A chromatogram of sodium nitroprusside, 100 μg/mL in 5% dextrose, is shown in Fig. 1. Using the previously described chromatographic conditions, the retention time is ~5 min. Also shown in Fig. 1 is a chromatogram of the same solution of sodium nitroprusside after exposure to light for 4 h. At 230 nm, the degradation of sodium nitroprusside is manifested as a decrease in the peak height; none of the breakdown products are visible on the chromatogram. Beer's law is obeyed over the sodium nitroprusside concentration range of 1–200 μg/mL. The precision of the assay was evaluated by injecting four replicate samples of 12.5, 25, 50, and 100 μg/mL of sodium nitroprusside; the coefficient of variation was <1%.

The results of the stability studies of sodium nitroprusside in 5% dextrose, lactated Ringer's, and normal saline are shown in Table I. When a glass or plastic container is wrapped in aluminum foil and then left exposed to light for 48 h, there is no appreciable breakdown of sodium nitroprusside at a concentration of either 50 or 100 μg/mL. Other studies have found that sodium nitroprusside is stable in 5% dextrose in glass (8, 9) and plastic (10) containers when protected from light, and this study extends those observations to include normal saline and lactated Ringer's solution. There appears to be no factual basis for the current recommendation that sodium nitroprusside be administered solely in 5% dextrose.

Table II shows the effect of light exposure on sodium nitroprusside solutions while traversing plastic intravenous infusion sets. Duplicate determinations in either 5% dextrose, normal saline, or lactated Ringer's solution at flow rates of 10 or 50 mL/h showed no deterioration in the delivered concentration of the sodium nitroprusside solution over 24 and 8 h, respectively. This finding contrasts with that of Baaske *et al.* (8) who noted a small (3.5%), but consistent, decrease in the potency of a nitroprusside solution delivered from an intravenous infusion set exposed to light for 5 h. This discrepancy may possibly be explained by differences in the composition, and therefore the light diffusion characteristics, of the infusion sets.

Influence of Isotonic Agents on the Stability of Thimerosal in Ophthalmic Formulations

M. J. READER

Received September 9, 1982, from the *Central Analytical Laboratories (Chemical), The Wellcome Foundation Limited, Temple Hill, Dartford, Kent DA1 5AH, U.K.* Accepted for publication April 5, 1983.

Abstract □ Storage tests on the stability of thimerosal in trimethoprim-polymyxin B eyedrop formulations containing isotonic agents other than sodium chloride have been carried out. The HPLC assay of thimerosal in stored formulations containing boric acid and EDTA decreased with time and temperature, while formulations containing propylene glycol, glycerol, and mannitol showed no significant decrease in thimerosal assay compared with a formulation containing no isotonic agent. The latter group provide suitable alternatives to sodium chloride, which has been shown to have a seriously detrimental effect on thimerosal stability.

Keyphrases □ Thimerosal—stability in ophthalmic formulations, influence of isotonic agents, boric acid, EDTA, propylene glycol, glycerol, mannitol □ Isotonic agents—boric acid, EDTA, propylene glycol, glycerol, mannitol, effect on the stability of thimerosal, ophthalmic formulations □ Ophthalmic solutions—thimerosal stability with isotonic agents, boric acid, EDTA, propylene glycol, glycerol, mannitol

Thimerosal, ethyl (sodium *o*-mercaptobenzoato)mercury (I), is an effective antibacterial and antifungal agent widely used as a preservative in pharmaceutical formulations, particularly liquid formulations such as ophthalmic solutions. Ophthalmic solutions also frequently contain agents to ensure that the formulation is isotonic with lachrymal secretions. While such formulations may be presented in a nonisotonic form, it is generally preferred to render them isotonic in order to avoid patient discomfort, biological damage to the patient, or ineffective treatment. The most commonly employed isotonic agents are ionic, in particular sodium chloride. However, it has been reported (1-3) that the presence of halides in solutions of thimerosal can have an adverse influence on the stability of I.

This study was undertaken to examine the effects of several isotonic agent alternatives to sodium chloride on the stability of thimerosal in aqueous formulations when stored under realistic and moderately accelerated conditions.

EXPERIMENTAL

Compounds and Reagents—Thimerosal was obtained commercially[1], and the isotonic agents listed in Table I were "AnalaR" grade[1], with the exception of boric acid which was "Aristar" [1] and propylene glycol which was "GPR" [1]. Methanol used for chromatography was HPLC grade[2], and all water used was freshly distilled.

High-Performance Liquid Chromatography—A constant-flow pump[3] was used to deliver the eluant to two stainless steel columns (each 250 mm × 4 mm i.d.) connected in series and packed with 10-μm silica particles bonded with octadecylsilane[4]. Injections were made with a rotary valve injector[5] equipped with a 50-μL loop. No attempt was made to control the column temperature. A variable-wavelength detector[6] set at 222 nm was employed at an attenuation of 0.04 AUFS.

The chromatographic mobile phase consisted of a mixture of methanol–water–phosphoric acid in a ratio of 60:50:1. The pressure, at a flow rate of 4.0 mL/min was, 4800 psig. Separations were effected isocratically at ambient temperature, and quantification was carried out by comparison of the height of the peak obtained from test solutions with the height of the peak obtained from the control solution.

Preparation of Test Formulations and Analytical Procedure—A series of eyedrop formulations containing thimerosal (0.001% w/v) in water, trimethoprim sulfate, polymyxin B sulfate (as active ingredients), and an isotonic agent (as shown in Table I) were prepared and stored at 5°C overnight. Aliquots (5 mL) of each test formulation were transferred to 10-mL glass ampules, which were then sealed and placed in storage at 5°C, 25°C, 37°C, and 50°C for periods up to 6 weeks. Solutions in ampules were allowed to warm or cool to ambient temperature for 1 h prior to analysis. These solutions were sampled directly for assay. The mean of duplicate determinations was taken, the two results generally showing an agreement of better than 2%. The formulation containing no excipient was used as a control for the initial assay (the results being normalized to 100% in Table II), and the same formulation, stored at 5°C, was used as a control in the subsequent assays.

RESULTS AND DISCUSSION

The results shown in Table II indicate that thimerosal manifested a significantly better stability using all five alternative isotonic agents when compared with its stability in saline. Previous published work (4) has shown only 36% thimerosal to remain after storage at 25°C for 3 d in normal saline.

The five formulations readily fell into two groups. The first group containing the ionic excipients (boric acid and EDTA) showed a decreased level of I throughout the study, dependent on time and temperature. Quite early in the trial a decrease in the assay of I was observed with eventually only 35-45% I remaining after 6 weeks at 50°C. In contrast, the second group of formulations containing the nonionic polyhydroxy alcohols (propylene glycol, glycerol, and mannitol) showed the thimerosal to have good stability compared with the control formulation with no excipient. Here 80-84% of I remained after 6 weeks at 50°C compared with 85% for the control, reflecting an essentially insignificant difference. At a more realistic temperature of 25°C, the first group showed a loss of 10-20% of I after 6 weeks, while the second group showed no decomposition after the same period.

The exact reasons for the marked effect of sodium chloride on the decomposition of thimerosal are not clear at present. It is well known that chloride and other halides have a marked affinity to coordinate with mercury(II) compounds, and this could be a contributory factor in the detrimental effect of sodium chloride on the stability of thimerosal in solution. There is some evidence (5) to show that the decomposition of thimerosal in water to thiosalicylic acid and ethylmercuric hydroxide is a reversible reaction. The effect of chloride anions could be to disturb this equilibrium by reaction with the ethylmercuric hydroxide to give ethylmercuric chloride, which does not combine nearly as readily with thiosalicylic acid in neutral solution to give thimerosal by the back-reaction. A possible reason for the improved stability of thimerosal in the case of the first group of isotonic agents (boric acid and EDTA) is that their respective anions may not have such a marked affinity to coordinate with mercury(II), and so the back-reaction to thimerosal is not so readily suppressed.

In contrast, the second group of isotonic agents (propylene glycol, glycerol, and mannitol) are nonionic, and the equilibrium of thimerosal with its hydrolysis products is not affected by their presence, hence the observed insignificant differences in thimerosal assay between the formulations containing these polyhydroxy alcohols and the control formulation containing no isotonic

Comparative Effects of Selected Phenothiazine Tranquilizers and Antihistaminics on Bacterial Cells and Possible Interactions with Antibiotics

A. M. SHIBL ˣ, Y. HAMMOUDA, and I. AL-SOWAYGH

Received January 13, 1983, from the *College of Pharmacy, King Saud University, Riyadh, Saudi Arabia.* Accepted for publication April 21, 1983.

Abstract □ Evaluation of the antibacterial effect of phenothiazine antihistaminics (trimeprazine, promethazine, and fonazine) and phenothiazine tranquilizers (promazine, chlorpromazine, triflupromazine, and propiomazine) on *Staphylococcus aureus* showed that tranquilizers were more active [minimum inhibitory concentration (MIC) 0.5–1.6 μg/mL] than antihistaminics (MIC > 1.6 μg/mL). The antibacterial activity was found to correlate with both the rate of adsorption of these drugs on the bacterial cells and the surface tension of their solutions. Phenothiazine tranquilizers caused rapid and extensive leakage of potassium ions from bacterial cells, while phenothiazine antihistaminics produced relatively slower leakage of these ions. A study of the effect of the phenothiazines on the antibacterial activity of some antibiotics showed that all phenothiazines produced a synergistic effect with erythromycin and an antagonistic effect with tobramycin. Variable effects were observed with chloramphenicol, and no effect was observed with penicillin. Results were explained on the basis of structural characteristics of the phenothiazines.

Keyphrases □ Phenothiazine tranquilizers—effects on bacterial cells, interaction with antibiotics, *Staphylococcus aureus* □ Phenothiazine antihistaminics—effects on bacterial cells, interaction with antibiotics, *Staphylococcus aureus* □ Antibiotics—interaction with phenothiazine tranquilizers and antihistaminics, *Staphylococcus aureus*

The phenothiazine group encompasses drugs of different therapeutic uses, most important of which are the antihistaminics and the tranquilizers. Most patients receiving these drugs are potential recipients of antibiotic therapy because of their increased susceptibility to infections (1). Synergism and antagonism between antibiotic combinations have been documented. Little attention, however, has been paid to possible interaction between antibiotics and phenothiazines. Some phenothiazines have measurable antibacterial activity *in vitro* (2–4), but are not used clinically for this purpose because of the high doses which would be required. The present work was undertaken to investigate the effect of a variety of combinations of antibiotics and phenothiazines against microorganisms, using *Staphylococcus aureus* as a model.

EXPERIMENTAL

Organism, Drugs, and Antibiotics—*Staphylococcus aureus* NCTC 6571 was used throughout this study. Cultures were maintained on blood agar slants. The drugs used were trimeprazine tartrate[1], fonazine mesylate[1], chlorpromazine hydrochloride[1], promazine hydrochloride[2], propiomazine hydrochloride[2], promethazine[3], and triflupromazine[3]. The antibiotics used were chloramphenicol[4], erythromycin[5], tobramycin[6], and penicillin[6]. Stock solutions of the phenothiazines and the antibiotics were prepared in sterilized distilled water to obtain concentrations of 1.0 mg/mL and 100 μg/mL, respectively.

Determination of Minimum Inhibitory Concentration (MIC)—The MIC values were determined by a standard twofold serial dilution method in brain-heart infusion (BHI) broth[7]. Tubes were inoculated with 10^5 colony forming units (CFU)/mL of *S. aureus*. The lowest concentration showing no visible growth after 18 h of incubation at 37°C was considered as the MIC.

Measurement of Surface Tension—Surface tension was measured by the ring method using a torsion balance[8]. All experiments were carried out in duplicate at 25°C. Distilled water was used as the reference ($\gamma_{25} = 72.4$).

Determination of Potassium Ion Efflux—The test organism was grown at 37°C for 18 h in BHI broth, and the cells were washed with saline to remove extracellular potassium ions before they were suspended in saline. Five milliliters of the suspension was boiled for 30 min, and the amount of potassium

Trimeprazine	0.03 + 0.26	0.41	0.25 + 1.6	1.5	0.12 + 0.8	1.5	0.01 + 0.8	1

[a] Minimum inhibitory concentration. [b] Fractional inhibitory concentration.

ions released was determined using a flame photometer[9]. The result was calculated as a percentage of the result obtained for untreated control cells. All experiments were performed in duplicate.

Adsorption and Interaction Experiments—Adsorption was carried out as previously described (5). MIC determinations were performed on BHI broth with an inoculum of 10^5 CFU. Antibiotics and drugs were mixed in checkerboard fashion. Incubation took place at 37°C for 18 h. Synergism was defined as a fractional inhibitory concentration (FIC) index as follows:

$$\text{FIC} = \frac{(A)}{(\text{MIC}_A)} + \frac{(B)}{(\text{MIC}_B)}$$

Where (A) is the MIC of drug A in the presence of drug B, and (MIC_A) is the MIC of drug A alone. (B) and (MIC_B) are defined in the same fashion for drug B. Synergism is present if the FIC index is <1, and antagonism is present if the FIC index is >1. An index value of 1 shows addition (6).

Spectrophotometric Assay—When solutions of the phenothiazines and the antibiotics, separately and in combination at different molecular ratios, were scanned in the UV region[10], no evidence of interaction could be observed in the resulting spectra.

RESULTS AND DISCUSSION

The results (Table I) suggest that there is some relationship between the antibacterial activity of the phenothiazines studied and their surface activity, rate of adsorption, and potassium ion release. Chlorpromazine and triflupromazine, which possess the highest antibacterial activity also showed the highest values for potassium ion release and adsorption and the lowest surface tension. It is possible that by virtue of their high surface activity, these compounds adsorb to the bacterial surfaces, thereby changing the permeability characteristics of the cell membrane. Both drugs have a halogen substitution at R (Cl or CF_3), which increases their lipophilic character and thereby their surface activity. On the other hand, fonazine, which contains the relatively polar *N*-dimethylsulfonyl functional group at R [$SO_2N(CH_3)_2$], causes only a slight potassium ion release and exhibits the least antibacterial activity. The lower antibacterial activity of promethazine and trimeprazine as compared with promazine, all of which have a hydrogen atom at R′, could be attributed to the length of the carbon chain between the two nitrogen atoms in their substituents and also to the branching of their side chain. The relatively higher activity of trimeprazine when compared with promethazine could be due to the additional methylene group at R′ in trimeprazine, which could confer a lipophilic property to the drug.

The antibacterial activity of the phenothiazines and antibiotics, separately and in combination, is shown in Table II. The phenothiazines did not enhance the antibacterial activity of penicillin, and they had an antagonistic effect on the action of tobramycin. The antibacterial activity of erythromycin, on the other hand, was enhanced in the presence of the phenothiazines. Fonazine and promethiazine potentiated the activity of chloramphenicol, while trimeprazine had an antagonistic effect. The remaining phenothiazines did not affect the antibacterial activity of chloramphenicol. The variable results obtained in these experiments are in agreement with previously published reports (7).

The potassium ion efflux from bacterial cells after exposure to the phenothiazines could be due to the effect of these drugs on the bacterial cell membrane. The same type of effect could facilitate the entry of an antibiotic into the bacterial cell and thus potentiate the activity of that antibiotic. The antagonistic effects observed with some phenothiazine-antibiotic combinations might be explained on the basis that these drugs could unselectively block certain receptor sites essential to the action of the antibiotics.

The present results suggest that the action of phenothiazines on the bacterial membrane cannot be the sole factor that determines the type and degree of interaction with antibiotics. Since spectrophotometric measurements of mixtures of antibiotics and phenothiazines excluded chemical interaction, there must be another site of activity of the phenothiazines in the bacterial cell. This type of interaction may have clinical implications in psychotic patients who have to take antibiotics while on phenothiazine tranquilizers. Further work, using different antibiotics in combination with these drugs against different organisms, as well as *in vivo* studies are needed to investigate such interactions.

Structural Determination of Nootkatol, a New Sesquiterpene Isolated from *Alpinia oxyphylla* Miquel Possessing Calcium-Antagonistic Activity

N. SHOJI *, A. UMEYAMA *, Y. ASAKAWA *, T. TAKEMOTO *, K. NOMOTO ‡, and Y. OHIZUMI §x

Received February 24, 1983, from the **Faculty of Pharmacy, Tokushima-Bunri University, Tokushima-shi, Tokushima 770*, the ‡*Suntory Institute for Bioorganic Research, Wakayamadai, Shimamoto-cho, Mishima-gun, Osaka 618*, and the §*Mitsubishi-Kasei Institute of Life Sciences, Machida-shi, Tokyo 194, Japan.* Accepted for publication April 28, 1983.

Abstract □ Nootkatol, a new sesquiterpene possessing calcium-antagonistic activity, was isolated from *Alpinia oxyphylla* Miquel and characterized as (2*R*,4*R*,5*S*,7*R*)-eremophil-1(10),11-dien-2-ol.

Keyphrases □ Nootkatol—isolation from *Alpinia oxyphylla* Miquel, calcium-antagonistic activity □ Calcium antagonists—isolation of nootkatol from *Alpinia oxyphylla* Miquel

In the course of our survey of various crude drugs prepared from plant materials for pharmacologically active metabolites, we have found that a methanolic extract of the fruit of *Alpinia oxyphylla* Miquel (Zingiberaceae) has calcium-antagonistic activity in the rabbit aorta. Other work (1–3) on calcium antagonists, such as verapamil and gallopamil, have revealed that such drugs selectively inhibit the potassium chloride-induced contraction of vascular smooth muscle. In this paper, we have isolated for the first time a substance possessing calcium-antagonistic activity from a plant source.

EXPERIMENTAL[1]

Method of the Bioassay—Rabbits (2–3 kg) were killed by cervical dislocation. The aortas (60 × 4 mm) were removed and cut into helical strips. The strips were mounted vertically in a 20-mL organ bath containing Krebs-Ringer bicarbonate solution of the following composition (mM concentration): NaCl, 120; KCl, 4.8; $CaCl_2$, 1.2; $MgSO_4 \cdot 7H_2O$, 1.3; KH_2PO_4, 1.2; $NaHCO_3$, 25.2; and glucose, 5.8, pH 7.4. This was bubbled with a gas mixture of oxygen-carbon dioxide (95:5) and maintained at 37°C. A resting tension of 1 g was applied to the strips and tension changes were isometrically recorded with a force-displacement transducer.

Isolation—The dried, powdered fruit[2] (10 kg) of *A. oxyphylla* Miquel were extracted three times with cold methanol (20 L). The methanolic extract was concentrated *in vacuo*, and the residue (1 kg) was partitioned between ethyl acetate and water. The aqueous layer was extracted with 1-butanol. The pharmacologically active ethyl acetate fraction (605 g) was chromatographed on silica gel[3] (benzene–ethyl acetate). The fractions containing the bioactive material [benzene–ethyl acetate (9:1)] were combined and further purified on a silica gel column with *n*-hexane–acetone (97:3) to afford 3.0 g of an active substance (Ia, 0.03% yield), named nootkatol, as colorless needles, mp 78–80°C (recrystallized from *n*-hexane), $[\alpha]_D$ + 208° (*c* 1.1 $CHCl_3$); IR (KBr): 3250 cm^{-1} (OH); MS: *m/z* 220 (M^+, 53%) and 177 (100); ^{1}H-NMR ($CDCl_3$): δ 0.89 (s, 3, C(5)—CH_3), 0.89 (d, 3, *J* = 6 Hz, C(4)—CH_3), 1.01 (t, 1, *J* = 13 Hz, C(6)—βH), 1.24 (dq, 1, *J* = 12 Hz and *J* = 4 Hz, C(8)—βH), 1.55 (m, 1, C(3)—βH), 1.63 (dt, 1, *J* = 13 Hz and *J* = 4 Hz, C(3)—αH), 1.71 (m, 3, C(11)—CH_3), 1.71 (m, 1, C(4)—βH), 1.79 (m, 1, C(8)—αH), 1.89 (dt, 1, *J* = 13 Hz and *J* = 3 Hz, C(6)—αH), 2.13 (m, 1, C(9)—βH), 2.23 (tt, 1, *J* = 13 Hz and *J* = 3 Hz, C(7)—H), 2.32 (m, 1, C(9)—αH), 4.06 (m, 1, C(2)—H), 4.68 (m, 2, C(12)—H_2), and 5.49 ppm (bd, 1, *J* = 5 Hz, C(1)—H); ^{13}C-NMR ($CDCl_3$): δ 15.21 (q, C-14), 16.83 (q, C-15), 20.79 (d, C-4), 32.54 (t, C-6*), 32.62 (t, C-8*), 34.98 (q, C-13), 36.21 (t, C-3), 38.32 (s, C-5), 40.72 (d, C-7), 44.60 (t, C-9), 64.37 (d, C-2), 108.71 (t, C-12), 121.73 (d, C-1), 148.55 (s, C-11), and 150.13 ppm (s, C-10). Assignments are interchangeable between carbon atoms with asterisks.

Anal.—Calc. for $C_{15}H_{24}O$: C, 81.76; H, 10.98. Found: C, 81.53; H, 11.28.

Reduction of Nootkatone (II)—To the ether solution (50 mL) of nootkatone[4] (1.9 g), 200 mg of $LiAlH_4$ was added and stirred overnight at room temperature. The suspension was treated as usual and extracted with ether. The organic phase was dried over Na_2SO_4 and the solvent was removed under reduced pressure. The residue was chromatographed on silica gel [*n*-hexane–acetone (97:3)]. Nootkatol (Ia) (40 mg) was eluted, followed by epinootkatol (Ib) (oily, 1980 mg). The aforementioned synthetic nootkatol was identical by IR, optical rotation, and melting point comparison with the material isolated from *A. oxyphylla*.

RESULTS AND DISCUSSION

From the fruit of *A. oxyphylla* Miquel, a calcium-antagonistic substance, named nootkatol, was isolated. In the mass spectrum the molecular ion (*m/z* 220) indicates a molecular formula of $C_{15}H_{24}O$. The single oxygen func-

tionality is ascribable to a hydroxyl group based on the absorption band at 3250 cm^{-1} in the IR spectrum. The ^{13}C-NMR signals at 108.71 (t), 121.73 (d), 148.55 (s), and 150.13 (s) ppm suggest that the molecule has two double bonds and, therefore, it appears to be bicyclic. Furthermore, the ^1H-NMR spectrum shows the presence of a tertiary methyl group at 0.89 (s, 3), a secondary methyl group at 0.89 (d, 3, J = 6 Hz), and isopropenyl groups at 1.71 (m, 3) and 4.68 ppm (m, 2). From the above data the structure of Ia appears to be similar to that of nootkatone (II), which has been isolated from *Chamaecyparis nootkatensis* (Lamb.)sprach and *Citrus paradisi* Macfad. (4–6). The main difference appears to be the presence of a hydroxyl group in the newly isolated material. The proton attached to the hydroxyl-bearing carbon is observed as a multiplet at 4.06 ppm in the ^1H-NMR spectrum, suggesting the hydroxyl group was β-oriented. To verify the proposed structure, II was reduced with $LiAlH_4$ in ether to yield two products (Scheme I). As expected, the minor one was identical with Ia on the basis of its melting point, IR spectrum, and optical rotation. Thus, Ia is characterized as (2*R*,4*R*,5*S*,7*R*)-eremophil-1(10),11-dien-2-ol.

It has been reported that in vascular smooth muscle, contractile response to potassium chloride is caused for the most part by increasing membrane permeability to Ca^{2+}, while the response to norepinephrine is caused mainly by releasing an intracellular pool of Ca^{2+} (7). Calcium antagonists such as verapamil and gallopamil have been shown to selectively inhibit the contractile activity produced by potassium chloride without having any effect on that induced by norepinephrine (8). In the present experiment, purified Ia (3×10^{-5} M) markedly inhibited the potassium chloride (40 mM)-induced contraction of the aorta, but did not have any effect on that produced by norepinephrine (10^{-6} M). The 50% inhibitory doses of Ia and verapamil for the potassium chloride (40 mM)-induced contraction were $\sim 10^{-5}$ and $\sim 10^{-7}$ M, respectively, indicating that the potency of Ia was approximately 100 times less than that of verapamil[5]. Furthermore, Ia (3×10^{-5} M) profoundly inhibited the increase in the $^{45}Ca^{2+}$ uptake of the aorta induced by potassium chloride[5]. These observations suggest that Ia specifically blocks the Ca^{2+}-influx into the muscle cell of the aorta.

Reverse-Phase Liquid Chromatography and Pharmacokinetic Study of Two Hydroxylated Analogues of Quinidine in Dogs

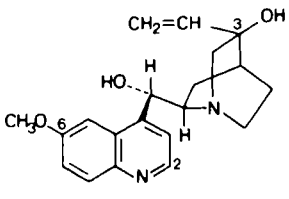
R. LEROYER *, C. JARREAU ‡, M. PAYS ‡x, O. VAROQUAUX §, and C. ADVENIER §

Received August 12, 1982, from the **Department of Analytical Chemistry, Faculty of Pharmaceutical and Biological Sciences, CAEN University, 14032 CAEN Cedex,* ‡*Department of Clinical Biochemistry,* and the §*Department of Pharmacology, Centre Hospitalier, 78000 Versailles, France.* Accepted for publication April 20, 1983.

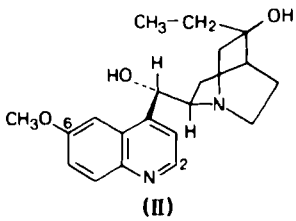
Abstract □ Two hydroxylated analogues of quinidine with antiarrhythmic properties, 3*S*-hydroxyquinidine and 3*R*-hydroxydihydroquinidine were assayed by reverse-phase high-performance liquid chromatography. The analytical technique uses plasma protein precipitation and direct injection on a C_{18} column, with an isocratic mobile phase and spectrofluorometric detection. 3*R*-Hydroxyquinidine is employed as the internal standard. Linearity is verified up to 5 mg/L for the two drugs; concentrations between 0.5 and 2.5 mg/L were measured with a *CV* of 0.5–2.07% for a given day and a sensitivity limit of 50 μg/L. Plasma concentration–time profiles and pharmacokinetic parameters in three dogs are presented after intravenous or oral administration. A significant difference is observed in terminal half-life, terminal rate constant, and total clearance of the two polar analogues of quinidine.

Keyphrases □ Quinidine analogues—hydroxylated, HPLC, pharmacokinetics in the dog □ Pharmacokinetics—hydroxylated analogues of quinidine in the dog, HPLC

Some of the metabolites of quinidine, especially 3*S*-hydroxyquinidine (I), 2′-oxoquinidine, and *O*-demethylquinidine, possess antiarrhythmic activity in mice and rabbits (1) and possibly in humans (2). Other analogues of quinidine, derived from *O*-demethylquinidine (3–6) or 7′-trifluoromethyldihydrocinchonidine (7), have recently been tested. Preliminary studies of I and 3*R*-hydroxydihydroquinidine (II) (8) indicate pharmacological activity of these two compounds when tested against chloroform-induced ventricular fibrillation and aconitine-induced arrhythmia in mice and rats or against coronary ligature in dogs.



(I)



(II)

This report describes a rapid, specific, accurate, and sensitive high-performance liquid chromatographic (HPLC) method for the determination of I and II in plasma. The procedure involves a modification of a recently published reverse-phase HPLC method for quinidine (9) using 3*R*-hydroxyquinidine as internal standard, with an isocratic mobile phase of acetonitrile–acetic acid–water and sensitive spectrofluorometric detection. Preliminary pharmacokinetic parameters of these two hydroxylated analogues of quinidine in the dog are reported.

EXPERIMENTAL

Reagents and Standards—All solvents used were analytical reagent grade[1]: acetonitrile for spectrometry, methanol, and 100% acetic acid. A phosphate buffer (0.05 M, pH 7.4) was prepared in distilled water. Pure standards of

Reverse-Phase Liquid Chromatography and Pharmacokinetic Study of Two Hydroxylated Analogues of Quinidine in Dogs

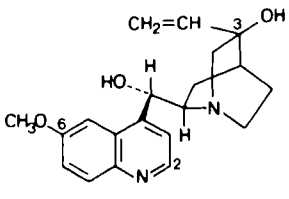
R. LEROYER *, C. JARREAU ‡, M. PAYS ‡x, O. VAROQUAUX §, and C. ADVENIER §

Received August 12, 1982, from the **Department of Analytical Chemistry, Faculty of Pharmaceutical and Biological Sciences, CAEN University, 14032 CAEN Cedex,* ‡*Department of Clinical Biochemistry,* and the §*Department of Pharmacology, Centre Hospitalier, 78000 Versailles, France.* Accepted for publication April 20, 1983.

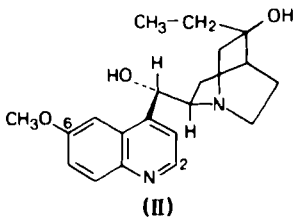
Abstract □ Two hydroxylated analogues of quinidine with antiarrhythmic properties, 3*S*-hydroxyquinidine and 3*R*-hydroxydihydroquinidine were assayed by reverse-phase high-performance liquid chromatography. The analytical technique uses plasma protein precipitation and direct injection on a C_{18} column, with an isocratic mobile phase and spectrofluorometric detection. 3*R*-Hydroxyquinidine is employed as the internal standard. Linearity is verified up to 5 mg/L for the two drugs; concentrations between 0.5 and 2.5 mg/L were measured with a *CV* of 0.5–2.07% for a given day and a sensitivity limit of 50 μg/L. Plasma concentration–time profiles and pharmacokinetic parameters in three dogs are presented after intravenous or oral administration. A significant difference is observed in terminal half-life, terminal rate constant, and total clearance of the two polar analogues of quinidine.

Keyphrases □ Quinidine analogues—hydroxylated, HPLC, pharmacokinetics in the dog □ Pharmacokinetics—hydroxylated analogues of quinidine in the dog, HPLC

Some of the metabolites of quinidine, especially 3*S*-hydroxyquinidine (I), 2′-oxoquinidine, and *O*-demethylquinidine, possess antiarrhythmic activity in mice and rabbits (1) and possibly in humans (2). Other analogues of quinidine, derived from *O*-demethylquinidine (3–6) or 7′-trifluoromethyldihydrocinchonidine (7), have recently been tested. Preliminary studies of I and 3*R*-hydroxydihydroquinidine (II) (8) indicate pharmacological activity of these two compounds when tested against chloroform-induced ventricular fibrillation and aconitine-induced arrhythmia in mice and rats or against coronary ligature in dogs.



(I)



(II)

This report describes a rapid, specific, accurate, and sensitive high-performance liquid chromatographic (HPLC) method for the determination of I and II in plasma. The procedure involves a modification of a recently published reverse-phase HPLC method for quinidine (9) using 3*R*-hydroxyquinidine as internal standard, with an isocratic mobile phase of acetonitrile–acetic acid–water and sensitive spectrofluorometric detection. Preliminary pharmacokinetic parameters of these two hydroxylated analogues of quinidine in the dog are reported.

EXPERIMENTAL

Reagents and Standards—All solvents used were analytical reagent grade[1]: acetonitrile for spectrometry, methanol, and 100% acetic acid. A phosphate buffer (0.05 M, pH 7.4) was prepared in distilled water. Pure standards of

quinidine, dihydroquinidine, I, the internal standard, II, and quinidine *N*-oxide (as bases) were used as supplied[2]. Quinine was used in the sulfate form. Purity of these compounds was verified by HPLC as described here or by TLC on precoated silica gel plates (20 × 20 cm × 0.25 mm)[3], developed in methanol–acetone (4:1) and visualized under UV light (366 nm).

Stock solutions were prepared in methanol at a concentration of 1 g/L (stable for 2 months at 4°C), and working solutions at concentrations of 0.5–5 mg/L were prepared by diluting the stock solutions in acetonitrile–phosphate buffer 0.05 M (1:1). The stock solution of 3*R*-hydroxyquinidine was used to prepare a standard solution at 2.5 mg/L in pure acetonitrile.

Apparatus and Operating Conditions—The analysis was performed using a high-performance liquid chromatograph[4] equipped with an injection system[4] with a 10-μL loop, a stainless steel column[5], 30 cm × 3.9 mm i.d. (particle size 10 μm)[5], a spectrofluorometer[6] (λ_{ex} = 340 nm, λ_{em} = cut-off filter 418 nm) set at 0.5 μAUFS sensitivity with a time constant of 6 s. The mobile phase was a deaerated mixture of acetonitrile–acetic acid–water (8:4:88) with a flow rate of 1.8 mL/min (2200 psi).

Experimental Protocol in Dogs—Fasting mongrel dogs, 10–20 kg, received 10 mg/kg of I or II orally (capsules) or as an intravenous bolus dose (parenteral solutions in acidified saline, pH 4). Sixteen blood samples were collected from the saphenous vein in heparinized tubes and centrifuged at 1200×*g*; the plasma was stored at −18°C until assayed.

After intravenous administration of I or II, plasma concentrations declined biexponentially; pharmacokinetic parameters corresponding to a two-compartment open model were determined with a nonlinear least-squares Graphakin program, according to:

$$C_p = Ae^{-\alpha t} + Be^{-\beta t} \quad \text{(Eq. 1)}$$

where C_p is the plasma concentration at time t, A and B are ordinate intercept constants, and α and β are first-order rate constants. For oral administration of II, a one-compartment open model was used with the following:

$$C_p = X(e^{-k_e t} - e^{-k_a t}) \quad \text{(Eq. 2)}$$

where X is a hybrid intercept term, and k_a and k_e are respective apparent first-order absorption and elimination rate constants. Area under the plasma concentration curve from zero to infinity (AUC_∞), total plasma drug clearance (CL_T), central compartment volume (V_c), apparent volume of distribution (Vd) were calculated by the following equations:

$$AUC_\infty = \int_0^{C_{24\,h}} C_p dt + \frac{C_{24\,h}}{\beta} \quad \text{(Eq. 3)}$$

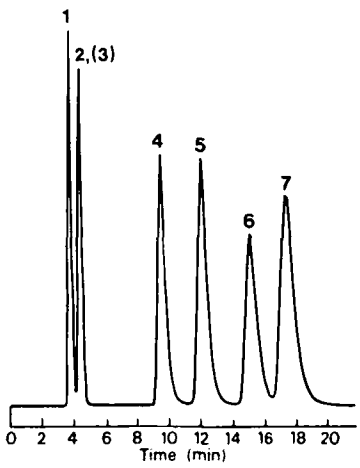

Figure 1—*Chromatogram of pure standards. Key: (1) 3R-hydroxyquinidine (retention time 3.8 min); [2, (3)] I (4.4 min); (4) quinidine N-oxide (9.5 min); (5) quinidine (12.2 min); (6) quinine (15.1 min); (7) dihydroquinidine (17.3 min).*

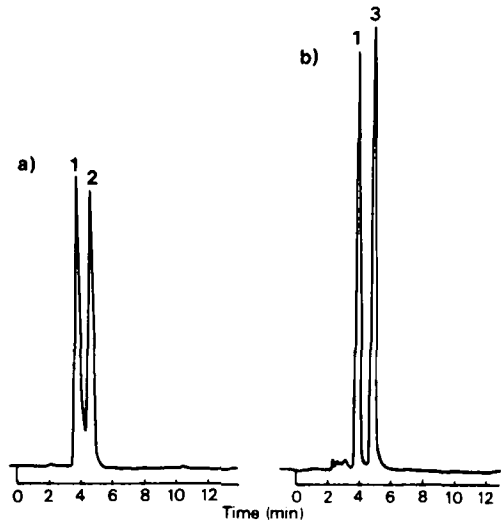

Figure 2—*Chromatogram of a 0.1-mL dog plasma sample after a dose of 10 mg/kg. Key: (1) 3R-hydroxyquinidine, internal standard, 2.5 mg/L; (2) I, (2.78 mg/L, 4.4 min); (3) II (2.95 mg/L, 4.8 min).*

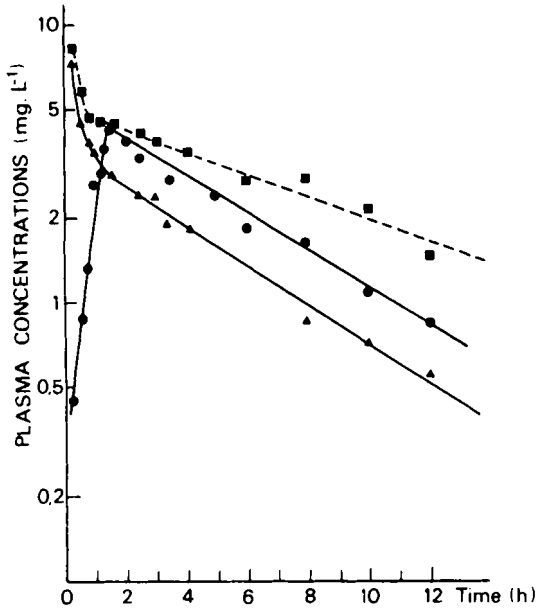

Figure 3—*Plasma concentration in a dog following oral administration of II (●) and intravenous administration of I (■), and II (▲) (10 mg/kg).*

$$CL_T = \frac{\text{Dose}}{AUC_\infty} \quad \text{(Eq. 4)}$$

$$V_c = \frac{\text{Dose}}{A + B} \quad \text{(Eq. 5)}$$

$$Vd_\beta = \frac{CL_T}{\beta} \quad \text{(Eq. 6)}$$

The Student's t test was used to evaluate statistical significance of observed differences between pharmacokinetic parameters of I and II.

Procedure—To precipitate proteins, 100 μL of plasma or diluted plasma was added to 100 μL of a 2.5-mg/L solution of the internal standard in acetonitrile. After closing with laboratory film[7], the mixture was shaken gently on a vortex mixer, centrifuged at 1200×g for 10 min, and 10 μL of the resultant clear supernatant was injected directly into the column. Peak height ratios were measured and reported on standard curves established with loaded plasma sample concentrations.

RESULTS AND DISCUSSION

Figures 1 and 2 show typical chromatograms of pure standards with the retention times observed in these conditions (Fig. 1) and dog plasma samples (Fig. 2). Because of their excessively long retention times, quinidine, quinine, and dihydroquinidine were not used as the internal standard. Quinidine *N*-oxide, a new metabolite described by Guentert *et al.* (10), has the same retention times as an unidentified metabolite in a previous assay for quinidine (9); because of its limited availability, it was not used. 3*R*-Hydroxyquinidine seems to be the most convenient internal standard, because of its same fluorescence characteristics with I and II. As shown in Fig. 2a and b, it is possible to resolve the internal standard from that of I (resolution factor = 1) or II (resolution factor = 1.66); incomplete resolution between I and II (resolution factor = 0.66) is never observed in the determination of plasma levels of either of these two drugs (no simultaneous administration).

The reproducibility assay gave small coefficients of variation (Table I) and recovery was 100 ± 3% when the concentrations of plasma loaded with different compounds were compared with standards solutions in a mixture (1:1) of acetonitrile and 0.05 M phosphate buffer. Linearity of the standard curves was verified by measuring the peak height ratio for concentrations up to 5 mg/L for I and II. An external standardization, by measuring peak height, may be used (no internal standard added to plasma) to detect the possible presence of a peak with retention time identical to that of the internal standard and corresponding to an eventual polar metabolite of I or II. The same results (linearity and plasma levels) are obtained in this procedure. When setting the detector at 0.2 μAUFS, the limit sensitivity, corresponding to a 2:1 signal-noise ratio, is 50 μg/L for the two compounds.

Table III—Pharmacokinetic Parameters for II after Oral Administration (10 mg/kg) in Dogs [a]

Parameter	II
k_a (h^{-1})	1.73 ± 1.18
$t_{1/2a}$ (h)	0.56 ± 0.38
k_e (h^{-1})	0.134 ± 0.0073
$t_{1/2e}$ (h)	5.15 ± 0.24
Vd (L/kg)	2.238 ± 0.176
CL_T (L/h·kg)	0.302 ± 0.036
AUC (mg/L·h)	33.42 ± 4.06
C_{max} (mg/L)	4.53 ± 0.34
t_{max} (h)	1.83 ± 0.61

[a] n = 3.

As shown in Fig. 3 for a representative animal, the plasma concentration-times curves for I and II decline biexponentially after intravenous administration (10 mg/kg). Corresponding pharmacokinetic parameters (Table II) indicate a significant difference between the two tested drugs for β, $t_{1/2\,\beta}$, AUC_∞, and CL_T, but not for V_c and Vd_β. The terminal half-life value for I (7.95 ± 0.68 h) is in good agreement with the observed values reported by Jaillon and Kates (11) in dogs (7.27 ± 2.79 h) after oral administration of quinidine, but II is eliminated more rapidly ($t_{1/2\,\beta}$ = 4.36 ± 0.27 h, CL_T = 0.325 ± 0.037 L/h·kg). Similar values for α indicate that I and II are initially distributed in the same order in the body.

For oral administration of II (10 mg/kg), the peak plasma level (4.53 ± 0.34 mg/L) was obtained 1.83 ± 0.61 h after the dose. A higher value for elimination half-life (5.15 ± 0.24 h) was observed than for the intravenous route, but AUC_∞ and CL_T were of the same magnitude, as shown in Table III.

Nuclear Magnetic Resonance Spectrometry and Liquid Chromatography of Two Bile Acid Epimers: Ursodeoxycholic and Chenodeoxycholic Acid

A. BAILLET-GUFFROY, D. BAYLOCQ ˣ, A. RABARON, and F. PELLERIN

Received February 5, 1981 from the *U.E.R. de Chimie Therapeutique, Centre d'Études Pharmaceutiques, 92290 Chatenay-Malabry, France.* Accepted for publication October 14, 1982.

Abstract □ A specific reverse-phase high-performance liquid chromatographic (HPLC) technique is described for the analysis of bile acids and their conjugates in human serum. Precise quantitation is obtained using UV detection. ^{13}C-NMR spectrometry suggests a structural explanation for the different HPLC retention times of chenodeoxycholic acid, its epimer (ursodeoxycholic acid), and their methyl esters.

Keyphrases □ Ursodeoxycholic acid—HPLC in human serum, ^{13}C-NMR elucidation of structure, methyl ester □ Chenodeoxycholic acid—HPLC in human serum, ^{13}C-NMR elucidation of structure, methyl ester

Determination of individual bile acids in biological fluids by TLC, fluorometry, and GC has been reported (1–3). The glycine and taurine conjugates were determined by TLC; however, the resolution was unsatisfactory. Fluorometry (4) using 3α-hydroxy steroid dehydrogenase allows one to quantitate total bile acids only, while the GC method is tedious. High-performance liquid chromatography (HPLC) offers the possibility of separation and quantitation of individual bile acids without sample derivatization. This method is rapid and sensitive and can be used for many routine applications.

EXPERIMENTAL

Apparatus—A high-performance liquid chromatograph[1] equipped with a 20-μL loop injector[2] and a variable-wavelength absorbance detector[3] set at 201 nm was used. The chromatograms were plotted on a strip-chart recorder[4]. The stainless-steel column (3.9 × 15 mm) was packed with C_{18}-bonded microparticles[5].

Reagents and Solvents—The free bile acids and the taurine and glycine conjugates were obtained commercially[6]. Methyl esters of chenodeoxycholic acid and ursodeoxycholic acid were prepared by treatment of the acids with diazomethane. Further purification was carried out by TLC on silica gel (benzene–acetone–methanol, 85:5:10). UV-grade methanol[7] and double-distilled water were filtered[8] (pore size, 0.5 μm), stored in glass apparatus, and deaerated before use. Perchloric acid[9], analytical reagent grade, was used to adjust the pH of the mobile phase.

Samples—Serum (1 mL) was passed through a C_{18} microparticulate microcolumn[10] fixed onto a syringe. The column was washed with double-distilled water (2 × 4 mL), then by four methanol–water mixtures with increasing concentration of methanol (0–50%) (2 × 2 mL). Bile acids were eluted with pure methanol (3 mL). The filtrate was evaporated under nitrogen at 80°C. The residue was dissolved in 50 μL of double-distilled water, and a 20-μL aliquot was injected onto the column using the injector loop.

No internal standard was used. A 20-μL portion of external standard was also analyzed under the same chromatographic conditions. The standard solution was prepared daily by dissolving weighed amounts of each bile acid in water. The extraction ratio depended on each bile acid, ranging from 95 to 100%.

Chromatographic Conditions—Methanol (76%) in aqueous potassium dihydrogen phosphate (30 mmol/L) was used as the mobile phase. The pH of the mobile phase was adjusted after addition of methanol using perchloric acid (0.02%). The flow rate was 1.2 mL/min. The absorbance was measured at 201 nm (0.02 AUFS). The limit of sensitivity was 1 ng/μL of injected solution.

pK_a Determination—The apparent ionization constants (pK'_a) for ursodeoxycholic and chenodeoxycholic acid and their methyl esters were determinted by potentiometry[11] with a hydrogen electrode at 25°C in methanol–water (70:30, w/w). The pK_a values were calculated by the usual method (5).

^{13}C-NMR Spectra—A Fourier transform ^{13}C-NMR spectrometer[12] was used at probe temperature. Samples were dissolved in methanol-d_4 giving final concentration of 1 mol/L. Shifts from the methanol reference were measured on a 2000-Hz sweep width with 8192 data points (0.488 Hz/resolution point). The spectral parameters were: flip angle 45° (10-μs pulse width); repetition rate, 2.05 s; weighting function for sensitivity enhancement, 0.4 s; decoupling power, 4500 Hz; decoupling frequency, offset 52 (CFT 20 program); noise bandwith, 1000 Hz; and total experiment time, 160 nm (4700 scans). For S.F.O.R.D., the experimental decoupler frequency offset was 42 (cft 20 program) and the noise bandwith was off.

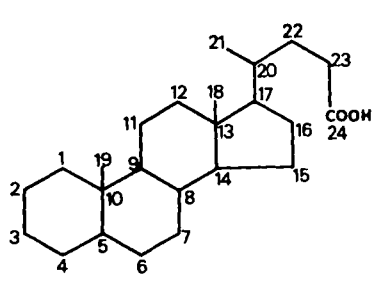
These typical experimental conditions were specially adapted to noise decoupling spectra of steroid molecules. They were determinated empirically for this spectrometer to obtain different signal heights for CH_3, CH_2, CH, and quaternary C. The association of information provided by this method with single frequency off-resonance spectra has improved the assignment of carbon signals in steroids.

RESULTS AND DISCUSSION

Bile acids have a 5β-cholanic acid skeleton and possess one, two, or three hydroxyl groups; they are found in serum as free acids (pK_a 5.5–7.0) and the glycine and taurine conjugates (pK_a 3.5–4.5 and ~2, respectively).

Separation and quantitative analysis of bile acids can be used in the diagnosis and study of hepatic and biliary diseases. Using reverse-phase HPLC, the taurine conjugates are eluted first, followed by the glycine conjugates, and then the free bile acids (6). Ursodeoxycholic acid (I) is eluted earlier than the epimeric chenodeoxycholic acid (II). Figure 1 shows a chromatogram under the described conditions; the retention times of ursodeoxycholic and chenodeoxycholic acids, the calculated capacity factors k', were very different: $k' = 3.4$ for ursodeoxycholic acid (I) and $k' = 11.4$ for chenodeoxycholic acid (II).

This surprising observation led to a study of the physical properties and



Cholanic Acid
(I) Ursodeoxycholic Acid: 3α,7β - dihydroxy 5β - cholanic acid
(II) Chenodeoxycholic Acid: 3α,7α - dihydroxy 5β - cholanic acid

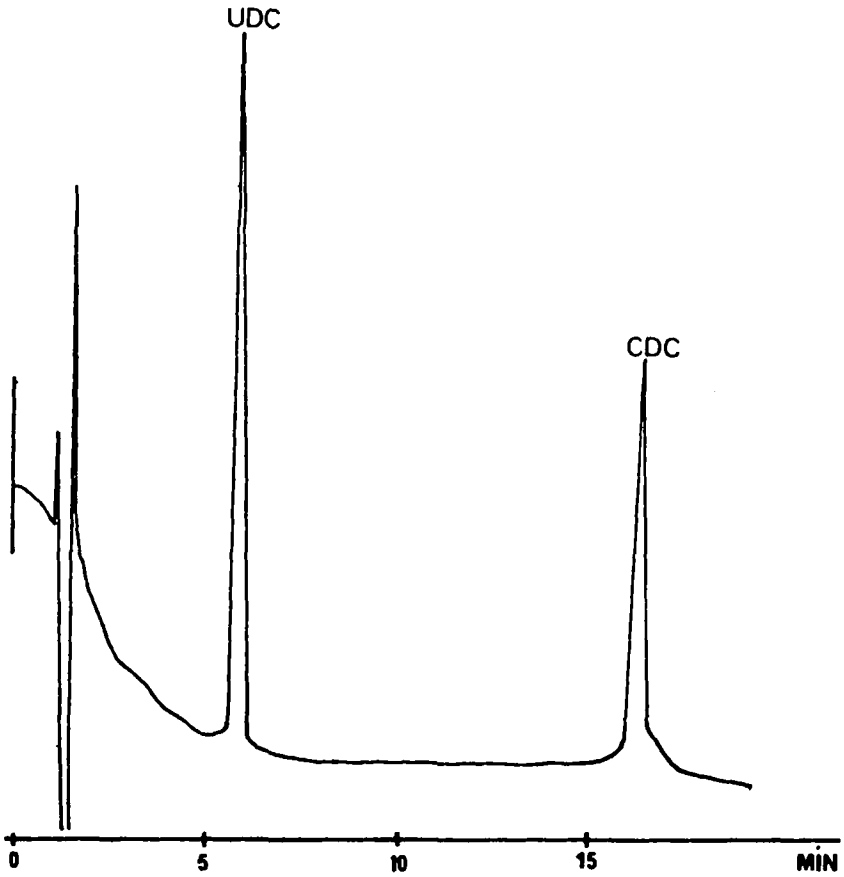

Figure 1—*Chromatogram of ursodeoxycholic acid (UDC) and chenodeoxycholic acid (CDC). Operating conditions were: flow rate, 1.2 mL/min; detector, 201 nm; scale, 0.2 AUFS; sample size, 70 μg/20 μL.*

structural characteristics of these compounds. The melting points and rotations $[\alpha_D]$ of each compound were quite different: ursodeoxycholic acid, mp 203°C, $[\alpha]_D$ +11.5°; chenodeoxycholic acid, mp 143°C, $[\alpha]_D$ +57° (7).

This report describes the pK_a values and the ^{13}C-NMR spectra of these compounds. The pK_a values of ursodeoxycholic acid, chenodeoxycholic acid, and their methyl esters were determined by potentiometry using a hydrogen electrode. The results (Table I) are inconsistent with the physical and chromatographic data in the case of the methyl esters, with the carbonyl function masked; only the hydroxyl group are weakly acidic and the pK_a values are similar. However, the variation of pK_a values in the free acids should be more significant than the observed values obtained by electrochemical methods.

Our hypothesis was that these differences could be explained by a hydrogen bond involving the 7-hydroxyl group of chenodeoxycholic acid. This hydrogen-bonded internal complex could react with the nonpolar stationary phase in liquid chromatography and increase its elution time.

We attempted to show the existence of the hydrogen bond by ^{13}C-NMR spectrometry. The ^{13}C-NMR spectra of common bile acids and their methyl esters have been described and attributions discussed (8, 9) (Table II). Blunt and Stothers (10) describe substitution increments in the steroid carbon skeleton of 5α- and 5β-androstane. With these increments, it is possible to predict the effect of hydroxyl inversion of C-7 on the chemical shifts of neighboring carbon atoms. The corresponding increments were calculated from the published values and are presented in Table III.

The ^{13}C-NMR spectra of ursodeoxycholic acid and its methyl ester have not been described. We assigned carbon signals and compared these with observed chemical shifts using the inversion increment from ursodeoxycholic acid, to obtain the chemical shifts on chenodeoxycholic carbon atoms. Table II compares the values of the observed chemical shifts of ursodeoxycholic acid, chenodeoxycholic acid, and their methyl esters with the calculated chemical shifts of chenodeoxycholic acid and its methyl ester (Fig. 2). Observed and calculated chemical shifts of chenodeoxycholic acid carbons are very similar (deviations, 1 ppm) for all carbons except C-7 (bearing a hydroxyl group) and

[a] UDC = ursodeoxycholic acid; CDC = chenodeoxycholic acid.

C-5 and C-9, which support an important γ-effect from the axial hydroxyl group.

The carbon chemical shifts of the methyl esters also agree closely. Nevertheless, the increments used involve the isolated variation of C-7 configuration and do not take into account the hypothetical intramolecular hydrogen bond between the C-7 hydroxyl and neighboring protons.

Thus, the observed deviations in the chemical shifts of C-4, C-5, C-7, and C-9 as compared with shifts calculated by the increment method may be explained by the existence of a hydrogen bond involving the axial C-7 hydroxyl group of chenodeoxycholic acid and C-4 protons. The values of these deviations agree with a delocalization of σ-bond on a hydrogen bond and an improvement of the γ-axial effect of the C-7 hydroxyl group taking part in a hydrogen bond with C-5 and C-9.

The existence of a hydrogen bond and steric congestion around the C-7 hydroxyl group appears to explain the polarity of these bile acids. Chenodeoxycholic acid appears to be less polar than ursodeoxycholic acid, in agreement with the experimental results obtained by HPLC.

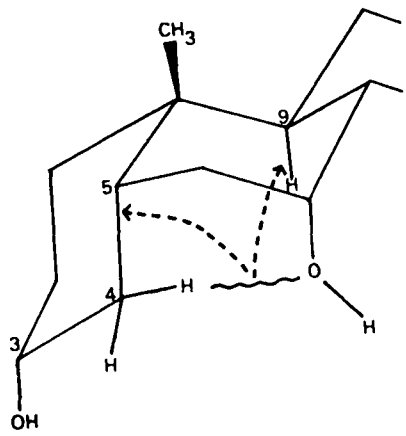

Table III—Substitution Increments in the Steroid Carbon Skeleton: Effect of Hydroxyl Inversion on C-7

Carbon of Steroid Skeleton	Effect of 7αOH [a]	Effect of 7βOH [a]	Effect of 7β → 7α Inversion

Triazolines XIII: Δ^2-1,2,3-Triazolines, a New Class of Anticonvulsants

PANKAJA K. KADABA

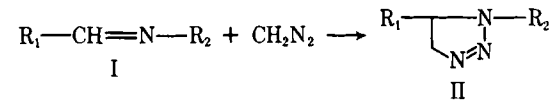
Received June 15, 1981, from the *Division of Medicinal Chemistry and Pharmacognosy, College of Pharmacy, University of Kentucky, Lexington, KY 40506.* Accepted for publication March 23, 1983.

Abstract □ A series of 1,5-diaryl-Δ^2-1,2,3-triazolines has been synthesized and evaluated for the first time as potential anticonvulsant agents using the standard subcutaneous pentylenetetrazol seizure threshold and maximal electroshock seizure tests. Out of the 31 triazolines that were screened, 11 exhibited moderate anticonvulsant activity; 9 of the compounds afforded protection against pentylenetetrazol-induced seizures, while two antagonized electrically induced convulsions.

Keyphrases □ 1,5-Diaryl-Δ^2-1,2,3-triazolines—synthesis, anticonvulsant activity in mice □ Anticonvulsants—potential, 1,5-diaryl-Δ^2-1,2,3-triazolines, synthesis, screening in mice

Although several five-membered heterocyclic ring systems containing up to four nitrogen atoms have been synthesized and screened for anticonvulsant activity (1, 2), no studies have appeared describing the Δ^2-1,2,3-triazolines(4,5-dihydro-1*H*-1,2,3-triazoles; II). Since better anticonvulsants are needed in the treatment of epilepsy (2, 3) and since the triazolines are a new class of heterocyclic compounds (4), we decided to investigate these compounds as potential anticonvulsants.

Although triazolines are formed when Schiff bases (I) react with diazomethane (5, 6) (Scheme I), earlier synthetic procedures have either failed to give a triazoline adduct or have yielded insignificant amounts of the products (5).



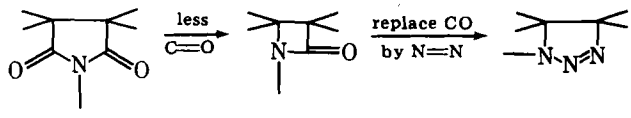
I II

Studies in our laboratories on the role of protic and dipolar aprotic solvents in 1,3-cycloaddition reactions (7–10) have led to a versatile method for the synthesis of the rarely encountered triazolines (11). By utilizing the accelerating effect of protic solvents, such as water, on the addition of diazomethane to Schiff bases, a variety of previously unknown triazolines bearing aryl (11) or heteroaryl (12) substituent groups has become readily available in sufficient quantities to permit, for the first time, a detailed screening of these compounds for biological activity. Two earlier papers reported the results of screening for herbicidal activity (13) and pesticidal properties (14). The present paper investigates the potential of the triazoline heterocycles as anticonvulsant compounds.

RESULTS AND DISCUSSION

The triazoline ring system is different from those of the conventional anticonvulsant drugs, the majority of which have a dicarboximide (ureylene) —CO—NH—CO—, function as in barbiturates, hydantoins, succinimides, and oxazolidinediones or a closely related structure as in primidones. The absence of the dicarboximide function, which contributes to the inherent hypnotic and sedative activity of the barbiturates and related compounds, may be expected to reduce the toxic side effects in potential triazoline anticonvulsants.

The triazolines may be considered to be derived from the succinimides (III) by the loss of one C=O moiety (IV) and the replacement of the other by an N=N group (II). Several azetidinones have been reported to have varying degrees of anticonvulsant activity (15) as well as some 2-azetidinthiones (16).



III IV II

Pharmacology—The compounds were evaluated for anticonvulsant activity in two seizure models in the mouse, the maximal electroshock seizure (MES) test and the subcutaneous pentylenetetrazol seizure threshold (scMet) test. These two methods of seizure provocation are known to reliably elicit well-characterized seizure phenomena (17) and are the standard screens of choice for identification of anticonvulsant activity in a compound (18). CNS toxicity is determined in the rotorod ataxia test (19). This test has a clear end-point, is quantifiable, and correlates well with the clinical assessment of minimal toxicity. Testing is done in the dose range of 30–600 mg/kg (with a few exceptions) at both 30-min and 4-h intervals. This provides a profile of the anticonvulsant activity, toxicity, potency, and pharmacokinetics of each compound and minimizes the likelihood of failing to identify slowly absorbed compounds or those with possible anticonvulsant activity in a metabolite.

Structure–Activity Relationships—The results of screening 31 1,5-diaryl-substituted Δ^2-1,2,3-triazolines are reported in Table I. Eleven compounds exhibited moderate anticonvulsant activity; while nine of these afforded protection against scMet-induced seizures, only two (IX and XVI) were active in the MES test. The parent compound (V) is the most potent and is active at the 100-mg/kg dose level. Six other compounds (XVI, XX, XXI, XXIV, XXIX, and XXXIV) afforded protection in the scMet test at 300 mg/kg and three more (VI, VII, and XIX) at the 600-mg/kg dose level. Compounds IX and XXI show delayed activity after 4 h: IX in the MES test at 600 mg/kg and XXI in the scMet test at 300 mg/kg. Compound XVI, in addition to its activity in the scMet test, shows activity in the MES test at the 600-mg/kg level at both 0.5 and 4 h. With the exception of XVI and XXIV, the triazoline compounds are relatively nontoxic.

Certain structure–activity relationships have emerged from the varying substitution patterns on the phenyl rings of the parent compound. Introduction of a 2-chloro substituent on the 5-phenyl ring gives VI, which affords 75% protection at 0.5 h and 50% at 4 h with no symptoms of neurological deficit. When the chloro group is in the 4-position of either phenyl ring, activity disappears in the scMet test, although the 5-(4-chlorophenyl) compound, IX, evinces delayed activity in the MES test.

Compounds XV–XXIII illustrate the effect of different substituents on the 1-phenyl of VI. A 3-CF_3 group increases activity as well as toxicity, while a 4-CF_3 or 4-C_2H_5 affords protection at the same dose level without signs of neurotoxicity. The almost parallel activities of VI and XIX are interesting, since the 4-F analogue XIX provides minimal change in π and σ effects (20) compared with the unsubstituted VI. The presence of 4-Cl, 4-Br, 4-OCH_3, or 3,4-Cl_2 yields inactive compounds XVIII, XVII, XXII, and XXIII, respectively. However, with the introduction of a second chloro group in the 6-position of the 5-phenyl ring of XVII, activity reappears, as in XXXIV; similar substitution in XIX leads to a loss of activity in XXXV. A more meaningful analysis of the structure–activity pattern to obtain information on parameter dependency using the Topliss manual approach (20) to Hansch analysis in this compound group, XV–XXIII, has not been possible, since the activity spread between the members is not large enough (20). However, the structure–activity relationships do indicate the anticonvulsant potential of appropriately substituted 1,2,3-triazolines.

Finally, the effect of a nitro substituent is noteworthy. While a 4-NO_2 on either phenyl ring does not contribute to activity, a 3-NO_2 by itself, as in VII, or in combination with 2,4-Cl_2, as in XXIX, yields an active compound.

EXPERIMENTAL

Chemistry—The 1,5-diaryl-Δ^2-1,2,3-triazolines were prepared as described previously (7–12). All compounds except XIII–XVI, XVIII–XXII, XXIV, XXVIII, XXX, and XXXII–XXXV have been reported previously (11). Data on the newly synthesized compounds are presented in Table II.

[a] At the same dose level, the compound afforded 100% protection in the MES test after 4 h. [b] The delayed effect could be because it is slowly absorbed or it has anticonvulsant activity in a metabolite. [c] Only one animal was tested. [d] At 600 mg/kg, this compound protected 100% animals in the MES test at 0.5 and 4 h, but it also showed 100% toxicity at both time periods.

Pharmacology—The 31 triazolines were screened by the Anticonvulsant Screening Project (ASP) under the Antiepileptic Drug Development (ADD) program of the Epilepsy Branch of the National Institute of Neurological and Communicative Disorders and Stroke (NINCDS).

The compounds were solubilized in 30% polyethylene glycol 400. The solvent was tested for anticonvulsant and toxic effects and was found to introduce no significant bias into the testing of anticonvulsant activity. The compounds were administered intraperitoneally in a volume of 0.01 mL/g to male Carworth Farms #1 mice weighing ~20 g (21). Testing was done at dose levels of 30, 100, 300, and 600 mg/kg, and a total of 16 animals were used, four for each dose. After 30 min, each animal was examined for toxicity in the rotorod test (19). Immediately thereafter, anticonvulsant activity was evaluated by subjecting one mouse to the MES test and another to the scMet test. The same tests were repeated 4 h later on the two remaining mice at each dose level. When compounds were found to afford protection, the test was repeated at that dose level and time using four animals, and the results were expressed as number of animals protected/number of animals tested or as percent of animals protected (Table I).

The maximal electroshock seizure test (MES) was performed according to the method of Swinyard *et al.* (22), and abolition of the hind limb tonic extension component of the seizure was defined as protection. In the subcutaneous pentylenetetrazol seizure threshold test (scMet), 85 mg/kg of pen-

[a] Melting points were determined in a Thomas-Hoover apparatus and are uncorrected. [b] The elemental analyses (C, H, and N) for all new compounds were within ±0.4% of the theoretical values. [c] Quantitative.

tylenetetrazol was administered as a 0.5% solution subcutaneously in the posterior midline, and failure to observe even a threshold seizure (a single episode of clonic spasms of at least 5-s duration) was defined as protection (22).

Neurotoxicity was evaluated by the rotorod ataxia test (19). The animal was placed on a wooden rod of 2.8-cm diameter rotating at 6 rpm. Normal mice can remain on a rod rotating at this speed indefinitely. Neurologic toxicity was defined as the failure of the animal to remain on the rod for 1 min and was expressed as number of animals exhibiting toxicity/number of animals tested or as percent of animals showing toxicity.

ACKNOWLEDGMENTS

The author wishes to acknowledge and thank the ASP of NINCDS for conducting the screening studies under the liaison of Dr. Gill D. Gladding, Pharmacy Consultant, Epilepsy Branch. The author is grateful to the National Institute of Neurological and Communicative Disorders and Stroke for the award of research grant 1RO1 NS16843-01A1, which made this work possible. All the anticonvulsant compounds reported in this paper are protected by patents.

Depletion of Endogenous Inorganic Sulfate in the Mammalian Central Nervous System by Acetaminophen

Keyphrases □ Acetaminophen—cerebrospinal fluid, sulfate depletion in rats □ Endogenous inorganic sulfate—depletion in cerebrospinal fluid of rats by acetaminophen

To the Editor:

Acetaminophen is metabolized in part by conjugation with sulfate (1, 2), a process that causes transient depletion of endogenous inorganic sulfate in plasma of rats and humans (3, 4). Sulfate activation (5) and conjugation (6) occur in the mammalian brain and may have a significant role in regulating the levels of biogenic amine neurotransmitters (7). Sulfate is also needed for the synthesis of certain brain tissue constituents such as mucopolysaccharides and sulfatides (5). It is of interest, therefore, to determine if the widely used analgesic and antipyretic agent acetaminophen can deplete inorganic sulfate in the central nervous system.

Female Lewis rats, 170–195 g, were cannulated (right jugular vein) under light ether anesthesia 1 d before the experiment. On the next day, the animals were placed in individual plastic metabolism cages, and food and water were withdrawn. Acetaminophen (10 mg/mL in normal saline solution) was infused at a rate of ~12 mg/h/rat for 6 h; control rats received an infusion of drug-free saline solution. At the end of the infusion, the animals were anesthetized with ether, ~0.1 mL cerebrospinal fluid (CSF) was obtained from the cisterna magna, and blood was collected from the abdominal aorta into heparinized tubes. The concentrations of inorganic sulfate in CSF and plasma were determined by single-column ion chromatography, using a mobile phase of 4 mM potassium hydrogen phthalate adjusted to pH 4.5 with potassium hydroxide, a Wescan anion exchange column, and conductivity detection (8). Potassium nitrate was added to the plasma samples as an internal standard; CSF samples were assayed without internal standard because of the presence of interfering peaks. Heparin did not affect the assay.

The results of the study are summarized in Table I. The normal concentration ratio of endogenous sulfate, CSF-plasma, was on average 0.224. This is similar to the reported concentration ratio of 0.24 in cats (9), 0.17 in rabbits (9), and 0.30 in humans (10). The 6-h infusion of acetaminophen caused a pronounced reduction of inorganic sulfate concentrations in plasma, as already reported (3), and also reduced the concentration of inorganic sulfate in CSF. However, the CSF-plasma concentration ratio increased to 0.530 on the average. There was a significant negative correlation between the CSF-plasma concentration ratio and the plasma concentration of inorganic sulfate ($r = -0.926$, $p < 0.01$).

Table I—Effect of Acetaminophen Administration on Endogenous Inorganic Sulfate Concentrations in the Cerebrospinal Fluid and Plasma of Rats [a]

	Controls ($n = 5$)	Acetaminophen Treated ($n = 8$)
Cerebrospinal fluid	0.164 ± 0.023	0.067 ± 0.022[b]
Plasma	0.731 ± 0.020	0.132 ± 0.055[b]
CSF-plasma concentration ratio	0.224 ± 0.028	0.530 ± 0.141[b]

[a] Results are expressed as mean ± *SD*. Concentrations are millimolar. [b] Significantly different from corresponding control value, $p < 0.01$ by two-sample rank test.

These observations demonstrate that treatment with acetaminophen can cause depletion of endogenous inorganic sulfate not only in plasma but also in the central nervous system. Since plasma protein binding of inorganic sulfate is negligible (10, 11), the substantially lower concentration of the anion in CSF than in plasma suggests that sulfate is transported by a specialized process from CSF to plasma, as already suggested by others (12). Moreover, the increased CSF-plasma concentration ratio in the sulfate-depleted acetaminophen-treated rats (Table I), and the decreased ratio when plasma sulfate concentrations are increased by intravenous injection of sodium sulfate (9), indicate that the transport process is saturable. In this respect, sulfate homeostasis in CSF is facilitated as is plasma sulfate homeostasis, the latter by a specialized renal transport process (4, 13). While the specialized transport processes dampen fluctuations of endogenous sulfate concentrations, they do not prevent substantial concentration changes due to depletion of endogenous sulfate resulting from its utilization for sulfate conjugation of phenolic drugs such as acetaminophen. It is desirable, therefore, to determine the effect of acetaminophen on endogenous sulfate concentrations in the CSF of human subjects and such studies are now in progress.

Organ Perfusion Studies: A Rebuttal

Keyphrases □ Organ perfusion—pharmacokinetics, sampling □ Pharmacokinetics—organ perfusion, effect of sampling

To the Editor:

Colburn *et al.* (1) discussed the influence of sampling in organ perfusion studies. In this respect we want to make the following critical remarks. These authors defined the elimination rate constant K as Q/V_R, in which Q represents the perfusion flow rate and V_R represents the reservoir volume. According to this equation, however, K is *not* the elimination rate constant.

It is explicitly stated by Rowland *et al.* in their Table I (2), that the rate constant k_{12} of the compartmental model corresponds to $\dot{V}_B/V_R$ of the perfusion model. In Colburn's terminology $\dot{V}_B = Q$. Since Colburn states that $K = Q/V_R$, it is erroneous to call K an elimination rate constant; it simply is the transport rate constant from the reservoir to the eliminating perfused organ in terms of the perfusion model. Similarly, the rate constant k_{12} of the compartmental model represents the transport rate constant from the central to the peripheral compartment in the compartmental model. The elimination rate constant itself, k_e, contrary to the opinion of Colburn *et al.*, is independent of the perfusion flow rate, since it reflects the intrinsic ability of the organ to eliminate drug. As we have pointed out (3), the drug decrease in the reservoir will be more rapid under the influence of sampling than without sampling. Consequently, a pharmacokinetic analysis based on the uncorrected time course of drug concentration in the reservoir will result in overestimation of the parameter k_e.

Colburn *et al.* stated that clearance will be unaffected by sampling from the reservoir. We do not agree with their statement. They define clearance as:

$$CL_o = Q\left(\frac{C_{in} - C_o}{C_{in}}\right) \qquad \text{(Eq. 1)}$$

where C_{in} and C_o represent the inflow and outflow concentrations of the eliminating organ. This expression, however, defines *instantaneous* clearance (2), which is time- and concentration-dependent. A more relevant measure of clearance is the *mean* clearance, which essentially is a steady-state concept. The mean clearance equals:

$$CL = \frac{Q \cdot k_e}{Q/(K_p \cdot V_o) + k_e} \qquad \text{(Eq. 2)}$$

where V_o is the physical organ volume and K_p is the apparent partition coefficient of drug between the eliminating organ and the emergent perfusion fluid (2). This leaves K_p and k_e as two independent parameters to be estimated from the concentration *versus* time curve as measured in the reservoir.

As discussed above, the parameter k_e will be overestimated due to sampling. Similarly, the estimate of the parameter K_p is biased, in a complicated way, by sampling (3). It follows that sampling from the reservoir definitely influences the estimate of clearance. The extent to which clearance is biased by neglecting corrections for sampling is dependent on the numerical values of Q, K_p, k_e, and of course the sample volumes.

In conclusion it can be stated that the instantaneous clearance is the wrong parameter to look at and that the mean clearance estimated from concentration *versus* time curves in the reservoir will certainly depend on sampling from this reservoir.

Estimation of Mean Residence Time from Data Obtained when Multiple-Dosing Steady State Has Been Reached

Keyphrases □ Pharmacokinetics—multiple dosing, mean residence time

To the Editor:

When the plasma concentration (C) *versus* time (t) profile of a drug, on single dosing, can be described, irrespective of dosing route, as an exponential series:

$$C = \sum_{i=1}^{n} A_i \cdot \exp(-k_i t) \qquad \text{(Eq. 1)}$$

then the concentration *versus* time profile on multiple dosing to steady state, at a constant interval, Υ, can be described (1) as:

$$C_{ss} = \sum_{i=1}^{n} \frac{A_i}{1 - \exp(-k_i \Upsilon)} \cdot \exp(-k_i t) \qquad \text{(Eq. 2)}$$

where C_{ss} represents the plasma concentration at multiple-dosing steady state and, in this case, t is time after the last dose administered. Equation 2 is valid on the assumptions that the dose remains constant, the dosing interval is constant, and clearance is constant. It has been demonstrated (see Ref. 1) that under these conditions:

$$\int_0^\infty C dt = \int_0^\Upsilon C_{ss} dt \qquad \text{(Eq. 3)}$$

When the time course of drug concentration is regarded as a statistical distribution curve (2) the mean residence time (MRT) of the drug, on single dosing, can be defined (3) as:

$$\text{MRT} = \int_0^\infty tCdt \Big/ \int_0^\infty Cdt = \left(\sum_{i=1}^{n} A_i/k_i^2\right) \Big/ \left(\sum_{i=1}^{n} A_i/k_i\right) \qquad \text{(Eq. 4)}$$

In addition to using the analytical integrals of Eq. 1, as shown in Eq. 4, the MRT has been calculated using integrals estimated by the trapezoidal rule (4).

On the basis of Eq. 2, the first moment curve at steady state would be:

Estimation of Mean Residence Time from Data Obtained when Multiple-Dosing Steady State Has Been Reached

Keyphrases □ Pharmacokinetics—multiple dosing, mean residence time

To the Editor:

When the plasma concentration (C) *versus* time (t) profile of a drug, on single dosing, can be described, irrespective of dosing route, as an exponential series:

$$C = \sum_{i=1}^{n} A_i \cdot \exp(-k_i t) \qquad \text{(Eq. 1)}$$

then the concentration *versus* time profile on multiple dosing to steady state, at a constant interval, Υ, can be described (1) as:

$$C_{ss} = \sum_{i=1}^{n} \frac{A_i}{1 - \exp(-k_i \Upsilon)} \cdot \exp(-k_i t) \qquad \text{(Eq. 2)}$$

where C_{ss} represents the plasma concentration at multiple-dosing steady state and, in this case, t is time after the last dose administered. Equation 2 is valid on the assumptions that the dose remains constant, the dosing interval is constant, and clearance is constant. It has been demonstrated (see Ref. 1) that under these conditions:

$$\int_0^\infty C dt = \int_0^\Upsilon C_{ss} dt \qquad \text{(Eq. 3)}$$

When the time course of drug concentration is regarded as a statistical distribution curve (2) the mean residence time (MRT) of the drug, on single dosing, can be defined (3) as:

$$\text{MRT} = \int_0^\infty tCdt \Big/ \int_0^\infty Cdt = \left(\sum_{i=1}^{n} A_i/k_i^2\right) \Big/ \left(\sum_{i=1}^{n} A_i/k_i\right) \qquad \text{(Eq. 4)}$$

In addition to using the analytical integrals of Eq. 1, as shown in Eq. 4, the MRT has been calculated using integrals estimated by the trapezoidal rule (4).

On the basis of Eq. 2, the first moment curve at steady state would be:

0022-3549/84/0600-0854$01.00/0
© 1984, American Pharmaceutical Association

$$tC_{ss} = \sum_{i=1}^{n} \frac{tA_i}{1 - \exp(-k_i\Upsilon)} \cdot \exp(-k_i t) \quad \text{(Eq. 5)}$$

The integral of Eq. 5 is:

$$\int_0^t tC_{ss}dt = \sum_{i=1}^{n} \frac{A_i}{1 - \exp(-k_i\Upsilon)} \left[\frac{1}{k_i^2}(1 - \exp(-k_i t)) - \frac{t}{k_i} \cdot \exp(-k_i t)\right] \quad \text{(Eq. 6)}$$

$\int_0^\Upsilon tC_{ss}dt$ is, therefore:

$$\int_0^\Upsilon tC_{ss}dt = \sum_{i=1}^{n} \frac{A_i}{k_i^2} - \sum_{i=1}^{n} \frac{A_i\Upsilon \cdot \exp(-k_i\Upsilon)}{k_i[1 - \exp(-k_i\Upsilon)]} = \int_0^\infty tCdt - \Upsilon \sum_{i=1}^{n} \frac{A_i \exp(-k_i\Upsilon)}{k_i[1 - \exp(-k_i\Upsilon)]} \quad \text{(Eq. 7)}$$

Rearranging Eq. 7:

$$\int_0^\infty tCdt = \int_0^\Upsilon tC_{ss}dt + \Upsilon \sum_{i=1}^{n} \frac{A_i \cdot \exp(-k_i\Upsilon)}{A_i[1 - \exp(-k_i\Upsilon)]} \quad \text{(Eq. 8)}$$

Equation 8 indicates that MRT cannot be estimated by using the area under the multiple-dosing first moment curve from time zero to time Υ as a numerator in an equation analogous to Eq. 4. However, since $\int_0^\Upsilon C_{ss}dt = \Sigma_{i=1}^{n} A_i/k_i$ and:

$$\int_0^\infty C_{ss}dt = \sum_{i=1}^{n} \frac{A_i}{k_i[1 - \exp(-k_i\Upsilon)]} \quad \text{(Eq. 9)}$$

then:

$$\sum_{i=1}^{n} \frac{A_i \cdot \exp(-k_i\Upsilon)}{k_i[1 - \exp(-k_i\Upsilon)]} = \int_0^\infty C_{ss}dt - \int_0^\Upsilon C_{ss}dt = \int_\Upsilon^\infty C_{ss}dt \quad \text{(Eq. 10)}$$

Equation 8 is equivalent to:

$$\int_0^\infty tCdt = \int_0^\Upsilon tC_{ss}dt + \Upsilon \int_\Upsilon^\infty C_{ss}dt \quad \text{(Eq. 11)}$$

Table I—MRT Calculation [a]

120.0	0.56	66.67	1637.0	38883.2
∞	0	0	1651.2	40942.2

[a] All integrals approximated by using the linear trapezoidal rule.

MRT may be estimated from multiple dosing data by:

$$\text{MRT} = \frac{\int_0^\Upsilon tC_{ss}dt + \Upsilon \int_\Upsilon^\infty C_{ss}dt}{\int_0^\Upsilon C_{ss}dt} \quad \text{(Eq. 12)}$$

The data necessary to compute MRT, using the trapezoidal rule, on multiple dosing to steady state may be obtained by continued sampling of the declining plasma concentrations until, perhaps, 4–7 drug half-lives have elapsed or the limit of detection of the assay is reached, rather than redosing at time Υ. The purpose is to ensure that the postabsorption and postdistribution phase has been reached and the area under the curve from the last sampling time can be properly extrapolated by $(C_m)_{ss}/k_n$ where $(C_m)_{ss}$ is the last sampled concentration and k_n the terminal rate constant. If the dosing interval has been such that the terminal data point, at Υ, were known to be well into the postabsorption and postdistribution phase, then Eq. 12 could be simplified to:

$$\text{MRT} = \frac{\int_0^\Upsilon tC_{ss}dt + \Upsilon(C_m)_{ss}/k_n}{\int_0^\Upsilon C_{ss}dt} \quad \text{(Eq. 13)}$$

In such a case it would be unnecessary to interrupt the dosing schedule.

Wagner (5) and Benet and Galeazzi (6) have used the equation:

$$C = 60.9545 \cdot \exp(-5.060t) + 39.0459 \cdot \exp(-0.03952t) \quad \text{(Eq. 14)}$$

to demonstrate methods of calculating steady-state volume of distribution. Substituting values from Eq. 14 into Eq. 4 to obtain analytical integrals yields MRT = 25.00 h. Values calculated for $\int_0^\infty tCdt$ and $\int_0^\infty Cdt$ by Benet and Galeazzi (6) using the linear trapezoidal rule yield MRT = 24.88 h.

If multiple dosing with Υ = 24 h is assumed:

$$C_{ss} = 60.9545 \cdot \exp(-5.0605t) + 63.7306 \cdot \exp(-0.03952t) \quad \text{(Eq. 15)}$$

Using Eq. 15, plasma concentrations were calculated over a 120-h period (Table I). The first moment curve and cumulative values of $\int_0^t tC_{ss}dt$ and $\int_0^t c_{ss}dt$, calculated using the linear trapezoidal rule, are also given. Using these trapezoidal rule values, according to Eq. 12:

$$\text{MRT} = \frac{9399.2 + 24(648.5)}{1002.7} = 24.90 \quad \text{(Eq. 16)}$$

The analytical integrals, derived from Eq. 15 and substituted into Eq. 12, yield MRT = 25.00 h.

Using analytical integrals, Eq. 4, for single dose data, and Eq. 12, for multiple dosing steady-state data, yield equivalent values for MRT. Using the trapezoidal rule approximations gave MRT 0.4% less than the actual MRT value. The difference is inherent in rounding the calculated plasma concentrations and in the trapezoidal rule approximations. It is, therefore, possible to obtain at least as accurate an estimate of MRT from multiple-dosing steady-state data as from single-dose data providing the plasma sampling schedule is adequate. It might, however, be necessary to interrupt the multi-

ple-dosing regime which might limit the application of the method in patient studies.

Bauer and Gibaldi (7) have proposed an alternative method for performing moment-analysis calculations on multiple-dosing data. It should be noted that their Eq. 7 is equivalent to Eq. 6 in this presentation. The Bauer and Gibaldi method requires the use of calculated concentrations to calculate area under the curve, while this presently proposed method employs only the data observed at multiple-dosing steady state. This raises the possibility of being able to determine whether pharmacokinetic changes, as observed in mean retention times or, perhaps, steady-state volumes of distribution, could have been induced during multiple dosing.

Alterations of α-Lactose During Differential Scanning Calorimetry

Keyphrases □ α-Lactose—alterations, differential scanning calorimetry

To the Editor:

Lactose is a natural disaccharide widely used as a diluent in tablet formations. As a solid it is known to occur either in one of four crystalline forms or in an amorphous state. α-Lactose monohydrate is obtained by crystallization from a super-saturated solution at temperatures <93.5°C, whereas β-lactose crystals are obtained at temperatures >93.5°C (1). During crystallization of β-lactose, no water is incorporated in the crystal lattice. The crystals of β-lactose exist in a nonhygroscopic anhydrous form only, in contrast with α-lactose, which occurs both as monohydrate and as anhydrous α-lactose. Thermal dehydration, or desiccation of the hydrate crystals with suitable liquids, converts α-lactose monohydrate into its anhydrous form. A very hygroscopic product, generally called unstable anhydrous α-lactose, is formed when α-lactose hydrate crystals are heated, mostly *in vacuo*, at temperatures of 100–130°C (2–4). Thermal treatment in a moist atmosphere at temperatures over ~110°C, or desiccation with suitable liquids, such as dry methanol, may result in a nonhygroscopic product, generally called stable anhydrous α-lactose (2, 4).

The different types of lactose are increasingly studied by thermal analysis. Berlin *et al.* (5) determined the heat of desorption of water from α-lactose monohydrate by differential scanning calorimetry. Itoh *et al.* (3, 6) used differential thermal analysis in studying the characteristics of α-lactose hydrate and of β-lactose, next to IR absorption and X-ray powder diffraction techniques. Differential scanning calorimetry has been applied by Ross (7) for the direct measurement of the amount of α- and β-lactose in whey powders.

This communication reports the occurrence of changes in the solid state during differential scanning calorimetry of α-lactoses. Figure 1 illustrates the DSC-curves of α-lactose monohydrate and of stable and unstable anhydrous α-lactose, respectively, as recorded by means of a thermal analyzer[1]. The DSC-curve of α-lactose monohydrate shows an endothermic

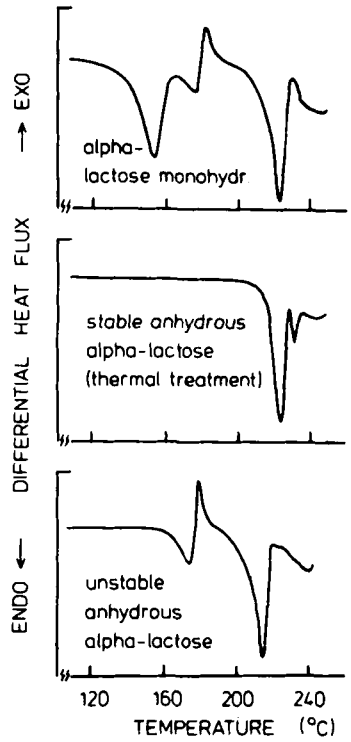

Figure 1—*DSC-curves of α-lactose monohydrate, stable anhydrous α-lactose, and unstable anhydrous α-lactose, respectively, recorded at a heating rate of 10°C/min.*

Alterations of α-Lactose During Differential Scanning Calorimetry

Keyphrases □ α-Lactose—alterations, differential scanning calorimetry

To the Editor:

Lactose is a natural disaccharide widely used as a diluent in tablet formations. As a solid it is known to occur either in one of four crystalline forms or in an amorphous state. α-Lactose monohydrate is obtained by crystallization from a super-saturated solution at temperatures <93.5°C, whereas β-lactose crystals are obtained at temperatures >93.5°C (1). During crystallization of β-lactose, no water is incorporated in the crystal lattice. The crystals of β-lactose exist in a nonhygroscopic anhydrous form only, in contrast with α-lactose, which occurs both as monohydrate and as anhydrous α-lactose. Thermal dehydration, or desiccation of the hydrate crystals with suitable liquids, converts α-lactose monohydrate into its anhydrous form. A very hygroscopic product, generally called unstable anhydrous α-lactose, is formed when α-lactose hydrate crystals are heated, mostly *in vacuo*, at temperatures of 100–130°C (2–4). Thermal treatment in a moist atmosphere at temperatures over ~110°C, or desiccation with suitable liquids, such as dry methanol, may result in a nonhygroscopic product, generally called stable anhydrous α-lactose (2, 4).

The different types of lactose are increasingly studied by thermal analysis. Berlin *et al.* (5) determined the heat of desorption of water from α-lactose monohydrate by differential scanning calorimetry. Itoh *et al.* (3, 6) used differential thermal analysis in studying the characteristics of α-lactose hydrate and of β-lactose, next to IR absorption and X-ray powder diffraction techniques. Differential scanning calorimetry has been applied by Ross (7) for the direct measurement of the amount of α- and β-lactose in whey powders.

