

Assay Method—*Preparation of Standard Solutions*—A stock solution of triamcinolone acetonide (I) was prepared by dissolving 100.0 mg of the powder in enough ethanol to make 100 ml. A stock solution of hydrocortisone (the internal standard) of identical concentration was also prepared in ethanol. The standard solution was prepared by mixing 8.0 ml of the stock solution of I and 3.2 ml of hydrocortisone solution with 20 ml of methanol and then bringing the volume to 100 ml with water. The solutions of other concentrations were prepared as needed. Each solution contained identical concentrations of methanol and hydrocortisone.

Assay Solutions—An 8.0-ml quantity of each solution was mixed with 0.8 ml of the stock solution of hydrocortisone and 5 ml of methanol, and the mixture was brought to volume (25 ml) with water. One gram of the ointment was mixed with 5 ml of methanol, 5 ml of water, and 0.8 ml of the hydrocortisone solution. The mixture was stirred until a clear solution was formed and then brought to volume (25 ml) with water.

HPLC Assay Procedure—A 20-μl aliquot of the assay solution was injected into the chomatograph using the described conditions (nonpolar column[3] and mobile phase 4). An identical volume of the appropriate standard solution was injected for comparison after the assay solution eluted. The standard solution contained exactly the same quantity of I as the label claim of the assay solution.

Calculations—Since preliminary investigations indicated that ratios of peak heights of I and the internal standard were directly related to concentrations of I, the results were calculated using:

$$\frac{(R_{ph})_a}{(R_{ph})_s} \times 100 = \text{percent contained in the assay solution} \quad \text{(Eq. 1)}$$

where $(R_{ph})_a$ is the ratio of peak heights of I to the internal standard (hydrocortisone) in the assay solution and $(R_{ph})_s$ is the ratio of the triamcinolone acetonide peak to the internal standard in the standard solution. If the standard solution does not contain an identical concentration of I, the results can be corrected by multiplying the percent found by: Factor = [actual concentration of I (mg/ml) in the standard solution] ÷ [label claim of I (mg/ml) in the assay solution].

When the triamcinolone acetonide peak was too small (<25% of the standard) to quantify accurately, a new assay solution containing a higher concentration of I was injected. Appropriate calculations were then made to determine the exact concentration of I in the assay solution.

RESULTS AND DISCUSSION

Assay Method—The assay method using a nonpolar column and mobile phase 4, containing 0.02 *M* KH_2PO_4 and 32% v/v acetonitrile in water, separated the decomposition products from the intact triamcinolone acetonide and the internal standard (Figs. 1 and 2). The results were reproducible, accurate, and precise with relative standard deviations ranging from 1.6 to 1.9% based on six readings. Before these chromatographic conditions were finalized, mobile phase 1 containing 16% v/v

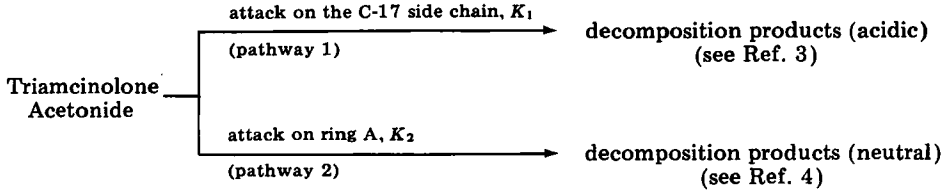
acetonitrile was tried with a semipolar column. With these chromatographic conditions, the second product of decomposition (the peak between peaks 1 and 2 in Fig. 1B) did not separate from peak 2. Therefore, the results obtained using a semipolar column were erroneous and did not follow first-order kinetics.

Decomposition Products—Corticosteroids usually decompose with two parallel routes of decomposition (2), producing either acidic or neutral products:



By changing the pH of the mobile phase (mobile phases 1–3), it was possible to decrease (with a mobile phase of higher pH) or increase (with a mobile phase of lower pH) the retention time of the first decomposition product (peak appearing after the solvent peak in Fig. 2). The retention time of the second peak (between peaks 1 and 2 in Fig. 2) was not affected. It appears, therefore, that the first decomposition product peak is from an acidic compound and the second is from a neutral substance.

In an ethanolic solution (solution 19), the peak from the neutral product was higher (Fig. 1B) than the peak from the acidic product. In the presence of glycerin (solution 20), these peaks were smaller and of approximately the same size (Fig. 2A). In propylene glycol (solution 21), the chromatogram (Fig. 2B) was similar to the ethanolic solution chromatogram (Fig. 1B). It is obvious that the ratio of K_1 and K_2 would be different in ethyl alcohol–propylene glycol than in glycerin.

Order of Reaction and Effect of pH—As expected, first-order kinetics were followed (Fig. 3). The rate constants varied with the pH of the buffer solution (Fig. 4) and an optimum pH of stability was estimated to be ~3.4.

Effect of Phosphate Buffer—It is apparent (Fig. 5) that the K_{obs} is directly related to the phosphate concentration. Therefore, triamcinolone acetonide is subject to general acid–base catalysis.

The decomposition of triamcinolone acetonide may be represented by:

$$K_{obs} = K_0 + K_1[H^+] + K_2[OH^-] + K_3[H_2PO_4^-] + K_4[HPO_4^{2-}] \quad \text{(Eq. 2)}$$

At constant pH, $K_1[H^+]$ and $K_2[OH^-]$ are constant and Eq. 2 may be rewritten as:

$$K_{obs} = K + K_3[H_2PO_4^-] + K_4[HPO_4^{2-}] \quad \text{(Eq. 3)}$$

where $K = K_0 + K_1[H^+] + K_2[OH^-]$.

Since the decomposition is first order (Fig. 3), the K_{obs} values were determined using first-order plots, and Eq. 3 may be rearranged as follows:

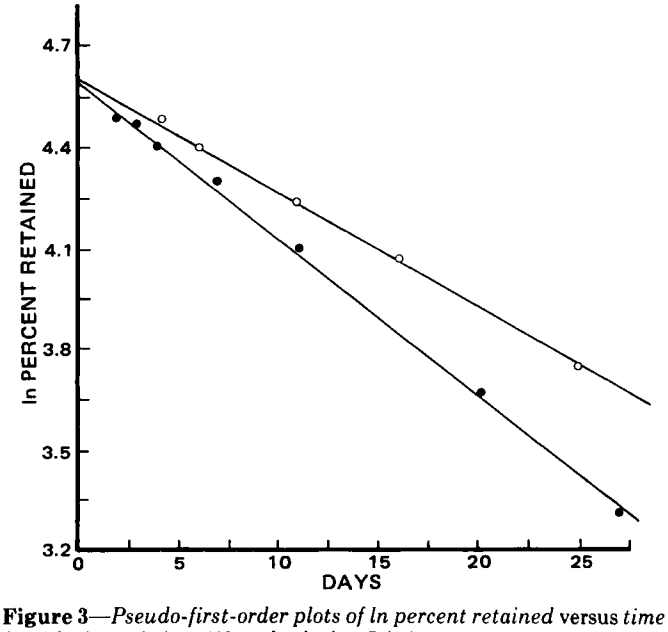


Figure 3—*Pseudo-first-order plots of ln percent retained* versus *time for solution 1 (●) at 50° and solution 7 (○) at 25°.*

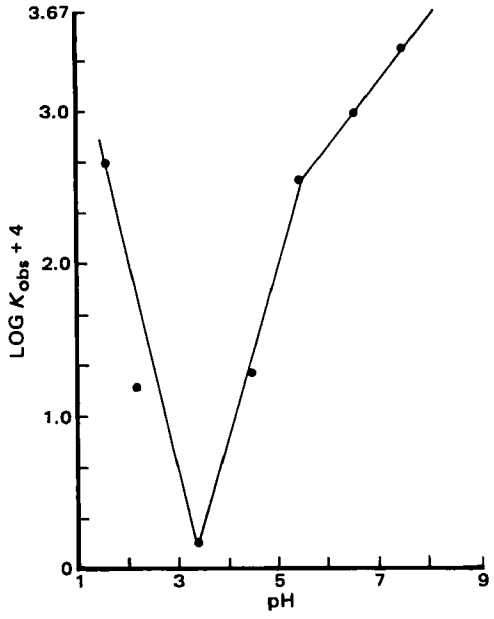

Figure 4—*pH-rate profile curve from* K_{obs} *values at 50°.*

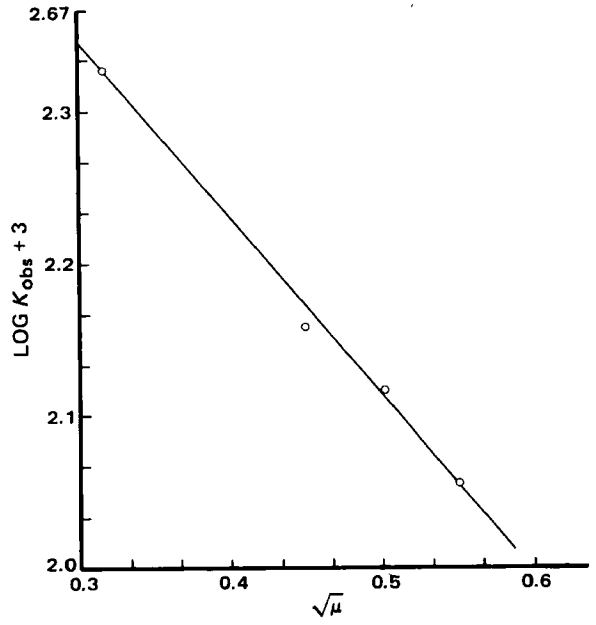

Figure 6—*Plot of log* K_{obs} versus $\sqrt{\mu}$ *at pH 7.6 (solutions 10–13).*

$$K_{obs} = K + [H_2PO_4^-]\left(K_3 + \frac{K_4}{q}\right) \quad \text{(Eq. 4)}$$

where $q = [H_2PO_4^-]/[HPO_4^{2-}]$. On plotting K_{obs} *versus* concentrations of $H_2PO_4^-$, straight lines were obtained (Fig. 5). From the slopes and q values of 3.98 and 0.398 at pH values of 6.6 and 7.6, respectively, the two simultaneous equations were solved for K_3 and K_4. The K_3 and K_4 values were estimated to be 0.575 and 3.79 M^{-1}·day^{-1}. Furthermore, by substituting these values in Eq. 3, K was determined to be negligible.

Effect of Hydrochloric Acid Buffer—In the presence of hydrochloric acid buffer (solution 1), it appears that the major reaction is hydrolysis of triamcinolone acetonide to triamcinolone and acetone. The triamcinolone peak was identified using pure powder and quantified by comparing the peak heights.

Effect of Ionic Strength—From Fig. 6, it is obvious that K_{obs} decreases with increasing ionic strength. Therefore, the reacting ions are probably the protonated form of I and $H_2PO_4^-/HPO_4^{2-}$. However, the slope of the line was ~1.16 *versus* the expected value of ~2.04. This may be due to high ionic strengths, since the equation log K = log K_0 + 1.02 $(Z_A Z_B)\sqrt{\mu}$ was deduced by assuming a value of ≤0.01 (5). In these studies, it was necessary to keep the concentration of buffering agent high in order to maintain constant pH values. Therefore, the ionic strengths were high. The equation cannot be expected to hold at salt concentrations much beyond the range of validity of the Debye–Huckel theory (5).

The other explanation may be that one route of decomposition involves reaction between the undissociated molecule of I and $H_2PO_4^-/HPO_4^{2-}$. If so, this route will not be affected by ionic strength and, hence, the slope will be reduced. Triamcinolone acetonide does decompose at lower pH (~1.6) and higher pH (~12.6) without the presence of phosphate ion. Therefore, H^+ and OH^- also catalyze the reaction only when present in high concentrations. The K_{obs} value at 25° and pH 1.6 was 0.0068 day^{-1} *versus* 18.2 day^{-1} at pH 12.6.

Later, it was determined that at lower pH (solution 1), an increase in ionic strength slightly increased the rate constant in hydrochloric acid buffer. This slight increase may be an experimental error or the difference could be due to a different reaction mechanism in hydrochloric acid buffer *versus* phosphate buffer, as explained above.

Effect of Temperature—As expected, the solutions were much more stable when stored at 25° than at 50°. From the estimated K values, the solutions were stable up to 9 times longer at 25° than at 50°.

Effect of Solvent—The data (solutions 19–21) indicate that ethanol is better than glycerin/propylene glycol for stability of I as long as the same pH is maintained. However, without pH or ionic strength adjustments (solutions 23, 26, 27), glycerin proved better than ethanol/propylene glycol. The estimated K values at 50° were 0.003, 0.004, and 0.007 day^{-1} for solutions 26, 23, and 27, respectively.

In polyethylene glycol ointment base USP (1), K_{obs} was estimated to be 0.008 day^{-1}, which is similar to solution 27 (Table I) which contained 25% v/v propylene glycol. The pH of a 1% aqueous solution of the ointment was 4.2.

In another experiment, an aqueous solution of I (40.0 μg/ml) containing 20% v/v methanol and 0.3% v/v hydrogen peroxide was stored at 50° in a 50-ml volumetric flask. After 5 days, it had decomposed 11.5%.

Comparison of Aspirin and Copper Aspirinate with Respect to Gastric Mucosal Damage in the Rat

AGNES A. ALICH *x, VICTORIA J. WELSH *, and LORENTZ E. WITTMERS, JR. ‡

Received July 26, 1982, from the *Department of Chemistry, College of St. Scholastica, Duluth, MN 55811 and the ‡Department of Physiology, School of Medicine, University of Minnesota-Duluth, Duluth, MN 55812. Accepted for publication November 4, 1982.

Abstract □ The copper salt of aspirin has been compared with aspirin in terms of damage to mucosal tissue. Using a protein-bound dye to highlight erosions, it has been found that copper aspirinate is at least as damaging as aspirin itself. This finding is not in agreement with previously published claims. Copper aspirinate produced more widespread superficial erosions and slightly less deep erosions than aspirin alone. Mixtures of the copper(II) ion and aspirin produced results similar to copper aspirinate, suggesting that the hydrolysis products of copper aspirinate, copper(II) ion and aspirin, together may be especially damaging to the mucosa. Copper alone was not damaging, but aspirin alone yielded intermediate results. Short incubation times produced only erosions (no ulcers), which were clearly differentiated into two classes by depth of color. Histological examination verified this classification into superficial and deep erosions.

Keyphrases □ Copper aspirinate—gastric mucosal damage in the rat, protein-bound dye, histology, comparison with aspirin □ Aspirin—gastric mucosal damage in the rat, protein-bound dye, histology, comparison with copper aspirinate □ Ulceration—gastric mucosa, rat, aspirin and copper aspirinate, comparison using protein-bound dye and histology

Gastric mucosal damage induced by the administration of aspirin has been studied for many years. The animal model most often used has been the rat, in which, following exposure to aspirin, numerous ulcers have been found in the corpus (with a few in the antrum) (1, 2). It has been demonstrated that aspirin is absorbed from the corpus and antrum, but not the rumen (3, 4). Buffered aspirin has been shown to produce fewer lesions than aspirin alone (1, 5–7), presumably because the buffered aspirin is not absorbed from the stomach but from the intestine.

In 1976 Sorenson (8, 9) reported that copper aspirinate [tetrakis(acetylsalicylato)-μ-dicopper(II)], the copper salt of acetylsalicylic acid, had a strong antiulcer effect compared with aspirin alone when administered during the period of ulcer development in the Shay rat (10). On the basis of his observations, Sorenson suggested that the copper complex of aspirin may be the pharmacologically active form of this drug. Numerous other researchers then investigated the lesion-producing ability of copper aspirinate in the rat model (11–16). Although some conclusions were drawn supporting Sorenson's claim, these studies leave considerable uncertainty concerning the relative ulcerogenic potential of copper aspirinate and aspirin.

The results presented here are an attempt to make a quantitative comparison of the effect of aspirin and copper aspirinate on the gastric mucosa of the rat, using a protein-bound dye to highlight lesions (17) and histological examination of the tissue to validate the interpretation of the dye observations. With respect to the copper aspirinate, experiments were included to differentiate between the effects of the complex and its hydrolysis products, aspirin and the copper(II) ion. A moderate (pharmacological) dose and short incubation period were used in all experiments. In a separate set of experiments, all compounds were given with a buffer system to assess the effect of the buffer when the drug is prevented from leaving the stomach by ligation of the duodenum.

EXPERIMENTAL

Since lesion formation due to aspirin is altered by the presence of food in the stomach (5, 17), all animals (male Sprague–Dawley-derived rats, 150–300 g body weight) were fasted 24 hr prior to the experiments. Anesthesia was induced with ether and maintained with an intraperitoneal injection of sodium pentobarbital[1] (50 mg/kg of body weight). An endotracheal cannula was inserted through a midline neck incision. The abdomen was opened and the duodenum ligated, care being taken not to obstruct the vascular supply to the stomach. An infant feeding tube was inserted through the esophagus into the stomach, and the stomach was rinsed with 10–15 ml of saline to remove bits of food and other foreign matter. The test suspension (0.5 ml/100 g of body weight) was instilled, and the tube removed. Preliminary experiments indicated that this volume of fluid resulted in an intragastric pressure of <4 cm H_2O when initially administered. The abdomen was closed with wound clips.

The compounds or mixtures employed in these experiments were ground to fine powders, and test suspensions in 0.1% aqueous nonionic surfactant[2] were prepared by sonicating the appropriate amount of the test compound or mixture for 10 min. A nonionic suspending agent was chosen in order to avoid decomposing the copper complex (18). Molar equivalents of the copper(II) ion and aspirin were used in the experiments, as shown in Table I. The suspension volume administered each animal was determined from its body weight (0.5 ml/100 g of body weight). In each case the dose was equivalent to 100 mg aspirin/kg. The suspensions tested were aspirin, copper aspirinate (19), copper sulfate plus aspirin, and copper alone (in the form of copper sulfate). All suspensions were given with and without a buffer. The buffered suspensions contained 3.0 mg/ml of dihydroxyaluminum glycinate[3] and 6.0 mg/ml of magnesium carbonate. This buffer system is the same as that used in a commonly available proprietary product (20).

The suspensions were allowed to incubate in the stomach for 120 min. Ten minutes prior to the end of the incubation period, the animals were given an intravenous (femoral vein) injection of 5% protein-binding dye[4] in saline (17). At 120 min of incubation, the animals were sacrificed. The stomachs were immediately removed, opened along the lesser curvature, and washed with ~10 ml of saline. When necessary, a camel's hair brush was used to remove the mucous layer. The stomachs were pinned over rubber stoppers and examined under a dissecting microscope. Lesions could easily be separated into two groups with well-defined boundaries depending on the intensity of the dye in the tissue. Each of the two groups (one a light blue, the other very dark) was scored by counting the number of lesions (x) in each of five size classes (y). The classes were defined according to Guth *et al.* (2, 21): $y = 1$ (pinpoint lesions), $y = 2$ (lesions <1 mm in diameter), $y = 3$ (lesions 1–2 mm in diameter), $y = 4$ (lesions 2–4 mm in diameter), and $y = 5$ (lesions >4 mm in diameter). A lesion index was computed by:

$$\text{Lesion Index} = \sum_{i=1}^{5} x_i y_i$$

Mean, standard deviation, and standard error were calculated for each group of rats; the number of rats per group ranged from 6 to 17. The stomachs were stored in 10% formalin in saline and recounted after 24

hr. The average of the two values was recorded as the lesion index. The Student's t test (unpaired) was applied as a test of significance ($p < 0.05$).

Representative samples of each type of lesion were taken from the stomach, embedded in paraffin, and stained (hematoxylin–eosin) for histological evaluation. The blocks were sectioned in a serial manner so that the lesions were not missed. The evaluation of the histological material was done under a double-blind procedure.

RESULTS

The lesions outlined by the blue dye were separated into two classes based on two distinct colors of damaged mucosal tissue. Histological examination revealed that the lighter of these were superficial erosions (penetrating less than halfway through the mucosa) and the darker were deep erosions (penetrating more than halfway through the mucosa). No true ulcers were produced in any of these systems. There is excellent agreement between the two methods for rats tested with copper aspirinate or a mixture of copper(II) ion and aspirin, but poor agreement in the experiments involving aspirin alone (Table II). In terms of the lesion index, agreement is good where the index is large, but poor where the index is small.

Figure 1 displays lesion index values calculated by the equation for superficial and deep erosions. In addition to differences in the depth of dye color (due to extent of leakage of the dye–protein complex from

[a] In the dye evaluation, assignment was made on the basis of color; in the histological evaluation, on the basis of penetration into the mucosal surface. [b] Superficial lesions extended less than one-half the mucosal thickness; deep lesions penetrated more than one-half the thickness. No lesion penetrated the muscularis mucosa.