This communication reports the occurrence of changes in the solid state during differential scanning calorimetry of α-lactoses. Figure 1 illustrates the DSC-curves of α-lactose monohydrate and of stable and unstable anhydrous α-lactose, respectively, as recorded by means of a thermal analyzer[1]. The DSC-curve of α-lactose monohydrate shows an endothermic

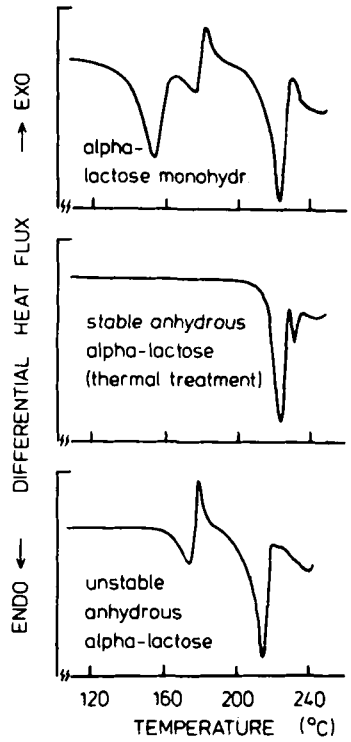

Figure 1—*DSC-curves of α-lactose monohydrate, stable anhydrous α-lactose, and unstable anhydrous α-lactose, respectively, recorded at a heating rate of 10°C/min.*

Table I—Change in β-Content (GLC Determination) and the Solid State (X-ray Diffraction Analysis) of α-Lactose During Thermal Treatment (DSC-cell 910; Heating Rate 10°C/min)[a]

	Temperature, °C

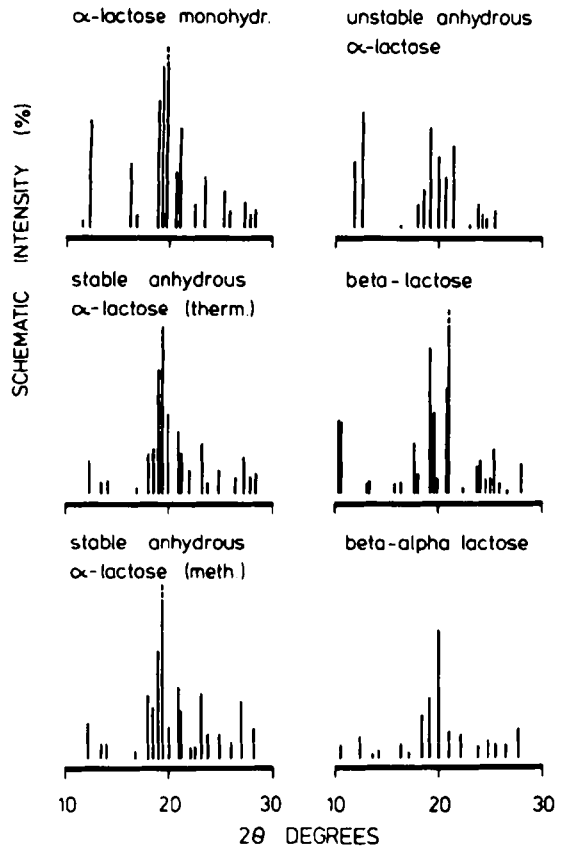

Figure 2—*Representation of the X-ray diffraction patterns of the different forms of lactose*[2].

transition starting at ~140°C, when scanned with a heating rate of 10°C/min, corresponding to dehydration of the product. All three α-lactoses exhibit a melting endotherm beginning at ~210°C. The melting endotherm of unstable α-lactose is, however, preceded, as reported earlier by Itoh *et al.* (3), by an endo- and exothermic peak at ~170°C and 180°C, respectively. This indication of thermal alteration was elucidated in our study by X-ray diffraction analysis and by determination of the β-content performed on samples which were heated to different temperatures as mentioned in Table I. The results show a conversion at ~180°C of unstable α-lactose into a product with a crystallographic structure different from both hydrous and anhydrous α-lactose and from β-lactose.

X-ray diffraction analysis showed the conversion product to agree with lactose crystals, which were prepared by Buma (8) by crystallization from methanol. Buma concluded from specific gravity measurements and sedimentation analysis that the "crystalline lactose obtained from methanol did not consist of α-lactose crystals and β-lactose crystals, as was reported by [Lim and Nickerson (9)], but of crystals consisting of α- and β-lactose." Analysis of the X-ray diffraction patterns (Fig 2) of α-lactose monohydrate, stable anhydrous α-lactose produced by thermal dehydration, stable anhydrous α-lactose obtained by methanol desiccation, unstable anhydrous α-lactose, β-lactose, and the conversion product mentioned before, indicate in our opinion that the last product can best be characterized as a crystalline β/α-lactose compound, having a β:α ratio of ~1:1. From these results it may be concluded, that the first endotherm at ~170°C as shown by the DSC-curves of unstable anhydrous α-lactose (Fig. 1), is the result of the melting of the unstable anhydrous α-lactose, whereas the second endotherm at ~210°C corresponds with the melting point of the crystalline β/α-lactose compound, which crystallized at ~180°C.

These results and the observation of endo- and exothermic transitions at ~160°C and 180°C, respectively, in the DSC-curves of α-lactose monohydrate gave rise to a detailed examination of the thermal treatment of this product. X-ray diffraction analysis performed on samples that were heated at a rate of 2°C/min (instead of the usual 10°C/min) showed at 160°C the occurrence of unstable next to stable anhydrous α-lactose (see Table I). As expected, the crystalline β/α-compound was consequently detected at 200°C. This implies that α-lactose monohydrate loses its water upon heating and changes into both stable and unstable anhydrous α-lactose, the latter being converted into the crystalline β/α-lactose compound at temperatures >180°C. Besides, it is interesting to note that the α-lactoses show a significant conversion into β-lactose upon melting at a temperature of ~220°C.

In conclusion, thermal treatment of α-lactoses involves changes in β-content and in crystal structure.

Amorphous lactose	(—)	BA
Ground α-lactose monohydrate	(—)	BA
Ground β-lactose	(—)	B

[a] B = β-lactose; BA = β/α-lactose compound crystal; (—) = amorphous lactose (no or only a few very weak diffraction lines could be detected.

of the physicochemical properties of solid materials. Size reduction is, however, a very active process, supplying energy to a particle during fragmentation. It is well known that mechanical treatment of minerals can result in activation and changes in surface properties, in polymorphic transitions and alterations in physical properties of the bulk phase, in uncrystallization, as well as in mechanochemical solid-state reactions (1).

Hüttenrauch, in his series on molecular pharmaceutics, studied the mechanical activation of drugs and excipients and showed uncrystallization of α-lactose monohydrate during milling (2). We reported earlier (3) changes in the β-content and in the solid state of α-lactose monohydrate, stable anhydrous α-lactose, and unstable anhydrous α-lactose, respectively, by thermal treatment. Continuing this study, amorphous lactose and intensively ground samples of α-lactose monohydrate and β-lactose, respectively, were examined for their thermal characteristics. Figure 1 illustrates the Differential Scanning Calorimetry (DSC)-curves of these preparations, obtained at a heating rate of 10°C/min, using a thermal analyzer[1].

The DSC-curve of the amorphous lactose, prepared by spray-drying, shows an exothermic transition at ~160°C and an endotherm at ~210°C. An analogous pattern was recorded for intensively ground α-lactose monohydrate. Its DSC-curve shows, in contrast to that of nonground α-lactose monohydrate, hardly a dehydration endotherm, but an exotherm at ~160°C. Intensively ground β-lactose exhibited an exotherm as well, but at a slightly lower temperature (≃140°C).

To elucidate the indication of thermal transition during the dynamic process of DSC, X-ray diffraction patterns were made of samples, both prior to and after thermal treatment by heating to ~180°C followed by immediate cooling to room temperature. As expected, the nonthermally treated but intensively ground samples showed no, or at least very weak, diffraction lines (Table I). This indicates that comminution had resulted in uncrystallization of both α-lactose monohydrate and β-lactose. The uncrystallized products crystallized on heating. X-ray diffraction analyses of samples of amorphous lactose and of intensively ground α-lactose hydrate, respectively, both proved to correspond with a crystalline β/α-lactose compound, when heated to 180°C with subsequent cooling to room temperatures.

Uncrystallized β-lactose was, however, found to crystallize into β-lactose on thermal treatment. This difference in thermal behavior between samples of intensively ground α-lactose monohydrate and β-lactose, respectively, is supported by the observation of an increase in β-content for ground α-lactose monohydrate from 2 to 42% and hardly any change in β-content for uncrystallized β-lactose on thermal treatment (Table I).

To investigate more thoroughly the formation of the crystalline β/α-lactose compound from amorphous lactose, six batches of amorphous lactose, differing in ratio from ~3:7 to ~8:2 and prepared by freeze- or spray-drying, were heated to different temperatures and subsequently cooled to room

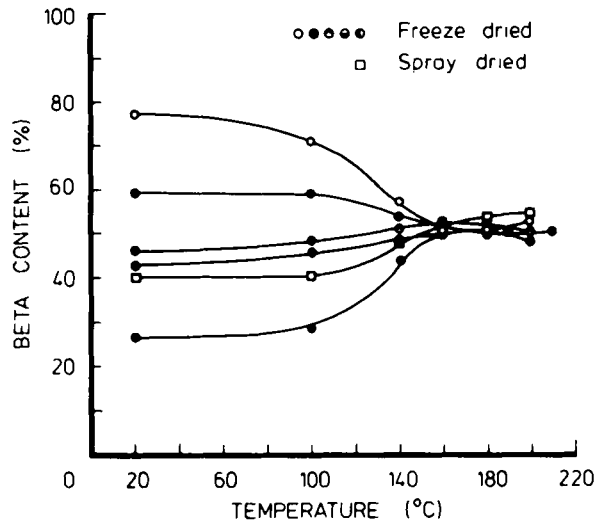

Figure 2—*Change in β-content of different amorphous lactose products with temperature[2] heating rate 10°C/min.*

[1] DuPont Model 990 with DSC-cell 910.
[2] Mettler TA 2000.

temperature. Determination of the β-content of the products showed that all preparations had a final β:α ratio of ~1:1 (see Fig. 2). X-ray diffractograms of the samples that were heated to ~200°C proved to correspond to a crystalline β/α-lactose compound.

In conclusion, α-lactose monohydrate is found to lose its water of crystallization and like β-lactose, changes into an amorphous state on intensive grinding. Thermal treatment of both amorphous lactose and uncrystallized α-lactose monohydrate results in crystallization of a crystalline β/α-lactose compound. This is in contrast to uncrystallized β-lactose, which crystallizes into β-lactose.

Concentration Ratio Method to Determine the Rate Constant for the Special Case when $k_a = k_e$

Keyphrases □ Pharmacokinetics—one-compartment open model, concentration ratio method to determine rate constant

To the Editor:

In a one-compartment open model with first-order absorption and elimination processes, the plasma concentrations (C_p) of a drug at any time, t, after its extravascular administration are generally described by:

$$C_p = \frac{FDk_a(e^{-k_e t} - e^{-k_a t})}{Vd(k_a - k_e)} \qquad \text{(Eq. 1)}$$

where F is the fraction of dose (D) absorbed, k_a and k_e are absorption and elimination rate constants, respectively, and Vd is the apparent volume of distribution. In the special case where k_a is equal to k_e, Eq. 1 becomes mathematically indeterminable, and the general equation (Eq. 2) describing the $C_p t$ profile can be explicitly obtained by setting $k_a = k_e = k$ and using the standard integration technique:

$$C_p = \frac{FDkte^{-kt}}{Vd} \qquad \text{(Eq. 2)}$$

It was proposed recently by Chan and Miller (1) that the $C_p t$ data of this special case could be described by Eq. 1 using the nonlinear regression program NONLIN (2) provided there was at least a small difference between k_a and k_e. This analysis will yield similar values for k_a and k_e which will, in essence, identify equality between k_a and k_e. This approach, applied successfully by the authors to one data set containing 5% random noise, seemed superior to the one proposed by Bialer (3). The shortcomings of the latter were recently discussed by Barzegar-Jalali and Toomanian (4).

In this study, a simple plasma concentration ratio method is proposed to determine the rate constant k using plasma concentrations at any two consecutive times, t_{n-1} and t_n (as defined by Eq. 2):

$$C_p^{n-1} = \frac{FDkt_{n-1}e^{-kt_{n-1}}}{Vd} \qquad \text{(Eq. 3)}$$

and

$$C_p^{n} = \frac{FDkt_{n}e^{-kt_{n}}}{Vd} \qquad \text{(Eq. 4)}$$

Dividing Eq. 4 by Eq. 3, taking the natural logarithm of the resulting expression, and solving for k yields the following relationship:

$$k = \frac{\ln(t_n/t_{n-1}) - \ln(C_p^n/C_p^{n-1})}{(t_n - t_{n-1})} \qquad \text{(Eq. 5)}$$

Where k represents the estimated rate constant between the time interval t_{n-1} to t_n. Since a datum set will usually contain several plasma concentrations, k can be estimated for each time interval and averaged to obtain an overall estimate of k:

$$k = \frac{1}{n-1}\sum_{i=2}^{n}\frac{\ln(t_n/t_{n-1}) - \ln(C_p^n/C_p^{n-1})}{(t_n - t_{n-1})} \qquad \text{(Eq. 6)}$$

It is apparent from Eq. 5 that the proposed method does not require blood sampling at close intervals. Also, the proposed method is applicable to the entire time course of a drug and even to those cases where sampling schedule is limited and regression analysis of the $C_p t$ data according to Eq. 1 is not practical.

The concentration ratio method was compared against the approach of Chan and Miller (1) as well as the theoretical method (Eq. 2). Plasma concentrations with only rounding error were calculated at 0.25, 0.5, 1, 1.5, 2, 2.5, 3, 4, 5, 6, 8, 10, 12, 14, and 16 h using Eq. 2 with $FD/Vd = 10.0$ and $k = 0.5$. Twelve additional datum sets were generated by adding normally distributed random error with an RSD of ±10%. Each set was analyzed by curve-fitting the data to Eqs. 1 and 2 using the NONLIN program as well as by the present concentration ratio method. The curve-fitting of the data to Eqs. 1 and 2 was performed using the reciprocal of plasma concentration as a weighting function. The results are compared in Table I.

The nonlinear regression analysis of the $C_p t$ data according to Eq. 1 identified equality[1] of k_a and k_e in several cases (cases 1, 6–12, Table I). The estimated k_e values by Eq. 1 were smaller (>10%) than that estimated by Eq. 2 in 4 of 14 cases. The mean k_e value estimated by Eq. 1, 0.458, was 8% smaller

[1] Equality was identified when $k_a \pm SD$ overlapped $k_e \pm SD$.

Concentration Ratio Method to Determine the Rate Constant for the Special Case when $k_a = k_e$

Keyphrases □ Pharmacokinetics—one-compartment open model, concentration ratio method to determine rate constant

To the Editor:

In a one-compartment open model with first-order absorption and elimination processes, the plasma concentrations (C_p) of a drug at any time, t, after its extravascular administration are generally described by:

$$C_p = \frac{FDk_a(e^{-k_e t} - e^{-k_a t})}{Vd(k_a - k_e)} \qquad \text{(Eq. 1)}$$

where F is the fraction of dose (D) absorbed, k_a and k_e are absorption and elimination rate constants, respectively, and Vd is the apparent volume of distribution. In the special case where k_a is equal to k_e, Eq. 1 becomes mathematically indeterminable, and the general equation (Eq. 2) describing the $C_p t$ profile can be explicitly obtained by setting $k_a = k_e = k$ and using the standard integration technique:

$$C_p = \frac{FDkte^{-kt}}{Vd} \qquad \text{(Eq. 2)}$$

It was proposed recently by Chan and Miller (1) that the $C_p t$ data of this special case could be described by Eq. 1 using the nonlinear regression program NONLIN (2) provided there was at least a small difference between k_a and k_e. This analysis will yield similar values for k_a and k_e which will, in essence, identify equality between k_a and k_e. This approach, applied successfully by the authors to one data set containing 5% random noise, seemed superior to the one proposed by Bialer (3). The shortcomings of the latter were recently discussed by Barzegar-Jalali and Toomanian (4).

In this study, a simple plasma concentration ratio method is proposed to determine the rate constant k using plasma concentrations at any two consecutive times, t_{n-1} and t_n (as defined by Eq. 2):

$$C_p^{n-1} = \frac{FDkt_{n-1}e^{-kt_{n-1}}}{Vd} \qquad \text{(Eq. 3)}$$

and

$$C_p^{n} = \frac{FDkt_{n}e^{-kt_{n}}}{Vd} \qquad \text{(Eq. 4)}$$

Dividing Eq. 4 by Eq. 3, taking the natural logarithm of the resulting expression, and solving for k yields the following relationship:

$$k = \frac{\ln(t_n/t_{n-1}) - \ln(C_p^n/C_p^{n-1})}{(t_n - t_{n-1})} \qquad \text{(Eq. 5)}$$

Where k represents the estimated rate constant between the time interval t_{n-1} to t_n. Since a datum set will usually contain several plasma concentrations, k can be estimated for each time interval and averaged to obtain an overall estimate of k:

$$k = \frac{1}{n-1}\sum_{i=2}^{n}\frac{\ln(t_n/t_{n-1}) - \ln(C_p^n/C_p^{n-1})}{(t_n - t_{n-1})} \qquad \text{(Eq. 6)}$$

It is apparent from Eq. 5 that the proposed method does not require blood sampling at close intervals. Also, the proposed method is applicable to the entire time course of a drug and even to those cases where sampling schedule is limited and regression analysis of the $C_p t$ data according to Eq. 1 is not practical.

The concentration ratio method was compared against the approach of Chan and Miller (1) as well as the theoretical method (Eq. 2). Plasma concentrations with only rounding error were calculated at 0.25, 0.5, 1, 1.5, 2, 2.5, 3, 4, 5, 6, 8, 10, 12, 14, and 16 h using Eq. 2 with $FD/Vd = 10.0$ and $k = 0.5$. Twelve additional datum sets were generated by adding normally distributed random error with an RSD of ±10%. Each set was analyzed by curve-fitting the data to Eqs. 1 and 2 using the NONLIN program as well as by the present concentration ratio method. The curve-fitting of the data to Eqs. 1 and 2 was performed using the reciprocal of plasma concentration as a weighting function. The results are compared in Table I.

The nonlinear regression analysis of the $C_p t$ data according to Eq. 1 identified equality[1] of k_a and k_e in several cases (cases 1, 6–12, Table I). The estimated k_e values by Eq. 1 were smaller (>10%) than that estimated by Eq. 2 in 4 of 14 cases. The mean k_e value estimated by Eq. 1, 0.458, was 8% smaller

[1] Equality was identified when $k_a \pm SD$ overlapped $k_e \pm SD$.

[a] Mean k value (n = 14 time intervals). [b] ±10% random error. [c] Standard deviation (*SD*) in parentheses. The standard deviations reported for parameters estimated by Eqs. 1 and 2 are the standard deviation estimated by NONLIN program whereas the standard deviation obtained from concentration ratio method is the standard deviation of the calculated k values for each interval.

than the input value of k_e (0.5) or that estimated by Eq. 2. In contrast, the k values estimated by the concentration ratio method correspond well with those estimated by Eq. 2 (0.5). The concentration ratio method performed adequately when the $C_p t$ data were limited (Table II) and even when k_a was larger than k_e by 10% (Table III).

It must be noted that the nonlinear regression analysis of the $C_p t$ data in terms of Eq. 2 represents the most appropriate method to calculate the rate constant for the special case of the one compartment open model where $k_a = k_e$ (Tables I and II). The pharmacokinetic analysis of the data using Eq. 1 with the NONLIN program is, as suggested by Chan and Miller, the only method known to date to identify the equality between k_a and k_e. The proposed concentration ratio method represents a simple, complimental method which can be applied even in those cases with limited, $C_p t$ data when the model is identified *a priori*.

OPEN FORUM

Problems Involved with Developing a Suitable Model for Evaluating Exposure to Bis(2-ethylhexyl) Phthalate from Medical Devices

In a recent article, "Effect of Renal Failure and Bis(2-ethylhexyl) Phthalate Pretreatment on the Disposition and Metabolism of Antipyrine in the Rat" [1], Pollack and Shen presented an experimental model for studying chronic exposure of hemodialysis patients to bis(2-ethylhexyl) phthalate (I) [also known as di-2-ethylhexyl phthalate or DEHP]. Their model, however, utilized oral administration (intragastric intubation) of I rather than a parenteral route. Since the authors did not demonstrate that the effects of I upon antipyrine metabolism and disposition were the same when I was administered orally as when it is given parenterally, one must question acceptance of this as a suitable model for evaluating I exposures from hemodialyzers or other medical devices.

A number of reports, including those of Albro and Thomas[2], Rowland[3], and Lake *et al.*[4], indicate that orally administered I leads to absorption primarily of its hydrolytic product, mono-2-ethylhexyl phthalate or MEHP (II). Therefore, the proposed model[1] should be suitable for evaluating exposure to I from food packagings or other oral exposure, but in order for it to be accepted as a suitable model for clinical exposure to I from medical devices it will be necessary to demonstrate that the parameters evaluated are not affected by the route of administration of I.

There is no dispute that I is metabolized *in vivo* to produce II along with other metabolic products. However, the unanswered question in this case is whether or not the diester (I), to which the patient would initially be exposed intravenously during hemodialysis, *etc.*, would produce qualitatively and quantitatively similar effects on antipyrine metabolism and disposition prior to its metabolic conversion, as would the monoester (II) and other metabolic products. A number of reports have indicated differences in biological activity between I and II, or oral *versus* parenteral administration of I. Some of these reported differences include acute LD_{50}[5], *mutagenicity in bacterial systems*[6], *pentobarbital sleeping time* and effects on aminopyrine-*N*-demethylase and aniline hydroxylase[7], and mitochondrial (state 3) respiration[8].

The authors[1] commented on the findings of Agarwal *et al.*[7], that effects on enzyme activities were associated with the route of I administration, but then they dismiss these findings by attributing the differences to doses administered, not route of administration. However, an examination of the data[7] reveal that when an enzyme or biochemical system was affected by oral or parenteral administration of I (*a*) there was generally a dose-related response, and (*b*) comparisons of similar doses (5.2 and 13.0 po *versus* 5.0 and 10.0 ip) often produced markedly different responses.

Thus, because of the various literature reports (a few of which were cited) showing or suggesting a difference in biological activity between I and II or II plus other metabolites, the model proposed to study the effects of I, from artificial kidneys or other medical device exposure, on antipyrine metabolism and disposition cannot be accepted until it is demonstrated that I produces the same effects on these parameters when administered parenterally as when given by gastric intubation.

REVIEWS

USAN and the USP Dictionary of Drug Names, 1984 Ed. Edited by MARY C. GRIFFITHS. United States Pharmacopeial Convention, Inc., 12061 Twinbrook Parkway, Rockville, MD 20852. 1983. 640 pp. 21 × 28 cm. Price $45.00 (discounts for 11+ copies).

The 1984 cumulative edition of *USAN* contains over 18,500 nonproprietary (USAN and INN) and proprietary drug names in one compact volume. Most entries include current CAS names, graphic formulas, and manufacturers. Combined with the cross-index by pharmacologic-therapeutic category, list of CAS registry numbers, and appendix of molecular formulas, this volume constitutes a definitive source of information on drug substances used in the United States. A must for all researchers in the pharmaceutical field.

The Merck Index, 10th Ed. Edited by MARTHA WINDHOLZ. Merck & Co., P.O. Box 2000, Rahway, NJ 07065. 1983. 2052 pp. 18 × 25.5 cm. Price $28.50.

This encyclopedia of chemicals, drugs, and biological substances, now in its 94th year of publication, is internationally recognized as an authoritative reference work. Written and edited by the chemists of Merck & Co., the 10th edition continues in the tradition, incorporating the considerable new knowledge in the field that has accumulated in the 7 years since the 9th edition was published. This reasonably priced single volume of precise up-to-date data is an essential laboratory and library resource.

Cologne Atherosclerosis Conference No. I: Inflammatory Aspects. Edited by MICHAEL J. PARNHAM and JOHANNES WINKELMAN. Birkhäuser Boston, Inc., 380 Green Street, Cambridge, MA 02139. 1982. 265 pp. 16 × 24 cm. Price $31.95.

If one were to judge a book by its title, this one would be a disappointment. The title suggests an exposition of the role of inflammation in the siting and development of atherosclerosis. Instead, this is a monograph on inflammation, particularly as it relates to arthritis. Hopefully, the right audience will find the book.

The material is divided into three sections: six chapters on the role of the microvasculature in inflammation, five chapters on the role of various cell types in inflammation, and six chapters on the mediators of inflammation. The "Microvasculature in Inflammation" section is very well covered. The four presentations of Hensen, Williams, Bray, and Bjork form a cogent and provocative overview of the field. The second section, "Cells in Inflammation," is largely limited to a discussion of the monocyte/macrophage. With that constraint, the inflammatory panoply had to be selectively unfolded. This is not a serious problem since the role of the neutrophil was well covered in the first section and the lymphocyte, although in the background, is ever present as a regulator of macrophage activity. For an integrated account of the role of helper and suppressor lymphocytes in the maintenance of chronic inflammation, one would need to look elsewhere. The third section, "Mediators of Inflammation," is a potpourri of topics ranging from complement to oxygen radicals to antigen-induced arthritis. The contribution of Bitter-Sauermann on the role of complement in inflammation is outstanding as a succinct essay on complement C3a and C5a anaphylatoxin activation and regulation. The difficult task of integrating all of this material is attempted in a summary overview. It is noteworthy principally for reminding us of the plurality of cells, products, and processes involved in inflammation.

In addition, a number of narrow contributions are scattered throughout the three sections. They may appeal to the specialist, but for most they will add to the cost rather than the value of the volume. Overall, this multicontributor book has ample good articles to recommend it to those seeking an up-to-date, albeit selective, overview of inflammation as related to the arthritides. It cannot be recommended to those whose primary interest is atherosclerosis.

MARTINDALE: The Extra Pharmacopeia, 28th Ed. Edited by JAMES E. F. REYNOLDS and ANNE B. PRASAD. The Pharmaceopeial Press, 1 Lamberth High Street, London, SE1 7JN. Distributed in the U.S. by Rittenhouse Book Distributors, Inc., King of Prussia, PA 19406. 1982. 2025 pp. 21 × 25 cm. Price $130.00.

A 25% increase in information, extensive revisions, and 900 new monographs have been incorporated in the 28th edition of *Martindale*. This longstanding reference for pharmacists, which has evolved over a 100-year period, contains monographs of current, new, and investigational drugs grouped by class. Each monograph contains the chemical name, molecular weight and formula, proprietary names, literature documentation, and other information.

Although *Martindale* continues to place emphasis on drugs used in the U.K., it is international in scope, listing proprietary names from many different countries. With an index of drug names containing over 50,000 entries to provide easy access, this volume is an essential reference tool for all pharmaceutical scientists and libraries.

Drug Fate and Metabolism: Methods and Techniques, Vol. 4. Edited by EDWARD R. GARRETT and JEAN L. HIRTZ. Marcel Dekker, Inc., 270 Madison Avenue, New York, NY 10016. 1983. 504 pp. 15 × 23 cm. Price $75.00 (20% higher outside the U.S. and Canada).

This book is the fourth in a series, each volume of which represents a compilation of individually authored chapters. The topics treated are concerned with various aspects of drug disposition and analytical methods that are useful for quantitating and characterizing drugs and metabolites in biological fluids. The present volume contains a cumulative subject index for this and the previous volumes.

This volume contains six chapters covering a wide range of interests. The first chapter, "Computer Use in Pharmacokinetics," will be useful to those individuals currently employing or contemplating the use of computer programs for the pharmacokinetic analysis of data. There is a good basic discussion of the statistical foundation for curve-fitting routines and practical concerns that arise from such analyses. A particularly attractive aspect of this chapter is a series of appendices (18, 68 pages) that discuss analog computation (Appendix 1) along with a brief summary of many currently available digital computer programs. Each summary includes a description, subroutines, input requirements, output, limitations, and practical considerations. To this re-

The Merck Index, 10th Ed. Edited by MARTHA WINDHOLZ. Merck & Co., P.O. Box 2000, Rahway, NJ 07065. 1983. 2052 pp. 18 × 25.5 cm. Price $28.50.

This encyclopedia of chemicals, drugs, and biological substances, now in its 94th year of publication, is internationally recognized as an authoritative reference work. Written and edited by the chemists of Merck & Co., the 10th edition continues in the tradition, incorporating the considerable new knowledge in the field that has accumulated in the 7 years since the 9th edition was published. This reasonably priced single volume of precise up-to-date data is an essential laboratory and library resource.

Cologne Atherosclerosis Conference No. I: Inflammatory Aspects. Edited by MICHAEL J. PARNHAM and JOHANNES WINKELMAN. Birkhäuser Boston, Inc., 380 Green Street, Cambridge, MA 02139. 1982. 265 pp. 16 × 24 cm. Price $31.95.

If one were to judge a book by its title, this one would be a disappointment. The title suggests an exposition of the role of inflammation in the siting and development of atherosclerosis. Instead, this is a monograph on inflammation, particularly as it relates to arthritis. Hopefully, the right audience will find the book.

The material is divided into three sections: six chapters on the role of the microvasculature in inflammation, five chapters on the role of various cell types in inflammation, and six chapters on the mediators of inflammation. The "Microvasculature in Inflammation" section is very well covered. The four presentations of Hensen, Williams, Bray, and Bjork form a cogent and provocative overview of the field. The second section, "Cells in Inflammation," is largely limited to a discussion of the monocyte/macrophage. With that constraint, the inflammatory panoply had to be selectively unfolded. This is not a serious problem since the role of the neutrophil was well covered in the first section and the lymphocyte, although in the background, is ever present as a regulator of macrophage activity. For an integrated account of the role of helper and suppressor lymphocytes in the maintenance of chronic inflammation, one would need to look elsewhere. The third section, "Mediators of Inflammation," is a potpourri of topics ranging from complement to oxygen radicals to antigen-induced arthritis. The contribution of Bitter-Sauermann on the role of complement in inflammation is outstanding as a succinct essay on complement C3a and C5a anaphylatoxin activation and regulation. The difficult task of integrating all of this material is attempted in a summary overview. It is noteworthy principally for reminding us of the plurality of cells, products, and processes involved in inflammation.

In addition, a number of narrow contributions are scattered throughout the three sections. They may appeal to the specialist, but for most they will add to the cost rather than the value of the volume. Overall, this multicontributor book has ample good articles to recommend it to those seeking an up-to-date, albeit selective, overview of inflammation as related to the arthritides. It cannot be recommended to those whose primary interest is atherosclerosis.

MARTINDALE: The Extra Pharmacopeia, 28th Ed. Edited by JAMES E. F. REYNOLDS and ANNE B. PRASAD. The Pharmaceopeial Press, 1 Lamberth High Street, London, SE1 7JN. Distributed in the U.S. by Rittenhouse Book Distributors, Inc., King of Prussia, PA 19406. 1982. 2025 pp. 21 × 25 cm. Price $130.00.

A 25% increase in information, extensive revisions, and 900 new monographs have been incorporated in the 28th edition of *Martindale*. This longstanding reference for pharmacists, which has evolved over a 100-year period, contains monographs of current, new, and investigational drugs grouped by class. Each monograph contains the chemical name, molecular weight and formula, proprietary names, literature documentation, and other information.

Although *Martindale* continues to place emphasis on drugs used in the U.K., it is international in scope, listing proprietary names from many different countries. With an index of drug names containing over 50,000 entries to provide easy access, this volume is an essential reference tool for all pharmaceutical scientists and libraries.

Drug Fate and Metabolism: Methods and Techniques, Vol. 4. Edited by EDWARD R. GARRETT and JEAN L. HIRTZ. Marcel Dekker, Inc., 270 Madison Avenue, New York, NY 10016. 1983. 504 pp. 15 × 23 cm. Price $75.00 (20% higher outside the U.S. and Canada).

This book is the fourth in a series, each volume of which represents a compilation of individually authored chapters. The topics treated are concerned with various aspects of drug disposition and analytical methods that are useful for quantitating and characterizing drugs and metabolites in biological fluids. The present volume contains a cumulative subject index for this and the previous volumes.

This volume contains six chapters covering a wide range of interests. The first chapter, "Computer Use in Pharmacokinetics," will be useful to those individuals currently employing or contemplating the use of computer programs for the pharmacokinetic analysis of data. There is a good basic discussion of the statistical foundation for curve-fitting routines and practical concerns that arise from such analyses. A particularly attractive aspect of this chapter is a series of appendices (18, 68 pages) that discuss analog computation (Appendix 1) along with a brief summary of many currently available digital computer programs. Each summary includes a description, subroutines, input requirements, output, limitations, and practical considerations. To this re-

Drug Fate and Metabolism: Methods and Techniques, Vol. 4. Edited by EDWARD R. GARRETT and JEAN L. HIRTZ. Marcel Dekker, Inc., 270 Madison Avenue, New York, NY 10016. 1983. 504 pp. 15 × 23 cm. Price $75.00 (20% higher outside the U.S. and Canada).

This book is the fourth in a series, each volume of which represents a compilation of individually authored chapters. The topics treated are concerned with various aspects of drug disposition and analytical methods that are useful for quantitating and characterizing drugs and metabolites in biological fluids. The present volume contains a cumulative subject index for this and the previous volumes.

This volume contains six chapters covering a wide range of interests. The first chapter, "Computer Use in Pharmacokinetics," will be useful to those individuals currently employing or contemplating the use of computer programs for the pharmacokinetic analysis of data. There is a good basic discussion of the statistical foundation for curve-fitting routines and practical concerns that arise from such analyses. A particularly attractive aspect of this chapter is a series of appendices (18, 68 pages) that discuss analog computation (Appendix 1) along with a brief summary of many currently available digital computer programs. Each summary includes a description, subroutines, input requirements, output, limitations, and practical considerations. To this re-

viewer's knowledge, this is the first time that such information appears in one publication.

"Preanalytical Methodology for Drug Analysis in Biological Fluids" discusses a variety of factors that need to be considered prior to performing an assay (subject selection; collection, handling, and storage of specimens; storage, processing, and treatment of sample). Each type of biological fluid is discussed in turn, with consideration for each of the preceding factors (blood, saliva, bile, urine, and feces). The chapter has many useful practical suggestions, and several drug examples are used as illustrations. Over 300 references are provided.

"Isotope Derivatization Analysis" describes the principles of this analytical technique and how it may be applied to the determination of drugs and metabolites, with emphasis given to the double-isotope method. The advantages and limitations of the technique are discussed with respect to sensitivity and specificity. There is also a discussion of the development of this method for a needed application. Numerous examples are provided throughout the chapter.

"Electron Capture Gas-Liquid Chromatography in Drug Analysis" presents a thorough discussion of the operation of the electron-capture detector and its utility in the analysis of drugs and metabolites. There is an extensive compilation of information from the drug assay literature with over 250 references. Numerous practical considerations are presented, along with a comparison of this detector with electron-capture-negative chemical-ionization GC MS analysis.

The chapter on "Animal Species" addresses the question of which animal species is the best metabolic model for the human for a particular type of chemical structure. This chapter is based on a survey of the literature between 1970 and 1979 and is divided according to metabolic pathways under phase I and phase II reactions. There is an extensive compilation of data using the above classification in numerous tables which present compound, species, and the presence or absence of the metabolic product discussed.

The final chapter is entitled "Quantitative Pharmaco-EEG in Determining Bioavailability and Bioequivalency of Psychotropic Drugs." This chapter addresses a specific pharmacodynamic technique, electroencephalography, for the quantitative measurement of response to psychotropic drugs. The authors present a thorough discussion of this technique with numerous drug examples. This is a relatively new area which has promise for a variety of investigations.

The chapters of this book are well written, current, and thorough. The book is recommended to those readers who have a specific interest in or who require an overview of any of the individual topics covered. Certainly it is worthwhile library purchase.

Nutrition and Drugs. (Current Concepts in Nutrition, Vol. 12.) Edited by MYRON WINICK. Wiley-Interscience, 605 Third Avenue, New York, NY 10016. 1983. 206 pp. 16 × 23.5 cm. Price $40.00.

For various reasons most pharmacy schools provide little education in nutrition. But just as nutrition is important in maintaining proper health, it is also important in ensuring the proper response to drugs and in limiting their side effects. This volume provides a diverse group of topics on the subject of nutrition and drugs. The following list provides for each chapter the title, the first three authors, the chapter length in pages, and the number, average date, and percentage of reference citations published in 1978 and subsequent years:

1. "Drug-Vitamin B_6 Interaction," H. Bhagavan and M. Brin, 12, 22, 1972, 35%.
2. "Effects of Drugs on Cellular Transport of Nutrients," R. Branda, 16, 61, 1976, 50%.
3. "Vitamin D Metabolism and Metabolic Bone Disease," Z. Gaut, 20, 80, 1977, 58%.
4. "Alcohol, Protein Nutrition, and Liver Injury," C. Lieber, 24, 105, 1972, 25%.
5. "Drugs and Vitamin B_{12} and Folate Metabolism," J. Lindenbaum, 16, 79, 1975, 40%.
6. "Drugs in the Food Supply," S. Miller and J. Harris, 12, 0, none.
7. "Lipid-Lowering Drugs and Low Fat Diets," R. Palmer, 10, 0, none.
8. "Effect of Diet and Sulfonylurea Drugs on Insulin Resistance and Insulin-Receptor Function," F. Pi-Sunyer, 18, 99, 1974, 30%.
9. "Drugs and Nutrient Absorption," D. Roe, 10, 40, 1973, 22%.
10. "Appetite Regulation by Drugs and Endogenous Substances," A. Sullivan, J. Triscari, and L. Cheng, 30, 235, 1978, 65%.
11. "Drugs and Diet Therapy," A. Stunkard, 6, 0, none.
12. "Diuretics and Salt Restriction in Blood Pressure Control," S. Wassertheil-Smoller, H. Langford, M. Blaufox *et al.*, 16, 20, 1966, 38%.
13. "Vitamin A Analogs in Skin Disease," D. Windhorst, 12, 34, 1978, 62%.

Statistical results obtained for the entire volume and each chapter indicate some shortcomings of this volume. This book provides 765 published and 10 in-press citations with an average reference date of 1975; although 50% of the references cited were published in 1978 or later years, some 30% were published prior to 1975, a fact which questions use of the word "current" in the series title.

Overall quality control was poor. Some chapters were good; others were far less so. Aside from being well done, chapters 2, 3, 10, and 13 had 50–65% of the cited references published in 1978 and subsequent years. Chapters 1, 4, 5, 8, 9, and 12 are satisfactory, in general, but have reduced utility because of dated references; only 22–40% of the cited references were published in 1978 and later years. Chapter 12, with some of the most recent references in this group, also had some of the most dated references.

Although the content was interesting, a few chapters seem to detract from this work more than they support it. Chapters 6, 7, and 11 have no reference citations at all. Moreover, many of the missing references would seem critical to the point being made; their absence is astonishing.

There are a few instances where anticipated topics and citations were not mentioned. This diminished the breadth of the article. Specifically, chapter 5 makes no mention of the depletion of vitamin B_{12} by chronic cyanide ingestion, a fact based on substantial research. Furthermore, it was also surprising that no mention was made of food additives and the possible link to hyperactivity in certain children in the discussion of chapter 6.

The volume contained a satisfactory index and although most chapters were easily read, chapter 11 warrants mention because of its complex and lengthy sentence structure. One example is both sufficient and classic:

> "We recommend this because they act, I believe, by lowering the body weight set point, they do not rapidly lose their efficacy, at least in humans, tolerance does not develop, and therefore, when they are withdrawn, the body weight set point that had been artifically suppressed by the drug is elevated to the pretreatment level, resulting in very severe pressures upon people to regain the weight they lost with the aid of these drugs."

In summary, the highly variable quality and topical approach makes this volume more valuable to established libraries than to a general home library. While scientists actively engaged in research involving nutrition and drugs or pharmacology–toxicology will find this work useful, interest in this volume by many scientists will probably depend instead on the topic discussed. Because of limited prior exposure to this subject, pharmacists may find many of the topics to be refreshing and relevant both to their continuing education and to their dealings with a public increasingly fascinated by "nutrition" and dieting. Clearly, however, individuals interested in this subject should examine the work before purchase.

Progress in Drug Metabolism, Vol. 7. Edited by J. W. BRIDGES and L. F. CHASSEAUD. John Wiley and Sons, One Wiley Drive, Somerset, NJ 08873. 1983. 440 pp. 24 × 15 cm. Price $90.00.

Within this volume are six independent, authorative reviews consisting of a monograph on the renal excretion of drugs; the absorption, distribution, and excretion of two therapeutic classes of compounds; the metabolism and toxicity of two environmentally important compounds; and the relationship between metabolism and toxicity in the avian species. Each chapter is concise, well written, and includes pertinent structures and graphic illustrations. As in the

viewer's knowledge, this is the first time that such information appears in one publication.

"Preanalytical Methodology for Drug Analysis in Biological Fluids" discusses a variety of factors that need to be considered prior to performing an assay (subject selection; collection, handling, and storage of specimens; storage, processing, and treatment of sample). Each type of biological fluid is discussed in turn, with consideration for each of the preceding factors (blood, saliva, bile, urine, and feces). The chapter has many useful practical suggestions, and several drug examples are used as illustrations. Over 300 references are provided.

"Isotope Derivatization Analysis" describes the principles of this analytical technique and how it may be applied to the determination of drugs and metabolites, with emphasis given to the double-isotope method. The advantages and limitations of the technique are discussed with respect to sensitivity and specificity. There is also a discussion of the development of this method for a needed application. Numerous examples are provided throughout the chapter.

"Electron Capture Gas-Liquid Chromatography in Drug Analysis" presents a thorough discussion of the operation of the electron-capture detector and its utility in the analysis of drugs and metabolites. There is an extensive compilation of information from the drug assay literature with over 250 references. Numerous practical considerations are presented, along with a comparison of this detector with electron-capture-negative chemical-ionization GC MS analysis.

The chapter on "Animal Species" addresses the question of which animal species is the best metabolic model for the human for a particular type of chemical structure. This chapter is based on a survey of the literature between 1970 and 1979 and is divided according to metabolic pathways under phase I and phase II reactions. There is an extensive compilation of data using the above classification in numerous tables which present compound, species, and the presence or absence of the metabolic product discussed.

The final chapter is entitled "Quantitative Pharmaco-EEG in Determining Bioavailability and Bioequivalency of Psychotropic Drugs." This chapter addresses a specific pharmacodynamic technique, electroencephalography, for the quantitative measurement of response to psychotropic drugs. The authors present a thorough discussion of this technique with numerous drug examples. This is a relatively new area which has promise for a variety of investigations.

The chapters of this book are well written, current, and thorough. The book is recommended to those readers who have a specific interest in or who require an overview of any of the individual topics covered. Certainly it is worthwhile library purchase.

Nutrition and Drugs. (Current Concepts in Nutrition, Vol. 12.) Edited by MYRON WINICK. Wiley-Interscience, 605 Third Avenue, New York, NY 10016. 1983. 206 pp. 16 × 23.5 cm. Price $40.00.

For various reasons most pharmacy schools provide little education in nutrition. But just as nutrition is important in maintaining proper health, it is also important in ensuring the proper response to drugs and in limiting their side effects. This volume provides a diverse group of topics on the subject of nutrition and drugs. The following list provides for each chapter the title, the first three authors, the chapter length in pages, and the number, average date, and percentage of reference citations published in 1978 and subsequent years:

1. "Drug-Vitamin B_6 Interaction," H. Bhagavan and M. Brin, 12, 22, 1972, 35%.
2. "Effects of Drugs on Cellular Transport of Nutrients," R. Branda, 16, 61, 1976, 50%.
3. "Vitamin D Metabolism and Metabolic Bone Disease," Z. Gaut, 20, 80, 1977, 58%.
4. "Alcohol, Protein Nutrition, and Liver Injury," C. Lieber, 24, 105, 1972, 25%.
5. "Drugs and Vitamin B_{12} and Folate Metabolism," J. Lindenbaum, 16, 79, 1975, 40%.
6. "Drugs in the Food Supply," S. Miller and J. Harris, 12, 0, none.
7. "Lipid-Lowering Drugs and Low Fat Diets," R. Palmer, 10, 0, none.
8. "Effect of Diet and Sulfonylurea Drugs on Insulin Resistance and Insulin-Receptor Function," F. Pi-Sunyer, 18, 99, 1974, 30%.
9. "Drugs and Nutrient Absorption," D. Roe, 10, 40, 1973, 22%.
10. "Appetite Regulation by Drugs and Endogenous Substances," A. Sullivan, J. Triscari, and L. Cheng, 30, 235, 1978, 65%.
11. "Drugs and Diet Therapy," A. Stunkard, 6, 0, none.
12. "Diuretics and Salt Restriction in Blood Pressure Control," S. Wassertheil-Smoller, H. Langford, M. Blaufox *et al.*, 16, 20, 1966, 38%.
13. "Vitamin A Analogs in Skin Disease," D. Windhorst, 12, 34, 1978, 62%.

Statistical results obtained for the entire volume and each chapter indicate some shortcomings of this volume. This book provides 765 published and 10 in-press citations with an average reference date of 1975; although 50% of the references cited were published in 1978 or later years, some 30% were published prior to 1975, a fact which questions use of the word "current" in the series title.

Overall quality control was poor. Some chapters were good; others were far less so. Aside from being well done, chapters 2, 3, 10, and 13 had 50–65% of the cited references published in 1978 and subsequent years. Chapters 1, 4, 5, 8, 9, and 12 are satisfactory, in general, but have reduced utility because of dated references; only 22–40% of the cited references were published in 1978 and later years. Chapter 12, with some of the most recent references in this group, also had some of the most dated references.

Although the content was interesting, a few chapters seem to detract from this work more than they support it. Chapters 6, 7, and 11 have no reference citations at all. Moreover, many of the missing references would seem critical to the point being made; their absence is astonishing.

There are a few instances where anticipated topics and citations were not mentioned. This diminished the breadth of the article. Specifically, chapter 5 makes no mention of the depletion of vitamin B_{12} by chronic cyanide ingestion, a fact based on substantial research. Furthermore, it was also surprising that no mention was made of food additives and the possible link to hyperactivity in certain children in the discussion of chapter 6.

The volume contained a satisfactory index and although most chapters were easily read, chapter 11 warrants mention because of its complex and lengthy sentence structure. One example is both sufficient and classic:

> "We recommend this because they act, I believe, by lowering the body weight set point, they do not rapidly lose their efficacy, at least in humans, tolerance does not develop, and therefore, when they are withdrawn, the body weight set point that had been artifically suppressed by the drug is elevated to the pretreatment level, resulting in very severe pressures upon people to regain the weight they lost with the aid of these drugs."

In summary, the highly variable quality and topical approach makes this volume more valuable to established libraries than to a general home library. While scientists actively engaged in research involving nutrition and drugs or pharmacology–toxicology will find this work useful, interest in this volume by many scientists will probably depend instead on the topic discussed. Because of limited prior exposure to this subject, pharmacists may find many of the topics to be refreshing and relevant both to their continuing education and to their dealings with a public increasingly fascinated by "nutrition" and dieting. Clearly, however, individuals interested in this subject should examine the work before purchase.

Within this volume are six independent, authorative reviews consisting of a monograph on the renal excretion of drugs; the absorption, distribution, and excretion of two therapeutic classes of compounds; the metabolism and toxicity of two environmentally important compounds; and the relationship between metabolism and toxicity in the avian species. Each chapter is concise, well written, and includes pertinent structures and graphic illustrations. As in the

previous volumes, the relationships between drug levels, therapeutic response, and special disease states are discussed.

The following monographs are contained in this volume:

Chapter I, "The Renal Excretion of Drugs" (W. R. Hewitt and J. B. Hook), provides a comprehensive review of the important physiological processes whereby drugs are processed by the kidney. This excellent review contains 202 references.

Chapter II, "Pharmacokinetics and Metabolism of Diuretics" (R. M. J. Ings and L. A. Stevens), containing 436 references, has been devoted to the following classes of diuretics: carbonic anhydrase inhibitors, thiazides, loop and uricosuric agents, potassium-sparing agents, mercurials, and osmotic diuretics.

Chapter III, "Metabolism and Pharmacokinetics of Antihyperlipidaemic Agents" (M. N. Cayen), describes the absorption, distribution, metabolism, and excretion of the following therapeutic agents: clofibrate and congeners, nicotinic acid, and absorbable and nonabsorbable lipid-lowering agents. The review also contains discussions concerning drug interaction and the effects of this class of compounds on the liver. A total of 314 references have been cited.

Chapter IV, "Aliphatic Nitriles: Metabolism and Toxicity" (A. E. Ahmed and N. M. Trieff), contains 257 references. This chapter summarizes the metabolism, toxicity, and environmental impact of aliphatic saturated, unsaturated, and substituted nitriles.

Chapter V, "The Metabolism and Activation of Benzo[*a*]pyrene" (C. S. Cooper, P. L. Grover, and P. Sims), is an outstanding monograph in which the authors have compiled and reviewed the information in 447 references concerning the metabolism and activation of benzo[*a*]pyrene. The reaction of its metabolites with DNA and their involvement with mutagenesis are discussed.

Chapter VI, "Relationship Between Metabolism and Toxicity of Xenobiotics in Avian Species" (A. R. Buckpitt and M. R. Boyd), provides valuable insights into the use of the avian species to predict specific metabolites of a toxicant and its relationship to target tissue toxicity (82 references).

Pharmaceutical Quality Control. By Dr. WILLIAM F. HEAD, JR. Exposition Press, Inc., 325 Rabro Drive, Smithtown, NY 11787-0817. 1983. 90 pp. 15.5 × 23.5 cm. Price $8.00.

In 90 pages Dr. Head covers an enormous amount of information about the manufacture and control of pharmaceutical products. When you start to read such a short book on such a vast subject, there is considerable doubt that it is possible to do the subject justice.

In order to cover the subject of pharmaceutical quality control, which Dr. Head does reasonably well, he is forced to use a great many generalizations. The style in which the book is written could have the uninformed reader believing that the approach stated in the multitude of situations discussed is the only accepted way to perform the task being discussed. This is certainly far from the actual situation in the pharmaceutical industry. For example, there are several references to the use of stickers to identify the status of incoming, in-process, and finished products. The use of stickers is just one of several ways pharmaceutical companies identify the status of materials. Today more and more companies use computerized systems for inventory control and find these systems equally effective as the sticker system at a considerably reduced cost. This is not to say that the sticker system is no longer used or acceptable; there are probably many companies still using this system effectively.

This brings us to the critical issue of the audience for whom the book is written. The author singles out students of analytical and pharmaceutical chemistry, who have relatively little idea of the objectives of how to manage or work within a quality control organization. This is a limited audience. But, on careful examination it represents the initial work experience of many of the people who manage the quality control organizations of a large number of pharmaceutical companies. By reading this book, you will not learn what a quality control manager in the pharmaceutical industry does, you will not learn quality control statistics, nor will you learn the various skills of the quality engineer as they apply to the pharmaceutical industry. However, you will get a good view of many of the basic situations the quality control professional in the pharmaceutical industry frequently faces and how some companies handle these tasks.

The Sad State of Current Research Instruments

Ever since the 1980 U.S. Presidential election, there has been a greater than usual national debate on the subject of what constitutes the most appropriate level of federal spending for national defense. In particular, those who have advocated budgetary increases have emphasized the need for committing major expenditures for new and up-to-date military "hardware." Ships, tanks, and planes all are very expensive, but they enable a smaller army to achieve military superiority over a much larger force that is inferiorly equipped. In short, more "firepower" requires less "manpower" to achieve the same military capability.

We do not pretend to have any expertise in the area of national defense; therefore, we will not venture any opinion as to the relative merits of our military establishment's need for the added funds it has been requesting for major armaments. However, we do see a striking parallel here to the hardware needed to successfully wage another type of "battle."

The "battle" in this case is research, and the "hardware" is laboratory instruments—modern, up-to-date equipment that is capable of increasing the performance and "firepower" of the laboratory scientist just as surely and as dramatically as the advanced technology weaponry will for military personnel.

Consequently, the state of usefulness of laboratory research equipment in the nation's university research and development centers is a critical factor in considering how effectively and how efficiently these centers are able to fulfill their primary mission.

The National Science Foundation (NSF) felt that this critical question was one that needed to be addressed and answered. As a result, it surveyed the state of academic research equipment during calendar year 1982 in three selected fields—computer sciences, physical sciences, and engineering. As a second stage, data are now being collected for the agricultural, biological, environmental, and medical sciences. There is little reason to expect that the pattern found for these latter areas will differ significantly from the pattern found in the original three test areas. Hence, it warrants our attention and consideration.

The NSF issued its initial report in the April 18, 1984, issue of its publication "Science Resource Studies Highlights" (NSF document 84-312). The report title bluntly and concisely summarized the bottom line of the agency's study: "One-fourth of Academic Research Equipment Classified Obsolete."

The study report describes the considerations given to methodology, purchase price, age, funding patterns, utilization, and equipment adequacy. In particular, the study was limited to "research instrument systems costing from $10,000 to $1,000,000." In this manner, very simple and expendable equipment was eliminated, as well as ultra-costly items that are not really representative and could distort the overall data.

Selected excerpts from the highlights of the report provide considerable information and insight as to the status of the subject. A number of the key points that we found of special significance are as follows:

- *University researchers classified about one-fourth of the 22,300 items in their 1982 research equipment inventories as obsolete and no longer in research use.*
- *Of all academic research equipment listed in the 1982 inventories, only 16% was characterized as "state-of-the-art."*
- *About one-half of department chairpersons reported existing equipment to be "insufficient."*
- *More than 90% of the departmental chairpersons reported that the lack of equipment inhibited the conduct of critical research.*
- *One-half of all academic research instrument systems in use in 1982 were purchased within the previous 5 years, but 31 percent were more than 10 years old.*
- *Two-thirds of all academic research instrument systems in use during 1982 were acquired partly or entirely with federal funds.*
- *Each instrument system in use in 1982 was used by a median of seven researchers.*

Undoubtedly, many of our readers—and especially those in academic research centers—will find little, if any, of this surprising. It simply confirms what they have felt all along.

But the important point is that it *does confirm* what previously had been only claims and conjecture. Solid data is in hand to support those past critical assessments.

Now given this situation, what, if anything, can or should be done about it?

We have read other recent reports released by pertinent government agencies that have been at least equally critical—or more so—of the condition of the nation's interstate highway system, of its major bridges, of its dams, and even the national air traffic control system. Considering that hundreds and even thousands of lives may be at substantial risk due to those faulty, antiquated, or overtaxed systems, many citizens would argue that they require federal funding priority over new research instruments.

Furthermore, as noted above, one of the NSF survey findings is that two-thirds of instrument systems currently in use were already partially or totally funded by the federal government.

It would seem, therefore, that universities should look, and will need to look, to the private sector for increased support in this area. But the philanthropy of industry also has limits, and fairness to the consuming public as well as to company stockholders dictates that only so much money can be given away no matter how worthy the cause.

But what about "quid pro quo" arrangements? For example, the company that needs a nuclear magnetic resonance study conducted might donate such an instrument to a university with the explicit understanding that the university will conduct the study without additional funding support, except perhaps for incidentals. The equipment could then be used at spare time during the period of the study, and full-time thereafter, for whatever other research applications the university staff might find it appropriate.

The point is that the quality of our academic research laboratories is deteriorating badly, and the situation will continue to grow worse unless some concerted efforts and innovative actions are soon initiated.

RESEARCH ARTICLES

Pharmacokinetics of Capacity-Limited Tissue Distribution of Methicillin in Rabbits

FRANCIS M. GENGO *‡x, JEROME J. SCHENTAG‡, and WILLIAM J. JUSKO

Received December 8, 1982, from the *Departments of Pharmaceutics and Pharmacy, School of Pharmacy, State University of New York at Buffalo and ‡The Clinical Pharmacokinetics Laboratory, Millard Fillmore Hospital, Buffalo, NY 14209. Accepted for publication April 21, 1983.

Abstract □ Single-dose and steady-state studies were carried out in rabbits to characterize the pharmacokinetics of methicillin elimination and tissue distribution. Serum methicillin concentrations after single doses exhibited a biexponential decline with a mean terminal half-life of 27 ± 5 min. Steady-state volume of distribution (Vd_{ss}) decreased twofold as doses increased from 5 to 125 mg/kg, while total clearance was consistent over this dosage range. During steady-state infusions of 8.7–87.2 mg/kg/h, the serum and extravascular fluid concentrations increased in proportion to dose, while clearance remained constant. Methicillin tissue concentrations did not increase in proportion to dose and serum concentration, and the Vd_{ss} measured from tissue recovery decreased as dosage and serum concentrations increased. Central compartment volume and serum protein binding did not change. The cause of the dose-dependent change in Vd_{ss} was a capacity-limited uptake of methicillin into essentially all nonexcretory tissues. This process was described by a partial physiological pharmacokinetic model based on the actual weights or volumes of the rabbit tissues. Distribution into extracellular fluids was assumed to be complete, while entry into cellular, nonexcretory tissue became capacity limited as the K_m (17.2 μg/mL) was exceeded. The result was a decline in Vd_{ss} with increasing serum concentrations to a limiting value which approached the volume of the central space (V_c) and was similar to the extracellular water volume of the rabbit (0.17 L/kg). In the dosage range where total clearance was independent of serum concentration, the distribution of methicillin was concentration dependent and could be predicted by equations derived from the Michaelis–Menten equation.

Keyphrases □ Methicillin—pharmacokinetics in the rabbit, capacity-limited tissue distribution, single-dose and steady-state conditions □ Pharmacokinetics—methicillin in the rabbit, capacity-limited tissue distribution, single-dose and steady-state conditions □ Tissue distribution—capacity limited, methicillin, rabbits, pharmacokinetics, single-dose and steady-state conditions

Nonlinear disposition of drugs commonly occurs as a result of saturation in transformation, transport, or binding with or by biological substrates. Processes that are most frequently nonlinear are the enzyme-mediated active biotransformations of compounds, such as the metabolism of salicylates, ethanol, and phenytoin (1). Renal tubular secretory mechanisms of compounds such as *p*-aminohippuric acid are capacity limited (2), while tubular reabsorption of at least two cephalosporins is also a nonlinear process (3). Some radiocontrast agents such as iodipamide undergo apparent Michaelis–Menten-type biliary excretion in dogs (4). The GI absorption of some penicillins appear to be zero-order or capacity limited (5). Transport between CSF and blood is often active, as demonstrated for benzylpenicillin (6), but a generalized nonlinear tissue distribution pattern has not been reported for penicillins or any other drugs. If protein binding sites can be saturated to produce nonlinear kinetics, there is no reason why the same process cannot occur in the tissues (7). As an example of capacity-limited tissue binding, DiSanto and Wagner (8) have proposed a nonlinear tissue binding model to account for methylene blue distribution. Saturable or nonlinear plasma protein binding can have diverse effects on both drug distribution and clearance as evidenced with prednisolone (9).

The purpose of this report is to provide a pharmacokinetic description of methicillin serum and tissue concentrations in rabbits. The model incorporates capacity-limited transfer between extravascular fluid and tissues, and utilizes and tests transit time concepts to convert between single-dose and steady-state conditions.

THEORETICAL SECTION

Saturable tissue uptake and linear plasma clearance are the fundamental mechanisms proposed to describe the pharmacokinetics of methicillin over most of the dosage range of interest. A minimal model which describes the experimental data is shown in Fig. 1. The plasma and interstitial fluid comprise the central compartment (V_c), while remaining body tissues were considered as V_T. Total clearance, or the systemic plasma clearance of the drug (CL), occurs from the central compartment. Methicillin uptake into cellular spaces (CL_{12}) was nonlinear and Michaelis–Menten kinetics (T_{max}, K_m) were used to describe the rate-limiting mechanism. Return of drug from tissue to plasma (CL_{21}) was assumed to be linear.

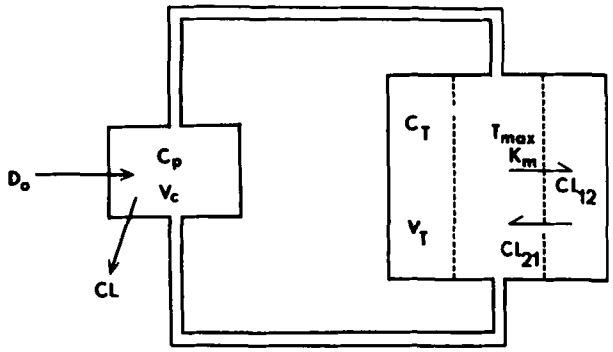

Figure 1—*Partial physiological model for methicillin distribution and clearance in the rabbit. The central volume (V_c) is assumed to comprise plasma and interstitial fluid, from which systemic clearance (CL) occurs. Remaining body tissues (V_T) attain drug concentrations (C_T) by nonlinear transport clearance [$CL_{12} = f(T_{max}, K_m)$] and linear distribution clearance (CL_{21}).*

The differential equations which describe serum (C) and overall tissue (C_T) concentrations are:

$$V_c \frac{dC}{dt} = -CL \cdot C - C \cdot CL_{12} + CL_{21} \cdot C_T \qquad \text{(Eq. 1)}$$

$$V_T \frac{dC_T}{dt} = CL_{12} \cdot C - CL_{21} \cdot C_T \qquad \text{(Eq. 2)}$$

where:

$$CL_{12} = \frac{T_{max}}{K_m + C} \qquad \text{(Eq. 3)}$$

reflects the nonlinear nature of tissue uptake of the drug. Unlike a perfusion model, where the concentration of drug in venous blood should be used in Eq. 2, V_T and C_T are employed here as the actual tissue (cellular) volumes and concentrations (excluding plasma and interstitial fluid). Equilibration between plasma and interstitial fluid was assumed to be very rapid in comparison with the rates of tissue uptake, and cellular transport or binding was considered to be the only mechanism for tissue uptake and retention. The nonlinearity of Eq. 3 prevents direct integration of these equations, but some of the model parameters can be estimated under initial, time-average, low-dose, and steady-state conditions.

Single-Dose Conditions—Serum concentrations following single intravenous bolus injections declined in a biexponential manner and were initially described by their SHAM (slope, height, area, moment) characteristics (10) with:

$$C = C_1^{-\lambda_1 t} + C_2^{-\lambda_2 t} \qquad \text{(Eq. 4)}$$

where C_i are intercepts and λ_i are slope values. These coefficients yield the total area (AUC) and first moment (AUMC) of each curve from:

$$\text{AUC} = \sum C_i/\lambda_i \qquad \text{(Eq. 5)}$$

$$\text{AUMC} = \sum \frac{C_i}{\lambda_i^2} \qquad \text{(Eq. 6)}$$

This permits calculation of mean transit time ($\bar{t}$) for each dose as:

$$\bar{t} = \text{AUMC}/\text{AUC} \qquad \text{(Eq. 7)}$$

The total plasma clearance of a drug is independent of distribution parameters (except for blood flow to the eliminating organ) and can be calculated from:

$$CL = \frac{D_0}{\text{AUC}} \qquad \text{(Eq. 8)}$$

where D_0 is the intravenous bolus dose. The volume of distribution at steady state (Vd_{ss}) can be obtained (11) as:

$$Vd_{ss} = CL \cdot \bar{t} \qquad \text{(Eq. 9)}$$

This parameter is generated initially as a time-average parameter, and its meaning and limitations will be described in more detail below. The volume of the central compartment is calculated from:

$$V_c = D_0/\sum C_i \qquad \text{(Eq. 10)}$$

If very small intravenous doses are used, the system operates under linear conditions, thus collapsing to the conventional two-compartment model within the context of this treatment. This permits the slope/intercept values to be defined as (7):

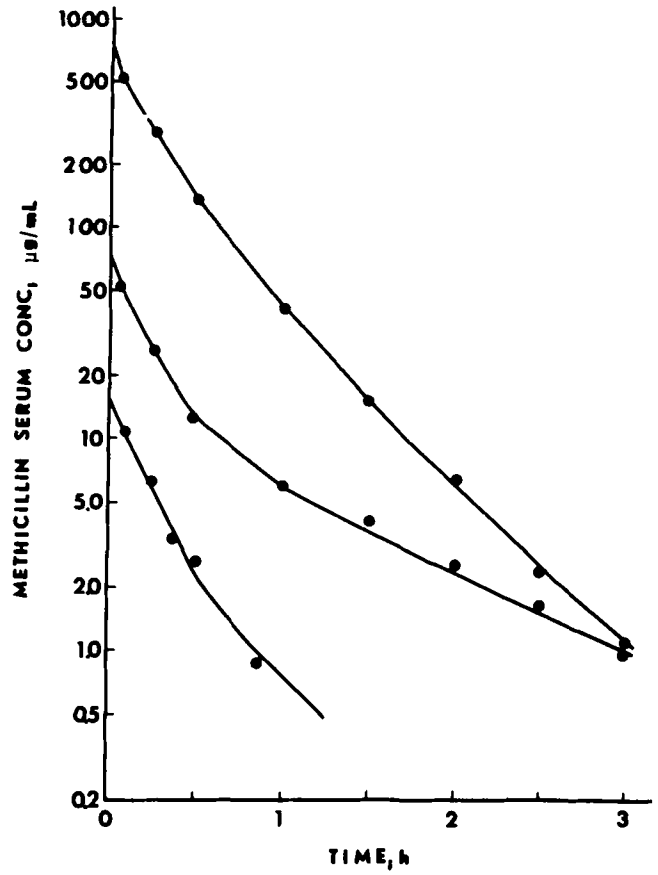

Figure 2—*Concentration-time course of 15-, 50-, and 500-mg/kg iv doses of methicillin in three different rabbits.*

$$\lambda_1 + \lambda_2 = CL/V_c + CL_{12}/V_c + CL_{21}/V_T = -b \qquad \text{(Eq. 11a)}$$

$$\lambda_1\lambda_2 = \frac{CL_{21} \cdot CL}{V_c \cdot V_T} = c \qquad \text{(Eq. 11b)}$$

$$\lambda_1,\lambda_2 = \frac{(-b \pm \sqrt{b^2 - 4c})}{2} \qquad \text{(Eq. 12)}$$

$$C_1 = \frac{D_0\left(\frac{CL_{21}}{V_T} - \lambda_1\right)}{V_c(\lambda_2 - \lambda_1)} \qquad \text{(Eq. 13)}$$

$$C_2 = \frac{D_0\left(\frac{CL_{21}}{V_T} - \lambda_2\right)}{V_c(\lambda_1 - \lambda_2)} \qquad \text{(Eq. 14)}$$

Estimates of the primary model parameters can be obtained, since CL, V_c, and Vd_{ss} are already solved. It is initially assumed (and will be demonstrated) that V_c and V_T have physiological meaning and represent the extracellular water and remaining body spaces of the animal. Thus:

$$V_T = \text{TBW}_t - V_c \qquad \text{(Eq. 15)}$$

where TBW_t is the total body weight of the animal. For convenience, these equations assume a body density of one, and thus body weight and volume are considered equivalent. From Eq. 11b we obtain:

$$CL_{21} = \frac{\lambda_1\lambda_2 \cdot V_c \cdot V_T}{CL} \qquad \text{(Eq. 16)}$$

thus providing CL_{12} from rearrangement of Eq. 11a:

$$CL_{12} = V_c(\lambda_1 + \lambda_2 - CL/V_c - CL_{21}/V_T \qquad \text{(Eq. 17)}$$

Alternatively, since (see below):

$$Vd_{ss} = V_c + \frac{CL_{12} \cdot V_T}{CL_{21}} \qquad \text{(Eq. 18)}$$

[a] Eq. 8. [b] Eq. 7. [c] Eq. 31. [d] Eq. 9. [e] Eq. 10. [f] Eq. 17. [g] Eq. 16.

a more direct solution is:

$$CL_{12} = \frac{CL_{21} \cdot (Vd_{ss} - V_c)}{V_T} \quad \text{(Eq. 19)}$$

Both Vd_{ss} and CL_{12} are time-average parameters when calculated in this manner and must be used cautiously when nonlinear conditions exist.

Steady-State Conditions—Ordinarily, the only pharmacokinetic parameter that can be obtained at steady state is the total clearance (CL). This value is usually calculated from the infusion rate (k_0) and the steady-state serum concentration (C^{ss}) as:

$$CL = k_0/C^{ss} \quad \text{(Eq. 20)}$$

However, the analysis and recovery of total body drug content (X_B^{ss}) also yields a direct value of Vd_{ss} from:

$$Vd_{ss} = X_B^{ss}/C^{ss} \quad \text{(Eq. 21)}$$

The conventional definition of Vd_{ss} is:

$$Vd_{ss} = V_c + \sum K_{pi} \cdot V_{ti} \quad \text{(Eq. 22)}$$

where K_{pi} and V_{ti} represent the partition coefficients and actual tissue weights or volumes for either the nonplasma or noncentral spaces of the body. In whole body terms, this can be written as:

$$Vd_{ss} = V_c + K_d \cdot \sum V_{ti} = V_c + (K_d \cdot V_T) \quad \text{(Eq. 23)}$$

where K_d is the overall tissue–serum distribution ratio. For the present model, K_d can be solved by considering steady-state conditions with Eq. 2 set to zero, yielding:

$$K_d = C_T^{ss}/C^{ss} = CL_{12}/CL_{21} \quad \text{(Eq. 24)}$$

or:

$$K_d = \frac{T_{max}}{CL_{21}(K_m + C^{ss})} \quad \text{(Eq. 25)}$$

or:

$$Vd_{ss} = V_c + \frac{T_{max} \cdot V_T}{(K_m + C^{ss})CL_{21}} \quad \text{(Eq. 26)}$$

With appropriate data, the unknown parameters of Eq. 26 can be solved by nonlinear least-squares iteration. To assist in resolution of such parameters, consider that as C^{ss} becomes very large ($C^{ss} \gg K_m$), the limiting value of Vd_{ss} is:

$$\lim_{C^{ss} \to \infty} Vd_{ss} = V_c \quad \text{(Eq. 27)}$$

At very low serum concentrations where linear distribution applies ($C^{ss} < K_m$):

$$\lim_{C^{ss} \to 0} Vd_{ss} = V_c + \frac{T_{max}V_T}{K_m \cdot CL_{21}} \quad \text{(Eq. 28)}$$

A typical Michaelis-Menten function usually has sufficient degrees of freedom to solve only two parameters. Equation 26 contains five parameters. In the present study, the single-dose experiments and large-dose infusions yield values of V_c (Eqs. 10 and 27). Retaining physiological equivalence for V_T permits its calculation from Eq. 15. The upper limit of CL_{12} (the quotient of T_{max}/K_m) and CL_{21} can be generated from single low-dose data (Eqs. 16 and 19). This leaves one unknown parameter. If Eq. 26 is rearranged to:

$$G = CL_{21} \cdot \frac{Vd_{ss} - V_c}{V_T} = \frac{T_{max}}{K_m + C^{ss}} \quad \text{(Eq. 29)}$$

then, the function G *versus* C^{ss} can be cast into linear form:

$$1/G = K_m/T_{max} + C^{ss}/T_{max} \quad \text{(Eq. 30)}$$

where a graph of $1/G$ *versus* C^{ss} yields a slope of $1/T_{max}$ and the ordinate intercept is K_m/T_{max}. However, by this stage the function G contains several inserted parameters and may be inaccurate. Thus, Eq. 30 is most useful for obtaining initial estimates. This allows the least-squares values of CL_{21}, T_{max}, and K_m to be generated by NONLIN curve-fitting of Eq. 26, using individual values of V_c and V_T from each animal and Vd_{ss} and C^{ss} as the dependent and independent variables. Because an array of T_{max} and CL_{21} values would yield an identical Vd_{ss} in Eq. 26, it is important to obtain reasonable parameter estimates to initiate computer fitting and to restrict the upper limit of T_{max}/K_m to CL_{12} as generated from the low-dose data (Eq. 3).

Single-Dose to Steady-State Conversion—For drugs with linear pharmacokinetic properties, any single-dose parameters apply directly to the steady-state situation. For drugs with nonlinear CL or Vd_{ss}, the parameters generated using Eqs. 8 and 9 were obtained as time-average values and must be considered valid only for the corresponding time-average serum concentration C_{av}. This is easily calculated as:

$$C_{av} = \text{AUC}/\bar{t} \quad \text{(Eq. 31)}$$

Thus, the equivalence between single-dose and steady-state conditions can be described as:

$$CL = \frac{k_0}{C_{av} \text{ or } C^{ss}} \quad \text{(Eq. 32)}$$

and:

$$Vd_{ss} = \frac{X_B^{ss}}{C^{ss}} = \frac{D_0}{C_{av}} \quad \text{(Eq. 33)}$$

These concepts are experimentally tested in this report.

EXPERIMENTAL SECTION

Protocol—A total of 31 male New Zealand White rabbits ranging in weight from 2.5 to 5.5 kg were studied. Fifteen animals were given single, rapid intravenous bolus doses of methicillin ranging from 5.0 to 125.0 mg/kg. Blood samples were collected from the marginal ear vein over the following 7 h.

Another group of 11 rabbits were given methicillin by constant infusion through a jugular vein catheter. Dosages ranged from 8.6 to 87.2 mg/kg/h, and infusion times ranged from 6.5 to 10 h. Cumulative total urine was collected from all of the animals over the next 24-h period, or until sacrifice. Five additional rabbits (2.5–2.7 kg) were each given a 15-, 50-, and 500-mg/kg bolus dose on different days in random sequence. Blood samples were collected from the marginal ear vein.

For collection of extravascular fluid, 5 of the 31 rabbits had perforated plastic balls (17-mL capacity) placed subcutaneously at 10–14 d prior to the methicillin infusion. In the other rabbits, peritoneal fluid was collected at sacrifice in a capillary tube or onto filter disks. The preweighed filter disks were placed in the abdominal cavity immediately after the animals were

[a] Eq. 20. [b] Eq. 21.

sacrificed. Fluid in the abdominal cavity was tested for occult blood[1]; only negative samples were used for analysis.

At the end of the sampling procedures, all rabbits given continuous infusion were sacrificed, and samples of essentially all organs and tissues were obtained for methicillin assay. Urine was collected from the intact bladder. All organs and the remaining carcass were weighed for use in determining the organ content of methicillin.

Assays—Methicillin concentrations in serum, peritoneal fluid, and urine were determined by an agar well diffusion microbiological assay as outlined by Kavanaugh (12) using *Bacillus subtilis* as the test organism. The range of concentrations assayed without dilution was 0.5–25.0 μg/mL, and the day-to-day coefficient of variation was <10%. Samples were assayed in triplicate on two or more occasions and quantitated in reference to appropriate standards prepared in blank tissue homogenate, urine, or pooled rabbit serum. Plasma protein binding was measured by equilibrium dialysis at 37°C.

Tissue concentrations were determined by methods similar to those used previously (13). Necropsy samples were blotted on gauze and two 100–200-mg samples were weighed to be within 10 mg of each other. Each sample was individually homogenized following the addition of 1–2 mL of phosphate buffer (pH 7.4). To one of the two samples, a known amount of methicillin was also added. Samples were allowed to stand for 24–48 h at 4°C and then centrifuged. The supernatant was assayed using the microbiological assay and homogenate standards. The phosphate buffer in the homogenized tissue was replaced, and the extraction procedure was repeated until no further methicillin could be measured.

Extraction recovery was calculated using the following:

$$\frac{\begin{pmatrix}\text{Methicillin recovered}\\ \text{from "spiked" sample}\end{pmatrix} - \begin{pmatrix}\text{Methicillin recovered}\\ \text{from "unspiked" sample}\end{pmatrix}}{\text{Amount of Methicillin "spiked"}} \quad \text{(Eq. 34)}$$

The fractional extraction recovery using this method ranged from 0.9 to 1.05 in all tissues.

Tissue concentrations were calculated by dividing the amount recovered from a tissue sample by the weight of the tissue sample. The total amount recovered from each animal was the product of the specific organ concentration and the individual organ weight. The sum of all tissue weights in each animal approximated the total body weight minus the total weight of any GI contents and urine.

RESULTS

Single-Dose Pharmacokinetics of Methicillin—Following single bolus doses of methicillin, serum concentrations declined in a biexponential fashion, as shown for three representative rabbits in Fig. 2. Such profiles were fitted to Eq. 4 by nonlinear least-squares regression (14). The SHAM properties were then inserted into Eqs. 7–17 to obtain the pharmacokinetic parameters describing clearance and distribution in the 15 rabbits given single doses. These data are given in rank order of dose in Table I, and show that the average serum concentration remains proportional to dose with increasing doses, while the plasma clearance remained essentially constant, averaging 0.60 ± 0.15 L/h/kg. The terminal half-life averaged 27 ± 2 min in the rabbits. The other parameters that remained constant over this dosage range were V_c, which averaged 0.20 ± 0.03 L/kg, and CL_{21}, which averaged 1.86 ± 0.60 L/h/kg. The t, Vd_{ss}, and CL_{12} values varied with dose. Vd_{ss} decreased by approximately twofold as the dose covered a 10-fold range. The change in t with dose was a direct result of the Vd_{ss}/CL ratio, as the plasma clearance remained unchanged with increasing doses. The distributional clearances (CL_{12}) listed in Table I exhibited a fourfold range (0.10–0.35 L/kg/h) with increasing doses of methicillin.

[1] A Hemoccult pad was placed in the abdominal cavity next to the collection tube or filter disk.

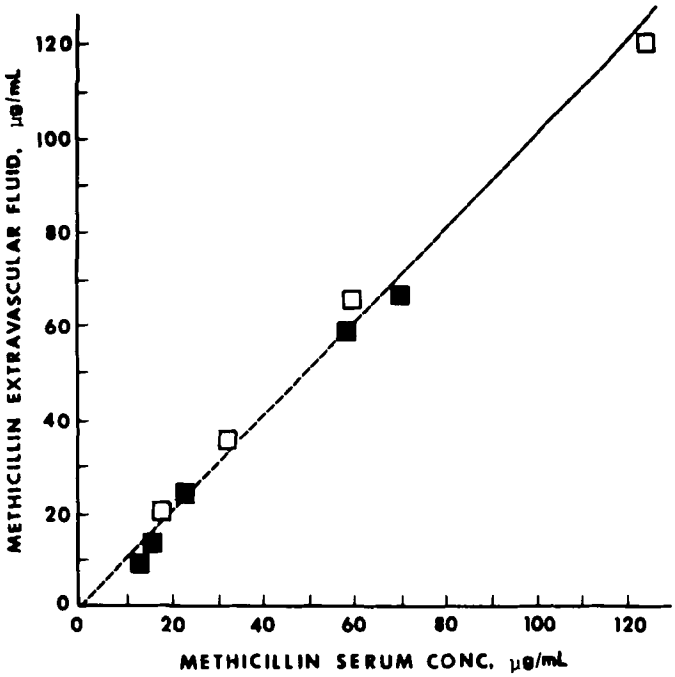

Figure 3—*Simultaneous steady-state concentrations of methicillin in serum and extravascular fluids: Key: (■) tissue chamber fluid; (□) peritoneal fluid.*

To assess the possibility of protein binding changes altering the distribution volume, we measured protein binding by equilibrium dialysis on serum samples over a 20-fold range of serum concentrations. The binding of methicillin to serum proteins averaged 17 ± 2%.

Methicillin Pharmacokinetics after Continuous Infusions—Methicillin was infused into 11 different rabbits for 6–10 h. The infused doses, clearances, volumes of distribution, total body methicillin content (X_B^{ss}), and serum concentrations measured at steady state are listed in Table II for each of these rabbits. The C^{ss} values were proportional to the infusion rate, yielding relatively constant CL values which averaged 0.86 ± 0.19 L/kg/h. These values were in good agreement with the single dose CL values of Table I. As was observed in the single-dose rabbits, Vd_{ss} steadily declined as doses and steady-state serum concentrations increased.

Steady-State Extravascular Fluid Distribution—Table III gives the steady-state serum drug concentrations for all 11 rabbits, ranging from 13.0 to 125.0 μg/mL. As serum concentrations increased as a result of the increasing dosing rates, a proportional rise was noted in the extravascular fluid concentrations, *i.e.*, both the tissue chamber and peritoneal fluid. The data indicate complete and dose-independent penetration of methicillin into extravascular fluids, as shown by the identity line in Fig. 3.

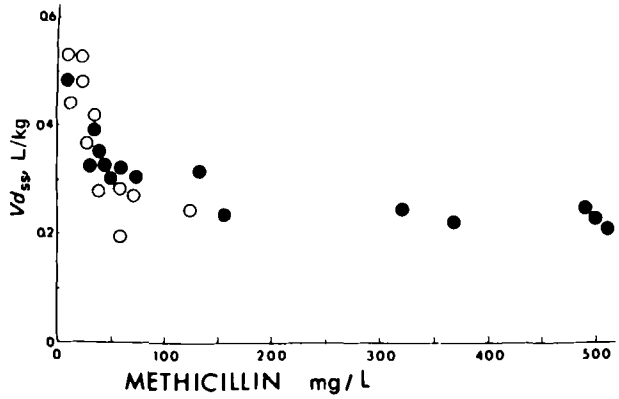

Figure 4—*Steady-state volume of distribution following a single dose (●) and constant infusion (○) of methicillin in relation to time average (C_{av}) and steady-state (C^{ss}) serum drug concentrations.*

26	125.0 ± 6.3	120.0[d]	31.0	35.0	35.0	24.0

[a] Steady-state methicillin serum concentration verified by measurement every 30 min over the 6-10-h infusion period (values ± *SD*). [b] Steady-state methicillin concentration measured in fluid obtained from a subcutaneously implanted perforated plastic catheter. [c] Methicillin concentrations measured at the time of sacrifice, immediately following the infusion. [d] Peritoneal fluid samples. [e] Not analyzed because sample contained occult blood.

The methicillin content of the bile was <5% of the infused dose, but represented only the bile present in the gallbladder at the time of sacrifice. The volume of bile that entered the GI tract during the infusion period was not assessed.

Urinary Excretion—Urine collected over the first 24 h from animals receiving single doses of methicillin contained 80 ± 2% of the administered dose. In animals infused to steady state and sacrificed, urine was collected from the intact bladder at the end of infusion. Greater than 85% of the administered dose could be accounted for in the serum, tissue, and urine of this group of rabbits. The percentage of the total dose that appeared in the urine at the time of sacrifice consistently increased as the cumulative dose infused increased. At the lowest infusion dose, 67% of the dose appeared in the urine, while at the highest dose, 96% of the total dose appeared in the urine. Despite this finding, the total body clearance of methicillin in these two rabbits was similar: 0.67 and 0.69 L/kg/h.

In vitro experiments revealed that methicillin was not completely stable in rabbit urine. The half-life for methicillin degradation in rabbit urine maintained at 39°C averaged 31 ± 4 h. If a degradation rate constant is incorporated into the urine recovery and the total amount of methicillin excreted in the bile estimated, essentially all of the total infused dose can be accounted for in the rabbits sacrificed at steady state.

Steady-State Tissue Penetration—The steady-state concentrations of methicillin in representative nonexcretory tissue are listed in Table III along with simultaneous C^{ss} and extravascular fluid concentrations. Unlike steady-state serum and extravascular concentrations, steady-state concentrations in nonexcretory tissue did not increase proportionally with increases in infusion rate. Steady-state tissue concentrations seemed to reach an apparent plateau as steady-state serum concentrations exceeded 25–30 μg/mL. Furthermore, the total amount in the body at the time of sacrifice (X_B^{ss}) appeared to approach a maximum value as infusion rates increased. Steady-state kidney concentrations of methicillin were generally 10-fold greater than concentrations in nonexcretory tissue, and the plateau of concentrations with increased doses was less marked. However, true renal tissue concentrations could not be discerned because we were also measuring drug in retained urine in the kidney samples.

Consistent with the individual values in tissue, the total amount of methicillin recovered from each rabbit at steady state also failed to increase proportionally to increased infusion doses, as shown in Table III. The steady-state volume of distribution of methicillin varied over twofold, but values consistently diminished as steady-state concentrations were increased with increasing dosing rates.

Nonlinear Steady-State Volume of Distribution—The nonlinear relationship between Vd_{ss} and methicillin steady-state serum concentrations can be evaluated directly from the data in Table II. The single-dose studies in Table I yield time-average Vd_{ss} values which can be assessed only at the time-average serum concentration (C_{av}). Figure 4 depicts all methicillin Vd_{ss} values in relation to either C_{av} or C^{ss}; these data are consistent with a single nonlinear curve. It should be noted that the largest C_{av} range produced Vd_{ss} values which approach a limiting value of ~0.20 L/kg, similar to the mean central compartment volume of distribution.

The decline in both Vd_{ss} and CL_{12} with increasing C^{ss} suggested that limiting tissue uptake was a common factor. Equation 26 was employed to characterize the data of Fig. 4 in the following manner. The NONLIN computer program was used to fit individual Vd_{ss} values as a function of actual C_{av} from each animal dosed by rapid intravenous bolus doses. Individual values of V_c were available, and specific values of V_T were then directly calculated for each animal using Eq. 15. This left three unknown parameters, T_{max}, K_m, and CL_{21}. These were generated using least-squares regression. Initial estimates were obtained as described in the *Theoretical Section.*

The mean (± *SD*) least-squares values which described the nonlinear extravascular penetration of methicillin in the rabbit following single intravenous bolus doses were: T_{max} = 9.79 ± 4.3 mg/kg/h; K_m = 17.2 ± 7.0 μg/mL; and CL_{21} = 1.02 ± 0.6 L/kg/h. To test the ability of this model to predict distribution at steady-state from single-dose data, the parameter estimates from the single-dose data were used to calculate the Vd_{ss} in animals infused to steady state, using Eq. 26. As shown in Fig. 5, these calculated values were in good agreement with the measured values in all rabbits infused to steady state.

Multiple Single Doses—Additional studies were performed using a wider range of single doses (15–500 mg/kg) in crossover fashion to further examine the linearity of the disposition of methicillin. The *CL* from Eq. 8 and Vd_{ss} from Eq. 9 following these doses of methicillin in each of five rabbits are shown in Table IV. The Vd_{ss} following the 15-mg/kg dose was significantly larger than the Vd_{ss} following the 50-mg/kg dose. The Vd_{ss} changes are in agreement with those predicted in previous rabbits given large doses of methicillin either by rapid bolus or continuous infusion. The Vd_{ss} following the 500-mg/kg doses approximates the total extracellular fluid volume of 0.17 L/kg in New Zealand White rabbits (15).

The 500-mg/kg methicillin dose yielded a lower clearance compared with those following the lower doses. The *CL* values from the lower doses were similar. These data indicate that the assumption of linearity in total methicillin clearance is tenable only over a limited dose and concentration range.

DISCUSSION

Disposition in Rabbits—From measurements of the drug in serum and urine, it appears that methicillin is primarily cleared by the kidney and excreted in the urine of the rabbit. This is in agreement with other reports of methicillin pharmacokinetics in rabbits (16) and is also consistent with human studies (17). The renal clearance of methicillin, like other penicillins, has been attributed to both glomerular filtration as well as active tubular secretion (18). Concomitant administration of organic acids such as *p*-aminohippuric acid and probenecid have shown to competitively inhibit the active secretion process (19, 20). At sufficiently high methicillin concentrations, renal clearance also becomes nonlinear, as was observed after single 500-mg/kg doses in these studies (Table IV). The model assumptions only apply to the region of linear clearance.

There was a consistent, near-total recovery of the infused dose of methicillin from tissue, serum, and urine in all animals dosed to steady state, regardless of the total dosage. Furthermore, the unrecovered drug can be accounted for by the instability of methicillin in rabbit urine and incomplete collection of bile. Thus, the pharmacokinetic model can be applied in a setting where mass balance is essentialy complete without uncertainties related to incomplete tissue extraction or analytical difficulties. The pharmacokinetic characterization of serum concentration *versus* time profiles yielding nonlinear tissue distribution properties was directly confirmed by analysis of actual tissue drug uptake. This diminishes the need for speculative inferences regarding the physiological relevance of the pharmacokinetic analysis of only serum concentrations.

Tissue Distribution—The distribution of methicillin into extravascular spaces can be described by two processes. Methicillin distributed freely and rapidly between serum and extravascular fluids since peritoneal fluid and tissue chamber fluid concentrations are in good agreement with serum concentra-

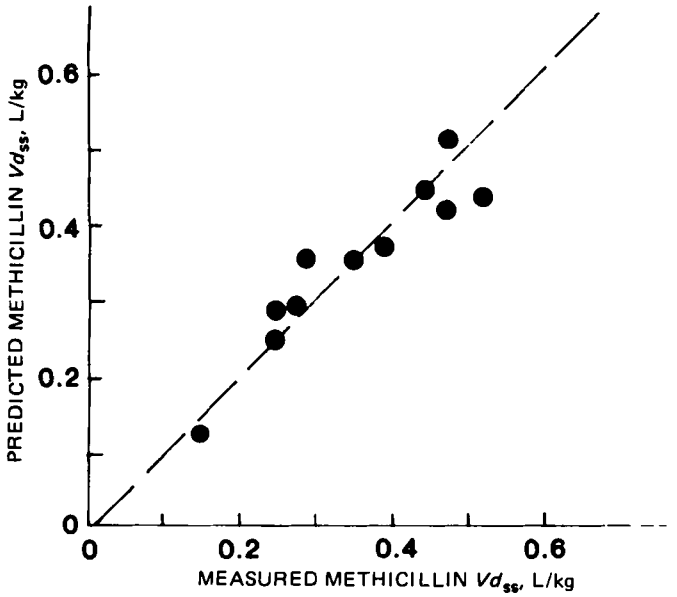

Figure 5- *Agreement between predicted* Vd_{ss} *(Eq. 26) using the* V_c, V_T, T_{max}, K_m, *and* CL_{21} *values obtained from single-dose studies and measured* Vd_{ss} *based on recovery of drug from body tissue.*

tions, even following single doses. This process is a simple linear relationship. Similar findings with other penicillins have been reported in animals (21) and in humans (22). In contrast, the intracellular distribution of methicillin appears to be governed by a different process. A plateauing of steady-state tissue concentrations occurred as C^{ss} exceeded 20–25 μg/mL. Linear uptake occurs at low serum concentrations, but saturation begins to occur as the K_m (17 μg/mL) is exceeded. Each tissue analyzed contains cells, interstitial fluid, and trapped blood. Interstitial fluids are in rapid equilibrium with drug in plasma (Fig. 3). When the conglomerate of tissue and interstitial fluid is homogenized for assay, measured concentrations of methicillin continue to rise slightly as C^{ss} increases, but not to a proportional degree. Apparently, interstitial fluid concentrations continue to parallel serum, while true tissue concentrations reach a limiting value. Similar tissue penetration data using ampicillin have recently been reported by Cars and Ogren (23). Skeletal muscle concentrations of ampicillin were substantially lower than serum concentrations, but concentrations declined at a similar rate from both tissue and serum. They, like we, suggest that ampicillin concentrations in interstitial fluid are considerably higher than whole tissue concentrations.

The capacity-limited nature of methicillin tissue distribution in rabbits was best described by a pharmacokinetic model incorporating a linear systemic clearance and a Michaelis-Menten-type, nonlinear distributional clearance. The unique pharmacokinetic manifestation of the nonlinear distributional clearance is that the Vd_{ss} changes as serum concentrations or doses change. At high serum concentrations, Vd_{ss} approaches its minimal value, which is V_c. This occurs following both rapid intravenous bolus or steady-state infusion of the drug. The volume of the central compartment was consistent for all rabbits and was independent of dose. The central volume takes on physiological significance because it is slightly larger than the value for extracellular fluid volume in New Zealand White rabbits (15). The excellent agreement between measured concentrations of methicillin in serum and extravascular fluids confirms that V_c is comprised of the plasma and interstitial volumes. The tissue volume V_T also retains physiological significance because it is simply the summation of the tissue weights excluding the weight of blood and interstitial fluids.

This is not the first observation of an apparent capacity-limited process with penicillins. Active processes for tubular secretion have been known. The active tubular secretion of penicillins can be saturated (24) and inhibited by *p*-aminohippuric acid (19). Saturable renal tubular processes have also been observed following the administration of mezlocillin (25), cephapirin (3), and cephaloridine (3) to human volunteers. This also appears to occur for methicillin at very high doses.

Regarding tissue uptake, Bergholtz *et al.* (26) reported that probenecid, an inhibitor of the active secretion of penicillin, can affect skeletal muscle concentrations of penicillin. Pappenheimer *et al.* reported an active transport process for the movement of organic acids from CSF to plasma (27) which has been shown to be operative for benzylpenicillin (6). There are numerous reports of penicillin neurotoxicity following massive dosing, presumably overwhelming the central nervous system active transport system for penicillin

Table IV—Methicillin Clearance and Vd_{ss} in Five Rabbits, Each Given Three Doses of Methicillin in Randomized Order

	Clearance, L/h/kg			Vd_{ss}, L/kg		
Rabbit	15 mg/kg	50 mg/kg	500 mg/kg	15 mg/kg	50 mg/kg	500 mg/kg
27	0.97	0.70	0.55	0.42	0.27	0.19

		$p < 0.05$		$p < 0.05$		

removal (28, 29). Studies by Fishman (30) suggest that probenecid may cause CNS accumulation of penicillin.

Similar active transport systems have been proposed to explain the concentration dependence of ampicillin excretion into bile (31). Recent data obtained from rats suggest that the absorption of amino penicillins is best described by Michaelis-Menten kinetics and postulate that similar saturable absorption processes govern cephalexin and cephradine absorption (5).

In addition to concentration dependence in renal and biliary secretion and GI absorption, another recently described concentration-dependent process with β-lactam antibiotics occurs with protein binding. The third generation caphalosporin, ceftriaxone, is a particularly good example of this phenomenon, as the saturation of binding occurs at plasma concentrations in the usual therapeutic range (32).

Concentration-dependent tissue distribution has not been described for β-lactam antibiotics. The data presented here for methicillin suggest that essentially all nonexcretory tissues can be involved in this process, and establish a limit to achievable "tissue" concentrations for these antibiotics. Such an observation, if confirmed for other β-lactam antibiotics, has clinical relevance to the treatment of infection. However, not only do other drugs need study for similar concentration dependence, but also it is not yet possible for the data presented to differentiate whether this phenomenon is caused by capacity limits in binding to tissue proteins or a saturable cellular uptake process. It does appear from these data that whichever the underlying mechanism, the process limits the concentrations of methicillin that can be realistically achieved in normal tissue.

Transit Times—An innovative approach was evolved to relate a single-dose disposition of methicillin to true steady-state conditions. The analysis of single-dose kinetics based on the SHAM characteristics is valid for linear conditions, but entails the generation of dose and time-average pharmacokinetic parameters in the nonlinear dosage range. In the latter case, these time-average parameters ought to directly apply to steady-state conditions only at an equivalent time-average substrate concentration. This was confirmed experimentally for Vd_{ss} (Fig. 4, Table IV) and by the dual characterization of single-dose and steady-state data with a single nonlinear function (Eq. 26). Other uses of transit-time analysis have been reviewed recently (33).

APPENDIX: GLOSSARY

Concentrations

C	Serum or plasma concentration
C_T	Mean tissue concentration
C^{ss}	Steady-state serum concentration
C_i	Intercepts of C_p *versus* time curve
C_{av}	Time-average serum concentration
K_m	Michaelis-Menten constant for transport

Time

t	Experimental time
$\bar{t}$	Mean transit time

Slopes

λ_i	Slope of C_p *versus* time curve

Integrals

AUC	Area of C_p *versus* time curves
AUMC	Area of $t \cdot C_p$ *versus* time curve (moment)

Volumes, Weights

V_c	Volume of plasma and interstitial fluid
Vd_{ss}	Steady-state volume of distribution
TBW_t	Total body weight
V_T	Cellular tissue volume
V_{Ti}	Individual tissue weights

Clearances

CL	Systemic plasma clearance

CL_{12}	Clearance from plasma to cell water = $f(T_{max},K_m)$
CL_{21}	Clearance from cell water to plasma
Amounts	
D_0	Dose
X_B^{ss}	Amount in body at steady-state
Rates	
k_0	Zero-order infusion rate
T_{max}	Maximum cellular transport rate
Ratios	
K_d	Tissue-plasma partition coefficient
K_{pi}	Individual tissue-plasma partition coefficients

Pharmacokinetics of Nitroglycerin after Parenteral and Oral Dosing in the Rat

HO-LEUNG FUNG ˣ, H. OGATA *, A. KAMIYA ‡, and G. A. MAIER §

Received May 17, 1982, from the *Department of Pharmaceutics, School of Pharmacy, State University of New York at Buffalo, Amherst, NY 14260.* Accepted for publication June 23, 1983. Present addresses: *National Institute of Hygienic Sciences, Tokyo, Japan, ‡Kyoto University Hospital, Kyoto, Japan, and § Schering Corporation, Bloomfield, NJ 07003.

Abstract □ The pharmacokinetics of nitroglycerin was characterized in detail using venous plasma after different intravenous bolus doses (0.15-2.48 mg/kg), intra-arterial infusion (8.2 μg/min over 5 h), and oral doses (7-100 mg/kg). Venous plasma clearance was found to be ~650 mL/kg and was independent of the intravenous or intra-arterial dose. This confirmed earlier reports that the venous plasma clearance of nitroglycerin in rats exceeded the value of normal cardiac output. A terminal half-life of ~15 min was observed after high intravenous bolus doses of nitroglycerin. This slow disappearance phase was likely rate limited by redistribution of drug back into the plasma. The bioavailability of oral nitroglycerin (F) showed an apparent Michaelis-Menten dependency on dose. F was <5% at doses <20 mg/kg, but increased to a plateau of ~20% from 50-100 mg/kg. First-pass metabolism of nitroglycerin is thus apparently controlled by at least two systems (sites or enzymes). Coadministration of mannitol hexanitrate, a potential competitive inhibitor of first-pass metabolism, did not increase F.

Keyphrases □ Pharmacokinetics—nitroglycerin, parenteral and oral dosing, rats □ Nitroglycerin—pharmacokinetics, parenteral and oral dosing, rats

Interest in the clinical use of intravenous nitroglycerin has intensified in recent years because of its demonstrated efficacy in treating the resultant manifestations of myocardial infarction, congestive heart failure, and unstable angina. Several reports (1-3) have shown that intravenous infusion of nitroglycerin can appreciably decrease cardiac work load and relieve the increase in left ventricular and diastolic pressure secondary to congestive heart failure or myocardial infarction (2).

Despite the increasing popularity of the use of intravenous nitroglycerin in therapy, very little is known about the pharmacokinetic behavior of this potent drug. There are indications

(4–6) that circulatory changes in heart rate and blood pressure in humans may parallel those in nitroglycerin plasma concentrations. Several reports have also suggested the observed systemic clearance in humans (7–9) and in rats (10) to be greater than the normal cardiac output in the respective species. However, the underlying mechanism for this observation is still unclear, and many of the basic aspects of nitroglycerin kinetics remain unknown.

Another important issue in nitroglycerin therapy relates to the efficacy of this drug when given orally. Numerous metabolic and pharmacological studies show that nitroglycerin undergoes nearly complete first-pass metabolism when the drug is administered at <3 mg/kg in several animal species (11–14). It was argued (14) that similar first-pass metabolism of oral nitroglycerin also exists in humans, and that oral use of this drug and other organic nitrates in therapy is irrational and ineffective. This viewpoint was strongly contested and refuted by Krantz and Leake (15) based on clinical experience. Convincing clinical data have appeared (16) that also affirm the prophylactic effectiveness of oral nitroglycerin against angina attacks.

There is no literature report on the effect of an oral dose on the extent of first-pass inactivation of nitroglycerin in humans or animals. If the extent of inactivation is capacity limited, oral bioavailability of nitroglycerin may be dose dependent and, thus, extrapolation of absorption data from trace or low doses to infer lack of bioavailability at other doses may be incorrect.

In this report, we describe the effect of intravenous dose on nitroglycerin disposition kinetics and the effect of oral dose on the bioavailability of nitroglycerin in the rat. Since the aqueous solubility of nitroglycerin is limited to ~1 mg/mL (17) and doses of nitroglycerin in this study necessitated the use of an organic solvent mixture of 10% ethanol in propylene glycol, a comparison of the bioavailability of nitroglycerin from this organic vehicle and water was carried out. Finally, the possible interference of nitroglycerin bioavailability by coadministration of another organic nitrate, *viz.*, mannitol hexanitrate, was explored.

EXPERIMENTAL SECTION

Materials—All reagents were of analytical grade unless otherwise stated.

Preparation of Stock Nitroglycerin Solutions—Nitroglycerin was isolated from the lactose adsorbate[1]. The powder was dissolved in distilled water and nitroglycerin was extracted with ether in a separatory funnel. The ether was separated and evaporated under a gentle stream of dry nitrogen. Nitroglycerin was recovered as a liquid and a weighed amount was dissolved in the appropriate solvent. The precise concentration of the stock solution was determined either by the USP assay (18) or the kinetic method developed by Fung *et al.* (19).

Intravenous Bolus Dosing—Male Sprague-Dawley rats, 250–360 g, underwent right jugular vein cannulation according to the procedure developed by Weeks and Davis (20). The animals were fasted overnight and administered an intravenous bolus dose into the jugular vein cannula, followed by flushing with saline and then with circulating blood. Blood samples were collected into heparinized tubes *via* the jugular vein cannula. The dosing volume was 0.5–0.75 mL in aqueous vehicle after appropriate dilution of the stock solution; the doses administered were 0.15, 0.35, 1.75, and 2.48 mg/kg of nitroglycerin with 4, 7, 5, and 6 animals in each group, respectively. A bolus intravenous dose of 3.5 mg/kg was also attempted but was found to cause severe convulsions in the animals. Pharmacokinetic information was not obtained from this group of animals.

Intra-Arterial Infusion—Four male Sprague-Dawley rats, 250–300 g, had jugular vein and carotid artery cannulas surgically implanted. One day after surgery, nitroglycerin was infused into the carotid artery, and blood samples were withdrawn *via* the jugular vein cannula at appropriate intervals. The infusion time was 5 h and the infusion rate was 6.8 μL/min *via* an infusion pump. The infusion solution concentration was 1.2 mg/mL, and the dosing rate was 8.2 μg/min in each animal.

Crossover Study of Oral Dosing—Six male Sprague-Dawley rats, weighing ~300 g, underwent jugular vein cannulation and were given an oral dose of either 20 or 100 mg/kg of nitroglycerin in a randomized crossover fashion. The vehicle was 10% alcohol in propylene glycol. All animals were fasted overnight, and the drug was given *via* gastric intubation under light ether anesthesia. The interval between doses was 3 d. Blood was harvested from the jugular vein cannula. The separated plasma was assayed for nitroglycerin as described later.

Bioavailability of Nitroglycerin at Five Different Oral Doses—Different male Sprague-Dawley rats were each given an oral dose of nitroglycerin in 10% alcohol in propylene glycol. Each dose, 7, 20, 50, 75, and 100 mg/kg, was adminstered by oral intubation under light ether anesthesia. The oral dose of vehicle was normalized to body weight so that each animal received the same volume on a mL/kg basis (~1 mL per animal). Blood (~0.3 mL) was collected from the tail vein at appropriate intervals, and the plasma was separated immediately for determination of nitroglycerin concentrations. All animals were fasted overnight with free access to water prior to drug administration.

Organic Nitrate Interaction Study—Since mannitol hexanitrate has been shown (12) to be a better *in vitro* substrate for organic nitrate reductase (the enzyme responsible for nitroglycerin metabolism), the possibility of enhancement in nitroglycerin bioavailability with the coadministration of mannitol hexanitrate was tested. Seven rats received an oral dose of nitroglycerin or a combination dose of mannitol hexanitrate and nitroglycerin, in a randomized crossover fashion. Essentially the same procedure was used as in the oral dosing experiments described previously. The molar ratio of mannitol hexanitrate to nitroglycerin was ~1.6. Preliminary studies showed that mannitol hexanitrate did not interfere with the assay: mannitol hexanitrate did not alter the plasma recovery of nitroglycerin; after an intravenous dose of mannitol hexanitrate at 60 μg/kg, no noticeable peaks were observed in the chromatogram which would interfere with the determination of nitroglycerin.

Nitroglycerin Assay—Blood samples were centrifuged immediately, and 0.1–0.2 mL of plasma was removed. A 10–20-μL aliquot of silver nitrate was added to each plasma sample to prevent degradation of the drug. Plasma samples were stored overnight at −20°C and nitroglycerin levels were determined according to the GC assay developed by Yap *et al.* (21). Isosorbide dinitrate was added as the internal standard. In this study, the average recovery of nitroglycerin from plasma was ~92% with a coefficient of variation of 10%.

Pharmacokinetic Calculations—*Parenteral Doses (Model-Independent Parameters)*—The plasma concentration *versus* time profiles after various bolus intravenous doses exhibited biexponential characteristics. The composite data were therefore fitted (NONLIN[2]) to the biexponential equation C_t =

Table I—Mean Estimated Values of Model-Independent Pharmacokinetic Parameters of Nitroglycerin at Various Intravenous Bolus Doses [a]

Parameter [b]	Dose, mg/kg			
	0.15	0.35	1.75	2.48
A_1 (ng/mL)	69.8(4.9)	160(9)	506(54)	809(49)
λ_1 (min^{-1})	0.41(0.01)	0.35(0.01)	0.24(0.02)	0.27(0.02)
A_2 (ng/mL)	1.7(0.2)	3.0(0.3)	33.1(3.9)	43.6(8.0)
λ_2 (min^{-1})	0.045[c]	0.045[c]	0.036(0.002)	0.044(0.0004)
Venous plasma clearance (mL/min/kg)	669(46)	642(40)	528(60)	654(49)
Vd_{ss} (L/kg)	3.9(0.3)	4.4(0.3)	6.1(0.6)	6.2(0.5)

[a] Expressed as mean (*SE*). [b] Typical parameters used to describe a biexponential equation, $C_t = A_1e^{-\lambda_1 t} + A_2e^{-\lambda_2 t}$. [c] Set as corresponding value obtained from curve-fitting of normalized, composite data of the two high doses.

$A_1e^{-\lambda_1 t} + A_2e^{-\lambda_2 t}$, where C_t is the plasma concentration of nitroglycerin at time t and A_1, A_2, λ_1 and λ_2 are the pharmacokinetic constants used to describe a biexponential decay curve. Initial estimates for the NONLIN computer program were either obtained graphically (method of residuals) or from CSTRIP[3]. Various weighting factors (1, $C_t^{-1/2}$, C_t^{-1}, and C_t^{-2}) were used to obtain the best fit, as determined by the residual sum of squares, parameter standard deviations, and r^2 values.

The apparent systemic plasma clearance was calculated by dividing the intravenous dose by the area under the plasma concentration *versus* time curve (AUC) from time zero to infinity. The individual concentration at time zero (C_0) for each animal in the low-dose group was estimated by extrapolation of the linearly regressed line composed of the first three plasma concentration *versus* time points. For the two high-dose groups C_0 was obtained either by linear extrapolation, as described, or from computer estimates, whichever was considered more accurate. The AUC from time zero to the last concentration-time point was calculated by the Spline Method[4]. The residual AUC was calculated from C^*/λ_2 where C^* is the last concentration-time point determined experimentally. For the two small doses, where the λ_2 phase could not be characterized fully because of assay limitations, the residual AUC was calculated using the mean λ_2 obtained from the higher doses. The volume of distribution at steady state was obtained by a model-independent approach which relied on AUC calculations (22). Thus:

$$Vd_{ss} = \frac{\text{Dose}_{iv} \cdot \text{AUMC}}{\text{AUC}^2} \qquad \text{(Eq. 1)}$$

where AUMC is the area under the moment curve, obtained *via* Eq. 2:

$$\text{AUMC} = \int_0^{t^*} tC_t dt + t^*C^*/\lambda_2 + C^*/\lambda_2^2 \qquad \text{(Eq. 2)}$$

where t^* is the time at which the last data point was collected. All other terms were defined previously.

Oral Doses—AUC from time zero to t^*, $AUC_{0\text{-}t^*}$, was estimated by the Spline Method[4]. The residual area from time t^* to ∞ was calculated by C^*/λ_t where λ_t was the terminal rate constant. In several cases, only two or three data points could be identified in the terminal phase. Nevertheless, the residual portion of the curve accounted for ≤10% of the total area and would not be expected to bias the overall analysis seriously.

The apparent bioavailability (F), defined as the fraction of the dose reaching the systemic circulation intact, was calculated from $CL \times AUC_{0\text{-}\infty}/\text{dose}$, where CL is the plasma clearance observed after intravenous dosing, set here at a value of 650 mL/min/kg. The paired t test was used to determine statistical differences in the two crossover studies, and the Kruskal-Wallis test was used in the study in which the effect of dose was examined in separate animals.

RESULTS AND DISCUSSION

Parenteral Dosing—Figure 1 shows the plasma nitroglycerin concentrations obtained after the highest and lowest intravenous bolus doses (*i.e.*, 2.48 and 0.15 mg/kg, respectively). Because of the relatively small plasma sample size that could be obtained from the rat (0.1-0.2 mL), the detection limit of nitroglycerin was ~0.5-1 ng/mL of plasma in these studies. Consequently, with the two lower doses, measurable concentrations were only recorded up to 20 min after injection. At the two higher doses, sample collection (and detectable concentrations) could be extended to 90 min after dosing. In fitting these data with the NONLIN program, a weighting factor of C_t^{-2} was found to produce the best fit in the groups given the two high doses. This weighting factor was then used in all other curve fittings.

Table I shows the pharmacokinetic parameters obtained from these fittings. The fit of data from all four doses appeared quite reasonable, since, for each dose, the AUC_∞ calculated directly from the experimental data agreed well with that estimated from the curve fit. A striking feature observed from Table I is that the apparent plasma clearance is independent of dose and is on the order of 500-700 mL/min/kg, well in excess of the normal cardiac output of ~300 mL/min/kg in this species (23). This large plasma clearance, which is now documented for several doses and from more detailed sampling, is consistent with the preliminary observation in the rat reported by Yap and Fung (10) and also with all the available human data (7-9, 24). The apparent volume of distribution at steady state, Vd_{ss}, was 4-6 L/kg. This large volume is consistent with the moderate binding (~60%) of nitroglycerin to rat plasma protein (25), and the location of rather high radioactivity in the carcass and other soft tissues after oral administration of [^{14}C]nitroglycerin (26).

After intravenous doses of 1.75 and 2.48 mg/kg, nitroglycerin disappearance from plasma was clearly biphasic. At lower doses, this biexponential decay was less evident because assay limitations did not permit characterization of the second disappearance phase. The λ_1 half-life observed here, at 2-3 min, is consistent with values reported previously in rats (10) and in humans (7-9). The second disappearance phase, with a half-life of 15-20 min, has not been reported previously in the literature.

Recent experiments by Kamiya *et al.*[5] showed that when nitroglycerin was incubated in whole blood, the *in vitro* degradation half-life was ~11 min. This half-life could be assumed to represent the slowest possible elimination half-life of nitroglycerin in the systemic circulation. Interestingly, however, this half-life is somewhat shorter than the observed *in vivo* plasma λ_2 half-life of 15-20 min. This would seem to indicate that tissue redistribution rather than elimination is an important factor in describing the second disappearance phase.

Although there was no apparent dose dependency in the venous plasma clearance of nitroglycerin, examination of the data presented in Table I suggested that there are possibly minor differences in the λ_1 and Vd_{ss} terms between the two lower doses (0.15 and 0.35 mg/kg) and the two higher ones (1.75 and 2.48 mg/kg). There are some theoretical reasons to anticipate possible dose dependency in nitroglycerin disposition kinetics. The venous plasma clearance is so large that flow limitation may be expected to play an important role. The higher bolus doses administered were close enough to an observed toxic dose of 3.5 mg/kg that dose-dependent changes in blood perfusion to various tissues are likely. Recently, Wu *et al.* (27) suggested that the rate constant for the loss of nitroglycerin from human blood decreases as the initial concentration of nitroglycerin increases. The implication of this finding to the present situation is unclear.

A possible contribution to the large plasma clearance observed for nitroglycerin is the existence of pharmacokinetic phases that were undetected because of the methodological difficulties involved. Johnson *et al.* (28) and recently Stein *et al.* (29) suggested the presence of a rapid disappearance phase of nitroglycerin in blood that exhibited a half-life of ~15 s. In both of these studies, however, the drug ([^{14}C]nitroglycerin) was introduced into the jugular

Table II—Normalized AUC of Nitroglycerin in Rats Given Both 20-mg/kg and 100-mg/kg Oral Doses

Animal	AUC/Dose × 10^4 min·kg·mL^{-1}	
	20 mg/kg	100 mg/kg
1	1.11[a]	3.35
2	1.16	2.10[a]
3	1.53	2.07[a]
4	1.76[a]	2.09
5	1.76[a]	2.77
6	0.91	3.37[a]
Mean	1.37	2.63[b]
SE	0.15	0.26

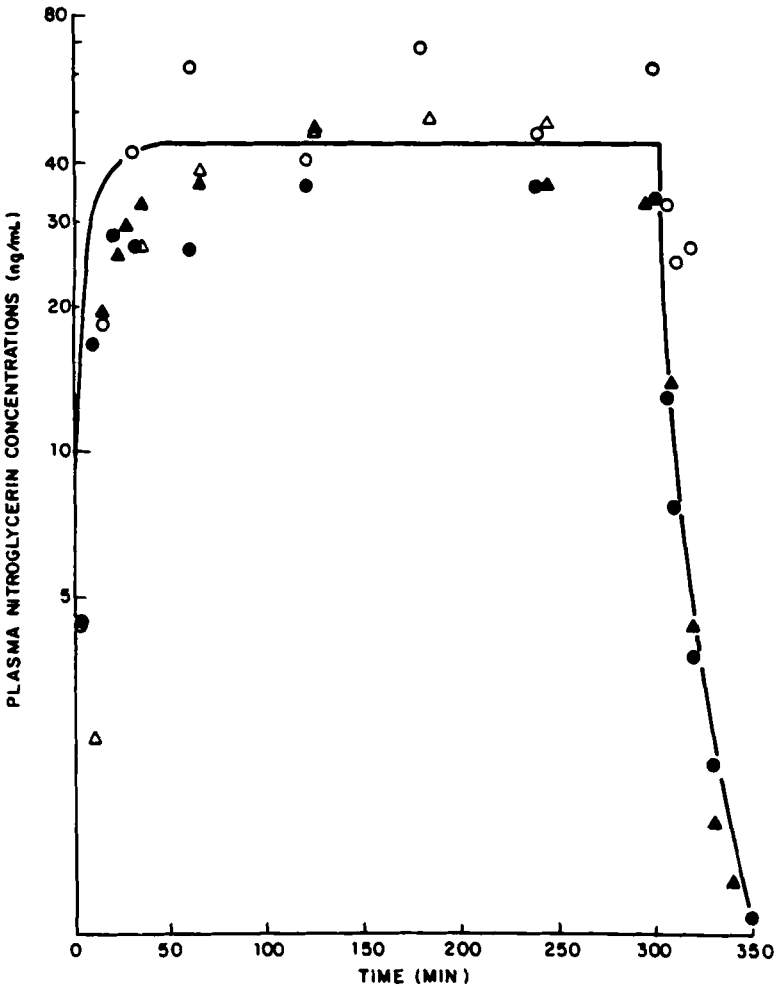

Figure 2—*Venous plasma nitroglycerin concentrations obtained after intra-arterial infusion at 8.2 μg/min. Symbols represent different animals (250–300 g). The line was drawn using the pharmacokinetic parameters generated compositely from the two high intravenous bolus doses.*

vein and blood was collected from the carotid artery. Thus, the early blood samples might have been collected before the dose was distributed throughout the systemic circulation, and the existence of a true pharmacokinetic phase with such a short half-life is uncertain. On the other hand, if such a fast "distributional" phase does exist and the sampling protocol adopted here was incapable of detecting it, an erroneously large plasma clearance could have resulted because a significant portion of the AUC was not included in the calculation. This problem also can exist if a slow terminal-phase λ_3 is present, but it, too, could not be detected because of assay limitations.

Figure 2 shows the venous plasma concentrations of nitroglycerin in four rats infused intra-arterially for 5 h at 28.5 μg/min/kg. Since the drug was infused *via* the carotid artery and blood was collected from the jugular vein [reverse of Johnson *et al.* (28) and Stein *et al.* (29)], drug mixing in the systemic circulation was unlikely to be a complicating factor. Under these conditions an apparent steady-state in nitroglycerin concentration was observed. The plasma concentrations observed from this infusion were generally consistent with those predicted using the pharmacokinetic parameters generated from the composite data of the two high-dose groups (Table I). It would thus appear unlikely that a rapid disappearance phase had been missed in the bolus injection study. The data also suggested that if a hidden λ_3 phase existed, its half-life would be considerably longer than 1–2 h, since infusion for 5 h failed to detect its presence. Since the pharmacokinetic parameters obtained are similar after bolus injection and after slow infusion, it would appear that the errors incurred in assuming instantaneous input after bolus injection (30, 31) are not large for nitroglycerin.

Table III—Effect of Solvent on the Area Under the Plasma Nitroglycerin Concentration *versus* Time Curve after a 7-mg/kg Oral Dose

Animal	$AUC_{0-\infty} \times 10^{-2}$, ng·min·mL^{-1}		AUC Ratio (Alcohol Co-solvent/Water)
	Water	Alcohol Cosolvent[a]	
7	5.2[b]	7.8	1.5
8	6.4	7.2[b]	1.1
9	3.2	3.7[b]	1.1
10	1.5[b]	2.8	1.9
11	2.0[b]	2.2	1.1
12	1.3	2.2[b]	1.8
Mean	3.3	4.3[c]	1.4
SE	0.9	1.0	0.2

[a] 10% Ethanol in propylene glycol. [b] Animal given this vehicle first. [c] $p < 0.05$ compared with animals dosed with aqueous vehicle.

Another consideration in the interpretation of the observed plasma clearance is how it may be related to the blood degradation clearance of nitroglycerin. Our group, in a separate study[5], has examined the *in vitro* partitioning of nitroglycerin between red blood cells and plasma and the rate of *in vitro* degradation of nitroglycerin in these components of rat blood. It was found that the partitioning of nitroglycerin into red blood cells was nearly instantaneous; the ratio of nitroglycerin concentration in red blood cells *versus* that in plasma was a constant, $\simeq 2.6$, over an incubation period of 30 s to 30 min at 37°C. The rate of degradation of nitroglycerin in red blood cells was approximately the same as that found in plasma. If a hematocrit value of 0.45 for the rat (23) is used, blood nitroglycerin concentrations could be estimated to be 1.72 times the corresponding plasma concentrations. Thus, *in vivo* venous blood nitroglycerin clearance could be estimated by dividing the venous plasma clearance by 1.72; *i.e.*, $650/1.72 \simeq 378$ mL/min/kg. This value is near that of cardiac output.

The extent of contribution of blood degradation *per se* to the total *in vivo* venous blood clearance of nitroglycerin could also be estimated. Assuming a blood volume of 65 mL/kg in the rat and a degradation half-life of 11 min, the clearance due to blood degradation is $65 \times 0.693/11 \simeq 4.1$ mL/min/kg, which accounts for <1% of the total *in vivo* venous blood clearance.

A further complication in interpreting nitroglycerin pharmacokinetics is the existence of concentration differences in the systemic circulation depending on the sampling site. Thus, Hill *et al.* (32) showed that after intranasal administration of nitroglycerin in humans, the apparent clearance was about twice as large in peripheral venous blood (~37 L/min) than in the arterial circulation (~19 L/min). Armstrong *et al.* (24) recently showed that arterial plasma clearance of nitroglycerin in 20 patients with heart failure was ~12

[5] A. Kamiya, T. Schmitt, and H.-L. Fung, unpublished results.

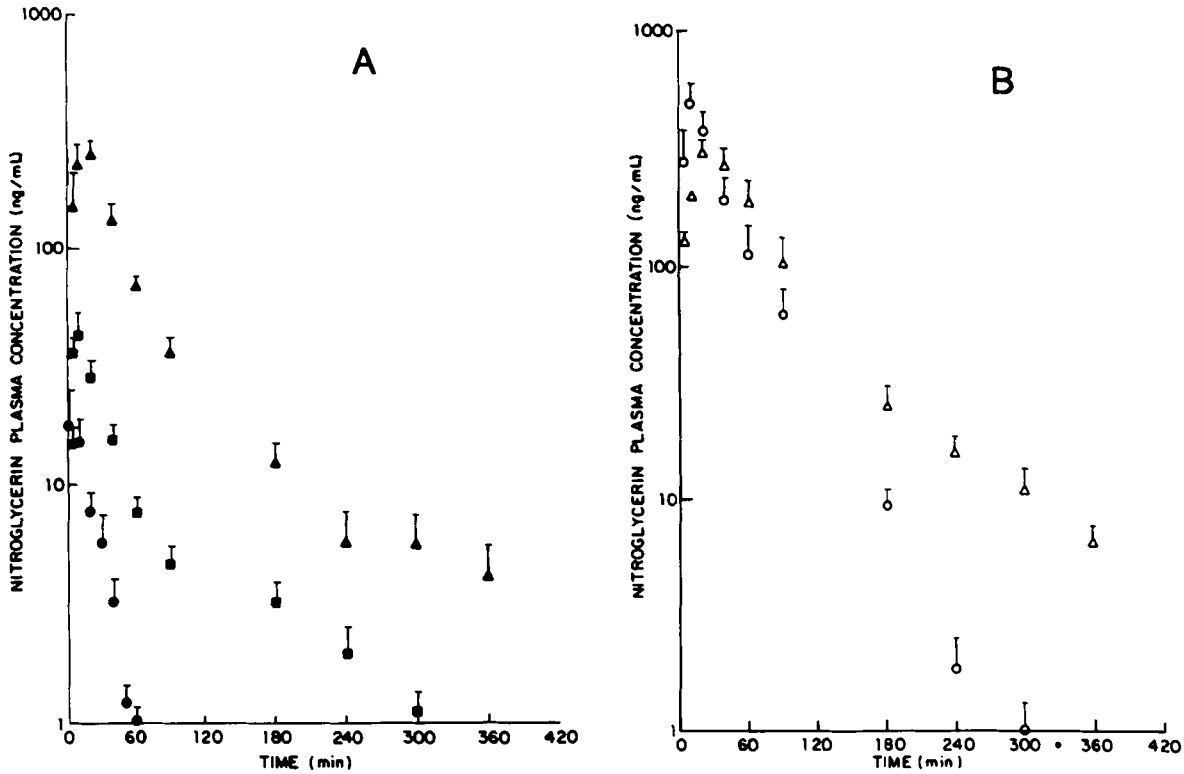

Figure 3 *Plasma nitroglycerin concentrations (mean ± SE) at various times after oral dosing at 7 (●), 20 (■), 50 (▲), 75 (○), and 100 (△) mg/kg.*

L/min compared with a venous clearance of 39 L/min. These authors calculated an extraction ratio of 61% for nitroglycerin across the arterial-venous bed. The existence of arterial-venous differences in blood concentrations have been shown for several drugs by Chiou and co-workers (31, 33). In these examples, however, the arterial drug clearance was always found to be similar to its venous clearance, suggesting that distributional factors were primarily responsible for the observed arterial-venous difference in concentration. In contrast, metabolic factors may be involved in the case for nitroglycerin, because an arterial-venous difference in systemic clearance has been demonstrated and *in vitro* metabolic activity toward nitroglycerin by isolated blood vessels has also been shown (34).

Oral Dosing—Table II shows the results of the randomized crossover study in which six rats were given both 20 and 100-mg/kg oral doses. The normalized AUC was statistically different between the two doses, at $p < 0.01$, using the paired t test. Since the apparent venous plasma clearance of nitroglycerin was not concentration dependent, the increase in normalized AUC after the 100-mg/kg dose is probably due to an increase in bioavailability at this dose. Using an average value of 650 mL/min/kg for the apparent plasma clearance of nitroglycerin, the mean apparent bioavailability at 20 and 100 mg/kg could be estimated as 10.3 and 19.4%, respectively.

These apparent bioavailability values were considerably higher than those suggested by Needleman *et al.* (14) and by Yap and Fung (10) at lower doses. The former group of authors estimated the bioavailability of nitroglycerin to be ≃2% at a dose of 0.5 mg/kg while the latter workers, in a preliminary study, reported a bioavailability estimate of ~2% after an oral dose of nitroglycerin at 7 mg/kg. It must be pointed out that in the second study (10), an aqueous vehicle was used, while in the present work a vehicle containing 10% ethanol in propylene glycol was administered. The possible effect of solvent was examined in a randomized crossover study in which six rats were dosed alternately with nitroglycerin dissolved in water or in 10% ethanol in propylene glycol. The AUC data can be found in Table III. It is apparent that there is a substantial degree of variability in each of the treatment groups, but this observation was quite typical of other kinetic studies of this high-clearance drug (7-10). Nevertheless, there is a modest, but significant ($p < 0.05$), increase in AUC when nitroglycerin administration was changed from the aqueous to the alcoholic vehicle (Table III). It is not known, at present, how much of this increase was influenced by the effect of the vehicle on the systemic clearance and how much was due to a change in presystemic metabolism. Oguma and Levy showed recently that ethanol infusion into the portal vein, from −3 to +3 h of propoxyphene dosing, increased both the systemic clearance and the systemic availability of this analgesic (35). Since the alcohol mixture was administered with the drug, it might be speculated that the apparent plasma clearance of nitroglycerin, which is well in excess of liver blood flow (23), might not be greatly affected by the organic solvents. Regardless of the mechanism involved, the effect of solvent on the apparent systemic availability of nitroglycerin at 7 mg/kg appeared to be relatively small.

An expanded study was carried out to examine, in further detail, the relationship between oral nitroglycerin dosage and bioavailability. Since five to six different doses were involved, a crossover design was not practical and, therefore, was not attempted.

Figure 3A and B shows the mean plasma concentrations of nitroglycerin obtained in different rats after oral doses of 7, 20, 50, 75, and 100 mg/kg administered in the alcohol solvent mixture. Peak plasma drug concentrations were observed generally between 2-20 min after dosing for all doses; however, the values of peak concentrations were not proportional to dose. The profiles of these curves were generally biphasic, except in the case of the lowest dose, 7 mg/kg, where characterization of plasma nitroglycerin concentrations beyond 60 min was impossible due to assay limitations. The apparent terminal half-life observed after oral dosing at 20, 50, and 100 mg/kg ranged from 60-140 min, considerably longer than the λ_2 half-life of 15-18 min observed after intravenous administration. The data suggested, therefore, that absorption "flip-flop" kinetics (36) is operative here and that the apparent terminal half-life observed reflected more of absorption than of elimination. After a dose of 75 mg/kg, the apparent terminal half-life was shorter ($t_{1/2}$ at ~30 min) than those observed for doses >20 mg/kg. Interestingly, after this dose, peak concentration was higher and the time to peak was shorter than found with the highest dose, 100 mg/kg. These observations suggest that the absorption rate might be faster at 75 mg/kg than at other doses; however, the reasons for these observations are unknown at present.

The relationship between dose and dose-normalized AUC is shown in Table

Table IV—Effect of Dose on the Normalized AUC and Apparent Bioavailability (F)

Dose	n	AUC/Dose × 10^4	F, %[e,f]
3.5[a]	5	0.25 ± 0.05[d]	1.6 ± 0.3
7[a]	6	0.47 ± 0.12	3.2 ± 0.8
7[b]	11	0.64 ± 0.05	4.2 ± 0.3
14[b,c]	7	0.51 ± 0.19	3.3 ± 1.2

[e] Mean ± SE; $F = (AUC_{0-\infty}/Dose) \times CL$; CL = 650 mL · min^{-1} · kg^{-1}. [f] F is found to be dose dependent (Kruskal-Wallis test, $p < 0.001$).

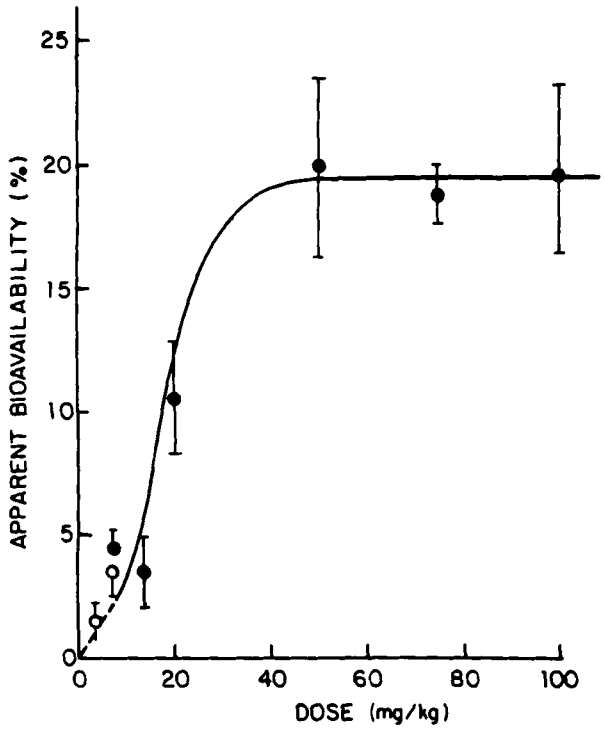

Figure 4—*Apparent oral bioavailability of nitroglycerin (mean ± SE) as a function of dose. The drug was administered either in water (○) or alcohol cosolvent (●).*

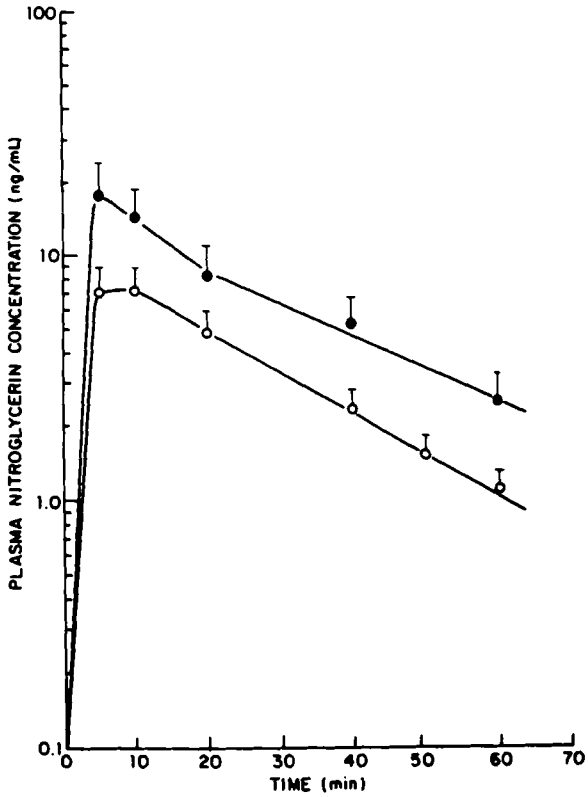

Figure 5— *Plasma nitroglycerin concentrations (mean ± SE) after a 14-mg/kg oral dose of nitroglycerin by itself (●) or in combination with 47 mg/kg of mannitol hexanitrate (○).*

IV. Similar data obtained with the aqueous vehicle at 3.5 mg/kg (37) and 7 mg/kg (10) are included for comparison. It is evident that, as the dose increased, the normalized AUC increased and then plateaued. If the systemic clearance obtained after intravenous administration of nitroglycerin in aqueous solution is assumed to be applicable under these experimental conditions, then the apparent bioavailability obtained after these oral doses may be estimated (Table IV). Thus, the apparent bioavailability appeared to increase with dose between 0–50 mg/kg. Between doses of 50–100 mg/kg, however, the apparent bioavailability remained constant at ~19%.

The interesting relationship between oral dose and apparent bioavailability, as observed here, supports the following conclusions. First, consistent with previous reports (14, 17, 21, 38), the oral bioavailability of nitroglycerin in the rat is indeed very small (< 3%) at doses <5 mg/kg. This poor bioavailability is probably a result of extensive first-pass metabolism (10, 14) rather than of lack of absorption *per se*, since radioactivity studies (39) showed absorption of the dose to be essentially complete. Second, the oral bioavailability of nitroglycerin is a rather complex function of dose. A possible model consistent with the data is that nitroglycerin is metabolized during absorption by at least two enzyme systems (or sites) which have different affinities and/or capacities for the drug substrate. This model is consistent with the observation by Jacoby (40) who suggested that organic nitrate reductase may, in fact, be one of several activities inherent to the glutathione-*S*-transferase system, which may consist of several "enzyme units." One could speculate that these different "enzyme units" may possess different substrate affinities and maximal velocities. Third, the bioavailability of oral nitroglycerin is highly variable at any dose. We have examined the source of this inter-animal variability and have shown (41) that it was due, in part, to the variability of the intrinsic hepatic organic nitrate reductase activity in individual rats. In view of the observed dose-dependent increase in bioavailability and the high inter-animal variability, some animals could have substantial or near complete bioavailability when given high doses of oral nitroglycerin. Thus, the general statement that nitroglycerin is poorly bioavailable has to be qualified by consideration of the dose administered and the individual animal being examined.

The dependency of F on dose (and thus also on hepatic drug concentration) points out a possibly important consideration in designing oral controlled-release dosage forms of nitroglycerin. If a similar relationship exists in humans, the dependency of F on drug release rate will have the same temporal pattern as is shown for dose (Fig. 4).

Figure 5 shows the plasma concentration of nitroglycerin after coadministration with mannitol hexanitrate. Surprisingly, the mean plasma concentration profile and AUC were actually smaller in the presence of the hexanitrate. However, despite a threefold difference in the mean AUC, statistical significance was not achieved due to the large coefficients of variation (100 and 50%, respectively, for nitroglycerin alone and combined administration). The effect of mannitol hexanitrate (if any) on bioavailability was extremely variable. For example, one rat exhibited almost a 10-fold decrease in AUC, whereas another showed a 1.6-fold increase in AUC in the presence of mannitol hexanitrate. In any event, mannitol hexanitrate did not apparently improve the bioavailability of nitroglycerin under the conditions tested.

There are several possible explanations for the apparent lack of effect. One possibility may be that an insufficient amount of mannitol hexanitrate was absorbed due to its poor aqueous solubility. Consequently, the organ concentration of mannitol hexanitrate would be too small to exert an inhibitory effect on nitroglycerin metabolism by organic nitrate reductase. Second, because of permeability and flow considerations, the relative affinity of mannitol hexanitrate *versus* nitroglycerin for the enzyme site *in vivo* may not be as favorable as *in vitro* determinations have suggested. Third, it is possible that mannitol hexanitrate coadministration may have altered the systemic clearance of nitroglycerin. Because of the very poor aqueous solubility of mannitol hexanitrate, a rigorous experiment involving intravenous administration of mannitol hexanitrate at the same dose was not carried out. Whatever the mechanism(s), however, oral coadministration of mannitol hexanitrate with nitroglycerin, under the conditions described, did not lead to any apparent increase in nitroglycerin bioavailability.

Phase Separation Induced in Gelatin–Base Coacervation Systems by Addition of Water-Soluble Nonionic Polymers I: Microencapsulation

HIROAKI JIZOMOTO

Received January 17, 1983, from the *Shionogi Research Laboratories, Shionogi & Co., Ltd., Fukushima-ku, Osaka 553, Japan.* Accepted for publication June 13, 1983.

Abstract □ A microencapsulation procedure in which water-soluble nonionic polymers (especially, polyethylene oxide or polyethylene glycol) were added to gelatin–base coacervation systems is described. The advantages of this method are: (*a*) The addition of a small amount of polyethylene glycol (PEG) or polyethylene oxide (PEO) to a complex coacervation system (*e.g.*, gelatin–acacia) allows microencapsulation to occur over an expanded pH region (pH 2–9 in gelatin–acacia). (*b*) These polymers induce phase separation in an aqueous solution of gelatin alone and enable the preparation of gelatin-coated microcapsules not only in the vicinity of the isoelectric point (pH 9.0), but over a wide pH range (pH 5.5–9.5). (*c*) Spherical single-seeded microcapsules can be obtained.

Keyphrases □ Microencapsulation—gelatin–base coacervation systems, water-soluble nonionic polymer □ Phase separation—coacervation induced by the addition of water-soluble nonionic polymer □ Coacervation—gelatin–acacia, polyethylene glycol, polyethylene oxide, phase separation, microencapsulation

Microencapsulation using coacervation of gelatin or gelatin–acacia is the most popular of the aqueous media procedures. The practicality of the gelatin–acacia complex coacervation method (1–3) is evidenced by products such as no-carbon paper and liquid crystal thermometers. Complex coacervation is the phase separation caused in a mixture of anionic and cationic polymers (*e.g.*, acacia and gelatin) under restricted pH conditions and colloid concentration. This limitation is the disadvantage of the conventional microencapsulation procedure by complex coacervation.

On the other hand, under certain conditions the addition of a water-miscible organic solvent (*e.g.*, ethanol) or salt (*e.g.*, sodium sulfate) to the aqueous solution of a polymer (*e.g.*, gelatin) causes phase separation. This phenomenon has been used in microencapsulation as a simple coacervation method (4–8). The disadvantages of the simple coacervation method are the requirement of a large quantity of the organic solvent, the necessity of desalting, and the difficulty of setting the optimum conditions to obtain satisfactory microcapsules. Therefore, in this work, improvement of the conventional coacervating techniques was attempted.

EXPERIMENTAL SECTION

Materials—The gelatin used has the following specifications as provided by the manufacturer[1]: bloom, 300; viscosity, 60.9 millipoises; pH 4.2; moisture, 9.9%; and isoelectric point, 9.0. The anionic polymers were acacia[2], carboxymethylcellulose (CMC)[3], and ethylene–maleic anhydride copolymer

(EMA)[4]. Nonionic polymers used were polyethylene glycol (PEG)[5], polyethylene oxide (PEO)[6], polysaccharide[7], polyvinylpyrrolidone[8], dextran[9], and polyvinyl alcohol[10]. All the polymers were used as supplied by the manufacturers.

Both PEG and PEO have the same general structural formula: HO—$(CH_2CH_2O)_nH$. The former is usually used for polymers having molecular weights $< \sim 20{,}000$ and the latter for those with molecular weights greater than tens of thousands.

Microencapsulation Procedures—The microencapsulation methods are illustrated in Fig. 1. Examples a and b demonstrate the procedure for the complex coacervation system using PEO-18 and for the aqueous solution of gelatin using PEG-6000, respectively. In these example, high concentrations (11%) of acacia and gelatin were used as starting concentrations according to the method of Green and Schleicher (9, 10), although low concentrations [*e.g.*, 3% (11)] can also be used. First, the core substances were emulsified above 40°C with a homogenizer[11] in aqueous solutions containing acacia (Example a) or gelatin (Example b) in 100-mL beakers. After emulsification, the colloidal dispersions were added to 500-mL beakers in which three-blade metal propellers with 2.5-cm blades were fixed 1.5 cm from the bottom, and water, and aqueous solution of gelatin (Example a), and nonionic polymers were successively added with stirring until the final concentrations of gelatin and acacia were adjusted to 1.5–3.0%. In this step, the nonionic polymers may be added in a neat state (powder or flakes) instead of as an aqueous solution.

After adjusting the pH with 20 and 1% NaOH solutions at 40°C, the mixtures were cooled gradually to 20°C with continuous stirring at 400–900 rpm and then cooled abruptly to ≤10°C. The mixtures were subjected to hardening treatment for 14 h after a dropwise addition of diluted glutaraldehyde (8%, 10 mL) and/or formaldehyde (7.4%, 10 mL)[12]. The products

[12] It is described in the patent (Japan 52-38097) that the combined use of glutaraldehyde and formaldehyde prevents yellowing. Formaldehyde is preferable to glutaraldehyde for hardening of microcapsules in a neutral pH region, because the latter has some tendency to cause aggregation of microcapsules in this pH region.

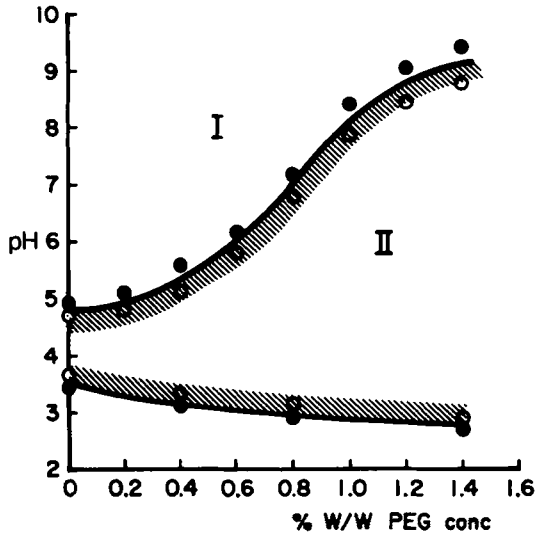

Figure 3—*Phase diagram of the acacia-gelatin (2.2% w/w each) complex coacervation system containing PEG-20,000. The coacervating region is represented by the shaded area (II); I represents a region of one-phase colloidal solution. Key: (●) no coacervation; (○) formation of coacervate.*

were then removed by filtration and washed. Microcapsules in the form of a free-flowing powder can be obtained according to the method of Madan *et al.* (6) or Palmieri (12) by the use of colloidal silica. The unhardened microcapsules can also be recovered as discrete free-flowing particles according to the aforementioned methods.

Phase Diagram—The nonionic polymers were added to the aqueous gelatin-acacia (2.2% each) solution or the aqueous gelatin (2.2%) solution without core materials under stirring at 40°C, and the formation of coacervates at various pH values was observed with a microscope at room temperature (~23°C). The dependence of the phase diagram on the concentrations of gelatin and acacia was also observed for PEO-1 and PEG-20,000.

RESULTS AND DISCUSSION

Microencapsulation—The various types of microcapsules formed in gelatin-base systems using water-soluble nonionic polymers are listed in Tables I and II. Examples of complex coacervation systems are shown in Table I, while examples of simple gelatin coacervation systems are shown in Table II.

In Examples 3 and 8, carboxymethylcellulose (CMC) and ethylene-maleic anhydride copolymer (EMA) were used instead of acacia as the anionic polymer, respectively. Examples 4–7 are of microencapsulation using polyvinyl

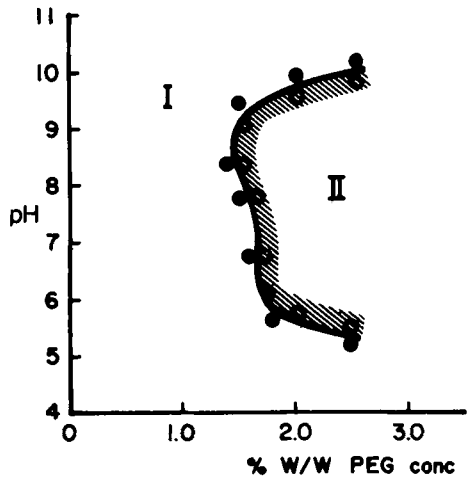

Figure 4—*Phase diagram of a simple coacervation of gelatin (2.2% w/w) with PEG-20,000. The coacervation region is represented by the shaded area (II); I represents a region of one-phase colloidal solution. Key: (●) no coacervation; (○) formation of coacervate.*

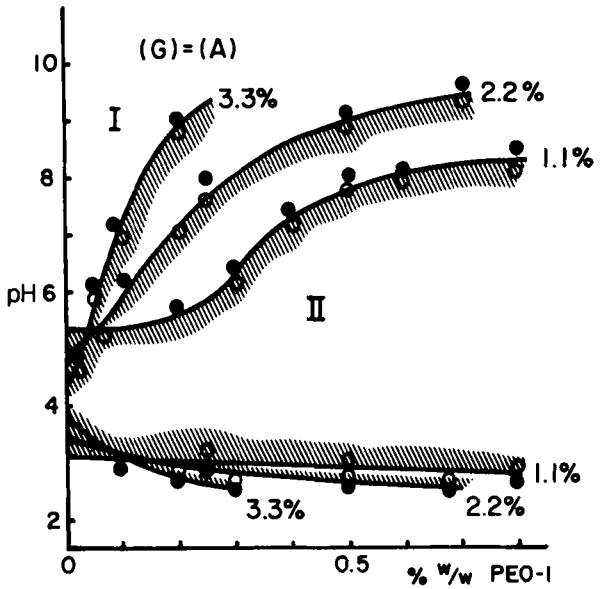

Figure 5—*Phase diagrams of acacia-gelatin complex coacervation systems containing PEO-1. The effect of colloidal concentrations of acacia and gelatin (1.1, 2.2, and 3.3% w/w) on the phase diagram was observed. alcohol (PVA) dextran, polyvinylpyrrolidone (PVP), and polysaccharide as the nonionic polymers, respectively. PEO and PEG were better than these nonionic polymers, which gave coacervation systems of high viscosity in the cooling process and made it difficult to prepare good microcapsules. On the other hand, the results of experiments on the homologous series of PEO and PEG indicated that the minimum concentrations of the molecules required to obtain microcapsules became lower with increasing molecular weight, although the system containing the larger molecule was more viscous. In the conventional method, spindle-shaped microcapsules are usually formed under the conditions used for obtaining single-seed microcapsules; in the present method, however, spherical shapes were obtained in many cases using PEO with a higher molecular weight than PEO-1. Although the viscosities were not measured, the systems in which the spherical shapes were obtained were, in general, more viscous in appearance. Therefore, the viscosity of the medium is considered an important factor in forming spherical shapes, but extended polymer chains with high molecular weight included in the medium might prevent the deformation (from sphere to spindle) of the microcapsule induced by the stress of distortion. On the other hand, stirring speed is also an important factor, and a speed of 400–900 rpm was necessary to overcome the retardation or to stop the flow of the dispersion in the vicinity of gelation temperature.

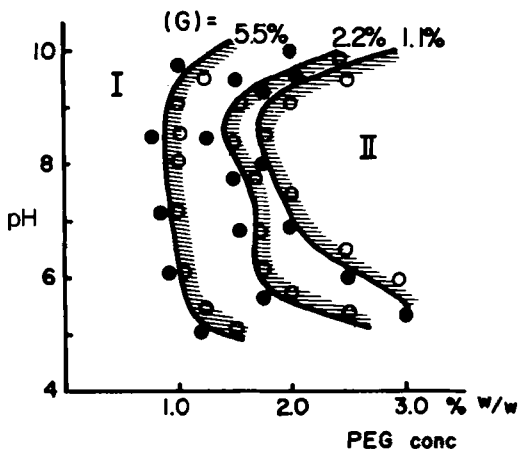

Figure 6—*Phase separations induced in the simple coacervation systems containing different amounts of gelatin (1.1, 2.2, and 5.5% w/w) by the addition of PEG-20,000. The coacervating regions are represented by shaded areas (II); I represents the regions of one-phase colloidal solution. Key: (●) no coacervation; (○) formation of coacervate.*

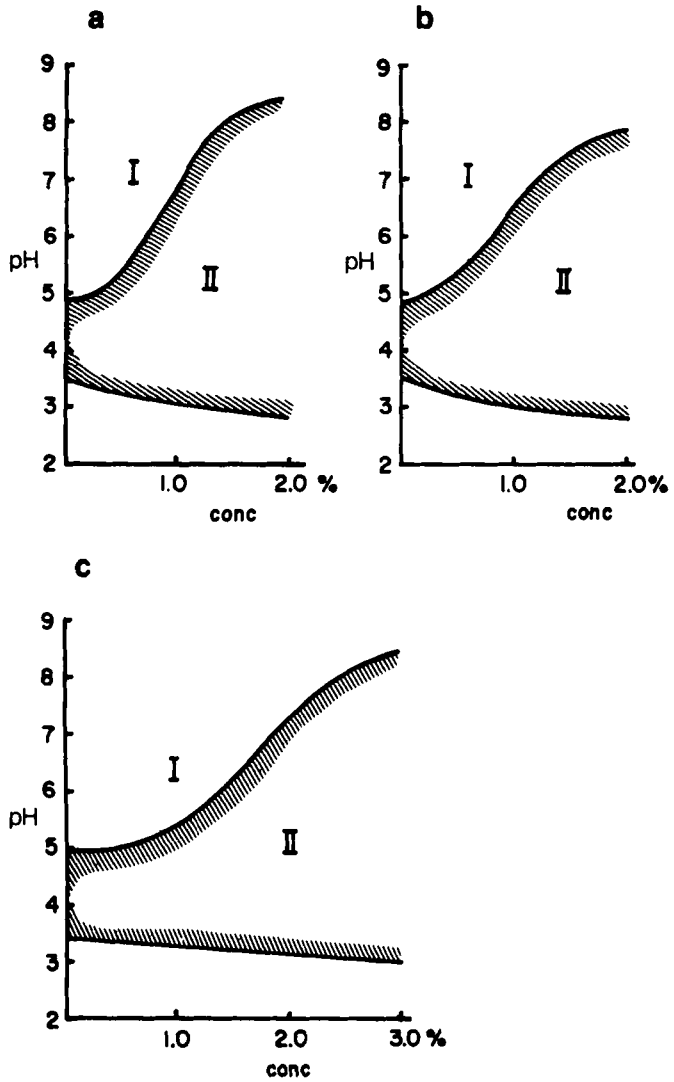

Figure 7—*Phase diagrams of acacia-gelatin (2.2% w/w each) complex coacervation systems with various water-soluble nonionic polymers. Figure 2 shows a photomicrograph of spherical single-seed microcapsules obtained from the dispersion systems of gelatin-acacia (1.6% each) and liquid paraffin (4.7%) by the addition of PEO-18 (0.3%) at pH 6.5. The product was recovered as free-flowing powder (diameter, 30–100 μm) after filtration without hardening treatment, according to the method of Madan *et al.* (6).

Phase Diagram—The coacervation areas are represented by shading (indicated by the symbol II) in the phase diagrams. The areas represented by the symbol I indicate one-phase colloidal dispersions.

Figure 3 shows the result of the gelatin-acacia complex coacervation systems and Fig. 4 the results of the aqueous solution of gelatin alone. Figure 3 indicates that the intercept of the shaded area to the ordinate is in the pH range of conventional complex coacervation and that the addition of a small amount of PEG-20,000 to the gelatin-acacia coacervation system causes phase separation in a remarkably expanded pH range. Figure 4 shows that in the aqueous solution containing gelatin alone, phase separation does not take place at every pH value without the addition of foreign molecules, but with the addition of PEG-20,000, the pH range is expanded.

Figure 5 shows that the pH range of complex coacervation without the addition of foreign molecules (conventional method) decreases with increasing colloidal concentration, but that the addition of PEO-1 expands the effective pH range of phase separation with increasing colloidal concentrations of gelatin and acacia. The minimum concentration of PEG-20,000 required to cause the phase separation in the aqueous solutions of gelatin alone becomes lower with increasing gelatin concentration, as shown in Fig. 6.

The results of other water-soluble nonionic polymers (polysaccharide, dextran, and PVP) can be seen in Fig. 7. Although all of these nonionic polymers have molecular weights greater than that of PEG-20,000, they are not more effective.

Coacervation from ethylcellulose-cyclohexane solution is widely used in the microencapsulation of water-soluble drugs, using a combination of coacervation-inducing agents (*e.g.*, polyethylene and polyisobutylene) (13, 14). However, the role and effect of the coacervation-inducing agents in the organic solvent systems differ from those of the water-soluble nonionic polymers in the aqueous coacervation systems described in the present paper.

In the coacervation system of ethylcellulose-cyclohexane, the coacervation-inducing agents effectively cause phase separation and prevent aggregation of microcapsules, but the microcapsules can also be prepared without these agents. In the aqueous solution of gelatin, on the other hand, phase separation does not occur without the addition of the water-soluble nonionic polymers. In the acacia-gelatin complex coacervation system, the nonionic polymers can cause phase separation even at pH values at which separation does not occur using the conventional method. The phenomenon of inducing coacervation in these two solvent systems might be caused (possibly common to both systems) by the contributions of the added polymers to the thermodynamic properties of mixing (ΔH_{mix} and ΔS_{mix}).

CONCLUSIONS

The addition of a small amount of high molecular weight PEO or PEG to a gelatin-acacia coacervation system enables coacervation over an expanded pH range (pH 2–9). These polymers also induce phase separation in the aqueous solution of gelatin alone over a wide range (pH 5.5–9.5). The microencapsulation procedure using this phenomenon is useful for the microencapsulation of materials which are labile or water-soluble in the acidic pH region but stable and insoluble in the neutral pH region.

Prediction of Drug Disposition Kinetics in Skin and Plasma Following Topical Administration

RICHARD H. GUY *x and JONATHAN HADGRAFT ‡

Received February 28, 1983, from the **Departments of Pharmacy and Pharmaceutical Chemistry, School of Pharmacy, University of California-San Francisco, San Francisco, CA 94143* and the ‡*Department of Pharmacy, University of Nottingham, University Park, Nottingham, NG7 2RD, U.K.* Accepted for publication May 23, 1983.

Abstract □ The development of a physically based pharmacokinetic model for percutaneous absorption is described. The simulation includes four first-order rate constants assigned the following significance: (*a*) absorption across the stratum corneum; (*b*) diffusion through the viable tissue; (*c*) a retardation process which retains penetrant in the stratum corneum (and hence provides a means to mathematically produce a "reservoir" effect, for example); and (*d*) uptake from the skin into the systemic circulation and subsequent elimination from the body. The kinetic equations of the model are solved and expressions are obtained for the concentration of penetrant within the stratum corneum (and available to subsequently partition into the viable epidermis) and the plasma concentration of the administered substance, as a function of time. Using example values for the four rate parameters, disposition profiles for the penetrant in skin and plasma were derived. The cases considered cover slow and fast stratum corneum penetrants, substances which are excreted rapidly or slowly from the body, and absorbing molecules with a variety of relative stratum corneum-viable tissue affinities. The results suggest a framework for the prediction of pharmaceutically and clinically relevant information following the topical administration of therapeutic agents for local or systemic effect.

Keyphrases □ Percutaneous absorption—pharmacokinetics of skin penetration, plasma concentration prediction □ Plasma concentration prediction—pharmacokinetics, percutaneous absorption, topical administration □ Pharmacokinetics—percutaneous absorption, plasma concentration prediction, topical administration

Percutaneous absorption is a complex phenomenon which is currently attracting an increasing level of study. In addition to the fundamental goal of more completely understanding skin penetration, an important reason for this expanded effort is the somewhat recently realized potential for effective systemic drug delivery using the transdermal route (1-3). Equally pertinent, and now subject to some reexamination, is consideration of the efficaciousness of existing drugs and dosage regimens for the treatment of local dermatological disease.

The heightened interest in percutaneous absorption encompasses many aspects: (*a*) the development of new delivery systems (4-6), (*b*) the search for agents capable of enhancing penetration (7-11), and (*c*) the continuing effort to understand skin absorption rate and extent in terms of accepted biological facts and penetrant physicochemical properties (12-20). In the first group, one may cite the appearance of transdermal therapeutic systems containing nitroglycerin for the treatment of angina pectoris (21) and the surprising suggestion that topically applied liposomes are able to exert an influence on the local and systemic distribution of an encapsulated drug (22, 23). Of the agents offered as penetration enhancers, pyrrolidone, formamide, and sulfoxide derivatives are recent examples (7-11, 24). Another new compound, dodecylazacycloheptan-2-one (25, 26), appears to have enhancement potential, although its mechanism of promotion remains unclear.

It is the third category, however, to which this paper is directed. Specifically, the objectives are to present a physically based pharmacokinetic model for percutaneous absorption and to demonstrate its application to the prediction of drug disposition kinetics in skin and plasma following topical administration. The simulation is that recently described by Guy *et al.* (27). The approach is simplistic in concept, but sensitive to physicochemical changes in penetrant properties and to the manner in which the absorbing molecule may be expected to interact with the various strata of the skin. Four rate constants are specified in the model and are assigned specific physical significance. The previous work (27) showed that the urinary excretion rate data of three compounds (testosterone, benzoic acid, and hydrocortisone), obtained following topical application, can be successfully explained by the simulation and that rate constants, which are physicochemically consistent, can be derived. In this paper, the rate equations of the model are solved for (*a*) the concentration of penetrant within the stratum corneum and (*b*) the concentration of drug in plasma. Reasonable, representative values are assigned to the four kinetic parameters and drug disposition profiles are generated for a variety of example cases. The predictive capacity of the approach in clinically relevant situations is indicated and discussed.

THEORETICAL SECTION

Schematic and compartmental representations of the pharmacokinetic model are shown in Fig. 1 and are designed to indicate the putative physical significance on which this work is based. The simulation is linear and includes four first-order rate constants. The first (k_1) describes drug input across the stratum corneum and is a parameter that might be estimated, for example,

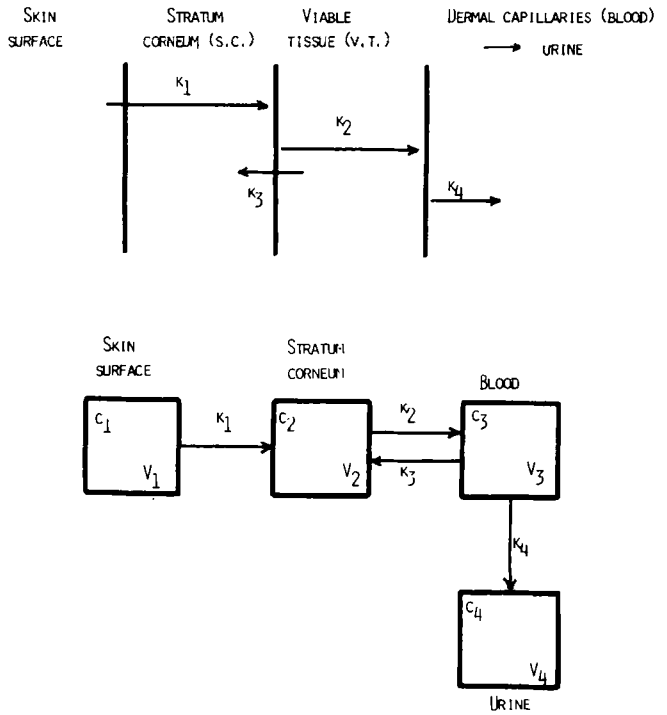

Figure 1—*Schematic and compartmental representations of the percutaneous absorption pharmacokinetic model.*

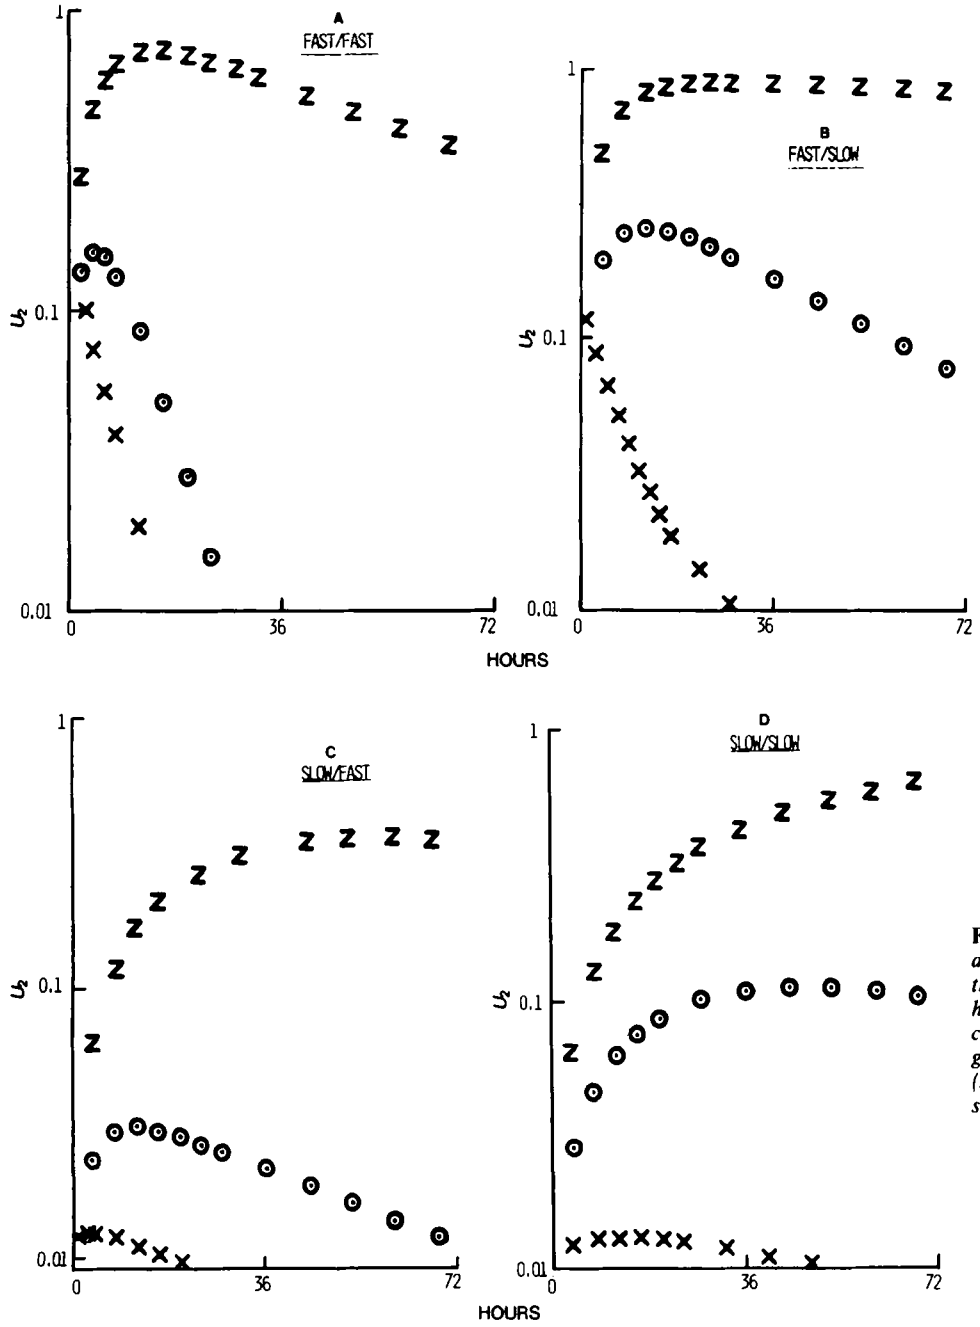

Figure 2—*Prediction of skin disposition kinetics as a plot of normalized concentration* u_2 versus *time. The curves correspond to penetrants with high (Z), medium (⊙), and low (X) stratum corneum affinities. Rate constants* k_1-k_4 *are given in Tables I and II. Key: (A) case fast/fast; (B) case fast/slow; (C) case slow/fast; (D) case slow/slow.*

by the disappearance of radioactivity from the skin surface following topical application of labeled compound (28, 29). The second, k_2, relates to drug penetration further into the skin, specifically movement across the aqueous viable tissue. The kinetic constant k_3 reflects the relative affinity of the penetrant for the stratum corneum compared with the viable tissue; in other words, k_3 will be large (relative to k_2) for substances that bind tightly to the stratum corneum or that exhibit a marked "reservoir" effect (30–33). Finally, k_4 describes drug elimination from the systemic circulation into the urine. The assignment of a first-order process for this step may, of course, be inadequate, in which case a more complex formulation will be necessary. In this instance, the theoretical treatment becomes more complicated but far from intractable. The previous description of this model indicates that it is particularly useful if the elimination of drug following parenteral administration is known (27, 29). Thus, ideally, application of the simulation includes independent assessment of the elimination process described by k_4 or a more sophisticated alternative.

Four concentrations are identified by the compartmentalization of the model. Surface concentration is C_1 and, in the following mathematical development, $C_1 = C_0$, the initial applied concentration, at time $t = 0$, *i.e.*, at the beginning of the experiment. Because of the assigned significance of k_2 and k_3, C_2 may be equated with the concentration of drug in the stratum corneum and available for subsequent partitioning into the viable tissue. Estimation of this parameter is useful, therefore, in terms of the dermatological application of the model. The concentration of drug in blood is represented by C_3. No attempt is made to differentiate between drug in the local cutaneous

Table I—Input (k_1) and Output (k_4) Rate Constants Selected for Application of the Model

Case	k_1, h^{-1}	k_4, h^{-1}
Fast/Fast	0.180	0.360
Fast/Slow	0.180	0.036
Slow/Fast	0.018	0.360
Slow/Slow	0.018	0.036

Table II—Rate Constants (k_2 and k_3) Chosen for Application of the Model

k_2, h^{-1}	k_3, h^{-1}	k_3/k_2	Relative Stratum Corneum Affinity
1.440	28.800	20.00	"High"
1.440	0.720	0.50	"Medium"
1.440	0.029	0.02	"Low"

Table III—Rate Constants (k_1–k_4), Previously Determined for Testosterone, Benzoic Acid, and Hydrocortisone, Used to Generate the Disposition Profiles[a]

Compound	k_1, h^{-1}	k_2, h^{-1}	k_3, h^{-1}	k_4, h^{-1}
Testosterone	0.058	1.44	2.70	0.104
Benzoic acid	0.184	2.88	0.014	0.592
Hydrocortisone	0.022	1.44	0.180	0.158

[a] See Figs. 3 and 5; the values were taken from Ref. 27.

microvasculature and drug systemically available. Because it is not possible to sample the dermal capillaries, such a refinement is not presently justified by experimental capabilities. Lastly, C_4 is the concentration of drug in the urine; it follows that attention is focused on the renal excretion of the drug and this may or may not be an appropriate decision. However, because of the stipulation suggested above that drug excretion following intravenous dosing be assessed as a matter of course, then suitable corrections can be applied to take into account the elimination of the drug by other routes (29).

Four rate equations describe the kinetics of the model in Fig. 1:

$$\frac{dC_1}{dt} = -k_1 C_1 \qquad \text{(Eq. 1)}$$

$$\frac{dC_2}{dt} = \frac{V_1}{V_2} k_1 C_1 - k_2 C_2 + \frac{V_3}{V_2} k_3 C_3 \qquad \text{(Eq. 2)}$$

$$\frac{dC_3}{dt} = \frac{V_2}{V_3} k_2 C_2 - (k_3 + k_4) C_3 \qquad \text{(Eq. 3)}$$

$$\frac{dC_4}{dt} = \frac{V_3}{V_4} k_4 C_3 \qquad \text{(Eq. 4)}$$

where V_1–V_4 correspond to the volumes of compartments 1–4, respectively. Manipulation of the equations to obtain an expression for the amount of drug appearing in the urine as a function of time has been presented previously (27). The reduction to achieve relationships pertaining to drug levels in skin (C_2) and plasma (C_3) follow parallel steps (see *Appendix*). The drug concentration in the stratum corneum available for partitioning into the viable epidermis is:

$$u_2 = \frac{V_1}{V_2} k_1 \left[\frac{(k_3 + k_4 - k_1) \cdot \exp(-k_1 t)}{(k_1 - \alpha)(k_1 - \beta)} + \frac{(k_3 + k_4 - \alpha) \cdot \exp(-\alpha t)}{(\alpha - \beta)(\alpha - k_1)} + \frac{(k_3 + k_4 - \beta) \cdot \exp(-\beta t)}{(\beta - k_1)(\beta - \alpha)} \right] \qquad \text{(Eq. 5)}$$

The drug concentration in blood is given by:

$$u_3 = \frac{V_1}{V_3} k_1 k_2 \left[\frac{\exp(-k_1 t)}{(k_1 - \alpha)(k_1 - \beta)} + \frac{\exp(-\alpha t)}{(\alpha - \beta)(\alpha - k_1)} + \frac{\exp(-\beta t)}{(\beta - k_1)(\beta - \alpha)} \right] \qquad \text{(Eq. 6)}$$

In Eqs. 5 and 6, u_2 and u_3 are normalized concentrations (with respect to the initial applied concentration, C_0), *i.e.*:

$$u_2 = C_2/C_0 \qquad \text{(Eq. 7)}$$

$$u_3 = C_3/C_0 \qquad \text{(Eq. 8)}$$

and α and β are the roots of a quadratic (see *Appendix*) such that:

$$\alpha\beta = k_2 k_4 \qquad \text{(Eq. 9)}$$

$$\alpha + \beta = k_2 + k_3 + k_4 \qquad \text{(Eq. 10)}$$

As discussed previously for drug in urine (27), Eqs. 5 and 6 may be multiplied by a factor F, which is the fraction of the applied topical dose and metabolites recovered (and corrected for nonrenal excretion) in compartment 4.

EXPERIMENTAL SECTION

Using Eqs. 5 and 6, it is now possible to predict drug disposition kinetics in skin and plasma for various combinations of the four rate constants k_1–k_4. To illustrate this ability, the following approach is adopted. The input (k_1) and output (k_4) processes are arbitrarily defined as "fast" and "slow," thereby allowing four possible combinations (fast/fast, fast/slow, slow/fast, and slow/slow). Then, for each of these combinations, u_2 and u_3 are calculated for "high," "medium," and "low" ratios of k_3/k_2, *i.e.*, for different relative stratum corneum–viable tissue affinities. The numerical values selected for the rate constants are given in Tables I and II. The choice of the k_1 and k_4 ranges reflects the span observed previously between benzoic acid, testosterone, and hydrocortisone (27, 29). The k_3/k_2 ratios are designed to illustrate the ramifications of varying the effective stratum corneum–viable tissue partition coefficient[1] of the penetrant over a range of three orders of magnitude. A value of $40 \times 10^{-5}\ s^{-1}$ ($1.44\ h^{-1}$) was assigned to k_2 throughout. Such a figure has been shown to correspond to an effective solute diffusion coefficient through the viable tissue of $\sim 10^{-7}\ cm^2/s$; this is in reasonable agreement with earlier independent assessments (34). The k_3 values employed again span, but also extend, the range identified for the three penetrants given above (27). Because it is unlikely that a penetrant with less reservoir-forming ability than benzoic acid will be identified, the k_3 range has been extended in the direction of increasing stratum corneum affinity. Finally, to evaluate u_2 and u_3, V_1 and V_2 have been estimated as essentially equal for typical topical applications (*i.e.*, $V_1/V_2 \simeq 1$) and V_1/V_3 has been set equal to 2×10^{-5}, based on an applied volume of 100 μL and a plasma volume of 5 L. Hence, with four combinations of k_1 and k_4 and three k_3/k_2 values, twelve assessments each of u_2 and u_3 can be made.