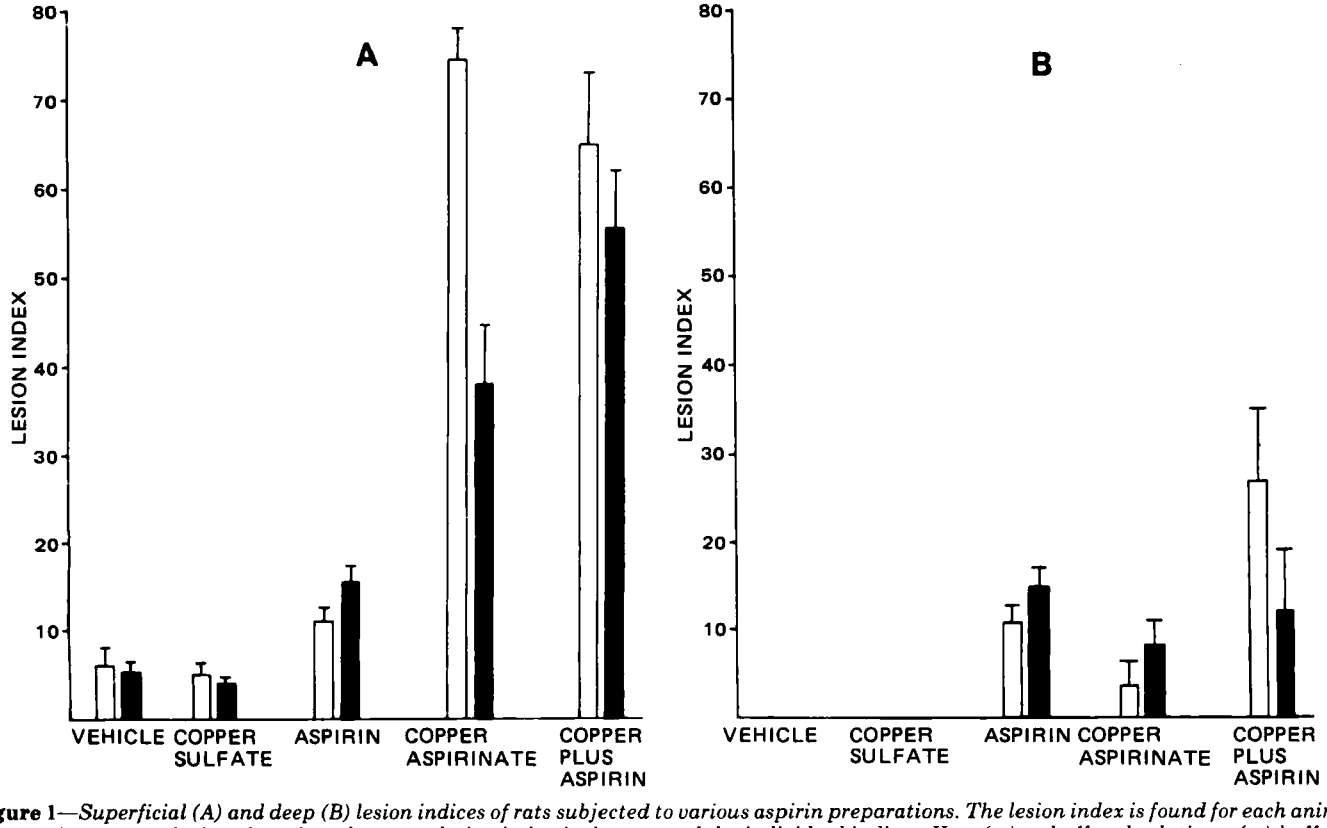

Figure 1—*Superficial (A) and deep (B) lesion indices of rats subjected to various aspirin preparations. The lesion index is found for each animal by summing over each size of erosion; the group lesion index is the mean of the individual indices. Key: (□) unbuffered solutions; (■) buffered solutions. The bars represent +1* SEM.

[a] The diameter of individual lesions determined the category into which they fell for counting. The mean represents the average number of lesions of each size, and the lesion index is the score obtained by summing.

damaged blood vessels), deep lesions were small and circular or oval, whereas superficial erosions were irregular in shape and considerably larger. The difference in size is apparent from the comparative lesion indices for the two types of erosions, which are plotted on the same scale in Fig. 1A and B. In general, the presence of the buffer had no significant effect on the extent of damage produced under these experimental conditions.

Copper aspirinate and a mixture of aspirin and copper sulfate caused significant increases over controls in both the superficial and deep lesion indices. Copper aspirinate and copper(II) ion plus aspirin had significantly higher superficial lesion indices than aspirin alone ($p < 0.001$), but were not significantly different from each other. The copper aspirinate deep lesion index was significantly less than the aspirin deep lesion index in the unbuffered systems ($p < 0.001$), but not in the buffered systems.

Tables III and IV contain data from which the lesion indices were calculated. It is clear from this data that the higher superficial lesion index of copper aspirinate and copper(II) ion plus aspirin represent both more and larger erosions than are found for aspirin alone. There does not appear to be a clear difference between the deep erosion data of copper aspirinate and aspirin.

Some deep erosions in categories 3, 4, and 5 were observed to have red or brown centers to which the blue dye had not penetrated; it was initially supposed that these represented ulcers. On histological examination, however, these lesions were found to be erosions, indicating that disruption of the circulation occurs prior to ulcer development. A small number of these appeared in aspirin-treated rats, somewhat more in copper aspirinate-treated rats, and the most in copper-plus-aspirin-treated rats. When copper sulfate was used in the absence of aspirin, the lesion indices were not significantly different from the controls for either superficial or deep erosions.

DISCUSSION

Initial damage to the mucosa from absorption of aspirin is more easily and accurately assessed by the use of a protein-binding dye. Two stages prior to ulcer formation can be clearly distinguished by the loss of the dyed protein into the tissue. The darker blue lesions, as can be seen from the agreement of histological and dye diagnoses (Table II), are deep erosions, penetrating more than halfway through the mucosa. Of the 16 lesions diagnosed as deep by the dye method, 76% were in agreement using the histological diagnosis.

For lesions diagnosed as superficial erosions by the dye method, agreement was poor; less than half were in agreement with the histological diagnosis. Of those that did not agree, the majority were found to have no erosion by the microscopic examination. Thus, the superficial erosions identified by the dye technique included both erosions penetrating less than halfway through the mucosa and pre-erosion lesions which allowed loss of the protein–dye complex from the gastric capillaries. The minimal pathological change necessary to allow the dye to accumulate in the mucosa would be an alteration in capillary permeability of sufficient magnitude to allow transendothelial movement of the protein–dye complex. Robins (22) has shown, by transmission electron microscopy, that the first structural change after administration of aspirin is alteration of the capillary endothelial basement membrane, which leads to the breakdown of small blood vessels before any other cytolytic effects appear. Thus, bleeding (and the loss of the protein–dye complex into the tissue) could occur without gross visible damage to the mucosal structures. Williams *et al.* observed no erosions when copper aspirinate was given to rats, but even after 18 hr, noted that bleeding had occurred (12). Their technique would not have allowed detection of these lesions.

In those experiments in which the superficial lesion index was highest, the correlation between dye and histological evaluation was remarkable. Table II indicates that in copper aspirinate experiments, agreement was 7 of 9, and in copper-plus-aspirin experiments, agreement was 5 of 6. In experiments where the superficial lesion index was low, correlation was poor: for aspirin alone, agreement was 4 of 9, and for buffered aspirin, 2 of 6. Thus, in terms of the calculated superficial lesion indices, the difference between copper aspirinate and aspirin is even larger than it appears to be from Fig. 1A. For the deep lesion index, the only disagreements in diagnosis were overdiagnosis by the dye method in the aspirin and aspirin-plus-buffer classes. Thus, the calculated deep lesion index for aspirin would be less than that indicated in Fig. 1B, whereas those for copper aspirinate and copper-plus-aspirin would be unchanged. It is clear that these data do not support the Sorenson conclusions that copper aspirate is less damaging to stomach mucosa than aspirin.

The Shay rats (10) used by Sorenson are prepared by ligating the duodenum and allowing acid to accumulate in the stomach for 16–19 hr, resulting in ulcer formation. In Sorenson's experiments (8), the aspirin or copper aspirinate was placed in the stomach during the period of ulcer formation. At the end of the experiment, an ulcer index was calculated. The substance was deemed active if the ulcer index was less than that of the controls. Under this protocol, both aspirin and copper aspirinate were reported to be active antiulcer agents, with copper aspirinate much more so than aspirin. These conclusions actually refer to the change in the rate of ulcer formation or healing in the Shay rat model. The excess acid and very long incubation times make Sorenson's results unique and of questionable value in the study of lesion formation by aspirin and related compounds under normal conditions of absorption.

With respect to the other studies in which copper aspirinate was tested, conditions varied greatly (11–16). Williams *et al.* (12) did not fast rats prior to experimentation and did not examine the stomachs for 18 hr after dosing. It has been shown that fed rats develop fewer stomach lesions from aspirin than do fasted rats (5, 17) and that spontaneous healing of lesions begins within 6 hr after damage (5). These authors tallied numbers of erosions, but did not assess size or severity of lesions. They reported that while rats treated with aspirin developed 50% more lesions (histological evaluation of lesion type was not done) than controls, those treated with copper aspirinate developed no erosions (though bleeding was observed). The significance of these data is not clear due to the aforementioned variations in the experimental protocol. Rainsford and Whitehouse (13) reported ulcers formed in groups of five fasted rats given aqueous suspensions of aspirin or copper aspirinate. Those given copper aspirinate were also subjected to cold stress. These authors concluded that since the copper aspirinate-treated rats (with cold stress) did not have significantly more mucosal damage than the aspirin-treated rats, copper aspirinate caused less damage to the mucosa. The data reported in this paper, using larger groups of rats, does not support their conclusions. Boyle *et al.* (11), reporting the percentage of rats having at least one "area of erosion," found that for aspirin alone this figure was ~98% and for copper aspirinate ~15%. Their paper refers to both erosions and ulcers, and it is not clear which were counted. The difference in results is perhaps due to the difference in assessment—the lack of a protein-binding dye to enhance preulcer lesions and a counting formula that did not include both number and size of lesions. Sorenson's results were also tested by Lewis *et al.* (14–16). The rats they used were very young, and it has been shown that juvenile rats do not have the same susceptibilities to aspirin-induced lesions as adult rats (23). Results were about the same for free aspirin as for the copper complex. Observations were made after 6 hr of incubation without magnification or the aid of a dye.

The experiments reported in this paper eliminated as many of these variables as possible. Using a protein-binding dye and summing over both number and sizes of lesions, clear differences appeared between the effects of copper aspirinate and aspirin. Figure 1B shows that copper aspirinate produced fewer deep erosions than aspirin alone although there was apparently a greater disruption of blood flow from copper aspirinate as indicated by the absence of dye in the center of some of these erosions. The difference in the deep lesion indices for these two systems was not significant when buffer was present. The copper aspirinate yielded larger numbers of superficial lesions than aspirin alone (Fig. 1A). The combination of copper plus aspirin caused more deep lesions than either aspirin or copper aspirinate alone, suggesting that it is the hydrolysis products of the copper aspirinate that are the most potent lesion-producing system. The smaller deep lesion index of copper aspirinate *versus* aspirin may be due, in part, to the slow hydrolysis of the complex. The concentration of the hydrolysis products (copper and aspirin) may be sufficient to produce large numbers of superficial lesions, but not enough to produce as many deep lesions as the aspirin alone.

With the exception of one experimental group, in the experimental protocol employed here, the addition of buffer did not result in a significant decrease in lesion formation. Only in the group of animals receiving copper aspirinate did the addition of buffer result in a significant decrease in the formation of deep erosions (Fig. 1B). This should not be interpreted as contradicting the known fact (24) that buffered aspirin is less damaging to stomach mucosa than aspirin alone. In these experiments, the stomach was isolated from the intestinal tract so that the drug was held in the stomach for the duration of the experiment.

The data presented allow several conclusions. First, if one employs protein-bound dye to mark or outline gastric lesions, the severity or type of lesion must be verified by histological methods. The appearance of the dye on the mucosal surface can result from prelesion capillary endothelial damage, erosions, or ulcers. The protocol employed here did not produce ulcers, and it was possible to differentiate between deep and superficial erosions by the color characteristics of the extravasated dye. The dye method includes pre-erosion capillary endothelial damage with superficial erosions. Secondly, the administration of copper aspirinate produced larger numbers and sizes of superficial erosions than did aspirin alone. The frequency of deep erosions was slightly less for copper aspirinate than for aspirin alone. Thirdly, the combination of copper(II) ions and aspirin resulted in a greater effect (a larger deep lesion index) than the copper complex, suggesting that it may be the hydrolysis products of the copper aspirinate complex which cause the more severe gastric mucosal damage. Finally, the addition of a buffer to the preparation resulted in a decrease in lesion formation only in the case of copper aspirinate and only as evaluated from superficial erosions.

Hemolysis Caused by Cetomacrogol 1000: Evidence for Hydroxyl Radical Participation

RUTH SEGAL ˣ and ILANA MILO-GOLDZWEIG

Received June 1, 1982, from *The Hebrew University of Jerusalem, School of Pharmacy, Department of Pharmacognosy and Natural Products, P.O.B. 12065 Jerusalem, Israel* Accepted for publication October 28, 1982.

Abstract □ The mechanism of cetomacrogol 1000-induced hemolysis was investigated. Previous conclusions that peroxides are involved in the hemolytic process were confirmed. The possibility that hydrogen peroxide, superoxide, hydroxyl radical, or singlet oxygen, which are known to induce hemolysis, are involved in cetomacrogol 1000-induced hemolysis was tested by using specific inhibitors and inactivators. The hydroxyl radical ($OH^{\cdot}$) was shown to be the only apparent oxygen species involved in cetomacrogol 1000-induced hemolysis. Its contribution to the hemolytic potency of the surfactant is ~30%.

Keyphrases □ Cetomacrogol 1000—induction of hemolysis, peroxidation, hydroxyl radical participation, erythrocytes □ Surfactants—cetomacrogol 1000-induced hemolysis, peroxidation, hydroxyl radical participation □ Peroxides—role in surfactant-induced hemolysis, cetomacrogol 1000, hydroxyl radical participation

Polyoxyethylene-derived surfactants are widely used as pharmaceutical aids, although their tendency to form peroxides is well known (1–4) and their deleterious effects on various drugs have been proven (5–7). Like other surface-active compounds, the polyoxyethylene surfactants cause hemolysis when they come in contact with red blood cells (7–9). Results recently published (10) indicate that the hemolytic activity of polyoxyethylene surfactants may be ascribed to their tendency to form peroxides. It should, however, be emphasized that hemolysis is only one form of cytotoxicity.

Peroxidation is believed to be one of the main mechanisms that give rise to membrane damage and cellular death (11–16). Destruction of normal tissue as a consequence of inflammatory reactions is also ascribed to oxygen radicals. The superoxide anion radical ($O_2^{\cdot-}$), hydrogen peroxide, the hydroxyl radical ($OH^{\cdot}$), and the oxygen radicals ($^1O_2$) are highly reactive and can damage most types of cellular polymers. They have been shown to oxidize proteins, peroxidize fatty acids, and cleave polysaccharides *in vitro* (15). All were found to induce lysis of various types of cells (17–19). The abundance of polyunsaturated fatty acids in cell membranes and the facility with which these undergo oxidation are assumed to be the cause of peroxide-induced lysis (20).

Because of the widespread use of these surfactants and the awareness of the pernicious effect of free radicals and especially peroxides, we decided to study the mechanism by which these compounds induce peroxidation, with the ultimate aim of finding potential antidotes to these harmful effects. Their simple structure, easy availability, and the facility with which cell damage can be estimated by means of hemolysis make erythrocytes the ideal model for such research. Cetomacrogol 1000 (polyethylene glycol 1000 monocetyl ether) was chosen as the model polyoxyethylene surfactant in this research.

EXPERIMENTAL

Materials—Cetomacrogol 1000, polyethythelene glycol 1000 monocetyl ether[1], is a solid and, thus, not sensitive to autooxidation (4). Solutions of cetomacrogol 1000 were freshly prepared. Histidine[2], tryptophan[3], mannitol[3], thiourea[4], and digitonin[2] were commercial samples. Hydroquinone[5] was crystallized from benzene prior to use. Catalase[6] was dialyzed against water (specific activity 1.57×10^6 U/ml), superoxide dismutase[3] had a specific activity of 2650 U/mg of protein. Saponin-A was obtained from *Styrax officinalis* (21).

Determination of Hemolytic Activities—All experiments were performed on citrated blood freshly drawn from albino rats. The erythrocytes, freed of plasma by three washings in cold isotonic saline, were diluted with isotonic buffer (3.95 g of $Na_2HPO_4 \cdot 2H_2O$, 0.76 g of KH_2PO_4, 7.2 g of NaCl, *q.s.* to 1000 ml with water; pH adjusted to 7.4) to give a 1% suspension. Varying quantities of hemolysin, dissolved in buffer, were added to 2 ml of the erythrocyte suspension, and the volume was increased to 4 ml with buffer. The components were added in the following order: erythrocyte suspension, buffer, and the hemolyzing agent. The mixtures were incubated for 60 min at 37° in a shaking water bath, and then were centrifuged at $1000 \times g$; the absorbance of the supernatant was determined at 540 nm. The percentage of hemolysis was determined by comparison with a sample in which 100% hemolysis was obtained by the addition of digitonin.

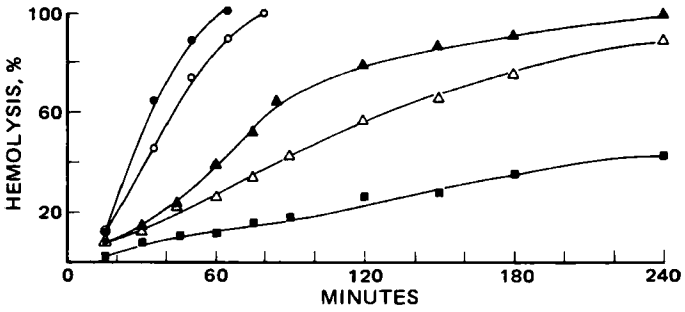

Figure 1—*Time dependence of cetomacrogol 1000-induced hemolysis. Cetomacrogol 1000 concentration: (●) 1.5 × 10⁻⁵ M; (○) 1.3 × 10⁻⁵ M; (▲) 9.5 × 10⁻⁶ M; (△) 7.6 × 10⁻⁶ M; (■) 5.7 × 10⁻⁶ M.*

of experiments were run in parallel: (*a*) a regular hemolysis test and (*b*) the same incubation mixture as in (*a*) but with inhibitor solutions (in buffer) substituting for part of the buffer. The components were added as follows: erythrocytes, buffer, inhibitor, hemolysin. Percentage inhibition was determined as:

$$100 \times \left(1 - \frac{\%\text{ hemolysis with inhibitor}}{\%\text{ hemolysis without inhibitor}}\right)$$

Effect of Visible Light on Cetomacrogol 1000-Induced Hemolysis—Equal volumes of mixtures consisting of erythrocytes, buffer, and cetomacrogol 1000 were introduced into eight test tubes. Four of the test tubes were shielded from light by covering them with aluminium foil. All eight of the test tubes were incubated for 1 hr at 37° and processed as described above.

RESULTS

Figure 1 shows the cetomacrogol 1000-induced hemolysis at various time intervals. The five curves represent different cetomacrogol 1000 concentrations; their shape is in accordance with previous observations that hemolysis produced by polyoxyethylene cetostearyl ethers progresses slowly toward 100% irrespective of the surfactant concentration (10).

To ensure reproducibility of the results and to provide a common basis for comparison of results of different experiments, the extent of the hemolysis was tested after exactly 1 h of incubation at 37°. The percentage of hemolysis was, therefore, reproducible to within 3% hemolysis.

No information is available on the identity of the active tissue-damaging radical produced during autooxidation of the polyoxyethylene surfactants, especially when they are in contact with living cells. We therefore decided to test the inhibitory influence of a variety of enzymes and chemicals which inactivate specific peroxides and radicals known to induce hemolysis. The effectiveness of the various inhibitors was tested at three cetomacrogol 1000 concentrations: 1.3×10^{-5} *M*, 1×10^{-5} *M*, and 7.6×10^{-6} *M*. These concentrations normally cause ~80, 50, and 30% hemolysis within 1 hr.

Catalase—Hydrogen peroxide either by itself or as a precursor of other active radical species is a well-known inducer of tissue damage and hemolysis (20, 22). The enzyme catalase, which catalyzes the conversion of H_2O_2 to O_2 and H_2O, was tested as a potential inhibitor for cetomacrogol 1000-induced hemolysis. The results (Table I) show that catalase had no inhibitory effect on cetomacrogol 1000-induced hemolysis even at levels as high as 625 U/ml.

Superoxide Dismutase—Superoxide radicals (O_2^-), generated enzymatically or photochemically, have been shown to induce lipid peroxidation, to damage membranes, and to kill cells (17, 20). The enzyme superoxide dismutase, which gives rise to the dismutation $O_2^- + O_2^- + 2H^+ \rightarrow H_2O_2 + O_2$ (23), was used to test the possibility of O_2^- being the active hemolyzing agent. No inhibition was obtained with superoxide dismutase (65 U/ml) nor with a superoxide dismutase–catalase mixture. All results are summarized in Table I.

Oxygen Radicals ($^1O_2$)—Hemolysis can be the result of the photosensitized production of $^1O_2$ using either endogenous or exogenous photosensitizers (19). The possibility that singlet oxygen was responsible for the cetomacrogol 1000-induced hemolysis was evaluated by adding specific $^1O_2$ quenchers, *i.e.*, the aromatic amino acids histidine and tryptophan, and hydroquinone (15, 18, 20). The three inhibitors were tested at the highest possible concentrations: hydroquinone at concentrations $>2.5 \times 10^{-4}$ caused damage to the erythrocytes (they turned brown); the maximal concentrations for histidine and tryptophan were those allowed by their solubility.

The results of these experiments are summarized in Table I. Of the three $^1O_2$ quenchers, only histidine caused slight inhibition of hemolysis, while tryptophan and hydroquinone produced no effect at all.

Hydroxyl Radicals—These radicals are very reactive and can interact with unsaturated fatty acids, which are components of the cell membrane, either through hydrogen abstraction or by addition to the unsaturated system (24). Among the oxidizing radicals the hydroxyl radical is the most powerful and most deleterious to the living membrane (25). The role of the hydroxyl radical in the hemolytic effect of cetomacrogol 1000 was tested by the addition of the specific hydroxyl radical quenchers, mannitol and thiourea. Both produced significant inhibition. Inhibition as function of mannitol and thiourea concentration is represented in Figs. 2 and 3, respectively. At high levels of hemolysis, an almost linear correlation between inhibitor concentration and inhibitor effect is observed, whereas at low levels, inhibition increases with inhibitor concentration until a plateau is obtained. In no case does inhibition exceed 35%. The possibility that the inhibition might be due to some nonspecific protective effect of the inhibitors on the red blood cell membranes was eliminated by testing their effect on saponin hemolysis. Digitonin and *Styrax* saponin, two highly potent crystalline compounds, were chosen to represent

the saponins. The experiments were performed at two levels of hemolysis (*i.e.*, saponin concentrations). Mannitol and histidine had no effect on saponin hemolysis. Thiourea produced some inhibition at high inhibitor concentrations. However at 1.3 × 10^{-3} *M*, a concentration at which maximal inhibition of cetomacrogol 1000-induced hemolysis was obtained, no effect was observed (Table II).

Free radical reactions are often light catalyzed. We therefore tested whether cetomacrogol 1000-induced hemolysis is promoted by visible light. The experiments were performed at four different surfactant concentrations, and the results are summarized in Table III. They clearly show that the extent of hemolysis is indeed enhanced under the influence of light.

DISCUSSION

The results of the present investigation confirm previous conclusions (10) that the hemolytic activity of polyoxyethylene-derived surface-active agents is to be ascribed, at least in part, to their tendency to form peroxides. Various oxygen radical species and peroxides are known to induce hemolysis as a result of lipid peroxidation (12, 13, 15, 20). Our experiments indicate that in cetomacrogol 1000-induced hemolysis, the hydroxyl radical is strongly involved in the process.

The polyoxyethylene surfactants are polyethers and, therefore, their spontaneous autocatalytic peroxidation has been described as taking place *via* a free radical chain reaction as follows (3):

$$RH + \text{light or catalyst} \rightarrow R\cdot + H\cdot$$

Scheme I—Initiation

$$R\cdot\, O_2 \rightarrow ROO\cdot$$

$$ROO\cdot + RH \rightarrow ROOH + R\cdot$$

Scheme II—Propagation

Free radicals also may be formed by the processes in Scheme III, and removed by those in Scheme IV:

$$ROOH \rightarrow ROO\cdot + H\cdot$$

$$ROOH \rightarrow RO\cdot + \cdot OH$$

$$2ROOH \rightarrow ROO\cdot + RO\cdot + H_2O$$

Scheme III

Scheme IV—Termination

This indicates that hydroxyl radicals may in fact be produced during polyoxyethylene surfactant autooxidation, as suggested by our findings on the active hemolyzing factor. The observation that visible light enhances cetomacrogol 1000-induced hemolysis further substantiates this suggestion.

The concentrations of inhibitors used in the present investigation were high when compared with those used by Kellog and Fridovich (20) to inhibit the hemolysis obtained by xanthine oxidase–acetaldehyde. These authors however used a much lower erythrocyte concentration for their experiments. This difference in the experimental conditions no doubt affects the extent of hemolysis as well as the extent of inhibition obtained by inhibitors.

The shapes of the curves representing the extent of inhibition by mannitol and thiourea as a function of inhibitor concentration are peculiar (Figs. 2 and 3). Although inhibition increases with inhibitor concentration, the curves reach a plateau at ~30% inhibition. The reason for the incomplete inhibition by $OH^{\cdot}$ scavengers may be due to other radicals obtained in the course of the surfactant autooxidation (see Schemes I–IV).

The possibility that histidine might scavenge such radicals seems controvertible since a mixture of histidine–mannitol did not enhance the inhibition beyond that of mannitol alone[7]. The assumption that other peroxide radicals take part in the hemolytic process also seems questionable in view of the fact that experiments conducted under a nitrogen atmosphere also produced only 30% inhibition (10). The high degree of consistency of these results suggests that although surface activity of the polyoxyethylene-derived surfactants could not be correlated with their hemolytic potency, the solubilizing properties of the surfactant contribute to the hemolytic process. Our present experiments suggest that the contribution of the surface activity factor to cetomacrogol 1000-induced hemolysis is ~70%, while the contribution of the $OH^{\cdot}$ radicals is ~30%.

Effects of Calcium and Neomycin on Phase Behavior of Phospholipid Bilayers

MADURAI G. GANESAN *, NORMAN D. WEINER *x, and JOCHEN SCHACHT ‡

Received June 25, 1982, from the **College of Pharmacy* and ‡*Kresge Hearing Research Institute, University of Michigan, Ann Arbor, MI 48109.* Accepted for publication October 14, 1982.

Abstract □ Calcium ion (Ca^{2+}, 5 m*M*) caused a large upward shift in the transition temperature (T_c) of dipalmitoyl phosphatidylglycerol liposomes, apparently interacting with external and internal lipid in the bilayer. Neomycin (1 m*M*) caused only a small shift, apparently not penetrating the internal lipid domains. When liposomes were first incubated with Ca^{2+} followed by neomycin, the shift in T_c indicated displacement of Ca^{2+} by the drug. Liposomes of dipalmitoyl phosphatidylcholine or distearoyl phosphatidylcholine did not interact significantly with either cation. In mixed dipalmitoyl phosphatidylcholine–dipalmitoyl phosphatidylglycerol and distearoyl phosphatidylcholine–dipalmitoyl phosphatidylglycerol liposomes, addition of Ca^{2+} or neomycin resulted in phase separation.

Keyphrases □ Calcium—effect on phase behavior of phospholipid bilayers, liposomes, neomycin □ Neomycin—effect on phase behavior of phospholipid bilayers, liposomes, calcium □ Liposomes—effects of calcium and neomycin on phase behavior of phospholipid bilayers □ Phase behavior—effects of calcium and neomycin on phospholipid bilayers, liposomes

Acidic phospholipids have been suggested as the membrane sites responsible for interactions with basic antibiotics in bacteria (1) and mammalian cells (2, 3). In the case of aminoglycoside antibiotics, such interactions have been discussed as mechanisms underlying their nephro- (2) and ototoxicity (3). The aminoglycosides also exert intracellular effects in bacteria and in afflicted eukaryotic cells. The mechanism of cell penetration is not clear. Internalization of aminoglycosides into lysosomes has been reported for the renal cortex (4), but not for other organs. Entry *via* a basic amino acid transport system (5) may be an alternate pathway.

Studies with monomolecular films (6) and liposomes (7) have shown that neomycin and other aminoglycosides affect Ca^{2+} binding to phospholipids, and that the degree of calcium displacement is strongly dependent on the head group of the anionic lipid. Differential scanning calorimetry is a valuable tool in determining physical changes of bilayers resulting from ion or drug interactions with liposomes, *e.g.*, gel-to-liquid phase transitions, phase separation, or membrane fusion (8–11). The present study investigates the actions of Ca^{2+} and neomycin, a highly toxic aminoglycoside, on thermotropic properties of synthetic negatively charged and neutral liposomes with well-defined transition temperatures.

EXPERIMENTAL

Liposomes were prepared from dipalmitoyl L-α-phosphatidylcholine (I), distearoyl L-α-phosphatidylcholine (II), and the ammonium salt of dipalmitoyl L-α-phosphatidyl-DL-glycerol (III)[1]. These lipids showed no impurities by TLC and by analysis of pretransition and main transition peaks of their liposomes.

Lipid samples (15 μmoles) dissolved in chloroform were dried under a nitrogen stream, and residual solvent was removed *in vacuo*. The dried lipid was suspended by vortexing in 10 m*M* tris buffer containing 100 m*M* NaCl and 0.1 m*M* EDTA (ethylenediaminetetraacetic acid), final pH 7.0. The resultant phospholipid concentration was 30 m*M*. Compounds I, III, and I–III (60:40 mole %) were suspended at 42°, II and II–III (60:40 mole %) at 58°. A 60:40 mole % ratio was selected, since at least 40 mole % negatively charged lipid was required to produce clearly defined thermal changes in the presence of Ca^{2+} at concentrations within the physiological range. Aliquots of the liposomal suspensions were incubated with 5 m*M* $CaCl_2$ or 1 m*M* neomycin for 60 min at 25° or 42° or, in the case of II-containing vesicles, at 58°.

Thermograms were obtained with a scanning calorimeter[2]. Aliquots of liposomal suspension (15 μl, containing 0.5–1 μmole of lipid) were transferred to volatile sample pans and properly sealed. Reference sample pans were prepared with the same amount of buffer. Inclusion of Ca^{2+} or neomycin or Ca^{2+}–neomycin mixtures in the reference sample pans did not affect the thermograms. Each sample was scanned between 5° and 70° at a rate of 5°/min and a range of 2 mcal/sec. Indium and water were used as calibration standards.

Phase-transition temperatures (T_c) were determined as the intercept between the slope of the ascending endothermic peaks and the base line. The midpoint value of transition was estimated as the maximal endothermic peak. After each run, the amount of lipid in the sample pan was determined (12). All experiments were repeated on at least three separate preparations.

RESULTS AND DISCUSSION

The thermograms for liposomes containing I or II (Fig. 1a and b) show well-defined sharp transition peaks with a broad pretransition peak. Incubation with Ca^{2+}, neomycin, or Ca^{2+} plus neomycin did not result in any changes in the thermograms. These data are in agreement with our previous monolayer (6) and liposome binding studies (7), which show no interaction between neutral phospholipids and Ca^{2+} or neomycin.

Liposomes containing III (Fig. 2a) have a clear transition peak at 41°. Incubation with Ca^{2+} (Fig. 2b) caused a 14° upward shift in T_c, in good agreement with previous observations (13). The extent of the T_c shift was related to the Ca^{2+} concentration, and 10 m*M* Ca^{2+} resulted in the loss of the transition peak up to 70°. This upward shift has been interpreted as the result of a combination of charge neutralization and specific complexation (13).

Incubation of liposomes containing III with neomycin at 25° (Fig. 2c) broadened the main transition peak of III and split it into two approximately equal components at 40° and 42°. These could represent two distinct domains of phospholipid molecules with different physical properties resulting from shallow perturbation of the bilayer primarily in the region of the phospholipid head-groups (14) and a coexistence between parent and modified phases (15). The split peak caused by neomycin thus suggests an interaction with the outer and lack of interaction

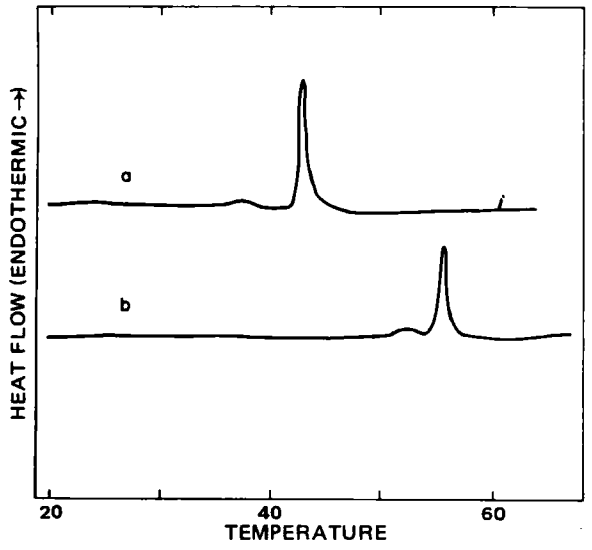

Figure 1—*Thermograms of liposomes containing I (a) and II (b). Conditions of liposome formation and incubation are described in the text.*

with the inner domains of the bilayer. Bilayers which are good permeability barriers to hydrophilic molecules above and below their T_c values (16, 17) are, however, highly permeable at their phase-transition temperature. Incubation of the liposomes with neomycin near their phase-transition temperature could conceivably alter the accessibility of the inner lipid layer. After such treatment at 42°, the split peak still remained (40° and 42°), but the 42° portion of the peak was clearly predominant (Fig. 2d). No such influence of temperature was seen with III and Ca^{2+}. This suggests that Ca^{2+} has access to the inner bilayer regions even when they are in the gel state, while the access of neomycin to the inner regions is limited by and dependent on the fluidity of the membrane. It should be pointed out, however, that the interaction of neomycin with III results in a T_c shift of only ~2°, whereas Ca^{2+} causes a much larger shift, indicating a solidifying effect (13). Thus, the resulting complexes with Ca^{2+} or neomycin have different thermal properties.

In another series of experiments, III was first incubated with Ca^{2+} at 42° and subsequently with neomycin. The resultant thermogram (Fig. 2e) shows the appearance of a distinct transition peak with a midpoint value of 43° and a very small peak at ~55°. Thus, it appears that neomycin, even at a concentration one-fifth that of Ca^{2+}, is essentially reversing the Ca^{2+} effect, *i.e.*, solidification, on the thermal properties of

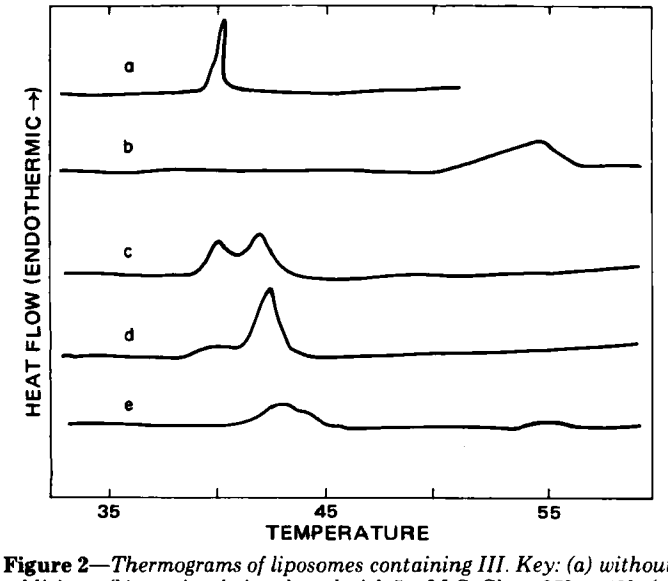

Figure 2—*Thermograms of liposomes containing III. Key: (a) without additions; (b) previously incubated with 5 mM $CaCl_2$ at 25° or 42°; (c) previously incubated with 1 mM neomycin at 25°; (d) previously incubated with 1 mM neomycin at 42°; (e) previously incubated with 5 mM $CaCl_2$ followed by 1 mM neomycin at 42°.*

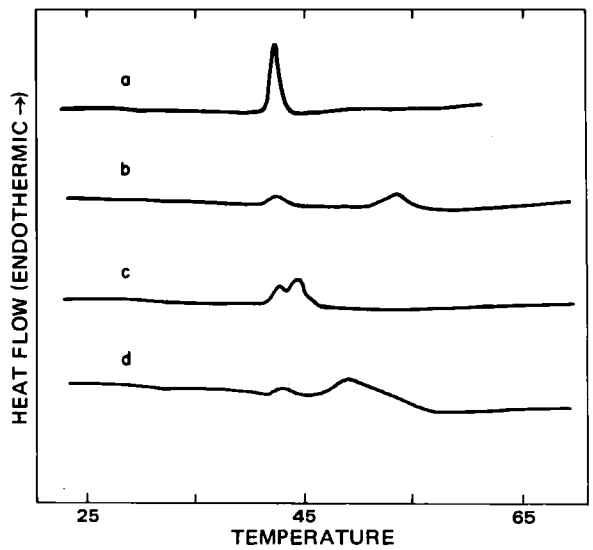

Figure 3—*Thermograms of mixed I–III liposomes (3:2 molar ratio). Key: (a) without additions; (b) incubated with 5 mM $CaCl_2$ at 42°; (c) incubated with 1 mM neomycin at 42°; (d) incubated with 5 mM $CaCl_2$ followed by 1 mM neomycin at 42°.*

the bilayers, indicating displacement of Ca^{2+} by neomycin.

Mixed liposomes containing I–III, 60:40 mole %, show a clear transition peak with a T_c value of 41.5° (Fig. 3a). This value is in agreement with that of Findlay and Barton (18), who pointed out that the almost identical T_c values for pure I, pure III, and I–III mixtures indicate complete miscibility of the components in the bilayer. In this mixed-lipid system, Ca^{2+} caused phase separation (Fig. 3b) with a small, but clearly defined peak at 41° and a major peak at 53°. Since the Ca^{2+}–III ratio is high and since there is free lateral movement of the lipid within the bilayer, the 41° peak should represent a population very rich in I and the 53° peak either a Ca^{2+}–III or a Ca^{2+}–I–III complex. The addition of neomycin to liposomes composed of I–III (Fig. 3c) resulted in a split peak centering at ~42° and 44°, which is shifted upwards ~2° from the split peak observed on incubation of liposomes composed of pure III with neomycin. This is possibly due to the incorporation of I into the neomycin–III complex.

Addition of neomycin to mixed I–III liposomes, preincubated with Ca^{2+} (Fig. 3d), produced a small transition peak at ~42.5° and a larger one at ~49°. Whereas neomycin clearly displaced Ca^{2+} from liposomes containing pure III (Fig. 2e), it appears that the presence of a neutral phospholipid in the bilayer reduced this capability. The appearance of a new peak at 49° may indicate that steric interactions in the Ca^{2+}–I–III complex interfere with neomycin binding.

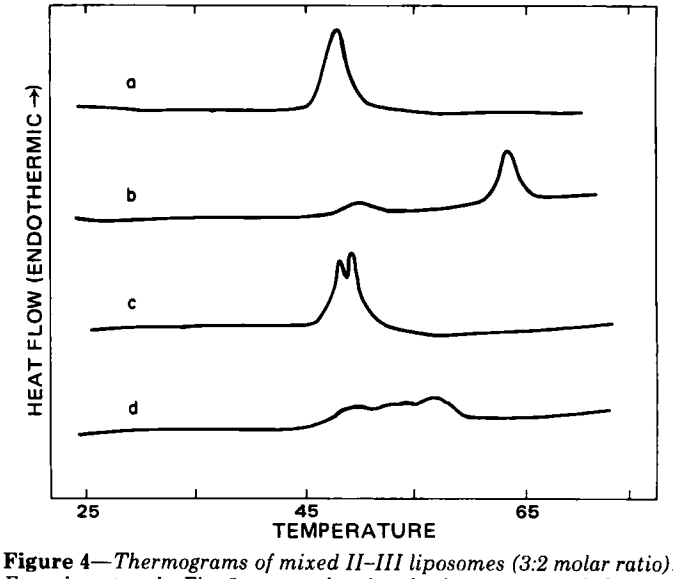

Figure 4—*Thermograms of mixed II–III liposomes (3:2 molar ratio). Experiment as in Fig. 3 except that incubations were carried out at 58°.*

The thermogram for liposomes containing II–III (60:40 mole %) shows a transition peak with a T_c value of 48° (Fig. 4a). This value is intermediate to the T_c values of pure II (57°) and pure III (41.5°), indicating good bilayer mixing. The thermograms after incubation with either Ca^{2+} or neomycin, or both (Fig. 4b, c, and d), are similar to those of liposomes composed of I–III, suggesting that the chain length of the neutral lipid does not drastically influence the overall nature of these interactions.

The displacement of calcium, which has been described for the interaction of the drug with bacteria (19), the neuromuscular junction (20), and inner ear tissues (21), may interfere with normal calcium-dependent physiological functions. The results of this study indicate that these effects may be due, in part, to resultant changes in the thermotropic properties, *i.e.*, degree of fluidity, of the lipid bilayer induced by neomycin.

Quantitation of Ketoconazole in Biological Fluids Using High-Performance Liquid Chromatography

V. L. PASCUCCI * ˣ, J. BENNETT ‡, P. K. NARANG *, and D. C. CHATTERJI * ¶

Received May 5, 1982, from the **Clinical Pharmacokinetics Research Laboratory, Department of Pharmacy, The Clinical Center, National Institutes of Health, Bethesda, MD 20205* and the ‡*Laboratory of Clinical Investigation, National Institute of Allergy and Infectious Diseases, National Institutes of Health, Bethesda, MD 20205.* Accepted for publication November 2, 1982. ¶Present address: Lyphomed Inc., Melrose Park, IL 60160.

Abstract □ A rapid, specific procedure is described for the quantitation of ketoconazole in biological fluids using high-performance liquid chromatography (HPLC). The procedure involves sample preparation using a reverse-phase C-18 cartridge prior to chromatography and quantitation using peak height ratios (UV absorbance detection, 231 nm) of ketoconazole to the internal standard, phenothiazine. A sensitivity of 0.2 μg/ml was achieved using a 0.5-ml sample. The mean recovery was 86.2%, and overall coefficient of variation of the procedure was 7.1%. This procedure has been used to determine ketoconazole levels in human serum, plasma, CSF, and synovial fluid. A comparison with a microbiological assay is presented, and adaptability of this procedure to quantitation by fluorescence to increase the sensitivity fivefold is discussed.

Keyphrases □ Ketoconazole—quantitation in biological fluids, high-performance liquid chromatography, humans □ High-performance liquid chromatography—quantitation of ketoconazole in biological fluids, humans

Ketoconazole, *cis*-1-acetyl-4-[4[[2-(2,4-dichlorophenyl)-2- (1*H*-imidazol-1-ylmethyl) -1,3-dioxolan-4 - yl] methoxy]phenyl]piperazine, an antifungal agent used to treat a wide variety of superficial and systemic mycoses (1–3), has the advantage over other imidazole derivatives of producing adequate, sustained blood levels following oral administration. Several microbiological assays (4–6) and three high-performance liquid chromatographic (HPLC) methods (7–9) have been described for quantitation of ketoconazole in biological fluids. HPLC techniques have the advantage of direct concentration measurement since the microbiological assays quantitate ketoconazole concentration indirectly as antifungal activity against a test organism. Microbiological procedures lack specificity for ketoconazole; thus, falsely elevated levels may be produced by active metabolites or other concurrently administered antifungal agents.

A rapid and reproducible HPLC method is described which is suitable for quantitation of ketoconazole in biological fluids both for routine monitoring (sensitivity to 0.2 μg/ml using UV detection) or for pharmacokinetic studies

0022-3549/83/1200-1467$01.00/0

(sensitivity to 40 ng/ml using fluorescence detection). Comparison of the results obtained using the described method with the values obtained using a microbiological assay (6) is also presented.

EXPERIMENTAL

Materials and Reagents—Ketoconazole[1], (R 41,400), was used in the preparation of spiked serum standards. Phenothiazine[2] was used as the internal standard. Methanol[3] was glass distilled and certified HPLC grade. Water was double-distilled in glass. All HPLC solvents were filtered[4] and then deaerated under reduced pressure prior to use. Reverse-phase C-18 sample cartridges[5] were used in sample preparation.

Chromatographic System and Conditions—The liquid chromatograph was equipped with a UV absorbance detector[6] operated at 231 nm and a solvent delivery system[7]. Alternatively, a spectrofluorometric detector[8] was operated with an excitation wavelength of 206 nm and a 370-nm emission filter. The analytical column[9] (4.6 mm i.d. × 25 cm, 5-μm particle size) was preceded by a 7-cm guard column[10]. The mobile phase consisted of of 75% (v/v) methanol and 25% (v/v) 0.02 *M* monobasic sodium phosphate. The pH of the mobile phase was adjusted to 6.8 with sodium hydroxide. The flow rate was maintained at 1.0 ml/min.