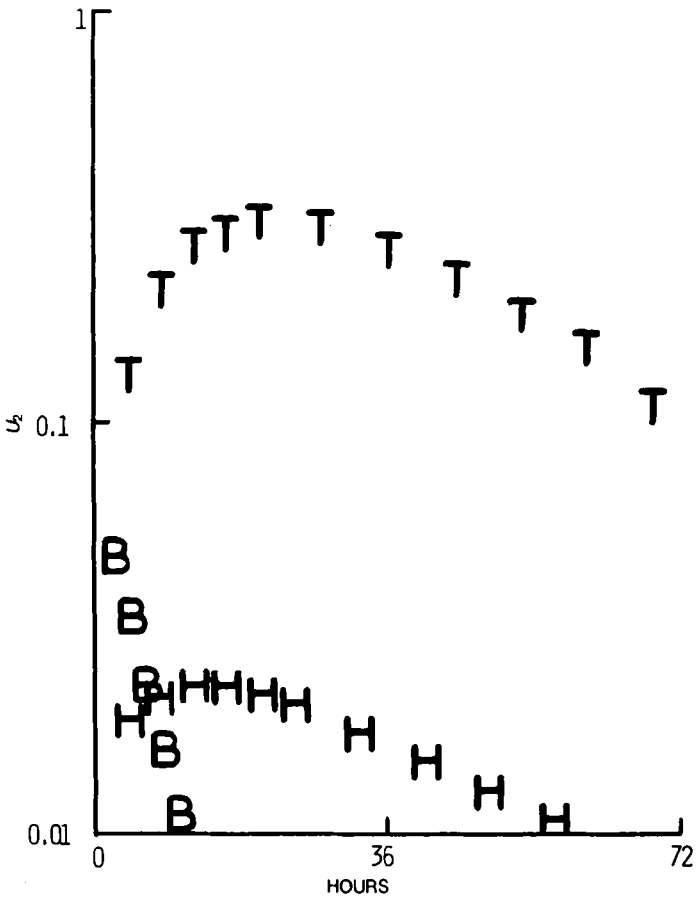

Figure 3—*Skin disposition profiles (u_2) as a function of time for testosterone (T), benzoic acid (B), and hydrocortisone (H). The curves were evaluated using the rate constants in Table III and Eq. 5.*

RESULTS AND DISCUSSION

Disposition Profiles in Skin—The graphs in Fig. 2 show a wide variety of behavior for the concentration–time course of a penetrant within the skin. There are marked differences between the curves in a quantitative sense of how much material can be found in the skin and for how long the substance is maintained within the cutaneous region. The curves clearly indicate combinations of rate constants which may not prove efficacious for the treatment of local (nonsurface) dermatological disease. For example, penetrants with low k_3/k_2 ratios fall into this category: either the drug is very rapidly eliminated from the skin (Fig. 2A–C) or it is present in relatively insignificant amounts (Fig. 2D). On the other hand, penetrants which are expected to ex-

[1] It is important to point out that the ratio of k_3/k_2 is not a true partition coefficient in the classical sense. However, because of the assigned significance of the rate processes which k_2 and k_3 describe, their ratio (a "pseudo-partition coefficient") will be related to the conventional, though not easily measurable, distribution constant of the drug between the stratum corneum and the viable tissue.

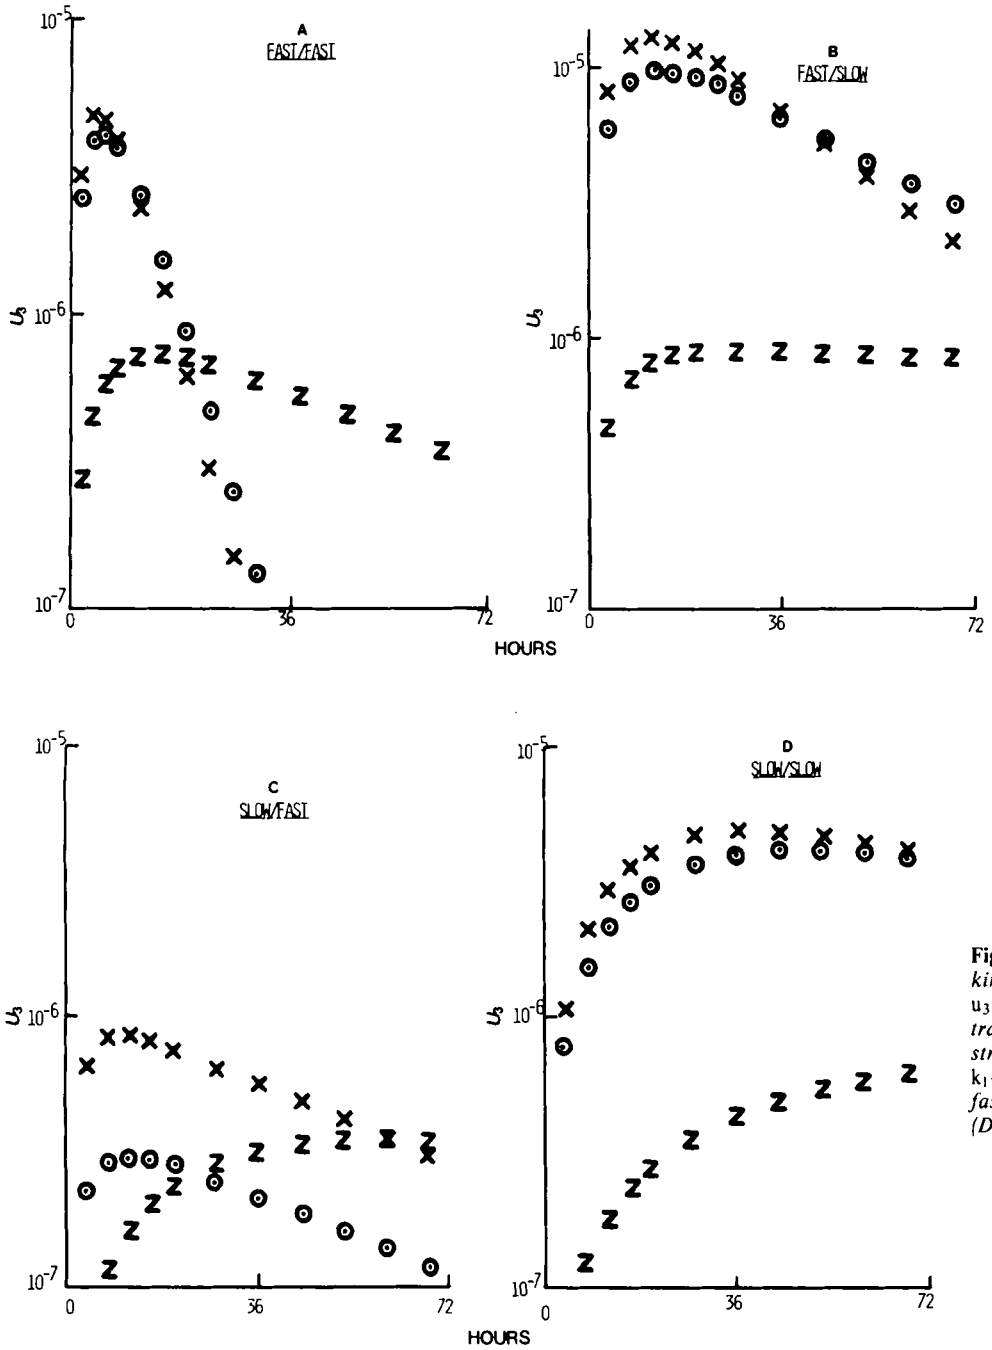

Figure 4—*Prediction of plasma disposition kinetics as a plot of normalized concentration* u_3 versus *time. The curves correspond to penetrants with high (Z), medium (⊙), and low (X) stratum corneum affinities. Rate constants* k_1-k_4 *are given in Tables I and II. Key: (A) case fast/fast; (B) case fast/slow, (C) case slow/fast; (D) case slow/slow.*

hibit substantial reservoir effects (30-33), *i.e.*, those with high k_3/k_2 values, achieve substantial and prolonged levels within the tissue. It may be noted that a fast/slow penetrant with $k_3/k_2 = 20$ (Fig. 2B, curve Z) produces potentially ideal local sustained-release characteristics over an extended time period. Of course, certain combinations of kinetic parameters may prove unlikely, *e.g.*, fast/fast with high k_3/k_2 and slow/slow with a low ratio. Furthermore, the model may not be able to distinguish between certain alternatives [the high k_3/k_2 curves in Fig. 2C (slow/fast) and D (slow/slow) provide such a case]. However, on the whole, the delineation between different permutations is good and the profiles, and their relative juxtaposition to one another, are consistent with the assigned physicochemical significance of the model.

In Figure 3, skin disposition curves are shown for testosterone, benzoic acid, and hydrocortisone. The profiles have been calculated using the rate constants quoted in the previous publication (27) of this kinetic model (see Table III). The distinction between the three compounds is striking—benzoic acid shows virtually no residence within the skin, merely a transient presence. The time course for the steroids is similar yet, quantitatively, testosterone achieves levels an order of magnitude greater than those of hydrocortisone. This observation is consistent with larger k_1 and k_3 values of testosterone and its consequently higher potential for stratum corneum reservoir formation.

Disposition Profiles in Plasma—Figure 4 shows the relative plasma disposition profiles for the various k_1-k_4 combinations considered. The curves provide a preliminary insight into the desirable transcutaneous properties required by a penetrant to be a candidate for systemic delivery *via* the topical route. Indication of sensible dosing intervals for such an objective is also available. Interestingly, the medium and low stratum corneum affinity penetrants are not distinguishable in terms of plasma level except for the slow/fast situation (Fig. 4C). Even then, the time course is identical; only the amounts are different. These observations are apparent despite a 25-fold difference between the k_3 values used in the medium and low cases. The reason for the apparent anomaly is straightforward. Only for slow/fast is the input (k_1) process substantially slower than the output (k_4) such that the differences in k_3 (medium *versus* low) can be reflected in the values of u_3.

In Figure 5, u_3 profiles for testosterone, benzoic acid, and hydrocortisone are plotted. The rate constants used for the calculations are given in Table III (27). Benzoic acid clearly falls into the fast/fast, low k_3/k_2 ratio, category. Testosterone and hydrocortisone climb to their maximum plasma levels more gradually and maintain appreciable concentrations over a prolonged period. The potential for sustained transdermal delivery of endogeneous corticosteroid hormones to treat clinical deficiencies would, therefore, appear attractive.

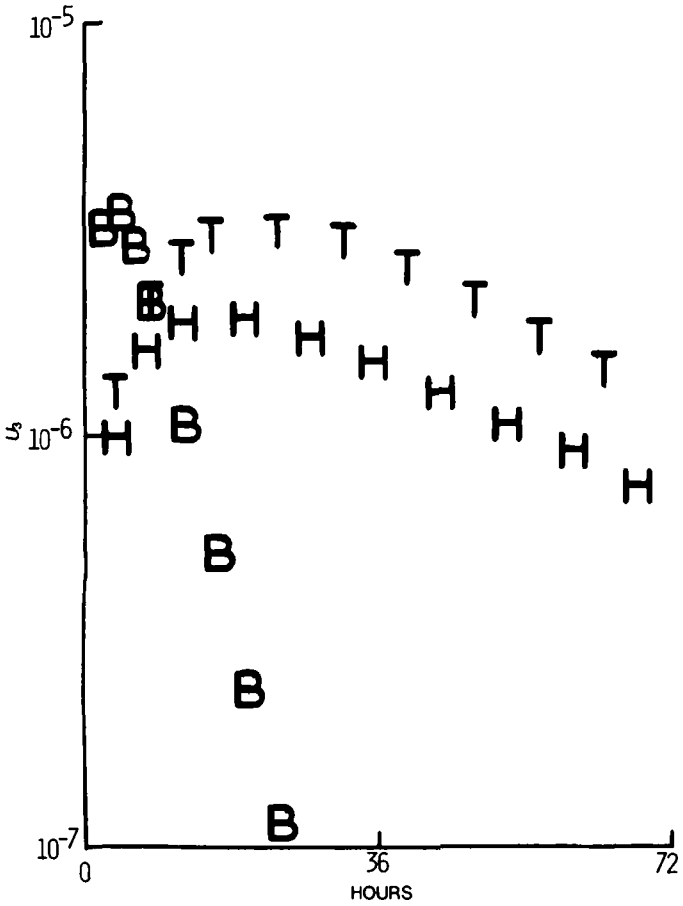

Figure 5—*Plasma disposition profiles (u_3) as a function of time for testosterone (T), benzoic acid (B), and hydrocortisone (H). The curves were evaluated using the rate constants in Table III and Eq. 6.*

APPENDIX

In this appendix, the derivation of Eqs. 5 and 6 is outlined. First, all concentrations are normalized with respect to C_0, the concentration in compartment 1 at $t = 0$:

$$u_i = C_i/C_0 \; (i = 1, 2, 3, 4) \qquad \text{(Eq. A1)}$$

Solutions for u_2 and u_3 are obtained using the technique of Laplace transformation. Substituting Eq. A1 into Eqs. 1-4 and transforming gives:

$$s\bar{u}_1 = 1 - k_1\bar{u}_1 \qquad \text{(Eq. A2)}$$

$$s\bar{u}_2 = \frac{V_1}{V_2}k_1\bar{u}_1 - k_2u_2 + \frac{V_3}{V_2}k_3\bar{u}_3 \qquad \text{(Eq. 3A)}$$

$$s\bar{u}_3 = \frac{V_2}{V_3}k_2\bar{u}_2 - (k_3 + k_4)\bar{u}_3 \qquad \text{(Eq. A4)}$$

$$s\bar{u}_4 = \frac{V_3}{V_4}k_4\bar{u}_3 \qquad \text{(Eq. A5)}$$

Equation A2 gives an expression for u_1, which may be substituted into Eq. A3. This latter equation and Eq. A4 then provide a pair of simultaneous equations which may be solved for u_2 and u_3. The algebra is trivial and the following results are obtained:

$$\bar{u}_2 = \frac{V_1}{V_2}\left[\frac{k_1(s + k_3 + k_4)}{(s + k_1)(s + \alpha)(s + \beta)}\right] \qquad \text{(Eq. A6)}$$

$$\bar{u}_3 = \frac{V_1}{V_3}\left[\frac{k_1k_2}{(s + k_1)(s + \alpha)(s + \beta)}\right] \qquad \text{(Eq. A7)}$$

where α and β are the roots of the quadratic:

$$s^2 + (k_2 + k_3 + k_4)s + k_2k_4 = 0 \qquad \text{(Eq. A8)}$$

Simple inversion of Eqs. A6 and A7 results in the expressions for u_2 and u_3 quoted in the text as Eqs. 5 and 6, respectively.

Effect of Film Irregularities on Sunscreen Efficacy

JOHN J. O'NEILL

Received March 28, 1983, from *Avon Products, Inc., Suffern, NY 10901.* Accepted for publication June 24, 1983.

Abstract □ The effect of distortion of a uniform film on its opacity has been calculated for a simple step film model. Nonuniform distribution of sunscreen films on skin and of the absorber within the film would account for large discrepancies between naively predicted efficacy and that observed clinically.

Keyphrases □ Film irregularities—effect on sunscreen efficacy, opacity □ Sunscreens—effect of film irregularities, opacity

Cosmetic sunscreen products are effective in protecting the user from sunburn by absorbing injurious UV radiation, but it is well known that their performance is not nearly as good as would be predicted from the absorption spectra of their active ingredients. Spectra of strongly absorbing materials are usually measured at weight concentrations of ~0.001% in transparent solvents like water or ethanol in a cuvette with an optical path length of 1 cm. A sunscreen on the skin contains several percent of the absorber in a film with an average thickness of ~0.002 cm. The fact that such lengthy extrapolation of spectrophotometric data leads to predictions of efficacy far greater than those obtained in clinical measurements is occasionally ascribed to misapplication or even to a failure of the physical laws underlying spectrophotometry. More often it is ascribed to vehicle effects and to skin topography.

In this paper the average opacity of a simple model film is calculated as a function of its departure from uniform thickness and chemical homogeneity. It is suggested that plausible irregularities can account for discrepancies of many orders of magnitude between naively predicted and observed sunscreen efficacy.

BACKGROUND

The pharmacological measure of sunscreen efficacy, the sun protection factor (SPF), is the factor by which the product allows the time of exposure to sunlight to be increased before a given degree of sunburn occurs. For example, someone who suffers a slight sunburn after 20-min exposure could remain in sunlight of the same intensity for 40 min wearing an ointment with an SPF of 2 before suffering the same slight burn.

The equivalent physical definition is:

$$\mathrm{SPF} = \frac{\int (S \times A) \cdot d\lambda}{\int (S \times A \times T) \cdot d\lambda} \qquad \text{(Eq. 1)}$$

where $S(\lambda)$ is the intensity of sunlight under standardized conditions of altitude, latitude, time of day, *etc.* (usually replaced in clinical practice with the more accessible and intense emission spectrum of a solar simulator); $A(\lambda)$ is the skin sensitivity or action spectrum, the reciprocal of the energy per unit area of exposed skin producing a standard degree of burn (usually the minimum perceptible erythema); and $T(\lambda)$ is the fractional transmission of the sunscreen.

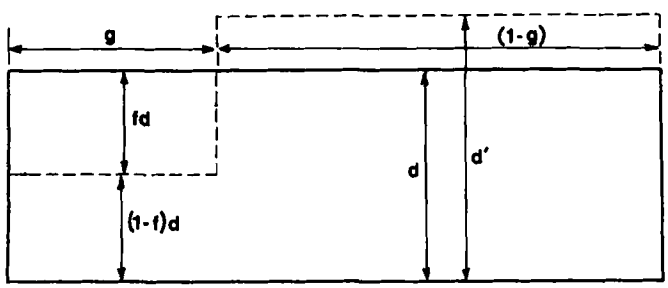

Figure 1—*Step film geometry: cross section of a rectangular slab of unit width.*

In both integrals the lower limit is ~290 nm because the function, $S(\lambda)$, is negligibly small in the standard solar spectrum at lower wavelengths. The upper limit is the wavelength above which the action spectrum, $A(\lambda)$, is so small that the product $S \times A$ is negligible. From our own experience with sunscreens, we take this limit as ~350 nm but its exact location is immaterial in the discussion that follows.

Since the dimensions of S in Eq. 1 are energy × area^{-1} × time^{-1} and those of A are erythema × energy^{-1} × area, and since T is the dimensionless ratio of transmitted to incident intensity, both the numerator and denominator have "dimensions" of erythema per unit of time. For a given degree of erythema, this reduces to the time ratio of the pharmacological definition.

For convenience, we define a protection factor for monochromatic radiation as:

$$\mathrm{MPF}(\lambda) = \frac{S(\lambda) \times A(\lambda)}{S(\lambda) \times A(\lambda) \times T(\lambda)} = 1/T(\lambda) = P(\lambda) \qquad \text{(Eq. 2)}$$

where $P(\lambda)$ is the opacity of the film. This definition is used rather than the more cumbersome Eq. 1 in the discussion that follows. For the most part, the notation of wavelength dependence is dropped, but we emphasize that MPF is a strong function of the wavelength and that it is not simply related to the SPF except in special cases (*e.g.*, where the transmission is a constant, independent of wavelength, as might be true of a dispersion of an opaque, reflective solid like aluminum powder; in this case SPF = P). The extension of conclusions regarding the effect of sunscreen film irregularities on MPF to that on SPF is discussed below where appropriate.

The opacity of a cosmetic sunscreen is given, in the first approximation, by the absorption spectrum of the active ingredient as measured in dilute solution in a transparent solvent expressed according to the Beer-Lambert law:

$$P(\lambda) = \left(\frac{I_0}{I}\right)_\lambda = 10^{k(\lambda)Cd} \qquad \text{(Eq. 3)}$$

where I_0 and I are the intensities of incident and transmitted light, $k(\lambda)$ is the absorptivity in units corresponding to those of the concentration, C, and the path length d.

Although the concentrations and path lengths in applied sunscreens differ by several orders of magnitude from those used in spectrophotometry, there are no obvious grounds for suspecting that the opacities will not be related according to Eq. 3. There are no known exceptions to Lambert's law relating opacity to path length through homogeneous bodies, and marked deviations from Beer's law (the concentration effect) are usually attributable to gross physicochemical departures from simple molecular solutions, such as ionization or complexation, which are not likely to occur with the absorbers used in sunscreens at either very high or very low concentrations. Nevertheless, sunscreen efficacy as predicted from spectrophotometry using Eq. 1, assuming a film thickness corresponding to the application level, is usually higher, sometimes by several orders of magnitude, than the SPF value measured clinically. The following calculations show that seemingly plausible deviations from uniformity of film thickness or of distribution of the absorber can account for these discrepancies.

DISCUSSION

Opacity of Step Films—Figure 1 shows the cross section of a uniform, homogeneous film of thickness d of a solution of concentration C of an absorbing solute whose absorptivity in the transparent medium is k. The broken lines show what we call a step film, produced by removing a fraction (f) of the uniform film over a fraction (g) of its area and redepositing it uniformly over the remaining area. The average intensity of light transmitted by the step film is:

$$I_s = gI_1 + (1 - g)I_2 \qquad \text{(Eq. 4)}$$

[a] A 20-μm thick film of an absorber solution whose molar extinction coefficient is 30,000 L · mol^{-1} · cm^{-1} reaches this opacity at a concentration of 0.1 mol/L; for octyl dimethyl *p*-aminobenzoate (Escalol 507 brand of padimate O) this corresponds to a weight concentration ~2.8%. [b] Depth fraction.

where I_1 and I_2 are the intensities of light transmitted by the depleted and augmented areas. These are given by the Beer-Lambert law as:

$$I_1 = I_0 \cdot \exp_{10}[-kCd(1-f)] \qquad \text{(Eq. 5)}$$

$$I_2 = I_0 \cdot \exp_{10}\left[-kCd\left(\frac{fg}{1-g}+1\right)\right] \qquad \text{(Eq. 6)}$$

where I_0 is the intensity of the light normally incident on both areas. In Eqs. 5 and 6 the expressions in parentheses are the factors by which the thickness of the film is changed; the expression in Eq. 6 can be derived by equating the volumes removed, $fd \times ga$, and redeposited, $(d' - d) \times (1 - g)a$, where a is the area of the film. The average opacity of the step film, P_s, as a function of f and g, is given by combining Eqs. 3-6:

$$P_s = P_c\left[g \cdot \exp_{10}(kCdf) + (1-g) \cdot \exp_{10}\left(\frac{-kCdfg}{1-g}\right)\right]^{-1} \qquad \text{(Eq. 7)}$$

where P_c is the opacity of the uniform parent film.

Tables I-III give the calculated opacities of the step films derived from uniform films of opacities 10, 1000, and 1,000,000. The most obvious feature of these tables is that all the calculated average opacities are less than that of the uniform parent film. It might have been expected that for some range of values of the distortion factors f and g, the increase in opacity of the area on which the film thickness is increased would more than offset the loss of opacity of the depleted area. This is not so in any case: the distorted film is always less opaque.

Another disturbing feature of the behavior of the model is the dependence of the relative loss in opacity on the opacity of the parent film: for any set of values of f and g, the greater the opacity of the parent film, the greater the relative decrease in opacity. For example, at $f = g = 0.9$ (removal of 90% of the film over 90% of the area) uniform films of opacities 10, 1000, and 1,000,000 are degraded to step films with respective opacities of 14%, 0.22%, and 0.00044% of those of the parent films.

The same behavior can be viewed in terms of the absorption spectrum of the active ingredient. Note that according to Eq. 7 the ratio of step film opacity, P_s, to that of the uniform film, P_c, depends on the wavelength, because for a given film distortion (fixed values of f and g) the ratio is the reciprocal of the sum of two terms which vary exponentially with k, the absorptivity. In this view, film distortion has its greatest relative effect at the absorption maxima where the absorber is expected to be most effective; distortion blunts the spectrum of the absorber.

In Tables I-III the bottom row, where $f = 1.0$, shows the result of completely removing part of the film. Even if only 10% of the area is so depleted ($g = 0.1$), the step film opacity drops to ≤10 as would be expected from ordinary experience: if the parent film were a metallic foil of virtually infinite opacity, a few pin pricks would degrade it into an imperfect screen transmitting a fraction of incident light equal to the areal fraction of the holes, as is the case, to four significant figures in the bottom row of Table III.

The right-hand column of each table illustrates Lambert's Law relating opacity to thickness over the entire area of the film ($g = 1.0$). Removal of 90% of the film ($f = 0.9$) reduces the opacity to the tenth root of that of the parent film—from 1,000,000 to 4.0 for example, as seen in Table III.

If the geometry of sunscreens on human skin corresonds to large values of f and moderate-to-large values of g, then the values of MPF(λ) predicted according to Eq. 7, and, by inference, of SPF itself, will be very modest compared with those predicted on the assumption of a uniform film.

The dependence of step film opacity on absorber concentration as given by Eq. 7 is illustrated in Fig. 2 where the opacity of the uniform film, P_c is also shown for comparison. The opacities for a given combination of f and g are plotted on semilogarithmic graphs against the $\log_{10}$ of the opacity of the uniform parent film, which, according to Eq. 3, is proportional to the concentration C for fixed k and d. In all cases, the curve is more or less concave down, near the origin ($C = 0$, $P = 1$) and then becomes nearly log-linear at high concentration. The latter occurs when the second term in Eq. 7 becomes negligible compared with the first (when the transmittance of the augmented area is negligible compared with that of the depleted area):

$$\log P_s = \log P_c - \log g - kCdf \qquad \text{(Eq. 8)}$$

or, since $\log P_c = kCd$:

$$\log P_s = (1-f)kCd - \log g \qquad \text{(Eq. 9)}$$

which corresponds to a straight line with the slope reduced by a factor of 1 − f relative to that of $\log P_c$ against C, and with an intercept of $-\log g$ (as shown by extrapolation in a few cases).

For $f = 0.9$, P_s or MPF appears to increase linearly with absorber concentration over the range covered in Fig. 2C, as can be seen from the linear plots

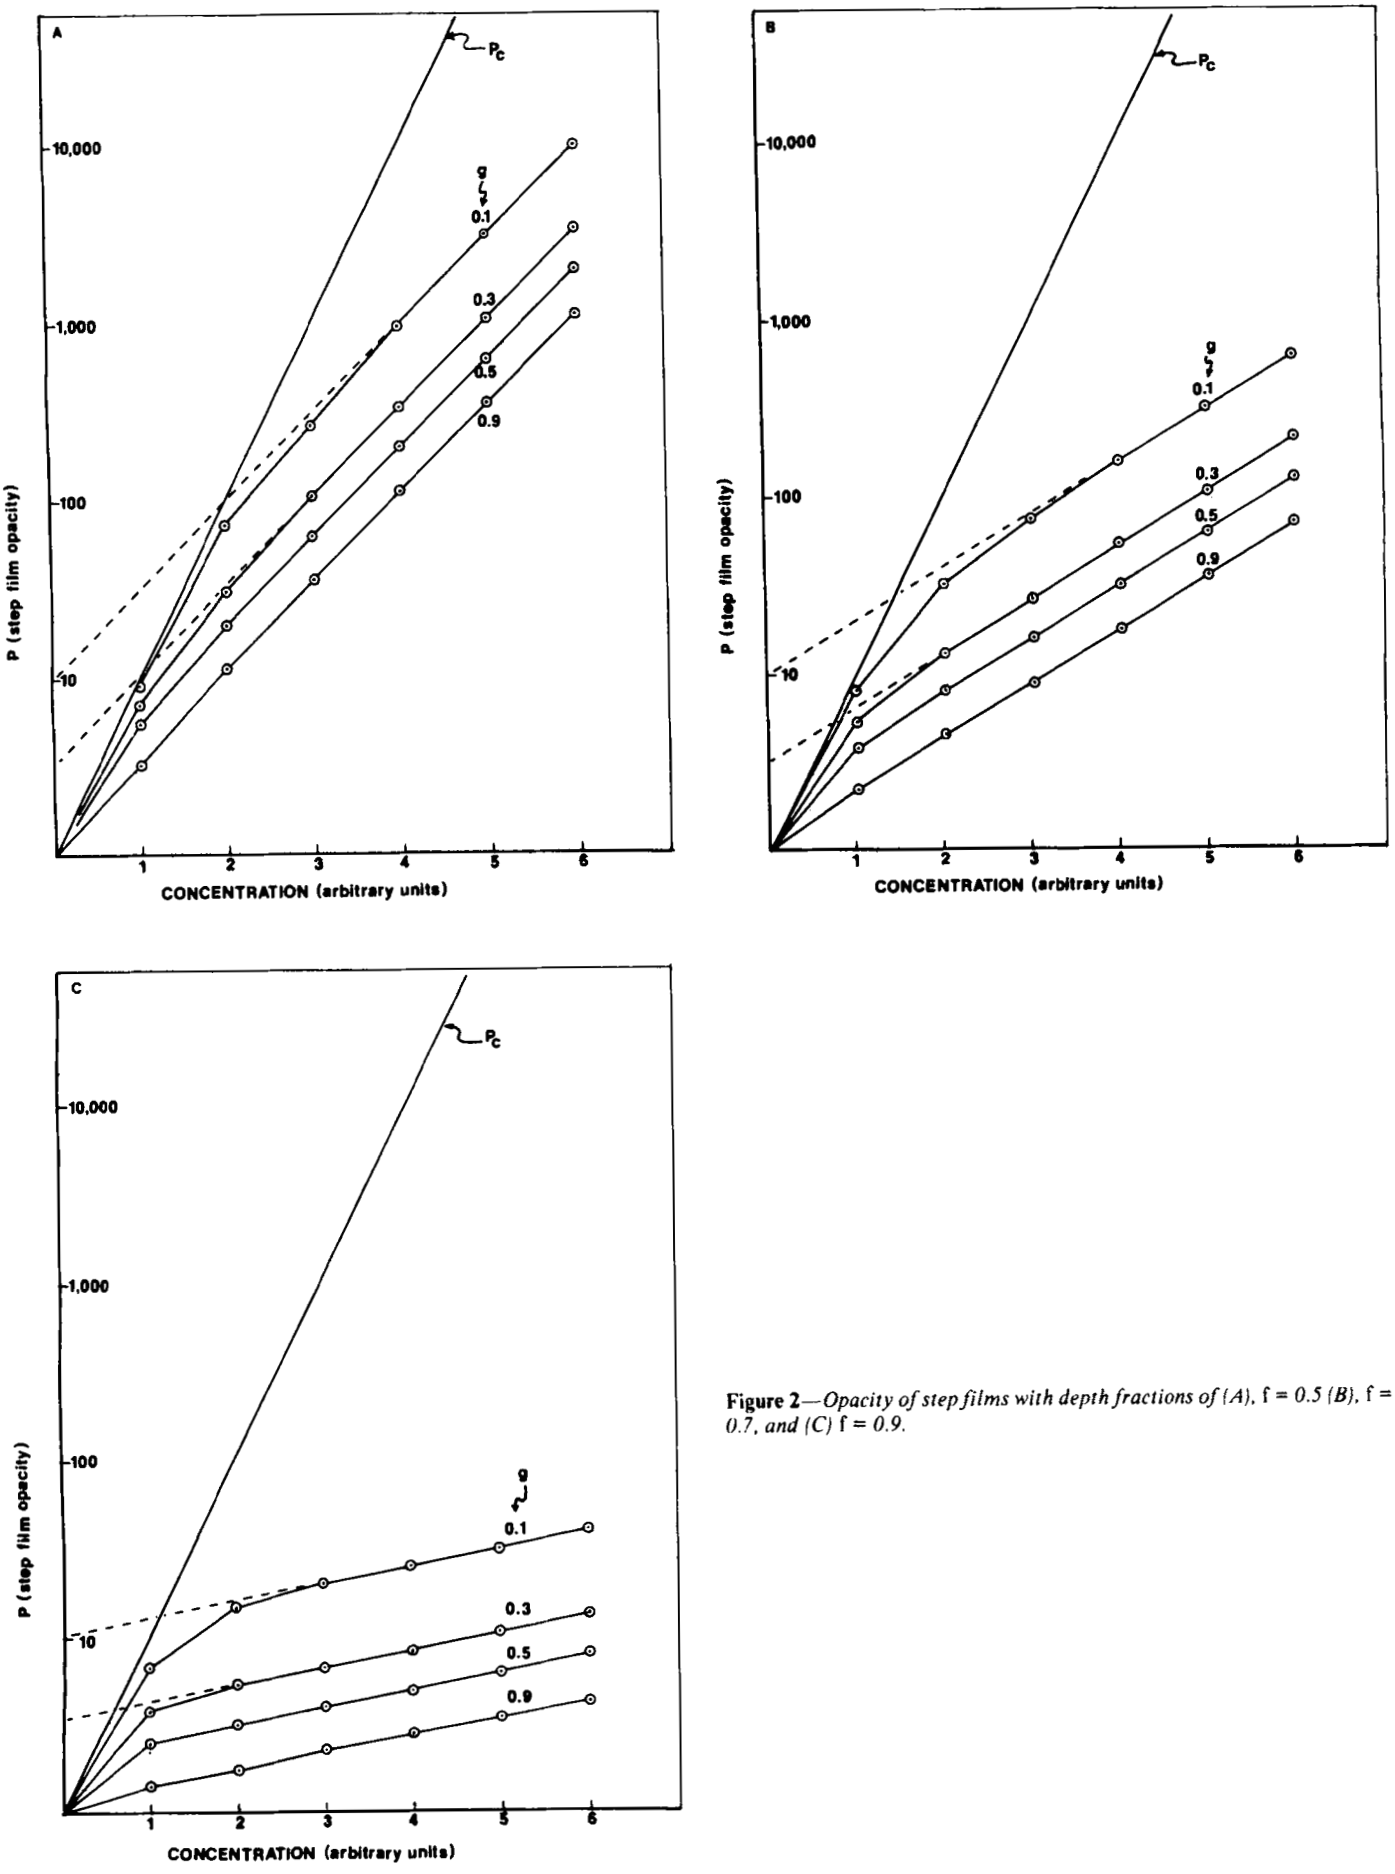

Figure 2—*Opacity of step films with depth fractions of (A), f = 0.5 (B), f = 0.7, and (C) f = 0.9.*

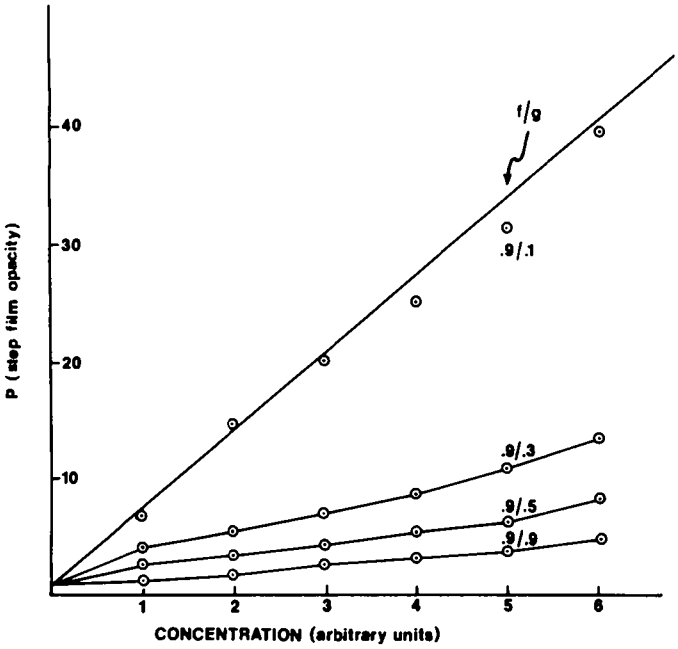

Figure 3—*Opacity of step films: linear plots against absorber concentration in arbitrary units.*

in Fig. 3. For $f = 0.7$ and 0.5, similar plots are distinctly concave up. We take this as an indication that high values of f apply to sunscreens on skin because in our clinical measurements SPF values increase roughly in proportion to absorber concentration rather than exponentially, as might be expected from Eqs. 2 and 3.

Opacity of Nonhomogeneous Films—The effect of nonuniform distribution of the absorber on the opacity of a film of uniform thickness can be treated in the same fashion as that of nonuniform thickness of a homogeneous film. The vertical dimension in Fig. 1 can be taken as a measure of absorber concentration by replacing d and d' with C and C', and deriving Eqs. 5 and 6 from conservation of the mass of absorber rather than film volume. Equation 7 follows identically; it is now immaterial whether the parameter f refers to the extent of transfer of the bulk of the film or to relocation of the absorber (except that the result of bulk transfer follows with certainty from Lambert's law while that of relocation of the absorber assumes that Beer's law applies with the same absorptivity, k, in both parts of the film; the latter is certainly not exact for some kinds of nonhomogeneity, such as recrystallization of the absorber).

Figures 2 and 3 can now be interpreted in terms of the transposed variables by labeling the abscissas as "thickness" rather than "concentration." They then show that nonhomogeneity frustrates the response of opacity to thickness (or product usage level) just as irregularities in thickness frustrates response to absorber concentration.

Origins of Irregularities—The particular geometry of the step film chosen in Fig. 1 does not enter into the derivation of average opacity. The depleted area can be broken up into any number of elements of arbitrary size and shape as seen from above (from the origin of the incident beam); only its fraction, g, enters the calculation. In fact, it is tacitly assumed in reference to sunscreens that the irregularities of thickness or concentration are distributed on a scale of distances fine enough that the resulting pattern of burned and protected skin will be averaged when subjectively scoring the degree of erythema. The only evident physical limitation is that the irregularities be large compared with the wavelength of UV light (of the order of 1 μm).

The topography of human skin is an obvious source of variation in the thickness of an applied film. Any fluid which wets the skin tends to accumulate in the sulci, the furrows which unfold to spare the inelastic epidermis from tensile stress when body movements, such as making a fist, increase the contour length along the surface. Heavily dyed mineral oil moderately applied to the skin discloses a map of the sulci; very little color is seen on the plateaus (the roughly triangular areas bounded by sulci). This pattern develops spontaneously on relaxed skin as soon as rubbing is stopped, partly because surface tension reduces the pressure of the fluid under the concave surfaces over unfilled sulci and pumps it away from the plateaus (except where it wicks up into a cone at the base of each hair). Dyed petrolatum gives somewhat more uniform coverage showing the importance of viscosity in retarding the effects of capillary action. With fluid mineral oil the plateaus are well covered only at repugnantly high levels of application.

This effect could be quantified by measurements of the cross-sectional area of the sulci and the length of sulci per unit area of skin on surface replicas (like those used in scanning electron microscopic studies of skin). The product of these two would give the sulcus volume per unit area of skin, and this would indicate the fraction of the residue of a sunscreen (or any other applied fluid) "lost" by this mechanism (which might vary from subject to subject and on different parts of the body); but, even in the absence of such data it seems evident from observation of dyed mineral oil on skin that the assumption of a uniform film thickness at tolerable application levels is a poor one.

Nonhomogeneity of the sunscreen residue on the skin is another likely cause of the disappointing performance of commercial products. When a typical sunscreen lotion is rubbed out on a microscope slide, dried at room humidity, and examined at moderate magnification, it has the irregular appearance of an ordinary emulsion residue. At least two phases are usually present: one probably derived from the water phase and another from the oil phase (as can be seen when an unrubbed, thin film is examined as it dries). Except in the very unlikely event that the UV absorber partitions between these residual phases at equal opacity, the resulting film must be optically more or less similar to a slice of Swiss cheese. If two or more absorbers are present, the array of possible distortions becomes more complex, especially if the absorbers were selected to be complementary on the basis of their dilute solution spectra, but the likelihood of a near optimal distribution seems remote.

A solution of *p*-aminobenzoic acid (PABA) in alcohol is an extreme case of poor absorber distribution in the residue. On glass the residue is a crust of small well-formed crystals with a large areal fraction of voids. On skin it is a loosely held, chalky-looking deposit which can be resolved into individual crystals with a magnifier. In either case it is obvious that even if the crystals are infinitely opaque, the residue can have an opacity no greater than the reciprocal of the areal fraction of voids (as in the bottom row of Table III). This situation is probably not altered much when a glycol or an oil is added to mask the chalkiness. Since neither of these fluids is a good PABA solvent, they would be almost as transparent to harmful radiation as the voids they fill.

CONCLUSION

The ideal sunscreen leaves a chemically and physically uniform residue on the skin. The physical form of the product as applied is not important. It may be a simple solution or a coarse emulsion but the residue after casual application should be a single continuous phase in which the absorbers are in true solution. It should tend to remain well spread on the plateaus of the skin and not accumulate in the sulci.

Quantitative Investigation of Renal Handling of Drugs in Dogs with Renal Insufficiency

AKIRA KAMIYA, KATSUHIKO OKUMURA, and RYOHEI HORI ˣ

Received January 13, 1983, from the *Department of Pharmacy, Kyoto University Hospital, Faculty of Medicine, Kyoto University, Sakyo-ku, Kyoto, 606, Japan.* Accepted for publication June 15, 1983.

Abstract □ A quantitative analytical method for studying renal handling of drugs in dogs with mild renal impairment is described. Renal damage was induced experimentally by pretreatment with mercuric chloride or neomycin. Analytical results of renal handling in those animals indicated a reduction in maximum transport of secretion, while the affinity of drugs to secretion site and reabsorption showed slight or no change. These results were consistent qualitatively with other renal function test values which demonstrated the state of glomerular or proximal renal tubular function. Evidence for the applicability of the proposed analytical method for quantitative validation of functional changes in the nephron in renally impaired animals, as well as the precise determination of the site of damage, was demonstrated. This work holds considerable promise for the study of dosage adjustments in patients with renal disease.

Keyphrases □ Renal insufficiency—effect on the renal handling of drugs, dogs, sulfamethizole, cephalexin, ampicillin, quantitative analytical method □ Sulfamethizole—renal handling in dogs, quantitative analytical method, effect of renal insufficiency □ Cephalexin—renal handling in dogs, quantitative analytical method, effect of renal insufficiency □ Ampicillin—renal handling in dogs, quantitative analytical method, effect of renal insufficiency

In the pharmacokinetics of drugs, renal excretion plays an important role. Recent reviews (1–3) have shown that the pharmacokinetics of drugs change in patients with renal failure necessitating dosage adjustments. However, there have been few reports on the quantitative measurement of renal excretion alterations. In previous papers (4–6) we have introduced a new and simple analytical method for studying renal handling of drugs in rabbits, dogs, and humans under normal conditions. Quantitative analyses of glomerular filtration, renal tubular secretion, and renal tubular reabsorption were performed simultaneously.

Patients with renal failure show complicated patterns of renal functional impairment. In some cases, such as the early phase of pyelonephritis, kidney stone, and prostatic hypertrophy, the patients have selective renal tubular dysfunction. However, changes in renal handling of drugs in such patients have not been investigated.

In this paper, we focused on the application of our method to disease models in dogs. Thus, dogs with acute renal insufficiency (induced by nephrotoxic compounds) were chosen as the model for selective renal tubular damage in humans. The changes of renal functions and renal handling of drugs on each of the transport processes were followed in these dogs. On the simultaneous measurement of the processes mentioned, the analysis indicated the great potential of the method for diagnosing the site of the dysfunction and/or the degree of severity of nephron disorders affecting the rates of urinary excretion of drugs in patients with renal impairment.

Table I—Effects of Mercuric Chloride on Renal Tubular Secretion and Reabsorption of Sulfamethizole in a 7.5-kg Dog

48 h[a]	11	98	0.21	1.5
72 h[a]	7	99	0.23	0.9

[a] Time after mercuric chloride injection. [b] Maximum velocity of secretion. [c] Michaelis constant. [d] Reabsorption fraction. [e] Corrected V_{max}.

EXPERIMENTAL SECTION

Materials—Sulfamethizole was of JP IX grade[1]. Cephalexin monohydrate[2], sodium ampicillin[2], and neomycin sulfate[3] were obtained commercially. All other chemicals were reagent grade.

Analytical Methods—*Sulfamethizole*—Plasma and urine samples were treated with deproteinizing reagents (7) and then analyzed by the procedure of Bratton and Marshall (8), using 2-dimethylaminoethyl-1-naphthylamine as the coupling reagent. Unbound (protein-free) sulfamethizole concentrations in plasma were determined by ultrafiltration using a membrane cone[4].

Cephalexin and Ampicillin—Drug concentrations in plasma and urine were determined fluorometrically (9, 10). Unbound drugs in plasma were assayed after ultrafiltration using cellulose tubing[5].

Inulin and Creatinine—Inulin concentrations in plasma and urine were measured by a modification of the method of Dische and Borenfreund (11). Creatinine levels in plasma and urine were analyzed by Jaffe's reaction using picric acid (12).

Other Urinalyses—Urine lysozyme activity was determined by the method of Litwack (13), and urine glutamic oxaloacetic transaminase (GOT) activity was assayed using 2,4-dinitrophenylhydrazine as the color reagent (14). Blood urea nitrogen (BUN) was measured by the modified diacetylmonoxime method (15). Urinary protein was estimated using urinalysis reagent strips[6].

Animal Model—Male mongrel dogs weighing 5–15 kg were used. The animals each received a single 15-mg/kg im injection of mercuric chloride or 45-mg/kg sc injections of neomycin sulfate daily for 7 d. These doses of nephrotoxic compounds were chosen to produce the selective renal tubular damage and the mild disease states, which changed slowly. Under these conditions, we could follow the changes in renal function and renal handling of drugs with time. These dosages did not cause diarrhea, and food intake and body weight did not change more than 10% throughout the experimental period. For the dogs with acute renal insufficiency induced by mercuric chloride, renal clearance experiments were performed before and after mercuric chloride injection. For the neomycin-treated dogs, the experiments were carried out before injection, 3 and 7 d after the first injection, and 1 and 2 weeks after the final injection.

Renal Clearance Experiment—Animals were anesthetized with pentobarbital (27 mg/kg ip). Each animal received a constant infusion of 4% (w/v) mannitol and 0.3% (w/v) inulin in saline at 3 mL/min throughout the experiment. Blood samples were taken by venipuncture. Urine samples were collected *via* a catheter. Urinary pH was measured immediately after collection.

Each drug was dissolved in saline and given intravenously. Urine was collected for 2 h beginning 5 min[1] after injection and at 10-min intervals thereafter. During this 2-h experiment, 6–10 blood samples were drawn, and total and unbound drug were determined in the plasma as described under *Analytical Methods*. Blood collection was performed at 1 min before the midpoint of the selected urine collection period in order to correct the delay time of drug appearance from blood to urine.

The glomerular filtration rate (GFR) was determined by inulin clearance. Clearance ratios were calculated for each sample using the unbound drug concentration in plasma (Pf) and expressed as the excretion ratio (ER) using the following:

$$ER = \frac{U \cdot V}{GFR \cdot Pf} \qquad \text{(Eq. 1)}$$

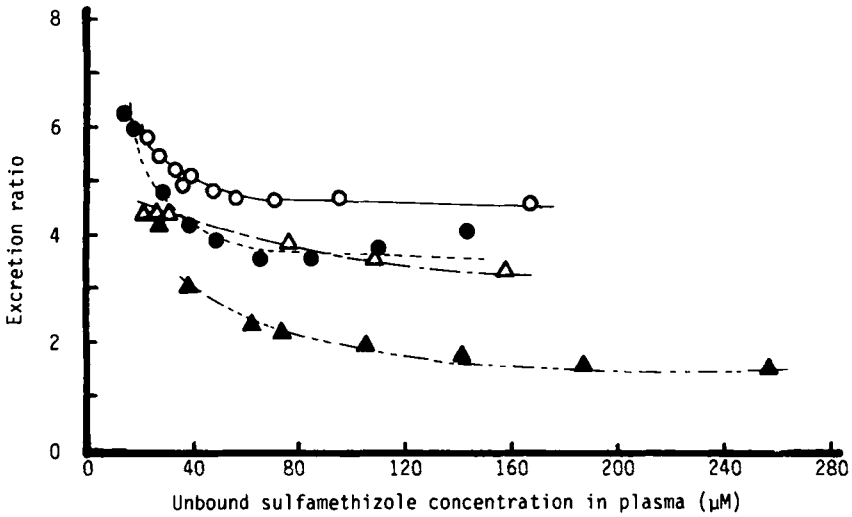

Figure 1—*Representative plot of renal clearance of sulfamethizole in a dog and computer-simulated curves before and after mercuric chloride injection. Key: (○) control (before mercuric chloride injection); (●) 24 h; (△) 48 h; (▲) 72 h.*

where U is drug concentration in urine and V is the urine flow rate. In some animals, the clearance experiments were repeated two to three times within 2–7 d under normal conditions to check the reproducibility of these experiments; the excretion ratios among the experiments were almost the same. The last clearance experiment was used as "control" in those cases.

Computer Analyses—Computer analyses were carried out using the following equation as previously described (4–6):

$$ER = \left(1 + \frac{V_{max}}{(K_m + Pf) \cdot GFR}\right) \cdot (1 - R) \qquad \text{(Eq. 2)}$$

where V_{max} is the maximum velocity of secretion, K_m is the Michaelis constant, and R is the reabsorption fraction.

RESULTS

The effects of disease on the renal clearance of various drugs injected intravenously were investigated in dogs with mild renal insufficiency induced by the administration of mercuric chloride. Figure 1 shows typical patterns of sulfamethizole secretion through the kidney and computer-simulated curves using the data listed in Table I. Excretion ratios of sulfamethizole declined as a function of time after administration of mercuric chloride. Using each curve, the maximum velocity of secretion (V_{max}), affinity constant of drug to the site of secretion (K_m), and tubular reabsorption fraction (R) were calculated. The analytical results indicated that the treatment with mercuric chloride markedly reduced the V_{max}, but K_m remained unchanged (Table I, Fig. 2). Also, administration of mercuric chloride produced an increase in renal tubular reabsorption as the urine pH decreased (Fig. 2), but glomerular filtration rate (GFR), creatinine clearance (Ccr), and BUN remained unaltered. Regarding the renal tubular functions, however, urine lysozyme activity, urine GOT activity, and urinary protein increased with time after mercuric chloride injection.

Concomitantly, the effects of disease on the renal clearance of ampicillin (Fig. 3a) and cephalexin (Fig. 3b) were also studied 48 h after the injection of mercuric chloride. Similar results as those for sulfamethizole were obtained using either drug; *i.e.*, V_{max} diminished substantially (50–60% of control), while K_m and R showed no significant change compared with the control values. Urine lysozyme activity increased markedly, while GFR decreased slightly.

Renal clearance experiments for sulfamethizole were then carried out on neomycin-treated dogs. Figure 4 shows representative results of this experi-

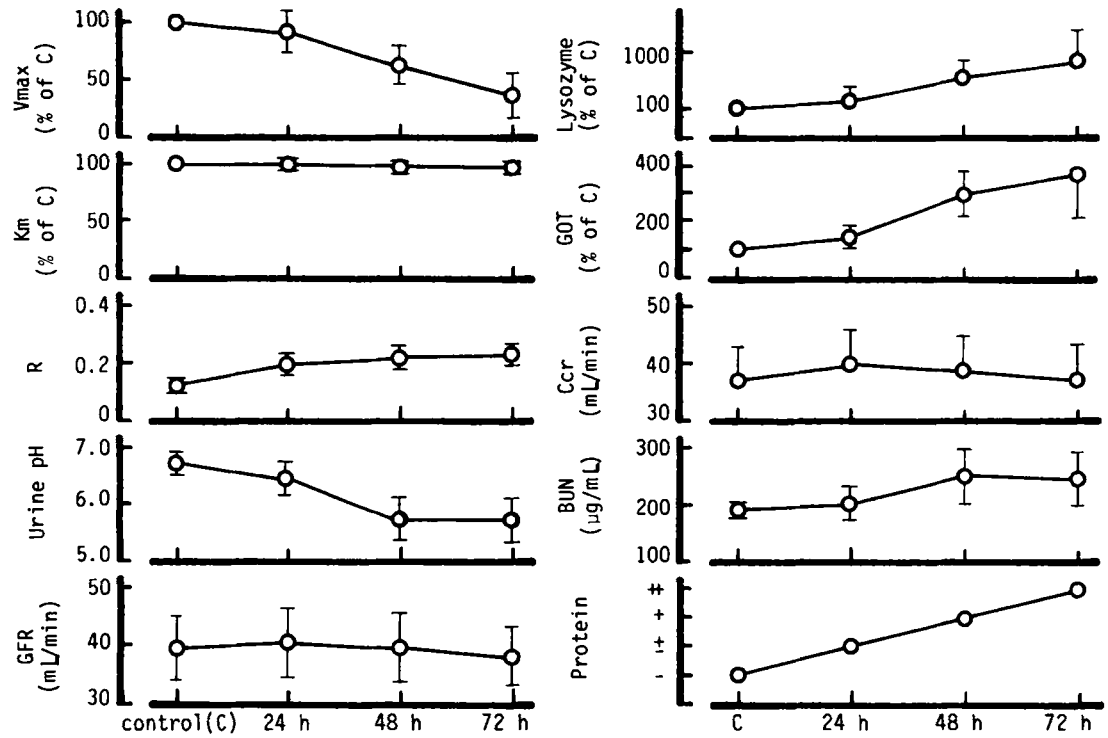

Figure 2—*Effects of mercuric chloride on various renal functions in dogs. Data represent mean ± SD of three animals. Key: (V_{max}) maximum velocity of secretion of sulfamethizole; (K_m) Michaelis constant for secretion of sulfamethizole; (R) reabsorption fraction of sulfamethizole; (GFR) glomerular filtration rate; (Lysozyme) lysozyme activity in urine; (GOT) glutamic oxaloacetic transaminase activity in urine; (Ccr) creatinine clearance; (BUN) blood urea nitrogen; (Protein) urinary protein; (C) control.*

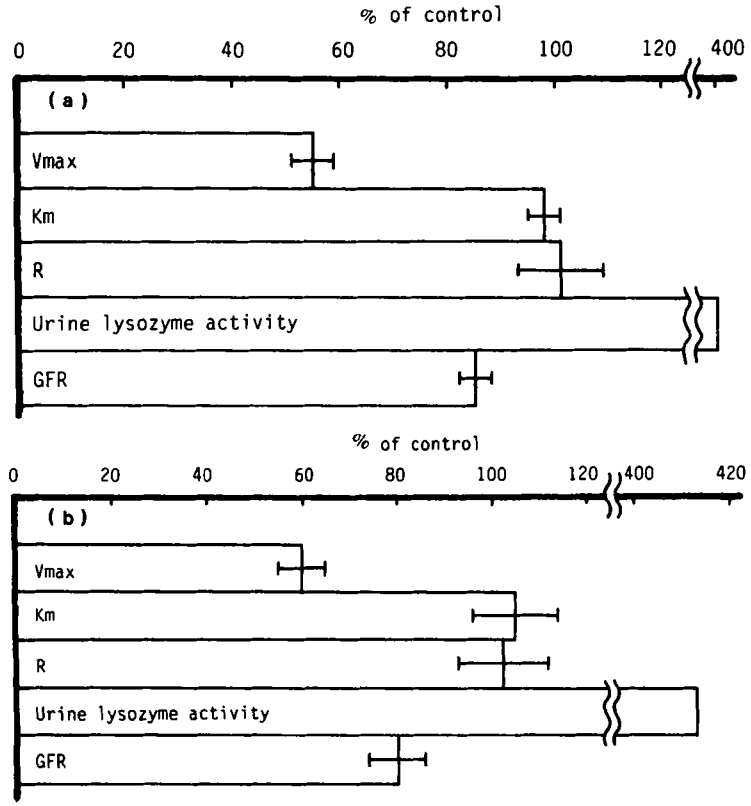

Figure 3—*Effects of mercuric chloride on the renal clearances of ampicillin (a) and cephalexin (b) and renal function of dogs 48 h after injection. Data represent mean ± SD of three animals. Abbreviations are as described in Fig. 2.*

ment with computer-simulated curves, and Table II presents the analytical data. The administration of neomycin decreased the excretion ratio for sulfamethizole, with a gradual recovery on the cessation of neomycin effect with time (Figs. 4 and 5). Our analysis clearly demonstrated the substantial reduction of V_{max} during the neomycin treatment (Table II, Fig. 5: 3 and 7 d). One and two weeks after the end of neomycin treatment, V_{max} increased and approached the values of the control, although K_m and R remained unmodified throughout the experiments (Table II, Fig. 5). Slight increases in lysozyme and GOT excretion in urine were detected (Fig. 5). GFR and Ccr were decreased ~20% as compared with the controls, but BUN showed no increase, except 7 d after the start of neomycin treatment (Fig. 5).

DISCUSSION

Some patients with renal failure show a nonparallel decrease of glomerular and tubular functions. However, the changes in renal handling of drugs in such patients are unknown. Thus, experiments were performed to clarify those quantitative changes using our proposed method. As a subclinical study, mercuric chloride- or neomycin-treated dogs were chosen as the model of selective renal tubular impairment.

Induction of renal impairment by mercuric chloride is well known. Histological studies have shown primary damage in the proximal tubular cells (16, 17). Thus, dogs treated with mercuric chloride were used as a model for the study of the effect of acute renal disease on drug clearance.

Dogs treated with mercuric chloride showed no significant change in the indices of glomerular filtration (GFR, Ccr, and BUN) as compared with the normal condition (Fig. 2). However, the urine pH decreased (Fig. 2), indicating alteration of the kidney function. The significant increases of lysozyme, GOT, and protein in the urine indicated renal tubular damage.

Lysozyme and GOT in urine have been reported to reflect the proximal tubular cell function (18, 19). As these two enzymes are actively reabsorbed by the proximal tubular cells, they are excreted into urine in minute amounts

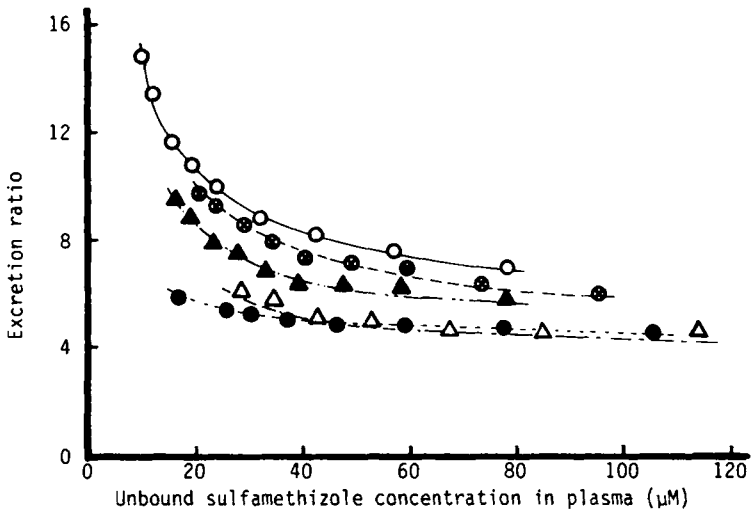

Figure 4—*Representative plot of renal clearance of sulfamethizole in a dog and computer-simulated curves before, during, and after neomycin injections. Key: (○) control (before injection); (●) 3 d and (△) 7 d after the first neomycin injection; (▲) 1 week and (⊗) 2 weeks after the final neomycin injection.*

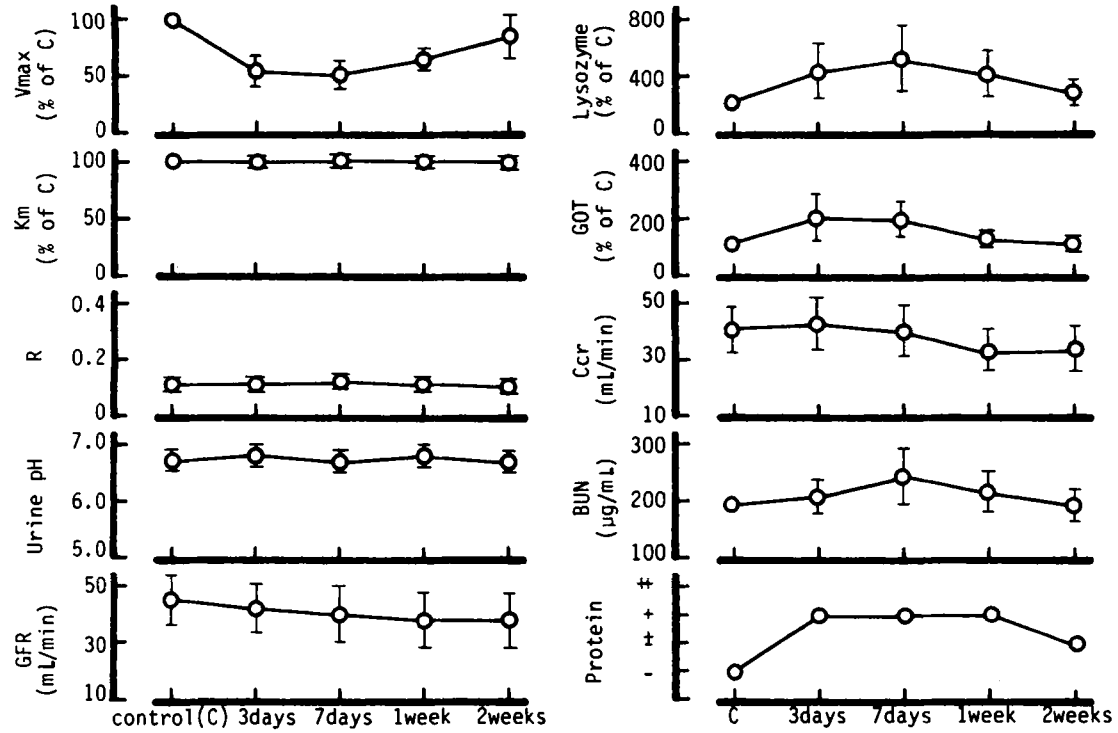

Figure 5—*Effects of neomycin on various renal functions in dogs. Data represent mean ± SD of three animals. Abbreviations are as described in Fig. 2.*

under normal conditions. The excreted amounts of these enzymes increase as the number of injured renal tubular cells increase. Increased lysozyme and GOT activities in urine, therefore, indicate damage of the proximal renal tubules (Fig. 2). Further, the increase in urinary protein has been considered due to cell debris from damaged tubular cells.

Results gathered in the study of sulfamethizole using the clearance method fitted the above findings with good qualitative compatibility, *i.e.*, a marked decrease in maximum velocity of secretion, V_{max}, and no change in the affinity constant of secretion, K_m, which suggested the reduction in the number of intact proximal tubules. Also, the absence of alteration in reabsorption for cephalexin and ampicillin, as shown in Fig. 3, and the pH-dependent changes in the reabsorption for sulfamethizole supported the finding that renal tubular reabsorptive function was intact. The analytical data clearly demonstrated that the reduction in excretion ratios were mainly due to decreases in V_{max} for secretion.

Specific proximal tubular cell damage has also been reported for neomycin (20, 21). Our results indicated only mild damage to the proximal tubules, as shown in Fig. 5. Subsequently, signs of recovery from damage caused by neomycin injections were detected. Under this slightly impaired condition (Ccr remained the same or decreased slightly), the excretion ratios were substantially diminished, and the analytical data revealed that this reduction was due to the decrease in V_{max} (Table II). These results were consistent with the early report of neomycin effects by Gol'dberg (20). He reported changes in the transport maximum of *p*-aminohippurate (Tm PAH) and Ccr under the conditions we used, with greater reduction of Tm PAH than of Ccr. Present results also showed a greater reduction of V_{max} than of Ccr.

Although body weights did not change more than 10% over the course of the experiment, since the dogs varied in weight from 5 to 15 kg, V_{max} per unit weight (V'_m) was calculated. V'_m showed small variation among dogs (Tables I and II).

Table II—Effects of Neomycin on Renal Tubular Secretion and Reabsorption of Sulfamethizole in a 15-kg Dog

	V_{max}[c], μmol/min	K_m[d], μM	R[e]	V'_m[f], μmol/min/kg
Control	33	90	0.90	2.2
3 d[a]	18	89	0.10	1.1
7 d[a]	18	98	0.12	1.2
1 week[b]	21	95	0.10	1.4
2 weeks[b]	28	93	0.09	1.9

[a] Days after the first neomycin injection. [b] Weeks after the final neomycin injection. [c] Maximum velocity of secretion. [d] Michaelis constant. [e] Reabsorption fraction. [f] Corrected V_{max}.

In conclusion, the quantitative data gathered on the renal handling of drugs in dogs with experimentally induced acute renal insufficiency provided conclusive evidence for the reliability of the clearance method for qualitatively testing renal function. Functional changes in the nephron could be also quantitatively estimated.

Recently, a kinetic model (using normal dogs) of the renal excretion of iodopyracet has been proposed (22). That method has not been useful clinically since data fitting for plasma concentrations must be done prior to the calculation of parameters for urinary excretion rates. Our equation was simple and suitable for clinical application in patients with renal failure and was found to be more appropriate than that method using the Akaike's information criterion (23, 24).

This study suggests the use of the described method in dosage adjustments for patients with renal disease. This possibility is now being tested clinically in patients with renal failure where the renal tubular functions are reduced more than their creatinine clearance.

Aqueous Conversion Kinetics and Mechanisms of Ancitabine, a Prodrug of the Antileukemic Agent Cytarabine

LEE E. KIRSCH * and ROBERT E. NOTARI ˣ

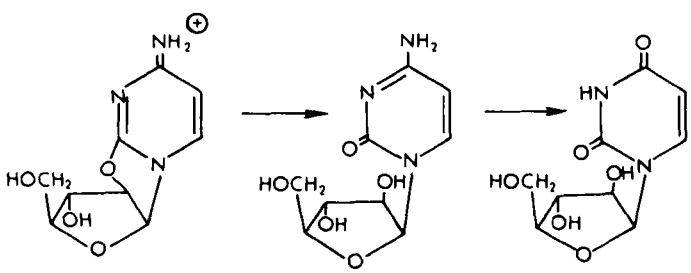
Received November 22, 1982 from *Lloyd M. Parks Hall, College of Pharmacy, The Ohio State University, Columbus, OH 43210.* Accepted for publication June 1, 1983. *Present address: Product Development Division, Eli Lilly and Co., Indianapolis, IN 46206.

Abstract □ The kinetics of conversion of the prodrug ancitabine to the anticancer drug cytarabine have been studied in aqueous solutions in the pH range of 1.5–10.7, temperature range of 19.5–80.0°C, ionic strength range of 10^{-4} to 1.5, and in the presence of several general-base catalysts. Under all conditions ancitabine was quantitatively converted to cytarabine. The pH–rate profiles were linear with slope = 1 in alkaline pH, becoming pH independent in the region of maximum stability at pH ≤ 4, where buffer catalysis was found to be insignificant and $k_{obs} \cong (1.12 \times 10^{11}\ h^{-1})\exp\{-10121\ deg/T\}$. At 30°C, pH ≤ 4, it is calculated that an aqueous ancitabine solution will maintain 90% of its initial concentration for 12 d. A novel method for measuring general-base catalysis in competition with predominating specific-base catalysis and in the presence of secondary salt effects at constant ionic strength was developed. Three mechanisms of hydrolytic prodrug conversion are proposed: nucleophilic hydroxide addition, general base-assisted nucleophilic water attack, and spontaneous water attack.

Keyphrases □ Ancitabine—conversion to cytarabine, kinetics, aqueous solutions □ Cytarabine—conversion of ancitabine, aqueous solutions, kinetics □ Kinetics—ancitabine conversion to cytarabine, aqueous solutions

Ancitabine (I), a prodrug of the antileukemic agent cytarabine (II), has been shown to be more effective than II in several animal tumor systems (1, 2) (Scheme I). The pharmacological activity of I is attributed to its conversion to II rather than any direct effect on nucleic acid synthesis (3, 4). Although incubation of I with Ehrlich ascites carcinoma cells demonstrated very little uptake of I, significant intracellular concentrations of II were nonetheless observed (5).

Intravenous doses of I are primarily excreted unchanged in urine together with II and its inactive metabolite, 1-β-D-arabinosyluracil (III) (3, 6, 7). The efficacy of II is limited by its rapid deamination to III (6). It has been suggested that a depot form of II might be useful in maintaining effective levels (8).



I II III

Scheme I

Unlike II, I is not phosphorylated nor deaminated (6, 9, 10). A prodrug may extend the biological duration of the drug through slow prodrug absorption or rate-limiting conversion to the drug (11). Ancitabine may act as a reservoir through hydrolytic production of II (8).

In vivo conversion of I is thought to be chemical rather than enzymatic hydrolysis (8, 12, 13). The purpose of this study was to investigate the kinetics and mechanisms of prodrug hydrolysis in aqueous solutions. Since I, like II, is not orally active (6), it is important to define its stability for preparation and storage of parenteral formulations.

EXPERIMENTAL SECTION

Stability in Sodium Hydroxide and Hydrochloric Acid Solutions Using Thin-Layer Chromatography—Samples of 0.01 M ancitabine (I)[1] in 0.1 M HCl and 0.05 M NaOH at 50°C were taken over a 4-d period, and 10-μL aliquots were spotted together with reference samples of I, II[2], III[3], and cyclouridine[4] on 20 × 20-cm TLC plates (0.25 mm silica gel GF)[5]. The plates were developed to 10 cm in water-saturated 1-butanol–propanol (3:1), air dried, and examined at 254 nm. A time zero plate was also impregnated with I_2 vapor, and 0- and 1-h plates were sprayed with sulfuric acid and heated. This procedure was also used periodically in the kinetic studies to identify the components in the reaction mixtures.

Spectrophotometric Analysis of Ancitabine and Cytarabine in Mixtures—Absorbance spectra from 220 to 330 nm were obtained for synthetic mixtures to determine which wavelengths could best be monitored for reaction time-course changes[6]. These showed an isosbestic point at 267 nm.

Beer's law plots in 0.1 M HCl provided molar absorptivities (ε) at 240 and 290 nm of 7.25×10^3 and 4.70×10^2 for I and 1.38×10^3 and 1.05×10^4 for II. Known concentrations in mixtures were successfully calculated using:

$$10^5 \cdot [I] = 13.914A_{240} - 1.828A_{290} \quad \text{(Eq. 1)}$$

$$10^5 \cdot [II] = 9.604A_{290} - 0.623A_{240} \quad \text{(Eq. 2)}$$

which were derived from simultaneous equations for total absorbance, A, at 240 and 290 nm for mixtures of I and II.

	HCl	0.002-1.00	1.5-2.7	4

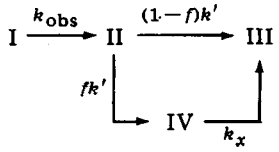
[a] All reactions aqueous unless otherwise specified. [b] Adjusted with sodium chloride. [c] Number of rate constants determined. [d] Calculated values. [e] Solvent was D_2O.

254-nm fixed-wavelength detection[7] was used to assay I, II, and III in mixtures. The mobile phase was filtered and deaerated, double-distilled water containing 12% (v/v) methanol[8], 0.01 M acetic acid, 0.01 M sodium acetate, and 0.005 M sodium heptanesulfonate as an ion-pairing agent, at 1.0 mL/min. The capacity factors of I, II, and III were 4.4, 1.8, and 0.52, respectively. The peak height *versus* concentration plots were linear in the 1.0×10^{-5} to 10^{-4} M range for all three compounds. Some analyses were carried out using the HPLC method of Tuncel *et al.* (14), with similar results.

Kinetics in Buffers and in Dilute Hydrochloric Acid—Reaction solutions containing I were prepared at various pH values and temperatures (Table I). Those in the pH range of 5.2-10 were assayed as a function of time by diluting aliquots with an appropriate volume of 0.1 M HCl before employing the spectrophotometric analysis (Eqs. 1 and 2) or the HPLC assay (14). In the pH range of 5.2-6.2, mass balance was confirmed by HPLC analysis of [I], [II], and [III] with time (14). For reactions in the pH range of 6.2-10, mass balance was confirmed by monitoring both the isosbestic point and the percent recovery of [I] and [II] as a function of time.

Reactions in the pH range of 1.5-4 were assayed as a function of time by cooling aliquots and applying the HPLC assay reported herein. The sum of the molar concentrations of I, II, and III did not equal the initial concentration of I, $[I_0]$. Complete conversion of I to II was confirmed by fitting concentration-time profiles of II to a biexponential equation using NONLIN (15), calculating the areas under these curves (AUC), and showing them to be equal to the expected values of $[I_0]/k'$, where k' is the rate constant for loss of II.

Kinetics of hydrolysis of I at 80°C were compared with that of II in 0.01 and 0.001 M HCl and in 0.01 M HCl containing 1.0 M NaCl. Samples were assayed as a function of time using the HPLC assay described herein. The concentration of IV (Scheme II) were determined as a function of time by subtracting the sum of the time-dependent concentrations from the initial concentrations of starting material. The rate constants k_{obs}, k', and k_x were determined by simultaneously fitting a series of differential equations describing the concentration-time courses of I, II, III, and IV in Scheme II.



Scheme II

Both k_{obs} and k' were independent of pH and ionic strength in acid. The two pairs of values for k_x provided fractional negative slopes for plots of log k_x *versus* pH or $[\sqrt{\mu}/(1+\sqrt{\mu})]$. Although data are limited, they may indicate that loss of IV may not be a single irreversible process as shown in Scheme II. The value for k' (0.076 h^{-1}) agrees with that previously reported under similar conditions (16).

Kinetics in Dilute Sodium Hydroxide—Distilled-deionized water was refluxed, cooled under nitrogen, and used to prepare solutions containing I in the presence of sodium hydroxide and sodium chloride (Table I). These were maintained at constant temperature under a stream of nitrogen and assayed as a function of time by acidifying aliquots with HCl, measuring absorbances, and applying Eqs. 1 and 2. The influence of ionic strength was quantitated by varying the sodium concentration at 19.5°C (Table II).

***In Situ* Spectrophotometric Analysis of Alkaline Reactions**—Studies for estimating the kinetic isotope effect required the analysis of I and II in reactions carried out in the spectrophotometer using either aqueous sodium hydroxide or sodium deuteroxide in deuterium oxide. Potentiometric titrations of 0.057 M I in 0.05 M HCl with sodium hydroxide showed no evidence for a pK_a. Spectrophotometric data were consistent with this observation. Spectra were superimposable below pH ~8.4. At pH 10.4 and 11.2 absorbance changed with time. The ϵ value at 230 nm, calculated from the intercepts of $\ln(A_t - A_\infty)$ *versus* time, was the same as in acidic solutions.

This pH-independent spectrum for I was compared with that for II in carbonate-free 1×10^{-4} M NaOH. The maximum absorbance differences occurred at 258 and 280 nm. Molar absorptivities (ϵ) at 258 and 280 nm were 1.01×10^4 and 4.69×10^3 for I in double-distilled water and 6.78×10^3 and 7.88×10^3 for II in carbonate-free 1×10^{-4} M NaOH. Concentrations of I and II were calculated from the following equations, derived from simultaneous equations for the total absorbances at 258 and 280 nm:

$$10^4 \cdot [I] = 1.651A_{258} - 1.420A_{280} \quad \text{(Eq. 3)}$$

$$10^4 \cdot [II] = 2.112A_{280} - 0.986A_{258} \quad \text{(Eq. 4)}$$

The accuracy was assumed to be similar to the acid-quenched assay although its assessment using known mixtures under basic conditions was not possible due to the instability of I.

Comparison of Ancitabine Kinetics in Sodium Hydroxide to Those in Sodium Deuteroxide—A closed system with nitrogen-flushed head space was used to limit uptake of atmospheric carbon dioxide and hydrogen-deuterium exchange. Polytef-capped cuvettes were filled with solutions containing either 1.9×10^{-4} M NaOD in deuterium oxide or 1.9×10^{-4} M NaOH in carbonate-free, double-distilled water. Stock solutions of I were prepared free of carbon dioxide and maintained at ambient temperatures. Each reaction in deuterated solvent was duplicated by a corresponding aqueous reaction. An aliquot of the stock solution was quickly added to each cuvette, capped, mixed, and the time of mixing was marked on the recorder[6]. The cuvettes were placed in the thermostated chamber along with a blank. Absorbances of each reaction mixture were automatically recorded at 258 and 280 nm as a function of time using a 2-s dwell time for each cuvette, with automatic reference compensation before and after each reading[6]. Reactions were allowed to proceed until absorbances were constant with time. The temperature in the cuvette chamber was automatically recorded before and after each run. The concentrations of I and II were calculated using Eqs. 3 and 4.

RESULTS

Hydrolysis Products—Reactions monitored by TLC showed I to be stable over a 4-d period at 50°C in water and in 0.1 M HCl, while converting immediately to II in 0.05 M NaOH. At pH ≅ 1.5-6, HPLC analyses detected subsequent deamination of II to III, in accordance with Scheme II. As the pH decreases in this range, the formation of III becomes detectable during the hydrolysis of I because k' passes through a maximum value at pH 3, whereas k_{obs} decreases to a minimum and is constant below pH 4. The AUC values

[a] The experimental conditions and results presented here are a representative sample of a much larger body of kinetic data. All buffer studies were adjusted to μ = 1.0 using NaCl. [b] Calculated values.

of the concentration–time profiles for II showed that I was quantitatively converted to II. The appearance of an additional, nonchromophoric intermediate in the chemical deamination of II to III, demonstrated previously (16), was confirmed.

Hydrolysis in Acid—In the presence of dilute hydrochloric acid, first-order rate constants $k_s a_{H_2O}$, obtained from linear plots based on:

$$\ln [I] = \ln [I_0] - k_s a_{H_2O} t \qquad \text{(Eq. 5)}$$

were found to be temperature dependent but independent of pH and ionic strength (Fig. 1, Table II).

Hydrolysis in Alkali—In the presence of dilute sodium hydroxide (or deuteroxide), the second-order rate constants, k_{OH}, were obtained from the slopes of linear plots based on:

$$\left\{\frac{1}{[I_0] - [OH_0]}\right\} \cdot \ln \left\{\frac{[I][OH_0]}{[I_0][OH]}\right\} = k_{OH} t \qquad \text{(Eq. 6)}$$

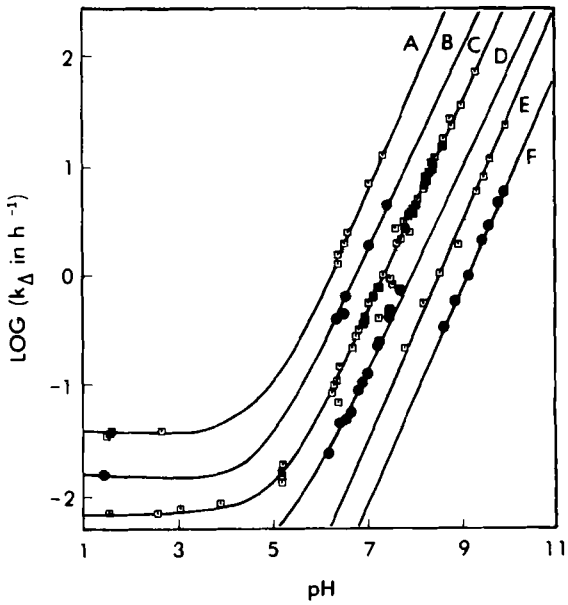

Figure 1—*The pH–rate profile for quantitative conversion of I to II. Data points (k_Δ) represent k_{obs} values corrected for buffer catalysis. Curves are calculated (Eq. 29) at 80°C (A), 70°C (B), 60°C (C), 50°C (D), 40°C (E), and 31.4°C (F). μ = 1.0.*

where [OH] is the concentration of either hydroxide or deuteroxide as determined from $[OH] = [OH_0] - [II]$.

Kinetics in Buffers—In the presence of excess buffer, first-order rate constants (k_{obs}) were obtained from linear plots based on $\ln [I] = \ln [I_0] - k_{obs} t$. Buffer participation was recognized in plots of log k_{obs} *versus* pH, which showed that hydroxide and solvent attack were not sufficient to describe the observed rate constants under all conditions (Fig. 2). General base-catalyzed water attack was hypothesized leading to the overall expression (17):

$$k_{obs} = \left(k^0_{OH}[OH]\frac{\gamma_{OH}\gamma_I}{\gamma_\dagger}\right) + \left(a_{H_2O}\sum_{i=1}^{n} k^0_{B_i}[B_i]\frac{\gamma_I\gamma_{B_i}}{\gamma_{\dagger i}}\right) + (k_s a_{H_2O}) \qquad \text{(Eq. 7)}$$

where k^0_{OH} is the rate constant for hydroxide attack at zero ionic strength, γ_{OH} is the activity coefficient for hydroxide, γ_I is the activity coefficient for I, $\gamma_\dagger$ is activity coefficient for the hydroxide-attack transition state, $[B_i]$ is the concentration of the ith general base, γ_{B_i} is the activity coefficient for the ith base, $\gamma_{\dagger i}$ is the activity coefficient for the transition state for B_i attack, $k^0_{B_i} a_{H_2O}$

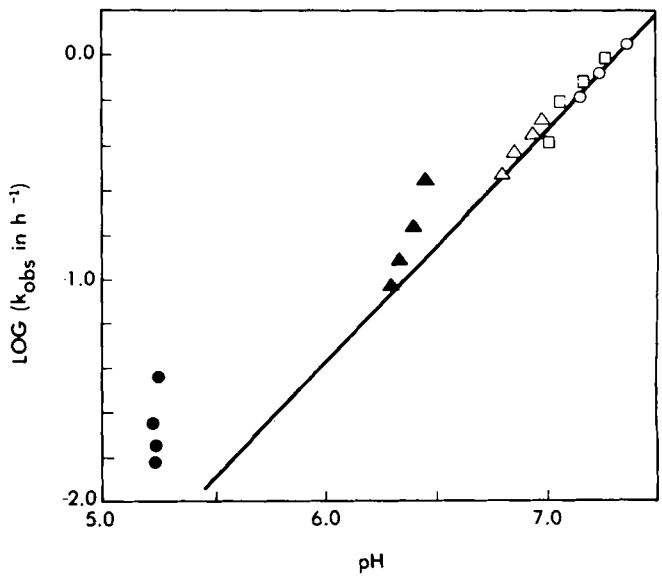

Figure 2—*Log k_{obs} versus pH for quantitative conversion of I to II in phosphate buffers at 60°C, μ = 1.0, where the ratios of $[NaH_2PO_4]/[Na_2HPO_4]$ are: 0.1 (○), 0.2 (□), 0.33 (△), 1.0 (▲), and 10 (●) (see Table II). The regression line, based on the 0.1 ratio buffers (○), has a slope of one.*

equals k^0_{cat}, the bimolecular rate constant for catalysis by the ith base at zero ionic strength, and k_s is the bimolecular rate constant for solvent attack.

Reaction kinetics were studied in solutions of Tris, borate, carbonate, acetate, glycine, and phosphate buffers. Tris, acetate, and borate buffers contained only one Brönsted base species. Although carbonate, glycine, and phosphate buffer contained two general bases, their acids differed by a minimum of four orders of magnitude in K_a values. According to the Brönsted relationship, the efficiency of a general base catalyst increases with the increasing pK_a of its conjugate acid (18). Therefore, the contribution of the more acid base species to k_{obs} was not detectable. The contribution of $k_s a_{H_2O}$ was also insignificant except in buffer solutions of pH ≤5.3. Above this, the observed rate constants in buffers can be described by hydroxide attack plus catalysis by one general base component, B, so that Eq. 7 can be rewritten:

$$k_{obs} = (k^0_{OH} a_{OH} \gamma_I / \gamma_\ddagger) + (k^0_B a_{H_2O} [B] \gamma_B \gamma_I / \gamma_\ddagger') \qquad \text{(Eq. 8)}$$

where $a_{OH} = \gamma_{OH}[OH^-]$ and $k_B{}^0 a_{H_2O} = k_{cat}{}^0$. After taking ionic atmosphere effects into account (see discussion below), observed first-order rate constants were adequately described by this equation. The pH-rate profiles, constructed by subtracting the general base contributions, were linear at pH > 6 with slopes approaching unity, which is the theoretical value when a reaction is first-order in hydroxide (Fig. 1).

Ionic Atmosphere Effects—In dilute hydroxide and buffered solutions, the activity coefficients of the reactants and transition states appear in the rate law for hydrolysis of I. The influence of ionic atmosphere effects on activity coefficients is greater for reactions between ions than for reactions between polar molecules or ions and dipoles (19). Under all conditions studied, I was a cation while hydroxide ion and the general bases (except Tris) were anions.

According to absolute reaction-rate theory, the rate constant is proportional to the concentration equilibrium constant ($k_c^\ddagger$) between the activated complex and the reactants (20). This concentration equilibium constant is affected by the ionic environment and is related to a thermodynamic equilibrium constant ($K_a^\ddagger$) by the ratio of the transition state activity coefficient to the product of the activity coefficients for the reactants (20). For a bimolecular reaction such as the reaction between hydroxide and I:

$$k_{OH} = (k^0_{OH} \gamma_{OH} \gamma_I) \gamma_\ddagger \qquad \text{(Eq. 9)}$$

where k^0_{OH} is the second-order rate constant expressed in terms of the thermodynamic equilibrium constant $K^\ddagger_a$. Carstensen (21) has shown that Eq. 10 adequately describes the logarithm of an activity coefficient based on the kinetic salt effects as reported for the degradation of a number of drugs over a wide range of ionic strengths:

$$\log \gamma_i = \frac{-AZ_i^2\sqrt{\mu}}{1+\sqrt{\mu}} \qquad \text{(Eq. 10)}$$

where γ_i is the activity coefficient of the ith ion, Z_i is its charge, μ is the ionic strength, and A is a function of the temperature and dielectric constant of the solution. According to theory the charge on the transition state is the sum of the charges on the reactants (20). Substitution of Eq. 10 into the logarithmic form of Eq. 9 yields Eq. 11, which predicts a linear relationship between log k_{OH} and $\sqrt{\mu}/(1+\sqrt{\mu})$ with a slope of $-2A$:

$$\log k_{OH} = \log k^0_{OH} - \frac{2A\sqrt{\mu}}{1+\sqrt{\mu}} \qquad \text{(Eq. 11)}$$

This relationship was observed for hydroxide attack on I. Kinetic analyses are more complex in buffers, wherein both primary and secondary salt effects can depend not only on ionic strength but also on specific ionic interactions (22). Activity coefficients of buffer ions can be influenced by the concentration of ions of opposite charge, which often are added as neutral salts to maintain constant ionic strength. This is reflected in the final term of the Guggenheim equation:

$$\log \gamma_i = \frac{-AZ_i^2\sqrt{\mu}}{1+\sqrt{\mu}} + \sum_j \beta_{ij} C_j \qquad \text{(Eq 12)}$$

where β_{ij} represents the interaction coefficients between ion i and all other j ions of opposite charge (20, 22). The activity coefficients in the Henderson-Hasselbach equation:

$$pH = pK_a + \log [B]/[HB] + \log (\gamma_B/\gamma_{HB}) \qquad \text{(Eq. 13)}$$

can be described by Eq. 12 to give:

$$pH = pK_a + \log \frac{[B]}{[HB]} + \frac{(Z_{HB}^2 - Z_B^2)A\sqrt{\mu}}{1+\sqrt{\mu}} + \sum_j \Delta\beta C_j \qquad \text{(Eq. 14)}$$

where HB designates the buffer conjugate acid, $\Delta\beta = \beta_{B_j} - \beta_{HB_j}$, and the summation involves the concentration (C_j) of all the ions of charge opposite to that of buffer ions.