Procedures—Deproteinization and elimination of polar serum constituents were accomplished using C-18 reverse-phase sample preparation cartridges. The cartridges were conditioned by washing with 2.0 ml of methanol followed by 5.0 ml of water. A 0.5-ml aliquot of serum sample or serum standard was placed in a 1.5-ml capped plastic tube[11]. Phenothiazine, 20 μl of a 25-μg/ml solution (for UV detection) or 30 μl of a 100-μg/ml solution (for fluorescence detection), was added to each sample to serve as an internal standard. An alkaline pH was achieved with the addition of 0.125 ml of 0.1 *N* NaOH to each sample. The samples were mixed by inversion, and each was added to a reverse-phase cartridge. Each cartridge was then washed with 6.0 ml of water followed by 2.0 ml of methanol. The eluant from the final 1.5 ml of methanol was collected in a disposable 12- × 75-mm borosilicate culture tube[12] and evaporated to dryness using a gentle air stream at 40°. The residue was reconstituted with 250 μl of methanol–water (1:1) and mixed by vortexing. A 50-μl aliquot was injected onto the HPLC.

Ketoconazole serum standards were prepared by spiking human serum with ketoconazole stock solution (100 μg/ml in methanol) to give final concentrations ranging from 0.5 to 15.0 μg/ml. Ketoconazole was quantitated by comparison of the peak height ratio of the drug to the internal standard using a calibration curve. The peak height ratios were plotted against concentrations of ketoconazole and analyzed by linear regression to generate daily calibration curves. The lower sensitivity limit of the procedure was determined by assaying spiked serum samples at concentrations ranging from 20 ng/ml to 1.0 μg/ml. The sensitivity limit was then defined as the concentration at which the signal-to-noise ratio was 3.

Interday variability was determined by the reproducibility of the daily standard curves ($n \geq 6$) with respect to both their slopes and the calculated values for ketoconazole at various concentrations (0.5, 1.0, 2.0, 5.0, 10.0, and 15.0 μg/ml). The intraday variability was assessed by performing replicate analyses ($N = 6$) using spiked serum samples containing 0.8 and 14.0 μg/ml of ketoconazole. These concentrations were chosen as a representation of the lower (0.8 μg/ml) and higher (14.0 μg/ml) serum concentrations observed in patients receiving ketoconazole for whom routine therapeutic drug monitoring was performed. Aqueous solutions containing known amounts of ketoconazole were compared with spiked serum standards undergoing analysis to calculate the percent recovery at various concentrations. Statistical analyses to determine means, standard deviations, correlation coefficients, coefficients of variation, and linear regressions were performed using a computer[13].

The microbiological assay procedure was performed as described by Drouhet and Dupont (6). The test organism was *Kluyvermyces fragilis* strain 55-1[14].

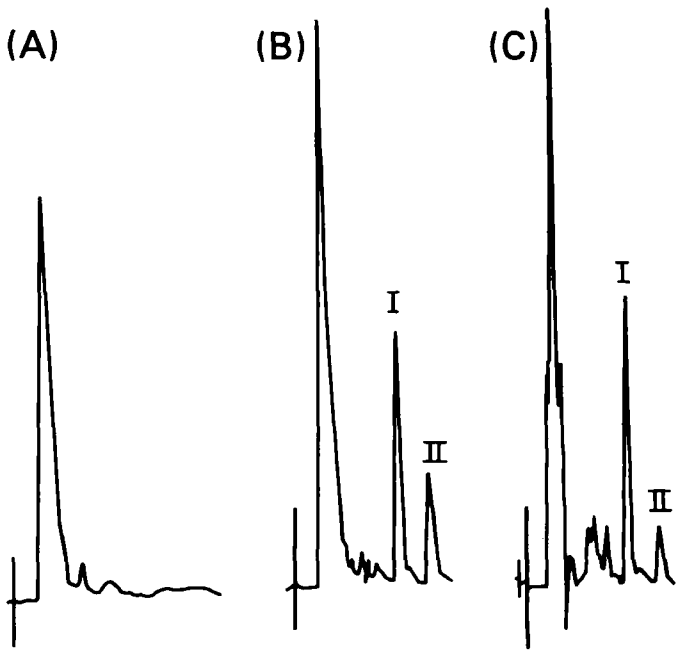

Figure 1—*Representative chromatograms of (A) blank human serum, (B) serum obtained from a patient receiving ketoconazole and spiked with phenothiazine at 0.04 AUFS (observed ketoconazole concentration = 1.13 μg/ml), and (C) human serum spiked with 0.50 μg/ml of ketoconazole (retention time 9.6 min) and phenothiazine (retention time 7.4 min) at 0.04 AUFS. Sample preparation was as described in the text. Key: (I) phenothiazine (internal standard); (II) ketoconazole.*

RESULTS AND DISCUSSION

HPLC Using UV Detection—Representative chromatograms from assayed samples of control human serum, human serum spiked with phenothiazine and ketoconazole, and a serum sample obtained from a patient receiving ketoconazole are shown in Fig. 1. Retention times for phenothiazine and ketoconazole are 7.4 and 9.6 min, respectively. No interfering peaks were observed in the blank serum sample. Miconazole, another imidazole antifungal agent, as well as trifluoperazine, chlorpromazine, diazepam, chlordiazepoxide, doxepin, thiothixene, imipramine, and amitriptyline did not interfere with either the ketoconazole or internal standard peaks. The reverse-phase cartridge separation procedure described helped eliminate several additional peaks which were observed when the serum samples were extracted using various organic solvents.

The standard calibration curves constructed from daily runs of spiked serum standards were linear and highly reproducible. Serum standards containing up to 25 μg/ml have been assayed periodically, and the assay results indicate that the linearity of the curves extends at least to this level. The mean slope of six calibration curves run over a 3-month period was 0.456, with a standard deviation of 0.032; the overall coefficient of variation of the procedure was 7.1%. The correlation coefficient of the six curves was 0.998. Table I lists the results of the interday variability (mean, *SD*, *CV*) from the six runs at each concentration measured. These data indicate the assay procedure is highly reliable and reproducible.

Intraday variability of the method determined from serum standards containing 0.8 and 14.0 μg/ml of ketoconazole was 6.4 and 4.4%, respectively. The average recovery of ketoconazole obtained from the sample preparations over the range of concentrations used in the standard curve was 86.2% (*SD* 4.6%). The recovery of phenothiazine was 91.0% (*SD* 6.4%). Using the described procedure, 0.2-μg/ml concentrations of ketoconazole can be detected while maintaining a signal-to-noise ratio of 3.

15.0	15.04	0.08	0.53
Overall Mean			7.1

The procedure presented here has significant advantages over two previously published HPLC procedures (7, 8). The major advantage of our method is the use of an internal standard, which facilitates accurate and precise ketoconazole quantitation. Neither of the previous HPLC methods used internal standardization, although they involved either extraction and concentration procedures (7) or a reverse-phase cartridge filtration procedure (8). In addition, the sample preparation of one of the published methods (7) involves multiple time-consuming extraction steps, whereas the other published procedure (8) does not include the statistical analyses necessary for detailed evaluation. Finally, the sensitivity, efficiency, and overall variability of the procedure presented here compare favorably with the previously published HPLC procedures.

This procedure has been used to successfully analyze various biological fluids from patients receiving ketoconazole, including serum, plasma, CSF, and synovial fluid. Serum samples from several patients receiving 200-, 400-, or 800-mg/day doses of ketoconazole were collected at 2 and 6 hr postdose and analyzed using this procedure. It is apparent that the procedure sensitivity is adequate for such routine therapeutic monitoring. When a single 200-mg dose of ketoconazole is administered to adults, peak levels of 3–4.5 μg/ml are observed, and concentrations at 8 hr postdose are at least 0.2 μg/ml (10). On chronic administration, even higher levels are observed. Our own experience indicates that levels in the patients studied at the stated doses range between 1 and 15 μg/ml. For routine serum level monitoring of ketoconazole at therapeutic doses, the present HPLC method using UV detection has been found to be rapid, reliable, and sensitive.

Comparison with a Microbiological Assay—Serum samples from 32 patients were divided and assayed for ketoconazole by both the HPLC method and a microbiological procedure (6). A comparison of the two procedures is shown graphically in Fig. 1, a plot of the results of the microbiological *versus* the HPLC analyses of the patient samples. Linear regression analysis of the comparative data yields a correlation coefficient of 0.92. However, when a line with a slope of unity that passes through the origin is superimposed on the plot (as in Fig. 2), it can be seen that there is a large amount of scatter as well as a negative deviation of the microbiological assay results from the HPLC results at concentrations >10 μg/ml. The scatter can largely be attributed to the imprecision inherent in the bioassay. (This microbiological procedure had a coefficient of variation of 28% for 18 patients' serum samples run 2–5 times for a total of 56 assays.) However, the general agreement of the results of the two assays suggests that the ketoconazole quantitated in patient samples represents a microbiologically active agent.

HPLC Using Fluorometric Detection—Ketoconazole concentrations may be quantitated using the sample preparation and assay conditions described here with a spectrofluorometric detector as well as a UV absorbance detector. There are two advantages of using fluorescence measurement. First, the reverse-phase cartridge separation procedure is not required for routine monitoring of biological fluids. Using a fluorometric detector, a simple acetonitrile protein precipitation followed by centrifugation and direct injection of the supernatant is an adequate sample preparation to achieve sensitivity equivalent to that seen with cartridge filtration and UV absorbance detection. However, by using the reverse-phase cartridge preparation described, the sensitivity of the HPLC procedure can be increased fivefold, detecting <40 ng/ml of ketoconazole using the spectrofluorometric detector. This enhanced sensitivity is an additional advantage over other HPLC methods, including one procedure which also uses fluorometric detection (9). The increase in sensitivity is a distinct advantage for detailed pharmacokinetic studies of ketoconazole disposition where it is likely that the sensitivity requirements will exceed those of all previously published methods. Data obtained using an unpublished GC procedure for ketoconazole indicate that following a dose of ketoconazole, there is an initial rapid decline in serum levels followed by a much slower elimination phase (10). To fully characterize its biphasic elimination, detection of <100 ng/ml of ketoconazole is required.

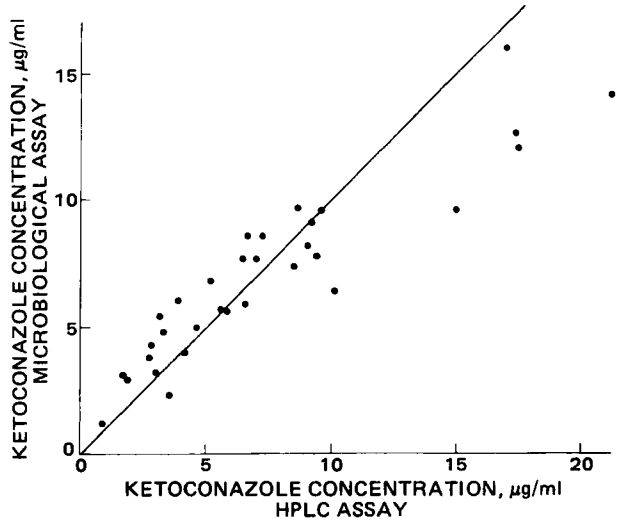

Figure 2—*Comparison of the results of ketoconazole quantitation by microbiological* versus *HPLC analyses. Each point represents parallel determinations of a single patient sample by both methods. The line superimposed on the plot has a slope of unity and passes through the origin.*

In summary, the sensitive, rapid, and reproducible procedure described offers advantages over both microbiological and other HPLC methods. It can be adapted to either UV or fluorometric detectors for routine monitoring of ketoconazole in various biological fluids. Fluorometric detection offers the additional advantage of the increased sensitivity required for application of the procedure to detailed pharmacokinetic studies of ketoconazole disposition.

Quantitation of Amikacin, Kanamycin, Neomycin, and Tobramycin in Pharmaceutical Dosage Forms Using the Hantzsch Reaction

V. DAS GUPTA *×, KENNETH R. STEWART ‡, and JAMES M. GUNTER ‡

Received July 6, 1982, from the *Department of Pharmaceutics, University of Houston, Houston, TX 77030 and the ‡Ben Taub General Hospital Pharmacy, Texas Medical Center Houston, TX 77030. Accepted for publication September 10, 1982.

Abstract □ A spectrophotometric assay method for the quantitative determination of amikacin, kanamycin, neomycin, and tobramycin in pharmaceutical dosage forms has been developed. The method is based on the Hantzsch reaction, forming dihydrolutidine derivatives which can be measured spectrophotometrically. The excipients EDTA, phenol, sodium bisulfite, and sodium citrate do not interfere, while salts of ammonia do interfere. The relative standard deviations based on seven readings were 1.64, 1.88, 2.10, and 1.93% for amikacin, kanamycin, neomycin, and tobramycin, respectively. Assay results have been compared with microbiological assay results provided by the manufacturers. The assay method appears to be stability indicating.

Keyphrases □ Amikacin—quantitation in pharmaceutical dosage forms using the Hantzsch reaction, kanamycin, neomycin, tobramycin □ Kanamycin—quantitation in pharmaceutical dosage forms using the Hantzsch reaction, amikacin, neomycin, tobramycin □ Neomycin—quantitation in pharmaceutical dosage forms using the Hantzsch reaction, amikacin, kanamycin, tobramycin □ Tobramycin—quantitation in pharmaceutical dosage forms using the Hantzsch reaction, amikacin, kanamycin, neomycin

The aminoglycoside antibiotics, amikacin sulfate (I), kanamycin sulfate (II), neomycin sulfate (III), and tobramycin sulfate (IV) are usually quantified by the microbiological procedures established by the Food and Drug Administration (1). The high experimental errors inherent in microbiological assays have been reported previously (2). A spectrophotometric assay technique for I using purified kanamycin acetyltransferase has been reported (3). In addition, a radioimmunoassay procedure for I has been developed (4) and compared with the microbiological assay (5). A previously described spectrofluorometric method (6) involves the purification of I–IV in urine using ion-exchange chromatography followed by formation of the dehydrolutidine derivative. Recently, this methodology, involving the formation of the dehydrolutidine derivative has been extended to provide a colorimetric assay for neomycin sulfate in urine (7). This study reports a spectrophotometric assay technique for the quantitative of amikacin, kanamycin, neomycin, and tobramycin in pharmaceutical dosage forms, based on the formation of the dehydrolutidine derivative (Hantzsch reaction) (7).

EXPERIMENTAL

Chemicals and Reagents—All chemicals and reagents were USP, NF, or ACS quality and were used without further purification. Amikacin sulfate[1], kanamycin sulfate[1], neomycin sulfate[2], and tobramycin sulfate[3] powders were used as received.

Preparation of Stock and Standard Solutions—Stock solutions of I–IV containing 50.0, 40.0, 60.0, 40.0 mg/100 ml (as the free base) in water, respectively, were prepared daily. These stock solutions were diluted further with water to obtain standard solutions as needed. The usual concentrations of I–IV standard solutions were 50.0, 40.0, 60.0, 40.0 μg/ml, respectively.

Preparation of Assay Solutions—All commercial injectable formulations were diluted stepwise with water to obtain antibiotic concentrations similar to the standard solutions. Ten tablets/capsules were weighed, and the tablets or capsule contents were ground to a fine powder. An appropriate quantity of the powder (containing 40–60 mg of the antibiotic) was weighed, mixed with 40 ml of water, brought to volume (100 ml) with water, and mixed thoroughly. The mixture was filtered, rejecting the first 20 ml of the filtrate, and a portion of clear filtrate was diluted further to an appropriate concentration (similar to standard solutions).

Preparation of a Solution of Acetylacetone and Formaldehyde—A buffer solution containing 0.2*M* each of acetic acid, boric acid, and phosphoric acid in water was prepared. The pH of this solution was adjusted to 2.5 (±0.05) with ~1 *N* NaOH, measured by a pH-meter[4]. To a 10-ml portion of the buffer, 0.8 ml of acetylacetone and 1.5 ml of formaldehyde solution (40% in water) were added; the mixture was brought to 30 ml with water and thoroughly mixed. The buffer solution was stable for at least 30 days at room temperature. The reagent was prepared daily.

Assay Procedure—A 2-ml quantity of standard/assay solution was mixed with a 2-ml portion of the acetylacetone–formaldehyde solution in a glass tube. The tube was sealed, placed in a boiling water bath for 20 min, cooled to room temperature, and the contents mixed with 5 ml of water. The absorbance of the solution was measured at 356 nm using a spectrophotometer[5]. A reagent blank was prepared by substituting water for the antibiotic solution.

Calculations—Concentrations were calculated by comparing the absorbance value of the assay solution with that of a standard solution of identical concentration. Since Beer's law (7) was followed:

$$\frac{(A_a)}{(A_s)} \times \text{Actual concentration of the standard solution} = \text{concentration of assay solution found}$$

where (A_a) is the absorbance of the assay solution and (A_s) the absorbance of the standard solution.

Determination of Excipient Interference—To determine the possibility of interference from inactive ingredients, the above assay procedure was followed substituting the inactive ingredient(s) for the antibiotic.

Selectivity of the Method—To determine if the method was stability indicating, solutions of amikacin (50 μg/ml) and tobramycin (40 μg/ml) were mixed with a 250-μg/ml concentration of carbenicillin disodium. Aminoglycoside antibiotics are known to be unstable in the presence of carbenicillin and other penicillins (8). The mixtures of aminoglycoside antibiotics with carbenicillin were stored at 50° and reassayed after 48 hr. Solutions of amikacin, tobramycin, and carbenicillin disodium alone were also stored at 50° for 48 hr and reassayed as controls. The results were calculated as described above, except that the absorbance values were corrected for a slight interference from carbenicillin disodium, measured using a carbenicillin blank.

Table I—Assay Results of Various Dosage Forms

Dosage Form	Label Claim, mg/ml	Antibiotic	Potency Found, % (Based on the Label Claim) Developed Method[a]	Microbiological Method[b]
Injectable				
Lot 1	250	Amikacin	103.7	101.2
Lot 2	250	Amikacin	108.1	104.8
Lot 3	250	Amikacin	104.1	103.6
Lot 4	250	Amikacin	100.6	104.0
Injectable	50	Amikacin	101.7	101.6
Injectable	333.3	Kanamycin	103.6	105.3
Injectable	37.5	Kanamycin	104.2	104.0
Capsule	500	Kanamycin	103.4	101.0
Tablet	350	Neomycin	99.6	100.9
Injectable				
Lot 1	40	Tobramycin	106.3	108.8
Lot 2	40	Tobramycin	104.2	107.5

[a] The relative standard deviations based on seven readings were 1.64, 1.88, 2.1, and 1.93% for I–IV, respectively. [b] As provided by the manufacturers.

RESULTS AND DISCUSSION

The results indicate (Table I) that the method can be used for the quantitation of amikacin, kanamycin, neomycin, and tobramycin in pharmaceutical dosage forms. The relative standard deviations based on seven readings were 1.64, 1.88, 2.10, and 1.93% for amikacin, kanamycin, neomycin, and tobramycin, respectively. It is well known that standard deviations are usually very high when microbiological assay techniques are used.

A 20-min reaction time was determined to be optimal for the completion of the reaction. The reaction usually starts 5–6 min, after the mixture reaches the water bath temperature. The results are highly reproducible and precise (see Table I for standard deviations) when the standard solution is assayed simultaneously with each sample determination. The excipients present in the injectable formulations [EDTA (ethylenediaminetetraacetic acid), phenol, sodium bisulfite, and sodium citrate] did not interfere with the assay procedure (Table II). Also, methylparaben and propylparaben, which are present in injectable formulations of some other aminoglycoside antibiotics, showed no interference (Table II), while salts of ammonia did interfere with the assay procedure (Table II).

Using the recommended wavelength of 356 nm (7) provided a low blank reading and high absorbance value for the dihydrolutidine derivatives. The mechanism of the reaction has been postulated (6). It has been determined that it is not necessary to add all the buffering agents (acetic acid, boric acid, and phosphoric acid) to the solution as recommended (7). Either boric acid or phosphoric acid (0.6 *M*) can be used at pH 2.5. The color that developed was stable for at least 20 min.

Aminoglycoside antibiotics contain amino groups, which react with acetylacetone to form dihydrolutidine derivatives. The method developed appears to be stability indicating (Table III) when applied to the interaction of aminoglycoside antibiotics with penicillins. Tobramycin assayed for only 47.2% of the original after 48 hr of storage at 50° in the presence of carbenicillin disodium, and amikacin assayed for 73.5% in a similar solution. These results are in agreement with an earlier report (8) in which tobramycin was reported to be less stable in the presence of carbenicillin disodium than other aminoglycoside antibiotics, *i.e.*, gentamicin and netilmicin. Tobramycin is also less stable than amikacin in the presence of carbenicillin.

Table II—Effect of Excipients on Absorbance

Inactive Ingredient	Concentration in Solution[a], μg/ml	Absorbance Value Against Blank
EDTA	2.5	0.00
Methyparaben	3.6	0.00
Propylparaben	0.4	0.00
Phenol	10	0.00
Sodium bisulfite	14	0.00
Sodium citrate	5	0.00
Ammonium chloride	14	0.14

[a] These are at least 2 times the concentrations expected in the assay solutions except ammonium chloride, which is not usually added to the dosage forms of these antibiotics.

Table III—Assay Results of Solutions Stored at 50°

Solution Composition	Assay Results (Percent of Label Claim) 0 hr	48 hr
Amikacin (50 μg/ml)	100.5	100.1
Tobramycin (40 μg/ml)	99.8	100.4
Carbenicillin disodium (250 μg/ml)	19.8[a]	14.3[a]
Amikacin (50 μg/ml) and carbenicillin disodium (250 μg/ml)	97.4[b]	73.5[b]
Tobramycin (50 μg/ml) and carbenicillin disodium (250 μg/ml)	97.1[b]	47.2[b]

[a] When assayed as tobramycin, *i.e.*, the assay absorbance value was compared with the absorbance value from a standard solution of tobramycin (40 μg/ml). [b] After correcting for interference from carbenicillin disodium.

Minimizing the Aggregation of Neutral Insulin Solutions

R. QUINN and J. D. ANDRADE ˣ

Received November 16, 1981, from the *Department of Bioengineering, University of Utah, Salt Lake City, UT 84112.* Accepted for publication October 21, 1982.

Abstract □ Various solution additives affect the solubility and macroaggregation of insulin in buffered aqueous solutions at physiological pH. The solubility of insulin may be improved with the addition of small amounts of aspartic acid, glutamic acid, EDTA (ethylenediaminetetraacetic acid), lysine, Tris buffer, or bicarbonate buffer. In addition, the propensity of dissolved insulin to reaggregate and precipitate may be inhibited by such additives. Buffered physiological (pH 7.4) saline solutions containing 0.001–0.003 *M* lysine in the presence of 0.005 *M* EDTA or 0.01 *M* lysine in the absence of EDTA improve insulin solubility and are effective in minimizing aggregation. Solutions thus prepared may be suitable for application in intravenous insulin infusion devices and may be useful commercial insulin preparations.

Keyphrases □ Insulin—minimizing aggregation, neutral solutions, lysine, solubility □ Aggregation—minimization, solubility of neutral insulin solutions, lysine solubility □ Lysine—minimizing aggregation of neutral insulin solutions, solubility □ Solubility—minimizing aggregation of neutral insulin solutions, lysine

The tendency of insulin solutions to form macroaggregates is an obstacle in the development of long-term insulin delivery systems (1–5). The macroaggregation of the insulin molecule often limits prolonged infusion to a few days unless the device is regularly flushed during the test period. This problem, as well as a desire to characterize the adsorption of insulin, have led us to search for a physiological solvent or additive that will stabilize insulin solutions. Insulin solubility and prolonged prevention of macroaggregation has been achieved by addition of various agents to dilute insulin solutions (4–8).

EXPERIMENTAL

The Tris buffer contained 0.1 *M* NaCl, 0.005 *M* EDTA (ethylenediaminetetraacetic acid) (Tris-HCl 14.04 g/liter; Tris, 1.34 g/liter)[1]. The phosphate-buffered saline solution was prepared using 1.36 g of Na_2HPO_4, 0.22 g of KH_2PO_4, 0.005 *M* EDTA, and 8.5 g of NaCl/liter (0.01 *M* phosphate and 0.145 *M* NaCl). The pH of both solutions was adjusted to 7.2–7.4, as needed, by addition of 0.1 *M* HCl or 0.1 *M* NaOH. Bicarbonate buffer was prepared using 1.428 g of $NaHCO_3$ and 8.070 g of NaCl diluted to 1 liter. A mixture of 5% CO_2 and compressed air was bubbled through the solution to adjust the pH to 7.4. Amino acids and other additives were added to the buffered solutions in varying concentrations as desired.

Crystalline insulin[2] at a potency of 25.2 U/mg was used in an attempt to regulate solution additives. Many other studies have used commercially available insulin preparations which usually contain additives that influence solubility and aggregation.

Solutions of 1 ml were sealed with paraffin film in 16-ml glass tubes (16 mm × 100 mm) and continuously agitated in a shaking water bath at 100–200 cycles/min and 37°. Solution turbidity was evaluated twice daily. The degree of aggregation of the solution was assessed visually on a five-plus scale: (+) meant clear, no observable particles, and (+++++) meant large aggregates or cloudy. Initially instrumental turbidity measurements were used to assess the degree of aggregation, but because of the macroscopic nature of the aggregate, this method did not accurately reflect the amount of aggregation. "First day" results indicate apparent solubility of insulin after 2–4 hr. The "5–6 day" results indicate degree of aggregation present at that time.

RESULTS

Additives tested were aspartic acid, EDTA, glutamic acid, bicarbonate buffer, ethanol, glycerol, leucine, lysine, and Tris buffer. When increased solubility or prolonged prevention of aggregation was observed, an attempt was made to determine the minimum amount of the additive required to produce the observed result. This was done by serially diluting the additive in the buffered solution while other buffer conditions were held constant. Results are given in Table I.

Ethanol, Glycerol, and Leucine—These three compounds proved to be very unsatisfactory as additives in the concentration range tested (0.001–0.1 *M*). None of the compositions demonstrated delayed onset

Table I—Effect of Additives on Insulin Aggregation

Major Additive	Buffer[a]	pH	EDTA (0.005 *M*)	Insulin Concentration, mg/ml	Effective in Blocking Aggregation?

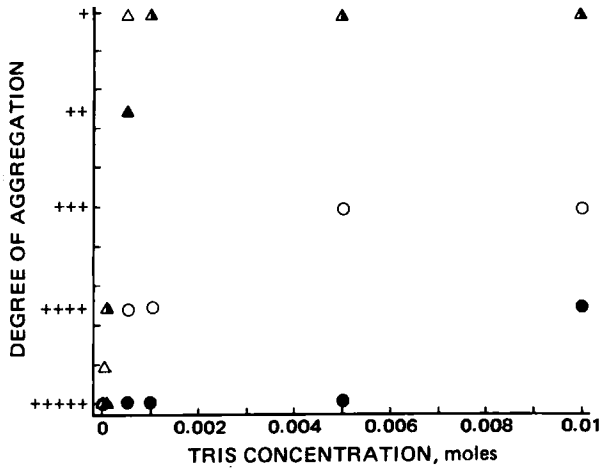

Figure 1—*Comparison of aggregation of insulin in phosphate-buffered saline as a function of Tris concentration. Solution conditions: phosphate-buffered saline, pH 7.2–7.4, temperature 37°, and insulin concentration, 6 mg/ml. Key: Degree of aggregation of solutions with 0.005 M EDTA at 1 (△) and 5 (▲) days; aggregation of solutions without EDTA at 1 (○) and 5 (●) days; (▲) point overlap.*

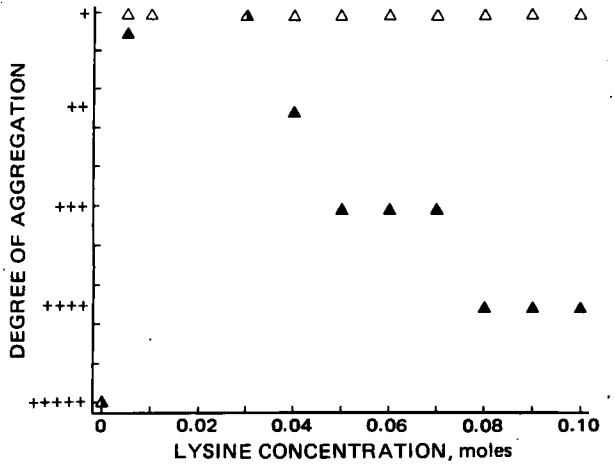

Figure 2—*Concentrations of 0.001–0.01 M lysine in 0.005 M EDTA and phosphate-buffered saline, pH 7.4. Key: degree of aggregation of solutions with 0.005 M EDTA at 1 (△) and 5 (▲) days; (▲) point overlap.*

of aggregation.

Tris Buffer—Phosphate-buffered saline solutions were prepared with and without 0.005 *M* EDTA, at various Tris concentrations (0.001–0.1 *M*). Figure 1 summarizes the aggregation of insulin as a function of Tris concentration in the presence and absence of EDTA, demonstrating that both additives are important in delaying the onset of insulin aggregation.

Lysine—Phosphate-buffered saline solutions containing lysine showed rapid dissolution of insulin, with the dissolution time decreasing as the pH was raised to 8.5–9.0. Solutions containing lysine at pH 7.2–7.4 maintained a clear, unaggregated appearance for 5–6 days. Higher lysine concentrations (0.1–0.01 *M* in 0.005 *M* EDTA) tended to aggregate more than those solutions containing lower lysine concentrations (0.01–0.001 *M*). Lysine (0.001 *M* in 0.005 *M* EDTA) is effective in minimizing aggregation (Fig. 2). However, when 0.005 *M* EDTA was eliminated from the phosphate-buffered saline solution, 0.01 *M* lysine was required to significantly minimize aggregation. Solutions of 0.01 *M* lysine and 0.005 *M* EDTA maintained at 4° without agitation remained not aggregated for periods up to 3 weeks.

Aspartic and Glutamic Acid—Earlier studies in other laboratories (5) showed that glutamic and aspartic acids were important in delaying the onset of aggregate formation. Our studies confirm the results of Bringer *et al.* (5) wherein aggregation was prevented for 6–7 days; however, serial dilution resulted in a decrease in the aggregation time. Aspartic acid proved to be more successful than glutamic acid at blocking insulin aggregation (Table I). It is important to note that due to the acidic nature of these amino acids, the pH of these solutions was 3.5 rather than 7.4. If the solutions were adjusted to pH 7.4, the aggregation was lost. This observation was also noted by Bringer *et al.* (5).

Bicarbonate—Two-milliliter solutions of sodium bicarbonate saturated with insulin were titrated to pH 6.3 with 0.1 *M* HCl, resulting in insulin precipitation. If solutions were back-titrated to pH 7.4 with 0.1 *M* NaOH the insulin remained undissolved. However, if a 5% CO_2–compressed air mixture was bubbled through the solution until pH 7.4 was reached, the insulin redissolved. A similar observation was noted by Lougheed *et al.*, where dissolution times were monitored as a function of bicarbonate concentration (8).

DISCUSSION

These results support the findings of previous researchers that agitation, additives, temperature, pH, and insulin concentration influence the solubility and macroaggregation of insulin. Recent work by Sato *et al.*, demonstrates that urea is effective in minimizing aggregation (9).

Several mechanisms for the prevention of aggregation have been proposed including the possibility of a serum substance (4) that prevents aggregation [newly published data from this group suggests that the bicarbonate concentration is the major factor in mediating insulin solubility (8)]. The chelation effect of the carboxyl groups of amino acids for zinc is believed to block aggregate formation by resulting in a more soluble form of insulin. This data is somewhat supported by the improvement of solubility and prolongation of aggregation time observed in solutions containing EDTA. As a chelating agent, EDTA may compete with insulin for zinc and, therefore, slow aggregate formation (10). Another possible mechanism for minimizing aggregation is that amino acid additives, especially lysine, may interact with the insulin molecule by hydrophobic and ionic means, thereby decreasing insulin–insulin interactions and preventing or slowing the formation of aggregates. More definitive work should be done with detailed analysis of the types of interactions and the conformation of the insulin molecule in these solutions.

Buffered physiological saline solutions containing 0.001 *M* lysine and 0.005 *M* EDTA improve insulin solubility and are effective in delaying the onset of macroaggregation. In the absence of EDTA, 0.01 *M* lysine solutions improve initial solubility and minimize the degree of aggregation. One advantage of the lysine additive is that the solutions are maintained at pH 7.4. A second advantage is that lysine is a common amino acid and is therefore not a synthetic additive.

Results summarized in this study emphasize the importance of additives in improving the solubility and stability of insulin solutions. It should be remembered that the type of insulin and additives used in various insulin preparations influence the properties discussed above, so a comparison of these results with other studies must be done with caution. The only way to accurately assess the contribution of each additive as to its solubility and aggregate-blocking properties is in a study such as this which minimizes the contributions of other solution variables or insulin additives.

Michael-Type Reactions of Tenulin, a Biologically Active Sesquiterpene Lactone

THOMAS G. WADDELL ˣ, PAUL H. GEBERT, and DAVID L. TAIT

Received August 9, 1982, from the *Department of Chemistry, University of Tennessee at Chattanooga, Chattanooga, TN 37402.* Accepted for publication November 1, 1982.

Abstract □ The antitumor pseudoguaianolide tenulin has been exposed to a wide variety of biological and model nucleophilic reagents and has been shown to react exclusively with sulfur nucleophiles in a Michael-like fashion. The biological implications of these results are discussed.

Keyphrases □ Tenulin—sesquiterpene lactone, Michael-type reactions, nucleophilic reagents □ Sesquiterpene lactones—tenulin, Michael-type reactions, nucleophilic reagents □ Michael-type reactions—tenulin with nucleophilic reagents, biologically active sesquiterpene lactones

The sesquiterpene lactone tenulin (I) (1) is the major bitter principle of the medicinal herb *Helenium amarum* (2). This compound has received considerable attention with regard to its antitumor (2–5), anti-inflammatory (6, 7), and antihyperlipidemic (8) activity. Recent structure–activity studies have related the biological properties of tenulin to the presence of the cyclopentenone moiety (4, 7, 8). The potential of this unit to act as an electrophile in Michael-like addition reactions is reminiscent of the *in vivo* role of the α-methylene-γ-lactone group (II) as a sulfhydryl (SH) acceptor in cytotoxic natural products (9). Indeed, the efficient Michael-like addition of cysteine (SH) to the tenulin enone has been reported (3). The α-methylene-γ-lactone group is reactive toward a variety of sulfur (9), oxygen (10), and nitrogen (11) nucleophiles. Therefore, it is important to the understanding of the mechanism of action to establish systematically the reactivity and selectivity of the cyclopentenone group of tenulin toward a variety of S, N, and O nucleophilic reagents. Such a study is of broad significance since the cyclopentenone unit appears in several antitumor terpenoids (12, 13).

RESULTS AND DISCUSSION

Table I presents a summary of this work and, for completeness, includes data taken from earlier work (entries 4–8 and 22). Reactions were attempted in aqueous alcohol solutions at room temperature and observed for periods up to 7 days. With the exception of entries 4–8, where spectral methods were used (3), negative reaction results were determined by TLC.

Nucleotides and nucleic acids exposed the cyclopentenone unit of tenulin to various nitrogen and oxygen nucleophiles. However, in no case was any reaction observed. Indeed, cyclopentenone itself does not react with adenosine 5′-monophosphate. Similarly, the amino acids alanine, serine, cysteine, histidine, and lysine contain nitrogen, oxygen, and sulfhydryl nucleophiles. Methanolic solutions of serine, histidine, or lysine (phosphate buffer, pH 7.2), when treated with tenulin, resulted only in the retroaldol conversion of tenulin to isotenulin (III) (14). In striking contrast, the efficient Michael addition of cysteine (SH) to the enone of tenulin (and cyclopentenone) to produce the adduct IV has been reported (3). The results summarized above suggest a strong Michael selectivity of the electrophilic cyclopentenone group for sulfur nucleophiles.

This notion was further tested (entries 14–22) by treating tenulin and cyclopentenone with glutathione (SH) and small model nucleophiles. Tenulin and methylamine interacted in aqueous methanol to produce the Schiff base, tentatively assigned structure V. Compound V was insoluble in water but readily soluble in dilute hydrochloric acid. The IR spectrum showed ν_{max} at 1770 br (γ-lactone and ester) and 1660 cm^{-1} (C=N), but lacked OH and enone absorption. The Schiff base portion of the molecule was confirmed by the UV spectrum where λ_{max} 246 nm (methanol) shifted to 265 nm on addition of two drops of 50% HCl. This bathochromic shift is characteristic of conjugated azomethines (15). An analogous reaction of 2-cyclopentenone with methylamine to form the Schiff base was demonstrated spectrophotometrically (see *Experimental*). Thus, the nucleophilic nitrogen of methylamine prefers the electrophilic carbonyl group of the cyclopentenone unit rather than the β-carbon. Methanol and ethanol do not react with tenulin even at reflux,

Table I—Reactions of Tenulin and 2-Cyclopentenone with Nucleophiles

Entry	Nucleophilic Reagent	With Tenulin	With 2-Cyclopentenone
1	Adenosine 5′-monophosphate	No reaction	No reaction
2	Adenosine	No reaction	
3	Adenine	No reaction	
4	Deoxyguanosine 5′-monophosphate	No reaction (3)	
5	Deoxyguanosine 5′-triphosphate	No reaction (3)	
6	Deoxyadenosine 5′-monophosphate	No reaction (3)	
7	Deoxyadenosine 5′-triphosphate	No reaction (3)	
8	Deoxyribonucleic acid	No reaction (3)	
9	L-Alanine	No reaction	
10	L-Serine	Conversion to isotenulin	
11	L-Cysteine	Michael addition (3)	Michael addition (3)
12	L-Histidine	Conversion to isotenulin	No reaction
13	L-Lysine	Conversion to isotenulin	No reaction
14	Methylamine	Schiff base	Schiff base
15	Sodium methoxide	Skeletal rearrangement	
16	Methanol	No reaction	
17	Ethanol	No reaction	
18	Thiourea	No reaction	No reaction
19	1,3-Propanedithiol	Bis Michael addition	
20	Glutathione (SH)		Michael addition (3)
21	Sodium bisulfite	Michael addition	Michael addition
22	1-Propanethiol		Michael addition (18)

whereas the more reactive sodium methoxide affects the known skeletal rearrangement of tenulin to deacetylneotenulin (VI) (16).

The reactivity of tenulin toward several types of sulfur nucleophiles is summarized in entries 18–22 (Table I). Although the sulfur atom of thiourea has been shown to act as a nucleophile in Michael-like additions (*cf.* 17), this reagent does not react with tenulin or 2-cyclopentenone. In contrast, cyclopentenone does form Michael adducts with the sulfhydryl-containing glutathione (3) and 1-propanethiol (18). The high reactivity of the cyclopentenone toward SH groups is further demonstrated in the reaction of tenulin with one mole equivalent of 1,3-propanedithiol where the major product is the crystalline bis adduct VII, $C_{37}H_{52}O_{10}S_2 \cdot H_2O$. Compound VII showed IR absorption at 3300–3500 (OH), 1780 (γ-lactone), and 1740 cm^{-1} (cyclopentanone). Sulfhydryl absorption near 2550 cm^{-1} was absent. The UV spectrum lacked the characteristic enone absorption of tenulin and chemical analysis for SH (19) was negative.

The known reactivity of sodium bisulfite as a sulfur nucleophile in Michael-like additions (20) prompted the examination of this reagent as a potential nucleophile. The reaction of tenulin with excess sodium bisulfite in aqueous methanol cleanly produced the water-soluble Michael adduct VIII. The IR spectrum of VIII lacked enone carbonyl absorption near 1700 cm^{-1}. A broad band centered at 1740–1770 cm^{-1} indicated γ-lactone and cyclopentanone functional groups. Further evidence for Michael addition was seen in the NMR spectrum of VIII which featured the absence of olefinic proton signals and the presence of a new one proton multiplet at 3.70 ppm (H-2, $HCSO_3Na$). In an analogous manner, 2-cyclopentenone forms the Michael adduct IX when treated with either one or two equivalents of sodium bisulfite.

These experiments have demonstrated that the cyclopentenone unit of tenulin is highly selective for sulfur nucleophiles (SH, bisulfite) in Michael-like addition reactions. This selectivity is not surprising in view of the classification of sulfur and enone as soft Lewis base and Lewis acid, respectively, whereas nitrogen and oxygen nucleophiles are considered to be hard Lewis bases (21).

There are biological implications of this new chemistry of tenulin. The hypothesis that the *in vivo* activity of cyclopentenone-containing natural products may be due to the enone unit alkylating essential sulfhydryl groups of cellular enzymes (3) now stands more firmly with this additional support.

EXPERIMENTAL

Attempted Reactions of Tenulin with Model Nucleophiles—In separate experiments, tenulin (50 mg) was treated with 2 ml of an aqueous methanol solution containing one equivalent of thiourea, adenine, or adenosine. Analogously, in 2 ml of methanol–phosphate buffer (pH 7.2) tenulin was treated with one equivalent of adenosine 5′-monophosphate, L-serine, L-histidine, L-lysine, or L-alanine. Reaction vessels were stoppered, left at room temperature for several days, and monitored by TLC[1]. No reactions were observed. Quantitative yields of tenulin (or isotenulin) were recovered on extraction with chloroform, drying over anhydrous magnesium sulfate, filtration, and evaporation of the filtrate.

Attempted Reactions of 2-Cyclopentenone with Model Nucleophiles—In separate experiments, 2-cyclopentenone (50 mg) was treated with 2 ml of an aqueous methanol solution containing one equivalent of thiourea, L-histidine, L-lysine, or adenosine 5′-monophosphate (in methanol–phosphate buffer, pH 7.2). Reaction vessels were stoppered, left at room temperature for several days, and monitored by TLC. No reactions were observed.

Isotenulin Methylimine (V)—To a solution of 0.051 g (0.17 mmole) of tenulin in 0.5 ml of methanol was added 0.5 ml (excess) of 40% aqueous methylamine. After 2 days at room temperature, the reaction solution was poured into 20 ml of water and extracted twice with 15 ml of chloroform. The combined chloroform extract was dried (magnesium sulfate), filtered, and evaporated to dryness at room temperature. Ether trituration yielded a crystalline compound (8 mg) tentatively assigned as V, mp 155–156° dec.[2] IR[3] ($CHCl_3$): 1770 (γ-lactone and ester) and 1660 cm^{-1} (C=N); UV[4]: 246 nm (MeOH) and 265 nm (MeOH + 2 drops 50% HCl). Compound V was water insoluble but readily soluble in dilute hydrochloric acid.

Deacetylneotenulin (VI)—To a solution of 0.100 g (0.32 mmole) of tenulin in 3 ml of methanol was added dropwise a sodium methoxide solution prepared by dissolving 4 mg (0.17 mmole) of sodium in 2 ml of methanol. After 80 min the reaction mixture was diluted to 50 ml with distilled water and extracted with three 25-ml portions of chloroform. The combined organic layer was dried (magnesium sulfate), filtered, and evaporated to dryness to give 0.075 g (87% yield) of a colorless gum. Ether trituration and recrystallization from acetone–ether gave deacetylneotenulin (VI), mp 242–245° dec. [lit. (22) mp 239–240°]. IR and UV spectra of VI were identical to published data.

Tenulin-1,3-propanedithiol Bis Adduct (VII)—To 0.304 g (0.99 mmole) of tenulin in 2 ml of methanol was added 0.10 ml (0.99 mmole) of 1,3-propanedithiol. The solution was swirled, deoxygenated under a nitrogen stream, sealed, and left at 0° for 3 days. After careful evaporation of the solvent, the yellow oily product was taken up in chloroform–ether whereupon a crystalline solid (136 mg) slowly separated in several crops. Recrystallization from hot methanol gave the bis adduct VII (69 mg, 19% yield), mp 244–248°. IR (nujol): 1780 (γ-lactone) and 1740 cm^{-1} (cyclopentanone); UV(MeOH): 205 mm.

Anal[5].—Calc. for $C_{37}H_{52}O_{10}S_2 \cdot H_2O$: C, 60.14; H, 7.36, S. 8.68. Found: C, 60.27; H, 7.55; S, 9.09.

Tenulin–Sodium Bisulfite Adduct (VIII)—Tenulin (0.052 g, 0.17 mmole) and sodium bisulfite (0.034 g, 0.33 mmole) were dissolved in 1.5 ml of aqueous methanol. After 4 days at room temperature, the reaction solution was allowed to slowly evaporate on a watchglass. The remaining crystalline material was taken up in methanol and filtered through a 1-cm

[1] EM Reagents precoated plates, silica gel 60, 0.25 mm thickness.