Equation 14 shows that the pH can change as a function of the concentration of ions of charge opposite to that of the buffer ions ($\Sigma_j \Delta\beta C_j$) at constant μ and buffer concentration ratio ([B]/[HB]). For example, the decreasing pH at each constant ($[HPO_4^{2-}]/[H_2PO_4^-]$) ratio observed in Table II is due to increasing sodium ion concentration. In the extreme case, hydroxide activity was observed to decrease from 1.79×10^{-6} to 0.98×10^{-6}, which will have a pronounced effect when hydroxide attack is significant. Therefore, the rate constants for hydrolysis of I in buffers with high concentrations of added neutral salts are not adequately described in terms of concentration.

The following method was developed to solve for the contributions of hydroxide attack and general-base catalysis to the observed first-order rate constants in buffers. Equation 8 was employed to calculate $k_{OH}{}^0$ and $k_{cat}{}^0$ using approximations for $\gamma_\ddagger$, $\gamma_\ddagger'$, and γ_I in the following manner. According to theory the charge on the transition state is the sum of the charges on the species involved in its formation, $Z_\ddagger = Z_A + Z_B + \cdots Z_N$ (20). Therefore, the transition state formed from the hydroxide anion and the I cation was assumed neutral, and its activity coefficient was taken as unity, *i.e.* $\gamma_\ddagger \cong 1$.

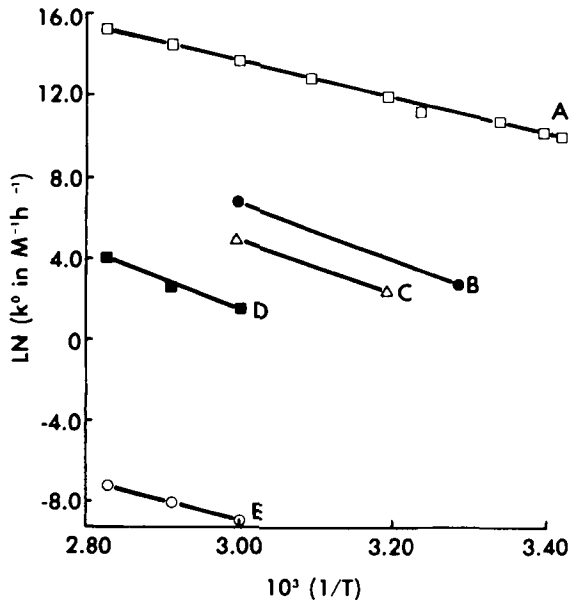

Figure 3—*Arrhenius plots for rate constants at infinite dilution where* k^0 *is* k^0_{OH} *(A),* k^0_{cat} *for carbonate (B), borate (C), and dibasic phosphate (D), and* k_s *(E).*

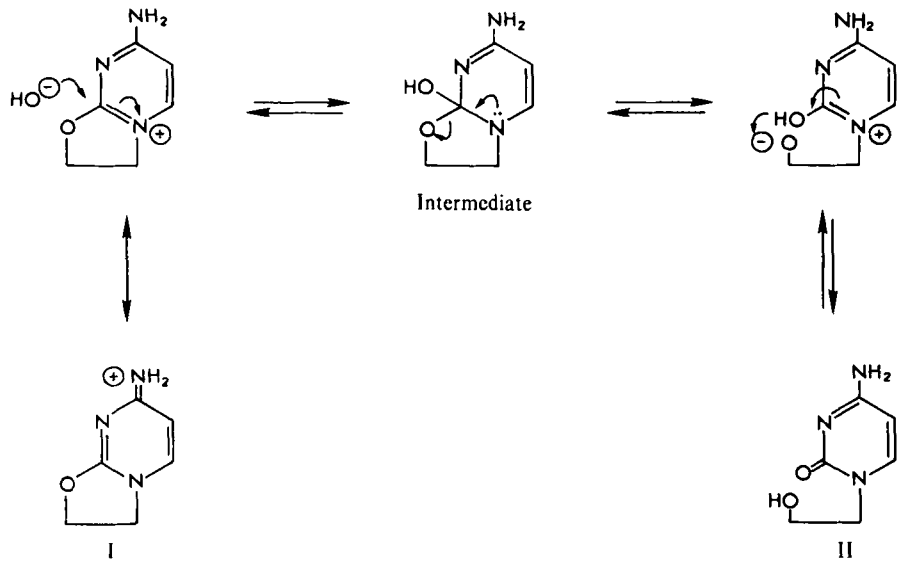

Scheme III

Table IV—Energetics of I Hydrolysis

Rate Constant $M^{-1}h^{-1}$	E_a, kcal/mol-deg	A, $M^{-1}h^{-1}$ [a]	$\Delta H^{\ddagger}$ (kcal/mol-deg) Obs.[a]	Calc.[b]	$\Delta S^{\ddagger}$, e.u.[c]

k^0_{cat}					
Phosphate	29.84	1.45×10^{20}	29.2	29.2	23.6
Carbonate	28.26	2.96×10^{21}	27.2	26.9	28.2
Borate	26.00	1.51×10^{19}	25.4	26.7	17.7
k_s	20.11	2.02×10^{9}	19.4	—	−10.6

[a] Values were calculated at each temperature studied using Eq. 21; the mean values are tabulated. [b] Values were calculated at each temperature studied using Eq. 22 where ΔH^0_{HB} and $\Delta H^0_{H_2O}$ were calculated from literature equations (24). The mean values are tabulated. [c] Values were calculated at each temperature studied using literature equations (25); the mean values are tabulated.

General base-assisted water attack on I would produce the same net charge as protonation of the base to form its conjugate acid, $Z_{\ddagger}' = Z_{HB}$. On this basis, it was assumed that the activity coefficients of these transition states and their corresponding buffer conjugate acids were sufficiently similar to use the approximation $\gamma_{\ddagger}' \cong \gamma_{HB}$. Substitution into Eq. 8 yields:

$$k_{obs} = (k^0_{OH} a_{OH} \gamma_I) + (k^0_B a_{H_2O} [B] \gamma_B \gamma_I / \gamma_{HB}) \qquad \text{(Eq. 15)}$$

Substituting $(K_w[B]\gamma_B/K_a[HB]\gamma_{HB})$ for a_{OH} and dividing the equation by $([B]\gamma_B/\gamma_{HB})$ provides:

$$\frac{k_{obs}}{[B]\gamma_B/\gamma_{HB}} = \left\{\frac{k^0_{OH}\gamma_I K_w}{K_a}\right\} \frac{1}{[HB]} + k^0_B \gamma_I a_{H_2O} \qquad \text{(Eq. 16)}$$

The buffer activity coefficient ratio, γ_B/γ_{HB}, was calculated from pH measurements, known buffer concentrations, and literature values for K_a using:

$$(\gamma_B/\gamma_{HB}) = K_a[HB]/[B]10^{-pH} \qquad \text{(Eq. 17)}$$

which is a rearrangement of the antilogarithmic form of Eq. 13.

Plots of $k_{obs}/([B]\gamma_B/\gamma_{HB})$ *versus* $1/[HB]$ were linear ($r^2 \geq 0.994$) with intercepts of $k_B{}^0\gamma_I a_{H_2O}$ and slopes which allowed the calculation of $k_{OH}{}^0\gamma_I$ after substituting for K_w and K_a. Borate buffers gave the poorest reproducibility ($r^2 = 0.985$), which was probably due to borate polymerization (23) making the true B and HB concentrations unknown.

While Eq. 16 corrects for secondary ionic atmosphere effects, γ_I (a multiplier of both the slope and intercept) is subject to primary salt effects, which are influenced by both ionic strength and specific ionic interactions. The importance of specific ionic interactions appear minor judging from the large r^2 values for each series of buffers at constant ionic strength but varying ion concentrations. To determine the effect of ionic strength on γ_I, a series of 22 reactions were studied in phosphate buffers at 50°C and $\mu = 0.05, 0.20, 0.50$, and 1.00. All reactions were described by a single linear plot ($r^2 = 0.995$) based on:

$$\frac{k_{obs}}{[B]\gamma_B\gamma_I/\gamma_{HB}} = \left\{\frac{k^0_{OH}K_w}{K_a}\right\} \frac{1}{[HB]} + k^0_B a_{H_2O} \qquad \text{(Eq. 18)}$$

since γ_I values were estimated by Eq. 10.

Temperature Dependence—From values of $k^0_{OH}\gamma_I$ and $k^0_{cat}\gamma_I$ obtained in buffers at various temperatures (Eq. 16) and the estimates for γ_I (Eq. 10), k^0_{OH} and k^0_{cat} were calculated at each temperature. Additional k^0_{OH} values were calculated from dilute hydroxide reactions using Eq. 11. Where k_{obs} (*i.e.*, $k_s a_{H_2O}$) values were independent of pH and ionic strength in hydrochloric acid, k_s values were calculated from k_{obs}/a_{H_2O} (Table III). The Arrhenius relationship:

$$\ln k = \ln \underline{A} - E_a/RT \qquad \text{(Eq. 19)}$$

was used to determine the temperature dependence of k^0_{OH}, k^0_s, and k^0_{cat}, where E_a is the activation energy, $\underline{A}$ is the preexponential constant, R is the molar gas constant, and T is the absolute temperature (Fig. 3). The activation energies are given in Table IV.

General Base Catalysis—At 60°C and $\mu = 1.0$, a series of buffers were studied and a Brönsted linear-free energy correlation was demonstrated using:

$$\log\left(\frac{k}{q}\right) = \log G_B + \beta(pK_a + \log p/q) \qquad \text{(Eq. 20)}$$

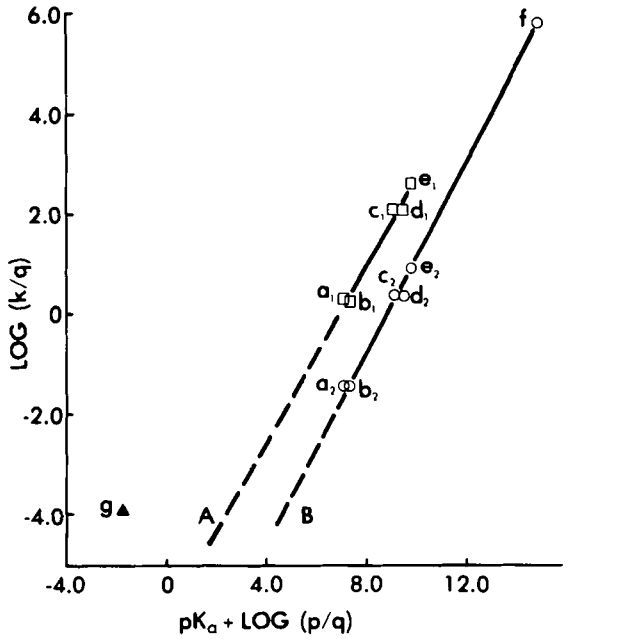

Figure 4—*Brönsted plot relating the rate constants at 60°C for general-base, specific-base, and solvent attack at infinite dilution to the dissociation constants of their conjugate acids (24). Data points represent phosphate (a), Tris (b), glycine (c), borate (d), carbonate (e), k^0_{OH} (f), and k_s (g). Buffer values with subscript 1 (A) represent k^0_{cat}, whereas those with subscript 2 (B) are the corresponding ($k^0_{cat}/55.5$) values. The slopes are 0.90 ($r^2 = 0.95$) for line A and 0.97 ($r^2 = 0.98$) for B.*

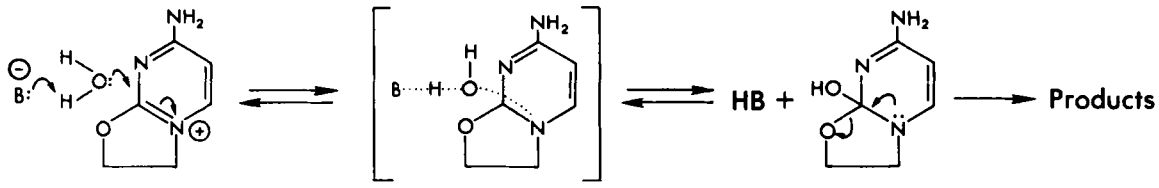


I Intermediate

Scheme IV

where k is the bimolecular rate constant (k^0_{cat}, k_s, or k^0_{OH}), G_B is a constant, β is the Brönsted coefficient, p is the number of equivalent protons which can be transferred from the conjugate acid, and q is the number of sites on the general base which can accept a proton (25). The catalytic constants for general base attack, $k^0_{cat} = k^0_B a_{H_2O}$, were calculated from plots based on Eq. 16 and comprise correlation line A in Fig. 4. As is often observed (18, 26), k^0_{OH} shows negative deviation from the plot and k_s does not fall on the line. Line B is composed of the k^0_{OH} value and those for $k^0_{cat}/55.5$. The agreement between the factor 55.5 and the molarity of pure water may be significant or fortuitous. However, this relationship (line B) will be employed to develop a predictive equation for k_{obs}.

Isotope Effect in the Hydroxide Attack of I—Studies conducted simultaneously in sodium hydroxide and sodium deuteroxide solutions yielded ratios of k^0_{OD}/k^0_{OH} which varied from 0.8 to 1.4. Thus, no significant isotope effect was observed.

DISCUSSION

Mechanism of Hydroxide Attack: Nucleophilic Addition—Scheme III illustrates nucleophilic attack of hydroxide anion at the C-2 position of I, with rate-determining formation of a C—O bond and simultaneous loss of the positive charge to form the tetrahedral intermediate. Subsequent loss of this intermediate could take place as depicted or with general-base assisted transfer of the C-2 hydroxyl proton. Rate-determining formation of the intermediate is consistent with the absence of a significant deuterium isotope effect. Simultaneous loss of the positive charge is supported by a negative ionic strength effect and a positive entropy of activation (Table IV), which is common for reactions in which charge is destroyed in polar media (25).

Mechanism of Buffer Attack: General-Base Assisted Solvent Attack—According to Scheme IV, protonation of the general base, ionization of a water, and formation of the tetrahedral intermediate occur during or prior to the rate-determining step. This is consistent with the observed linear free energy correlation, which includes both hydroxide and general-base assisted solvent attack together with a Brönsted coefficient of unity (Fig. 4). The Brönsted correlation implies that proton transfer is involved at the rate-determining step, and the coefficient value of unity implies that proton abstraction is nearly complete in the transition state (18, 26).

Confirmatory evidence for Scheme IV can be obtained from the activation energies for the rate constants (k^0_{OH} and k^0_{cat}). The enthalpies of activation can be calculated using (26):

$$\Delta H^{\dagger} = E_a - RT \qquad \text{(Eq. 21)}$$

The enthalpy of activation for general base-assisted solvent attack ($\Delta H_B^{\dagger}$), was calculated in two ways. In addition to employing the activation energy in Eq. 21, $\Delta H_B^{\dagger}$ was approximated by:

$$\Delta H_B^{\dagger} = \Delta H_{OH}^{\dagger} + \Delta H^0_{H_2O} - \Delta H^0_{HB} \qquad \text{(Eq. 22)}$$

based on Scheme IV where $\Delta H_{OH}^{\dagger}$ is enthalpy for the formation of the C—O bond calculated from the activation energy of hydroxide attack and Eq. 21, $\Delta H^0_{H_2O}$ is the enthalpy for ionization of water, and ΔH^0_{HB} is the enthalpy for ionization of the conjugate acid (therefore, it is equal to the negative enthalpy of general base-protonation process). There is excellent agreement between the values of $\Delta H_B^{\dagger}$ computed under the assumptions of Scheme IV and those values calculated directly from the experimentally observed activation energies (Table IV).

Mechanism of Solvent Attack—Scheme V depicts a mechanism for solvolysis involving intramolecular general base participation by removal of a proton during nucleophilic attack at C-2. Although there is no direct kinetic support for this anchimeric mechanism, it is consistent with the fact that solvent attack becomes prominent below the reported pK_a (4.2) of II (16) (see Fig. 1). Assuming the ability of the tetrahedral intermediate to accept a proton at N-3 is approximately the same as that of II, Eq. 20 with $pK_a = 4.2$ was used to calculate k^0_{cat}. The ratio of $k_s a_{H_2O}/k^0_{cat}$, which represents the "effective concentration" of intramolecular catalyst in the vicinity of I, was calculated to be 3 M. This value suggests that the intramolecular rate enhancement can be accounted for by local concentration effects (27).

Stability Prediction for Ancitabine Conversion—The rate constant for conversion of I to II was shown to be the sum of the rate constants for water attack (Eq. 5), hydroxide attack, and general base-catalyzed water attack (Eq. 8) and therefore can be defined:

$$k_{obs} = k^0_{OH} a_{OH} \gamma_I + k^0_{cat}[B]\left[\frac{\gamma_B \gamma_I}{\gamma_{HB}}\right] + k_s a_{H_2O} \qquad \text{(Eq. 23)}$$

It was observed that using $k^0_{cat}/55.5$ values resulted in a common Brönsted plot which included the k^0_{OH} value. The agreement between 55.5 and the molecularity of pure water may be coincidental, but the observation was used to derive a predictive equation for k_{obs}. Since $\beta \cong 1$ (line B, Fig. 4) the antilogarithmic form of Eq. 20 may be written:

$$k^0_{OH} = G_B/K'_a \qquad \text{(Eq. 24)}$$

where $p = q = 1$ and $K'_a = K_w/a_{H_2O}$ and:

$$k^0_{cat}/55.5 = G_B p/K_a \qquad \text{(Eq. 25)}$$

Therefore, k^0_{cat} can be described in terms of $k_{OH}{}^0$ as:

$$k^0_{cat} = 55.5 k^0_{OH} K'_a p/K_a \qquad \text{(Eq. 26)}$$

Arrhenius parameters were determined for k^0_{OH} and k_s (Fig. 3, Table IV) from:

$$k^0_{OH} = \underline{A} \cdot \exp(-E_a/RT) \qquad \text{(Eq. 27)}$$

$$k_s = \underline{A}' \cdot \exp(-E_a'/RT) \qquad \text{(Eq. 28)}$$

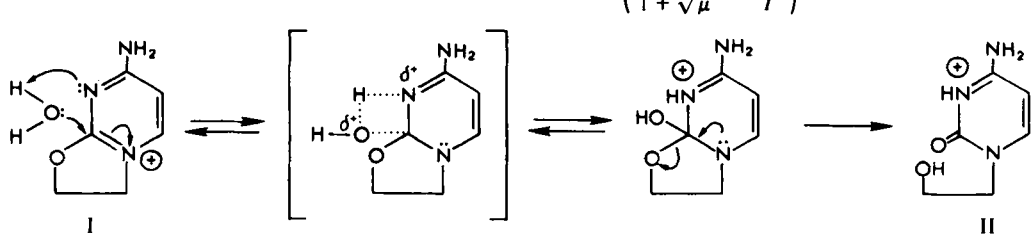
Substitution for γ_I (Eq. 10), γ_B/γ_{HB} (Eq. 17), k^0_{cat} (Eq. 26), k_s (Eq. 28), and $a_{OH} = K_w 10^{pH}$ into Eq. 23 yields:

$$k_{calc} = (1 + X)\underline{A} a_{OH} \cdot \exp\left(\frac{-2.3A\sqrt{\mu}}{1 + \sqrt{\mu}} - \frac{E_a}{RT}\right) + \underline{A}' a_{H_2O} \cdot \exp\left(-\frac{E_a}{RT}\right) \qquad \text{(Eq. 29)}$$

where a_{OH} is calculated from measured pH and K_w at temperature T. This describes the first-order rate constant for loss of I, k_{calc} in h^{-1}, as a function of pH, ionic strength, and temperature where $X = p \cdot [HB]/1$ M reflects the concentration [HB] and type (p) of the conjugate acid. Figure 5 demonstrates the agreement between rate constants calculated by Eq. 29 (k_{calc}) and those observed in this study (k_{obs}).

Substitution for the constants provides the following:

$$k_{calc}\,(h^{-1}) = (1 + X)1.74 \times 10^{17} a_{OH} \cdot \exp\left(\frac{-1.15\sqrt{\mu}}{1 + \sqrt{\mu}} - \frac{8662}{T}\right) + 1.12 \times 10^{11} \cdot \exp(-10{,}121/T) \qquad \text{(Eq. 30)}$$



I II

Scheme V

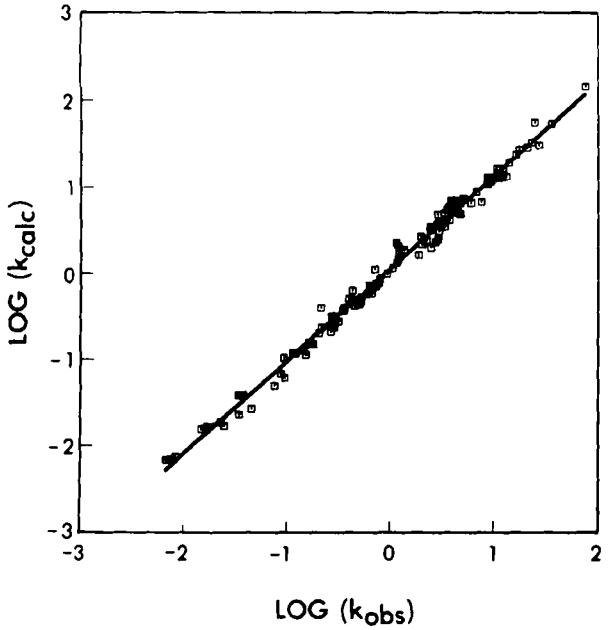


Figure 5—*Correlation between first-order rate constants for conversion of I calculated using Eq. 29 (k_{calc}) and observed (k_{obs}) in 125 reactions in the pH range 1.5–10.7, the temperature range 19.5–80°C; the ionic strength range 1×10^{-4} to 1.5; and in various concentrations of phosphate, borate, glycine, Tris, carbonate, and acetate buffers, hydrochloric acid, and sodium hydroxide solution. These rate constants were plotted* versus *the calculated rate using a log–log scale to facilitate visualization of the entire range of values. The slope of the log–log plot is 1.060 ($r^2 = 0.992$).*

which requires only the measured pH (for a_{OH}), temperature, concentration [HB], and type (p) of conjugate acid to solve for k_{calc}.

Preformulation Method for Parenteral Preservative Efficacy Evaluation

MICHAEL J. AKERS *x, ARTHUR V. BOAND ‡, and DORIS A. BINKLEY §

Received February 24, 1983, from *Parenteral Products Development, ‡Microbiological Assay Development, and the §Statistical and Mathematical Services, Lilly Research Laboratories, Indianapolis, IN 46285. Accepted for publication May 12, 1983.

Abstract □ A method is described for rapidly and reliably evaluating parenteral preservative efficacy. Solutions containing antimicrobial preservatives were challenged with microorganisms, sampled from 0.5 to 6 h following introduction of the challenge, cultured, and counted for surviving microbial cells. Data were analyzed by computer according to two models: linear and quadratic. Decimal reduction times (D values) were calculated for each microbial challenge in each preservative solution. A D value of ≤2 h for bacteria predicts that the preservative system will pass the British Pharmacopoeia (BP) preservative efficacy test, a more rigorous test than the USP test. Fourteen preservative systems were tested in both neutral isotonic saline solutions and neutral regular insulin solutions. D values and correlation coefficients for both models were calculated. The ranking of preservative effectiveness in neutral saline solutions closely correlated with the results found using neutral regular insulin solutions. The most effective preservative systems were found to be 0.3% m-cresol and various combinations of m-cresol and phenol. The advantages and limitations of this method are discussed.

Keyphrases □ Preservatives—parenteral formulations, efficacy, preformulation determination □ Parenteral formulations—efficacy of preservatives, preformulation determination □ Antimicrobial screening—preservatives, parenteral formulations, efficacy, preformulation determination

The British Pharmacopoeial (BP) test for preservative efficacy requires that the number of bacteria recovered per milliliter in injectable preparations intended for multiple use be reduced by a factor of 10^3 within 6 h following challenge (1). This requirement imposes a far stricter criterion for antimicrobial action than the USP preservative efficacy test, which requires the bacterial concentration to be reduced by a factor of 10^3 14 d following microbial inoculation (2). A large number of preservatives at bacteriostatic concentrations will pass the USP test but will fail the BP test. Parenteral drug manufacturers who wish to market their products in countries abiding by BP requirements must reformulate their products to obtain a preservative system which, in fact, is self-sterilizing to pass the BP preservative test.

There is a need for a rapid, reliable, and inexpensive screening method to determine effective preservative systems in parenteral products. Several methods for screening and evaluating preservative efficacy have been reported (3–6); most employed the construction of time-log survivor curves during a short-time exposure period. However, previous studies have been limited in the number of preservative systems evaluated and have not attempted to correlate results from a test model to results obtained from an actual parenteral drug product. In this work, neutral isotonic sodium chloride solution was selected as the model parenteral solution, while neutral regular insulin was chosen as the actual drug product. The use of neutral isotonic saline was based on the assumption that bacteria would not be adversely affected by such an inoffensive formulation and, thus, bacterial destruction would be solely the result of preservative activity.

An additional unique feature of the work reported herein is the application of a computer statistical program generating two types of models fitted to the experimental data. The use of models to analyze the microbial survivor data facilitates the decision-making process in the selection of appropriate preservative systems in the formulation development of multidose parenteral products.

EXPERIMENTAL SECTION

Solution Preparation—The preservatives used in this study were USP grade, tested by and obtained in-house: phenol (0.2% and 0.5%), m-cresol (0.1–0.3%), benzyl alcohol (1% and 2%), methylparaben (0.1% and 0.2%), propylparaben (0.01% and 0.02%), and chlorobutanol (0.5%). Preservative combinations studied were phenol-m-cresol, methyl- and propylparabens, and methylparaben-benzyl alcohol. A total of 14 preservative systems were evaluated.

Solutions in isotonic saline were prepared using sterile glass flasks and sterile 0.9% NaCl irrigating solution[1]. The accurately weighed or measured volume of preservative was dissolved in the saline solution, and the pH was adjusted to 6.8–7.4 using sterile filtered 1.0 M NaOH or 1.0 M HCl. Solution volume was then adjusted quantitatively to the correct volume with saline.

Insulin solutions were prepared and sterile-filtered using a regular insulin formulation without a preservative. Preservatives were accurately weighed or measured and added to the insulin solution. All insulin solutions were pH 6.9–7.4.

Test Organisms—The test organisms used in this study were *Staphylococcus aureus* (ATCC 6538), *Pseudomonas aeruginosa* (ATCC 9027), *Escherichia coli* (ATCC 8739), *Candida albicans* (ATCC 10231), and *Aspergillus niger* (ATCC 16404). The bacterial cultures were grown for 18–24 h in soybean-casein digest agar[2] and the growth washed from the slants with 10 mL of sterile saline (0.85% NaCl). The stock suspensions were prepared by dilution with sterile saline to give a cell concentration of ~5×10^8 organisms/mL. Sufficient suspension was added to the test solution to obtain ~1×10^6 organisms/mL.

Yeasts and molds were grown on Sabouraud dextrose agar plates[2] at 25°C until sufficient growth appeared. Cells were washed from the plates with sterile saline, sedimented by centrifugation, and the sediment was suspended in sufficient sterile saline to yield ~5×10^8 organisms/mL. Suspensions were further diluted to give ~1×10^6 organisms/mL when added to the test solutions.

Test Procedure—A 0.1-mL amount of the test organism suspension was added to each 5-mL portion of the test solution. After mixing on a vortex mixer, an initial sample was taken for the time zero plate count. A saline control sample prepared in the same manner was also tested; this was used as the time zero count in some instances because of the very rapid bactericidal effect of some test solutions. Test samples were then retested after incubation, typically at 0.5, 1, 2, 4, and 6 h for bacteria and at 4, 8, and 24 h for yeasts and molds. All test samples were held at room temperature unless otherwise specified.

All dilutions were prepared in phosphate buffer solution, pH 7.2 ± 0.1. After shaking, 0.1- and/or 1.0-mL aliquots were transferred into duplicate petri plates. Letheen agar[3] was used as the test medium: it contains polysorbate 80 and lecithin, known to inhibit most phenolic and paraben antimicrobial agents (7, 8). Tests in our laboratories confirmed the effectiveness of this medium. Bacterial and yeast plates were incubated for 48 h at 35°C and mold plates at 25°C for 4 to 7 d. Average plate counts were calculated for each sample.

Data Analysis—The data analysis was accomplished *via* a computer program utilizing the statistical software package SAS[4]. When values of the variables "Hours" and "Counts" were entered, the program generated two types of fitted models relating log (count + 1) to hours and produced plots of the fitted equations superimposed by the original observations. The two

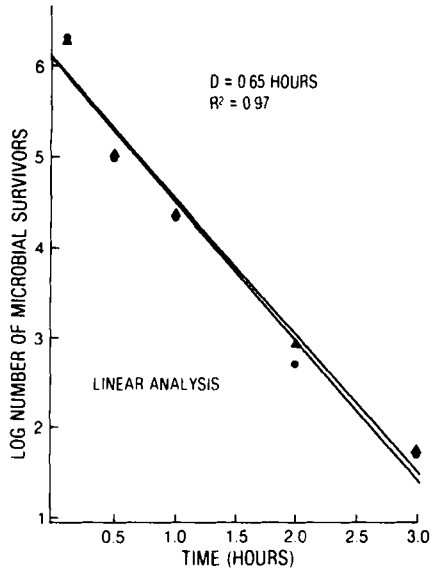

Figure 1—*Linear regression fit of the log number of microbial survivors versus time as calculated by the SAS linear analysis method. Data points represent two separate experiments;* D *and* R^2 *values are the average of two linear regression analyses.*

models used were a linear model and a quadratic model. The linear model is given by:

$$y = \alpha + \beta x + \epsilon \qquad \text{(Eq. 1)}$$

where y = log (count + 1) at hour x, α is the intercept, β is the slope of the line, and ϵ is the experimental error associated with the observation of y. The quadratic model is given by:

$$y = \alpha + \beta x + \gamma x^2 + \epsilon \qquad \text{(Eq. 2)}$$

where the additional term γx^2, represents the departure from linearity of the log (count + 1). The purpose of these model-fitting programs is to calculate estimates of the parameters α, β, and γ in the two theoretical models.

The *D* value refers to the decimal reduction time describing the death rate of the microorganisms; it represents the length of time in which a 1-log reduction in the number of survivors will be achieved. Since the term "*D* value" has heretofore been used in conjunction with a model in which the death rate is independent of the current number of survivors, it has been convenient to calculate it by the formula:

$$D = \frac{U}{\log N_0 - \log N_u} \qquad \text{(Eq. 3)}$$

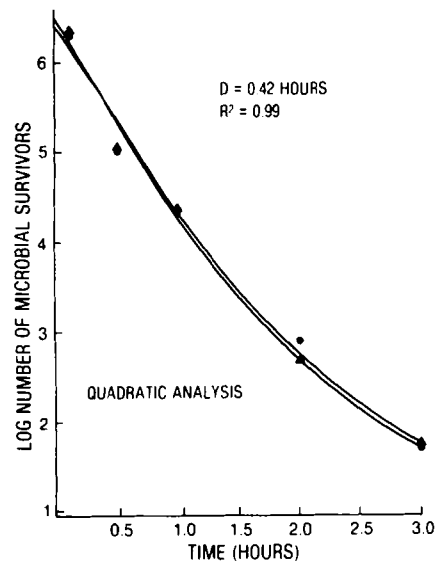

Figure 2—*Linear regression fit of the log number of microbial survivors versus time as calculated by the SAS quadratic analysis method. Data points represent two separate experiments;* D *and* R^2 *values are the average of two linear regression analyses.*

Table I—Comparison of *D* Values for the USP Challenge Organisms in Neutral Saline Solutions Containing Various Preservative Systems

Organism	Linear Method		Quadratic Method	
	D, h	R^2	*D*, h	R^2
	0.2% Phenol			
S. aureus	10.9	0.96	15.6	0.99
P. aeruginosa	7.0	0.99	4.2	1.00
E. coli	26.2	0.96	27.4	.95
A. niger	250.0	0.84	81.3	1.00
	0.3% *m*-Cresol			
S. aureus	0.7	0.98	0.4	0.99
P. aeruginosa	1.9	0.39	0.6	0.57
E. coli	1.8	0.82	0.8	0.97
A. niger	3.2	0.98	2.3	0.99
C. albicans	9.0	0.87	3.5	1.00
	0.2% Phenol + 0.3% *m*-Cresol			
S. aureus	0.5	0.78	0.2	0.95

E. coli	2.5	0.92	3.6	0.97
A. niger	3.1	0.99	2.1	1.00
C. albicans	2.8	0.84	1.5	0.90

where U is the time exposure interval at constant temperature, N_0 is the initial number of surviving microorganisms, and N_u is the number of surviving microorganisms after exposure period U. This equation is applicable to our model, in which the log of the number of survivors is treated as a linear function of time.

A typical semilogarithmic plot of the number of living microorganisms in a preserved solution *versus* time is shown in Fig. 1. If the R^2 value was ≥0.9, the linear model shown in Fig. 1 was considered sufficient for determining the *D* value of the microorganism in the preserved parenteral system. Preservative systems especially effective in inactivating microorganisms tended to yield curvilinear plots of log count *versus* time. The rate of kill during the first 30–60 min was more rapid than the rate of kill at later times. Fitting the data according to a linear model generally resulted in a poorly fit straight line with an R^2 of ≤0.9. Also, the calculated *D* value often underestimated the actual rate of kill produced initially.

A better fit of the data was achieved by employing the quadratic equation. According to this model, a hyperbolic fit of the data is obtained, as shown in Fig. 2. The *D* value shown here corresponds to the length of time before the first log reduction in count. The fit of the data using the quadratic model improved the R^2.

RESULTS

Preliminary results comparing *D* values of USP challenge organisms in neutral saline solutions containing various preservative systems are reported in Table I. The *D* values for the mold and yeast were higher than those for bacteria. However, both USP and BP requirements for yeast and mold survival in preserved solutions are less stringent than those for bacterial survival. Of the three bacterial challenges, *E. coli* was most resistant to the antimicrobial agents tested. However, *E. coli* is not required by the BP test for injections. Either *S. aureus* or *P. aeruginosa* can be used as a prototype challenge organism to provide early predictions regarding the success or failure of a preservative system to pass the BP preservative efficacy test. *S. aureus* was selected as the model challenge organism, primarily because of the data reported in Table II. In solutions containing lower concentrations of preservatives, the *D* values for *S. aureus* were greater than those for *P. aeruginosa*.

D values for *S. aureus* in 14 different preservative systems were compared in both neutral isotonic saline and neutral regular insulin solution (Table III). The combination of 0.2% phenol + 0.3% *m*-cresol consistently produced the lowest *D* values, while 0.2% phenol consistently produced the highest *D* values. Preservative systems ranked 1–5 in Table III passed the BP requirement of reducing the bacterial population by 1 log in 2 h in both neutral saline and

[a] All data are the average of two experiments.

neutral regular insulin solutions. D values, generally, were lower in insulin solution compared with saline. Thus, the neutral isotonic saline solution conservatively estimated the preservative effectiveness against *S. aureus* observed in neutral regular insulin solutions.

Fits of the linear models of log count *versus* time were very good ($R^2 \geq 0.93$) for the majority of the saline solutions tested. Fits were not as good for the insulin solutions using the linear method, but the quadratic model improved the fits. Additionally, the quadratic model ranked the effectiveness of the various preservative systems in nearly the same order as that found using the linear model. Thus, the choice of the model did not cause any major change in the identification of best and worst systems.

DISCUSSION

The logarithmic order of death of microorganisms (9) facilitates the study of the effectiveness of destroying microorganisms within a convenient time frame. Simple techniques of microbiological assay and computer data analysis permit the generation of microbial kinetic data easily and rapidly. The methodology described in this paper can be used to evaluate preservative effectiveness in a given formulation as a function of any number of variables: type and concentration of preservatives, combination of preservatives, microbial challenge organism, solution pH, formulation differences, and temperature. The results reported in this paper show that D values can be easily obtained and used to compare the effectiveness of different preservative systems. Computers aid in the analysis of data that employ different models for an adequate fit. From the data one can select the best preservative system for the formulation being developed.

Like most experimental screens, this method has certain limitations and precautions. The initial microbial concentration cannot be determined accurately from the test sample because of the immediate action of the antimicrobial agent. Initial values must be determined using a control solution with no antimicrobial activity. At least three, preferably four, samples should be taken from the test solution for microbial analysis at various times over a maximum of 6 h. In the studies reported here, four samples were taken.

Rapid-acting preservative systems require sampling times at intervals much sooner and shorter than for long-acting preservative systems. For example, rather than taking samples at 1, 2, 4, and 6 h following the addition of the microbial challenge, rapid-acting preservative systems need to be sampled at 0.25, 0.5, 1, and 2 h after time zero. Many preservative systems caused a precipitous initial reduction in the microbial population followed by a more gradual decline. This produced curvature in the log count *versus* time graph, which necessitated the use of the quadratic model for analyzing the data. The D value calculated gave a more representative estimate of the destructive action of the preservative system than that obtained from the standard linear model.

It may not be advisable to study only a single species challenge in a screening test. Of course, the fewer the types of microorganisms used, the more expedient the test. Ideally, the most resistant microorganism in the test system is identified at the beginning of the screening study. The hazard of employing a single challenge to evaluate a large number of preservative systems is the potential for a different microbial species than that used as the challenge to be significantly more resistant in a particular preservative system. For example, *S. aureus* might be the most resistant microorganism in phenolic preservative systems, while *E. coli* might be more resistant in paraben preservative systems. It is because of these possibilities that the most effective preservative system selected as a result of its activity against one microorganism should subsequently be studied in the presence of all other compendial challenge microorganisms. This screening method is not a substitute for the USP and/or BP preservative efficacy tests, but rather serves to reduce the potential number of preservative systems to be tested by the compendial methods.

The D values reported in this study represented the average of two experiments. Preliminary investigation found that the standard deviations calculated from five replicate D value experiments of the same organism in separately prepared solutions containing the same preservative system ranged from 4.2 to 8.7%. This seemed adequate for a preformulation screening test, especially one involving a plate count microbiological test procedure.

Several of the data sets showed significant departures from linearity ($p \leq 0.01$ for the improvement in fit gained by including a quadratic term in the model). By fitting both linear and quadratic models and comparing the rankings of D values from these models, it was possible to verify that the ranking of these preservative systems was not dependent on the choice of model. Although the linear models proved to be adequate for the screening of preservatives, a quadratic model based on an adequate number of time points should be considered whenever an accurate estimate of the actual value of D is desired.

While this method provides an excellent initial estimate of preservative activity in parenteral solutions, it is not intended to evaluate other issues concerning antimicrobial preservatives, such as stability and compatibility characteristics in the final formulation and package system. The most promising systems identified by this method will be studied in greater detail for compliance to compendial standards of effectiveness, stability, and compatibility in the newly developed parenteral formulation.

Importance of Viscosity in the Dissolution Rate of Cholesterol in Monooctanoin Solutions

JOSEPH B. BOGARDUS

Received June 22, 1983, from the *College of Pharmacy, University of Kentucky, Lexington, KY 40506.* Accepted for publication July 14, 1983. Present address: Bristol-Myers Co., P.O. Box 4755, Syracuse, NY 13221-4755.

Abstract □ Several factors affecting the dissolution rate of cholesterol in monooctanoin were investigated. This solvent is used clinically for dissolution of residual cholesterol gallstones in the bile duct after cholecystectomy. The effect of added water on dissolution rate, measured using the static- or rotating-disk methods, was not consistent with the previously measured solubility. The discrepancy was found to be due to the decreasing viscosity of the solvent as water was added. Addition of cholesterol, however, increased the viscosity of monooctanoin. The viscosity effect on dissolution rate was investigated further by addition of polymers (povidone and poloxamer 237) which increased solvent viscosity. Dissolution rate was proportional to viscosity to the −0.4 power with these polymers. An equation was derived which predicts that dissolution rate should be proportional to viscosity to the $-\frac{2}{3}$ power. The predicted exponent was very close to reported experimental values for benzoic acid, but the dissolution rate/viscosity relationship for cholesterol in aqueous monooctanoin was nonlinear with apparent exponents of −0.65 to −2.3. Although the Arrhenius activation energies for viscosity (3.79 kcal/mol) and dissolution rate constant (3.66 kcal/mol) were almost equal for benzoic acid, a nonlinear relationship was again observed for cholesterol in aqueous monooctanoin with approximate E_a values of 5.6 10 kcal/mol. The strong influence of viscosity on dissolution rate in this system is attributed to the viscosity-increasing effect of cholesterol in the diffusion layer. The increased viscosity at higher cholesterol concentrations reduces the diffusion coefficient of cholesterol and causes the dissolution rate to be slower even though solubility may have been higher. The data suggest that it may be possible to increase cholesterol gallstone dissolution by addition of water to monooctanoin.

Keyphrases □ Cholesterol dissolution—monooctanoin, viscosity, effect of water addition □ Monooctanoin—cholesterol (gallstone) dissolution, viscosity, effect of water addition □ Viscosity—monooctanoin, cholesterol (gallstone) dissolution, effect of water addition

Monooctanoin (glyceryl monooctanoate) is being used clinically for dissolution of common bile duct cholesterol gallstones (1, 2). The solvent is infused into the bile duct through an abdominal T-tube drain inserted after cholecystectomy. Although cholesterol has high solubility in monooctanoin, most clinical studies indicate that infusion for 1–2 weeks is necessary for gallstone dissolution.

In a previous communication, the solubility of cholesterol in monooctanoin was found to be dependent on the water content of the solvent (3). With addition of water the solubility increased and then decreased with a maximum occurring at 5% water (37°C). The solubility maximum was coincident with the transition of solid cholesterol from the anhydrous to monohydrate form. Since the clinical efficacy of the solvent is primarily dependent on the dissolution rate of cholesterol, the effect of water and other factors influencing cholesterol dissolution rate in monooctanoin were investigated.

THEORETICAL SECTION

The simple Nernst diffusion layer theory is adequate for most dissolution rate studies. The dissolution rate is assumed to be proportional to the concentration gradient across an unstirred diffusion layer on the solid surface:

$$J = DA/h(C_s - C_b) \qquad \text{(Eq. 1)}$$

where J is the dissolution rate, A is the surface area of dissolving solid, D is the diffusivity of solute, C_s is the solubility of solute, C_b is the concentration of solute in bulk solution, and h is the effective diffusion layer thickness. This equation is often used with the static-pellet method for comparative dissolution rate determinations because it assumes that the dissolution rate is only affected by diffusional processes and that the factors in Eq. 1, other than solubility, are constant (4).

When diffusion and convection are both important, the Levich equation applies for a rotating dissolving disk (5):

$$J = 0.62AD^{2/3}/\nu^{1/6} \cdot \omega^{1/2}C_s \qquad \text{(Eq. 2)}$$

where ν is the kinematic viscosity and ω is the angular velocity of rotation. Since the parameters in Eq. 2 can be independently determined, the calculated dissolution rate may be compared with experimental data. Upon combination of these equations, the effective diffusion layer thickness for the rotating disk is obtained:

$$h = 1.6D^{1/2}\nu^{1/4}/\omega^{1/2} \qquad \text{(Eq. 3)}$$

EXPERIMENTAL SECTION

Dissolution Rate—Dissolution of cholesterol monohydrate from a rotating disk was measured using an apparatus similar to that reported previously (6), consisting of a synchronous motor and stirring assembly in a water-jacketed beaker. The sample was compressed in a 1.27-cm diameter die with a load of 3180 kg[1], and the die was attached to a plate on the end of the stirring shaft using cyanoacrylate glue[2] (the die was later removed by soaking the assembly in acetone). The rotation speed was changed using synchronous motors from 60–600 rpm[3]. In the static disk studies the die/disk was placed facing upward on the bottom of the beaker, and the solution was stirred at 150 rpm. To simulate the conditions of gallstone dissolution *in vivo*, 0.5-g cholesterol disks were accurately weighed and placed in screw-capped test tubes containing 40 g of solvent. The samples were left undisturbed at 37°C for 24 h and the residual cholesterol was determined gravimetrically after removing excess solvent by blotting with tissue.

Analysis—Cholesterol was analyzed by HPLC using a modification of a literature procedure (7) using an acetonitrile–methanol (5:1) mobile phase, a reverse-phase column[4], and a variable-wavelength detector at 215 nm. Dissolution samples were diluted with mobile phase and injected directly on the system. Benzoic acid was analyzed spectrophotometrically at 229 nm in 0.01 M HCl.

Water in cholesterol monohydrate and dissolution media was determined by automated Karl Fischer titrimetry[5]. Viscosity was measured using a cone-plate viscometer[6] with a circulator bath for temperature control. Cholesterol solubility was determined as previously described (3).

Fractionation of Monooctanoin—The mono- and diglyceride fractions of commercial monooctanoin were separated by column chromatography on silica gel. The diglyceride fraction was eluted with ethyl acetate–hexane (1:1) and the monoglyceride fraction was then displaced with ethyl acetate. The purity of the fractions was checked by TLC (1:1 ethyl acetate–hexane on precoated silica gel plates) and the solvent was removed by rotary evaporation. The monoglyceride melted at 36°C, and the diglyceride was an oil. The samples contained <0.5% water.

Materials—Cholesterol USP[7], monooctanoin[8], and glyceryl monolaurate[9] were obtained commercially. The ~30% diglyceride content in monooctanoin reported by the manufacturer was consistent with the column chromatography yields. Solvents were HPLC grade, and the other chemicals were reagent grade.

Cholesterol monohydrate was prepared by recrystallization from 10% aqueous acetone. The wet crystals, after filtration, were air-dried for ~1 h

and then stored in a chamber containing water. The water content of the crystals was equal to theory for a monohydrate (4.4% water). Although 95% ethanol has been widely used for preparing the monohydrate, problems were encountered in removing the residual ethanol when using this solvent. This may be due to the formation of a hemiethanol solvate (8). The vacuum drying required to remove ethanol also removed the water of hydration, so the sample was rehydrated in the water chamber. The water of hydration was quite labile. After a few hours in an open container, the water content of cholesterol monohydrate decreased to ~1%.

RESULTS AND DISCUSSION

Static-Disk Studies—Dissolution rate measurements by the static-disk method were conducted. In Fig. 1 the relative dissolution rate and solubility of cholesterol in monooctanoin solutions is plotted as a function of the water content of the solvent. At this stirring rate, there was poor agreement between the previously determined solubilities and the static-disk dissolution data. The difference was most apparent at >5% water where the dissolution rate did not decrease along with the solubility. The dissolution rate determined in the dry solvent (4.7×10^{-3} mg cm^{-2} s^{-1}) was in good agreement with the value of 4×10^{-3} reported by Thistle *et al.* (1).

Other data corroborated the poor correlation between solubility and dissolution rate. Table I shows the effect of sodium chloride on solubility and dissolution rate in 5% aqueous monooctanoin. A mixture of 0.9–2.5% aqueous NaCl with monooctanoin increased cholesterol solubility, presumably by inducing association of cholesterol with itself or the nonpolar fatty acid chains of the glycerides. As before, however, the solubility increase did not cause a corresponding change in the dissolution rate. The viscosity of the solutions was not affected by sodium chloride. Cholesterol solubility increased with addition of longer-chain glycerides. When monooctanoin was mixed with an equal amount of glyceryl monolaurate and 5% water, cholesterol solubility increased from 16.1 to 23%, whereas the dissolution rate was essentially unchanged. These data clearly show that the direct proportionality between solubility and dissolution rate expected from the Nernst equation is not being followed in this system.

Rotating-Disk Studies—Because of the uncertainty of the static-disk method with regard to hydrodynamic conditions in this system, the effect of water was redetermined using the rotating disk at 150 rpm (Fig. 1, upper

Table I—Effect of Salt on Cholesterol Solubility and Dissolution Rate (Static-Disk Method)

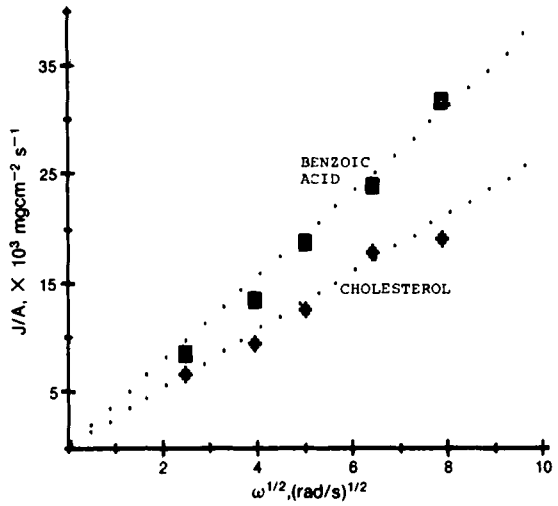

Figure 2—*Levich plots of the dissolution rate* versus *(rotation speed)*$^{1/2}$ *at 37°C for cholesterol in 10% aqueous monooctanoin and benzoic acid in 0.01 M HCl. Dotted lines were calculated using Eq. 2.*

curve). The dissolution rate and solubility data diverged still further, with an almost constant 50% increase in dissolution rate at >5% water.

The dissolution apparatus was calibrated using benzoic acid in 0.01 M HCl at 37°C. Under these conditions the dissolution rate is diffusion controlled (6). In addition, the diffusion coefficient and solubility of benzoic acid in 0.01 M HCl have been reported (4), allowing calculation of the dissolution rate according to Eq. 2. The theoretical line in Fig. 2 is in excellent agreement with the experimental data for benzoic acid.

Also shown in Fig. 2 is the dissolution rate of cholesterol in aqueous monooctanoin. The diffusion coefficient of cholesterol in the solvent was estimated to be 1.53×10^{-7} cm^2 s^{-1} using the Stokes-Einstein equation (see Eq. 4 below). With this and the other constants of Eq. 2, the theoretical line for cholesterol in Fig. 2 was calculated and found to be in good agreement with the experimental data. It may, therefore, be concluded that the dissolution rate of cholesterol under the conditions studied is a diffusion-convection-controlled process according to Eq. 2.

Effect of Water and Cholesterol on the Viscosity of Monooctanoin—During preparation of the dissolution media the viscosity of monooctanoin appeared to be reduced by the addition of water. These observations were confirmed by measuring the viscosities with a cone-plate viscometer (Fig. 3). The viscosity-lowering effect of water is generally observed with glycerol and glycols and has been attributed to the breaking of solvent-solvent hydrogen bonds by addition of water (9, 10). These data are important since viscosity changes could be an explanation for the anomalous dissolution rate results. The decreasing viscosity could be counteracting the lower cholesterol solubility, causing the dissolution rate at >5% water to be essentially constant.

Addition of cholesterol had the opposite effect on the viscosity of monooc-

tanoin (Fig. 3). In addition, the upward curvature indicated a greater than first-order dependence on cholesterol concentration. The similarity of the two curves showed that the amount of water present had little effect on the viscosity-inducing properties of cholesterol. Since the higher concentrations in Fig. 3 are similar to the solubility of cholesterol in the dissolution experiments, the diffusion layer during dissolution must be significantly more viscous than the bulk solution. This implies also that a viscosity gradient must be present across the diffusion layer. Although it is probably not rigorously applicable to this system, the Stokes-Einstein equation predicts an inverse relationship between the diffusion coefficient and viscosity:

$$D = kT/(6\pi\eta r) \qquad \text{(Eq. 4)}$$

where k is the Boltzmann constant, T is the absolute temperature, η is the viscosity, and r is the radius of the molecule.

Viscosity Effects on Dissolution Rate—Two independent approaches were investigated for probing the effect of viscosity on dissolution rate: addition of polymers and temperature effects. The former approach has been extensively investigated in aqueous systems (11-13). In aqueous polymer solutions the exponential relationship betweeen dissolution rate and viscosity usually lies between −0.25 and −0.8 (11). The exponent was dependent on the experimental system, polymer, and dissolving solute. This specificity was proposed to be due to the difference between the measured bulk solution viscosity and the effective viscosity (resistance to solute diffusion), which controls the dissolution rate (12). In a recent study, several equations for the diffusion coefficient in polymer solutions were compared for their ability to represent benzoic acid dissolution (13). None was found to be significantly better than Eq. 4 and the average viscosity exponent was −0.62 (13).

Rearrangement of Eq. 2 gives the dissolution rate constant:

$$J/(AC_s = 0.62\nu^{-1/6}\omega^{1/2}D^{2/3} \qquad \text{(Eq. 2a)}$$

By substituting D from Eq. 4, the hypothetical effect of viscosity on dissolution rate is obtained:

$$J/(AC_s) = 0.62\nu^{-1/6}\omega^{1/2}(kT/(6\pi r))^{2/3}\eta^{-2/3} \qquad \text{(Eq. 5)}$$

$$= k'\eta^{-2/3} \qquad \text{(Eq. 5a)}$$

where $k' = 0.62\nu^{-1/6}\omega^{1/2}(kT/(6\pi r))^{2/3}$.

At constant temperature the terms of k' should be constant except for $\nu^{-1/6}$. This term, however, is almost constant over the range of viscosity usually studied. For example, a 50% increase in viscosity would change this term by only −6.5%. Equation 5 predicts that J/AC_s should be proportional to viscosity to the $-2/3$ power. This predicted value is quite similar to that experimentally determined (11-13), although previous investigators have apparently not considered this simple relationship.

In preliminary studies several polymers were screened for their effects on cholesterol solubility and monooctanoin viscosity. Povidone K-30 and poloxamer 237 were chosen because viscosity was increased without change in cholesterol solubility. In Fig. 4 the viscosity of aqueous monooctanoin is plotted as a function of polymer concentration. The povidone data are linear but the Poloxamer 237 viscosities are not, and higher concentrations were required to reach a given viscosity. Figure 5 shows the log-log relationship between dissolution rate and viscosity for these two polymers plotted according to Eq. 5a. The slopes were −0.39 for povidone and −0.36 for poloxamer 237, smaller than the $-2/3$ power predicted above.

The effect of temperature on dissolution rate has not been previously utilized for investigating viscosity effects. In Eq. 2, for the rotating disk, changing temperature affects ν, D, and C_s. Since the $\nu^{-1/6}$ term is negligible under most conditions and solubilities can be readily measured, the effect of viscosity on dissolution rate can be isolated to the changing diffusion coefficient. If Eq. 4 adequately represents the proportionality between D and η, then Eq. 5 should also be applicable for dissolution rate-temperature data. Since $T^{2/3}$ changes only 5% with the present data (20-45°C), whereas J/AC_s increases threefold, dividing J/AC_s by $T^{2/3}$ has no significant effect (Fig. 5). The slopes for this curving line are approximately −0.6 to −2.3, with the smaller value occurring at the higher temperatures (37°C and 45°C). Thus, it appears that the dissolution rate approaches theoretical behavior ($-2/3$ power of viscosity) with increasing temperature.

Activation Energies for Viscosity and Dissolution Rate—Viscosity-temperature data are commonly plotted in the Arrhenius manner to obtain the energy of activation, E_a. Figure 6 shows the temperature effect on viscosity of aqueous monooctanoin and water (14). The apparent activation energy for monooctanoin was higher than that for water. Although viscosity decreases with increasing temperature, these activation energies are reported as endothermic constants.

Previous rotating-disk dissolution rate studies reported activation energies

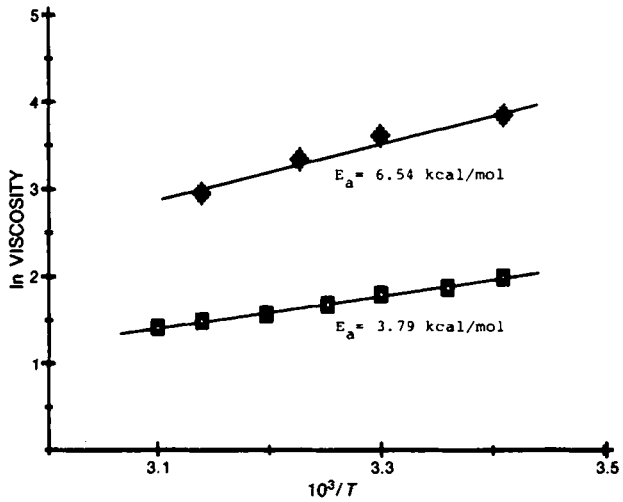

Figure 6—*Arrhenius plots of the viscosity of 10% aqueous monooctanoin (◆) and water (2 + ln η) (■) from Ref. 14.*

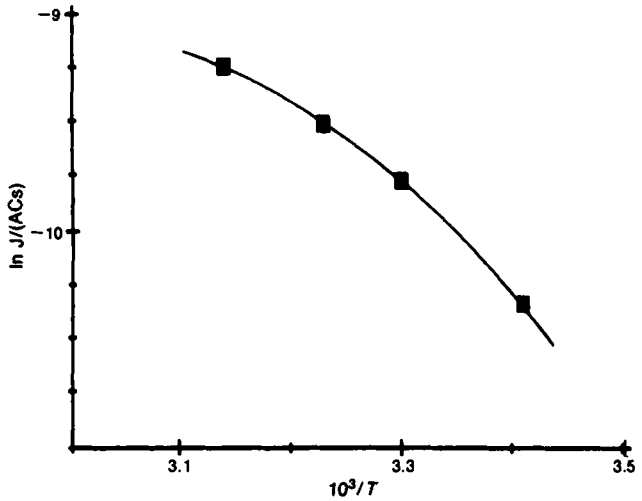

Figure 7—*Arrhenius plot for the dissolution rate constant of cholesterol in 10% aqueous monooctanoin.*

of 3.3–3.7 kcal/mol (15–17). By calculating the dissolution rate constant (J/AC_s) of benzoic acid in 0.01 M HCl from Eqs. 2 and 4, Touitou and Donbrow (17) obtained a theoretical E_a of 3.66 kcal/mol. Their experimental data showed an E_A of ~3.3 kcal/mol with some curvature in the Arrhenius plot. The difference was ascribed to the influence of interfacial kinetics at lower temperatures. The similarity between the E_a for the dissolution rate constant of benzoic acid indicates that viscosity change can almost entirely account for the change in dissolution rate.

In Fig. 7 the experimental dissolution rate constants for cholesterol are plotted against reciprocal temperature. The data again show significant curvature with an apparent range of E_a values from ~5.6 to 10 kcal/mol. As discussed previously, separation of the $T^{2/3}$ term had a negligible effect on E_a. The heat of solution for cholesterol in aqueous monooctanoin was found to be 4.1 kcal/mol (3). When ln J was plotted against T^{-1} the total heat of dissolution was ~11.5 kcal/mol. The difference in these activation energies (7.4 kcal/mol) would be the average E_a for the viscosity effect. Therefore, temperature changes exert a greater influence on dissolution rate through viscosity–diffusion coefficient effects than through solubility.

Solubility and Dissolution Rate in Mono- and Diglyceride Fractions—The monooctanoin used in these studies is a mixture containing ~30% diglyceride. The uncertainty about the individual effects of the solvent components and the previously discussed influence of viscosity prompted measurement of cholesterol solubility and dissolution rate in the mono- and diglyceride fractions of monooctanoin isolated by column chromatography. Table II compares the viscosity, solubility, and dissolution rate of the solvent and its components. The highest dissolution rates were obtained for the diglyceride fraction, even though the solubilities were the lowest. Although the data are limited, a good correlation is apparent between viscosity and dissolution rate.

A difficulty in the interpretation of Table II is that cholesterol monohydrate was used for the dissolution rate measurements, whereas the equilibrium solubility form was anhydrous (3). Curvature was not detected in the rotating-disk dissolution runs at 150 rpm, indicating that surface conversion, if occurring, was not significantly affecting the rate. This is consistent with the similar solubilities of the two forms (3). Whether conversion occurs in stirred systems depends on the hydrodynamic conditions and the potential for crystallization (supersaturation and nucleation factors).

Table II—Cholesterol Dissolution Rate in Monooctanoin and its Mono- and Diglyceride Fractions

Solvent	Water, %	Viscosity, cP	Solubility, %	10^3 Dissolution Rate, mg cm^{-2} s^{-1}

Monoglyceride fraction	0.4	58	12.8	4.6
Diglyceride fraction	0.4	20	9.8	12.4

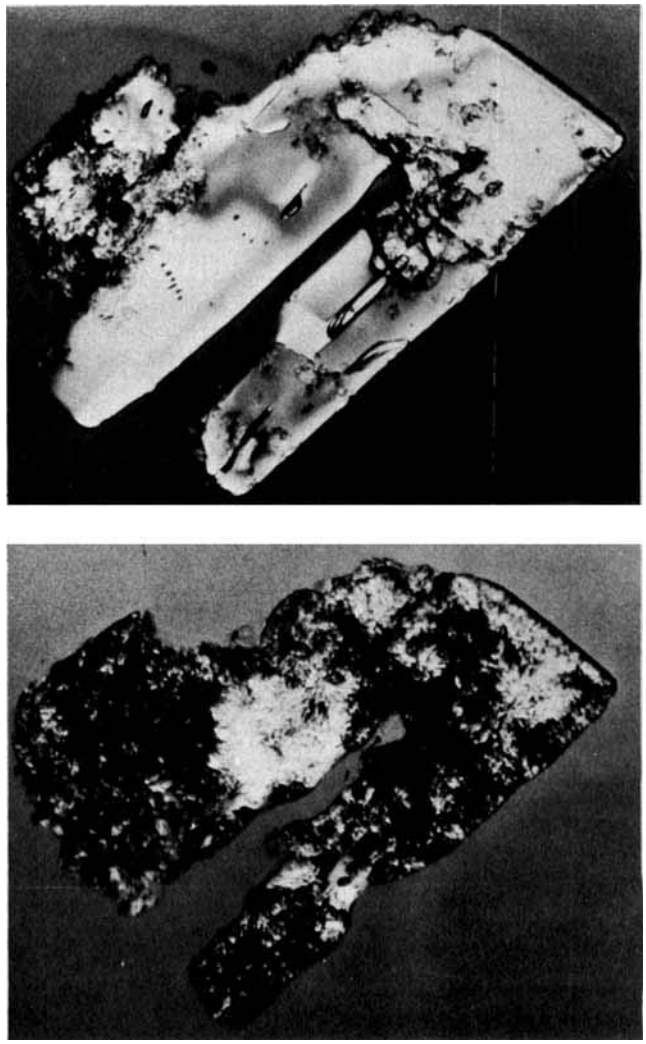

Figure 8—*Polarized light photomicrographs of a cholesterol monohydrate crystal in dry monooctanoin solution immediately upon immersion (top) and after 2 min (bottom).*

Cholesterol Dissolution in Unstirred Media—Under static (unstirred) conditions, surface transformation to the anhydrous form was observed. The photomicrographs in Fig. 8 show a cholesterol monohydrate crystal immediately and 2 min after incubation with dry monooctanoin. The darkening of the crystal is due to crystallization of the anhydrous form on the dissolving surface. In this case, the crust of anhydrous cholesterol inhibited further dissolution of the monohydrate, as shown in Table III. In the dry solvent the weight loss of tablets made from cholesterol monohydrate was less than that from the anhydrous form. The effect of water on the monohydrate in Table III parallels the results in Fig. 1, which show an essentially constant dissolution rate at >5% water. Since the conditions of these experiments are more similar to the clinical situation, which involves slow infusion into the bile duct, significant improvement in gallstone dissolution *in vivo* may be possible with monooctanoin containing water.

CONCLUSIONS

The strong effect of viscosity on dissolution rate in this system has its origin in the solute–solvent interactions which cause high solubility. These interac-

tions increase the viscosity of the diffusion layer on the dissolving cholesterol monohydrate surface. The resulting decrease in the diffusion coefficient of cholesterol in the diffusion layer causes the dissolution rate to be slower even though solubility may have been higher. For these reasons, the preferred approach for increasing the dissolution rate of cholesterol gallstones in monoglycerides would be to investigate solvents with low viscosity rather than to try to optimize solubility. The validity of this statement is supported by the data in Table II, which show that dissolution rate is greater in the diglyceride fraction of monooctanoin although cholesterol solubility is lower.

In terms of clinical applications, this study suggests that it may be possible to increase the cholesterol gallstone dissolution rate by addition of water to monooctanoin. Water may also improve local tolerance of the drug during infusion. Since the solubility of water in monooctanoin is ~15% at 37°C, the aqueous solvent would have much less potential for extraction of water from the bile duct and intestinal walls. The importance of temperature should be emphasized, since the dissolution rate of cholesterol increases 50% from 30°C to 37°C. Some of the reported variability in clinical results may be due to inadequate control of solvent temperature. Lastly, addition of water overcomes a practical problem with handling monooctanoin, *i.e.*, crystallization. By its effect on the colligative properties of the solvent, water depresses the solidification point of monooctanoin to well below room temperature.

Effects of Acrylic Acid Polymer and Its Arrangement on Drug Release from a Wax Matrix

HISATOSHI EMORI, TAKAFUMI ISHIZAKA ˣ, and MASUMI KOISHI

Received December 23, 1982, from the *Faculty of Pharmaceutical Sciences and Institute of Colloid and Interface Science, Science University of Tokyo, 12, Ichigaya Funagawara-machi, Shinjuku-ku, Tokyo, Japan.* Accepted for publication June 23, 1983.

Abstract □ The release of phenacetin from a wax matrix was improved by the addition of an acrylic acid polymer. Increasing the amount of polymer increased the release rate of phenacetin due to the formation of pores and channels in the matrix resulting from leaching of the polymer. The leaching was affected by the pH of the dissolution medium as well as by the methods used to prepare the granules. The polymer in ordered powder mixes behaved differently from that uniformly dispersed in a wax matrix. The drug appeared to be released by an approximate zero-order process at pH 7.5 from tablets containing the polymer.

Keyphrases □ Wax matrices, inert—release of phenacetin, effect of acrylic acid polymer □ Phenacetin release from inert wax matrices, effect of acrylic acid polymer □ Acrylic acid polymer—effect on release of phenacetin from inert wax matrices, action as a channeling agent

Recently, various methods have been developed to prolong the action of drugs by controlling their release rates. One method involves the incorporation of drugs into a wax matrix. The mechanism of drug release from a wax matrix involves the leaching of the drug by a permeating fluid that enters the drug-matrix phase through the pores, cracks, and intergranular spaces. Higuchi has treated the drug release from the matrix model in a theoretical manner (1).

Several investigators have described the incorporation of additives, such as surfactants, into the matrix (2, 3). These additives act as channeling agents and improve drug release. The drug appears to be released by a zero-order process. Others have investigated ordered powder mixes (4, 5). For example, the wettability of α-lactose powder was appreciably changed by modifying its surface with other powders (6). The purposes of this work are to evaluate an acrylic acid polymer as a channeling agent in the wax matrix and to examine the effects of powder arrangement on drug release.

EXPERIMENTAL SECTION

Materials—Carnauba wax[1] was obtained commercially, and the stearyl alcohol, sodium chloride, disodium phosphate, and hydrochloric acid were reagent grade. The phenacetin[2] was JP grade; the powder was ground with an automatic mortar[3] and then sieved to 49–105-μm particle size with stainless steel sieves. The water used in this experiment was prepared with a water purification apparatus[4]. Acrylic acid polymer[5] was cross-linked and had a viscosity of 3000 cps as a 1% aqueous solution. Molecular weight, solubility, and carboxyl group content of the acrylic acid polymer were ~2,000,000, 5% (w/w), and 60%, respectively.

Preparation of Granules—Carnauba wax (15.0 g) and stearyl alcohol (15.0 g) were mixed and melted at 90 ± 3°C. Phenacetin powder was added into the melt in small portions with constant stirring for 5 min at 90 ± 3°C, to achieve an even distribution; the mixture was then poured onto a glass plate kept at 0°C and allowed to congeal. The plate-like mass was crushed for 10

tions increase the viscosity of the diffusion layer on the dissolving cholesterol monohydrate surface. The resulting decrease in the diffusion coefficient of cholesterol in the diffusion layer causes the dissolution rate to be slower even though solubility may have been higher. For these reasons, the preferred approach for increasing the dissolution rate of cholesterol gallstones in monoglycerides would be to investigate solvents with low viscosity rather than to try to optimize solubility. The validity of this statement is supported by the data in Table II, which show that dissolution rate is greater in the diglyceride fraction of monooctanoin although cholesterol solubility is lower.

In terms of clinical applications, this study suggests that it may be possible to increase the cholesterol gallstone dissolution rate by addition of water to monooctanoin. Water may also improve local tolerance of the drug during infusion. Since the solubility of water in monooctanoin is ~15% at 37°C, the aqueous solvent would have much less potential for extraction of water from the bile duct and intestinal walls. The importance of temperature should be emphasized, since the dissolution rate of cholesterol increases 50% from 30°C to 37°C. Some of the reported variability in clinical results may be due to inadequate control of solvent temperature. Lastly, addition of water overcomes a practical problem with handling monooctanoin, *i.e.*, crystallization. By its effect on the colligative properties of the solvent, water depresses the solidification point of monooctanoin to well below room temperature.

Effects of Acrylic Acid Polymer and Its Arrangement on Drug Release from a Wax Matrix

HISATOSHI EMORI, TAKAFUMI ISHIZAKA ˣ, and MASUMI KOISHI

Received December 23, 1982, from the *Faculty of Pharmaceutical Sciences and Institute of Colloid and Interface Science, Science University of Tokyo, 12, Ichigaya Funagawara-machi, Shinjuku-ku, Tokyo, Japan.* Accepted for publication June 23, 1983.

Abstract □ The release of phenacetin from a wax matrix was improved by the addition of an acrylic acid polymer. Increasing the amount of polymer increased the release rate of phenacetin due to the formation of pores and channels in the matrix resulting from leaching of the polymer. The leaching was affected by the pH of the dissolution medium as well as by the methods used to prepare the granules. The polymer in ordered powder mixes behaved differently from that uniformly dispersed in a wax matrix. The drug appeared to be released by an approximate zero-order process at pH 7.5 from tablets containing the polymer.

Keyphrases □ Wax matrices, inert—release of phenacetin, effect of acrylic acid polymer □ Phenacetin release from inert wax matrices, effect of acrylic acid polymer □ Acrylic acid polymer—effect on release of phenacetin from inert wax matrices, action as a channeling agent

Recently, various methods have been developed to prolong the action of drugs by controlling their release rates. One method involves the incorporation of drugs into a wax matrix. The mechanism of drug release from a wax matrix involves the leaching of the drug by a permeating fluid that enters the drug-matrix phase through the pores, cracks, and intergranular spaces. Higuchi has treated the drug release from the matrix model in a theoretical manner (1).

Several investigators have described the incorporation of additives, such as surfactants, into the matrix (2, 3). These additives act as channeling agents and improve drug release. The drug appears to be released by a zero-order process. Others have investigated ordered powder mixes (4, 5). For example, the wettability of α-lactose powder was appreciably changed by modifying its surface with other powders (6). The purposes of this work are to evaluate an acrylic acid polymer as a channeling agent in the wax matrix and to examine the effects of powder arrangement on drug release.

EXPERIMENTAL SECTION

Materials—Carnauba wax[1] was obtained commercially, and the stearyl alcohol, sodium chloride, disodium phosphate, and hydrochloric acid were reagent grade. The phenacetin[2] was JP grade; the powder was ground with an automatic mortar[3] and then sieved to 49–105-μm particle size with stainless steel sieves. The water used in this experiment was prepared with a water purification apparatus[4]. Acrylic acid polymer[5] was cross-linked and had a viscosity of 3000 cps as a 1% aqueous solution. Molecular weight, solubility, and carboxyl group content of the acrylic acid polymer were ~2,000,000, 5% (w/w), and 60%, respectively.

Preparation of Granules—Carnauba wax (15.0 g) and stearyl alcohol (15.0 g) were mixed and melted at 90 ± 3°C. Phenacetin powder was added into the melt in small portions with constant stirring for 5 min at 90 ± 3°C, to achieve an even distribution; the mixture was then poured onto a glass plate kept at 0°C and allowed to congeal. The plate-like mass was crushed for 10

Table I—Formulations for Method 1

Acrylic Acid Polymer Conc. % (w/w)	Weight, g			
	Carnauba Wax	Stearyl Alcohol	Acrylic Acid Polymer	Phenacetin
1.0	14.775	14.775	0.45	15.0
3.0	14.325	14.325	1.35	15.0
6.0	13.650	13.650	2.70	15.0
9.0	12.975	12.975	4.05	15.0

min in a ceramic mortar and then screened to prepare a granule size of 420–590 μm.

Incorporation of Acrylic Acid Polymer into the Wax Matrix—*Method 1*—When a homogeneous melt carnauba wax and stearyl alcohol was attained at 90 ± 3°C, the polymer powder was gradually added to the melt followed by phenacetin powder, which was added in small portions at the same temperature while stirring. After pouring the mixture onto a cold glass plate, the plate-like mass was crushed and sieved to obtain the required granule size. The formulations are shown in Table I

Method 2—A 30.0-g portion of phenacetin powder and various loadings (1.0, 2.0, 3.0, and 6.0 g) of acrylic acid polymer were thoroughly blended in an automatic mortar for 5 min. Figure 1 shows scanning electron micrographs of the phenacetin and blended powders. Samples equivalent to 15.0 g of phenacetin were homogeneously incorporated into the melted mixture of carnauba wax and stearyl alcohol according to the formulations shown in Table II. The 420–590-μm granules were obtained by the same procedure described in method 1.

Preparation of Tablets—A KBr disk press[6] was used to compress the granules into tablets using a compression force of 100 kg/cm^2. The average tablet weight was ~500 mg, with a thickness and diameter of ~3.6 and 13 mm, respectively.

Dissolution Procedures—The fluids of pH 1.2 and 7.5 included in JP IX were used as the dissolution media. The former was prepared by mixing 2.0 g of sodium chloride, 24.0 mL of 10% (w/w) HCl, and a sufficient amount of water to give 1000 mL of solution; the latter was prepared by mixing 35.8 g of disodium phosphate, 6.0 mL of 10% (w/w) HCl, and water to give 1000 mL of solution.

The apparatus shown in Fig. 2 was used for the dissolution tests. The dissolution flask was covered during the experiment to prevent water evaporation. A paddle with six blades was set at 3 cm from the bottom of the flask and rotated at constant rate of 200 rpm. A stirring speed of 200 rpm was adequate to disperse the granules uniformly in the fluid. Granules (0.3 g) were added into the flask containing 500 mL of a dissolution medium maintained at 37 ± 0.1°C. After adding the granules, 3-mL aliquots of the test fluid, containing granules, were withdrawn with syringes at intervals over a 10-h period. The sample was then filtered through 0.6-μm pore membrane filter[7].

[a] Mixed powder.

A method similar to the USP rotating-basket method was used to investigate drug release from the tablets. A basket, in which a tablet was placed, was immersed into a flask containing 600 mL of a dissolution medium maintained at 37 ± 0.1°C. The basket was set at a height of 3 cm from the bottom of the flask and rotated at a rate of 200 rpm; this was necessary to prevent air bubbles from adhering to the basket and the tablet surface. Aliquots (3 mL) of the test fluid were then withdrawn at intervals over a 10-h period. Each sample was replaced with 3 mL of fresh dissolution medium kept at 37 ± 0.1°C to maintain the constant volume of the test fluid. The amount of phenacetin released was determined by direct measurement of the absorbance at 245 nm.

RESULTS AND DISCUSSION

Effect of Acrylic Acid Polymer Added According to Method 1 on Phenacetin Release—The release of phenacetin from the wax matrix containing acrylic acid polymer made according to method 1 was investigated. The particle sizes and concentration of phenacetin were 49–105 μm and 33.3% (w/w), respectively, the granule sizes were 420–590 μm, the compression force was 100 kg/cm^2, and acrylic acid polymer concentrations were 1.0, 3.0, 6.0, and 9.0% (w/w).

Figure 3a and b illustrates the drug release profiles at pH 1.2 from granules and tablets, respectively. The addition of acrylic acid polymer into the wax matrix affected the drug release. As is evident from Fig. 3, there was a slight increase in the release rates, in both cases, with increasing amounts of added polymer. A similar observation has been reported for a water-soluble nonelectrolytic polymer by Dakkuri *et al.* (3). The drug release from tablets for the initial 1.5 h at pH 1.2 seemed to be in accordance with the Higuchi equation, but a negative deviation was seen when the added polymer concentrations were 0, 1.0, 3.0, and 6.0% (w/w) and a positive deviation was noted when the polymer concentration was 9.0% (w/w).

The release profiles from granules and tablets at pH 7.5 are shown in Fig. 3c and d, respectively. For granules, the addition of the polymer markedly increased the drug release as compared with the polymer-free formulation. A 100% release was achieved in 10 h for the 6.0% (w/w) and in 2 h for 9.0% (w/w) polymer concentrations. Also, in the case of tablets at pH 7.5, an obvious increase in the drug release rate was associated with the amount of polymer added. The drug release appeared to follow a quasi-zero-order kinetics at high polymer concentrations (6.0 and 9.0%). Similar observations were reported by Dakkuri *et al.* (2). The deviation from a straight line after 7 h for the 9.0% (w/w) polymer concentration (Fig. 3d) could be explained by the total exhaustion of the solid drug phase.

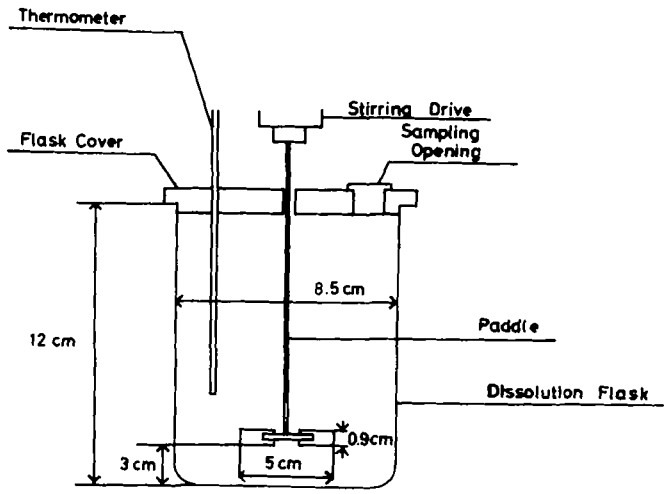

Figure 2—*Schematic diagram of apparatus for the dissolution test of granules.*

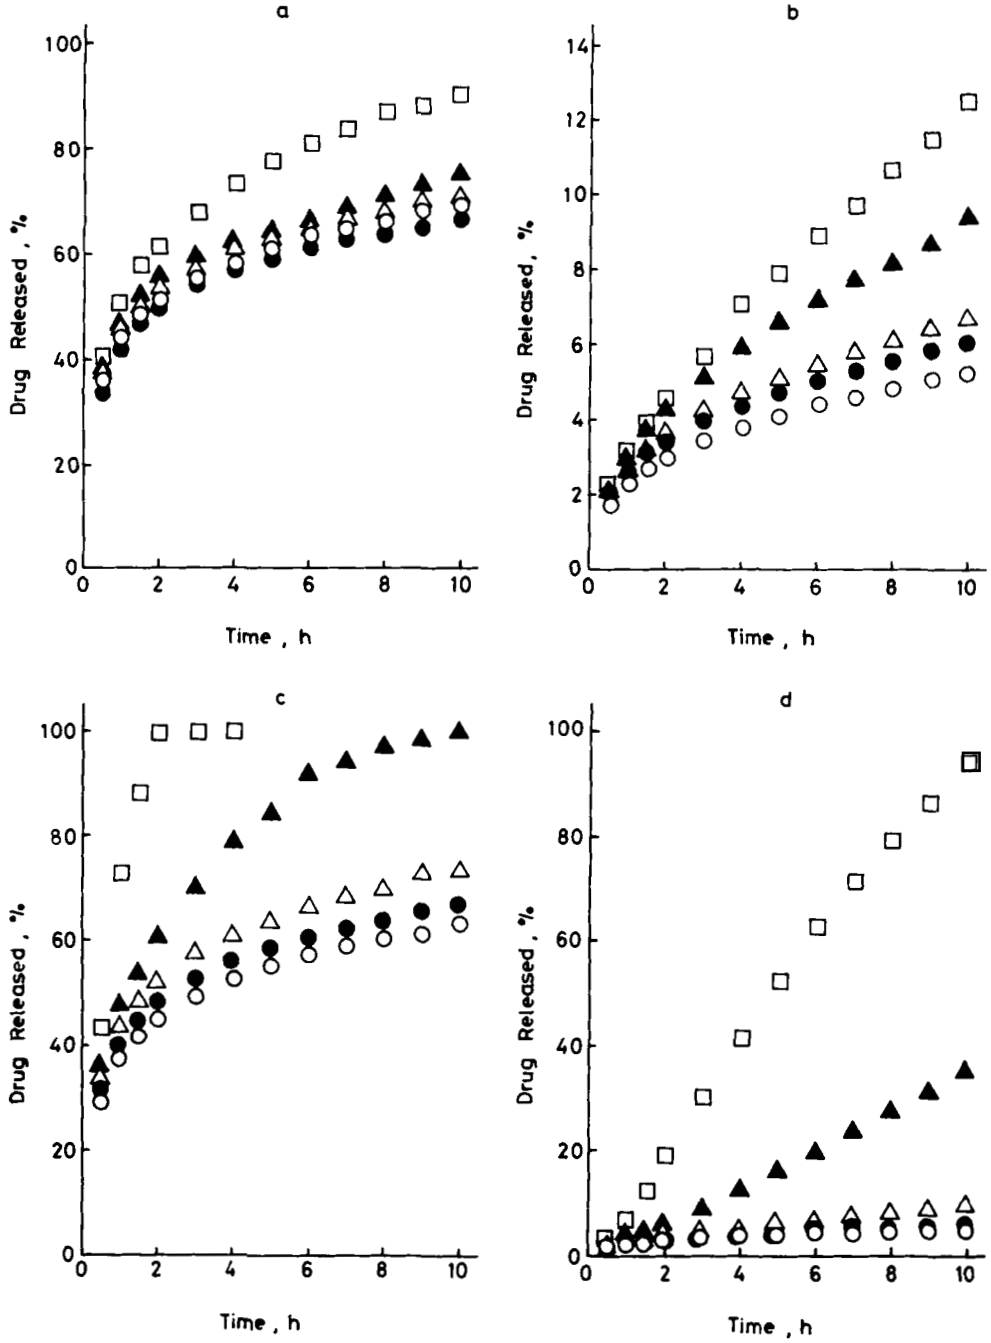

Figure 3—*Effect of acrylic acid polymer concentration on the release of phenacetin from granules at pH 1.2 (a) and pH 7.5 (c) and from tablets at pH 1.2 (b) and pH 7.5 (d), using method 1. Key: (○) 0% (w/w); (●) 1% (w/w); (△) 3% (w/w); (▲) 6% (w/w); (□) 9% (w/w).*

These distinct effects of the polymer were due to the formation of pores and channels in the matrix, which resulted from swelling and leaching of the polymer powder. The degrees of swelling and leaching of the polymer were controlled by a change in the dissolution medium pH. When the polymer in the matrix was hydrated by the dissolution medium, the degree of ionization of the carboxyl groups of the acrylic acid polymer was lower at pH 1.2 than at pH 7.5. As a result, the partially hydrated polymer molecules at pH 1.2 formed a dense jelly structure, which caused most of the polymer molecules dispersed in the matrix to be held in the pores and channels. Therefore, the drug molecules were released slowly through the pores and channels that were filled with the less-hydrated polymer molecules.

At pH 7.5, however, because the polymer chains were extended due to the repulsion of negatively charged carboxyl groups, the fully hydrated polymer became swollen. Consequently, the hydrated polymer molecules in the matrix were liberated into the dissolution medium. Leaching out of the polymer increases the internal porosity and decreases the tortuosity, as suggested by Samuelov *et al.* (7). Therefore, the drug was released rapidly at pH 7.5. The apparent quasi-zero-order kinetics of drug release from tablets at pH 7.5 and high polymer concentrations can be attributed to the increase of the diffusion rate of the drug in the channels and to the increasing number of channels after leaching of the polymer.

Effect of Acrylic Acid Polymer Added According to Method 2 on Phenacetin Release—The release of phenacetin from the wax matrix containing acrylic acid polymer made according to method 2 was studied. The particle sizes and the concentration of phenacetin were 49–105 μm and 33.3% (w/w), respectively, the granule sizes were 420–590 μm, and the compression force was 100 kg/cm^2.

The release profiles at pH 1.2 and 7.5 from granules are shown in Fig. 4a and c, respectively. These results indicated that the increase in the polymer concentration increased the release rate of phenacetin. It is also obvious that the addition of the polymer into the matrix according to method 2 significantly improved the drug release as compared with method 1. Higher release rates were also observed at pH 7.5 than at pH 1.2. Figure 4b and d illustrates the release profiles from tablets at pH 1.2 and 7.5, respectively. As described above, leaching of the polymer into the pH 1.2 dissolution medium was slight, and the effect of the addition of the polymer on the drug release at pH 1.2 was

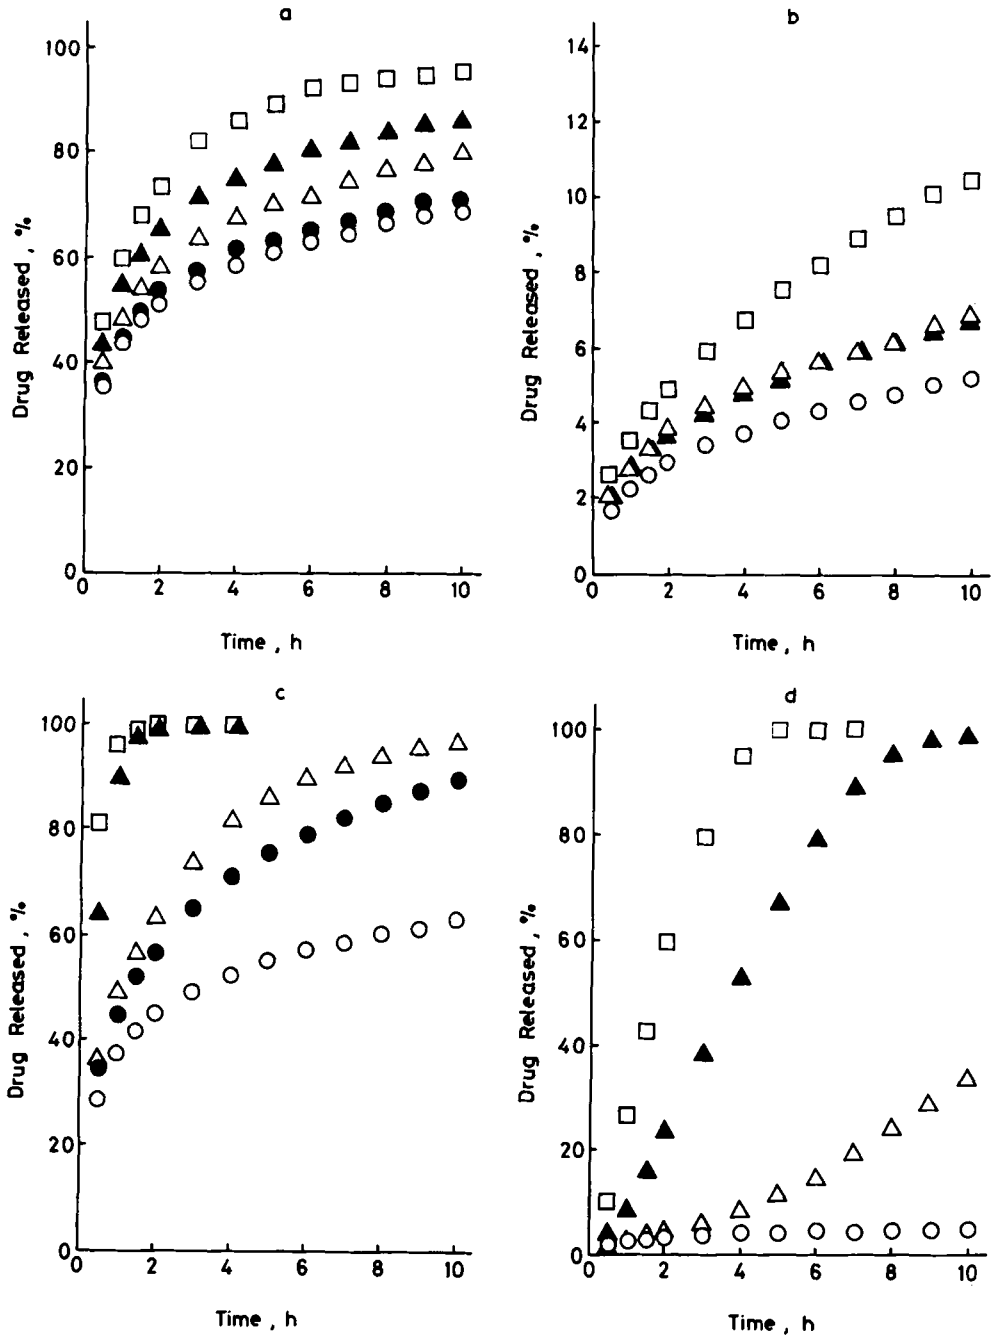

Figure 4—*Effect of acrylic acid polymer concentration on the release of phenacetin from granules at pH 1.2 (a) and pH 7.5 (b) and from tablets at pH 1.2 (b) and pH 7.5 (d), using method 2. Key: (○) 0% (w/w); (●) 1.1% (w/w); (△) 2.2% (w/w); (▲) 3.3% (w/w); (□) 6.6% (w/w).*

also negligible. At pH 1.2, the drug release from tablets in the initial period seemed to be in accordance with the Higuchi equation, and then a negative deviation was observed. However, at pH 7.5, the addition of the polymer markedly increased the drug release from tablets. The drug release followed quasi-zero-order kinetics at high polymer concentrations (3.3 and 6.6%). Moreover, tablet disintegration was observed in some cases at this pH. The drug release at a polymer concentration of 2.2% (w/w) had two zero-order rate constants, caused by slow tablet disintegration after 5 h. The tablets containing 3.3 and 6.6% (w/w) acrylic acid polymer began to disintegrate after ~1 h and 30 min, respectively. However, no burst phenomenon was observed with all the tablets. The change of the release pattern (to quasi-zero-order kinetics) at pH 7.5 and at high polymer concentrations could be caused by an increase in the diffusion rate of drug molecules through channels that resulted from leaching of the polymer and also by a shortening of this channel length due to tablet disintegration.

Differences Between the Two Methods—When the release data obtained using the two methods of polymer addition are compared (Figs. 3 and 4), it was shown that method 2 gave a more rapid release of drug than method 1

Table III—Effects of Acrylic Acid Polymer Concentration on the Zero-Order Release Rate Constant (k) for Tablets at pH 7.5

Acrylic Acid Polymer Conc., % (w/w)	k, mg/h	r
	Method 1	
1.0	0.60	0.998
3.0	1.29	0.999
6.0	6.00	0.999
9.0	18.22	0.998
	Method 2	
2.2	2.97[a]	0.998
	4.75[b]	1.000
3.3	22.89	0.999
6.6	51.63	1.000

[a] For the period up to 5 h. [b] For the period after 5 h.

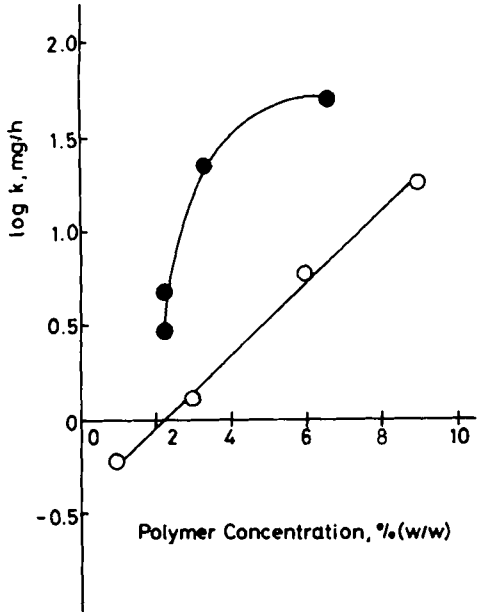

Figure 5—*Relationships of log k to the concentration of acrylic acid polymer at pH 7.5. Key: (○) method 1; (●) method 2.*

for both granules and tablets. For example, those tablets which were prepared by method 1 and contained 6.0% (w/w) polymer released only 17% of the drug in 5 h at pH 7.5, while those prepared by method 2 released 100% at pH 7.5.

The zero-order release rate constant (k) at pH 7.5 for the tablet increased with increasing polymer concentration, as shown in Table III, where k was calculated from the plots in the initial period of the test at low polymer concentrations. Attempts to relate mathematically the zero-order release rate constant, k, to the polymer concentration yielded the best results when log k was plotted against polymer concentration, giving an empirical equation similar to that suggested by Borodkin and Tucker (8). Plots of log k against polymer concentration for method 1 were linear, as shown in Fig. 5. However, log k for method 2 suddenly increased as the polymer concentration increased; there was no linear relationship between the two quantities. This difference could be explained by the formation of a polymer particle layer which adhered physically around phenacetin particles in the matrix prepared by method 2. Leaching of the polymer would, therefore, result in the formation of larger pores and channels around the phenacetin particles, increasing the surface area of the drug particle in contact with the dissolution medium. Slow disintegration of the matrix, coupled with the enhanced pore formation, would affect the drug release rate since the polymer added according to method 2 acts as a disintegrator at high concentrations (see the previous section).

Scanning electron micrographs of the tablet surface are shown in Figs. 6, 7, and 8, where the particle sizes and the concentration of phenacetin were 49–105 μm and 33.3% (w/w), respectively, the granule sizes were 420–590 μm, and the compression force was 100 kg/cm². After dissolution tests at pH 1.2 and 7.5, small pores (which had not been observed before the tests) were formed on the surface of a polymer-free tablet, as shown in Fig. 6. This was the result of phenacetin dissolution. In the case of tablets containing the polymer, larger pores were seen on the tablet surface after dissolution tests at pH 1.2 and 7.5. Figure 7 shows a tablet prepared by method 1 containing 3.0% (w/w) of the polymer. A tablet made by method 2 containing 3.3% (w/w) of the polymer is shown in Fig. 8. The pores in both tablets were formed by leaching of the polymer; the pore size was larger at pH 7.5 than at pH 1.2, and for method 2 than for method 1. The above results are in accordance with the results obtained for drug release.

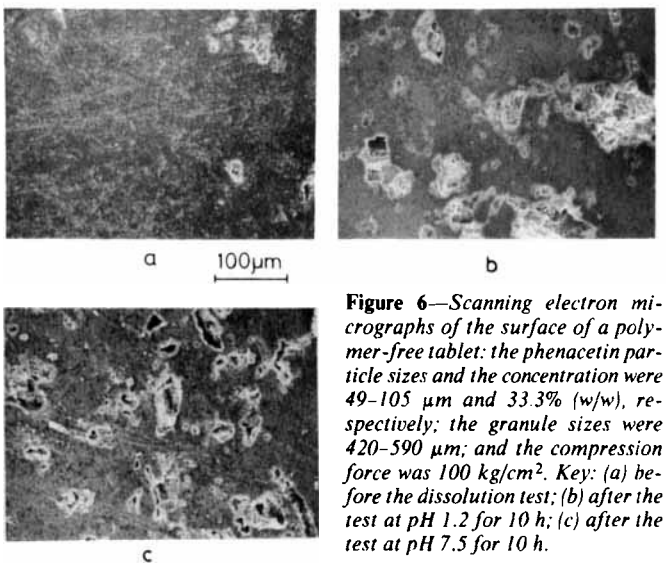

Figure 6—*Scanning electron micrographs of the surface of a polymer-free tablet: the phenacetin particle sizes and the concentration were 49–105 μm and 33.3% (w/w), respectively; the granule sizes were 420–590 μm; and the compression force was 100 kg/cm². CONCLUSIONS

Acrylic acid polymer added to inert wax matrices by methods 1 and 2 acts as a channeling agent, enhancing the drug release. At high polymer concentrations, the drug release from tablets at pH 7.5 appears to follow quasi-zero-order kinetics. For both methods, the drug release rates increased with increasing polymer concentration, but method 2 was more effective than method 1. In this regard, the location of acrylic acid polymer relative to the drug particles is important, *i.e.*, leaching of the uniformly dispersed polymer in the wax matrix causes the formation of more pores and channels in addition to those formed by leaching of the drug, whereas leaching of the polymer when physically adhered around the drug particles makes the pores and channels produced by drug release larger. Therefore, the effects of powder arrangement could be one of the important factors in pharmaceutical formulation. Since addition of acrylic acid polymer to the inert wax matrix, as a channeling agent and a disintegrator, enhances the controlled release of the drug at alkaline

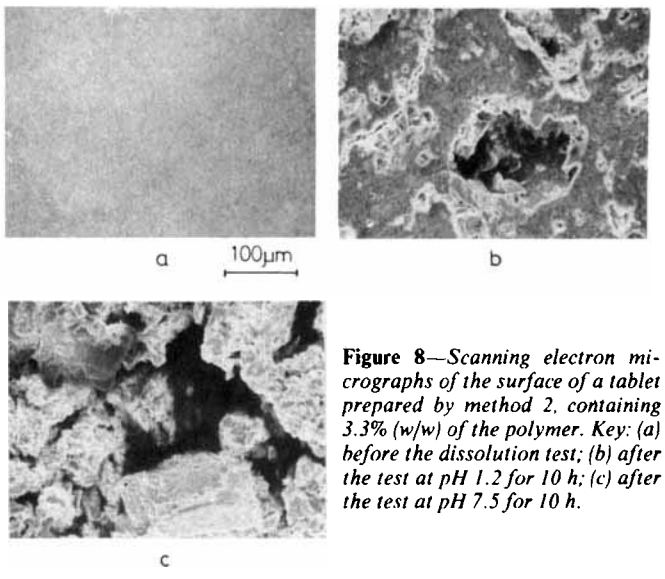

Figure 8—*Scanning electron micrographs of the surface of a tablet prepared by method 2, containing 3.3% (w/w) of the polymer. Key: (a) before the dissolution test; (b) after the test at pH 1.2 for 10 h; (c) after the test at pH 7.5 for 10 h.*

pH, the polymer could be useful in preparing an orally administered wax matrix product which releases most of its drug content in the intestinal tract.

Particle Size Analysis of Latex Suspensions and Microemulsions by Photon Correlation Spectroscopy

B. W. MÜLLER ˣ and R. H. MÜLLER

Received December 20, 1982, from the *Department of Pharmaceutics, Christian-Albrechts University of Kiel, Gutenbergstrasse 76-78, D-2300 Kiel 1, West Germany.* Accepted for publication June 7, 1983.

Abstract □ The particle size in microemulsions and other highly dispersed systems was determined by means of photon correlation spectroscopy (PCS). As PCS cannot be applied to highly concentrated dispersed phases, the measurement accuracy was tested for its dependence on the particle concentration using latex suspensions. The data obtained by clipping and scaling were compared. The particle size determination was expected to provide information about the influence of the structure of the surfactant system on microemulsions, using a homologous alcohol series as cosurfactant and potassium oleate as surfactant. In this system the region of solubilization is characteristically divided from the region of microemulsification by a zone of instability. Furthermore, there are distinct differences in mean particle sizes between microemulsions (9–30 nm) and micellar solutions (4–6 nm).

Keyphrases □ Particle size analysis—photon correlation spectroscopy, latex suspensions, microemulsions □ Photon correlation spectroscopy—particle size analysis, latex suspensions, microemulsions □ Microemulsions—particle size analysis, photon correlation spectroscopy, latex suspensions

Microemulsions appear as monophasic, more or less stable and transparent or slightly translucent, systems. They have been defined as dispersed liquid–liquid systems in which the particle size of the dispersed phase is <2000 Å. Shinoda and Friberg (1) assumed the existence of discrete micelles (oil-in-water) and reverse micelles (water-in-oil). According to the emulsion theory of Prince and co-workers (2, 3), these systems can be described as emulsions with highly dispersed internal phases. This definition includes the premise that there are essential differences between the microemulsion and the solubilization regions. The description of the structure of microemulsions as droplets is only valid for low concentrations of the internal phase. For high concentrations, Scriven (4) postulates bicontinuous microstructures. This bicoherence of microemulsions was confirmed by Lindman *et al.* (5).

These are of interest since drugs applied topically are liberated more efficiently from microemulsions than from ointments composed of the same ingredients (6). Up to now most of the known microemulsions were made with toxic surfactants or with surfactants in very high concentrations, precluding pharmaceutical use. Therefore, an attempt is made herein to determine the dependence of microemulsion formation on the structure of the emulsifier system and on other such factors, in order to find suitable excipients in suitable concentrations.

Table I—Particle Radii of Latex Suspensions (19 nm)

[a] Determined by photon correlation spectroscopy.

THEORETICAL SECTION

Light-scattering techniques are used extensively when testing microemulsions (7–12). In the following, the mean particle diameter was determined by photon correlation spectroscopy (PCS) (13, 14). A laser beam is sent through a sample and the scattered light is detected by a photomultiplier at a certain angle. The time-dependent periodical fluctuations of the scattered light are analyzed. Smaller particles diffuse faster than larger ones and, thus, cause a more rapid fluctuation of the intensity of the scattered light. The signal received by the photomultiplier is evaluated by a correlation function $C_{(\tau)} = e^{-\tau/tc}$, where τ stands for the time and tc for the correlation coefficient that describes the decay of this correlation function. The correlation coefficient is related to the diffusion coefficient D by $tc = 1/2DK^2$, where K is the absolute value of the scattering vector. As tc and K can be calculated, the diffusion constant D can be obtained; this is related to the particle radius by the Einstein relationship:

$$\bar{r} = \frac{k \cdot T}{6\pi D\eta}$$

Particle Size Analysis of Latex Suspensions and Microemulsions by Photon Correlation Spectroscopy

B. W. MÜLLER ˣ and R. H. MÜLLER

Received December 20, 1982, from the *Department of Pharmaceutics, Christian-Albrechts University of Kiel, Gutenbergstrasse 76-78, D-2300 Kiel 1, West Germany.* Accepted for publication June 7, 1983.

Abstract □ The particle size in microemulsions and other highly dispersed systems was determined by means of photon correlation spectroscopy (PCS). As PCS cannot be applied to highly concentrated dispersed phases, the measurement accuracy was tested for its dependence on the particle concentration using latex suspensions. The data obtained by clipping and scaling were compared. The particle size determination was expected to provide information about the influence of the structure of the surfactant system on microemulsions, using a homologous alcohol series as cosurfactant and potassium oleate as surfactant. In this system the region of solubilization is characteristically divided from the region of microemulsification by a zone of instability. Furthermore, there are distinct differences in mean particle sizes between microemulsions (9–30 nm) and micellar solutions (4–6 nm).

Keyphrases □ Particle size analysis—photon correlation spectroscopy, latex suspensions, microemulsions □ Photon correlation spectroscopy—particle size analysis, latex suspensions, microemulsions □ Microemulsions—particle size analysis, photon correlation spectroscopy, latex suspensions

Microemulsions appear as monophasic, more or less stable and transparent or slightly translucent, systems. They have been defined as dispersed liquid–liquid systems in which the particle size of the dispersed phase is <2000 Å. Shinoda and Friberg (1) assumed the existence of discrete micelles (oil-in-water) and reverse micelles (water-in-oil). According to the emulsion theory of Prince and co-workers (2, 3), these systems can be described as emulsions with highly dispersed internal phases. This definition includes the premise that there are essential differences between the microemulsion and the solubilization regions. The description of the structure of microemulsions as droplets is only valid for low concentrations of the internal phase. For high concentrations, Scriven (4) postulates bicontinuous microstructures. This bicoherence of microemulsions was confirmed by Lindman *et al.* (5).

These are of interest since drugs applied topically are liberated more efficiently from microemulsions than from ointments composed of the same ingredients (6). Up to now most of the known microemulsions were made with toxic surfactants or with surfactants in very high concentrations, precluding pharmaceutical use. Therefore, an attempt is made herein to determine the dependence of microemulsion formation on the structure of the emulsifier system and on other such factors, in order to find suitable excipients in suitable concentrations.

EXPERIMENTAL SECTION

Materials—To determine the functional capacity of the measuring apparatus, monodispersed latex suspensions[1] (10% dry weight) were used which had particles of the following diameters (±*SD*): 0.038 (±0.0075) μm, 0.109 (±0.0027) μm, 0.220 (±0.0065) μm, 0.497 (±0.0059) μm. The quantity of particles was 1.37×10^{14}/mL for the 109-nm suspension. The stock suspensions were diluted with fresh twice-distilled water. To eliminate dust, the samples were purified using membrane filters[2] (0.22–0.8 μm), which were attached to 10-mL disposable syringes. The microemulsions were prepared using twice-distilled water, potassium oleate[3], liquid paraffin oil[4], and pentanol[5], hexanol[5], or heptanol[5]. The potassium oleate was taken from one homogeneous batch. The alcohols were used without further purification.

Apparatus—The measuring apparatus consisted of an argon laser[6], a temperature-stabilized measuring cell, and a photomultiplier[7]. This setup was fitted on an optical bank, which was stabilized against vibrations by placement on a slab of marble buffered with special shock absorbers. The sample was tempered (±0.05 K) by means of a matching fluid, regulated by a temperature controller. To eliminate the vibrations of the elastic-tube pump, the matching fluid flowed through a collecting vessel before it was returned to the measuring cell. The photomultiplier detected the scattered light to an angle of 90°.

On the basis of the photomultiplier signals the correlation function was calculated in a correlator[8]. If necessary a clipping counter[9] was added. The correlator data were analyzed in a computer[10] and simultaneously stored in a data logger. The data were transferred from the correlator to the computer using an interface constructed specifically for this purpose. This interface was connected between the punch-outlet of the correlator and the computer input terminal. This not only allowed the data transfer, but also permitted the computer to control the correlator functions.

[a] Determined by photon correlation spectroscopy.

RESULTS AND DISCUSSION

The mean radii of the particles were determined by photon correlation spectroscopy (PCS) on the basis of the diffusion coefficients. This required an unhindered diffusion. Higher particle concentrations resulted in measuring faults because of an interaction between the particles on the one hand and the multiple scattering on the other. The use of a structure factor should correct for these errors (15–19). While the interactions between the particles leads to lower diffusion constants, the multiple scattering produces a higher fluctuation of scattered light intensity. The described effects result in a stronger decaying correlation function together with a higher diffusion constant and a smaller particle radius. Therefore, the determination of highly concentrated suspensions and emulsions is difficult. To determine the dependence of the measurements on the particle concentration, latex suspensions with different particle sizes were measured in a dilution series (Tables I–IV). The measuring errors obtained in the clipping and scaling modes are also compared (Tables III and IV).

In the latex suspensions of 19-nm particles (Table I) the particle radii were almost constant over a wide range of concentrations (50–1000 μg/L). In higher concentrations, the measured value was markedly low. Comparable results were obtained for the other particle sizes (Tables II–IV). In some cases, measuring errors of >60% were observed. Hence, from the standpoint of accuracy of measurement, the results of some reports (20) which neglect this effect for microemulsions are in doubt. The observed error is less in emulsions than in suspensions, but in certain concentrations, errors result whereby the data is >50% too low. If Nicholsen *et al.* (20) measure a particle radius of 2–3 nm in their microemulsions, the consideration that the micelle diameter must be at least twice the molecule length of the surfactant plus the diameter of the aqueous (oily) core reveals that their value must be too low. Moreover, the PCS determines the hydrodynamic diameter, which means that higher values are more probable.

If the scattering intensity is plotted against the particle concentration, the curves show a maximum of the scattered light (Fig. 1). When this maximum is exceeded, back-scattering predominates and the measuring error increases. The reproducibility of the experimental results is dependent on the scattering quality of the sample. It decreases when the scattering intensity, *i.e.*, the signal–noise ratio, is low. With low particle concentrations, the relative standard deviation of the results was ~1–3%. If the measuring conditions were good, a reproducibility of ±0.5% could be obtained. At a measuring angle of 90°, an optimal reproducibility within a wide concentration range of latex particles was observed.

[a] Measured by photon correlation spectroscopy shortly after production; water content 3.6%.

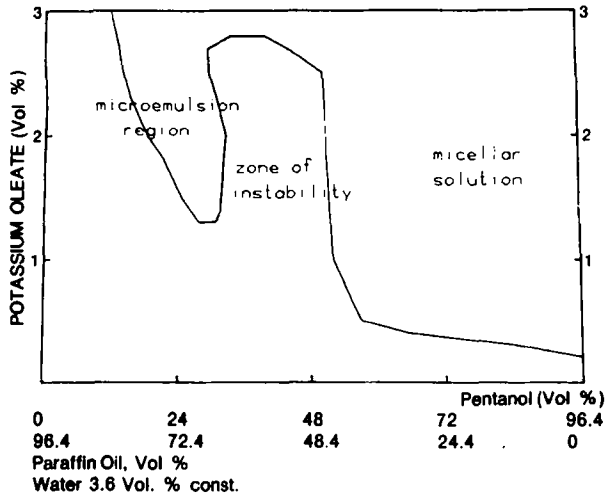

Figure 2—*Component diagram with pentanol.*

To eliminate the concentration error, microemulsions with low concentrated dispersed phases (3–6%) were measured. Microemulsion formation could already be found at a surfactant-cosurfactant concentration of 5–10% (w/w). Thus, the sample remains in a measurable concentration range for the PCS, which is also characterized by a 5–10% particle concentration in other reports (8, 19). Shinoda (21) describes microemulsions with such low surfactant-cosurfactant fractions, but he defines them as "solubilized solutions."

The tested systems consisted of a constant water fraction of 3.6%, a potassium oleate component of 0.5 3.0%, alcohol as cosurfactant, and liquid paraffin oil, added to obtain 100% volume. To determine the microemulsion region, component diagrams for each alcohol were established. They show the dependence of the microemulsion formation on the surfactant structure. The homogeneous alcohol series butanol, pentanol, hexanol, heptanol, octanol, and decanol was used. A distinct microemulsion region could only be observed for pentanol, hexanol, and heptanol at these concentrations (Figs. 2–4). Other ranges of concentration also show a distinct microemulsion formation using the remaining alcohols. Baviere *et al.* (22) describe that—in addition to the surfactant structure—factors such as salt concentration have an influence, but they are not considered here.

Figure 3 shows that hexanol is a particularly good cosurfactant. A minimum surfactant quantity (~1%) must exist before water-in-oil microemulsions are formed. Higher surfactant concentrations (2%) result in a lower particle diameter due to an optimization of the surfactant-cosurfactant ratio. The optimal surfactant-cosurfactant ratio is ~1:3 for hexanol. If the surfactant content is below the optimum, it can be compensated to a certain degree by a higher quantity of cosurfactant. With pentanol, microemulsion formation requires higher quantities of surfactant and cosurfactant. The microemulsion region is smaller than that of hexanol and shifts to higher pentanol and potassium oleate concentrations. The more hydrophilic pentanol has a larger region of solubilization than hexanol. The microemulsion region of heptanol is smaller than the other alcohols. Heptanol is more lipophilic; therefore,

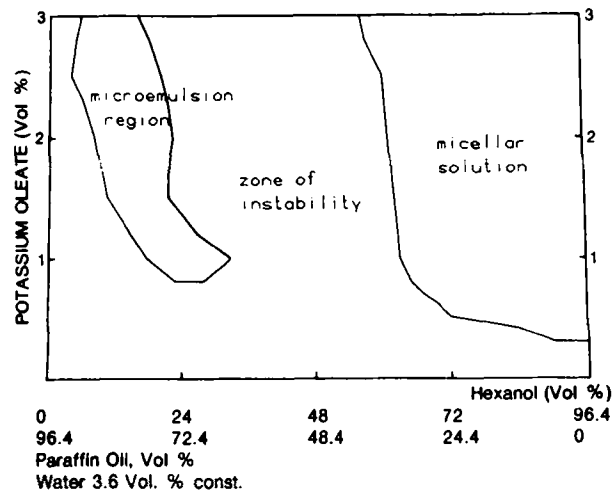

Figure 3—*Component diagram with hexanol.*

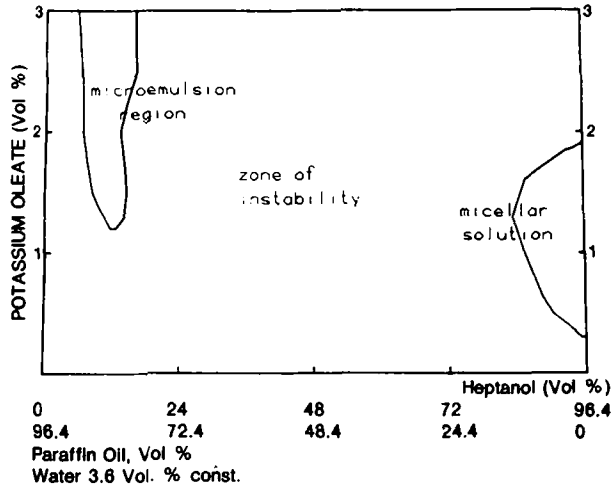

Figure 4—*Component diagram with heptanol.*

microemulsions are formed at a lower cosurfactant concentration. However, the solubilization region is narrower.

If microemulsions are considered as swollen micelles, an abrupt diminution in particle size from the macroemulsion to the microemulsion region, and after that a continuous transition to a micellar solution, should be expected. According to the emulsion theory, there should be a distinct separation between the solubilization and the microemulsion regions due to the transition of a single-phase liquid into a system with at least two phases characterized by micelles with different diameters. Between the two regions an instability zone is assumed, with big particles (in the dimension of macroemulsions) caused by coalescence. Such a zone was discovered in the component diagrams of the above systems. The storage tests showed that the microemulsions are unstable and that the dispersed phase undergoes coalescence toward the macroemulsion and also toward the solubilization regions. This fact was unexpected.

The change in particle diameter can be investigated by PCS with great accuracy and little difficulty using the specimen tubes as storage containers for the emulsions. The measured particle diameters of the microemulsions were 9–30 nm; those of the micellar solutions were 4–6 nm and smaller (Figs. 5–7). The most apparent increase in particle size before the zone of instability toward the solubilization region was observed in microemulsions prepared with hexanol. Curve B in Fig. 6 (1.5% potassium oleate) reveals a relatively big particle diameter of 225 Å at the border of the microemulsion region toward the macroemulsions. With increasing alcohol concentration, the particle diameter decreases to 160 Å. This is the smallest possible particle size at this surfactant-cosurfactant ratio, and it is constant over a wide range. Before the zone of instability, a distinct increase in particle diameter of up to 225 Å can be seen. This effect is even more obvious in the case of microemulsions with 1.0% potassium oleate (Fig. 6, curve A). After having reached 280 Å, the smallest possible particle size, a considerable increase (up to 400 Å) was found. The particle sizes measured in microemulsions with pentanol

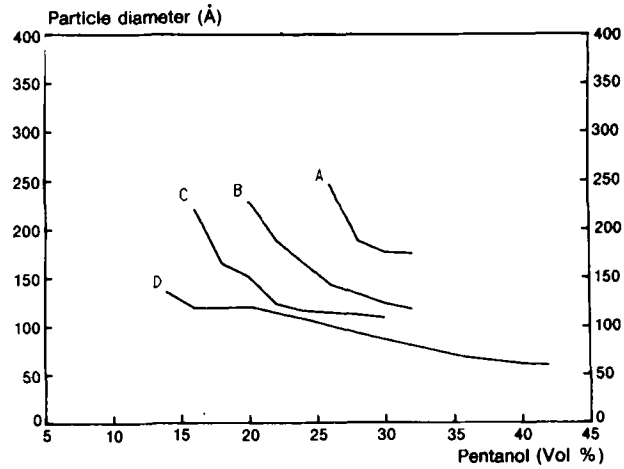

Figure 5—*Particle sizes of microemulsions with pentanol (cf. Fig. 2), measured shortly after production. Composition: 3.6% water, potassium oleate, and pentanol, q.s. to 100% with paraffin oil. Potassium oleate content: (A) 1.5%; (B) 2.0%; (C) 2.5%; (D) 3.0%.*

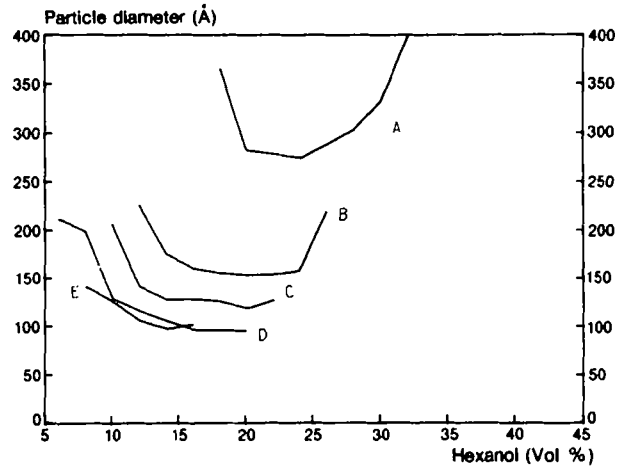

Figure 6—*Particle sizes of microemulsions with hexanol* (cf. *Fig. 3*), *measured shortly after production. Composition: 3.6% water, potassium oleate, and hexanol, q.s. to 100% with paraffin oil. Potassium oleate content: (A) 1.0%; (B) 1.5%; (C) 2.0%; (D) 2.5%; (E) 3.0%.*

(Fig. 5) show a comparable alteration. However, the increase in droplet diameter before the zone of instability appears only during the aging process and is less distinct. Constant surfactant concentration together with low cosurfactant concentrations result in big particles. If the cosurfactant concentration increases, the particle sizes decrease toward a minimal limiting value. It is remarkable that in microemulsions with hexanol, a minimal particle size of 95 Å appears (Fig. 6, curve D), which cannot be lowered by a further increase of the surfactant and cosurfactant concentrations (Fig. 6, curve E). The same limiting value can be found in microemulsions with pentanol.

The particle sizes of the emulsions formed by a minimum fraction of cosurfactant (*e.g.*, pentanol) decreased from 246 to 135 Å relative to increasing surfactant concentration (1.5 to 3.0%), due to the optimization of the surfactant-cosurfactant ratio. Figure 5 shows a continuous transition from the microemulsion to the solubilization region if the microemulsion contains ~3% potassium oleate. This seems to contradict the results described before. However, it has to be considered that the emulsions in this region break after a short storage time (23). Thus, a separation in the microemulsion and solubilization regions was obtained, and the continuous transition disappeared. With regard to the particle sizes and their alteration during the storage, the cosurfactant heptanol is comparable with pentanol. On the other hand, the formation of microemulsions is reduced to a smaller region. What is important is that the particle sizes decrease with the increasing chain length of the alcohol. Table V compares the particle sizes of microemulsions prepared with the same molar concentrations of differing alcohols.

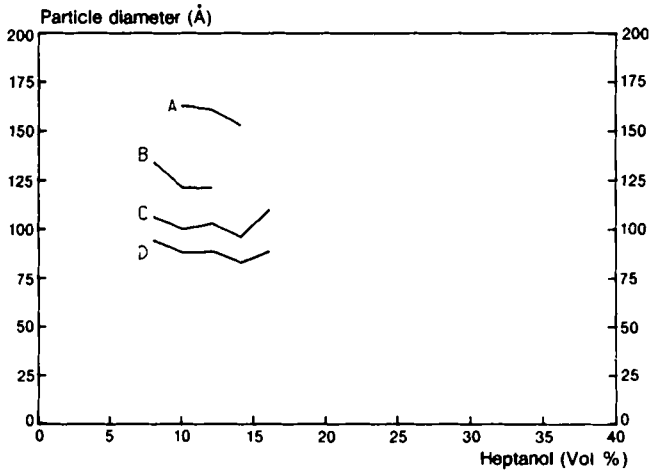

Figure 7—*Particle sizes of microemulsions with heptanol* (cf. *Fig. 4*), *measured shortly after production. Composition: 3.6% water, potassium oleate, and heptanol, q.s. to 100% with paraffin oil. Potassium oleate content: (A) 1.5%; (B) 2.0%; (C) 2.5%; (D) 3.0%.*

Particle Size Distributions and Particle Size Alterations in Microemulsions

B. W. MÜLLER [x] **and R. H. MÜLLER**

Received December 20, 1982, from the *Department of Pharmaceutics, Christian-Albrechts University of Kiel, Gutenbergstrasse 76-78, D-2300 Kiel 1, West Germany.* Accepted for publication June 7, 1983.

Abstract □ Several component diagrams for different alcohols as cosurfactants and potassium oleate as the surfactant were investigated. Between the regions of the water-in-oil microemulsion and the micellar solution (reverse micelles), and diagrams showed a zone of instability which was determined by particle size analysis by means of photon correlation spectroscopy (PCS). The polydispersity of the internal phase was determined at the instant of microemulsion formation and after fixed intervals of storage. At the edge of the microemulsion region, a rapid increase in particle size due to coalescence followed by breaking was observed. If a slow transition toward the region of solubilization could be seen by a slow decrease of the droplet size, coalescence was observed after storage. In the middle of the microemulsion region, the particle radius, however, was almost constant for a long interval. The velocity of the microemulsion formation depended on the alcohol used. In some cases a very fast formation (milliseconds) was observed; in others, macroemulsions were formed which became transparent within a few hours or days. PCS was used to follow the dynamic process of formation and breaking of such systems with droplet diameters of 5-200 nm by obtaining the mean hydrodynamic diameters. Distribution curves were calculated by the Laplace transform of the correlation function. The practicability of the method was demonstrated with mono- and polydispersed latex suspensions and microemulsions.

Keyphrases □ Particle size analysis--microemulsions, photon correlation spectroscopy, latex suspensions, Laplace transforms □ Emulsions--particle size analysis, photon correlation spectroscopy, Laplace transforms □ Stability--microemulsions, particle size analysis, photon correlation spectroscopy, Laplace transforms

Three types of microemulsions seem to exist: discrete micelles, microdroplets, and bicontinuous structures. To obtain an insight into the dynamics of microemulsion formation and breaking, photon correlation spectroscopy (PCS) can be used for the first two types (1). To eliminate measuring errors, interparticle effects and multiple scattering must be avoided by using low concentrations of the noncontinuous phase (5-10 %). Under these conditions, PCS might be a valid method of measuring mean particle diameters and, in combination with a Laplace transform of the data, estimating the particle size distributions. By following alterations after spontaneous emulsification, it should be possible to develop thermodynamically stable microemulsions with drugs and to find essential differences between a solubilization and a microemulsion if the system contains microdroplets or micelles.

THEORETICAL SECTION

The polydispersity of microemulsions and model suspensions was analyzed using PCS. With this method, the intensity autocorrelation function of the light, scattered by particles of the suspension, is obtained. The autocorrelation function $g(\tau)$ may be obtained from the intensity autocorrelation function $g^2(\tau)$:

$$g^2(\tau) = 1 + |g(\tau)|^2 \qquad \text{(Eq. 1)}$$

$g(\tau)$ contains information about the size distribution.

In the case of monodispersed particles, the autocorrelation function $g(\tau)$ is given by:

$$g(\tau) = g_0 \exp(-\gamma\tau) \qquad \text{(Eq. 2)}$$

where $\gamma = 2Dk^2$, D is the diffusion constant, and k is the line width constant. The decaying of the correlation function depends on the Brownian motion of the particles and may be derived from the statistics of the scattered light. In polydispersed suspensions and emulsions the autocorrelation function $g(\tau)$ can be derived from the size distribution $G(\gamma)$ by the Laplace transform:

$$g(\tau) = g_0 \int_0^\infty \exp(-\gamma\tau) \cdot G(\gamma) d\gamma \qquad \text{(Eq. 3)}$$

Ostrowsky (2) introduced a method for the inversion of this formula based on eigenvalues and eigenfunctions of the Laplace transform. The inversion problem in general has an "ill-conditioned nature" (3). This means that there is an upper limit of information about the size distribution function in the experimentally obtained correlation function. Using the method of Ostrowsky, the most complete information about the polydispersity may be obtained. Ostrowsky points out that the truncation of the correlation function due to noise leads to a band-limited Laplace transform. This is due to the fact that the maximum information about the polydispersity may be obtained by a discrete spectrum with exponentially spaced samples:

$$\gamma_{n+1} = \gamma_1 \exp(n\pi/\omega_{max})$$

$$g(\tau)_{\omega_{max}\to\infty} = \sum_{n=1}^{N} \frac{\pi}{\omega_{max}} \cdot G_D(\log \gamma_n) \cdot \exp(-\gamma_n \tau) \qquad \text{(Eq. 4)}$$

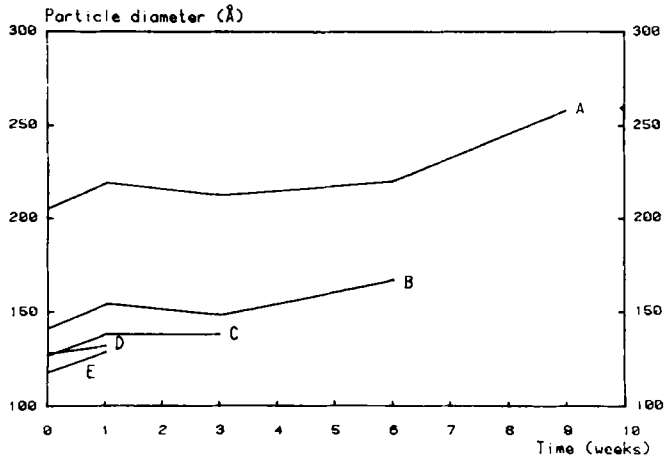

Figure 3—*Particle sizes* versus *time in microemulsions with hexanol as cosurfactant. Composition: 3.6% water, 2.0% potassium oleate, and hexanol, q.s. to 100% with paraffin oil. Hexanol content: (A) 10.0%; (B) 12.0%; (C) 14.0%; (D) 16.0%; (E) 18.0%. (Broken systems, marked by x in the Figs. 1 and 2, were not investigated.)*

where ω_{max} is the band limit. These discrete spectra points are computed from the autocorrelation function by minimizing the equation:

$$\Delta = \sum_{i=1}^{M} \left[g(\tau_i) - \sum_{n=1}^{N} \frac{\pi}{\omega_{max}} \cdot G_D(\log \gamma_n) \cdot \exp(-\gamma_n \tau_i) \right]^2 \quad \text{(Eq. 5)}$$

The continuous polydispersity spectrum can be derived from the development of the discrete spectrum:

$$\tilde{G}(\gamma) = \sum_{n=1}^{N} G_D(\log \gamma_n) \sqrt{\frac{\gamma_n}{\gamma}} \frac{\sin \omega_n \cdot \left(\log \frac{\gamma}{\gamma_n} \right)}{\omega_n \cdot \left(\log \frac{\gamma}{\gamma_n} \right)} \quad \text{(Eq. 6)}$$

This polydispersity spectrum was calculated by a computer program which includes the method of Ostrowsky (2). It must be pointed out that in addition to this method, there are other possibilities using other primary information about the polydispersity spectrum (4, 5).

EXPERIMENTAL SECTION

Materials—The microemulsions were prepared using fresh twice-distilled water, potassium oleate[1], liquid paraffin oil[2], and pentanol[3], hexanol[3], or heptanol[3]. The potassium oleate was taken from one homogeneous batch and was used without further purification. The alcohols were used as received.

To determine the accuracy of the polydispersity analysis by means of the Laplace transform of the correlation function, model suspensions were prepared by mixing latex particles of various sizes using monodispersed latex suspensions[4] (10% by weight). The stock suspensions were diluted with distilled water and mixed in different ratios. The suspensions were passed through membrane filters[5] (0.22–0.8 μm) to remove as many particle impurities as possible from the samples; the filters were attached to 10-mL disposable syringes[6].

A commercial oil-in-water emulsion was tested as an example of a pharmaceutical product; it was composed of 200 g of soybean oil, 15 g of soy oil phosphatide, and 50 g of xylitol, q.s. to 1000 mL with water. Because the concentration of the dispersed phase was too high for PCS measurements, a dilution with twice-distilled water was necessary (50 μL of the emulsion was diluted to 100 mL). To avoid contamination with dust, the samples were prepared using the laminar flow technique.

Apparatus—For the measuring apparatus used in this experiment (1), the refractive indexes were determined by a refractometer[7]. To measure the viscosity of the dispersion media, a viscometer[8] with light barriers as an automatic timing device was used. The thermostated bath had a constant temperature of ±0.05°C.

RESULTS AND DISCUSSION

A series of four-component phase diagrams was established to determine the microemulsion regions. The quaternary systems, water–paraffin oil–potassium oleate as the surfactant and various alcohols as cosurfactants, were investigated; some of the results are published in the companion paper (1). The homologous series butanol, pentanol, hexanol, heptanol, octanol, and decanol was used. A "single-phase" microemulsion region could be observed only for pentanol, hexanol, and heptanol. In this report these systems were investigated to study the variations of the particle sizes as a function of the storage time.

Most of the microemulsions stored for a period of several weeks at room temperature were found to be unstable. The particle size alterations were extreme. The instability of the tested systems was due to their composition. These systems were located at the edge of the water-in-oil microemulsion region in the tetrahedral phase diagram. A basic difficulty with PCS studies is that the concentration of the dispersed phase cannot be higher than ~10% in order to avoid concentration faults due to interparticle forces and multiple scattering (1). Only low concentrations allowed the use of the Stokes–Einstein equation without a correction factor (so called "structure factor"). The systems examined were composed of 1.0–3.0% (by volume) potassium oleate and a constant 3.6% volume of water. The following assumptions were made:

1. Some of the alcohol molecules, together with the oleate, are needed to stabilize the amphiphilic layer between the aqueous core of the microdroplets and the dispersion medium.
2. The surrounding paraffin oil contains the remainder of the alcohol.
3. All oleate molecules are in the water phase and the bilayer of the emulsifier mixture (*i.e.*, the oleate concentration in the lipophilic continuous phase is neglected). Thus, the concentration of the dispersed phase cannot be higher than ~7% (3.6% water + a maximal 3.0% potassium oleate) and the Stokes–Einstein equation is valid.

The experimental points in the compared systems were chosen to clarify the variation in particle diameter of the microemulsions for which the amount of alcohol changes at constant potassium oleate concentrations. The results are presented in the form of curves of particle size against time. All concentrations are given as volume percent.

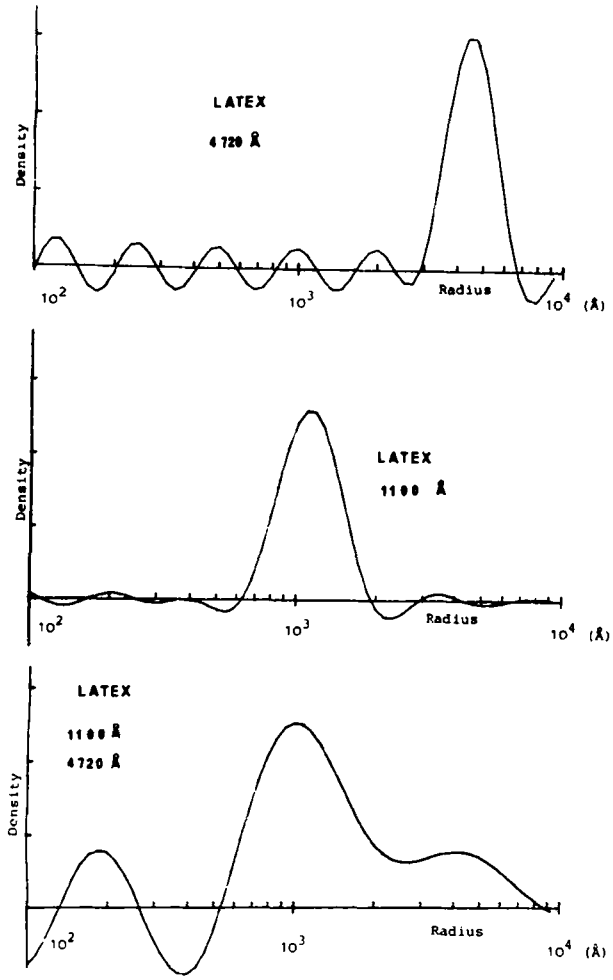

Figure 5—*Distribution curves of monodispersed latex suspensions (radii: 1100 and 4720 Å) and their mixture at the ratio of 5:1.*

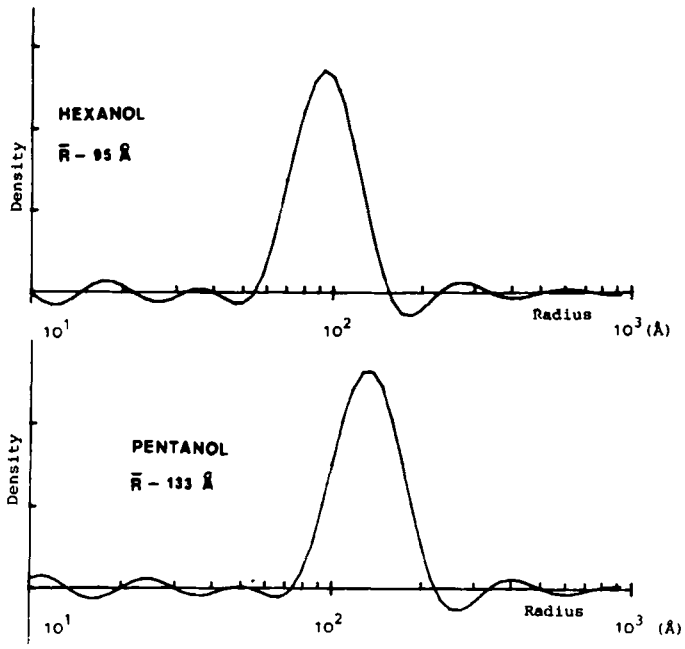

Figure 6—*Distribution curve of two microemulsions produced with equal volume fractions of hexanol and pentanol. Composition: 3.6% water, 1.5% potassium oleate, and 13.0% alcohol, q.s. to 100% with paraffin oil.*

The results obtained with pentanol are shown in Figs. 1 and 2. The phase diagram of the pseudoternary system of paraffin oil, pentanol, potassium oleate, and a constant water fraction of 3.6% showed a zone of instability between the microemulsion and the micellar solution [see Fig. 2 in the previous paper (1)]. A continuous transition from the microemulsion to the solubilization region was found only if the system contained ~3% potassium oleate. In the diagrams for the other alcohols, no continuous transition according to the swollen micelles theory was observed.

Figure 1 shows the particle sizes along a composition line with a constant concentration of 2.0% potassium oleate. Microemulsion A is formed with the smallest possible amount of alcohol, microemulsion D with a maximum amount of alcohol. Both systems are located at the edge of the microemulsion region. Microemulsion formation with a lower or higher concentration of pentanol is not possible. System A is located at the edge bordering on the macroemulsions with a low pentanol concentration. It showed a nearly constant particle size of ~230 Å for 1 week. After 3 weeks it was broken (marked by x in the curve) and an aqueous phase had formed at the bottom of the specimen cell. There was, however, still a microemulsion in the upper phase with a particle size of 260 Å, which decreased during storage. An analogous behavior was found for microemulsion D, which is located at the edge of the microemulsion region towards the solubilization region. The values obtained for compositions B and C proved that the systems in the middle of the microemulsion region were more stable.

The particle size alteration is more obvious in Fig. 2, and the reason for the alterations can easily be explained as follows. Figure 2 shows the particle sizes during the continuous transition from the microemulsion region (systems A–F) to the solubilization region (system G). After 6 weeks of storage, the "single-phase" systems in the zone of instability (systems E and F) were broken and a separation between microemulsions and micellar solutions occurred. After 3 additional weeks, systems D and A were also broken and the microemulsion field was narrowed from both sides. Microemulsion A showed a rapid increase in particle size from 135 Å to 266 Å due to the coalescence of the dispersed phase. After 9 weeks the system was broken, but a microemulsion still remained in the upper phase with a particle size of 233 Å. Relatively large unstable microdroplets had coalesced, and an aqueous subphase had formed. The remaining microdroplets in the upper phase increasingly coalesced in proportion to the length of the storage. After a period of 1 year, only a micellar solution remained, whereas the volume of the aqueous subphase had increased. Microemulsion D had a nearly constant particle size for some weeks. An increase before phase separation was not observed, as this occurred between two measurements. Systems E and F in the unstable zone at the edge of the micellar solution region showed a very slow increase in particle size. For micellar solution G, no alteration was observed. Pentanol as cosurfactant caused rapid microemulsion formation, but also rapid coalescence.

The use of hexanol as cosurfactant also results in rapid microemulsion formation, within milliseconds, but the coalescence is less distinct. Figure 3 shows that the particle size is almost constant for a long time, and the systems are more stable compared with those using pentanol. Another important difference is that only the microemulsions in the unstable zone toward the micellar solution region break at the beginning of the storage period (Fig. 3, systems D and E). The microemulsions on the opposite side (Fig. 3, system A) are, on the other hand, stable in contrast with those formed with pentanol.

Heptanol as cosurfactant causes very slow microemulsion formation. During the formation process the smallest possible particle size was not reached at

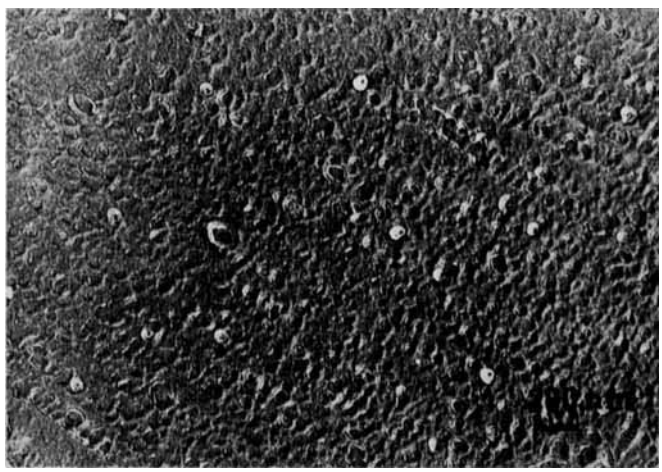

Figure 7—*Electron micrograph of an oil-in-water emulsion after 5 d of storage. The narrow distribution of the particle sizes is obvious. The determined mean radius (25 nm) is almost the same as yielded by photon correlation spectroscopy.*

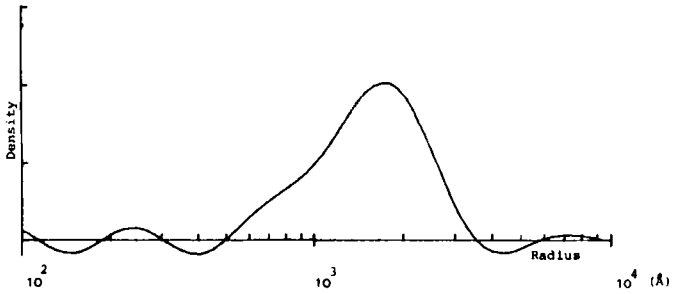

Figure 8—*Distribution curve of an oil-in-water emulsion for infusion.*

once but, rather, after 1 week of storage (Fig. 4, curves A, B, and C). In some cases, macroemulsions were first formed, becoming transparent after a few days (Fig. 4, curves D and E). These emulsions showed the same instability as those of hexanol and broke rapidly. In general, the systems with heptanol were as unstable as those with pentanol, showing a rapid increase in particle size.

In summary, pentanol and hexanol in combination with potassium oleate cause rapid microemulsion formation. The smallest possible particle size is reached at once in contrast with heptanol, where this takes some days. Pentanol and heptanol form unstable systems with a rapid increase in particle size; hexanol, however, shows more constant particle sizes during storage. Hexanol and heptanol have in common that the microemulsion systems at the edge of the solubilization region break at the beginning of the storage time, whereas those bordering the macroemulsion region only coalesce after an induction period. A simultaneous breaking on both sides of the microemulsion region occurred using pentanol. The tested microemulsions showed the same instability due to coalescence as found with macroemulsions, because they are located at the edge of the microemulsion region.

The particle size distribution can be determined with the polydispersity analysis by the Laplace transformation of the correlation function as described above. The efficiency of the method was tested using monodispersed latex suspensions and their mixtures. The two upper curves of Fig. 5 show the distributions of monodispersed latex suspensions with radii of 1100 and 4720 Å. As the particles are not exactly monodispersed and the Laplace transform inherently has some uncertainty, two relatively narrow logarithmic normal distributions are obtained. The distribution of the smaller particles is not as narrow as that of the larger ones because the signal-noise ratio is small, which results in a higher standard deviation of the values and a wider distribution. The mixing of these two types of particles in a ratio of 5:1 results in a distribution curve where the peak heights reflect the particle proportion. Most of the commercial apparatuses, however, calculate only an unsatisfactory polydispersity index.

All the tested microemulsions showed a narrow particle size distribution. Two microemulsions prepared with equal volume fractions of hexanol and pentanol are given as an example (Fig. 6). The mean diameters calculated using the Stokes-Einstein equation were 113 Å for the pentanol system and 80 Å for that with hexanol. This corresponded exactly to the peak maxima in Fig. 6. The measured distributions were confirmed by electron microscopic studies. The structure of microdroplets and the obtained particle sizes were verified (Fig. 7) using the freeze-fracture technique (6).

The described polydispersity analysis can be applied in the pharmaceutical industry. An example is process control of the liposome production, especially small unilamellar vesicles of diameters <100 nm. The liposome size can hardly be controlled during production. Up to now these analyses were made by separating the different liposome sizes into monodispersed systems using a Sephadex column and measuring each system, *e.g.*, with a particle counter. A polydispersity index of ≤2 confirmed the successful separation. A higher polydispersity index indicates a bad separation and does not allow any further statement about the distribution. Such analyses can be carried out faster with the method described herein. An illustration of the practicability is the determination of particle size distributions in oil-in-water emulsions for parenteral use. The tested emulsion[6] had a mean diameter of 446 nm. The corresponding distribution curve shows that it is a polydispersed system (Fig. 8), and the droplet distribution is not logarithmic as is generally assumed for emulsions.

Determination of Picogram Nitroglycerin Plasma Concentrations Using Capillary Gas Chromatography with On-Column Injection

PATRICK K. NOONAN, ISADORE KANFER *, SIDNEY RIEGELMAN †, and LESLIE Z. BENET ˣ

Received December 13, 1982, from the *Department of Pharmacy, University of California, San Francisco, CA 94143.* Accepted for publication June 8, 1983. * Present address: School of Pharmaceutical Sciences, Rhodes University, Grahamstown, 6140, South Africa. † Deceased.

Abstract □ A specific, sensitive, and precise capillary gas chromatographic (GC) assay capable of analyzing picogram concentrations of nitroglycerin in human plasma was developed. The analytical procedure involves a double extraction of 1 mL of plasma with pentane, after the addition of internal standard (1 ng of 2,6-dinitrotoluene), followed by evaporation and reconstitution in 50 μL of heptane. The extract (1 μL) was injected onto a capillary column using the on-column injection technique. The GC oven temperature was programmed from 120°C to 180°C at a rate of 5°C/min. The oven temperature was then programmed to 250°C and was maintained for 10 min. The nitroglycerin and internal standard retention times were 8.6 and 11.4 min, respectively. The position of the end of the capillary column inside the detector is a critical determinant of sensitivity: the column exit must be positioned such that nitroglycerin adsorption to the detector is minimized (*i.e.*, sensitivity maximized). The assay limit of quantitation was 25 pg/mL (CV = 7.6%) using 1 mL of plasma. This GC assay, specific for nitroglycerin in the presence of its metabolites, isosorbide dinitrate, and several other drugs, may be used to quantitate plasma levels obtained after therapeutic nitroglycerin doses.

Keyphrases □ Nitroglycerin—GC, picogram quantitation □ GC—nitroglycerin, picogram quantitation

Nitroglycerin is a potent vasodilator used in the treatment of angina pectoris and congestive heart failure associated with acute myocardial infarction (1). The pain of angina may be relieved and/or prevented by the administration of sublingual, oral, or topical nitroglycerin. Although a definitive therapeutic plasma concentration range has not yet been defined, it is still important to identify the nitroglycerin concentration–response relationship so that dose adjustments in patients may be made more effectively. Nitroglycerin administration results in venous plasma concentrations ranging from <50 pg/mL to 10 ng/mL, depending on the route of administration (2–4). Studies in the rhesus monkey (5) indicate that concentrations of ^{14}C-labeled nitroglycerin metabolites are 10- to 300-fold higher than the parent drug. Therefore, an analytical method for nitroglycerin must be both sensitive (25-pg/mL detection limit) and specific (*i.e.*, must measure nitroglycerin in the presence of metabolites).

Several different analytical methods have been developed. HPLC methods have been developed to measure nitroglycerin amounts and concentrations in dosage forms (6), waste water (7), trace level explosives (8), and blood (9). Of these HPLC methods, the last (9) used a thermal energy analyzer–detector and was the most sensitive. This method was capable of detecting 500 pg (injected on column) and required 2 mL of plasma (CV = 12% at 13 ng/mL). None of these methods are capable of detecting nitroglycerin concentrations of 50 pg/mL.

Within the past few years, four GC–MS assays for nitroglycerin have been described (10–13). These assays possess some advantages over HPLC and conventional gas chromatographic (GC) assays. GC–MS assays are selective for the parent drug and quite sensitive (typically 50 pg/mL). Several disadvantages of GC–MS methods are readily apparent. The cost and time to set up a GC–MS instrument is often prohibitive for most clinical laboratories. Several of these assays (11–13) require the use of specially synthesized internal standards labeled with stable isotopes. These internal standards often are not commercially available, which may certainly limit the utility of these assays for routine clinical monitoring.

Several GC assays utilizing conventional packed columns have been developed (14–16). These were not fully satisfactory due to lack of sensitivity (14), complicated extraction procedure and questionable precision [*i.e.*, CV = 23% at 100 pg/mL (15)], and lack of specificity (16). Wu *et al.* (16) found interfering chromatographic peaks, which varied between individuals and even varied within individuals with time. Another major obstacle to the determination of picogram concentrations of nitroglycerin with conventional packed-column GC is adsorption of nitroglycerin to the column components. Several investigators have found that preloading columns, *i.e.*, injecting large amounts of nitroglycerin immediately before analyses of plasma samples, resulted in decreased column adsorption (17–19).

Drug adsorption to GC columns may be greatly reduced, if not eliminated, with the use of inert fused-silica capillary columns (20). Douse (20) reported a fused-silica capillary GC assay capable of detecting 5 pg and quantifying 100 pg of nitroglycerin (CV = 13%). Sved *et al.* (21) recently reported nitroglycerin plasma levels after a topical dose of nitroglycerin ointment. Although a detection limit of 50 pg/mL (using a fused-silica column) was reported, details of the assay validation have not been reported to date. In the present assay, the use of an on-column injector, a syringe with a fused-silica capillary needle, and fused-silica capillary columns allows the quantitation of picogram concentrations of nitroglycerin in plasma samples.

This report describes the capillary GC determination of nitroglycerin in plasma using on-column injection and electron-capture detection (EC). The assay described possesses the precision, sensitivity, and selectivity required to analyze picogram nitroglycerin concentrations in human plasma.

EXPERIMENTAL SECTION

Chemicals and Reagents—Nitroglycerin was obtained as a 10% triturate on lactose[1] and was extracted from the lactose with ether. The internal standard was 2,6-dinitrotoluene[2]. All solvents[3] (pesticide quality) were used as supplied, with the exception of heptane. Heptane was further purified with activated charcoal. Dimethyldichlorosilane[4] was commercially obtained.

Glassware Silanization Procedure—All glassware was silanized before use. A 5% (v/v) dimethyldichlorosilane solution in toluene was prepared fresh monthly and stored at 4°C. Glassware was soaked in this solution for 20 min, rinsed in toluene, and soaked in methanol for 20 min to neutralize excess reagent. The glassware was rinsed a final time with fresh methanol, dried at 100°C for 1 h, and baked at 260°C for 6 h.

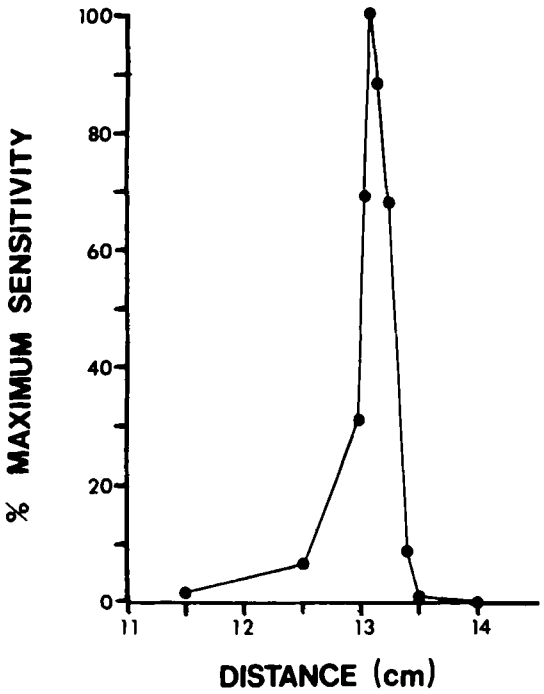

Figure 1—*Effect of capillary column alignment inside the GC detector* (i.e., *distance column is inserted through the detector insert) on nitroglycerin sensitivity.*

Instruments—The gas chromatographs[5] were equipped with ^{63}Ni electron-capture detectors (EC) and on-column injectors[6] (this assay has been validated on two separate instruments). The columns were 30 m × 0.25-mm fused silica capillary columns coated with a cross-linked methyl polysiloxane stationary phase[7]. The capillary column was wrapped in a single sheet of aluminum foil; this technique was found to eliminate peak splitting, which occurred due to uneven heat distribution within the GC oven. Helium was used as a carrier gas at a flow rate of 1.5 mL/min (inlet pressure = 40 psi). Nitrogen flow rates to the EC and column make-up were 5 and 25 mL/min, respectively. Column position inside the EC was optimized for maximum sensitivity. The detector temperature was maintained at 300°C. The oven temperature was programmed from 120°C to 180°C at 5°C/min. A second temperature ramp was used to "burn-off" the residual extract. This was accomplished by programming the oven at 50°C/min to 250°C and maintaining this final temperature for 10 min. Chromatograms were recorded and peak height ratios calculated using a recording integrator[8].

With routine use (every 100 injections) a 40-cm length of column (at the injector end) should be removed. This procedure, which results in more reproducible standard curves, removes nonvolatile extract components that accumulate and eventually cause chromatographic peaks to broaden and the sensitivity to decrease. An alternative to removing portions of the analytical column is the use of a precolumn. The precolumn is a 1-m section of column with the same liquid phase as the analytical column. The precolumn should also be wrapped in aluminum foil and connected directly to the injector. The opposite end of the precolumn is connected to the analytical column using a zero dead-volume union[9]. After ~100 injections, the precolumn may be changed and column efficiency is not lost.

Clinical Blood Sampling—Serial blood samples were drawn into chilled 7-mL evacuated tubes[10] through an indwelling venous catheter kept patent with heparin. The blood was immediately centrifuged at 12,800×*g* for 20 s. The plasma was then immediately frozen in a dry ice bath. The total amount of time required to withdraw the blood sample and centrifuge to obtain plasma prior to freezing was <2 min. This procedure minimizes the *in vitro* degradation of nitroglycerin by blood.

Sample Preparation—Nitroglycerin calibration standards were prepared as follows. Primary stock solutions (1 mg/mL each) of nitroglycerin and 2,6-dinitrotoluene were prepared in ethanol. Secondary stock solutions (10 μg/mL) were prepared fresh monthly by diluting the primary standards in ethanol (1:100, v/v). Fresh aqueous solutions of nitroglycerin (10 ng/mL) and 2,6-dinitrotoluene (20 ng/mL) in distilled water were prepared daily from the secondary stock solutions. Nitroglycerin calibration standards (0, 25, 50, 100, 200, 300, 400, 500, 750, 1000, and 2000 pg/mL) were prepared by adding the appropriate aliquot of the nitroglycerin standard and 50 μL (1 ng) of 2,6-dinitrotoluene to 1-mL samples of blank human plasma in 16 × 150-mm silanized test tubes with polytef-lined screw caps. Clinical plasma samples (1 mL) were transferred to silanized test tubes and mixed with 50 μL of the 2,6-dinitrotoluene.

Each calibration standard or clinical sample was extracted with 10 mL of pentane by vortexing for 2 min, followed by centrifugation for 10 min at 2000×*g*. The pentane layers were transferred to clean test tubes. The residual plasma layers were extracted and centrifuged a second time, as described above. The combined pentane extracts were evaporated under a stream of nitrogen (at room temperature) to a final volume of ~1 mL. The extracts were then transferred to 1-mL vials[11] and evaporated to dryness under a stream of nitrogen. Immediately after the solvent had been completely removed, 25 μL of *n*-heptane was added to each vial, and the vials were vortexed (~5 s). A 1.0-μL aliquot of each extract was injected into the gas chromatograph.

Sample application to the column was performed *via* the injector stopcock using a 10-μL gas-tight syringe which was modified to hold a 0.21 × 190-mm fused-silica capillary "needle." All extracts were stored at −20°C until chromatographed and on dry ice between GC injections.

Assay Specificity—Assay specificity was determined by injecting solutions of several drugs and some of their known metabolites on column. The oven temperature was programmed from 120°C to 200°C at a rate of 5°C/min, then ballistically to 250°C. This temperature program is only slightly different than that described earlier and will not affect the retention time of nitroglycerin, nitroglycerin metabolites, or the internal standard. This temperature program was used to show the relative retention times of a related drug, isosorbide dinitrate, and it metabolites. The analytical method described may be modified in this manner to determine plasma isosorbide dinitrate and metabolite concentrations. All of the compounds tested for possible interferences were tested using these same conditions.

Nitroglycerin Stability—Nitroglycerin stability in frozen human plasma was evaluated at −20°C. Drug-free plasma was obtained from four volunteers

Table I—Retention Times of Nitroglycerin, Nitroglycerin Metabolites, and Several Other Commonly Prescribed Drugs

Compound	GC Retention Time, min

(three male, one female) and pooled. Nitroglycerin was added to two separate 100-mL aliquots of plasma (at 0°C) to obtain final concentrations of 0.1 and 1.0 ng/mL. Each plasma solution was subdivided into multiple 1-mL aliquots, quick-frozen in dry ice, and stored at −20°C. Six aliquots of each concentration were assayed (as described above) after 0, 7, 14, 24, 40, and 60 d of storage.

Column/Electron-Capture Detector Optimization—The position of the capillary column exit inside the detector was optimized for maximum sensitivity. Sensitivity was evaluated from multiple injections of a 1.0-μL aliquot of a nitroglycerin standard solution (1.0 pg of nitroglycerin/μL and 40 pg of 2,6-dinitrotoluene/μL, in heptane). The position of the column in the detector was adjusted to increase sensitivity (maximum nitroglycerin/2,6-dinitrotoluene peak height ratio).

RESULTS AND DISCUSSION

Injector and Detector Optimization—Initial attempts to use a capillary GC system to quantitate picogram amounts of nitroglycerin were unsuccessful. Nitroglycerin may adsorb and degrade on active surfaces of capillary injectors, glass columns, and detectors. Several injection systems were evaluated. Significant nitroglycerin adsorption occurred with splitless and direct injectors[12]. Use of the split injection technique (90:1 split ratio) decreased the apparent adsorption of nitroglycerin to the injector. Lower split ratios were necessary to increase assay sensitivity, but the coefficient of variation was >20%. Finally, injector precision and assay sensitivity were evaluated using the on-column injection technique. Use of this technique allowed nitroglycerin to be applied directly onto the capillary column, thus avoiding glass and metal surfaces which may adsorb and/or degrade nitroglycerin.

Adsorption and degradation of nitroglycerin may occur not only on surfaces of conventional injectors, but also on active surfaces present in the EC. An advantage of using narrow-bore fused-silica capillary columns is that the column may be inserted entirely into the EC. Optimization of the position of the column exit inside the EC is an important determinant of assay sensitivity. The EC contains highly active surfaces which may bind or degrade labile drugs such as nitroglycerin. Therefore, the column must be positioned to both minimize nitroglycerin loss and maximize detector sensitivity.

Figure 1 shows that detector sensitivity sharply increases as the column is inserted further into the EC and peaks at 13.1 cm, *i.e.*, 13.1 cm as measured from the EC detector insert to the end of the column. Further insertion of the column into the detector results in a sharp decrease in sensitivity. Note that if the column alignment varies by as little as 1–2 mm, 50% of the maximum sensitivity is lost.

The position of the column within the EC may not be as critical in the chromatography of other compounds. For example, lindane and aldrin are easily detected even when the column outlet is placed only 0.5 cm inside the detector insert.

Extraction Precision and Recovery—Initial assay development utilized an extraction procedure in which 1.0 mL of plasma was extracted once with 10 mL of pentane. Extraction efficiencies for nitroglycerin and 2,6-dinitrotoluene (1.0 ng/mL each) were 75 ± 7% and 93 ± 2%, respectively. When biological samples (plasma) were each extracted twice, assay precision, as measured by the decrease in coefficient of variation, was increased by two- to threefold. Coefficients of variation decreased from 13.7 to 6.1%, 15.9 to 2.3%, and 9.5 to 2.9% at plasma nitroglycerin concentrations of 50, 100, and 1000 pg/mL, respectively, when single and double extractions are compared.

Nitroglycerin Chromatography and Assay Specificity—Chromatograms of blank and nitroglycerin-fortified plasma are shown in Fig. 2. Figure 2A depicts a chromatogram for a blank plasma extract. The nitroglycerin and 2,6-dinitrotoluene retention times are indicated by arrows. The small peak, indicated by arrow a, has the same retention time as nitroglycerin. This peak is due to a contaminant present in the heptane and was eliminated by purifying the heptane with activated charcoal. Figure 2B shows a representative chromatogram of plasma fortified with 100 pg/mL of nitroglycerin and 1 ng/mL of 2,6-dinitrotoluene. The retention times for nitroglycerin and 2,6-dinitrotoluene were 8.6 and 11.4 min, respectively.

Both nitroglycerin and dinitrotoluene were resolved from nitroglycerin metabolites. The retention times for the metabolites are shown in Table I. Since the capillary GC assay will be used to measure nitroglycerin plasma concentrations in patient populations, several other drugs were tested for assay interference. Table I lists the retention times, when detected, of several drugs (and metabolites) which may be prescribed to patients in a hospital cardiac care unit. None of the drugs, nor the metabolites tested, interfered with the nitroglycerin capillary GC assay. Also note that nitroglycerin may be assayed in the presence of isosorbide dinitrate, which is often concurrently administered to patients. No interference was noted for this compound and its two major metabolites, isosorbide-5-mononitrate and isosorbide-2-mononitrate.

Assay Precision, Accuracy, and Linearity—The precision and accuracy of the nitroglycerin assay procedure was assessed by analysis of six replicate

plasma samples to which known amounts of nitroglycerin were added. Within-day assay precision and accuracy are summarized in Table II. Coefficients of variation over the concentration range, 25–10,000 pg/mL, were <10%. The relatively high coefficient of variation of the 10-ng/mL concentration may be due, in part, to the additional steps involved in sample analysis at higher concentrations, *i.e.*, extracting 100 μL of plasma diluted with 900 μL of blank plasma. Accuracy for all concentrations, except 25 pg/mL, was within ±5% of the actual fortified nitroglycerin concentrations. Between-day assay precision was evaluated over 2 months (40 standard curves), *i.e.*, each day for 40 d. Blank plasma samples were fortified with 0.1 and 1.0 ng/mL of nitroglycerin. These samples served as calibration controls until drug stability could be established. Coefficients of variation were 7 and 12% at 1.0 and

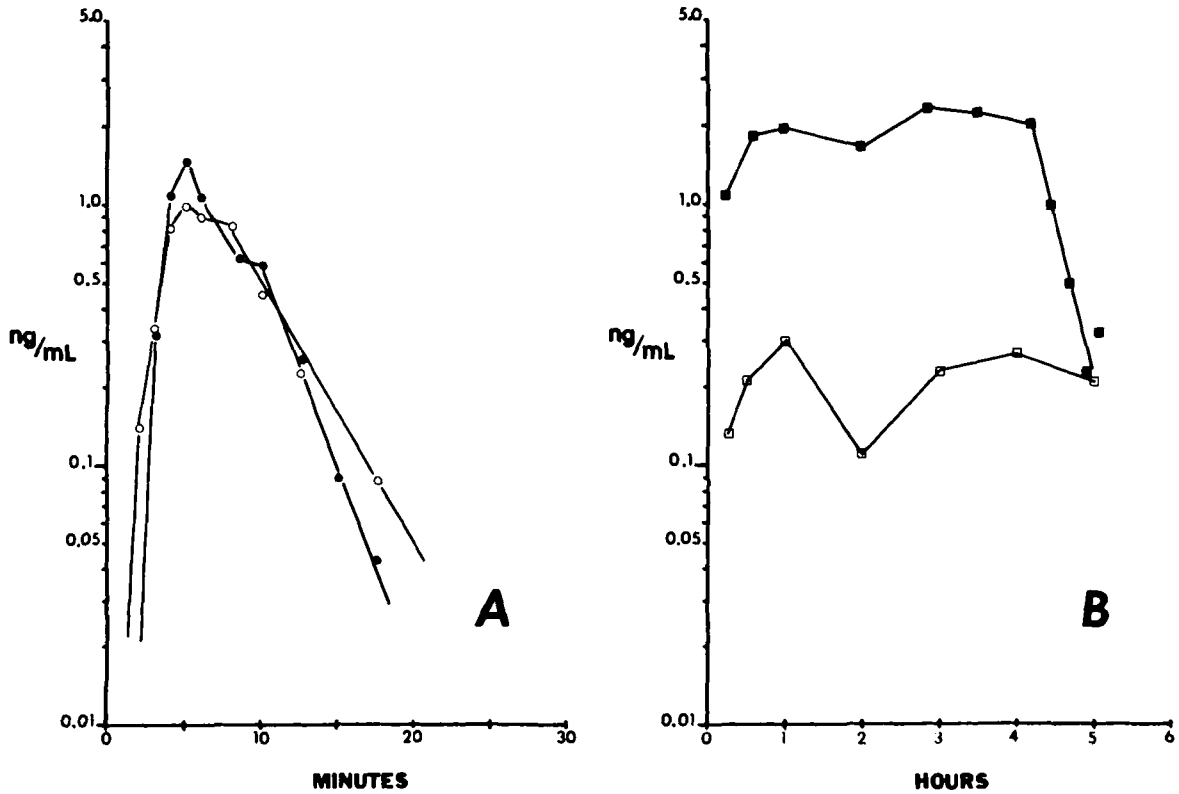

Figure 4—*Plasma nitroglycerin concentration* versus *time profiles for two subjects. Key: (A) after 0.4-mg sublingual doses to subject 1; (B) after topical doses to subject 2* via *ointment (■) and controlled-release patch (□).*

0.1 ng/mL, respectively. Accuracy (mean concentrations) were within the percent error noted for these two concentrations in Table II.

Nitroglycerin standard curves were not linear over the entire concentration range of 0–3000 pg/mL. At very low concentrations (<200–300 pg/mL) the standard curve slope was generally 50% greater than that of the high concentration range. Figure 3A shows a representative standard curve. The change in slope is not due to extraction efficiencies, since the slope change was also present when known concentrations of drug in heptane were injected. The "break-point" of the standard curve was consistent and did not change during any given day. Even when six different standard curves were averaged together (Fig. 3B), the break-point was still present. Therefore, this break-point is not due to assay variability.

The break-point may vary between different columns, instruments, or make-up gas flow rates. The standard curve in Fig. 3A was analyzed on a different instrument than the curves averaged in Fig. 3B. The break-point in Fig. 3A occurred at 200 pg/mL. In each of the six individual curves and the mean curve in Fig. 3B, the break-point occurred at 300 pg/mL. The position of the break-point may vary between instruments, but is constant within any one instrument. Although the occurrence of the break-point is quite consistent, the cause has not yet been identified.

Nitroglycerin Stability in Frozen Plasma—Nitroglycerin stability in frozen plasma has been determined in some detail by Maier *et al.* (22). Because these investigators determined nitroglycerin concentrations using a GC assay which utilized packed columns, it was necessary to validate the plasma storage conditions using the capillary GC assay reported here. The nitroglycerin stability data are shown in Table III. Nitroglycerin was stable in plasma for a minimum of 60 d when stored at −20°C.

Clinical Studies—As an illustration of the applicability of this assay procedure, nitroglycerin was administered to two healthy volunteers. Subject 1 received a 0.4-mg sublingual dose on two separate occasions (1 week apart); the plasma concentrations are shown in Fig. 4A. Nitroglycerin peak times were 5 min, and terminal half-lives were 2.0 and 3.0 min. Subject 2 received two topical doses of nitroglycerin on separate occasions. The subject received a 1-g dose of 2% nitroglycerin ointment (equivalent to 20 mg of nitroglycerin) which was spread evenly over a 200-cm^2 chest area and occluded. The second dose was a sustained-release nitroglycerin patch. Plasma concentrations are shown in Fig. 4B. The half-life (15 min) after removing the ointment was longer than that after sublingual dosing. The longer half-life is most likely due to continued absorption of nitroglycerin.

Dose-Dependent Pharmacokinetics and Hepatobiliary Transport of Bromophenol Blue in the Beagle

ROBERT J. WILLS *, GERALD J. YAKATAN [§x], and ROBERT S. PEARLMAN

Received September 17, 1982, from the *College of Pharmacy, University of Texas at Austin, Austin, TX 78712.* Accepted for publication May 26, 1983. Present addresses: *Hoffmann-La Roche, Department of Pharmacokinetics and Biopharmaceutics, Nutley, NJ 07110 and [§]Warner-Lambert Co., Pharmaceutical Research Division, Morris Plains, NJ 07950.

Abstract □ The pharmacokinetic profile of bromophenol blue (I) in the plasma, urine, and bile of beagle dogs was determined after intravenous administration of 5-, 20-, and 30-mg/kg doses. In addition, two competitors, probenecid and phenylbutazone, were interacted with I *in vivo* and with I and rat liver cytoplasmic protein fractions Y and Z *in vitro* as a means of elucidating the mechanism of intrahepatic transport of I. Compound I was determined spectrophotometrically at 587 nm. In plasma, I displayed apparent first-order dose-dependent kinetics. The percentage of I bound to plasma proteins was ~92.5% over the dose range studied. Consecutive injections of equal doses of I produced statistically different terminal half-lives ($p < 0.05$), suggesting the possibility of a saturable uptake process. In the presence of each competitor, the disposition of I was altered significantly ($p < 0.05$): phenylbutazone displaced I from plasma protein, while probenecid decreased the binding of I to liver proteins in the Z-fraction. The Z-fraction bound a larger amount of I than the Y-fraction, suggesting a larger binding capacity. Under no circumstances was the binding of I to the Y-fraction altered. Cumulative biliary excretion data showed that the elimination of I in bile accounted for 92–99% of the dose delivered. The biliary excretion σ^- plots displayed no dose dependency, suggesting that the dose-dependent plasma half-life is due to a dose-dependent liver uptake (as opposed to elimination) process.

Keyphrases □ Pharmacokinetics—bromophenol blue, dogs, hepatobiliary transport □ Bromophenol blue—pharmacokinetics, hepatobiliary transport, dogs □ Hepatobiliary transport—bromophenol blue, dogs, pharmacokinetics

An understanding of the complex processes involved in hepatobiliary transport will lead to a more complete understanding of the disposition of the many compounds eliminated by this route. Radiological (1–3) and pharmacological (4–7) investigations have addressed various aspects of these transport processes, but relatively few pharmacokinetic studies have been conducted. The use of blood, urine, and bile data to suggest or support a model of hepatobiliary uptake and elimination appears to be a promising research objective. Takada and coworkers (8–10) proposed the use of bromophenol blue (I) as a model compound for the study of hepatobiliary transport in rats. This was confirmed by Wills *et al.* (11), who noted that I is primarily excreted in bile, is not metabolized, elicits no pharmacological action, and is not intestinally reabsorbed. Although studies conducted in rats have been informative, the pharmacokinetics of the hepatobiliary transport of I have not been addressed in higher animals. Although a few studies using dogs have been conducted (1, 3, 12), the feasibility of obtaining a useful bile concentration profile has yet to be demonstrated.

In rat plasma, I displays a dose dependency which was related to the saturation of proteins involved in the liver uptake process (8). These proteins were separated as cytoplasmic protein fractions Y, Z, and T-binder (9, 13–15), and it was subsequently shown (10) that both Y and Z act as uptake sites, Z and T-binder act as storage sites, but only Y functions as an intracellular carrier to the bile canaliculi.

Takada and co-workers (8–10) used competitors to elucidate the hepatobiliary transport mechanism in rats. Two competitors, probenicid and phenylbutazone, were selected because of their ability to inhibit liver uptake of organic anions (13, 16, 17) and to displace drug from plasma proteins (18–20), respectively.

The nature of the hepatobiliary uptake and elimination processes in higher animals is still the subject of controversy. Shanker (21) hypothesized the existence of three different carrier systems for liver uptake of anionic, cationic, and neutral compounds. However, Schwenk (6) has recently presented conflicting data.

In this report, we discuss efforts to determine the pharmacokinetic profile (plasma and urine) of I following intravenous administration in intact beagle dogs, to determine the pharmacokinetic profile (plasma, urine, and bile) of I following intravenous administration in beagle dogs with cannulated common bile ducts and excised gallbladders, to observe the effect of probenecid and phenylbutazone on the pharmacokinetic parameters for I, and to examine the action of these two competitors by *in vitro* rat liver protein binding studies.

EXPERIMENTAL SECTION

Bromophenol blue[1] (I) was purchased from the manufacturer. Purity was established by melting point and TLC. A mixture of propylene glycol–ethanol–sterile water (4:1:5) was found to be a suitable intravenous injection vehicle[2].

One female and two male beagles, weighing 11–18 kg, were used in all studies; all three dogs were 7 years old. Hematology values were determined to be within normal limits. The dogs were fasted 18 h prior to drug administration, and at least 2 weeks were allowed between studies unless otherwise noted.

Bromophenol Blue Intravenous Bolus Studies—Compound I was administered as 5-, 20-, or 30-mg/kg doses. Sample times varied with dose, as indicated in the figures. Blood samples were transferred to stoppered evacuated tubes[3] containing sodium heparin and centrifuged. The plasma was removed and stored at −20°C until assayed. Urine was collected as produced and also stored frozen until assayed.

Competitor Studies—Probenecid[4] and phenylbutazone[5] were supplied by the manufacturers. Each competitor was administered 1 h before the I dose. The doses of probenecid, phenylbutazone, and I were 125, 75, and 20 mg/kg, respectively. The half-life of each competitor was ~8 h (17, 22).

Plasma Protein Binding Studies—The extent of binding of I was determined after dialysis using a rotary five-cell (volumes of 1.36 mL; membrane surface area of 4.52 cm^2) dialysis apparatus[6]. The dialysis apparatus was assembled with equivalent *in vivo* concentrations of I dissolved in pH 7.4 isotonic buffer on one side *versus* pooled dog plasma on the other side, placed in a water bath at 37°C, and incubated for 2 h at 10 rpm. The time required for equilibration was established by dialyzing spiked buffer against unspiked buffer.