[4] Hitachi 100-80.
[5] Galbraith Laboratories, Knoxville, Tenn.

column of silica gel. Evaporation of the solvent left a clear oil which crystallized to yield 45 mg (65% yield) of water-soluble VIII, mp gradual dec. up to 108°. IR (nujol): 1740–1770 cm^{-1} (γ-lactone and cyclopentanone). ^{1}H-NMR(CD_3OD)[6]: δ 5.10 (br t, 1, H-8), 4.00 (d, 1, H-6), 3.70 (br, 1, H-2), and 1.20–1.60 ppm (12, 4 Me groups).

2-Cyclopentenone–Sodium Bisulfite Adduct (IX)—2-Cyclopentenone (0.055 g, 0.67 mmole) and sodium bisulfite (0.063 g, 0.61 mmole) were taken up in 2 ml of distilled water. Methanol (0.5 ml) was added after 2 hr at room temperature, the mixture was poured onto a watchglass and the solvent was allowed to evaporate slowly. Recrystallization of the solid residue from methanol–ether yielded 57 mg (46% yield) of the adduct IX, mp 163–166° [lit. (23) mp 165°]. IR (nujol): 1740 cm^{-1} (cyclopentanone). ^{1}H-NMR (D_2O): δ 3.70 (m, 1, $HCSO_3Na$) and 2.10–3.00 ppm (6, complex). Identical results were obtained when this experiment was repeated using a 1:2 molar ratio of ketone to sodium bisulfite.

2-Cyclopentenone Methylimine (Schiff Base)—Excess methylamine was added to a reference 2-cyclopentenone–methanol solution in a UV cuvette. After 18 hr, the $\pi \rightarrow \pi^*$ absorption of the enone carbonyl (310 nm) disappeared. Addition of 2 drops of 50% HCl caused a bathochromic shift in the original $\pi \rightarrow \pi^*$ (230 nm) to 250 nm. A control experiment without methylamine revealed no changes in the original cyclopentenone UV spectrum. The above results are consistent with the formation of the cyclopentenone–methylamine Schiff base (15).

Quantitative Determination of Hexamidine Isethionate in Pharmaceutical Preparations by High-Performance Liquid Chromatography

P. TAYLOR ˣ, P. D. BRADDOCK, and S. ROSS

Received August 16, 1982, from the *Vick International R & D Laboratories, Egham, Surrey, England.* Accepted for publication November 10, 1982.

Abstract □ Hexamidine isethionate in various pharmaceutical formulations was analyzed quantitatively by high-performance liquid chromatography. The method is rapid, accurate, and precise. Excellent results were obtained from four commercial bases.

Keyphrases □ Hexamidine isethionate—quantitative determination in pharmaceutical preparations, high-performance liquid chromatography □ High-performance liquid chromatography—quantitative determination of hexamidine isethionate, pharmaceutical preparations □ Preparations, pharmaceutical—quantitative determination of hexamidine isethionate by high-performance liquid chromatography

Hexamidine isethionate [4,4′-(hexamethylenedioxy)-dibenzamidine bis(2-hydroxyethanesulfonate)], used as a topical antiseptic in pharmaceutical products, belongs to a group of compounds (aromatic diamidines) which have good antibacterial and antifungal properties (1). Diamidines can be identified in their pure form microscopically (2) and quantified colorimetrically in pharmaceutical preparations using glyoxal sodium bisulfite solution (3). The latter method is nonspecific and subject to interferences. This fact has prompted more recent workers to investigate the use of spectrophotometric (4), GLC (5, 6), and high-performance liquid chromatographic (HPLC) (7) techniques.

The purpose of this study was to develop a rapid HPLC method which would be suitable for the analysis of hexamidine isethionate (I) in pharmaceutical preparations. Validation data are presented for the analysis of a topical cream, and the methodology was found to be applicable to ointments and eyewash solutions.

EXPERIMENTAL

Reagents and Chemicals—The methanol[1] and water[1] used were HPLC grade and the glacial acetic acid[1], chloroform[1], and ether[1] were analytical reagent grade. Hexamidine isethionate[2] was used as received.

Apparatus—The high-pressure solvent pump[3] was connected to a fixed-wavelength detector[4], a fixed-volume injection valve[5], and a recording integrator[6]. The polar column[7] (30 cm × 3.9-mm i.d.) consisted of a monomolecular layer of cyanotrichlorosilane permanently bonded by silicone–carbon bonds to microparticulate silica.

The mobile phase consisted of water–methanol–glacial acetic acid (4:2:1, v/v/v) which was deaerated by vacuum filtration before use. The temperature was ambient, and the flow rate was 1.0 ml/min. The detector sensitivity was 0.02 AUFS (254 nm), the recorder/integrator attenuation was 8, and the chart speed was 0.5 cm/min.

[7] μBondapak-CN, Waters Associates, Hartford, Cheshire, England.

Hexamidine Isethionate Standard Solutions—Standard samples of I in the range of 0–75 mg were accurately weighed into 1000-ml volumetric flasks and diluted to volume with mobile phase. After mixing to dissolve the standards, 10.0-ml aliquots were diluted to 100.0 ml in volumetric flasks using the mobile phase. Twenty microliters of each solution was injected into the HPLC.

Preparation of Samples—*Creams*—Samples of cream (0.5 g) equivalent to 0.5 mg of I were accurately weighed into a 50-ml centrifuge tube and shaken with 40 ml of mobile phase. After centrifugation the supernatant liquid was transferred to a 250-ml separatory funnel, and the process was repeated with a second 40-ml aliquot of mobile phase. The combined extracts were then washed with two 40-ml portions of chloroform, transferred to a 100-ml volumetric flask, and diluted to volume with mobile phase.

Ointments—Samples (0.5 g) equivalent to 0.5 mg of I were first dissolved in 50 ml of hexane and then extracted with two 40-ml aliquots of mobile phase. Treatment was as described above for creams.

Eyewash Solutions—Eyewash solutions were diluted to 200 ml (20-fold) with water, and 20.0 ml of this solution (equivalent to 1 mg of I) was then extracted with three 20-ml aliquots of ether. The ether extracts were discarded, and the aqueous phase was transferred to a 200-ml volumetric flask and diluted to volume with mobile phase. Twenty-microliter aliquots of each sample solution were injected into the HPLC.

Calculations—The peak heights from the injections of the standard hexamidine isethionate solutions were measured manually and plotted as a function of concentration. Since the calibration curve indicated that peak heights were directly related to concentrations (0–0.0075, mg/ml) of I, sample results were calculated by:

$$\frac{(Ph)_a}{(Ph)_s} \times \frac{C}{1000} \times D \times 100 = \%\ \text{w/w (or w/v) of I}$$

where $(Ph)_a$ and $(Ph)_s$ are the peak heights of I in the assay and standard solution chromatograms, respectively, C is the concentration of standard solution of I in mg/ml, and D is the dilution factor.

Reproducibility and Accuracy—Replicate analyses (n = 6) were carried out on a single batch of cream formulated to contain 0.1% w/w of I to test reproducibility of the assay. Known weights of hexamidine isethionate representing levels between 50 and 150% of label claim were added to five 0.5-g samples of placebo cream to check the assay accuracy. After mixing, samples were prepared as described above and injected into the HPLC.

RESULTS AND DISCUSSION

The described method was validated using a topical cream developed in-house. A typical cream sample chromatogram is shown in Fig. 1. Hexamidine isethionate elutes as a sharp peak in <8 min. The calibration curve of the concentration of I *versus* peak height was found to be linear over 0–0.0075 mg/ml and passed very close to the origin (slope = 1.694×10^5, intecept = −1.53, and r = 0.9996). Recovery data from placebo samples with added I indicate that the procedure is quantitative for I over the range 0.25–0.75 mg/0.5 g (Table I). This range corresponds to 50–150% of label for the typical (0.1%, w/w) cream formulations (0.5 mg/0.5 g). The reproducibility of the method was found to be good at 0.9% *RSD* (Table II).

A placebo sample without I when carried through the procedure showed the absence of interferences from formulation excipients, although a small peak which elutes immediately after I could *potentially* interfere should column efficiency deteriorate. However, in this event the positive bias introduced would be small (<2%).

During sample preparation of creams and ointments, it was necessary to extract with chloroform to overcome severe chromatographic inter-

ferences. Eyewash solutions required extraction with ether to remove the methylparaben and propylparaben which were included in these formulations. The relatively high concentration of acetic acid used in the mobile phase was essential for adequate resolution and rapid analysis of I. Column stability was satisfactory throughout the experiments, although it was necessary to thoroughly cleanse the chromatograph and column of the corrosive mobile phase between analyses.

The results for the analyses of I in three different dosage forms is given in Table III. In general, results were very close to the label claim. The low result found with ointment 2 could have been due to incomplete extraction from the base.

Stability of Mezlocillin Sodium as Determined by High-Performance Liquid Chromatography

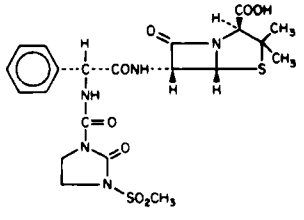
V. DAS GUPTA

Received September 13, 1982, from the *College of Pharmacy, University of Houston, Houston, TX 77030.* Accepted for publication October 27, 1982.

Abstract □ The stability of mezlocillin sodium solutions in water with either phosphate buffers or other ingredients used in intravenous admixtures (dextrose, fructose, and sodium chloride) has been studied using a stability-indicating high-performance liquid chromatographic method. This assay shows a relative standard deviation of 1.42% based on six injections. The optimum stability was shown at an approximate pH of 4.8, and solutions in dextrose (5%) and sodium chloride (0.9%) were stable for up to 4 days at 25°, 36 days at 5°, and for 60 days at −10°. When refrigerated, the solutions in 5% fructose and 10% dextrose were as stable as those in 5% dextrose.

Keyphrases □ Mezlocillin sodium—stability, determined by high-performance liquid chromatography □ Stability—mezlocillin sodium, determined by high-performance liquid chromatography □ High-performance liquid chromatography—stability of mezlocillin sodium

Mezlocillin, a new semisynthetic broad-spectrum penicillin antibiotic, commonly administered by intravenous admixture, is effective against a wide variety of microorganisms. Limited information on the stability is available (1): solutions for intravenous use appear to be stable from 24 to 72 hr at controlled room temperature, from 24 to 168 hr under refrigeration, and for 28 days at −12° (1). This investigation studies the stability of mezlocillin sodium at varying pH in some commonly used vehicles for intravenous administration. A stability-indicating high-performance liquid chromatographic (HPLC) method was developed.



Mezlocillin

EXPERIMENTAL

Materials—All chemicals and reagents were USP, NF, or ACS quality and were used without further purification. Mezlocillin sodium[1] powder was used as received. The liquid chromatograph[2] was equipped with a multiple-wavelength detector[3], a recorder[4], and an integrator[5]. A semipolar[6] column (30 cm long × 4-mm i.d.) was used. The mobile phase contained 0.02 *M* ammonium acetate and 42% (v/v) methanol in water. The flow rate was 2.0 ml/min, the sensitivity was 0.2 AUFS (230 nm), and the chart speed 30.5 cm/hr. The temperature was ambient.

Methods—A standard solution was prepared daily by dissolving 100 mg of mezlocillin sodium in enough water to make 100 ml of the solution. All of the antibiotic solutions were prepared as indicated in Table I using a simple solution method. After the initial data were obtained (physical appearance, pH values[7], and assays), the solutions were stored either at room temperature (25 ± 1°), under refrigeration (5 ± 1°), in the freezer (−10 ± 1°), or at all three temperatures.

Table I—Mezlocillin Solutions Prepared for Stability Studies

[a] Adjusted with KCl. [b] Stored in plastic bag; the original plastic Viaflex PL 146 bags from which either 0.9% NaCl or 5% dextrose injection in water was withdrawn for making the solutions. [c] Stored in bottle; sixty-milliliter amber-colored glass bottle; Brockway Glass Co., Brockway, Pa. [d] Ionic strength of this solution was not adjusted.

At appropriate intervals, solutions of mezlocillin were assayed using HPLC. Before analysis, all solutions were diluted with water to an appropriate concentration (identical to the standard solution based on the label claim). Before being diluted, the solutions were brought to room temperature by putting the bags/bottles in tap water. One set of 60-day-old frozen samples was thawed using a microwave oven[8]; the frozen solutions were exposed to microwaves for 3 min.

A 20.0-μl aliquot of the assay solution was injected into the chromatograph using the described conditions. For comparison, an identical volume of the appropriate standard solution was injected after the assay solution eluted.

Calculations—Since preliminary investigations indicated that the peak heights were related directly to the concentrations (range tested: 0.2–1.2 mg/ml), the results were calculated using:

$$\frac{(Ph)_a}{(Ph)_s} = \text{percent of label claim} \qquad \text{(Eq. 1)}$$

where $(Ph)_a$ is the peak height of the assay solution and $(Ph)_s$ is the peak height of a standard solution of identical concentration based on the label claim.

RESULTS AND DISCUSSION

HPLC Assay Method—The method developed is reproducible with a relative standard deviation of 1.42% based on six injections, and separates a number of decomposition products (Fig. 1B and C) from the intact drug (peak 1 in Fig. 1).

It is well documented (2) that at lower pH (~3), the β-lactam moiety undergoes hydrolysis and at higher pH (~8), the side chain undergoes hydrolysis. In Fig. 1B (as compared with Fig. 1A) the additional unidentified peaks are from the hydrolysis of the 3-(methylsulfonyl)-2-oxo-1-imidazolidine ring (see structure of mezlocillin) since the pH of the assay solution was 7.8. In Fig. 1C, the additional peaks are from the hydrolysis of the β-lactam ring. The decomposition of mezlocillin in this

assay solution (pH 2.9) was very fast. It is obvious that decomposition products from the side chain elute immediately after the solvent, while products from β-lactam ring hydrolysis elute immediately before the intact drug (peak 1 in Fig. 1).

The results indicate (Table II, solutions 1 and 2) that the manufacturer's recommended expiration of 48 hr (1) for intravenous solution prepared in 5% dextrose–0.9% NaCl can be extended to 96 hr with a loss in potency of <5%. Under refrigeration, the expiration date may be ex-

tended (Table III, solutions 1 and 2) to 36 days *versus* 7 days as recommended (1). The loss in potency after a 36-day storage was <3.2%, and the samples were clear. The expiration date for the frozen samples may be extended to 60 days (solutions 1 and 2, Table III) *versus* 28 days as recommended (1) by the manufacturer. There was a loss of <2 and 7% in potency in 60 days for solutions in 0.9% NaCl and 5% dextrose, respectively. There was no significant change in pH values, and the solutions were clear. Furthermore, the frozen samples can be thawed in <4 min using a microwave oven, without any observable decomposition.

It is interesting to point out that the manufacturer has recommended (1) an expiration of 24 hr under refrigeration for solutions in 5% fructose and 10% dextrose *versus* 7 days for solution in 5% dextrose. In our investigations (Table III, solutions 3–5), there was no difference in the stability of these three solutions. No decomposition was found in any sample for up to 4 days under refrigeration, which was also evident from the absence of any additional peak(s) in the chromatograms. After 14 days of storage there was only slightly more decomposition of drug in solutions containing either 10% dextrose or 5% fructose *versus* 5% dextrose (Table III, solutions 3–5). There were no significant changes in pH values, and all solutions were clear.

The optimum pH of stability (Fig. 2) appears to be ~4.8. The phosphate buffer did not catalyze the reaction (solutions 8 and 9, Table III). Trials to treat the data mathematically using first-order equations were not successful, which may be due to the complexity of the reaction as evidenced by a number of new peaks (Fig. 1C) in the chromatogram. The general information about the degradation of penicillins is available in the literature (2, 3).

Buccal Absorption of Protirelin: An Effective Way to Stimulate Thyrotropin and Prolactin

Keyphrases □ Protirelin—buccal absorption, stimulation of thyrotropin and prolactin, use as a diagnostic tool □ Buccal absorption—evaluation of protirelin, use as a diagnostic tool, measurement of thyrotropin and prolactin stimulation □ Thyrotropin and prolactin stimulation—buccal absorption of protirelin, use as a diagnostic tool

To the Editor:

Most of the biologically active oligopeptides are almost, or completely, inactive if administered perorally. This can be partly attributed to low chemical stability in the course of intestinal passage, and partly to low invasion rates along with rapid plasma degradation. For the same reasons some peptides, like thyrotropin-releasing hormone (TRH) (protirelin), need extremely high peroral doses in order to stimulate biological response. Therefore, intravenous injection is the most common form of peptide administration. However, few studies on nasal (1) and rectal (2) administration have been reported. The purpose of this investigation was to evaluate buccal absorption of protirelin as a model peptide. The major objective was to set the groundwork for future research on buccal peptide delivery and absorption. This study also evaluated buccal protirelin as a diagnostic tool.

Thyroid gland diagnostics by protirelin is mainly a domain of the intravenous test, although some doubts have emerged due to serious side effects (3–5). On the other hand, the peroral protirelin test exhibits only slow response at high doses, and usually needs a 3-hr period to attain maximum stimulation. This is often considered inconvenient for routine clinical diagnostics. Therefore, buccal protirelin could become an appropriate supplement with both intravenous and peroral protirelin, if absorbed properly. This study will show the overall feasibility of buccal protirelin for use in thyroid diagnostics. Buccal absorption will be followed by monitoring thyrotropin and prolactin stimulation.

Ten clinically healthy volunteers, five males and five females, took part in the study. The age range was 23–35 years. For all volunteers an euthyroid state was certified by determinations of triiodothyronine, thyroxine, and thyroxine-binding globulin. The body weights of all volunteers were within normal limits of the ideal body weight according to Broca. All tests were performed beginning at 2 p.m.

For the intravenous test, 200 μg of protirelin[1] was injected in the antecubital vein. Blood samples were taken immediately before and 30 min after injection. For buccal application a polytef disk was prepared with a diameter of ~3.5 cm, corresponding to an area of ~10 cm^2 and a height of 1 cm. The disk had a central circular depression depth of 4 mm, leaving an elevated rim. A previously water-soaked filter paper disk was placed into the depression, and 20 mg of crystalline protirelin[2] was spread onto the filter paper. The protirelin dissolved immediately. Subsequently, the device was put into contact with the buccal mucosa. After 30 min the device was removed, and the mouth was thoroughly washed with tap water. Blood samples were taken at 0, 30, 60, 120, and 180 min *via* a cannula placed into the antecubital vein.

After centrifugation the plasma was separated from the blood and stored at −20° until analysis of thyrotropin and prolactin.

Measurements of thyrotropin[3], prolactin[4], thyroxine-binding globulin[5], triiodothyronine[6], and thyroxine[6] were performed in duplicate using commercially available radioimmunoassays. Standard errors of the radioimmunoassays were from 6 to 8% within kits and from 3 to 9% between kits. A second, but slightly modified, test was per-

tended (Table III, solutions 1 and 2) to 36 days *versus* 7 days as recommended (1). The loss in potency after a 36-day storage was <3.2%, and the samples were clear. The expiration date for the frozen samples may be extended to 60 days (solutions 1 and 2, Table III) *versus* 28 days as recommended (1) by the manufacturer. There was a loss of <2 and 7% in potency in 60 days for solutions in 0.9% NaCl and 5% dextrose, respectively. There was no significant change in pH values, and the solutions were clear. Furthermore, the frozen samples can be thawed in <4 min using a microwave oven, without any observable decomposition.

It is interesting to point out that the manufacturer has recommended (1) an expiration of 24 hr under refrigeration for solutions in 5% fructose and 10% dextrose *versus* 7 days for solution in 5% dextrose. In our investigations (Table III, solutions 3–5), there was no difference in the stability of these three solutions. No decomposition was found in any sample for up to 4 days under refrigeration, which was also evident from the absence of any additional peak(s) in the chromatograms. After 14 days of storage there was only slightly more decomposition of drug in solutions containing either 10% dextrose or 5% fructose *versus* 5% dextrose (Table III, solutions 3–5). There were no significant changes in pH values, and all solutions were clear.

The optimum pH of stability (Fig. 2) appears to be ~4.8. The phosphate buffer did not catalyze the reaction (solutions 8 and 9, Table III). Trials to treat the data mathematically using first-order equations were not successful, which may be due to the complexity of the reaction as evidenced by a number of new peaks (Fig. 1C) in the chromatogram. The general information about the degradation of penicillins is available in the literature (2, 3).

The disk had a central circular depression depth of 4 mm, leaving an elevated rim. A previously water-soaked filter paper disk was placed into the depression, and 20 mg of crystalline protirelin[2] was spread onto the filter paper. The protirelin dissolved immediately. Subsequently, the device was put into contact with the buccal mucosa. After 30 min the device was removed, and the mouth was thoroughly washed with tap water. Blood samples were taken at 0, 30, 60, 120, and 180 min *via* a cannula placed into the antecubital vein.

After centrifugation the plasma was separated from the blood and stored at −20° until analysis of thyrotropin and prolactin.

Measurements of thyrotropin[3], prolactin[4], thyroxine-binding globulin[5], triiodothyronine[6], and thyroxine[6] were performed in duplicate using commercially available radioimmunoassays. Standard errors of the radioimmunoassays were from 6 to 8% within kits and from 3 to 9% between kits. A second, but slightly modified, test was per-

[a] A–E = male; F–J = female. [b] Intravenous dose = 0.2 mg of protirelin; plasma levels in ng/ml. [c] Buccal dose = 20 mg of protirelin; plasma levels in ng/ml. [d] Extra test under removal of excess saliva. [e] Increased prolactin levels due to metoclopramide medication previous to intravenous test; data excluded from further evaluation; no metoclopramide medication previous to buccal application.

formed with two of the subjects. In addition to the aforementioned procedure, excess saliva was constantly withdrawn by aspiration to prevent undesirable GI absorption of swallowed protirelin, which might stimulate thyrotropin and prolactin after intestinal absorption. Because plasma thyrotropin and prolactin levels of the subject could not be considered normally distributed, the Wilcoxin-Mann-Whitney *U*-test was used for statistical evaluation (6).