The effect of the competitors on the plasma protein binding of I was also determined. To 4 mL of pooled dog plasma, 100 μL of a 16-mg/mL solution of competitor was added to give a final concentration equivalent to an *in vivo* concentration (17, 22) of the competitor at time zero. This solution was dialyzed against spiked buffer, which encompassed the concentrations of I found

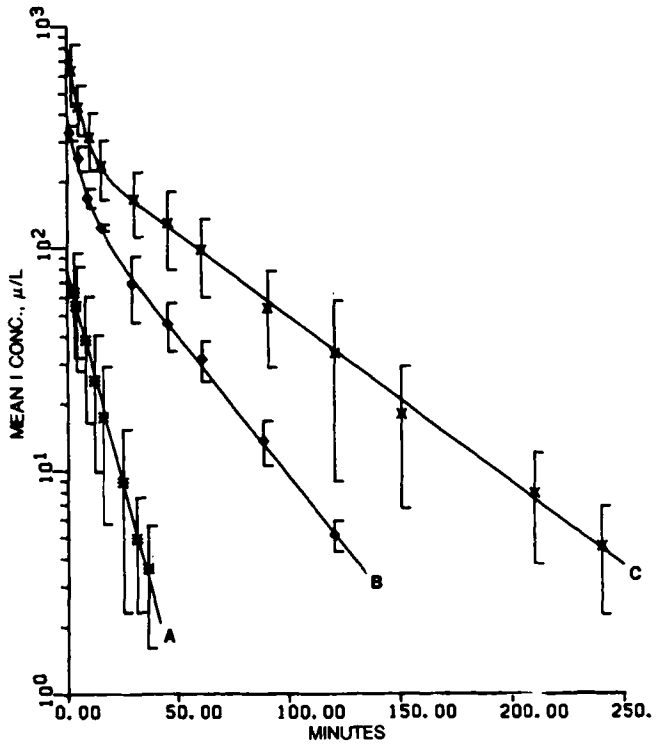

Figure 1—*Mean* ± SD (n = *3) plasma concentrations of I after an intravenous bolus injection to a dog. Key: (A) 5-mg/kg dose; (B) 20-mg/kg dose; (C) 30-mg/kg dose.*

in vivo. All solutions were collected and any cell volume changes were noted. The samples were assayed immediately after removal from the dialysis apparatus.

Bile Duct Cannulation Studies—Under pentobarbital anesthesia, a midline incision was made[7] and the common bile duct was exposed. After excising the gallbladder, a small incision in the common bile duct was made ~1 cm from its entrance to the duodenum, and a T-shaped cannula was inserted and ligated in place. A second T-shaped cannula was placed into the duodenum and both silicone rubber[8] cannulae were attached to a larger stainless steel cannula which was inserted through the abdominal wall. Although the cannula into the duodenum would have allowed the return of bile between experiments, previous experience indicated that this would subject the animals to an increased risk of hepatic infection. Thus, total bile was collected at all times. Bile salt dietary supplements[9] were given to maintain the animals' weights at constant values.

During experiments, bile was collected in pre-tared screw-capped vials[10] and frozen until assayed. In addition, blood and urine were collected. The sampling times varied with dose. Only 1 week was allowed between studies because animal viability was poor.

Liver Protein Binding Studies—Two male Sprague–Dawley rats, 400 g, were anesthetized by a 70-mg/kg ip injection of sodium pentobarbital. A midline laparotomy exposed the internal viscera. The hepatic vein was severed, followed by cannulation of the hepatic portal vein with a 22-gauge needle connected to an infusion pump[11] containing pH 7.4 isotonic phosphate buffer. The liver was perfused until the color appeared pink (after ~200 mL of buffer). The livers were then excised, dried, weighed, and stored frozen.

In preparation for extraction and purification of the liver protein fractions (9), the livers were homogenized[12] to a 25% homogenate with 0.25 M sucrose–0.01 M phosphate buffer (pH 7.4) and then ultracentrifuged[13] at 100,000 × *g* for 2 h at 20°C. After removing the surface lipids, the supernatant was collected. A 1-mL aliquot of supernatant was used for determination of the total protein concentration (23).

A total of nine mixtures containing supernatant, I, and the competitors were prepared as follows. To 5 mL of supernatant, 6.7 mg (10 μmol) of I and 0, 10, 20, 30, or 40 μmol of either probenecid or phenylbutazone were added. Each mixture was incubated for 24 h at 4°C and then eluted using 0.01 M phosphate buffer pH 7.4 on a Sephadex G-75 column (2.5 × 45 cm)[14] previously equilibrated with the phosphate buffer (24). Five-milliliter fractions were collected using a fraction collector[15]. Absorbances of I and protein for a given tube were determined at 587 and 280 nm, respectively, using a double-beam spectrophotometer[16]. The absorbances measured at 280 nm were used as a fingerprint for liver protein fraction identification.

The total amount of I bound to the void volume (X fraction), Y, and Z fractions was quantitated as follows. After determining the amount of I in each tube the amounts were then added together mathematically from tubes 0–7, 8–14, and 29–64 (representing I bound to the void volume, Y, and Z fractions, respectively). The total amount of I bound in the presence of each competitor

at different competitor concentrations was divided by the control to give the percent reduction in I binding to either the Y or Z fraction. The amount found in the void volume was used for mass balance calculations.

Assay—In all procedures, only I was assayed. Plasma, urine, bile, and the plasma and liver protein binding samples were diluted with phosphate buffer (pH 8), and the absorbance was measured directly at 587 nm. Standards were prepared and run daily. The standard curves were linear ($r = 0.9997$); the sensitivity was 0.6 μg/mL.

RESULTS

Plasma Concentrations of Bromophenol Blue—The mean plasma concentrations of I *versus* time are shown in Fig. 1. The low dose (5 mg/kg) declined monoexponentially, while the intermediate dose (20 mg/kg) and the high dose (30 mg/kg) declined biexponentially (Fig. 1). The data were fit to a sum of exponentials using NONLIN (25). The relevant pharmacokinetic parameters are given in Table I (26, 27).

The biological half-life ($t_{1/2}$) and plasma clearance (CL_p) were not constant over the range of doses studied (Table I). These results indicate that the elimination of I from plasma is a dose-dependent process in this dose range. The area under the plasma concentration–time curve ($AUC_{0\to\infty}$) increased at a greater than linear rate with increasing dose (Table I).

The percentage of I bound to plasma proteins was 92.5 ± 1.5% at 37°C and was essentially constant over the range of I concentrations examined (100–875 μg/mL). A slight increase in the free fraction of I with increasing I concentration occurred, but was found not to be statistically significant using the Student's *t* test.

The graph in Fig. 2 indicates the plasma concentrations following two identical 5-mg/kg doses of I administered 2 h apart. The first dose was no longer detectable in the plasma just prior to the second dose, yet the second dose was eliminated at a significantly ($p < 0.005$) slower rate. The half-lives were 6.7 and 12.7 min, respectively.

Drug Competition With Bromophenol Blue—The concentration–time profiles of I following prior administration of probenecid and phenylbutazone are shown in Fig. 3a and b. The data was fit to a sum of exponentials using NONLIN (25).

In the presence of each competitor, the half-life increased, the area under the plasma concentration–time curve increased, and the clearance decreased (Table II). The volume of distribution at steady state (Vd_{ss}) was essentially unchanged, indicating that the competitors had no effect on the overall distribution of I.

Phenylbutazone produced a significant change ($p < 0.05$) in the plasma protein binding of I. The percent of I bound was 86.1 ± 2.9%, corresponding to nearly a twofold increase in the free I concentration over that found in the absence of phenylbutazone. Probenecid had no effect on the plasma protein binding of I (92.2 ± 1.2%).

Liver Protein Binding Studies—The results of the *in vitro* studies of I binding to rat liver protein fractions are presented in Table III. Figure 4a and b shows the protein and I elution profiles. From left to right the protein peaks correspond to protein in the void (unidentified protein) volume, proteins in the Y-fraction, and proteins in the Z-fraction (13–15), while the I peaks indicate binding to the respective protein peaks. Probenecid competed with I for Z-fraction binding sites, resulting in a significant decrease in the amount of I bound and a corresponding increase in the amount of free I (Table III). In Fig. 4a the profile representing I bound to Z steadily decreased with an increase in probenecid concentration. Phenylbutazone did not affect I binding to Z-fraction (Fig. 4b, Table III). Neither competitor affected the amount bound to the Y-fraction; because the amount of I bound to the Y-fraction was ~1–3% of that bound to the Z-fraction, the results were not presented.

Biliary Excretion Studies—Although all three dogs were cannulated as described above, only one animal provided complete data. Dog A developed peritonitis despite intensive postoperative maintenance, and dog B developed a colateral bile duct which bypassed the cannula 2 weeks after the surgery.

Table II—Comparison of Pharmacokinetic Disposition Parameters of I (20 mg/kg) in the Presence of a Competitor

Dog	$t_{1/2}$, min[a]	CL_p, mL/min[a]	Vd_{ss}, L	$AUC_{0\to\infty}$, μg/mL·min[a]
		Probenecid, 125 mg/kg		
A	127	9.5	1.60	37,400
C	56.0	15.1	1.08	14,300
		Phenylbutazone, 75 mg/kg		
A	77.9	18.9	1.73	18,500
B	56.3	26.3	1.27	12,200

[a] Significantly different from the no competitor case ($p < 0.005$).

Table III—Effect on the Binding of I to the Z-Fraction in the Presence of a Competitor

Competitor Conc., μmol/mL	I Conc., μmol/mL	Total Amount I Bound, μg	Reduction in I Binding, %	*t* test
		Phenylbutazone		
0.0	2.0	755	—	—
2.0	2.0	748	1.0	$p > 0.05$
4.0	2.0	754	0.1	$p > 0.05$
6.0	2.0	748	0.9	$p > 0.05$
8.0	2.0	753	0.3	$p > 0.05$
		Probenecid		
0.0	2.0	755	—	—
2.0	2.0	704	6.9	$p < 0.05$[a]
4.0	2.0	699	7.3	$p < 0.05$[a]
6.0	2.0	693	8.2	$p < 0.05$[a]
8.0	2.0	687	9.0	$p < 0.05$[a]

[a] Paired *t* test performed on duplicate data sets.

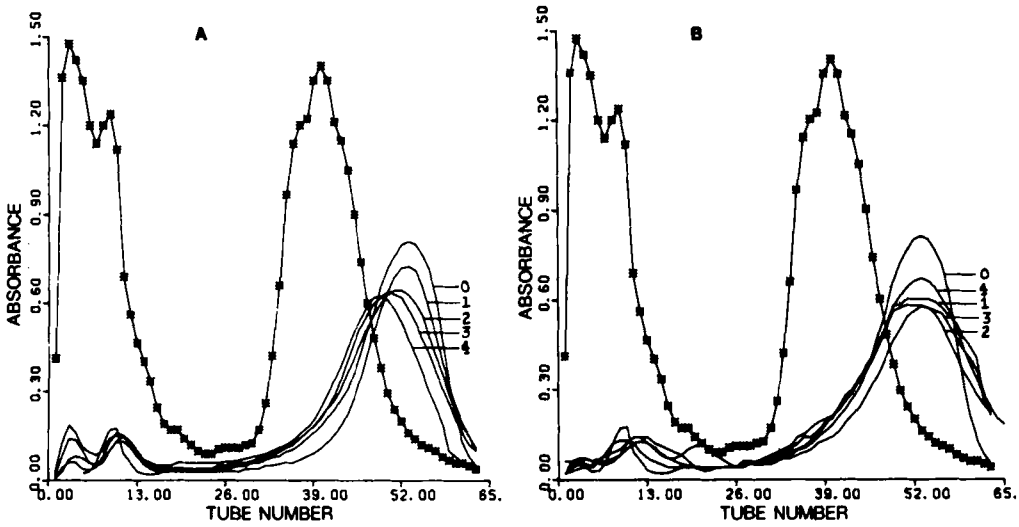

Figure 4—*Elution patterns of I, measured at 587 nm, in the presence of probenecid (A) and phenylbutazone (B) in the rat liver cytoplasmic fraction. 0, 1, 2, 3, and 4 indicate the amount of competitor added as a multiple of the amount of I present. The asterisks represent the protein fraction elution pattern measured at 280 nm. Each tube number represents a 5-mL collection.*

The pharmacokinetic parameters derived from I plasma concentrations following intravenous administration to the cannulated dogs showed an increase in half-life over the values observed in the same dogs before surgery (40.6 *versus* 24.8 min at 20 mg/kg and 11.7 *versus* 6.9 min at 5 mg/kg, respectively). Liver dysfunction did not appear to be the explanation, since hematology values were still within normal limits. The remaining parameters (clearance, volume of distribution, and area under the plasma concentration-time curve) were unchanged.

Biliary excretion σ^- is plotted in Fig. 5. The abnormalities in the curve for the 30-mg/kg dose were due to the temporary clogging of the cannula. Combined with the urine output, the amount recovered ranged from 95.7 to 101.1% of the dose. The amount recovered from the bile ranged from 92.3 to 98.9% of the dose. The σ^- plot appeared to be linear for all doses. There was no statistical difference ($p < 0.05$) between the half-lives at all doses (mean harmonic half-life = 163 min). Rate plots were also constructed, but were difficult to interpret. The biliary excretion rate data will be discussed briefly in another report (28).

Urinary Excretion Data—The amount of I recovered in urine from the intravenous and biliary excretion studies ranged from 1.5 to 7.2%. These data were considered significant in the pharmacokinetic interpretation of I and were used only for mass balance recovery purposes.

DISCUSSION

The plasma data presented in Fig. 1 and Table I clearly indicate that the rate of I elimination from plasma is dose dependent, and the rapid increase in AUC with increasing dose seems to suggest some saturable process. Since 95-101% of the dose was recovered as unchanged drug, it appears that the dose dependency is not due to I metabolism. Takada *et al.* (8) found that metabolic inhibitors did not affect the liver uptake of I in rats, suggesting that the dose dependence is not due to saturation of an active transport system. The fact that the extent of plasma protein binding of I remains essentially constant over the dose range indicates that the dose-dependent elimination kinetics are not due to changes in plasma protein binding. The data shown in Fig. 2 further suggest that, since the first dose was essentially eliminated from the plasma, the observed dose dependency may be due to the binding of I in other tissues. Accordingly, the binding of I to liver protein fractions was investigated.

The peak assignments (as discussed in the *Results*) in Fig. 4a and b are supported by earlier studies (13-15), but differ from those reported by Takada *et al.* (9). In the present study, each I peak corresponds to a protein peak while in the work of Takada *et al.* (9) the I supposedly bound to the Z-fraction did not have a corresponding protein peak; the I peak we have identified with the Z-fraction was labeled free I in their work (9). We observed free I eluting at much later times than are plotted (Fig. 4). Takada and co-workers also identified a fraction, T-binder, which elutes at a time similar to the Z-fraction. It is possible that this peak was masked by the large Z-fraction peaks in Fig. 4a and b. Since the only difference in methodology between our study and that of Takada *et al.* appeared to be the strain of rat (Sprague-Dawley in this study, Wistar in their work), further investigation may be warranted, because it is unlikely that strain differences would account for these discrepancies.

The data summarized in Table III indicate that neither competitor interfered with I binding to the Y-fraction and that probenecid competed with I for Z-fraction binding sites while phenylbutazone did not. Since both probenecid and I are anionic at physiological pH while phenylbutazone is neutral, these findings tend to support the hypothesis (21) of the existence of separate pathways for the biliary uptake and elimination of charged and neutral species.

We found that the amount of I bound to the Y-fraction is far smaller than the amount bound to the Z-fraction. This tends to support the earlier hypothesis (8, 9) that organic anions are taken up by the liver *via* two pathways (binding to the Y- and Z-fractions), one of which (Y-fraction) is of limited capacity and easily saturable. Once the Y-fraction is saturated, I is still eliminated from the plasma at a reduced, but apparently first-order, rate through uptake by the large-capacity Z-fraction.

The increased I plasma half-life following administration of probenecid appears to be due to competition for the Z-binding sites involved in the uptake process. The increased I plasma half-life following administration of phenylbutazone appears to be due to the displacement of I from plasma proteins

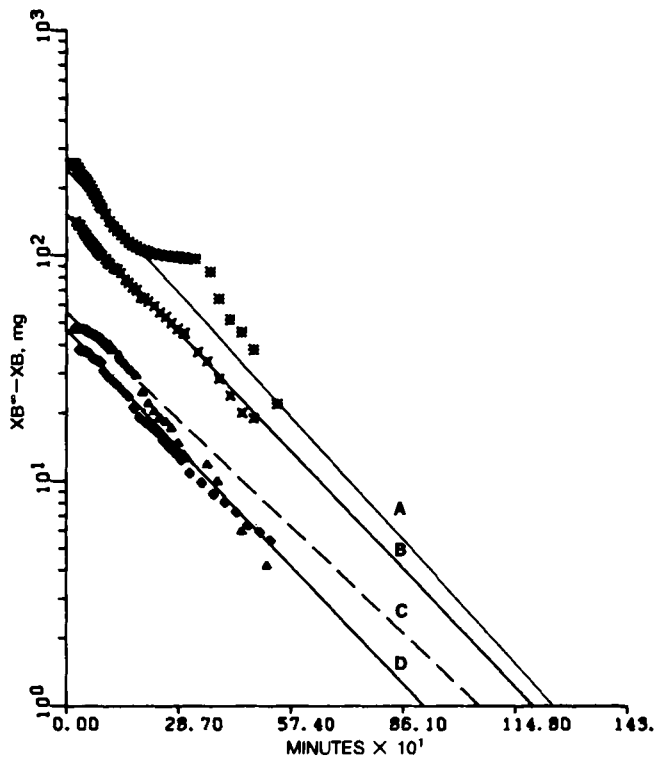

Figure 5—σ^- *Plot of I elimination in bile after doses of 30 mg/kg (A), 20 mg/kg (B), and 5 mg/kg (C) to dog C and a 5-mg/kg to dog B (D).*

and the subsequent increase in free I plasma concentrations, which saturate the uptake process in a manner similar to large doses of I.

Biliary excretion data obtained from rats (8–11) have often been of sufficient quality to enable the pharmacokinetic support of intrahepatic models such as that suggested above. Although our data was quite limited, it seems to suggest that data of sufficient quality may be difficult to obtain from dogs. The fact that the biliary excretion half-life was found not to vary with dose supports our contention that the changing plasma half-life reflects a saturable hepatic uptake rather than an elimination process.

Effect of Nonuniform Bile Flow Rate on the Rate of Biliary Excretion of Bromophenol Blue in the Beagle

ROBERT S. PEARLMAN ˣ, GERALD J. YAKATAN §, and ROBERT J. WILLS *

Received September 17, 1982, from the *College of Pharmacy, The University of Texas, Austin, Texas 78712.* Accepted for publication May 26, 1983.

Present addresses: *Hoffmann-La Roche Inc., Department of Pharmacokinetics and Biopharmaceutics, Nutley, New Jersey 07110 and §Warner-Lambert Co., Pharmaceutical Research Division, Morris Plains, NJ 07950.

Abstract □ Following the intravenous administration of bromophenol blue to beagle dogs, graphs of the biliary excretion rate *versus* time displayed drastic fluctuations which render them of little value for standard pharmacokinetic modeling purposes. It was shown that these fluctuations in excretion rate are highly correlated with corresponding fluctuations in the bile flow rate. An expression was derived which accounts for the primary effect of nonuniform bile flow rate on the biliary excretion rate. This treatment would enable the use of such biliary excretion rate data for pharmacokinetic modeling. Secondary effects of nonuniform bile flow on the biliary excretion rate are also discussed. It is suggested that the modeling of other flow rate-dependent elimination processes could benefit from such a treatment.

Keyphrases □ Bromophenol blue—biliary excretion, nonuniform bile flow rate, dogs □ Biliary excretion—bromophenol blue, dogs, nonuniform bile flow rate □ Bile flow rate—nonuniform, biliary excretion of bromophenol blue, dogs

Biliary excretion has long been a subject of intensive investigation (1). Within the past decade, there has been an increase in the number of studies in which the bile duct has been cannulated to permit the determination of drugs and metabolites in the bile. These studies typically involve collecting bile samples at relatively long intervals and, usually, the cumulative amounts of drug excreted are reported as a function of time (2–5). These studies have been particularly useful in assessing the magnitude of the first-pass effect and the role of hepatobiliary elimination in the overall elimination of a wide variety of compounds (1). More recently, it has been shown that high-quality bile data can provide pharmacokinetic support for an intrahepatic model for hepatobiliary elimination in rats (6, 7). Takada *et al.* (7) obtained biliary excretion rate data (mg/h *versus* time) of sufficient quality to enable a statistically significant fit to a tetraexponential function, which they identified with a five-compartment model for hepatobiliary transport.

The possibility of obtaining similar data in higher animals is appealing, yet the problem must be viewed somewhat pessimistically due to the fact that the bile flow rate fluctuates

0022-3549/84/0700-0932$01.00/0

and the subsequent increase in free I plasma concentrations, which saturate the uptake process in a manner similar to large doses of I.

Biliary excretion data obtained from rats (8–11) have often been of sufficient quality to enable the pharmacokinetic support of intrahepatic models such as that suggested above. Although our data was quite limited, it seems to suggest that data of sufficient quality may be difficult to obtain from dogs. The fact that the biliary excretion half-life was found not to vary with dose supports our contention that the changing plasma half-life reflects a saturable hepatic uptake rather than an elimination process.

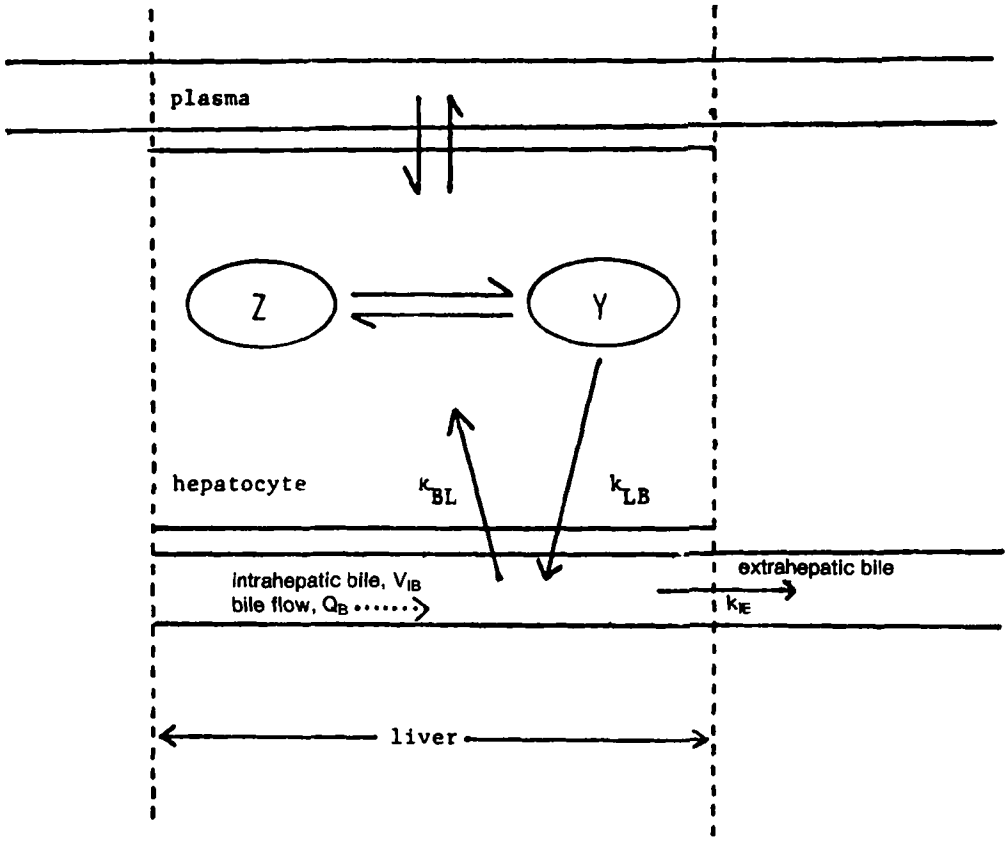

Figure 1—*Schematic representation of physiological transport and elimination via the hepatobiliary route. Y and Z represent two liver protein fractions which are involved in hepatobiliary transport (8).*

more markedly in higher animals than in the rat. The purpose of this brief communication is to present preliminary results which confirm that nonuniform bile flow rates seriously complicate the interpretation of biliary excretion rate data in the beagle dog. Possible explanations for the observed correlation between excretion rate and bile flow rate, as well as the basis for the development of a bile flow rate-dependent model for hepatobiliary transport, will be discussed.

THEORETICAL SECTION

To best treat excretion rate data, it will be necessary to develop a physical model of hepatobiliary transport which explicitly involves the biliary flow rate. Figure 1 depicts a simple model, similar to that suggested by Takada *et al.* (7) in that it distinguishes between intrahepatic and extrahepatic bile. The shaded region is intended to represent the bile canaliculus in contact with the hepatocytes. Let V_{IB} symbolize the volume of intrahepatic bile contained within the canaliculi and A_{IB} represent the amount of drug in intrahepatic bile. The transport of drug between the hepatocyte and intrahepatic bile is represented by k_{LB} and k_{BL}. If the bile production rate or flow rate, Q_B, were zero, then no drug would be excreted from the liver. The rate at which drug is actually excreted depends on the rate at which drug is eluted from the intrahepatic bile compartment, of volume V_{IB}, by newly produced bile flowing at a rate Q_B:

$$\frac{dA_{EB}}{dt} = k_{IE}A_{IB} = \frac{Q_B}{V_{IB}} \cdot A_{IB} \qquad \text{(Eq. 1)}$$

where A_{EB} is the cumulative amount of drug excreted in bile as a function of time and k_{IE} is the rate constant for transport from intrahepatic bile to extrahepatic bile[1]. In the event that Q_B is observed to vary between sample times, Eq. 1 could, as a first approximation, be assumed to hold over the individual sampling intervals. Thus, by dividing the fluctuating excretion rate by the fluctuating bile flow rate, estimation of pharmacokinetic parameters can be achieved by fitting the quotient to an expression for A_{IB}:

$$\frac{\text{excretion rate}}{\text{flow rate}} = \frac{(\Delta A_{EB})_j/\Delta t_j}{(Q_B)_j} = \frac{1}{V_{IB}} \cdot (A_{IB})_j \qquad \text{(Eq. 2)}$$

In Eq. 2, j is an index referring to the sampling interval, Δt, and V_{IB} is treated as a constant model parameter to be determined.

RESULTS

As described previously (9), bromophenol blue (I) was administered intravenously to three beagle dogs after they had each recovered from cannulation surgery. During surgery, the common bile duct was cannulated to permit collection of the total bile excreted and the gallbladder was removed to avoid bile storage and thus permit collection as the bile was produced. Bile salt dietary supplements[2] were given to maintain the body weight of each dog throughout the study.

The limited data obtained to date is shown in Figure 2a–d. The solid lines connect the biliary excretion rates of I plotted at the midpoints of the collection intervals and the dashed lines connect the corresponding bile flow rates. It is apparent that the fluctuations in the excretion rate correspond to fluctuations in the bile flow rate. It is also apparent that this excretion rate data is unsuitable for pharmacokinetic modeling in the present form.

By mathematically pooling successive samples, the rate plots can be smoothed to a considerable extent as shown in Fig. 3. In Fig. 3, the pooled collection intervals were 30 and, later, 60 min compared with actual collection intervals of 5, 10, and 15 min. Pooling the data smoothed the curve by replacing the rapidly fluctuating bile flow rate with an average flow rate. We should be somewhat critical of attempts to fit smoothed curves which are obtained by masking rather than explaining the details of the data. It should be noted that these details are analogous to excretion data when collected at longer sampling intervals.

Using Eq. 2, values for excretion rate divided by flow rate were generated and plotted, along with the excretion rate, against time (Fig. 4). It is apparent that this new treatment of bile data smoothed the curves to the extent that pharmacokinetic evaluation may be possible.

[1] Although the relationship $k_{IE} = Q_B/V_{IB}$ is discussed in any classical treatment of chromatography, the interested reader is referred to a pharmacokinetic application discussed by Gumtow *et al.* (8).

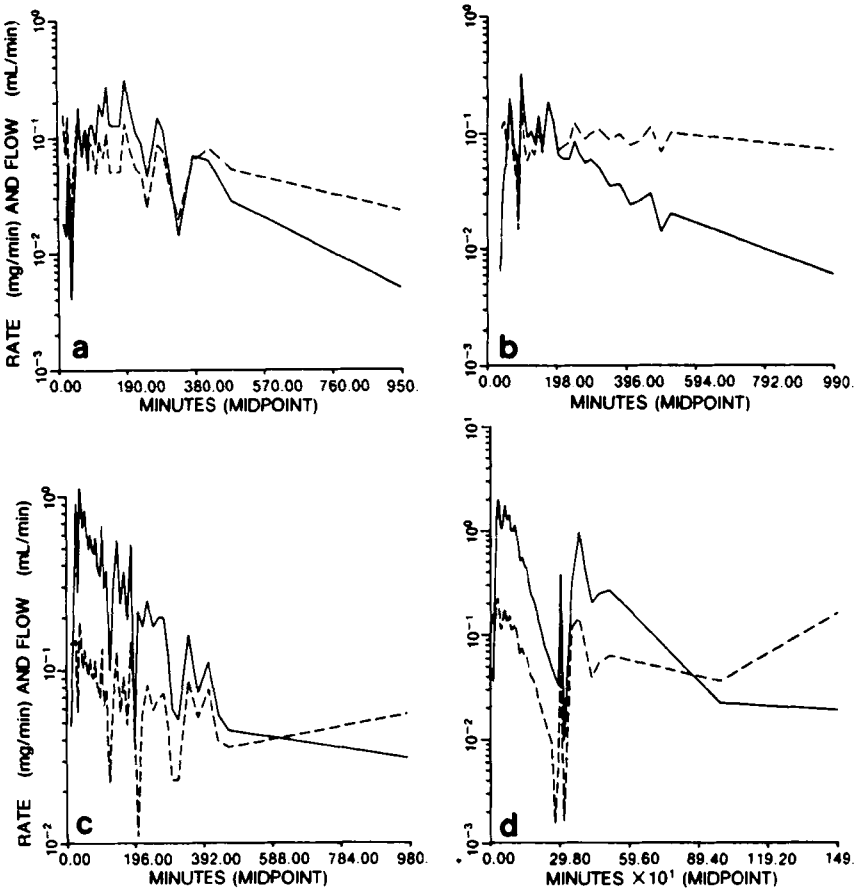

Figure 2—*Biliary excretion rate (—) and bile flow rate (- - -) of I following intravenous bolus injections of 5 mg/kg to dogs B (a) and C (b) and 20 (c) and 30 mg/kg (d) to dog C.*

DISCUSSION

Before addressing this apparent bile flow rate dependence, we note that limited information can be extracted from this data in a variety of ways. The excretion of drug in bile is somewhat analogous to the excretion of drug in urine, breast milk, sweat, saliva, and lacrimal fluid. Experimentally, we measure the accumulation (and rate of accumulation) of the amount of excreted drug in the excreted fluid, rather than the concentration, because the volume of the excreted fluid is changing. This could be contrasted with the treatment of plasma data, in which case we monitor the decreasing concentration of drug in an essentially constant volume of fluid.

In the preceding paper (9), we presented plots of the cumulative amount of bromophenol blue excreted as a function of time to indicate the extent to which various doses are eliminated through the bile, and we noted that σ^- plots of the same data seemed to suggest that the observed dose-dependent plasma elimination is due to a dose-dependent liver uptake rather than to a hepatobiliary elimination process. Both types of plots mask not only the random variability but the genuine detail (*i.e.*, fluctuations) in such excretion data (10). Excretion rate plots that provide a more precise presentation of the data are normally preferred, but as shown here, these may not be adequate for pharmacokinetic modeling.

In contrast, the data generated by Eq. 2 accounted for most of the effect of nonuniform bile flow rate and yield a graph to which one could fit a model-based expression for A_{1B}. It might be noted that the A_{1B} curve indicated in Fig. 4 is of the same shape as a corresponding curve (for X_4) that Takada *et al.* (7) simulated for a compartmental model which could be used to describe the physiological transfer processes indicated in Fig. 1. It should also be noted

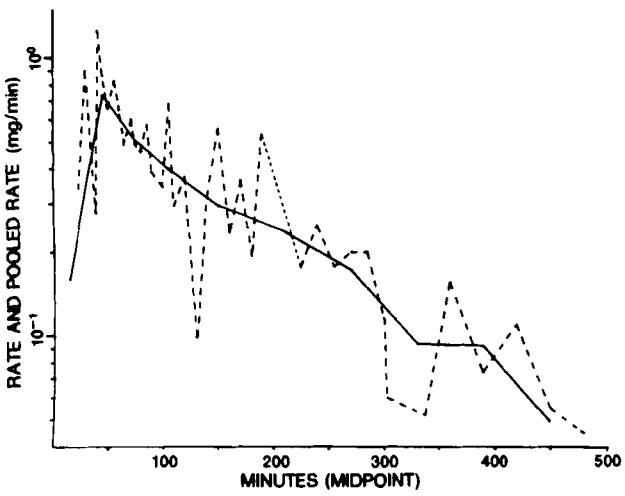

Figure 3—*Actual (- - -) and mathematically pooled (—) biliary excretion rate data for I following an intravenous bolus injection of 20 mg/kg. The small segment (· · ·) indicates missing data.*

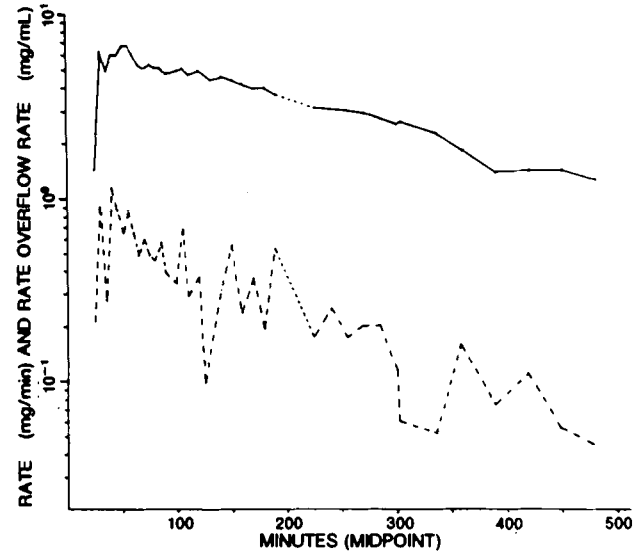

Figure 4—*Biliary excretion rate (- - -) and biliary excretion rate divided by bile flow rate (—) of I following intravenous bolus injection of 20 mg/kg. The small segments (· · ·) indicate missing data.*

that the fitting is complicated by the fact that A_{1B} is also dependent on k_{1E}, although far less markedly than A_{EB}.

We have chosen not to attempt such pharmacokinetic modeling at the present time, not only because of the incompleteness of our data but because additional analyses of the effects of nonuniform bile flow rate should be undertaken. It certainly appears that the primary effect of nonuniform bile flow rates is on k_{1E} and that our treatment of this effect describes the data. However, there are secondary effects which should also be addressed.

One example would be the effect of bile flow rate on the thickness of the diffusion layer adjacent to the bile canalicular membrane, which represents an additional barrier to the transport between the hepatocyte and intrahepatic bile. The diffusion layer thickness within a cylindrical tube is discussed by Levich (11) and it can be shown that $\delta \alpha v_0^{-1/3}$ (9), where δ is the diffusion layer thickness and v_0 is the maximum flow velocity at the axis of the tube. For a nonelastic tube of constant radius, v_0 is directly proportional to the flow rate, Q_B. Thus, passive diffusion between the hepatocyte and the canaliculi would proceed at a rate proportional to $Q_B^{1/3}$.

Nonuniform bile flow rates result in nonuniform hydrostatic pressure within the canaliculi (12), which, in turn, could affect the effective diameter of any pores existing in the canalicular membrane. If the transport between hepatocyte and intrahepatic bile involves pore filtration (12), then this secondary effect of nonuniform bile flow rates could become important. The relationship between pore size and pore filtration rate is discussed by Lakshminarayanaiah (13).

Lightfoot (14) discusses flow through elastic ducts and indirectly indicates the effect that flow rate might have on the rate of transport across the duct wall. It could also be pointed out that the elution approach discussed above is quantitatively correct only if there is perfect mixing within the intrahepatic bile compartment.

All of the secondary points mentioned above suggest that further analysis is required before biliary excretion data can be used to accurately describe a model for hepatobiliary uptake and elimination. However, if the objective is merely to use biliary excretion data to support a crude model which could be used for predictive (*i.e.*, dosing) purposes, then our treatment of nonuniform bile flow rate should be of some value.

Lastly, it should be noted that the elution approach discussed above could possibly be applied to other flow rate-dependent physiological processes. Whereas the effects of blood flow rate have received considerable attention in the pharmacokinetic literature, the effects of nonuniform flow rates on elimination *via* urine, milk, saliva, lacrimal fluid, *etc.* should account for some of the fluctuation or scatter frequently observed in that type of data.

Radiotelemetric Method for Evaluating Enteric Coatings *In Vivo*

J. B. DRESSMAN *x and G. L. AMIDON *

Received April 4, 1983, from *INTERx, Merck Sharp & Dohme Research Laboratories, Lawrence, KS 66044.* Accepted for publication July 20, 1983. *Present address: College of Pharmacy, University of Michigan, Ann Arbor, MI 48109.

Abstract □ A radiotelemetric method for the *in vivo* evaluation of enteric coating performance is described, and its advantages and disadvantages are compared with those of other available methods. Hydroxypropyl methylcellulose phthalate was used as the test enteric coating. Four dogs were administered several batches of enteric-coated tablets containing buffers. Tablet disintegration was determined by radiotelemetric detection of the pH drop in the upper intestine due to release of the buffer. Premature rupture of the coating in the stomach was detected by a rise and then a fall in gastric pH prior to gastric emptying. The average gastric emptying time was 80 ± 18 min (*SEM*), while the average time for a tablet to disintegrate in the upper intestine was 14.2 ± 2 min. The average disintegration time was not affected by a change in the batch (for a given tablet core pH) or the dog used, suggesting that the method yielded readily reproducible results. Although there was little correlation with *in vitro* disintegration times, the method gave results similar to those reported in the literature for the same enteric coating in a human study. Of the formulations tested, it was concluded that buffering the core to pH 4 was most suitable for studying enteric coating performance.

Keyphrases □ Enteric coating—*in vivo* disintegration, radiotelemetry, hydroxypropyl methylcellulose phthalate □ Hydroxypropyl methylcellulose phthalate—*in vivo* disintegration, tablet coating, radiotelemetry □ Radiotelemetry—*in vivo* disintegration, hydroxypropyl methylcellulose phthalate tablet coating

Enteric coating of dosage forms has been used in several ways to improve drug delivery. For example, the bioavailability of acid-labile drugs such as erythromycin can be improved by avoiding exposure of the drug to the gastric contents (1). A second reason for using an enteric coating is to avoid gastric irritation caused by drugs such as aspirin (2). Enteric coating has also been used to delay the release of a drug taken at bedtime with the aim of ensuring therapeutic blood levels when the patient awakes (3).

Several methods are available for evaluating enteric coatings. A widely used *in vitro* test is the USP disintegration test for enteric-coated tablets (4). *In vivo* methods of following the

fate of dosage forms in the GI tract utilize techniques such as endoscopy (5), X-rays (3, 6), external scintigraphy (7-9), whole body scintillometry (10, 11), or a combination of these techniques (12). Pharmacokinetic data (13, 14) can also be used to estimate release times for enteric-coated products. The USP and similar *in vitro* tests have been compared with *in vivo* methods in several reports (3, 6, 15). Results indicate that *in vitro* tests tend to underestimate the disintegration time in the human GI tract. However, they provide an inexpensive and convenient way of screening the performance of the enteric coating. *In vivo* techniques have various advantages and disadvantages. The most obvious advantage is that the coating is tested under the actual conditions of use. Endoscopic, X-ray, and scintigraphic techniques have the added attraction of providing visual information. For endoscopy and X-ray techniques, data are collected at intervals rather than continuously, so exact gastric emptying and disintegration times cannot be obtained. With X-ray, scintillometry, and external scintigraphy, care must be taken to minimize exposure of the subject to radiation, although this is less of a problem in the latter cases. All the techniques for *in vivo* studies described above require either a skillful technical staff, expensive equipment, or both. Pharmacokinetic analyses of blood levels or urinary excretion data do not necessitate exposure to radiation, but there is the disadvantage of being unable to distinguish long gastric emptying times from slow enteric-coat dissolution times.

In the current report, a radiotelemetric method for the *in vivo* evaluation of enteric coatings is described, and its advantages and disadvantages are compared with those of other available methods.

EXPERIMENTAL SECTION

Tablets—Appropriate ratios of citric acid to citrate were chosen to formulate buffered tablet cores at pH 3, 4, and 5. The pH values were chosen so that disintegration/dissolution of the tablet in the upper intestine would produce an easily detectable pH drop (typically from pH ≥6 to the pH of the tablet buffers). In addition, if the coating failed, causing release of the buffers in the stomach, there would be a detectable upward shift in the gastric pH. The formula for pH 4 tablets is as follows: disodium citrate[1], 396 mg; citric acid[2], 144 mg; microcrystalline cellulose NF (PH 101)[3], 100 mg; modified cellulose gum[4], 64 mg; and lubricant[5], 14 mg.

After passing all the powders, except the lubricant, through a 40-mesh screen, they were mixed together and then wet granulated with a 50:50 mixture of ethanol–methylene chloride in a planetary blender[6]. The granules were dried at 55°C for 2 h, and the lubricant was added. Tablets weighing 720 mg were compressed using a single-punch tablet press[7]. The tablets were coated with hydroxypropyl methylcellulose phthalate[8] in a small laboratory pan coater. Other batches were prepared using the method outlined. To obtain a pH 3 buffering system, 192 mg of citric acid and 70 mg of sodium citrate[9] per tablet were used. For pH 5, the amounts were 64 mg and 290 mg, respectively. Coating weights varied from 20 to 34 mg per tablet, depending on the batch.

***In Vitro* Disintegration Test**—The USP disintegration test (4) for enteric-coated tablets was used to determine the *in vitro* disintegration time for each batch. Enzymes were omitted from the disintegration media; otherwise, the method was followed as described. Disintegration time was recorded as the time required, after transfer to simulated intestinal fluid, for all material to pass through the screen.

Animals—Four healthy male beagle dogs, ranging in weight from 10.6 to 17.3 kg, were selected for study. Before each experiment, the dogs were fasted for 24 h. Control GI pH profiles were obtained by administering a calibrated Heidelberg capsule[10] followed by 20 mL of water. The control profiles were used for comparison with profiles obtained after administering the enteric-coated tablets.

Radiotelemetric Technique—For each experiment, a Heidelberg capsule was calibrated using pH 1 and pH 7 standard buffer solutions. The enteric-coated tablet was then attached to the capsule with thread and acrylic glue (see Fig. 1). An antenna was strapped around the midriff of the dog to detect output from the Heidelberg capsule. The capsule–tablet combination was administered followed by 20 mL water, and the pH was continuously monitored using the radiotelemetric system[10] for a 6-h period. Important parameters such as baseline gastric pH, gastric emptying time, intestinal pH subsequent to gastric emptying, and time of onset of core disintegration were determined by analyzing the pH–time profile.

Statistical Analysis—The following statistical tests were applied to the data:

1. Linear regression to determine the degree of correlation between gastric emptying time and disintegration time, and between *in vivo* and *in vitro* disintegration time;
2. Analysis of variance to assess dog-to-dog, pH-to-pH, and batch-to-batch variation in the time of onset of disintegration *in vivo;*
3. Bartlett's test to analyze scatter differences between different groups of data in the *in vivo* tests.

Table I—Times for Onset of Disintegration of Enteric-Coated Buffered Tablets After Leaving the Stomach

Batch	Time for Onset, Min

RESULTS AND DISCUSSION

Performance of an enteric coating is evaluated by interpreting the pH profile generated by the radiotelemetric technique. Figure 2A shows a typical pH profile of the canine GI tract following administration of a Heidelberg capsule

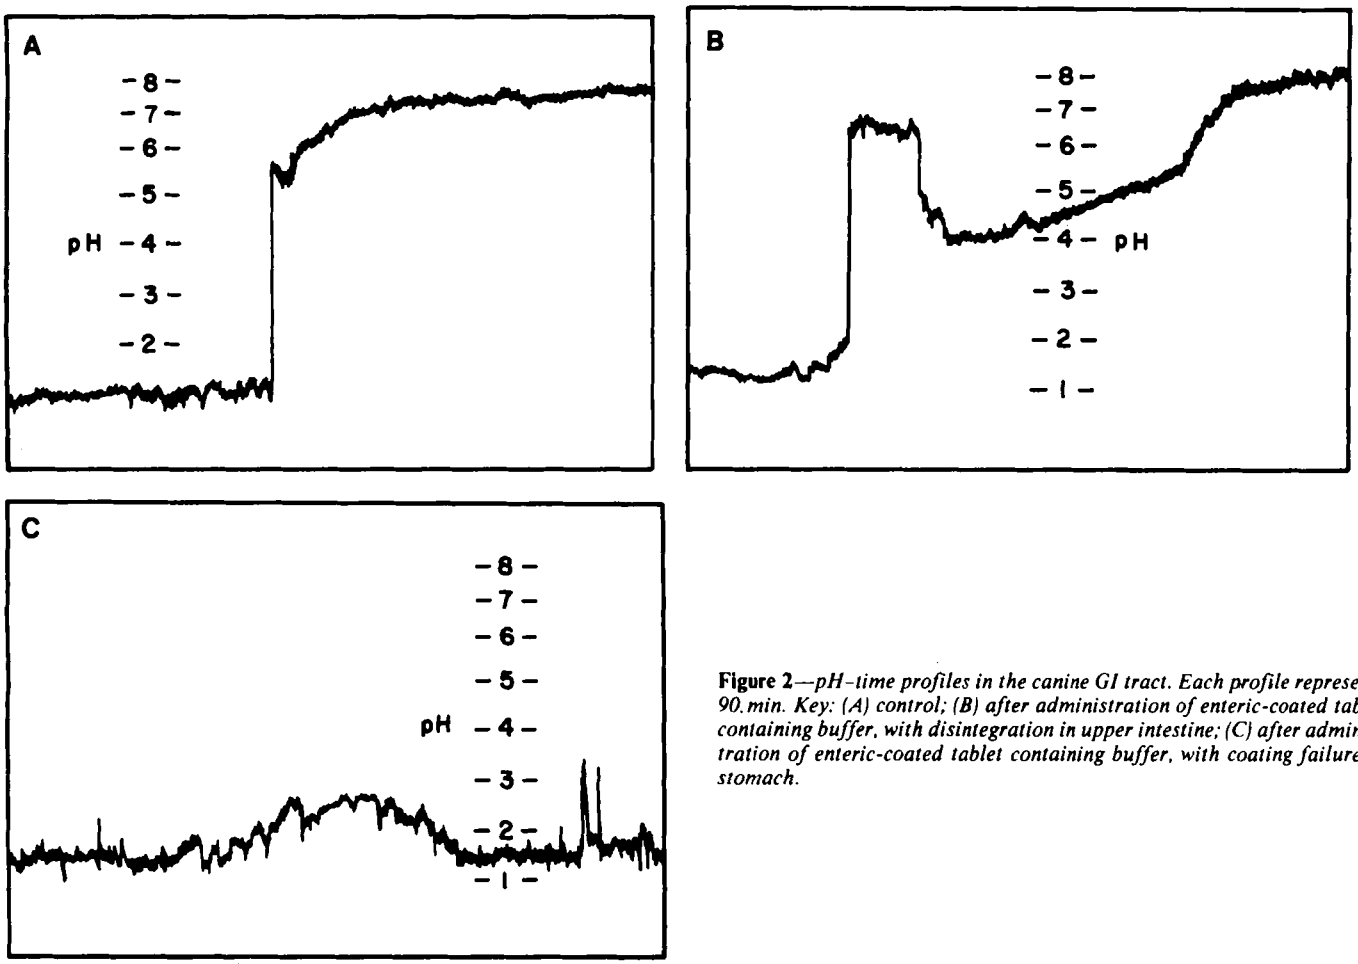

Figure 2—*pH-time profiles in the canine GI tract. Each profile represents 90 min. Key: (A) control; (B) after administration of enteric-coated tablet containing buffer, with disintegration in upper intestine; (C) after administration of enteric-coated tablet containing buffer, with coating failure in stomach.*

(control). In most cases, the gastric pH ranges from a pH slightly below pH 1 to ~2. Gastric emptying causes a sharp rise in pH to a value of 5.5–6.5, reflecting contact of the capsule with duodenal fluid. Thereafter, the pH rises gradually to ≥7.5. Note that the accurate measuring range of the Heidelberg capsule is pH 1–8, with a measuring error of ±0.5 pH units[11].

Unless the enteric coating ruptures prior to gastric emptying, the gastric pH after administration of an enteric-coated buffered tablet attached to a Heidelberg capsule is very similar to that observed in the control experiment. However, as shown in Fig. 2B, the pH profile in the upper intestine is altered distinctly when an enteric-coated buffered tablet is given. The pH rises at gastric emptying as in the control experiment, but when the coating dissolves the buffer materials are released and the pH drops rapidly. The time between gastric emptying and the start of the pH drop is designated as the time of onset of disintegration (t_{onset}). This method does not enable detection of completion of the core disintegration process. After the initial pH drop, there is a gradual rise in pH as the buffer materials are diluted and neutralized by secretion of bicarbonate ions until normal intestinal pH is recovered. Failure of the enteric coating to withstand gastric pH is detected by an increase in gastric pH from the baseline value, followed by a gradual return to the baseline value as shown in Fig. 2C.

A statistical analysis of the disintegration times for various formulations of enteric-coated buffered tablets in four dogs is presented in Table I. Twenty-nine tablets were administered: two failed in the stomach, one did not disintegrate within the observation period, and the rest disintegrated in the upper small intestine as expected. The mean disintegration time was 14.2 ± 2 min (*SEM*). Analysis of variance indicates that the mean disintegration time is not significantly different between dogs or between batches of tablets. However, there is a significant effect due to the tablet core pH ($p < 0.05$) with shorter mean disintegration time at pH 5 than at pH 3 or pH 4. Applying Bartlett's test to the results reveals that scatter in the disintegration time varies between dogs and between core pH values, but is not significantly affected (at a 95% confidence level) by the tablet batch. Overall, the statistical analysis suggests that the mean disintegration time is reproducible on both a dog-to-dog and batch-to-batch basis. Therefore, the radiotelemetric method is a reliable means of comparing enteric coating performance, provided tablet cores are formulated at the same pH. A convenient pH choice is pH 4, as in this case both gastric failure of the coat and disintegration of the coat in the upper intestine produce readily observable perturbations in pH.

The degree of correlation between *in vivo* and *in vitro* results can be judged by comparing the disintegration times presented in Table II. Linear regression analysis indicates that there is very little relationship between *in vivo* and *in vitro* disintegration test results ($r = -0.09$). The *in vivo* t_{onset} may be shorter, longer, or similar to the t_{disint} observed in the USP disintegration test for enteric-coated tablets; the times observed differed by as much as a factor of five. These results indicate that the USP test may not always be capable of predicting the *in vivo* performance of enteric coatings.

The extent of correlation between an *in vitro* test and results obtained *in vivo* depends on how closely the *in vitro* experimental conditions model the *in vivo* situation. Some specific differences between the USP test and the *in vivo* conditions encountered in this study include the following. The pH at which the hydroxypropyl methylcellulose phthalate coating used in this study begins to dissolve is pH 5.0[8]. The pH after gastric emptying in the dogs was typically between 5.5 and 6.5 (range 4.5–7.0), considerably lower than that of simulated intestinal fluid used in the *in vitro* test. This discrepancy in the *in vivo* and *in vitro* pH values, combined with the variation in the *in vivo* intestinal pH profile, may have contributed to the poor correlation in disintegration times for the coating studied. Another factor may have been the difference in the disintegration endpoints. *In vivo*, the t_{onset} was taken as the time

Table II—*In Vitro* and *In Vivo* Disintegration Times for Enteric-Coated Buffer Tablets[a]

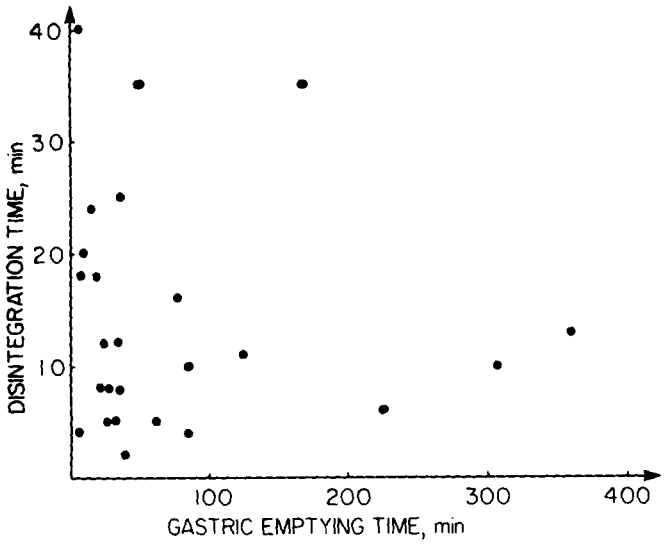

Figure 3—*Time of onset of disintegration of enteric-coated tablets in canine upper intestine* versus *gastric emptying time.*

when the pH first started to fall, whereas *in vitro* the time taken for complete disintegration was measured. Differences in other factors such as agitation and enzyme levels may also have played a role.

Two studies in the literature contain data which provide a comparison of disintegration times in humans with those observed in *in vitro* experiments (3, 14). In both cases the USP or similar test predicted shorter disintegration times than were observed *in vivo* [31 min *versus* >50 min (14), and <20 min *versus* 96 min mean disintegration time (3)]. A further study of *in vitro* and *in vivo* disintegration times of five batches of tablets in dogs (6) showed a variable ratio between *in vivo* and *in vitro* disintegration times, with up to a twofold difference in values. In that study, the batches were coated with different enteric coatings, so the variation between *in vivo* and *in vitro* results may have depended to some extent on the coating type. The value of *in vitro* disintegration tests has been further discussed by Aiache *et al.* (16).

In contrast to the poor *in vivo–in vitro* correlation, there appears to be some correlation between canine and human results. The data presented in this paper show that the average time for onset of disintegration in the canine upper intestine is 14.2 ± 2 min. This time compares closely with the time reported for disintegration in humans of tablets coated with hydroxypropyl methylcellulose phthalate. Using an endoscopic technique, Ehrhardt *et al.* (5) reported a disintegration time of 15 min after gastric emptying. This agreement suggests that use of the radiotelemetric technique in dogs gives a reasonable prediction of disintegration times in humans, at least for hydroxypropyl methylcellulose phthalate-coated tablets.

It has been proposed in the literature that the disintegration time may be dependent on the gastric emptying time. Blythe *et al.* (3) suggested that disintegration time is shorter for tablets which reside in the stomach for a long time than for those which are emptied quickly. In the current study, however, there was no significant correlation ($r = -0.08$) between gastric emptying time and disintegration time (Fig. 3).

The main advantage of the radiotelemetric method over other available methods is that the onset of disintegration of the enteric-coated tablet in the upper intestine can be accurately determined since the pH of the luminal contents is monitored continuously. It is also possible to pinpoint coating failures such as rupture in the stomach and nondisintegration in the intestine. The technique does not expose the subject or the investigators to radiation, as do other commonly used techniques. Because the dimensions of the Heidelberg capsule are fairly small (diameter, 7 mm; length, 20 mm) there is little chance of obstruction in the GI tract; no obstruction problems were encountered in the dogs studied. The Heidelberg capsule has little apparent effect on the gastric emptying of single-unit dosage forms; in the current study mean gastric-emptying time for the capsule-tablet combination was 80 ± 18 min (*SEM*) with a range of 5–360 min compared with a range of <30 min to >7 h (median 96 min) for tablets in the radiographic study by Blythe *et al.* (3).

The chief limitation of the method described in this report is that it is applicable only to monolithic dosage forms. A way of attaching more than one particle to the Heidelberg capsule must be devised, so that the method can be extended to evaluating enteric coat performance on multiparticulates. The fact that buffers must be incorporated into the test dosage form presents no more of a limitation than including barium in tablets to be evaluated by X-ray or γ-emitters in tablets studied by scintigraphic techniques. The advantages over pharmacokinetic methods lie in the greater accuracy with which the disintegration time can be determined and in avoiding blood or urine collection. The radiotelemetric technique requires less experimental expertise and less expensive equipment than other techniques and provides a facile and accurate means of evaluating enteric coating performance *in vivo.*

Dissolution Studies of Some Sustained-Release Theophylline Dosage Forms

KEITH J. SIMONS *x, F. ESTELLE R. SIMONS ‡, KIM D. PLETT *, and CHARLES SCERBO *

Received February 8, 1983, from the **Faculty of Pharmacy, and ‡Department of Pediatrics, Faculty of Medicine, University of Manitoba, Winnipeg, Manitoba, R3T 2N2 Canada.* Accepted for publication September 19, 1983.

Abstract □ Dissolution studies were carried out with the USP rotating-basket apparatus in both simulated gastric and intestinal fluids. Four different brands of sustained-release theophylline products of different strengths (nine formulations) were studied. The percentage of the dose released in 1 h in gastric fluid ranged from (mean ± *SD*) 6.6 ± 0.9 to 50.1 ± 3.8%. By 6 h, the percentage of the dose released ranged from 10.8 ± 1.8 to 86.5 ± 5.2%. Similar formulations of different strengths released significantly different fractions of their dose at respective sampling times. In intestinal fluid, some formulations released 100% of their dose within 3–4 h, behaving more like enteric-coated preparations. One dosage form appeared to release drug by an apparent zero-order rate. From one brand of theophylline (two strengths), only 48.1 ± 5.6 and 29.9 ± 4.1% of label strength, respectively, dissolved in 25 h in intestinal fluid. Some of these *in vitro* results were rank-correlated to previously reported bioavailability and pharmacokinetic studies.

Keyphrases □ Sustained-release formulations—dissolution, USP rotating-basket apparatus, theophylline □ Theophylline—dissolution, sustained-release formulations, USP rotating-basket apparatus, □ Bioavailability—theophylline, sustained-release formulations, USP rotating-basket apparatus

The importance of using sustained-release theophylline dosage forms for the treatment of respiratory diseases in adults (1–4) and children (5–9) is well established. The absorption characteristics of many sustained-release theophylline products have been defined by several investigators (10, 11), and correlations with *in vitro* dissolution studies have been described (12, 13). However, disintegration and dissolution tests are still the compendial standards of content release and uniformity (14), and only minimal data for theophylline sustained-release products are available. Therefore, dissolution studies were performed on several sustained-release dosage forms, some of which have already been evaluated for bioavailability and pharmacokinetic characteristics (10, 15).

EXPERIMENTAL SECTION

Dosage Forms—Nine commercially available sustained-release theophylline dosage forms were evaluated. Products A[1], B[1], C[2], and D[2] were capsule forms, and products E[3], F[3], G[3], H[4], and J[4] were tablets.

Dissolution Apparatus—The USP rotating-basket dissolution apparatus (14) was used in all experiments. Studies were carried out in simulated gastric or intestinal fluids. Simulated gastric fluid was prepared by dissolving 2 g of NaCl[5] and 3.2 g of pepsin[5] in 7 mL of concentrated HCl[6] and sufficient water to make 1000 mL; the pH of this solution was 1.2. Simulated intestinal fluid was prepared by dissolving 6.8 g of KaH_2PO_4[5] in 250 mL of water. To this were added 190 mL of 0.2 M NaOH[5] and 400 mL of water. The solution was thoroughly mixed, 10 g of pancreatin[5] was added, and the pH was adjusted to 7.5 ± 0.1 with 0.2 M NaOH before the volume was made up to 1000 mL with water.

Procedure—In each study, six dosage forms were tested simultaneously, with one dosage form in each position of the dissolution apparatus. The dosage forms were not added until 900 mL of the solution had reached 37°C in a water bath. This temperature was maintained throughout the study. The baskets were rotated at 100 rpm. All dosage forms were tested in both simulated gastric and intestinal fluids under sink conditions. In simulated gastric fluid studies, 1-mL samples were removed at 0.5- or 1-h intervals for up to 6 h. In simulated intestinal fluid, the sampling times were adjusted so that the rate of release of theophylline from each different dosage form could be optimally evaluated. For dosage forms A, B, E, F, and G, 3-mL samples were removed at 1-h intervals for 12 h and at 25 h. For dosage forms C and D, 3-mL samples were removed every 15 min for a total of 3 h. For dosage forms H and J, 3-mL samples were removed at 10, 20, 30, 40, 50, 60, 75, 90, 105, 120, and 240 min. Samples were not filtered, as no particles were observed, and the volume of sample removed was replaced by fresh dissolution medium at 37°C. All samples were refrigerated until the theophylline content was determined by a spectrophotometric or HPLC procedure (15).

Theophylline Quantitation—Stock solutions of theophylline were prepared in simulated gastric or intestinal fluid at concentrations of 5, 10, 15, 20, and 25 μg/mL. The theophylline content in gastric fluid samples was determined by diluting the samples 2–20 times with gastric fluid and measuring the absorbance at 271 nm[7]. Appropriately diluted simulated gastric fluid samples were used as a reference.

In simulated intestinal fluid samples, the theophylline content had to be extracted before the absorbance could be determined spectrophotometrically. A 0.5-mL aliquot of 2.5 M acetate[5] buffer (pH 6.4) and 6 mL of chloroform–isopropyl alcohol[5] (20:1) were added to 2-mL samples of intestinal fluid.

[a] Mean values; *SD* in parentheses. [b] — Samples not collected.

Samples were extracted by shaking on a reciprocating shaker for 5 min and then centrifuging for 5 min. The upper aqueous phase was removed by aspiration, and 5 mL of the organic layer was extracted with 5 mL of 0.1 M NaOH[5] by shaking for 5 min and centrifuging for 10 min. The upper aqueous phase was transferred directly to a spectrophotometric cuvette, and the absorbance was measured at 271 nm[7]. Simulated intestinal fluid samples containing no drug and extracted by the same procedure were used as references.

Calibration curves were constructed by plotting absorbance *versus* theophylline concentration with simulated gastric and intestinal fluid stock solutions. Theophylline concentrations from studies of dosage forms E, F, and G were determined by an HPLC procedure described previously (15). Analytical procedures were compared, and results from both tests were identical.

RESULTS AND DISCUSSION

It is not usually possible to differentiate between structurally related compounds, such as decomposition products or metabolites, by spectrophotometric methods of analysis. However, for dissolution studies of a dosage form containing a single chemical entity, this spectrophotometric procedure had excellent sensitivity and specificity. Since the results from these spectrophotometric assays were identical to those obtained by HPLC analysis, it was assumed that no detectable decomposition occurred during these dissolution studies. In the gastric fluid medium, calibration curves were linear over the concentration range of 0–50 μg/mL, and through a 10-week period they had a maximum coefficient of variation of 9.6%. Nevertheless, calibration curves were determined daily for each set of analyses. Similar results were obtained for the intestinal fluid samples, with a maximum coefficient of variation of 10.6% over a 10-week period. The results from the HPLC procedure had a maximum coefficient of variation of 3.6%. In all individual curves, correlation coefficients were always >0.995.

The maximum dose of theophylline evaluated in these studies was 300 mg, and the volume of sample removed for analysis was replaced by fresh dissolution medium at 37°C, so that the 900-mL initial volume was always maintained. The solubility of theophylline at 25°C is 1 g/120 mL in distilled water (16), so that if the total 300-mg dose dissolved during the study, only 4% of the total solubility of theophylline would be achieved. Therefore, sink conditions were maintained in all studies (17).

The absolute bioavailability of orally administered theophylline in aqueous solutions was calculated to be 100%; absorption was rapid, with peak serum concentrations occurring at 1 h after dose administration (18). The rate and extent of theophylline absorption after administration of sustained-release products would, therefore, be controlled by the rate and extent of drug release from the dosage form. Also, since these dosage forms may contain larger doses of drug than conventional preparations, the rate and completeness of drug release from the matrix must be uniform and well controlled. Fluctuations in serum theophylline concentrations will then be minimal, and efficacy will be achieved without toxicity.

The efficacy and safety of most sustained-release theophylline dosage forms has been well documented (1–9). However, variability and incompleteness

[a] Mean values; *SD* in parentheses. [b] Adjusted time intervals (h). [c] Adjusted time intervals (min).

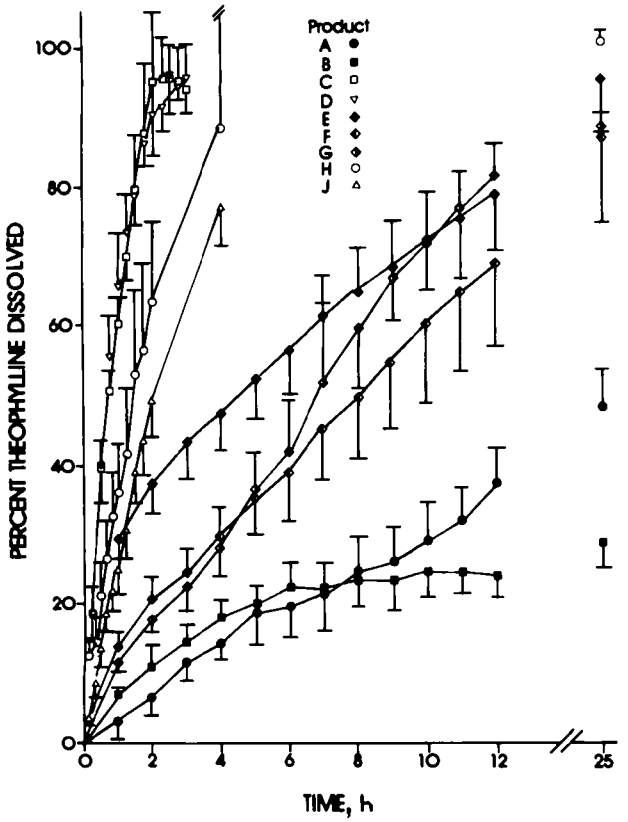

Figure 2—*Percent theophylline dissolved in simulated intestinal fluid* versus *time. Results are mean + or − SD; data are from six dosage forms.*

of theophylline release from some sustained-release preparations after single-dose administration to asthmatic patients has been demonstrated (10). Similar results have been found in the present dissolution studies with the rotating-basket dissolution apparatus (14) and by evaluating the products in both simulated gastric and intestinal fluids.

The percentages of theophylline dissolved at various times from the simulated gastric fluid studies are presented in Table I, and the percent dissolved *versus* time plot is shown in Fig. 1. The dosage forms studied released 6.6 ± 0.9 to 50.1 ± 3.8% of their drug content within 1 h in simulated gastric fluid. Although no simple correlation exists, the values obtained for the percentage of the dose released in 1 h *in vitro* from these products exhibit the same rank order as the values obtained at 1 h *in vivo* with some of these same products (10).

After the initial release of drug through the first 0.5–1.0 h, all of the products displayed some type of sustained-release characteristics (Fig. 1). However, the variability between products clearly demonstrates that these products are not readily interchangeable. Since the mean gastric residence time has been reported to be 3.61 ± 1.47 h (19), the dissolution studies in simulated gastric fluid were terminated after 6 h. At that time, the mean percentage of the dose released ranged from 10.8 ± 1.8 to 86.5 ± 5.2% (Table I).

Of greater concern is the differences in the rate of release of drug from similar preparations of different strength. Both at 3 and 6 h, products A and B, C and D, and H and J all released significantly different amounts of drug ($p \leq 0.005$). Product E released significantly more drug than F and G at 3 h ($p \leq 0.005$), but not at 6 h. Products F and G released similar amounts of drug at 3 and 6 h ($p = 0.005$). Theophylline doses are often individualized by using a combination of different strengths of the same brand of product (4). However, different strengths of the same brand cannot be arbitrarily assumed to release drug at similar rates. A more rational approach may be to adjust the dose by taking one-half of the higher strength dosage form to individualize the dosages. No significant difference was detected *in vivo* when this approach was used for product E (15). In addition, these *in vitro* studies may not reflect the *in vivo* situation. The *in vivo* results for products E and G were not significantly different (10).

Since these products were all sustained-release dosage forms, the dissolution studies in simulated intestinal fluid provide additional information. The percentage of theophylline dissolved at various times in simulated intestinal fluid is shown in Table II, and percent dissolved *versus* time plots for all dosage forms are presented in Fig. 2. The results from these studies show even greater product variability.

Almost all of the theophylline content, 93.9 ± 2.8 and 95.7 ± 5.1% from products C and D, respectively, was released in 3 h in simulated intestinal fluid. This means that the rate of release of drug from these dosage forms may be very dependent on gastric emptying time. These two products also yielded the fastest rate of drug release in simulated gastric fluid (Table I, Fig. 1) and displayed the characteristics of enteric-coated formulations rather than sustained-release dosage forms. These products also exhibited similar characteristics *in vivo* (10), as virtually 100% of the dose was absorbed in 6 h from these formulations. The results obtained from the two different strengths of this dosage form in simulated intestinal fluid were not significantly different at any time ($p = 0.005$).

Although the results from products E, F, G, and H were not significantly different in gastric fluid at 6 h ($p = 0.005$), the results obtained in intestinal fluid were different ($p \leq 0.005$). Products H and J released 88.5 ± 18.5 and 77.0 ± 5.7%, respectively, of their drug content within 4 h, whereas products E, F, and G released only 47.2 ± 4.9, 35.3 ± 5.1, and 30.6 ± 7.0%, respectively. Unfortunately, products H and J were not studied *in vivo* previously (10).

One interesting aspect of products E, F, and G is that the percent theophylline released *versus* time plots are linear after 3 h (Fig. 2). These results indicate that an approximation to zero-order release from these dosage forms was achieved. These findings have also been reported in previous studies *in vivo* (15). Despite the delayed release, virtually all of the dose was released from these products between 12 and 25 h. These results confirm the earlier *in vivo* studies (10) in which 100% of the dose appeared to be absorbed by 16 h.

Products A and B demonstrate very poor drug availability both in simulated gastric and intestinal fluids. At 25 h, only 48.1 ± 5.6 and 29.5 ± 4.1% of the dose was released, respectively, for products A and B. These results mirrored the earlier *in vivo* findings in which only 70% of the dose appeared to be absorbed by 20 h. Again, the results from the two dosage forms of different strengths were significantly different ($p \leq 0.005$).

All results were also analyzed by plotting the log percentage of the labeled dose remaining to be dissolved *versus* time. In some instances these plots were linear. However, the fact that these relationships may be simply artifacts of the systems has been thoroughly examined and discussed previously (20). Therefore, these results are not presented.

In conclusion, the *in vitro* dissolution results in this study were obtained with the rotating-basket dissolution apparatus and independent trials in both simulated gastric and intestinal fluids (14). The pattern of drug release from these sustained-release products obtained *in vitro* mirrored the *in vivo* absorption results obtained with some of these products (10, 15). These rank-order comparisons provide additional information as to the usefulness of dissolution studies as compendial methods for determining product content, uniformity, and rate and extent of drug release.

Abstract □ A new dosage form of levodopa, which has the characteristics of loading high concentrations of levodopa at the upper part of the intestine, has been developed to improve its bioavailability. It is shown that an effervescent tablet formulation, coated with hydroxypropyl methylcellulose phthalate (carboxybenzoyl radical content: 20–24%) as the enteric material, is suitable for the purpose of dissolution. This was confirmed from animal experiments, which showed that tablets of this composition disintegrate instantly on reaching the upper part of the intestine. This tablet was considered appropriate for the bioavailability tests described in this paper.

Keyphrases □ Levodopa—effervescent enteric-coated tablet, intestinal absorption, dissolution □ Effervescent enteric-coated tablet—levodopa, intestinal absorption, lag time of dissolution and absorption, effect of size and shape □ Film material—hydroxypropyl methylcellulose phthalate, effervescent enteric-coated tablet, levodopa

It has been shown in previous work in this series (1, 2) that the bioavailability of levodopa could be improved by loading high concentrations of the drug at the upper part of the intestine, the optimum site of absorption, and then inducing temporary saturation of levodopa decarboxylase. The present work describes the preparation of an oral solid dosage form of levodopa with improved bioavailability. The *in vitro* dissolution and *in vivo* disintegration behavior also are reported.

EXPERIMENTAL SECTION

Preparation of Effervescent Enteric-Coated Tablets of Levodopa [I]—A granular mixture of levodopa USP and carboxymethylcellulose[1] was prepared by the wet granulation method using an aqueous solution of hydroxypropyl cellulose[2] as a binder. All other diluents, effervescent agents, lubricants, and/or coloring agents were mixed with the dried granulation, and the mixture was compressed into tablets. These tablets were coated successively with hydroxypropyl methylcellulose USP (II) (5% w/w) and then with hydroxypropyl methylcellulose phthalate (III)[3] (10% w/w) in methylene dichloride–ethanol (1:1, w/w) solution[4] to obtain enteric-coated tablets. All the coating agents that were used here are accepted for drug use by the FDA.

Dissolution Tests—A modified disintegration test apparatus was used in the dissolution tests of levodopa and/or dyes (3). The frequency rate of the basket-rack assembly was set between 5 and 20 cpm. Ten-mesh stainless steel cloth was fitted over the top of the basket-rack assembly to prevent the tablet from floating out of the tube of the assembly during dissolution.

Dissolution media (900 mL) at various pH values, prepared by mixing test solutions 1 and 2 (JP IX), were heated to 37 ± 0.5°C and placed in the dissolution apparatus. One tablet was placed in the basket. The solution was drawn from the flask through the flow cell (length 5 mm) by a pump[5] and returned to the flask at a flow rate of ~25 mL/min. The differences in absorbance between λ_1 (258.5 nm) and λ_2 (281 nm) for levodopa, λ_1 (620 nm) and λ_2 (662 nm) for methylene blue, and λ_1 (600 nm) and λ_2 (522 nm) for erythromycin were measured with a dual-wavelength spectrophotometer[6] and

Total weight	423	423	423	423	423

recorded continuously. The following parameters were obtained from the dissolution curves in several runnings: t_{lag} (lag time of dissolution), t_{10} (time required to dissolve 10% of labeled drug), t_{90} (time required to dissolve 90% of labeled drug), and $t_{90} - t_{10}$.

Measurement of the Dissolution Time of the Enteric Coating Material—Fifty-milligram portions of 20-32-mesh fractions of each coating material were suspended in media of various pH values, as described in the dissolution test, and agitated with a magnetic stirrer (9 mm in diameter and 30 mm in length) at ~500 rpm at 37 ± 0.5°C. The dissolution time of the suspended particles was measured visually.

Lag Time Determination of Levodopa Absorption—Two samples were used for this study. Ten healthy male beagle dogs, 10.0–14.0 kg, were fasted for ~16 h and divided into two groups of five dogs each. Crossover experiments were carried out at 1-week intervals. The dogs were dosed orally, and levodopa absorption was measured by observing the time at which the dogs began vomiting, which indicated a significant release of the drug with subsequent absorption.

Measurement of the Disintegration Site of Tablets *In Vivo*—*Experiment No. 1*—Two male beagle dogs, 10.7 and 11.3 kg, were each orally dosed with two samples. Immediately after the dogs began vomiting, they were anesthetized with pentobarbital sodium[7] (0.6 mL/kg), placed on their backs, and killed by exsanguination. The abdomens were immediately opened and the entire GI tracts were excised and opened in order to observe the disintegration sites. Such observation was made possible by the dye contained in the tablets.

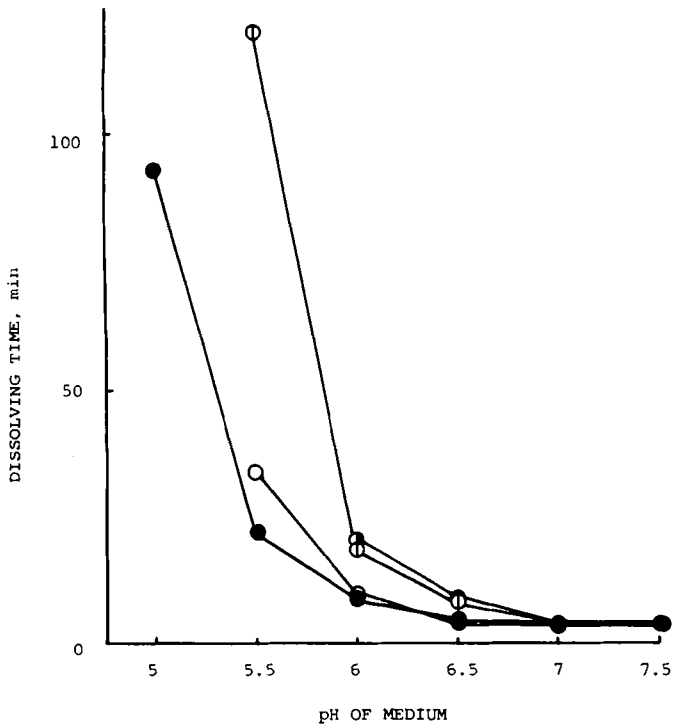

Figure 2—*pH profile of dissolution time of various enteric film materials. Key: (●) III-45; (○) III-50; (◐) III-55; (◑) IV.*

[7] Dainippon Pharmaceutical Co., Ltd.

Experiment No. 2—One male beagle dog, 13.9 kg, was orally dosed with two tablets from each sample. Fifty minutes after the dog began vomiting, it was anesthetized with pentobarbital sodium 6 and examined, as in experiment no. 1.

RESULTS AND DISCUSSION

From the results of the *in vitro* and *in situ* experiments of levodopa absorption characteristics, it was found that levodopa absorption from the solid dosage form was enhanced by:

1. Selecting the correct enteric dosage form to inhibit the levodopa decomposition in the stomach and ensure a high concentration of levodopa at the absorption site.
2. Selecting the appropriate enteric film materials to obtain rapid disintegration and dissolution characteristics in the upper part of the intestine.
3. Investigating dissolution characteristics so as to obtain a high concentration of levodopa at the onset of dissolution and to inhibit the conversion to dopamine (4) as much as possible by decarboxylase distributed in the intestine, during the absorption process.
4. Investigating product form and size to minimize variations in lag time of absorption and to shorten the lag time of absorption due to variability of individual gastric transit times.

The *in vitro* dissolution curve showing the aforementioned characteristics can be seen in Fig. 1. One of the main purposes of this report was to obtain a preparation having the dissolution characteristics shown in Fig. 1.

Selection of Enteric Film Material—The hydroxypropyl methylcellulose phthalate (III) used had different carboxybenzoyl radical contents (45[8], 50[9], 55[10]). Cellulose acetate phthalate (IV) was selected as a reference because

it is used extensively in the marketplace. The relationship between the dissolution time of the enteric film material and the pH of the medium is shown in Fig. 2. It can be seen from Fig. 2 that there is no difference in dissolution time between materials at pH 7.0 and at pH 7.5. However, at more acidic pH levels, the dissolution time of the material was longer in the order of III-45, III-50, III-55, and IV. The relationship between dissolution lag time (t_{lag}) of tablets coated with various enteric materials and medium pH was also determined (Fig. 3), from which the same pattern as the film materials themselves can be seen.

Intestinal pH is known to be between ~6 and 7.5. It has been reported, however, that the pH of the duodenum was ~pH 7 and varied according to the pH of the stomach (5). On the other hand, it has been reported that disintegration and dissolution behavior at more acidic medium levels than the disintegration test solution (pH 7.5) should be used in evaluating bioavail-

[a] Disintegrated completely. [b] Not disintegrated.

ability of enteric-coated tablets (6). Moreover, considering the prevention of disintegration in the stomach, it might be more appropriate to evaluate film dissolving time or lag time of dissolution of enteric-coated tablets at pH 6–6.5. Therefore, III-50 was selected as the most appropriate material from among the four kinds of films used.

Preparation of I—Effervescent tablets were investigated to obtain characteristics of fast disintegration and instantaneous dissolution of levodopa preparations. The compressibility of levodopa was such as to require additives. For this reason, it was difficult to obtain the characteristics mentioned above in other dosage forms. A sodium bicarbonate–tartaric acid system was selected as the effervescent component, and the five kinds of tablets shown in Table I were prepared.

For these tablets, the relationship between the amount of effervescent component and lag time of dissolution (t_{lag}) and between the amount of effervescent component and rate of dissolution ($t_{90\text{-}10}$) were studied. The results are shown in Figs. 4 and 5. In the determination of $t_{90\text{-}10}$, the frequency of the basket-rack assembly was set to 5 cpm to clarify the differences among the preparations. It can be seen from Fig. 4 that as the amount of effervescent component is increased, the dissolution lag time will decrease. However, the dissolution lag time was found to become constant, and as seen in Fig. 5, the dissolution rate became smaller with the addition of >28 mg/tablet of sodium bicarbonate. These results confirmed, therefore, that formulation 4 in Table I was the more appropriate.

It is difficult to say why the lag times are different among the preparations,

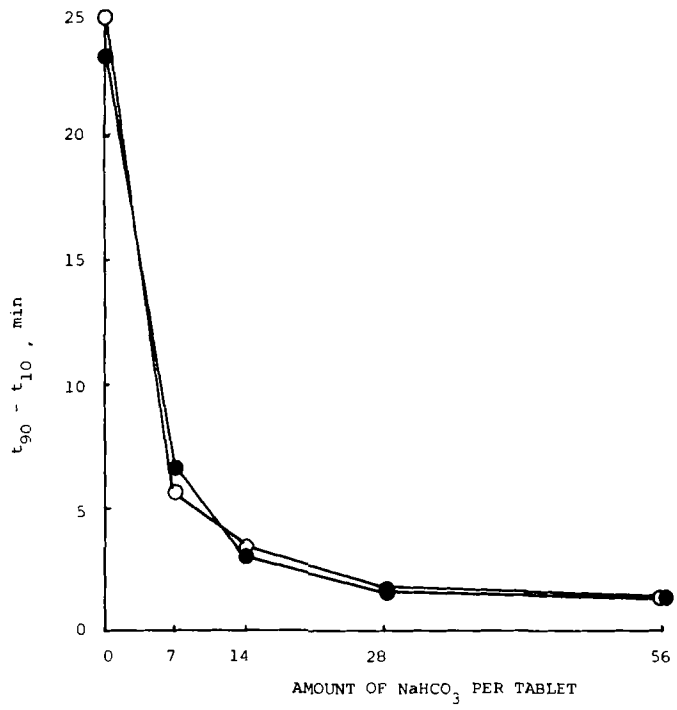

Figure 5—*Relationship between the dissolution parameter $t_{90\text{-}10}$ of effervescent enteric tablets of levodopa and the amount of sodium bicarbonate formulated in the tablet. The number of strokes was fixed at 5/min, and the pH was 7.5. Key: (●) uncoated tablet; (○) enteric tablet.*

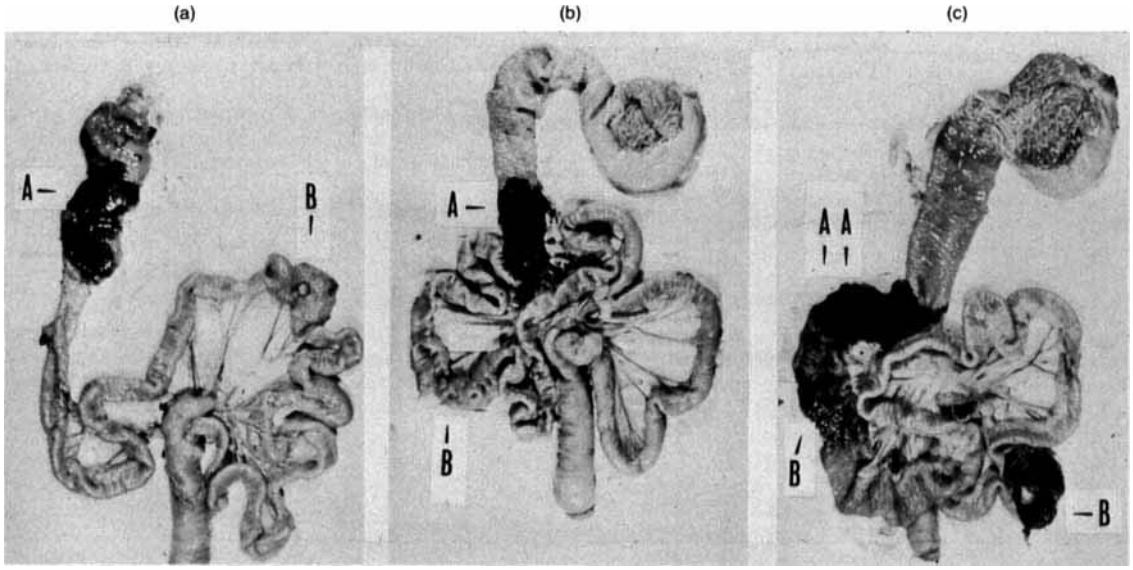

Figure 6—*Photographs of the* in vivo *disintegration site of samples A and B. Key: (a) dog 1; (b) dog 2; (c) dog 3. See Table III for experimental details.*

even with the same enteric film. One reason may be the variability in the rate of evolution of carbon dioxide due to slight differences in the rate of penetration of water into the tablet.

Disintegration Site of I—The disintegration site of I was investigated in beagle dogs to confirm *in vivo* behavior. Two samples, A and B, were used in the experiments; compositions and dissolution parameters are shown in Table II. Dyes were added to facilitate visual investigation of the site of and the rate of disintegration. Results are summarized in Table III and intestinal dissections are shown in Fig. 6.