The results of the study in terms of the baseline levels and the levels after stimulation by intravenous and buccal application of protirelin are shown in Table I for thyrotropin, and Table II for prolactin. After intravenous application of protirelin, the thyrotropin concentrations increased from a baseline range of 1.0–4.3 μU/ml to a 30-min stimulation range of 4.0–25.1 μU/ml. After buccal application there was a rise from the baseline range of 0.9–5 μU/ml to a 30-min range of 1.8–10.8 μU/ml and to a 60-min range of 3.2–17.5 μU/ml. The subsequent part of the plasma profiles did not show a general tendency among subjects: in some subjects there was a further increase of thyrotropin, whereas in others there was a drop-off. (A graph of the profile is shown in Fig. 1.) The increase from the initial values to the 30-min and the 60-min values is significant, as evidenced by the *U*-test ($p = 0.01$). With respect to prolactin, the intravenous test gave rise to levels in the range of 7.6–44.0 ng/ml after 30 min, with the baseline between 3.0–18.2 ng/ml. In the case of buccal application, the baseline range was 5.2–14.8 ng/ml, whereas upon stimulation prolactin increased to 11.7–35.7 ng/ml after 30 min, and to 13.1–31.4 ng/ml after 60 min. One subject was omitted from further evaluation because several plasma levels were below the limit of analytical sensitivity at 3.0 ng/ml of prolactin. In the subsequent part of the prolactin plasma profiles there was a decrease in levels in all but one subject (see Fig. 1). Like thyrotropin, the increase of prolactin above its baseline level after buccal protirelin application is statistically significant ($p = 0.01$) for the 30-min range, as well as for the 60-min range.

An additional set of data on two subjects showed that an increase of thyrotropin and prolactin levels also could be achieved when the buccal application of protirelin is accompanied by a constant withdrawal of excess saliva from the oral cavity. The values are presented in Table I; for graphical depiction see Fig. 2. It is also interesting to note that following the intravenous test all subjects reported side effects such as nausea, urge to urinate, and facial flushing, but no side effects were observed after buccal protirelin administration.

The conclusion drawn from the presented data is that protirelin is readily absorbed *via* the buccal mucosa, as indicated by a significant stimulation of both thyrotropin and prolactin. The response pattern observed seems to indicate that females exhibit a greater stimulation by protirelin than males do and that peak levels appear more rapidly with prolactin than with thyrotropin. This parallels the typical intravenous stimulation characteristics (3). Compared with the peroral application of protirelin, buccal absorption leads to earlier attainment of maximum thyrotropin and prolactin levels, at half the dose usually taken for the peroral test. Apparently, there is no difference in the maximum increments achieved by both routes of administration, as indicated by comparison with literature data on peroral protirelin stimulation (7).

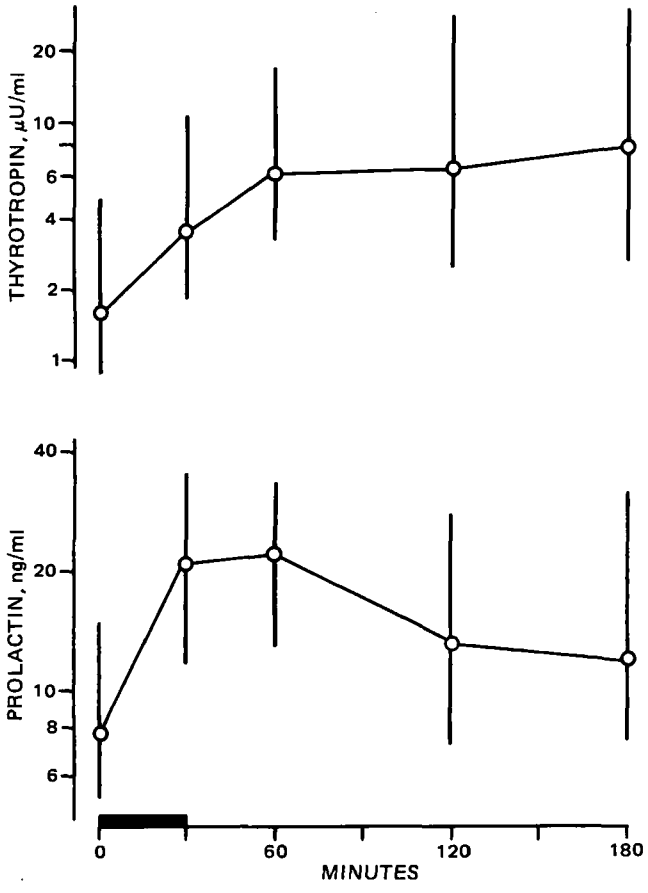

Figure 1—*Plasma thyrotropin and prolactin profiles after buccal application of 20 mg of protirelin. Circles are geometric means of 10 subjects (thyrotropin) and nine subjects (prolactin), respectively. Vertical bars indicate observed range. Horizontal bar indicates time of application.*

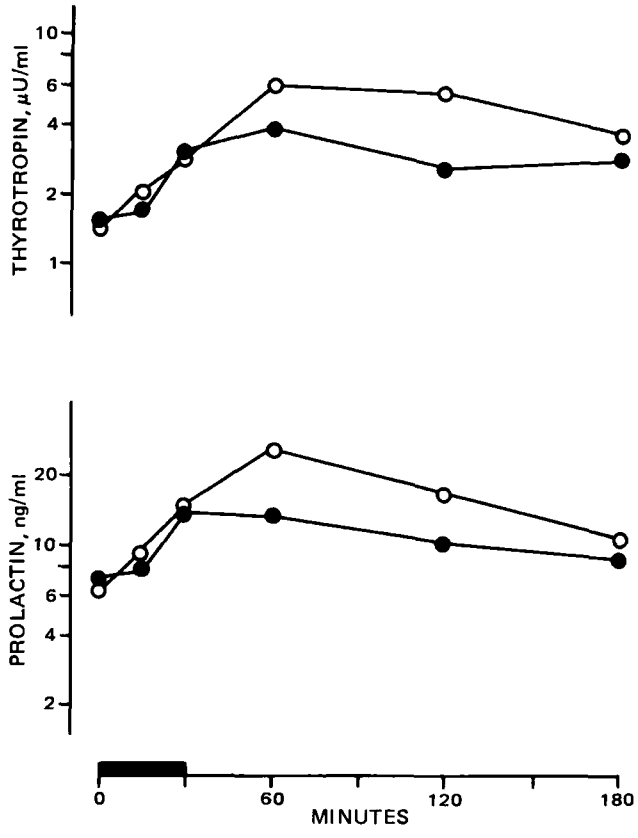

Figure 2—*Plasma thyrotropin and prolactin profiles after buccal application of protirelin under constant withdrawal of excess saliva. Filled and open circles indicate two subjects. Horizontal bar indicates time of application.*

These results also reveal that buccal protirelin administration is a clear alternative to both the peroral and the intravenous tests. As compared with the intravenous test, the obvious advantage of buccal protirelin is the fact that none of the aforementioned side effects were observed. This appears to be due to the lower incremental increase of plasma protirelin and, therefore, to the more moderate stimulation kinetics after buccal administration. In addition, buccal protirelin with a maximum stimulation 30 to 60 min after application, provokes a faster response than the peroral test, which usually requires a period of 2–3 hr to reach its peak (3, 7). We therefore suggest this test be evaluated for diagnostic use. Suitable dosage forms are presently under investigation.

Practical Solution to the Michaelis–Menten Equation

Keyphrases □ Michaelis–Menten equation—mathematical solution

To the Editor:

The mathematical solution of the Michaelis–Menten equation apparently only exists in implicit form. The explicit form required in practical usage is obtained by numerical means either using numerical integration or by solving the implicit form using a root-solving algorithm. To avoid this numerical complexity methods have been proposed which are based on a numerical solution in-

0022-3549/83/1200-1483$01.00/0

volving the use of a table of function values (1, 2). Such methods may be useful when operating a nonprogrammable calculator. However, if several calculations are required, such as in plotting curves, the methods become quite tedious and slow because of the repetitive readings of the table values. Furthermore, the published tables are also of limited usefulness because they do not extend far enough to include all values that may occur in clinical practice (1, 2). The following explicit method does not have this limitation. It enables the Michaelis–Menten equation to be evaluated quickly without the use of tables, numerical integration, or iterative techniques.

The solution to the Michaelis–Menten equation:

$$\frac{dC}{dt} = -V_m C/(K_m + C) \qquad \text{(Eq. 1)}$$

is accurately evaluated using the algorithm:

$$C(t) = K_m G(x) \qquad \text{(Eq. 2)}$$

where: $x = V_m t/K_m - C(0)/K_m + \ln [K_m/C(0)]$ (Eq. 3)

The G function in Eq. 2 is for $x \leq -1.9$ evaluated as:

$$G(x) = -x - \ln\left[-x + \frac{a_1 x}{a_2 - x} \ln(-x)\right] \qquad \text{(Eq. 4)}$$

$$a_1 = 0.99419 \qquad \text{(Eq. 5)}$$

$$a_2 = 1.1195 \qquad \text{(Eq. 6)}$$

and for $x > -1.9$:

$$G(x) = \exp\{-x - b_1 \exp(-b_2 x)/[b_3 + \exp(-b_4 x)]\} \qquad \text{(Eq. 7)}$$

$$b_1 = 1.1249 \qquad \text{(Eq. 8)}$$

$$b_2 = 1.0250 \qquad \text{(Eq. 9)}$$

$$b_3 = 0.98405 \qquad \text{(Eq. 10)}$$

$$b_4 = 0.76577 \qquad \text{(Eq. 11)}$$

The maximum global error in the evaluation of the Michaelis–Menten equation using Eq. 2 is 0.078% which is more than sufficient for practical applications.

Derivation—The Michaelis–Menten equation given by Eq. 1 can be transformed by setting:

$$C = K_m y(x) \qquad \text{(Eq. 12)}$$

with x given by Eq. 3. Then:

$$\frac{dC}{dt} = K_m \frac{dy}{dx}\frac{dx}{dt} = K_m \frac{dy}{dx}\frac{V_m}{K_m} = -\frac{V_m K_m y}{K_m + K_m y} \qquad \text{(Eq. 13)}$$

The last equality of Eq. 13 simplifies to:

$$\frac{dy}{dx} = -\frac{y}{1+y} \qquad \text{(Eq. 14)}$$

Separating variables and integration of Eq. 14 gives:

$$\ln y - \ln y_0 + (y - y_0) = -(x - x_0) \qquad \text{(Eq. 15)}$$

or

$$\ln y + y + x = \ln y_0 + y_0 + x_0 \qquad \text{(Eq. 16)}$$

The right-hand side of Eq. 16 is zero since according to Eqs. 12 and 3:

$$\ln y_0 + y_0 + x_0 = \ln [C(0)/K_m] + C(0)/K_m + (-C(0)/K_m + \ln [K_m/C(0)]) = 0 \qquad \text{(Eq. 17)}$$

Thus, Eq. 16 becomes:

$$\ln y(x) + y(x) = -x \qquad \text{(Eq. 18)}$$

Exponentiating both sides yields:

$$y(x) \exp[y(x)] - exp(-x) = 0 \qquad \text{(Eq. 19)}$$

The function $y(x)$ is the same as Toothill's function ϕ and Beal's function F with a change in sign of x; *i.e.*, $y(x) = F(-x) = \phi(-x)$ (1, 2). The implicit, parameterless function $y(x)$ can be approximated in many ways using various standard transcendental functions. The approximation $y(x) \simeq G(x)$ presented (Eqs. 4 and 7) appears to be a reasonable compromise between simplicity and accuracy. It is derived from the following considerations. From Eq. 18 it follows that:

$$y = -x - \ln y \qquad \text{(Eq. 20)}$$

by substituting the right-hand side expression for y on the right-hand side yields:

$$y = -x - \ln(-x - \ln y) \qquad \text{(Eq. 21)}$$

This equation can be used as an approximation for $y(x)$ if a sufficiently accurate approximation for $\ln y$ is used. By empirical numerical means it was found that for $x < 0$ $\ln y$ is quite well approximated by the function:

$$\ln y \simeq \frac{a_1 x}{a_2 - x} \ln(-x) \qquad \text{(Eq. 22)}$$

with a_1 and $a_2 \simeq 1$. Inserting this equation into Eq. 21 yields Eq. 3.

For positive values of x it is more accurate to use Eq. 19 in rearranged form:

$$y = \exp[-x - y] \qquad \text{(Eq. 23)}$$

This equation (Eq. 19) can be used to approximate $y(x)$ when a sufficiently accurate approximation for $y(x)$ is substituted on the right-hand side of Eq. 23. Previous research by the investigators involving empirical approximations of drug level profiles in Michaelis–Menten kinetics suggests that an empirical function of the form:

$$y \simeq b_1 \exp(-b_2 x)/[b_3 + \exp(-b_4 x)] \qquad \text{(Eq. 24)}$$

should be a suitable approximation to use. This was indeed the case. Inserting Eq. 24 into Eq. 23 yields Eq. 7.

The strategy above of expanding and rearranging the functional relationship to be approximated serves the purpose of producing an expression for y which is very little sensitive to errors in the "primary approximation" (*i.e.*, errors in Eqs. 22 and 24). For example, substituting Eq. 22 into Eq. 21 leads to better approximations than substituting into Eq. 20. Similarly the "primary approximation" Eq. 24 may not give sufficiently accurate results by itself. However, when substituted into Eq. 23 an excellent approximation can be obtained.

The constants a_1 and a_2 of Eq. 4 were obtained using FUNFIT (3) by minimizing the sum of squares expression:

$$ss = \sum_i [y(x_i) - G(x_i)]^2 \qquad \text{(Eq. 16)}$$

with x_i ranging from −1.9 to −8.0 in steps of 0.1. The $y(x)$ function was evaluated to an accuracy of at least six significant digits from Eq. 15 using Brent's numerical root-solving algorithm (4). The constants $b_1 - b_4$ of Eq. 7 were similarly evaluated with x_i ranging from −1.9 to 8.0 in steps of 0.1. The switch point $x = -1.9$ in the formula for $G(x)$ was derived empirically from preliminary observations which showed Eq. 4 starts to deviate significantly from $y(x)$ for $x > -1.9$, and the same is the case for Eq. 7 for $x < -1.9$. The maximum relative error $\epsilon = |y(x) - G(x)|/y(x)$ of Eq. 4 with the constants given is 0.078% ($x = -1.9$) in the range $x = -1.9$ to −8.0. From a mathematical analysis of Eq. 4 it can be shown that the relative error will continue to decrease beyond $x = -8$. This was confirmed by evaluating ϵ for $x = -8$ to −20. The maximum relative error for Eq. 7 with the constants given is 0.064% ($x = 2.2$) in the range −1.9–8. The relative error continues to decrease beyond $x = 8$ as expected from Eq. 7, and at about $x = 14$ reaches convergence and starts to oscillate tightly around the "machine precision value."

Pan Abrasion and Polymorphism of Titanium Dioxide in Coating Suspensions

Keyphrases □ Tablet-coating suspensions—titanium dioxide, pan abrasion from abrasive components □ Titanium dioxide—in coating suspensions, polymorphic modifications

To the Editor:

It is not generally recognized that aqueous tablet-coating suspensions may contain abrasive components which can cut into the surface of the coating pan causing deposition of metallic particles onto the tablets. Subsequent to a series of film-coating operations in a 24-in. coating pan[1], black specks were observed on the white tablet film coats derived from a commercial batch of color concentrate (Batch A)[2]. This phenomenon was not observed, however, when another batch of color concentrate (Batch B)[2] was employed. Isolation of the foreign material gave a positive test for iron, and it was confirmed that the actual rubbing of tablets coated with either batch against the pan surface produced black smudges. The streaks were, however, less intense on tablets coated with Batch B.

Titanium dioxide, an opacifier used in these aqueous film solutions, can exist in several polymorphic modifications, each with a different hardness (1). Anatase, for example, has a hardness on the Mohs' scale of 5.5–6, whereas rutile is in the range 6–6.5. For comparison, the common oxide of iron, hematite, gives values of 5–6 and magnetite, 5.5–6.5. The pan material itself, stainless steel 304, has a hardness range of 160–400 Brinnell (2). Conversion of the latter scale to the Mohs' scale (3) shows that the upper range lies somewhat below 6 on the Mohs' scale.

The Mohs' scale is a semiquantitative scale of hardness, which is a function of the elastic, plastic, and frictional properties of the surface. Materials with higher Mohs' numbers will scratch or abrade those with lower numbers.

In the range of Mohs' numbers considered here, the scale is linear and relatively sensitive, although hardness values tend to cluster at the high end. Abrasion or wear of the coating pan is essentially a surface phenomenon involving the removal of oxide films. A comparison of the Mohs' numbers shows that rutile is the harder of the two titanium dioxide polymorphs and would be expected to remove material through abrasion more readily than anatase. To confirm whether this could explain the observations, titanium dioxide was extracted from both batches of color concentrate and analyzed by X-ray powder diffraction. Batch A was found to contain 60:40 anatase/rutile in contrast to Batch B which was composed of 90:10 anatase/rutile.

Differences in surface roughness should theoretically not play a major role since, as the number of asperities in the film coating is increased, the number of contacting points would be increased proportionately. More scratches would be produced, but each would be of smaller cross-sectional area. This point was checked by measuring the advancing and receding contact angles of a series of liquids of varying surface tension on the film-coated tablet surfaces (4). There was no significant difference in surface roughness of films produced from either batch.

Pan Abrasion and Polymorphism of Titanium Dioxide in Coating Suspensions

Keyphrases □ Tablet-coating suspensions—titanium dioxide, pan abrasion from abrasive components □ Titanium dioxide—in coating suspensions, polymorphic modifications

To the Editor:

It is not generally recognized that aqueous tablet-coating suspensions may contain abrasive components which can cut into the surface of the coating pan causing deposition of metallic particles onto the tablets. Subsequent to a series of film-coating operations in a 24-in. coating pan[1], black specks were observed on the white tablet film coats derived from a commercial batch of color concentrate (Batch A)[2]. This phenomenon was not observed, however, when another batch of color concentrate (Batch B)[2] was employed. Isolation of the foreign material gave a positive test for iron, and it was confirmed that the actual rubbing of tablets coated with either batch against the pan surface produced black smudges. The streaks were, however, less intense on tablets coated with Batch B.

Titanium dioxide, an opacifier used in these aqueous film solutions, can exist in several polymorphic modifications, each with a different hardness (1). Anatase, for example, has a hardness on the Mohs' scale of 5.5–6, whereas rutile is in the range 6–6.5. For comparison, the common oxide of iron, hematite, gives values of 5–6 and magnetite, 5.5–6.5. The pan material itself, stainless steel 304, has a hardness range of 160–400 Brinnell (2). Conversion of the latter scale to the Mohs' scale (3) shows that the upper range lies somewhat below 6 on the Mohs' scale.

The Mohs' scale is a semiquantitative scale of hardness, which is a function of the elastic, plastic, and frictional properties of the surface. Materials with higher Mohs' numbers will scratch or abrade those with lower numbers.

In the range of Mohs' numbers considered here, the scale is linear and relatively sensitive, although hardness values tend to cluster at the high end. Abrasion or wear of the coating pan is essentially a surface phenomenon involving the removal of oxide films. A comparison of the Mohs' numbers shows that rutile is the harder of the two titanium dioxide polymorphs and would be expected to remove material through abrasion more readily than anatase. To confirm whether this could explain the observations, titanium dioxide was extracted from both batches of color concentrate and analyzed by X-ray powder diffraction. Batch A was found to contain 60:40 anatase/rutile in contrast to Batch B which was composed of 90:10 anatase/rutile.

Differences in surface roughness should theoretically not play a major role since, as the number of asperities in the film coating is increased, the number of contacting points would be increased proportionately. More scratches would be produced, but each would be of smaller cross-sectional area. This point was checked by measuring the advancing and receding contact angles of a series of liquids of varying surface tension on the film-coated tablet surfaces (4). There was no significant difference in surface roughness of films produced from either batch.

N-Nitroso Compounds: Occurrence and Biological Effects. Edited by H. BARTSCH, I. K. O'NEILL, M. CASTEGNARO, and M. OKADA. International Agency on Cancer, Health and Biomedical Information Programme, World Health Organization, 1211 Geneva 27, Switzerland, 1982. 753 pp. 17 × 24 cm. Price $55.00 (Sw. Fr. 110).

This volume is comprised of the Proceedings of the 7th International Symposium on *N*-Nitroso Compounds held in Tokyo, September 1981. It includes 73 papers and draws from a wide range of scientific disciplines. Numerous experts present information on the formation, occurrence, and biological effects of *N*-nitroso compounds. Formation of *N*-nitroso compounds within the body is reported by several workers and is discussed in relation to the ingestion of various materials. Data are given on exposure to *N*-nitroso compounds in the general environment and from tobacco usage. New and important developments of methods and approaches are presented that could promote the understanding of basic mechanisms of carcinogenesis and which could also be readily applied to the detection and analysis of *N*-nitroso compounds or their precursors. Also presented are suggestions for possible future research on nitroso compounds. A possible drawback of the book is the limited coverage of nitrosoureas, an important group of compounds in cancer research and treatment.

The papers are short, easy to read, and most present considerable background information. Concise figures and tables are used when appropriate. There is an author index and a thorough subject index. A list of references is given at the end of each chapter to assist readers seeking additional information. This book, written entirely in English, contains an enormous amount of useful information and is recommended as a general reference book to anyone directly involved in work on *N*-nitroso compounds.

Side Effects of Drugs Annual 7. Edited by M. N. G. DUKES. Elsevier Biomedical Press B.V., P.O. Box 1527, 1000 BM Amsterdam, The Netherlands. 1983. 539 pp. 15 × 25 cm. Price $70.25 (Dfl. 165.00).

Adverse reactions to therapeutic agents can result from many and diverse factors. Two reactions of major significance are the abnormal patient reaction to a drug and the development of unexpected toxicity when two or more drugs are administered together. *Side Effects of Drugs Annual*, which has been published annually in January since its inception in 1977, is designed to provide a critical evaluation of the literature and an up-to-date account of recent information relating to these drug reactions and interactions. In this regard, the current *Annual* covers reports published between July 1981 and June 1982. In general, only publications presenting new information are reviewed. The reports which are documented are based on material from the Excerpta Medica Database System, which screens approximately 4000 journals in nearly 20 languages.

Although each *Annual* edition can be used independently, they are best employed as supplements to the most recent edition of the parent reference, *Meyler's Side Effects of Drugs*, an encyclopedic resource that reviews all existing knowledge on adverse reactions. The greatest value of a regularly published supplement is that it permits a continuing discussion of problems associated with the use of drugs; the question of a drug-induced disease raised one year can be followed up in subsequent years as the evidence to confirm or deny its occurrence becomes available. In addition, the *Annual* is published at a time when scattered reports of an iatrogenic disease have appearerd in the medical and pharmaceutical literature, but have not been the subject of critical editorials and other review articles.

Each year an introductory chapter entitled "Side Effects of Drugs Essay" has been published as a forum for the discussion of topics that are of current interest. This year, the essay written by the Chief of the Product Related Disease Division of Canadian Department of Health and Welfare explores drug development and formulation in light of documented adverse reactions, suspected reactions, and mere accusations of the possibility of adverse drug reactions. As noted in the introduction to the essay, its writer has designed it to be controversial with the intention of exposing pitfalls and false conceptions. In addition, beginning in 1980 and continuing with the current edition, a valuable feature entitled "Special Reviews" printed in italic type and identified by the traditional prescription symbol has appeared. These reviews, found in many of the 51 chapters, are critical discussions of controversial areas or the publication of new findings that require revision of existing concepts. Many report the latest developments in issues of continuing concern such as interactions of lithium with other drugs, side effects of β-blockers given prophylactically after myocardial infarction, ketoconazole and the liver, and prediction of anthracycline cardiomyopathy. In addition to discussing the data, each review offers the reader information that is useful clinically in recognizing, evaluating, and managing the specific reaction.

The current edition continues the discussion of drugs used in nonorthodox medicine begun with the first *Side Effects of Drugs Annual*. This year, the authors review the reports of toxicity from herbal remedies as well as updating previous information on laetrile. The chapter on miscellaneous drugs incudes a special review and update on surgical materials and other appliances.

The drugs discussed in *Side Effects of Drugs Annual* are classified according to their pharmacological properties or therapeutic use. They are accessed by consulting an index of drugs, an index of side effects, or an index of interactions. In addition, an index of synonyms enables the reader to identify specific drugs by their foreign brand name, investigational number, chemical name, or abbreviation. To facilitate rapid searching, the three major indices in the current *Annual* provide a complete listing of all references discussed in the previous three volumes of this series. The references in each chapter have been uniquely coded to identify those reports in which (*i*) the information presented is reviewed in some detail; (*ii*) the original citation refers only briefly to the information presented; (*iii*) the original citation presents detailed clinical evidence; and (*iv*) the original citation provides a brief clinical description. The code allows the reader to select the original source most useful in documenting a specific drug-induced side effect.

This is a superb reference which provides an invaluable source of information on adverse drug reactions reported in the literature during a 1-year period. Even though the *Annual* series are not intended to be used as comprehensive references sources, many of the chapters, and in particular the special reviews, make fascinating reading. The major drawback of this reference is its cost, but it should be a part of the collection of medical libraries, drug information centers, and hospital pharmacies, where it would be available to those who dispense as well as those who prescribe drugs.

Pathology of Tumours in Laboratory Animals, Volume III: Tumours of the Hamster. V. S. TURUSOV, Editor-in-Chief. International Agency for Cancer Research Scientific Publication No. 34. World Health Organization, 1211 Geneva 27, Switzerland. 1983. 461 pp. 18 × 24 cm. Price $40.00 (Sw. Fr. 80).

This volume, sponsored by the World Health Organization, is the third in a series concerning tumors of laboratory rodents, *i.e.*, rat, mouse, and now hamster. The text contains a number of contributions from F. N. Ghadially, A. Cardesa, A. H. Handler, A. D. Kelman, A. Emminger, U.

Mohr, M. Greenblatt, G. Reznik, J. Althoff, F. C. Chesterman, H. Kirkman, R. L. Kempson, A. H. Dodge, L. D. Berman, E. Soto, I. S. Levenbook, O. L. Kolomiyets, M. A. Nikolayeva, P. Straüli, J. Mettler, P. Pour, M. Rustia, H. E. Pogosianz, and O. I. Sokova.

The book was organized, as were the two previous volumes, on an organ approach, giving a description of the individual tumors of each organ based on histological tissue type. Included in each chapter is a discussion of (*a*) normal structure, (*b*) morphology and biology of tumors, (*c*) spontaneous tumors, (*d*) induced tumors, and (*e*) comparative aspects. Included in the normal structure section is a description of the organ's gross anatomy, histological type of tissue, and cell types. The morphology and biology of tumor portion relates the most prevalent types of tumors found in the organ in hamsters based on standard histological classifications of tumors.

The spontaneous tumor section deals with the incidence of a given tumor occurring naturally in various hamster colonies throughout the world. Limited factual records were obviously available to the authors to make their evaluation. The induced-tumor section discusses the ability to induce a specific type of tumor in hamsters with either chemicals, environmental agents, hormones, or radiation. In some cases, the number of successfully induced cancers is included for the reader's perusal.

The portion on comparative aspects relates the probability of a hamster cancer being a good laboratory model in cancer research. Comparisons were made where appropriate, relating similarities of hamster cancers to specific human cancers. Certain hamster tumor models related positively with hormone-, chemical-, or virus-induced cancers in the human.

Each organ chapter contains black and white photographs of examplary tumors from hamsters demonstrating cell types, histology, and morphology points typical to that type of tumor, metastasis, viral inclusions, *etc.* A number of electron micrographs are included. Although expensive, the volume contains no color photographs, which could have enhanced the staining characteristic of the tissue.

The materials in each chapter are well referenced, although the citations are not of recent dates, *i.e.*, 1975–1983. Obviously, attempts were made to collect all available references on a given hamster tumor in this volume. The text is written in a concise, straightforward manner. It is complete and well organized in its treatment of the tumors. This particular volume would not interest most scientists in cancer research, since hamsters are not frequently utilized as tumor-bearing models. Nevertheless, the text is a good reference book and may interest some researchers in the future who wish to develop in hamsters a tumor model that mimics a specific tumor in humans.

Manual of Laboratory Pharmacokinetics. By STEPHEN H. CURRY and ROBIN WHELPTON. John Wiley and Sons, One Wiley Drive, Somerset, NJ 08863. 1983. 189 pp. 15 × 23 cm. Price $21.95.

In the preface, the authors state that their purpose in this book was to compile "experiments suitable for use in training laboratory workers in biopharmaceutics, drug metabolism, pharmacokinetics, and related topics." A review of this book must then address the relevance of this book to the pharmaceutical sciences and the degree to which it meets a perceived need.

The changing curricula of pharmacy schools, with an increasing emphasis on clinical relevance in contrast to basic science background of fundamentals, is of concern to many in education. Now with the growing need for pharmacokinetic input to dosage adjustment, the adequacy of the analytical chemistry component of the training becomes a concern. Some schools now seek to emphasize biopharmaceutical applications rather than compendial assays, but this trend is hampered by a scarcity of adequate texts and manuals, especially for instructors who are not personally involved in the biopharmaceutical and pharmacokinetic implications of drug and metabolite assay.

The use of this book as a text in an undergraduate sequence requires the cooperation of instructors in analytical chemistry, pharmacokinetics, and pharmacology. Any student who is exposed to the approach utilized here will be a better "relevant" pharmacist for the knowledge and experience obtained. First-year graduate students, not just in pharmaceutics but also in medicinal chemistry, deserve an exposure to this or an equivalent text if they are not already receiving this knowledge through related biopharmaceutic assay courses and appropriate support pharmaceutics and kinetics.

Each chapter of this book provides good theoretical treatment of the subject matter, has one or more laboratory experiments clearly illustrating the methodology but providing data for pharmacokinetic interpretation, and contains a set of references and reading material. Even more valuable, typical data from each experiment are considered in the Appendix to demonstrate how the data should be presented and interpreted.

A listing of the experiments provides a recognition of the diversity of techniques explored and reviewed. These include: (1) construction of tritium quench correction curve by the channels ratio technique, (2) absorption spectrum of potassium dichromate, (3) fluorescence of quinine, (4) thin-layer chromatography separation of mild analgesic anti-inflammatory drugs, (5) radioimmunoassay of digoxin, (6) measurement of pK_a values of sulfadimidine and its N-4 acetylated metabolite (including preparation), (7) relationship between pH and apparent partition coefficient, (8) tablet dissolution, (9) decomposition of indomethacin, (10) storage of nitroglycerin tablets, (11) Fisher–Parsons approach for the study of drug absorption *in vitro*, (12) determination of K and n for warfarin binding to bovine serum albumin, (13) displacement of warfarin from binding sites on serum proteins, (14) metabolism of drugs by enzymes of the liver microsomal fraction, (15) determination of K_m and V_{max} for butyral-cholinesterase using butyralthiocholine as the substrate, (16) excretion of imipramine and its metabolites by rats housed in metabolism cages (including preparation of imipramine N-oxide), (17) influence of urinary pH on salicylate excretion, (18) pharmacokinetics of sulfadimidine and N^4-acetylsulfadimidine, (19) urinary clearance of these two and determination of acetylator status, (20) kinetics of ethanol elimination with simple measurement of drug effect, (21) measurement of sleeping times in mice, use of drug effect to assess drug metabolism, and pretreated animal differences, (22) turn-over of noradrenaline in rat hearts, and (23) pharmacokinetic models and problems.

An interested student could read this book and its model answers to learn a great deal regarding techniques and methodology without actually having any hands-on experience. Many students deserve the opportunity of studying this book for this reason. In addition many of the faculty of our schools would profit from a similar reading of this book to enhance their background in this area of pharmacy practice. It is sincerely hoped that this and similar books will provide the necessary unification of concepts of fundamental basic sciences with animal and human pharmacology and pharmacokinetics.

Mohr, M. Greenblatt, G. Reznik, J. Althoff, F. C. Chesterman, H. Kirkman, R. L. Kempson, A. H. Dodge, L. D. Berman, E. Soto, I. S. Levenbook, O. L. Kolomiyets, M. A. Nikolayeva, P. Straüli, J. Mettler, P. Pour, M. Rustia, H. E. Pogosianz, and O. I. Sokova.

The book was organized, as were the two previous volumes, on an organ approach, giving a description of the individual tumors of each organ based on histological tissue type. Included in each chapter is a discussion of (*a*) normal structure, (*b*) morphology and biology of tumors, (*c*) spontaneous tumors, (*d*) induced tumors, and (*e*) comparative aspects. Included in the normal structure section is a description of the organ's gross anatomy, histological type of tissue, and cell types. The morphology and biology of tumor portion relates the most prevalent types of tumors found in the organ in hamsters based on standard histological classifications of tumors.

The spontaneous tumor section deals with the incidence of a given tumor occurring naturally in various hamster colonies throughout the world. Limited factual records were obviously available to the authors to make their evaluation. The induced-tumor section discusses the ability to induce a specific type of tumor in hamsters with either chemicals, environmental agents, hormones, or radiation. In some cases, the number of successfully induced cancers is included for the reader's perusal.

The portion on comparative aspects relates the probability of a hamster cancer being a good laboratory model in cancer research. Comparisons were made where appropriate, relating similarities of hamster cancers to specific human cancers. Certain hamster tumor models related positively with hormone-, chemical-, or virus-induced cancers in the human.

Each organ chapter contains black and white photographs of examplary tumors from hamsters demonstrating cell types, histology, and morphology points typical to that type of tumor, metastasis, viral inclusions, *etc.* A number of electron micrographs are included. Although expensive, the volume contains no color photographs, which could have enhanced the staining characteristic of the tissue.

The materials in each chapter are well referenced, although the citations are not of recent dates, *i.e.*, 1975–1983. Obviously, attempts were made to collect all available references on a given hamster tumor in this volume. The text is written in a concise, straightforward manner. It is complete and well organized in its treatment of the tumors. This particular volume would not interest most scientists in cancer research, since hamsters are not frequently utilized as tumor-bearing models. Nevertheless, the text is a good reference book and may interest some researchers in the future who wish to develop in hamsters a tumor model that mimics a specific tumor in humans.

Manual of Laboratory Pharmacokinetics. By STEPHEN H. CURRY and ROBIN WHELPTON. John Wiley and Sons, One Wiley Drive, Somerset, NJ 08863. 1983. 189 pp. 15 × 23 cm. Price $21.95.

In the preface, the authors state that their purpose in this book was to compile "experiments suitable for use in training laboratory workers in biopharmaceutics, drug metabolism, pharmacokinetics, and related topics." A review of this book must then address the relevance of this book to the pharmaceutical sciences and the degree to which it meets a perceived need.

The changing curricula of pharmacy schools, with an increasing emphasis on clinical relevance in contrast to basic science background of fundamentals, is of concern to many in education. Now with the growing need for pharmacokinetic input to dosage adjustment, the adequacy of the analytical chemistry component of the training becomes a concern. Some schools now seek to emphasize biopharmaceutical applications rather than compendial assays, but this trend is hampered by a scarcity of adequate texts and manuals, especially for instructors who are not personally involved in the biopharmaceutical and pharmacokinetic implications of drug and metabolite assay.

The use of this book as a text in an undergraduate sequence requires the cooperation of instructors in analytical chemistry, pharmacokinetics, and pharmacology. Any student who is exposed to the approach utilized here will be a better "relevant" pharmacist for the knowledge and experience obtained. First-year graduate students, not just in pharmaceutics but also in medicinal chemistry, deserve an exposure to this or an equivalent text if they are not already receiving this knowledge through related biopharmaceutic assay courses and appropriate support pharmaceutics and kinetics.

Each chapter of this book provides good theoretical treatment of the subject matter, has one or more laboratory experiments clearly illustrating the methodology but providing data for pharmacokinetic interpretation, and contains a set of references and reading material. Even more valuable, typical data from each experiment are considered in the Appendix to demonstrate how the data should be presented and interpreted.

A listing of the experiments provides a recognition of the diversity of techniques explored and reviewed. These include: (1) construction of tritium quench correction curve by the channels ratio technique, (2) absorption spectrum of potassium dichromate, (3) fluorescence of quinine, (4) thin-layer chromatography separation of mild analgesic anti-inflammatory drugs, (5) radioimmunoassay of digoxin, (6) measurement of pK_a values of sulfadimidine and its N-4 acetylated metabolite (including preparation), (7) relationship between pH and apparent partition coefficient, (8) tablet dissolution, (9) decomposition of indomethacin, (10) storage of nitroglycerin tablets, (11) Fisher–Parsons approach for the study of drug absorption *in vitro*, (12) determination of K and n for warfarin binding to bovine serum albumin, (13) displacement of warfarin from binding sites on serum proteins, (14) metabolism of drugs by enzymes of the liver microsomal fraction, (15) determination of K_m and V_{max} for butyral-cholinesterase using butyralthiocholine as the substrate, (16) excretion of imipramine and its metabolites by rats housed in metabolism cages (including preparation of imipramine N-oxide), (17) influence of urinary pH on salicylate excretion, (18) pharmacokinetics of sulfadimidine and N^4-acetylsulfadimidine, (19) urinary clearance of these two and determination of acetylator status, (20) kinetics of ethanol elimination with simple measurement of drug effect, (21) measurement of sleeping times in mice, use of drug effect to assess drug metabolism, and pretreated animal differences, (22) turn-over of noradrenaline in rat hearts, and (23) pharmacokinetic models and problems.

An interested student could read this book and its model answers to learn a great deal regarding techniques and methodology without actually having any hands-on experience. Many students deserve the opportunity of studying this book for this reason. In addition many of the faculty of our schools would profit from a similar reading of this book to enhance their background in this area of pharmacy practice. It is sincerely hoped that this and similar books will provide the necessary unification of concepts of fundamental basic sciences with animal and human pharmacology and pharmacokinetics.

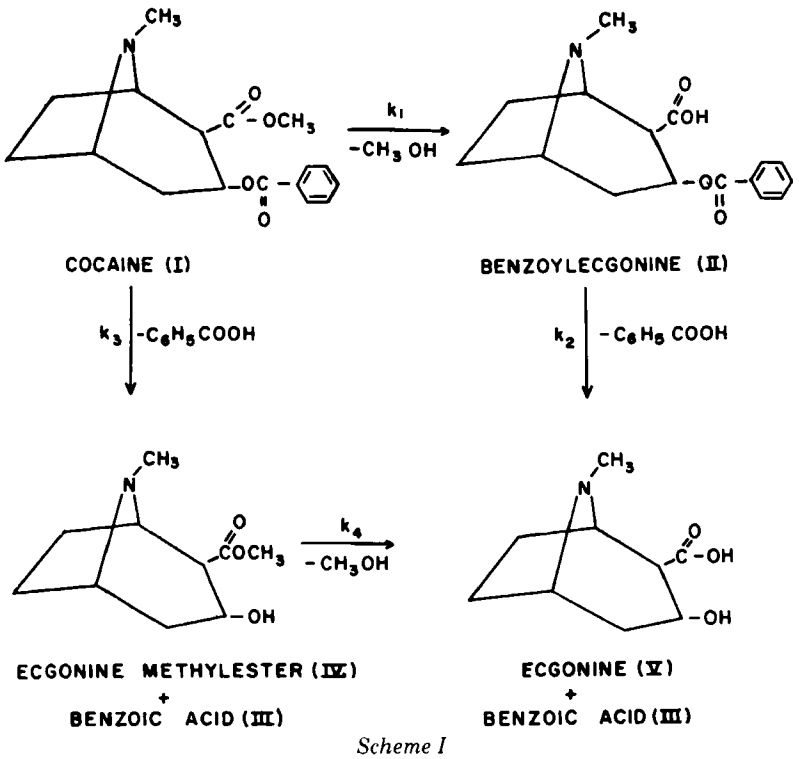
ERRATA

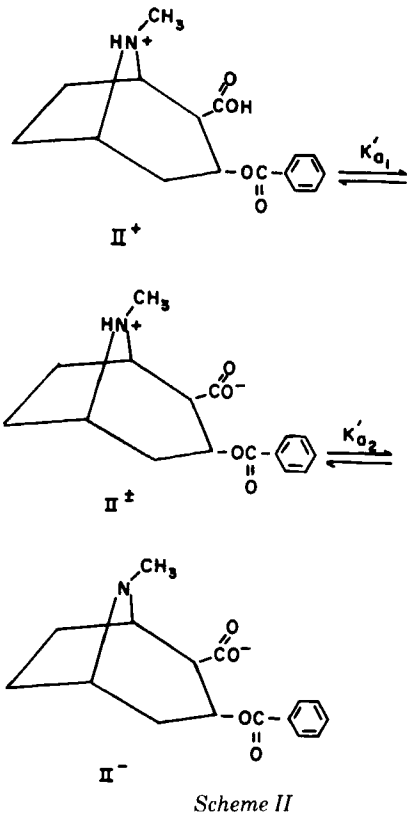
In the article titled "Prediction of Stability in Pharmaceutical Preparations XX: Stability Evaluation and Bioanalysis of Cocaine and Benzoylecgonine by High-Performance Liquid Chromatography" (1), the following corrections should be made:

On page 259, Scheme I should appear as shown here:



Scheme I

On page 267, Scheme II should appear as shown here:
(1) E. R. Garrett and K. Seyda, *J. Pharm. Sci.*, **72**, 258 (1983).



Scheme II

In the article titled "Evaluation of Various N-Substituted Azaspiranedione Derivatives as Potential Antimicrobial Agents" (1), the following should be noted:

On page 184 in Table I and Scheme II, two compounds were given the same number (XIII).

(1) K. R. Scott, P. G. Kennedy, M. Kemp, V. G. Telang, and H. W. Matthews, *J. Pharm. Sci.*, **72**, 183 (1983).

In the book review of "Hormone Drugs" (1), the following correction should be made:

The spelling of the third author's name should be Aubrey S. Outschoorn.

(1) J. M. Rosenberg (reviewer), *J. Pharm. Sci.*, **72**, 720 (1983).

Underscoring the Food-Pharmacy Relationship

I write in support and to underscore the importance of the remarks stated in your editorial "Food and Pharmacy—A Close Relationship" [1]. You have accurately pointed out that recent legislative history has not focused heavily on matters of food safety evaluation. Many of our colleagues in pharmacy and the other basic medical sciences have been deeply involved in drug legislative matters. However, on issues of food safety, I find myself in a somewhat unique, and at times lonesome, position. Many classmates and colleagues in pharmacy and pharmacology are active in appropriate pharmaceutical and pharmacological professional societies, so too it is with other colleagues in the Institute of Food Technologists. However, there are precious few pharmacists and pharmacologists/toxicologists who have looked beyond the world of pharmacy and pharmacology to the potential for the pharmacologic effects of foods. Many of us have tried to point out that numerous problems in toxicology and safety evaluation are common to both foods and drugs. With foods we are often dealing with longer term exposures of test materials administered at levels on the lower portions of the slope of the dose response curve. But the ultimate goal of these researchers is the same—extrapolation of toxicity findings, if any, to man.

The thrust of our testimony before Senator Hatch[2] was to call for an updating of the scientific thinking behind the Delaney Clause to give FDA scientists, specifically, and science in general discretion for scientific judgment as now allowable under the general provisions of the Food, Drug and Cosmetic Act, but not permitted by the absolute strictures of the Delaney Clause. We are not calling for a weakening of food safety laws as some have worried.

It is clear that advances in science and technology referred to by Senator Hatch and mentioned in your editorial, must include studies for the potential for food and drug interactions, both from the standpoint of potential benefits, as well as risks to the consumer, which may be, as you point out, every bit as important and critical as drug–drug interactions.

Unfortunately, ranking minority member Kennedy was not present throughout the hearings. It is hoped, however, that the hearings can and will result in meaningful bipartisan food safety legislation.

Full Disclosure Should Apply to All

I read with interest your editorial in the August issue of the *Journal of Pharmaceutical Sciences*[1]. At the same time I am concerned that you may not be aware that Dr. Jacobson of the Center for Science in the Public Interest (CSPI) is hardly a case study in full disclosure when it comes to addressing the issue of how CSPI is funded.

The American Council on Science and Health (ACSH), a scientific consumer education organization, has carefully documented[2] the secretive and inconsistent activities of CSPI, an organization which owes its existence to the perpetuation of consumer fear of technological advances. We have here a classic example of one living in a glass house and throwing stones. I would be happy to provide copies of the above mentioned article to interested readers.

My point is this—it is just as valid to question the motives of Jacobson and CSPI as it is the motives of scientists who take stands on public issues—and I wish you would have done so.

Author's response:

In quoting Dr. Jacobson, I intended to pass no judgment—nor did I so indicate in my editorial—regarding his personal prejudices, allegiances, or freedom from bias. I know really nothing about the man, but I felt then, as now, that what he wrote was right and proper behavior for all scientists to follow. And as a scientist himself, I would expect Dr. Jacobson to adhere to this same standard of performance along with the rest of us who regard ourselves as scientists.