The measured lengths of the duodenum and the small intestine are approximate. The lengths of the duodena measured were the same as that described in the literature (7) (*i.e.*, ~25 cm). As shown in Table III and Fig. 6, sample A disintegrated in the duodenum of each dog and the length of the dyeing site was short. These results suggest that disintegration of I started as soon as it reached the intestine and that the rate of disintegration or dissolution was instantaneous. In contrast, disintegration of sample B was very slow, and the sites of the disintegrations varied between the two tablets. In comparison with the dissolution parameters shown in Table III, it seems reasonable to assume that the dissolution lag time is correlated with the site of disintegration and that the rate of dissolution ($t_{90\text{-}10}$) is correlated with the length of the dyed site. Tablet I was designed for fast disintegration and high concentration in the upper intestine. From the above results, it was concluded that sample A was most suited to the purpose.

Effects of Tablet Shape and Size on the Lag Time of I—A 250-mg volume of levodopa was formulated into oval and round effervescent enteric-coated tablets. Table IV shows the characteristics of the two tablets. The tablets were compared with respect to lag time of levodopa absorption in dogs. The results (Fig. 7) indicate that the round tablet gives a shorter lag time and smaller intersubject variation in comparison with the oval one.

Three types of I, each containing 200 mg of levodopa but of different sizes, were prepared. Table IV shows the characteristics of the three sizes of tablets. Lag times of levodopa absorption were determined following oral administration of four kinds of I: the round tablet and the three types of tablets (samples 1–3) in Table IV. The results are shown in Fig. 8. The effects of size on lag time shown in Fig. 8 suggest that larger tablets have a longer levodopa absorption lag time in dogs.

Table IV—Characteristics of Effervescent Enteric Tablets of Levodopa used for the Measurement of Absorption Lag Time

	Round Tablets	Oval Tablets	Sample 1	Sample 2	Sample 3

CONCLUSIONS

An enteric formulation of levodopa can prevent drug absorption in the stomach and so can reduce the side effects of the drug on the stomach. Application of III-50 as an enteric coating film material resulted in an enteric tablet with rapid disintegration characteristics after passing through the stomach. Addition of an effervescent component to the tablet reduced the lag time of *in vitro* dissolution in intestinal fluid, and the rate of levodopa dissolution was accelerated. The conventional round shape was suggested as a suitable tablet shape and also a smaller size was recommended to minimize the lag time for the transit of the tablet into the intestine.

Dissolution and Ionization of Warfarin

V. J. STELLA ˣ, K. G. MOONEY *, and J. D. PIPKIN ‡

Received January 18, 1983, from the *Department of Pharmaceutical Chemistry, The University of Kansas, Lawrence, KS 66045.* Accepted for publication July 19, 1983. Present addresses: *American Cyanamid Co., Pearl River, NY 10965 and ‡Squibb Institute for Medical Research, New Brunswick, NJ 08903.

Abstract □ It has been shown in recent studies that warfarin exists in the solid state and in some nonaqueous solvents as a cyclic hemiketal. The present study was undertaken to investigate the ionization and ionization kinetics of warfarin, to confirm the probable existence of the cyclic hemiketal in aqueous solution, and to determine the possible consequences of the cyclic hemiketal to acyclic enol equilibrium and ionization kinetics on the dissolution rate of warfarin. The equilibrium aqueous solubility of un-ionized warfarin acid at 25°C and ionic strength 0.5 (with potassium chloride) was found to be 1.28×10^{-5} M, and its observed macroscopic pK_a was 5.03–5.06, depending on the method of determination. By comparing the aqueous pK_a of warfarin to phenprocoumin, a hydroxycoumarin that cannot exist in the cyclic hemiketal form, the hemiketal–acyclic enol ratio was estimated to be ~20:1. By stop-flow spectrophotometry, the ionization rate of warfarin (pH 3.5 jumped to pH 6.5) was found to have a $t_{1/2} < 1\text{–}2 \times 10^{-3}$ s. The dissolution rate of warfarin from a rotating disk (600 rpm), as a function of pH, was measured under nonbuffered but pH-stat conditions (μ = 0.5 with potassium chloride). The pH-dissolution rate profile for warfarin agreed with that calculated from an equation derived previously to describe the dissolution of instantaneous ionizing acids, *i.e.*, the profile was not perturbed from that expected from an acid of aqueous solubility 1.28×10^{-5} M (un-ionized form) and pK_a 5.06.

Keyphrases □ Dissolution—warfarin, ionization kinetics □ Warfarin—dissolution, ionization kinetics □ Ionization kinetics—warfarin, dissolution

The structure of the anticoagulant warfarin is usually depicted in the open-chain form (I) whereas it is known to exist in the solid state in the cyclic hemiketal form (II) (1, 2). Spectrometric studies (3–6) have confirmed that II is also the predominant form of warfarin in solution in various nonaqueous solvents. In water, un-ionized warfarin (I and/or II) exists in equilibrium with the enolate (III) (Scheme I).

Since warfarin exists as the hemiketal in the solid state and its ionization appears to be complex, we decided to study the dissolution rate *versus* pH (unbuffered, pH maintained by pH-stat) profile of warfarin to observe whether it behaved as an instantaneously ionizing acid (7, 8). To achieve this, the dissolution rate from a compressed rotating disk of warfarin at pH 2 and in the pH range 7–9.5 was studied along with its solubility, ionization characteristics, and ionization rate. By

CONCLUSIONS

An enteric formulation of levodopa can prevent drug absorption in the stomach and so can reduce the side effects of the drug on the stomach. Application of III-50 as an enteric coating film material resulted in an enteric tablet with rapid disintegration characteristics after passing through the stomach. Addition of an effervescent component to the tablet reduced the lag time of *in vitro* dissolution in intestinal fluid, and the rate of levodopa dissolution was accelerated. The conventional round shape was suggested as a suitable tablet shape and also a smaller size was recommended to minimize the lag time for the transit of the tablet into the intestine.

Dissolution and Ionization of Warfarin

V. J. STELLA ˣ, K. G. MOONEY *, and J. D. PIPKIN ‡

Received January 18, 1983, from the *Department of Pharmaceutical Chemistry, The University of Kansas, Lawrence, KS 66045.* Accepted for publication July 19, 1983. Present addresses: *American Cyanamid Co., Pearl River, NY 10965 and ‡Squibb Institute for Medical Research, New Brunswick, NJ 08903.

Abstract □ It has been shown in recent studies that warfarin exists in the solid state and in some nonaqueous solvents as a cyclic hemiketal. The present study was undertaken to investigate the ionization and ionization kinetics of warfarin, to confirm the probable existence of the cyclic hemiketal in aqueous solution, and to determine the possible consequences of the cyclic hemiketal to acyclic enol equilibrium and ionization kinetics on the dissolution rate of warfarin. The equilibrium aqueous solubility of un-ionized warfarin acid at 25°C and ionic strength 0.5 (with potassium chloride) was found to be 1.28×10^{-5} M, and its observed macroscopic pK_a was 5.03–5.06, depending on the method of determination. By comparing the aqueous pK_a of warfarin to phenprocoumin, a hydroxycoumarin that cannot exist in the cyclic hemiketal form, the hemiketal–acyclic enol ratio was estimated to be ~20:1. By stop-flow spectrophotometry, the ionization rate of warfarin (pH 3.5 jumped to pH 6.5) was found to have a $t_{1/2} < 1\text{–}2 \times 10^{-3}$ s. The dissolution rate of warfarin from a rotating disk (600 rpm), as a function of pH, was measured under nonbuffered but pH-stat conditions (μ = 0.5 with potassium chloride). The pH-dissolution rate profile for warfarin agreed with that calculated from an equation derived previously to describe the dissolution of instantaneous ionizing acids, *i.e.*, the profile was not perturbed from that expected from an acid of aqueous solubility 1.28×10^{-5} M (un-ionized form) and pK_a 5.06.

Keyphrases □ Dissolution—warfarin, ionization kinetics □ Warfarin—dissolution, ionization kinetics □ Ionization kinetics—warfarin, dissolution

The structure of the anticoagulant warfarin is usually depicted in the open-chain form (I) whereas it is known to exist in the solid state in the cyclic hemiketal form (II) (1, 2). Spectrometric studies (3–6) have confirmed that II is also the predominant form of warfarin in solution in various nonaqueous solvents. In water, un-ionized warfarin (I and/or II) exists in equilibrium with the enolate (III) (Scheme I).

Since warfarin exists as the hemiketal in the solid state and its ionization appears to be complex, we decided to study the dissolution rate *versus* pH (unbuffered, pH maintained by pH-stat) profile of warfarin to observe whether it behaved as an instantaneously ionizing acid (7, 8). To achieve this, the dissolution rate from a compressed rotating disk of warfarin at pH 2 and in the pH range 7–9.5 was studied along with its solubility, ionization characteristics, and ionization rate. By

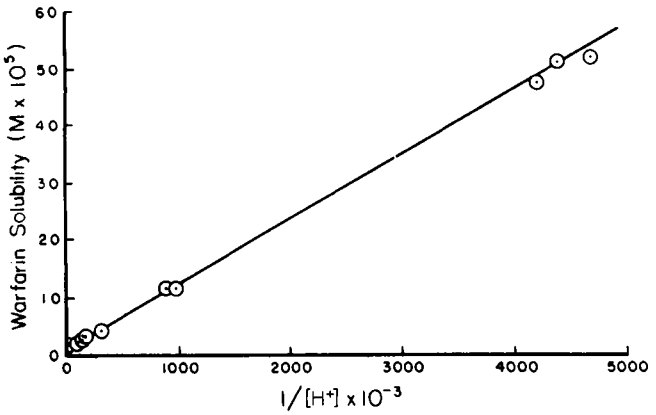

Figure 1—*Plot of the total solubility (S_T) of warfarin at 25°C* versus *$1/[H^+]$ for equilibrated 0.1 M acetate buffers, μ = 0.5 (potassium chloride): $S_T = 1.28 \times 10^{-5} + (112 \times 10^{-10}/[H^+])$ ($r = 0.999$; n = 29). $[HA]_0$ is obtained from the intercept, and K_a is obtained from slope/intercept.*

EXPERIMENTAL SECTION

Materials—Warfarin[1] and phenprocoumin[2] were used as supplied. All reactions, dissolution rates, and pK_a determinations were carried out in glass-distilled or doubly deionized carbon dioxide- and oxygen-free water. The buffer components, potassium chloride, and sodium hydroxide were of reagent or analytical reagent quality and were used without further purification.

pK_a and Solubility Determinations—*Method A*—The pK_a values of warfarin and phenprocoumin were determined spectrophotometrically[3] (9) at 282 (or 272) and 275 nm, respectively, at 25 ± 0.2°C and μ = 0.1 (with potassium chloride). The pK_a of warfarin was also determined spectrophotometrically at μ = 0.5 (with potassium chloride).

Method B—The solubility and pK_a of warfarin at 25 ± 0.5°C and μ = 0.5 (with potassium chloride) were determined by the solubility method (7, 10, 11). While determining solubility as a function of pH, care was taken to deoxygenate the solutions and to protect them from light. Analysis of the amount of dissolved warfarin was by spectrophotometry[3] of filtered samples, and the pH was adjusted to 11–12 with sodium hydroxide. A standard curve was prepared just before the measurements were taken.

Ionization Kinetics of Warfarin—The pH jump technique for studying ionization by stop-flow spectrophotometry[4] as previously described for the ionization of phenylbutazone (12), and phenindione (13, 14) was used to determine whether warfarin ionization might have a half-life measurable by this method ($t_{1/2} > 1\text{-}2 \times 10^{-3}$ s). Specifically, a 1.5×10^{-5} M (pH 3.5) solution of warfarin in 0.5 M KCl was jumped to pH 6.5 (0.1 M phosphate buffer; μ = 0.5 with potassium chloride), and transmission was recorded as a function of time (on the stop-flow spectrophotometer oscilloscope) at 272 nm[5] immediately after mixing (mixing time, $\sim 2 \times 10^{-3}$ s). Transmission changes as a function of time were observed down to 1×10^{-3} s/division on the oscilloscope.

Dissolution Study—Individual disks of 250 mg of warfarin were prepared by the method previously described for other acids (7, 8). Preslugging of the commercial warfarin and regrinding of the powder was necessary to produce disks which did not cap or crack on expulsion from the die. Dissolution rates were determined by previously described procedures (7, 8, 15). The continuous monitoring of dissolution was carried out at 285 nm for pH 2 (λ_{max} at pH 2) and at 292 nm (an isosbestic point) for all other pH values.

RESULTS AND DISCUSSION

The observed pK_a of warfarin and the macroscopic p$K_{a_{obs}}$, defined by Scheme I and Eq. 1:

$$K_{a_{obs}}{}^{warfarin} = \frac{[III][H^+]}{([I] + [II])} \qquad \text{(Eq. 1)}$$

and determined by method A at 25°C and μ = 0.1, was calculated to be 5.03 ± 0.01 (±*SD*). This was calculated from individual data points (in triplicate) for seven pH values in the range of 4.00–7.82, with the mean absorbance at pH 2.08, 2.88, and 3.02 representing the absorbancy of un-ionized warfarin and the absorbance at pH 11.77 representing the absorbancy of the enolate (9). A plotting technique described earlier (12–14) gave an identical result. The pK_a of phenprocoumin, under identical conditions, was determined to be 3.77 ± 0.01 (±*SD*). These determinations were carried out at μ = 0.1 for the purpose of comparison with earlier studies (12–14).

Inverting Eq. 1 and substituting the formulas for $K_{a_{enol}}{}^{warfarin}$ and K_a', as defined in Scheme I, gives Eq. 2 and 3, respectively:

$$\frac{1}{K_{a_{obs}}{}^{warfarin}} = \frac{[I]}{[III][H^+]} + \frac{[II]}{[III][H^+]} \qquad \text{(Eq. 2)}$$

$$= \frac{1}{K_{a_{enol}}{}^{warfarin}} + \frac{1}{K_a'} \qquad \text{(Eq. 3)}$$

The only difference in structure between warfarin enol (I) and phenprocoumin (IV) is the presence of a butanone group compared with an ethyl group at C-3, respectively. The presence of the carbonyl group in the butanone side chain of warfarin should have a negligible electron-withdrawing effect on the enol p$K_{a_{enol}}$ relative to the ethyl side chain in phenprocoumin. If it is also assumed that there is a negligible effect on p$K_{a_{enol}}$ by intramolecular hydrogen bonding and that warfarin and phenprocoumin do not exist significantly in a diketo form (12–14), then:

$$K_{a_{enol}}{}^{warfarin} \simeq K_a{}^{phenprocoumin} \qquad \text{(Eq. 4)}$$

By substituting $K_a{}^{phenprocoumin}$ for $K_{a_{enol}}{}^{warfarin}$ in Eq. 3, an estimate K_a' can be made. By using values of 9.33×10^{-6} for $K_{a_{obs}}{}^{warfarin}$ and 1.70×10^{-4} for $K_a{}^{phenprocoumin}$, Eq. 3 gives a value for K_a' of 9.87×10^{-6} or pK_a' of 5.00. Therefore, the fraction of un-ionized warfarin present in aqueous solution as II, which is defined by Eq. 5, is 0.95 or:

$$\frac{[II]}{[I] + [II]} = \frac{K_{a_{obs}}{}^{warfarin}}{K_a'} \qquad \text{(Eq. 5)}$$

The cyclic hemiketal–acyclic enol ratio is ~20:1 at 25°C and μ = 0.1. This conclusion is consistent with earlier spectrometric findings in other solvents (3–6).

Since the dissolution rate of warfarin was to be determined at μ = 0.5 for comparison with earlier studies (7, 8, 15), the pK_a of warfarin at this ionic strength was determined by both methods A and B. The observed pK_a of warfarin by method A was found to be 5.03 ± 0.02 (±*SD*).

The equilibrium solubility of a monoprotic weak acid in aqueous solution is given by:

$$S_T = [HA]_0 + [A^-] \qquad \text{(Eq. 6)}$$

where S_T is the total solubility of all the possible species, $[HA]_0$ is the saturated solubility of the un-ionized form(s) of the weak acid, *i.e.*, [I] + [II] in the case of warfarin, and $[A^-]$ is the amount of warfarin enolate, [III], present at equilibrium at the particular pH in question. Combining Eq. 6 with the K_a expression (Eq. 1) for warfarin yields:

$$S_T = [HA]_0 + \frac{K_{a_{obs}}{}^{warfarin}[HA]_0}{[H^+]} \qquad \text{(Eq. 7)}$$

A plot of S_T *versus* $1/[H^+]$ yields an intercept of $[HA]_0$ and a slope from which $K_{a_{obs}}{}^{warfarin}$ can be calculated. Figure 1 depicts this relationship for warfarin. From the intercept, the intrinsic solubility of un-ionized warfarin at 25 ± 0.5°C and μ = 0.5 was found to be 1.28×10^{-5} M, the $K_{a_{obs}}{}^{warfarin}$ was 8.75×10^{-6} ($pK_{a_{obs}}{}^{warfarin}$ = 5.06). The correlation coefficient for the plot was 0.999 (10 pH values, 2.20–6.67, and a total of 29 individual solubility determinations). The pK_a value of 5.06 correlates well with the value determined spectrophotometrically in this study and previous determinations (16, 17), and the aqueous solubility of the un-ionized warfarin acid of 1.28×10^{-5} M is similar to a recorded value in 0.1 M HCl of 1.43×10^{-5} (18).

Based on the findings that the predominant form of warfarin in the solid state and the probable predominant, un-ionized form of warfarin in solution is II, it was interesting to speculate that the conversion of II to III by whatever mechanism might not be a diffusion-controlled process. By using a stop-flow spectrophotometer and a pH jump technique, the transmission *versus* time oscilloscope tracing from mixing of an unbuffered pH 3.5 warfarin solution with a 0.1 M phosphate buffer solution of pH 6.5 (final pH on mixing, 6.5) gave a straight line (slope = 0). The absorbance calculated from the transmission tracing was consistent with a solution of 0.75×10^{-5} M warfarin of pH 6.5, *i.e.*, at all oscilloscope settings down to 1×10^{-3} s/division, the reaction (ionization) was found to be complete within the mixing time (2×10^{-3} s) of the stop-flow spectrophotometer, *i.e.*, $t_{1/2} < 1\text{-}2 \times 10^{-3}$ s. Under similar circumstances, the carbon acid phenylbutazone has a half-life of $\sim 12 \times 10^{-3}$ s (12).

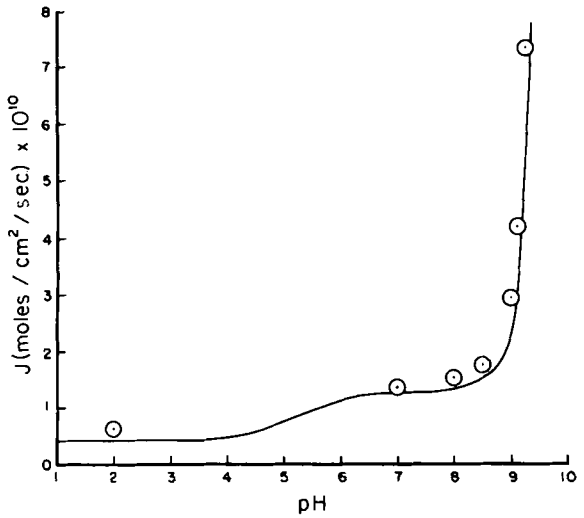

Figure 2—*Plot of the initial dissolution rate (flux) of warfarin from a rotating disk (600 rpm) as a function of pH, unbuffered but maintained by a pH-stat. Key: (⊙) experimental points (mean of 3–4 determinations at each pH); (—) predicted by Eq. 8.*

The dissolution rate of organic acids undergoing rapid ionization, dissolving from a rotating disk into nonbuffered aqueous solution under sink conditions in which the bulk solution pH has been maintained by a pH-stat, has been mathematically defined assuming a film model (7, 8) by:

$$J = \frac{D_{HA}}{h}[HA]_0 + \frac{D_H}{h}([H^+]_0 - [H^+]_h) + \frac{D_{OH}}{h}([\overline{O}H]_h - [\overline{O}H]_0) \quad \text{(Eq. 8)}$$

where J is the initial dissolution rate or flux with units of mol/cm²/s; D_{HA} is the diffusivity of the dissolving acid species in cm²/s; h is the film thickness of the diffusion resistance layer in cm; $[HA]_0$ is the molar saturated solubility of the dissolving acid under suppressed ionization conditions and is the amount of HA assumed to exist at the solid-liquid interface; D_H and D_{OH} are the diffusion coefficients (diffusivity) for hydrogen ion and hydroxide ion, respectively [2.8×10^{-5} cm²/s, (7)]; $[H^+]_0$ and $[H^+]_h$ are the hydrogen ion concentrations at the solid-liquid interface and in the bulk solution, respectively; and $[\overline{O}H]_h$ and $[\overline{O}H]_0$ are the hydroxide ion concentrations at the bulk solution and at the solid-liquid interface, respectively (calculated from the equation $[\overline{O}H] = K_w/[H^+]$). The aqueous diffusion layer thickness, h, can be calculated from (7, 8, 19):

$$h = 1.612 D_{HA}^{1/3} \nu^{1/6} \omega^{-1/2} \quad \text{(Eq. 9)}$$

where ν is the kinematic viscosity of the dissolution medium [9.77×10^{-3} stokes (7, 8)], and ω is the rotation rate of the disk in rad/s ($\omega^{1/2}$ at 600 rpm is 7.93). The value for $[H^+]_0$ can be calculated by solving Eq. 10 (7) for varying $[H^+]_h$ concentrations, as measured by the pH of the bulk medium:

$$-D_H[H^+]_0^2 + (D_H[H^+]_h - D_{OH}[\overline{O}H]_h)[H^+]_0 + K_w(D_{OH} + D_A K_1[HA]_0) = 0 \quad \text{(Eq. 10)}$$

where K_w is the dissociation constant for water at 25°C (10^{-14} M²); D_A is the diffusivity of the anionic form of HA and was assumed to be numerically equal to D_{HA} (7, 8); and K_1 is equal to K_a/K_w, where K_a is the dissociation constant of the acid. In the present case, K_a was assumed to be $K_{a_{obs}}^{warfarin}$ determined from the solubility study. Therefore, K_1 was numerically equal to 8.75×10^8.

An estimate of D_{HA} (and D_A), the diffusivity of the acid, is required to calculate J as a function of bulk solution pH (nonbuffered) with Eq. 8-10. In an earlier study, this was done by following J, the flux, as a function of $\omega^{1/2}$ under pH conditions in which ionization of the dissolving acid was suppressed and the diffusivity was calculated from the Levich equation (19). It was not possible to determine accurately the initial dissolution rate of warfarin at low pH because of its low solubility. For example, a saturated aqueous solution of warfarin at pH values < pK_a has an absorbance of only 0.16 at 285 nm, which is the absorbance maximum at pH values < pK_a. Therefore, the initial dissolution rate would require measuring very small absorbance readings[6]. The diffusivity of warfarin was, therefore, calculated from the earlier work by assuming the square root relationship to molecular weight using benzoic acid, 2-naphthoic acid, and indomethacin as standards (7). A mean value for D_{HA} for warfarin of 5.7×10^{-6} cm²/s at 25°C and $\mu = 0.5$ was therefore assumed in calculating J from Eq. 8.

Figure 2 is a plot of the initial dissolution rate of warfarin from a rotating disk (600 rpm) as a function of pH, unbuffered but maintained constant by a pH-stat (μ maintained at 0.5). The theoretical line tends to underestimate the dissolution rates by ~20%. The major differences appear to be between the estimated and calculated values for the dissolution rate at pH 2. However, as already discussed, it is very difficult to experimentally determine the initial dissolution rates at this or any acidic pH with certainty. Various parameters within Eq. 8 could be manipulated to give a better fit between the experimental and theoretical values. However, it was felt that this would serve no meaningful purpose at this stage, since the overall fit was reasonably good using parameters that were either determined experimentally or estimated from earlier studies.

If the dissolution of warfarin were to behave nonclassically due to slow ionization (15), the experimental dissolution rates would be overestimated by Eq. 8 since it is assumed in Eq. 8 that the dissolving acid dissociates at diffusion-controlled rates. If anything, Eq. 8 underestimated by ~20% the observed results in the present study. Therefore, it seems safe to conclude, based on the data in Fig. 2 and the ionization kinetics mentioned earlier, that warfarin behaves as if it were a fast-ionizing acid with a solubility in its unionized form of 1.28×10^{-5} M and a pK_a of 5.06.

[6] For example, true initial dissolution rates require measuring J under conditions at which <10% of the saturated solubility has been reached. Thus, accurate absorbance measurements of <0.02 are required. Under these restraints, problems such as fines on the pellet can lead to significant overestimation of the initial fluxes.

Gastrointestinal Absorption of the Strongly Acidic Drug Proxicromil

MICHAEL G. DAVIS *, CAROL N. MANNERS ‡, DAVID W. PAYLING ‡, DENNIS A. SMITH ‡x, and CAROL A. WILSON *

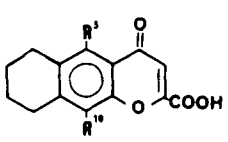
Received March 16, 1983, from *The School of Natural Sciences, Biological & Environmental Sciences Division, The Hatfield Polytechnic, College Lane, Hatfield, Herts. AL10 9AB and ‡Fisons Pharmaceutical Division, Bakewell Road, Loughborough, Leics. LE11 ORH, U.K. Accepted for publication July 25, 1983.

Abstract □ Gastrointestinal absorption of the strongly acidic drug proxicromil has been studied with respect to its physical organic chemistry. The lipophilicity of the drug above pH 6 in octanol–buffer partition experiments is dependent on ion pair formation. Similar trends were demonstrated for the *in vitro* partition of the compound into GI tissue. The absorption of the compound from the perfused GI tract of rats *in vivo* was not consistent with classical un-ionized drug absorption theories and indicated the operation of other processes, especially ion pair formation, as major mechanisms of proxicromil absorption.

Keyphrases □ Proxicromil—GI absorption, lipophilicity, ion pair formation □ Absorption, GI—proxicromil, lipophilicity, ion pair formation

The transfer of acidic drugs across membranes has usually been ascribed to the un-ionized form (1). Many acidic drug substances possess only a weak acidic function which allows a significant proportion of the un-ionized drug to be present at physiological pH. The oral anti-allergy agent proxicromil (FPL 57787, I) (2) and related compounds [FPL 55365(II) and FPL 57579(III)] are of considerable interest since the strong acidity of I (pK_a 1.93) (3) causes the proportion of the drug present as the un-ionized species at physiological pH to be very small. Despite this, the compound has been demonstrated to be well absorbed in a number of animal species and in humans (>60%) (4). The compound also crosses other membrane systems, since it is transferred into the milk from the plasma when administered to lactating albino rats (5). Since the processes involved in the passage of the drug are not adequately explained by the sole passage of un-ionized drug, alternative explanations must be sought.

Several works on GI absorption refer to ion pair partitioning (for a review, see Ref. 6) as a possible mechanism of ionized drug absorption. Ion pairing forms a neutral species by electrostatic attraction between oppositely charged ions in solution. Houston and Wood (6), in their monograph on the GI absorption of drugs, state that there is no *a priori* reason why any molecular entity, regardless of ionic status, should not be absorbed if it possesses adequate partitioning characteristics. We have therefore examined the partitioning characteristics of proxicromil and related compounds from buffer systems into octanol. The partitioning of proxicromil into GI tissues has also been examined. Similarly, we have investigated the absorption of the drug in the albino rat using a perfused intestine system.



I: R^5 = OH, R^{10} = $CH_2CH_2CH_3$
II: R^5 = H, R^{10} = H
III: R^5 = H, R^{10} = $CH_2CH_2CH_3$

EXPERIMENTAL SECTION

Chemicals—[^{14}C]Proxicromil (9.67 mCi/g) and unlabeled proxicromil, prepared in-house, had a radiochemical and chemical purity of 99%. The octanol[1] used had been specially purified for the determination of partition coefficient of drugs. For physicochemical and *in vivo* studies, McIlvaine's (7) citrate–phosphate buffer (for pH 2.2–6.4) and modified Sörensen's (7) phosphate buffer (NaH_2PO_4 replaced KH_2PO_4) (for pH 7.4–8.2) had the sodium ion concentration adjusted to 0.155 M by the addition of NaCl, where necessary. Krebs–Ringer bicarbonate buffer was modified to exclude Ca^{2+} and Mg^{2+} since these ions were found to cause precipitation of proxicromil. All other reagents[2] were of analytical reagent grade.

Solubility Determination—The aqueous solubility of proxicromil was measured (single determinations) in aqueous buffers at a series of pH values covering the range 0–7. Successive aliquots (1 mg) of the compound were added to the buffer (2 mL) at 20°C until saturation was indicated by the presence of undissolved material, for up to 3 h. The pH was checked, and the sample was filtered (cellulose filter, 0.45 μm)[3] and assayed spectrophotometrically for proxicromil (360 nm)[4].

Physicochemical Measurements—All distribution coefficients were measured by the shake-flask method (8). Results are reported as the mean of at least three determinations, together with the observed spread. Compounds were partitioned between 1-octanol saturated with buffer and the same aqueous phase saturated with 1-octanol; the concentration of compound in the organic phase was analyzed (UV spectrophotometry at 360 nm)[4] before and after equilibration. Volume ratios of the two phases were selected to give a reduction of ~50% in the UV absorbance of the solution after equilibration. Equilibration was carried out by shaking at room temperature for 1 h, followed

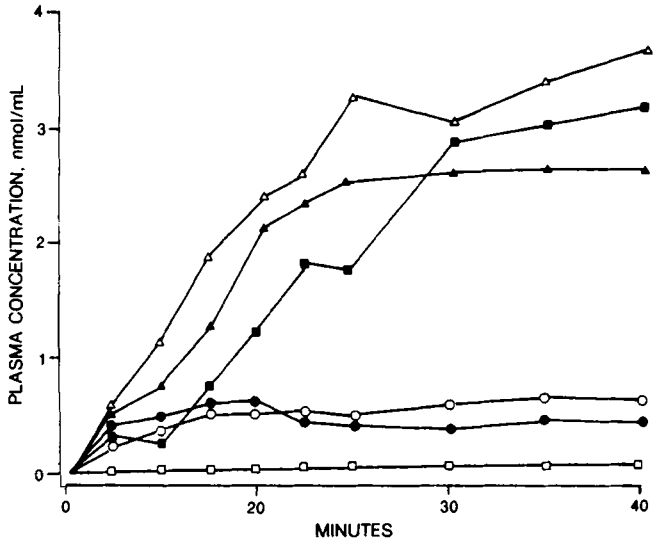


Figure 1—*Plasma concentrations of radioactivity (equivalent to proxicromil) after injection of [^{14}C]proxicromil into separate regions of the rat gut. Key: (△) duodenum; (▲) jejunum; (■) upper ileum; (○) lower ileum; (●) colon; (□) stomach and cecum. The stomach and cecum show very similar negligible absorption, and the results are represented therefore as a single point; n = 4 for each tissue.*

by centrifugation[5] at 2000 rpm for 1 h. The distribution coefficient (D) was calculated from the ratio of the overall concentration of compound in the ionized and undissociated states between the two phases (9).

Measurements of distribution coefficients were made over a wide pH range for II (pH 0-8.2), III (pH 3-8.2), and I (pH 3-8.2). Control of the aqueous phase pH was achieved using the buffers described above adjusted to a sodium ion concentration of 0.155 M. Experiments at pH 0-2 employed dilute hydrochloric acid with added sodium chloride (0.155 M). Values of log $D > 4$ could not be measured to an acceptable accuracy owing to practical limitations of the spectrophotometric method.

The sodium content in the octanol phase was measured in proxicromil distribution experiments at various aqueous phase pH values between 4.0 and 8.2, by atomic emission spectrometry[6]. Sodium content results are given as the average value from two experiments at each pH value. Control experiments were carried out under the same conditions, but omitting the proxicromil (I), to estimate background sodium levels in the octanol. All test solutions contained 4 mL of octanol made up to 50 mL with methanol. Where the volume of octanol available was smaller (pH 5-8.2), additional octanol was added in order to keep the overall solvent composition constant.

The effect of cationic concentration on the octanol distribution coefficient of proxicromil was measured at a constant pH of 7.4 in a dilute phosphate buffer system (0.02 M) containing varying concentrations of either sodium chloride or potassium chloride (0.02-0.24 M).

Experiments with Everted Gut Segments—Male Wistar rats[7] were killed by a blow to the head, and the jejunal section of the small intestine removed. This section (between 3 and 18 cm from the pylorus) was everted over a glass rod and cut into 2-3-mm segments (10). Three single segments from three separate rats were incubated together in 25-mL conical flasks at 37°C in Krebs-Ringer bicarbonate buffer (2 mL) containing the appropriate concentration of [^{14}C]proxicromil. Experiments were carried out in triplicate at various pH values between 3.5 and 8.5.

The flasks were aerated for 30 s with oxygen-carbon dioxide (95:5), sealed with rubber turnover closures[8], and shaken at 37°C for the determined period of time in a shaking water bath. At the completion of the incubation the tissue was removed, rinsed twice in 0.9% NaCl solution, blotted, and weighed.

After incubation, segments were placed in aqueous sodium hydroxide (0.5 mL, 1 M) in scintillation vials. The containers were then heated in an oven to ≤80°C to speed up tissue digestion, which was continued until a uniform solution was obtained. The contents were allowed to cool to room temperature and then acidified with an equal volume of aqueous hydrochloric acid (2 M), and Bray's scintillation fluid was added (5 mL). Aliquots of incubation medium (0.2 mL) were also taken for radioactivity determination. Radioactivity was measured in a scintillation counter[9], and counting efficiency was determined using channel ratios for quench correction.

Experiments with Gut *In Situ*—Male CR/CD rats[10] (weight range, 240-280 g; fed *ad libitum*) were anesthetized with pentobarbital solution administered *via* an indwelling needle in the caudal vein. Following an incision in the throat, the carotid artery was exposed and cannulated with polyethylene tubing. For experiments to investigate the site of absorption, a midline incision was made and the GI tract was ligated in each animal with surgical thread to isolate either the stomach, duodenum, jejunum, upper ileum, lower ileum,

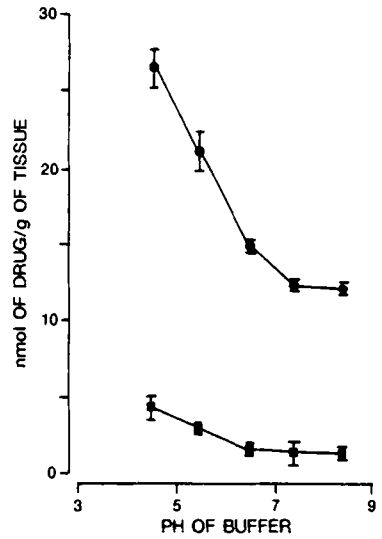

Figure 6—*Partitioning of proxicromil into everted jejunal segments with respect to pH. Incubation of the segments was conducted in proxicromil-buffer solutions for 30 min at concentrations of 1.0 mM (●) and 0.1 mM (■); n = 3 for each point.*

colon, or cecum. Proxicromil was administered as a bolus injection (0.2 mL) into the isolated segment in modified Sörensen's phosphate buffer, sodium ion concentration 0.155 M. Arterial blood samples were collected from the carotid artery at intervals for 60 min.

The absorption of the drug was investigated after single-pass perfusion at various pH values. For these experiments a midline incision was made and a 20-cm length of silicone rubber tubing (2 mm i.d.) was inserted ventrally into the duodenum 2 cm from the stomach pylorus. The end inserted into the duodenum had a number of turns of surgical thread glued to the extreme end which, in conjunction with ligation of the duodenum, secured the tubing. The other end of the tubing was adapted to take standard syringe fittings. A similar length of tubing was inserted dorsally into the jejunum and secured in an identical manner to give a 10-cm section of perfused gut. All perfusion solutions were maintained at 37°C. The gut was then flushed to remove debris by gentle perfusion of saline (5 mL) administered *via* a syringe, followed by flushing with buffer (5 mL) at the respective pH of investigation. Perfusion of the buffer was continued for a further 10 min at a steady rate of 1 mL/min. After this, a solution of [^{14}C]proxicromil (1 mM; 0.6 μCi/mL) dissolved in the same buffer was rapidly flushed through the intestine (5 mL) and then perfused at a rate of 1 mL/min for 20 min. Blood samples were collected into heparinized capillary tubes at 4-min intervals from the carotid vein cannula. The pH of the eluant buffer was monitored throughout the experiment.

In certain experiments the perfusion was performed using the segmented flow method of Winne (11). Total rate of buffer perfusion remained at 1 mL/min. Plasma was obtained by centrifugation of blood at 2500×*g* for 10 min. Radioactivity present in plasma was obtained by mixing the samples with liquid scintillation cocktail[11] followed by liquid scintillation counting. Counting efficiency was determined by the external standard channels ratio method.

RESULTS AND DISCUSSION

Site of Absorption—To determine if the absorption of proxicromil observed in animals was from the stomach or from other regions of the GI tract, a bolus of [^{14}C]proxicromil was injected into various regions of the gut, and blood samples were collected at intervals. Rapid absorption was observed from the duodenum, jejunum, and ileum, while much slower absorption occurred from the lower ileum and colon and very little absorption from the stomach and cecum (Fig. 1). Since little or no absorption occurred from the stomach, it is likely that proxicromil is absorbed in intact animals from regions of the GI tract in which the pH is approximately neutral. As little proxicromil is absorbed in the stomach *in vivo*, where the compound would be substantially in its un-ionized state, the aqueous solubility of the compound at various pH values was investigated since lack of solubility would limit absorption. Also the partitioning of the compound was determined in the octanol-aqueous buffer system over the same range of pH. Emphasis was given to the higher pH values corresponding to those of the region of the GI tract where absorption had been observed.

Solubility and Partitioning—The aqueous solubility of proxicromil is strongly pH dependent (Fig. 2). The insolubility at low pH reflects the low water solubility of the compound when its carboxyl group is undissociated (HA). At pH values above the pK_a (1.93) (3), solubility in water increases rapidly reflecting the abundant water solubility of the ionized compound (A^-). The lack of absorption of proxicromil from the stomach is paralleled by its lack of solubility and, hence, low availability at gastric pH.

The relationship between pH and partition was studied for I-III (Fig. 3). The partition coefficient (P) refers to the ratio of concentrations of the undissociated compound (HA) between the two liquid phases (Eq. 1). The distribution coefficient (D) represents the overall ratio of concentrations of proxicromil in the octanol and aqueous phases regardless of ionization (9) (Eq. 2). Equation 2 is expanded from its usual form (9) to show the possibility of the sodium salt as potentially contributing to the concentration of proxicromil in the octanol phase:

$$P = \frac{[HA]_{oct}}{[HA]_{aq}} \qquad \text{(Eq. 1)}$$

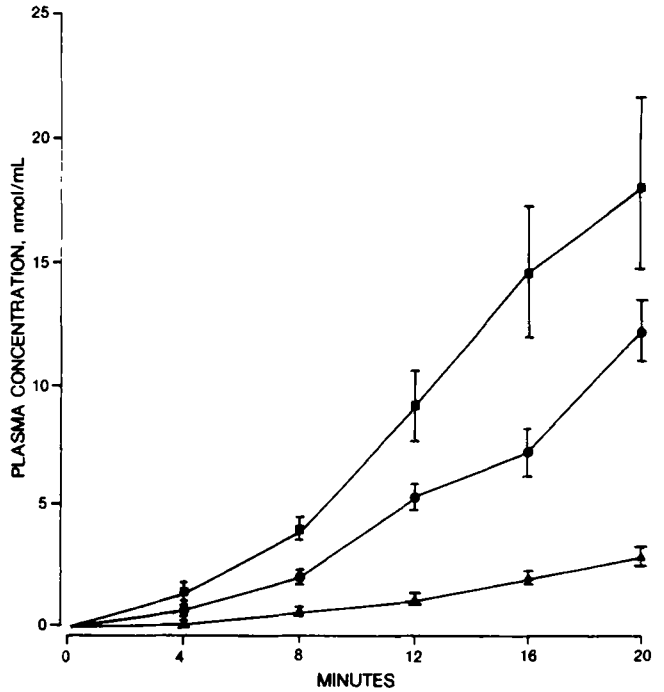

Figure 7—*Plasma concentrations of radioactivity (equivalent to proxicromil) during perfusion of the small intestine of the rat with [^{14}C]proxicromil-buffer solutions at pH 5 (■), 7 (●), and 9 (▲) (see text); n = 6 for each point.*

Table I—Influence of pH of Perfusing Buffer on Proxicromil Absorption Expressed as Absorption Relative To pH 6.98

pH of Eluant Buffer	Absorption Ratio Calculated Using: Un-ionized Drug[a]	$AUC_{0\text{-}20\ min}$[b]	Plasma Conc. at the End of Infusion[b]
8.93 ± 0.02	0.01	0.17	0.17
6.98 ± 0.01	1.00	1.00	1.00
5.23 ± 0.01	56	1.42	1.24

[a] Expected ratio if un-ionized drug was the sole form of drug absorbed. [b] Ratio calculated from perfusion experiments. See text and Fig. 7.

$$D = \frac{[HA]_{oct} + [Na^+A^-]_{oct}}{[HA]_{aq} + [A^-]_{aq}} \quad \text{(Eq. 2)}$$

The relationship of log D to pH was measured for II over the pH range 0–8. For the other two compounds, however, log D could not be obtained below pH 3 owing to limitations of the spectrophotometric analysis. At pH values ≤5, all three compounds decrease in log D, their behavior being described by the pH-partition relationship:

$$\log\left(\frac{P}{D} - 1\right) = pH - pK_a \quad \text{(Eq. 3)}$$

Substitution of the data for II (Fig. 3) into Eq. 3 yields a pK_a value of 1.65 ± 0.1, in agreement with other reports (3).

The proportion of undissociated proxicromil in the water phase falls from 0.0676 at pH 5.1 to ~0.0001 at pH 8.0 (calculated from dissociation constant pK_a = 1.93). Using Eq. 3, it can be calculated that the observed value of log D of 2.17 at pH 5.1 should fall to −0.83 at pH 8.0. In contrast to this, however, it was found that at higher pH the distribution coefficient became progressively independent of pH. This region was examined in more detail to identify the factors which now control the distribution ratio. At pH 7.4 a linear relationship was established between observed distribution coefficient (D) and concentration of potassium or sodium ion in the aqueous phase (Fig. 4). This is parallel to the findings on the lipophilic base chlorpromazine (12), where added counterions such as chloride (Cl^-) also produced a linear relationship to distribution coefficient. This is consistent with ion pair partition, whose extent is related to the product of proxicromil ion and sodium ion concentrations in the aqueous phase. Scheme I indicates a series of equilibria which are consistent with the observed behavior. Proxicromil anion entry into the organic phase is shown as a distribution rather than a partition ratio (9), since it is a complex effect dependent in magnitude on factors including, for example, counterion concentration.

$$\begin{array}{ccc} [HA]_{oct} & & [Na^+A^-]_{oct} \\ \Big\downarrow\uparrow P_{HA} & & \Big\downarrow\uparrow \\ [HA]_{aq} & \overset{K_a}{\rightleftharpoons} & [A^-]_{aq} \end{array}$$

Scheme I

Analysis of the octanol layer for sodium ion using atomic emission analysis showed the concentrations of proxicromil (UV spectrophotometry) and sodium (atomic emission) to be in 1:1 molar agreement in distribution experiments at pH 7.4. Similar experiments at a series of lower pH values (Fig. 5) showed the penetration of sodium into the octanol to be significant only at pH > 5. Below this pH, the ratio of sodium ion to proxicromil fell as conventional pH-partition of the undissociated compound (HA) became dominant. This evidence for ion pair partition was supplemented by analysis for sodium ion in octanol equilibrated with phosphate buffer containing sodium ion (0.155 M) but no proxicromil. The penetration of sodium ions into the octanol thus was insignificant, despite its high concentration in the aqueous phase, unless proxicromil anion was available.

Effect of pH on Absorption—The experiments utilizing octanol were reproduced using gut segments *in vitro*. Uptake of [^{14}C]proxicromil into jejunal segments was studied at 0.1 and 1.0 mM concentrations of proxicromil at various pH values. The results are shown in Fig. 6 and demonstrate that at pH < 6 the lower the pH, the greater the partitioning into the tissue. At pH >6 the uptake was approximately constant. Similar trends were shown at incubation times up to 90 min. The partitioning of proxicromil into gut tissue, therefore, closely follows the characteristics observed for the partitioning of the compound into octanol with pH-dependent partitioning at low pH and a constant partitioning of the drug at pH > 6. The change in behavior for the compound takes place in both octanol and in gut tissue at pH ~6 and very far from the value of the pK_a of the drug (1.93).

The effect of buffer pH on proxicromil absorption *in vivo* was studied using *in situ* perfused gut loops. Figure 7 illustrates the plasma concentrations of radioactivity present in plasma after perfusion of the gut of anesthetized animals with [^{14}C]proxicromil dissolved in buffers of varying pH. The plasma concentrations are increased by decreasing pH. Taking either peak plasma concentration or areas under the plasma curve ($AUC_{0\ 20\ min}$ as measured by the trapezoidal method) (Table I), absorption can be shown to be increased at a nominal pH 5 and decreased at a nominal pH 9 from that at pH 7. These increases are much smaller than would be expected if un-ionized drug was the sole determinant since over the pH range evaluated (5.23–8.93), there is an ~5000-fold change in free drug concentration. The absorption at pH 5.0 is not limited by the unstirred layer (13), since in experiments in which this layer was deliberately disrupted by alternating buffer perfusion with air using the method of Winne (11), there was no significant change in proxicromil absorption.

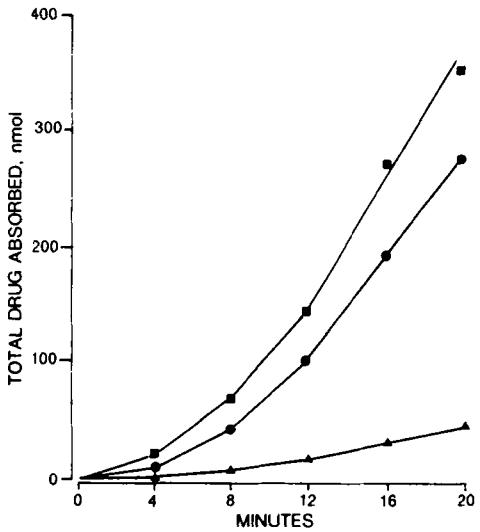

Figure 8—*Cumulative total absorption of radioactivity (equivalent to proxicromil) during perfusion of the small intestine of the rat with [^{14}C]-proxicromil–buffer solutions at pH 5 (■), 7 (●), and 9 (▲) (see text).*

The shape of the plasma curve, however, indicates that absorption is not defined by a single rate constant, since the zero-order input of drug, by perfusion, to the intestine should result in a curve resembling the classical curves following intravenous infusion. Calculation of clearance in the rat (0.3 mL/min) and volume of distribution (17 mL) from intravenous infusion experiments[12] allow calculation of the actual amount absorbed using the classical approach of Loo and Riegelman (14). Figure 8 illustrates the total amount absorbed with time during gut perfusion experiments.

The data can be interpreted by a model in which the mucosal tissue itself represents a compartment (6) in proxicromil absorption. The model is defined by Scheme II:

$$\text{proxicromil in lumen} \xrightarrow{k_0} \text{proxicromil in mucosa}$$

$$\xrightarrow{k_1} \text{proxicromil systemically absorbed}$$

Scheme II

The constant k_0 represents the zero-order absorption of the drug from the constant perfusion system and is a hybrid of the actual absorption rate constant and the perfusion rate. The constant k_1 represents the rate constant for the passage of drug from the mucosa to the circulatory system. Individual zero-order rates of absorption (k_0) were calculated by methods analogous to those used for intravenous infusion experiments (15). The linear portion of the curve for each pH value in Fig. 8 (12–20 min) represents the zero-order rate of absorption, yielding approximate values of 30, 20, and 4 nmol/min at pH 5, 7, and 9, respectively. The linear portion of the curves at each pH value can be extrapolated to give an intercept value from which k_1 can be calculated (0.14 min^{-1}).

CONCLUSIONS

The partitioning characteristics demonstrated in octanol and jejunal segments can partly be reproduced *in vivo* in the perfused intestine. While the perfusion results could be affected by a number of other factors, it is likely that at pH values > 6 ion pair formation operates to allow distribution of the

[12] Unpublished results.

compound into lipoidal phases. This process is likely to occur in the intestine as demonstrated both *in vitro* and *in vivo*. Since absorption of the compound occurs from regions of the GI tract which have pH values >6, it is suggested that ion pair formation with naturally abundant cations such as sodium plays a significant role in the absorption of proxicromil.

An alternative explanation for the GI absorption is that there is a difference between bulk and surface pH. The data of Lei *et al.* (15) suggest the real surface pH might be lower than that expected from bulk pH. To overcome surface pH effects in the intestinal perfusion experiments, we have equilibrated the gut for 10 min by perfusion of buffer at the appropriate pH at 1 mL/min. Under these conditions, surface pH and bulk pH should have tended toward an equilibrium (16), the true pH of which would be very close to that of the measured eluant buffer (see Table I). The linear rate of absorption at each pH indicated in Fig. 7 also demonstrates that an equilibrium has been achieved, since a decreasing rate of absorption would be expected at the lower pH values as the surface pH gradually increased. The significance of a surface pH of 6.5 in explaining absorption of acidic compounds is also of much greater relevance for compounds such as *n*-butyric acid (pK_a 4.9) (16) than proxicromil (pK_a 1.93).

The ion pair behavior described here is in marked contrast to the normally held concept (17). Proxicromil possesses intrinsic lipophilicity and requires only charge neutralization to partition into lipoidal phases. Endogenous ions such as sodium and potassium readily form such neutral lipophilic ion pair complexes. This can be contrasted to the facilitation of partitioning of a nonlipophilic drug by the incorporation of a lipophilic counterion, the concept of which has led Jonkman and Hunt (17) to consider ion pair absorption as more fiction than fact.

Relationship Between Molecular Structure and Cytochrome P_{450}–Metabolic Intermediate Complex Formation, Studied with Orphenadrine Analogues

AALT BAST ˣ, E. MARIA SAVENIJE-CHAPEL, and JAN NOORDHOEK

Received April 4, 1983, from the *Department of Pharmacology and Pharmacotherapy, Faculty of Pharmacy, State University of Utrecht, Catharijnesingel 60, 3511 GH Utrecht, The Netherlands.* Accepted for publication July 29, 1983.

Abstract □ Complexation of ferrous cytochrome P_{450} by metabolic intermediates formed during NADPH-catalyzed metabolism of compounds structurally related to orphenadrine was studied. This so-called metabolic intermediate complexation was determined in rat liver microsomes, obtained from phenobarbital-pretreated rats, at 455 nm using 33 μM of the orphenadrine derivatives. Using secondary amine derivatives with various *N*-alkyl substituents, a parabolic relationship between the logarithm of percentage of cytochrome P_{450} complexation and hydrophobic fragmental constant was observed. The derivative with a bulky tertiary butyl group, however, was devoid of metabolic intermediate-complexing activity. This indicates that steric factors besides lipid solubility may govern the complexing activity; also substitution at the phenyl group affects metabolic intermediate complex formation.

Keyphrases □ Cytochrome P_{450}—complexation with metabolic intermediates, orphenadrine analogues □ Orphenadrine—analogues, metabolic intermediate Complexation with cytochrome P_{450} □ Complexation—metabolic intermediate, orphenadrine analogues with cytochrome P_{450}

Several types of nitrogenous compounds have been shown to undergo cytochrome P_{450}-catalyzed metabolic conversions leading to metabolic intermediates that complex with cytochrome P_{450} (1–3). This complexed cytochrome P_{450} is inactive. Metabolic intermediate complex formation may therefore inhibit metabolic reactions (4). Among the nitrogenous compounds which elicit this complex formation, there are several classes of therapeutically important drugs.

Amphetamine derivatives form a metabolic intermediate complex with hepatic microsomal cytochrome P_{450} *in vitro*, but not *in vivo* (4, 5). With regard to amphetamine analogues, relationships between molecular structure and *in vitro* complexation have been described (4, 6). Recently, metabolic intermediate complex formation produced by macrolide antibiotics have gained much interest (7, 8). With a series of macrolide antibiotics, structural features which are important for the formation of metabolic intermediate complexes have been determined (9). However, with regard to compounds related to proadifen (like propoxyphene, desipramine, and orphenadrine) which produce such complexation both *in vitro* and *in vivo* (10, 11), little is known about the relationship between molecular structure and the ability to evoke complexes

Abstract □ Complexation of ferrous cytochrome P_{450} by metabolic intermediates formed during NADPH-catalyzed metabolism of compounds structurally related to orphenadrine was studied. This so-called metabolic intermediate complexation was determined in rat liver microsomes, obtained from phenobarbital-pretreated rats, at 455 nm using 33 μM of the orphenadrine derivatives. Using secondary amine derivatives with various *N*-alkyl substituents, a parabolic relationship between the logarithm of percentage of cytochrome P_{450} complexation and hydrophobic fragmental constant was observed. The derivative with a bulky tertiary butyl group, however, was devoid of metabolic intermediate-complexing activity. This indicates that steric factors besides lipid solubility may govern the complexing activity; also substitution at the phenyl group affects metabolic intermediate complex formation.

Keyphrases □ Cytochrome P_{450}—complexation with metabolic intermediates, orphenadrine analogues □ Orphenadrine—analogues, metabolic intermediate Complexation with cytochrome P_{450} □ Complexation—metabolic intermediate, orphenadrine analogues with cytochrome P_{450}

Several types of nitrogenous compounds have been shown to undergo cytochrome P_{450}-catalyzed metabolic conversions leading to metabolic intermediates that complex with cytochrome P_{450} (1–3). This complexed cytochrome P_{450} is inactive. Metabolic intermediate complex formation may therefore inhibit metabolic reactions (4). Among the nitrogenous compounds which elicit this complex formation, there are several classes of therapeutically important drugs.

Amphetamine derivatives form a metabolic intermediate complex with hepatic microsomal cytochrome P_{450} *in vitro*, but not *in vivo* (4, 5). With regard to amphetamine analogues, relationships between molecular structure and *in vitro* complexation have been described (4, 6). Recently, metabolic intermediate complex formation produced by macrolide antibiotics have gained much interest (7, 8). With a series of macrolide antibiotics, structural features which are important for the formation of metabolic intermediate complexes have been determined (9). However, with regard to compounds related to proadifen (like propoxyphene, desipramine, and orphenadrine) which produce such complexation both *in vitro* and *in vivo* (10, 11), little is known about the relationship between molecular structure and the ability to evoke complexes

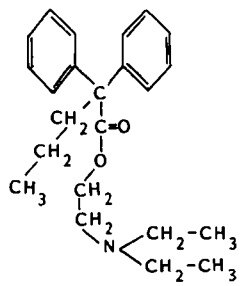
XVI (Proadifen)[e]						8.5

[a] Key: Me, methyl; Et, ethyl; Bu, butyl; *i*, iso-; *n*, normal; *t*, tertiary. [b] Determined using 2.5 μM cytochrome P_{450} and 33 μM of the compounds. [c] Not detectable. [d] Based on previous data. [e] Refers to the formula:



(1, 4). However, because of metabolic intermediate complex formation, peculiar kinetics (12) and adverse drug interactions may arise (4). On the other hand selective inhibition of cytochrome P_{450} subforms provides an interesting tool to manipulate these subforms. In this manner, formation of toxic metabolites might be reduced.

In the present study, therefore, we investigated the relationship between molecular structure and metabolic intermediate complex formation of several orphenadrine derivatives. In this way both structural features important in the formation of complexes as well as insight into the mechanism of complexation with this class of compounds were established.

EXPERIMENTAL SECTION

Chemicals—Orphenadrine and its derivatives were gifts[1]; NADPH was purchased[2]. All other chemicals and solvents used were of analytical-grade purity.

Preparation of Microsomes and Pretreatment of Animals—Liver microsomes were prepared from Wistar rats weighing 250–280 g, as described previously (13). The rats used were pretreated with phenobarbital, dissolved in saline, inasmuch as metabolic intermediate complex formation is specifically enhanced after induction with phenobarbital (4). The phenobarbital-pretreatment consisted of three daily injections of 80 mg/kg ip. On the fourth day the rats were killed by decapitation.

Spectral Measurements—All spectrophotometric observations were performed with the microsomal fraction (2 mg of protein/mL) suspended in 50 mM phosphate buffer (pH 7.4) containing 0.1 mM EDTA. The spectral determinations were performed with UV-visual spectrophotometer[3] at 37°C.

Metabolic intermediate complex formation was measured with the microsomal suspension containing substrate as indicated and 4.2 mM $MgCl_2$. The reaction, started with 400 μM NADPH, was followed by dual-wavelength spectrometry (455 nm *versus* 490 nm) unless stated otherwise in the text. To quantitate the percentage of cytochrome P_{450} complexed, a molar extinction coefficient (ϵ) of 65 mM^{-1} cm^{-1} was used (14, 15). The ϵ is merely a proportionality constant and not of decisive importance in this study. However, use of ϵ provides quantitation of the sequestered amount of cytochrome P_{450}.

Protein concentration (16) and cytochrome P_{450} (17) were determined according to standard procedures.

RESULTS

Scanning spectrometry (430–500 nm) with the spectrophotometer in the split-beam mode (11) was used to establish whether the compounds studied at 33 μM (Table I) exhibited a Soret absorption maximum at 455 nm due to metabolic intermediate complex formation. Inasmuch as this was the case[4], employment of dual wavelength (455–490 nm) spectrometry is valid to study this complex formation *in vitro*.

Substrate concentration dependency has been observed both for rate and extent of metabolic intermediate complex formation (11, 18). We therefore compared the extent of cytochrome P_{450} complexation with each derivative ($\Delta A_{455-490\ nm}$) at three substrate concentrations. Maximal complexation was achieved at 33 μM for each compound (Fig. 1). Moreover, using a concen-

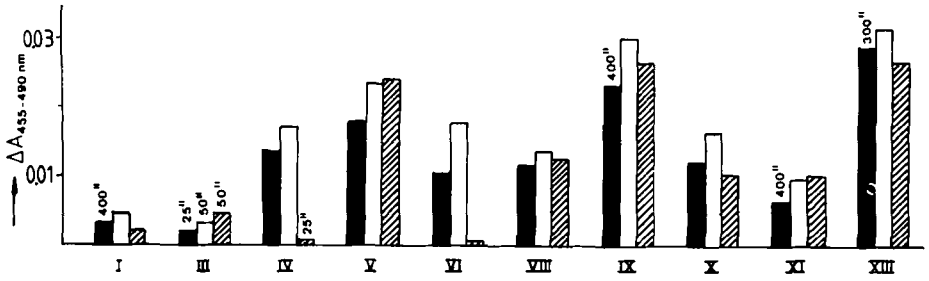

Figure 1—*Concentration dependency of extent of metabolic intermediate complexation ($\Delta A_{455\text{-}490\ nm}$) produced by various compounds (see Table I). For each compound, three concentrations were tested. Incubation has been performed for 650 s, unless stated otherwise in the figure. Key: (■) 10 μM; (□) 33 μM; (▨) 300 μM.*

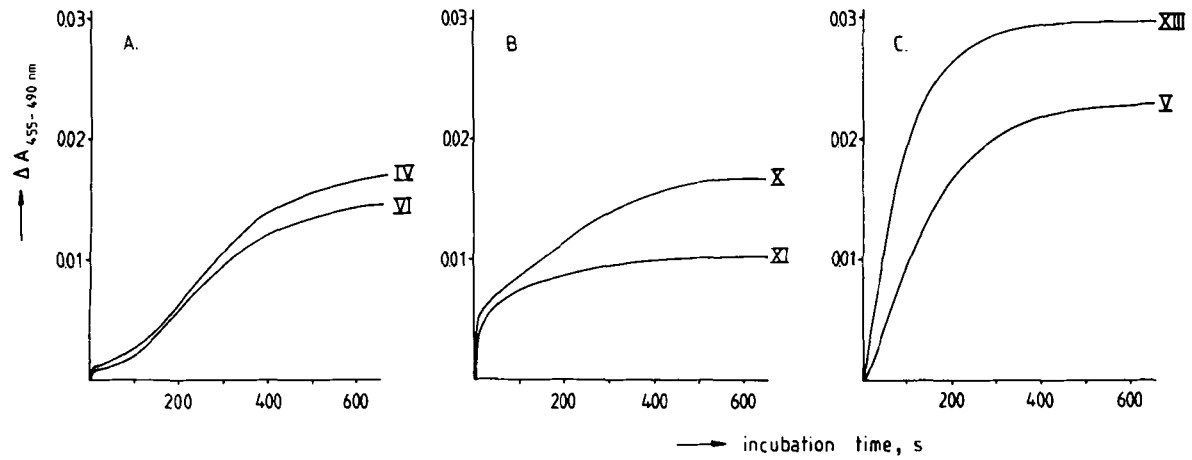

Figure 2—*Time course of metabolic intermediate complex formation, indicated by $\Delta A_{455\text{-}490\ nm}$ (see Table I). Experimental conditions as described in the* Experimental Section.

tration of 33 μM, maximal absorption at 455 nm was accomplished within an incubation time of 650 s and remained stable thereafter. The only exception, III, shows maximal absorption in 50 s, which decreased thereafter. Maximal complexation was used for further evaluation.

Within the series of compounds tested (Table I), the time course of development of absorption at 455 nm differed. Figure 2A shows that complexation produced by the tertiary amine structures (IV and VI) have a prominent initial lag phase. Compounds X and XI, containing an isopropyl substituent, display a biphasic increase in 455 nm absorption (Fig. 2B). With the secondary amines, in which an *n*-alkyl substituent is present on the nitrogen atom, (*e.g.*, V and XIII), neither a lag phase nor biphasic kinetics occur (Fig. 2C).

Using a concentration of 33 μM, the percentage of cytochrome P_{450} complexed was established for each compound (Table I). Evaluation of data of Table I reveals a possible parabolic dependence of metabolic intermediate complexation on lipophilicity. The latter was expressed by the fragmental constant (f) of the —NHR moiety of I, III, VIII, IX, X, and XIII (19) (Fig. 3). As shown in Table I, XIV, with a bulky tertiary butyl group, does not produce metabolic intermediate complexation. Substitutions on the aromatic part of the molecules give large variations in complex formation. Comparison of II with I, V with III, and XI with X shows that the effect of substitution at R_3 depends on the substituent at R_1. Moreover, XII, with a methyl substituent at R_4 and an isopropyl group at R_1, did not form a metabolic intermediate complex (Fig. 4).

DISCUSSION

The optimum concentration for metabolic intermediate complexation has often been found to be 33 μM, irrespective of whether hepatic microsomes were obtained from untreated or phenobarbital-pretreated rats (1). The same optimum concentration was established not only with different microsomal preparations, but also with different compounds (1, 11). Accordingly, the present data also suggest that 33 μM can be used for comparative purposes (Fig. 1). The concentration dependency, explained by substrate inhibition (11), hinders use of K_m values. Biphasic kinetics observed with X and XI (Fig. 2B) suggest that different forms of cytochrome P_{450} are involved in metabolic intermediate complex formation. The lag time observed with tertiary amines (Fig. 2A) is probably explained by initial *N*-demethylation, which has to occur before the complexing species can be formed (11). Because of the different time courses of metabolic intermediate complexation, we did not use the initial rate but rather the extent of such complexation.

A trend toward a parabolic relationship between percentage of cytochrome P_{450} complexed and lipophilicity was observed. The possible bilinear relationship describes transport of the substrate and, in addition, may also reflect a hydrophobic interaction (20). Dependency on the hydrophobic fragmental constant may reflect the fact that the active sites of cytochrome P_{450} are located in a hydrophobic pocket, submerged in the membrane (21). Transport between hydrophilic and hydrophobic phases as a rate-limiting step has also been suggested for *N*-oxidation of amphetamine derivatives (6). Compound X, which contains an isopropyl group, deviates (Fig. 3). This may indicate that steric factors besides lipid solubility may govern metabolic intermediate-complexing activity as well. This notion is substantiated by the fact that XIV, which has a bulky tertiary butyl group, is devoid of such complexing activity. Similar dependencies arise from literature reports, in which *N*-dealkylation of secondary amines have been described (22, 23). This suggests that the distinct correlation, which has been found between the rate of *N*-demethylation and metabolic intermediate complex formation (11, 24) can be extended to *N*-dealkylation and metabolic intermediate complexation. The differences in complex formation with secondary amines may therefore reflect *N*-dealkylation. This would correlate well with the suggestion that the actual

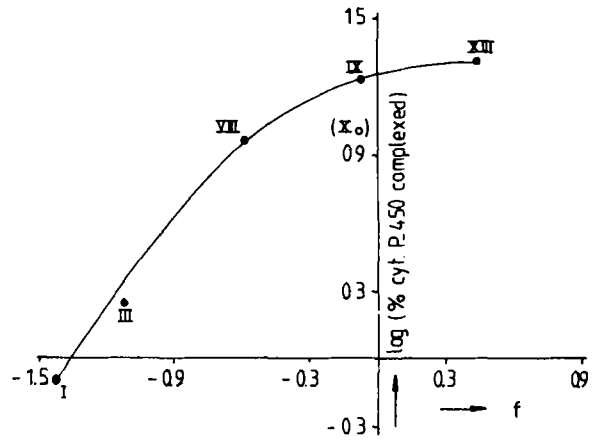

Figure 3—*Plot of the logarithm of percentage of cytochrome P_{450} complexed (obtained from Table I) against the sum of the hydrophobic fragmental constant of the substituted amine function (see text) for several compounds which vary in their amine function.*

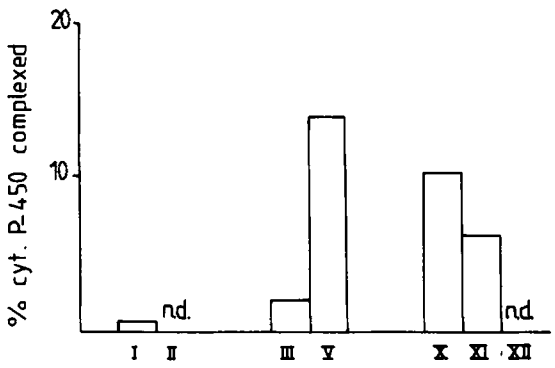

Figure 4—*Effect of substitution in the aromatic part of the substrates on metabolic intermediate-complexing activity, indicated as percentage of cytochrome* P_{450} *complexed (obtained from Table I).*

ligand responsible for such complex formation is an *N* oxidized primary amine, probably a nitroso compound or a nitroxide radical (11). Presumably the main mechanism leading to the ultimate metabolic intermediate ligand is *N*-oxidation of the secondary amines, since *N*-hydroxytofenacine (XV) leads to a large extent to complex formation. *N*-Oxidation of the *N*-hydroxy-*N*-alkylamine may lead to an unstable *N*-hydroxy-*N*-alkylamine *N*-oxide, which after rearrangement is readily *N*-dealkylated. The *N*-dealkylated *N*-hydroxylamine is rather unstable and may give the nitroxide radical. Direct *N*-oxidation of the primary amine does not have an important contribution to metabolic intermediate complex formation inasmuch as I and II do not produce a metabolic intermediate complex to any large degree.

Interpretations of data become more difficult if the effect of substitution at the aromatic portion of the molecule comes into play (Fig. 4). Substitution on one phenyl group greatly affects complexation. Moreover, the substituent on the amine function influences the effect of substitution on the aromatic part in an unpredictable manner. Clearly more compounds are needed to unravel the effect on metabolic intermediate complexation if substitution occurs in different parts of the molecule simultaneously.

In conclusion, evaluation of the relationship between structure and biological activity may be helpful in development of compounds which will show the desired pharmacological effect without metabolic intermediate complexation. One may also design compounds with prominent complexing activity with specific cytochrome P_{450} subforms, which may be used for pharmacological or toxicological purposes.

Hypolipidemic Activity of 3-*N*-(1′,8′-Naphthalimido)propionic Acid in Rodents

I. H. HALL ˣ, J. M. CHAPMAN, JR., P. JOSEÉ VOORSTAD, and G. H. COCOLAS

Received January 31, 1983, from the *Division of Medicinal Chemistry, School of Pharmacy, University of North Carolina at Chapel Hill, Chapel Hill, NC 27514.* Accepted for publication July 29, 1983.

Abstract □ 3-*N*-(1′,8′-Naphthalimido)propionic acid was synthesized and shown to effectively lower both serum cholesterol and triglyceride levels in rats and mice. In hyperlipidemic mice, serum lipid levels were lowered significantly, approaching normal levels of cholesterol and below normal levels of triglyceride. The serum lipid levels were reduced due to accelerated clearance of cholesterol *via* the biliary route as well as a lowering of available acetyl CoA in the cytoplasm for liver *de novo* cholesterol and triglyceride syntheses. The liver regulatory enzyme of fatty acid and triglyceride syntheses were depressed by drug treatment. Significant reduction of liver lipids as well as the lipid content of the lipoprotein fractions were observed. The agent possessed a safe therapeutic index when used as a hypolipidemic agent.

Keyphrases □ 3-*N*-(1′,8′-Naphthalimido)propionic acid—hypolipidemic activity in rodents, cholesterol and triglycerides reduction □ Antihyperlipidemic agents—3-*N*-(1′,8′-naphthalimido)propionic acid, activity in rodents, cholesterol and triglycerides reduction

N-Substituted cyclic imides have been shown to be potent hypolipidemic agents in rodents at the low dose of 20 mg/kg/d. Substitutions of four carbon atoms or an oxygen atom for one of the carbons provided the most active agent of the phthalimide, saccharin, and the 1′,8′-naphthalimide series (1). These agents effectively lowered both serum cholesterol and tri-

glyceride levels. They were active in both normal and hyperlipidemic mice. In the latter case, the agents lowered blood lipids to maintain normal ranges of cholesterol and triglycerides. The LD_{50} values of the drugs appeared to be high, *i.e.*, >2 g/kg, indicating a safe therapeutic index. No other deleterious side effects were noted, and the effects on lipid metabolism were totally reversible. The cyclic imides have been observed to reduce regulatory enzymes of lipid synthesis and to accelerate lipid excretion *via* the bile. The agents significantly lowered cholesterol and triglyceride content of the lipoprotein fractions of blood in rats. The *N*-propionic acid substitution of the cyclic ring provided one of the more active derivatives of the phthalimide (2) and saccharin (3) series in the hypolipidemic screen. Preliminary testing indicated the same findings for the propionic acid derivative of 1′,8′-naphthalimide. Thus, an in-depth study of the metabolic effects of 3-*N*-(1′,8′-naphthalimido)propionic acid was undertaken in rodents, and those results are reported.

EXPERIMENTAL SECTION

Source of Compounds—3-*N*-(1′,8′-Naphthalimido)propionic acid was prepared as follows. 1′,8′-Naphthalic anhydride (19.8 g, 0.1 mol) and 8.9 g (0.1 mol) of β-alanine were refluxed in 300 mL of dimethylformamide for 1.25 h. The resulting solution was cooled, and the solvent was removed *in vacuo* to yield a pink solid residue which was a single spot by TLC analysis. The solid was washed with ethanol to remove the pink color, yielding 24 g (89%) of an off-white solid, mp 225–243°C. Recrystallization of an analytical sample from ethyl acetate gave 3-*N*-(1′,8′-naphthalimido)propionic acid, mp 231–233°C. ^{1}H-NMR (Me_2SO-d_6): δ 7.62–8.47 (m, 6, ArH), 4.26 (t, 2, $N-CH_2$), and 2.60 ppm (t, 2, $CH_2-C=O$).

Anal.—Calc. for $C_{15}H_{11}NO_4$: C, 66.91; H, 4.12. Found: C, 66.96; H, 4.11.

Antihyperlipidemic Screens in Normal Rodents—3-*N*-(1′,8′-Naphthalimido)propionic acid was suspended in 1% aqueous carboxymethylcellulose, homogenized, and administered to male CF_1 mice (~25 g) intraperitoneally for 16 d or male Holtzman rats (~350 g) orally by an intubation needle for 14 d. Serum cholesterol (4) and triglycerides[1] were determined as described previously (2).

Testing in Atherogenic Mice—Male CF_1 mice (~25 g) were placed on a commercial diet[2] to produce a hyperlipidemic state. After the cholesterol and triglyceride levels were elevated, the mice were administered the test drug at 20 mg/kg/d ip for an additional 14-d period, and serum cholesterol (4) and triglyceride[1] levels were determined (2).

Toxicity Studies—Periodic animal weights were obtained during the experiments and expressed as a percentage of the weight of the animal on day 0 (2). The acute toxicity (LD_{50} value) (5) was determined in male CF_1 mice (~25 g) by administering the test drug intraperitoneally from 100 mg to 2 g/kg as a single dose. The number of deaths were recorded over a 7-d period for each group.

Enzymatic Studies—*In vitro* enzymatic studies were determined using 10% homogenates of male CF_1 mouse liver with 2.5–10 μmol of test drug. *In vivo* enzymatic studies were determined with 10% homogenates of liver from male CF_1 mice obtained after administering the agent for 16 d at a dose ranging from 10 to 60 mg/kg/d ip. The enzyme activities were determined by previously described techniques: acetyl CoA synthetase (6); ATP-dependent citrate lyase (7); mitochondrial citrate exchange (8, 9); cholesterol side-chain oxidation (10); 3-hydroxy-3-methylglutaryl CoA reductase (HMG CoA reductase) (11, 12); acetyl CoA carboxylase activity (13); fatty acid synthetase (14); *sn*-glycerol-3-phosphate acyl transferase (15); and phosphatidate phosphohydrolase (16). Details of the enzymatic assays have been published previously (2).

Liver, Small Intestine, and Fecal Lipid Extraction—In male CF_1 mice that had been administered test drugs for 15 d, the liver, small intestine, and fecal materials (24-h collection) were removed, extracted (17, 18) and analyzed for cholesterol (4), triglycerides[1], neutral lipids (19), and phospholipids (20).

[^{3}H]Cholesterol Distribution in Rats—Male Holtzman rats (~350 g) were administered test agents for 14 d orally. On day 13, 10 μCi of [^{3}H]cholesterol was administerted intraperitoneally in mice and orally in rats by a previously described procedure (2).

Cholesterol Absorption Study—Male Holtzman rats (~400 g) were treated with test drugs at 20 mg/kg/d orally for 14 d. [1,2-^{3}H]Cholesterol (40.7 mCi/mmol) (10 μCi) was administered orally 18 h before surgery. After the rats were anesthetized and the bile ducts were canulated by a method described previously (2), the bile was collected over the next 6 h and analyzed for tritium content (21).

Plasma Lipoprotein Fractions—Male Holtzman rats (~400 g) were administered test drugs at 20 mg/kg/d for 14 d. Blood was collected from the abdominal aorta, and lipoprotein fractions were obtained by the methods of Havel and co-workers (22, 23). Each fraction was analyzed for cholesterol (4), triglycerides[1], neutral lipids (19), phospholipids (20), and protein levels (24).

RESULTS

3-*N*-(1′,8′-Naphthalimido)propionic acid clearly demonstrated potent hypolipidemic activity in rodents. In rats, at 20 mg/kg/d orally, serum cholesterol levels were reduced 43% and serum triglyceride levels were reduced 34% (Table I). In mice, at 20 mg/kg/d ip, serum cholesterol levels were reduced maximally at 40 mg/kg/d by 36%, whereas serum triglyceride levels were reduced 42% at 20 mg/kg/d. In hyperlipidemic mice, serum cholesterol levels were elevated 183% (354 mg%) above normal control values (125 mg%). After treatment with 3-*N*-(1′,8′-naphthalimido)propionic acid for 14 d, serum cholesterol was elevated 23% above the control values, which were reduced 160% of the diet-induced cholesterol levels. The serum triglyceride levels in the hyperlipidemic mice were elevated 168% (367 mg/dL) above the control value (137 mg/dL). Drug treatment resulted in values 13% lower than the control. The drug had no effects on the consumption of food on a daily basis in the rats. Furthermore, the weight increase of the whole animal as well as the individual weights of the major organs were not affected by drug treatment for 2 weeks (Table II).

Examination of the *in vitro* effects of 3-*N*-(1′,8′-naphthalimido)propionic acid on the activities of enzymes required for *de novo* synthesis of cholesterol and triglycerides of mice showed that mitochondrial citrate exchange was markedly inhibited by drug treatment by 79% at 2.5 μmol (Table III). Citrate lyase, acetyl CoA synthetase, and HMG CoA reductase activities were inhibited marginally (20–30%).

Enzymes involved in the clearance of free cholesterol from the liver varied in the response to drug treatment. Cholesterol side-chain oxidation was inhibited at 2.5 μmol, and acyl CoA cholesterol acyl transferase activity was enhanced at 5 and 10 μmol (~35%). Activities of regulatory enzymes involved in fatty acid and triglyceride syntheses were significantly inhibited. Acetyl CoA carboxylase, *sn*-glycerol-3-phosphate acyl transferase, and phosphatidate phosphohydrolase activities were suppressed significantly, with the highest concentration (10 μmol) affording the maximum inhibition. Fatty acid synthetase activity was not affected by drug treatment.

Evaluation of some of the same enzymes after *in vivo* administration of 3-*N*-(1′,8′-naphthalimido)propionic acid demonstrated that citrate lyase was inhibited maximally at 20 mg/kg/d by 22% (Table IV). Acetyl CoA synthetase activity was suppressed 14% at 20 and 40 mg/kg/d. HMG CoA reductase activity was not altered by *in vivo* drug administration. 7-α-Hydroxylase, the regulatory enzyme for the conversion of cholesterol to bile acids, was significantly inhibited by drug administration, with 60 mg/kg producing the maximum effect (52% reduction). Acetyl CoA carboxylase activity was suppressed maximally 45% at 20 mg/kg/d. *sn*-Glycerol-3-phosphate acyl transferase activity was likewise inhibited maximally at 20 mg/kg/d by 51%. Phosphatidate phosphohydrolase activity was inhibited 31% at 20 mg/kg/d and 48% at 40 mg/kg/d. Fatty acid synthetase activity was marginally inhibited 19–20% at 20 and 40 mg/kg/d.

Lipid analysis of the liver of mice treated for 16 d with 3-*N*-(1′,8′-naphthalimido)propionic acid intraperitoneally showed that the number of milligrams per milliliter of total lipid was reduced 47 and 52% at 20 and 40 mg/kg/d, respectively (Table V). Cholesterol levels were reduced 20–30%. Triglyceride levels were markedly reduced (92–97%), whereas neutral lipid levels were reduced 72 and 84% at the same doses. At the dosage of 60 mg/kg/d, total lipid, cholesterol, triglycerides, and neutral lipids returned to more normal levels. The phospholipid levels were reduced at 10 mg/kg/d by 34%, but were significantly elevated at 20 and 40 mg/kg/d. Fecal samples obtained on day 16 demonstrated a marked increase in total lipid excreted as well as increases in cholesterol and neutral lipid levels; however, triglyceride and phospholipid levels were not elevated in the fecal samples.

Distribution studies in rats with [^{3}H]cholesterol showed that cholesterol absorption from the GI tract over a 24-h period was reduced 7%; however, excretion in the bile was accelerated 26% (Table VI). The milligram percent of cholesterol was elevated 38%, and the bile flow rate over 6 h was accelerated

[a] After 14-d administration at 20 mg/kg/d; expressed as percent of control (mean ± *SD*), $n = 6$. [b] $p \leq 0.001$. [c] $p \leq 0.010$.

18% (Table VII). Phospholipid content of the bile was also elevated 27% compared with the control. The [^{3}H]cholesterol content in the small intestine, large intestine, chyme, and feces was elevated three, two, five, and two times, respectively, after drug treatment. The urine excretion of [^{3}H]cholesterol was lowered in treated animals, and higher levels of [^{3}H]cholesterol were found in major organs, *e.g.*, brain, heart, lung, liver, and stomach (Table VIII). Adrenal weights for the treated mice were identical to the control weights, indicating that the drug did not cause hypertrophy of the adrenal cortex as a compensatory mechanism of reduced serum cholesterol levels (Table VIII).

Rat lipoprotein fractions (Table IX) were analyzed, and drug treatment reduced cholesterol and neutral lipid in the chylomicron, low-, and high-density lipoprotein fractions of rats. Neutral lipids and triglyceride levels were reduced in the very low-density fractions. Phospholipid levels were reduced in the low-density lipoproteins, but elevated significantly in the high-density lipoprotein fraction. Protein content was essentially unchanged in all of the lipoprotein fractions of the rats. The calculation of the percentage of each lipid or protein concentration of the total lipoprotein particle (Table X) demonstrated slightly different distributions of the lipids. The cholesterol content was reduced in the chylomicron, the low-, and high-density lipoprotein fractions, but not in the very low-density fraction. The cholesterol reduction by drug was most dramatic in the low-density fraction. The cholesterol ratio of high-density/low-density lipoprotein fractions for the control was 0.394 and for the treated group was 0.449. Thus, drug treatment raises the value of this ratio. Triglyceride content was lowered significantly in the chylomicrons and very low-density lipoprotein fractions. Alterations of the low- and high-density lipoprotein fractions probably are not important, since triglyceride content is low in these fractions. Neutral lipids were lowered by drug administration in all four lipoprotein fractions; however, the magnitude of reduction was not as great as for cholesterol and triglycerides. Phospholipids were lowered in the low-density fraction but raised in the other three fractions. Protein content was elevated in all four fractions, probably due to the lipid lost from the lipoprotein fraction after drug treatment.

Data in Tables I–IX are expressed as percentage of control ± *SD*. The probable significant level (p) between each test group and the control group was determined by the Student's t test.

Table VII—Effects of 3-*N*-(1′,8′-Naphthalimido)propionic Acid on Rat Bile [a]

DISCUSSION

3-*N*-(1′,8′-Naphthalimido)propionic acid was shown to be a potent hypolipidemic agent both by oral and intraperitoneal administration in normal and hyperlipidemic rodents. The suppression of serum lipids appeared to be related to the *in vitro* and *in vivo* inhibition of *de novo* cholesterol and triglyceride

syntheses in the liver. 3-*N*-(1′,8′-Naphthalimido)propionic acid lowered the cytoplasmic level of acetyl CoA *via* mitochondrial citrate exchange, citrate lyase, and acetyl CoA synthetase inhibition. Acetyl CoA is a key intermediate precursor required for both cholesterol and triglyceride syntheses. Reduction of its level should lower serum levels of both lipids. The regulatory enzyme of cholesterol synthesis, HMG CoA reductase activity, was not inhibited by the drug; although clofibrate inhibits this enzyme (25), phthalimide (2) and saccharin (3) have been shown to have no effect on its activity. 3-*N*-(1′,8′-Naphthalimido)propionic acid did suppress the activity of the regulatory enzymes for fatty acid synthesis (acetyl CoA synthetase) and the regulatory enzymes for triglyceride synthesis (*sn*-glycerol-3-phosphate acyl transferase and phosphatidate phosphohydrolase). These enzyme activities were also reduced by saccharin and phthalimide derivatives (2, 3). Furthermore, the magnitude of the reduction is of a level to account for the reduction of serum triglyceride levels.

The interference with liver cholesterol synthesis by 3-*N*-(1′,8′-naphthalimido)propionic acid was not significant enough to explain the lowering of serum cholesterol levels. Thus, the distribution and excretion of cholesterol after drug treatment was evaluated. First, the drug did not accelerate cholesterol conversion to bile acid; in fact, the regulatory enzyme for this conversion, 7-α-hydroxylase, was inhibited by drug treatment *in vivo*. Side-chain degradation of cholesterol also was not increased, as measured *in vitro*. Second, [^{3}H]cholesterol excretion was accelerated in the bile and feces, indicating that the drug was accelerating clearance of cholesterol from the blood *via* biliary excretion. High contents of labeled material could be observed in the small intestine and large intestine, as well as the chyme and fecal material, suggesting that the extrahepatic circulation of cholesterol was reduced by the drug. Cholesterol absorption from the intestine after oral administration was reduced 7%. Higher levels of [^{3}H]cholesterol were observed in some of the major organs; however, when the lipid content of the liver and small intestine was examined, there was a decrease in cholesterol, triglycerides, and neutral lipids. Phospholipid content was elevated in both the liver and bile. Clofibrate treatment results in an increase in phospholipid content in the liver and serum (26). Fecal lipid levels reflect the increase in bile cholesterol and neutral lipid levels, which were elevated compared with the control values.

The lipid content of the blood lipoprotein fractions was lowered. Chylomicrons, which normally contain large concentrations of triglycerides, showed lower levels of cholesterol, neutral lipid, and triglyceride. Low-density lipoproteins, which normally contain a high concentration of cholesterol had markedly reduced cholesterol, neutral lipids, triglycerides, and phospholipid levels after drug treatment. Low-density lipoproteins are responsible for lipid deposition in atherosclerotic plaque in blood vessels. Reducing lipid levels in this lipoprotein fraction should also show reduction in the quantity of lipids being deposited in these plaques. Although it is difficult to extrapolate data from lipoprotein studies in rats to lipoprotein levels in humans, since the lipoprotein fractions are different, these studies demonstrate that 3-*N*-(1′,8′-naphthalimido)propionic acid modulated the lipid levels in the lipoprotein fraction and that 3-*N*-(1′,8′-naphthalimido)propionic acid shows promise as a potential hypolipidemic agent.

High-Performance Liquid Chromatographic Determination of Metoprolol and α-Hydroxymetoprolol Concentrations in Human Serum, Urine, and Cerebrospinal Fluid

F. M. GENGO ˣ, M. A. ZIEMNIAK, W. R. KINKEL, and W. B. McHUGH

Received December 27, 1982, from *The Dent Neurologic Institute, Millard Fillmore Hospital, Buffalo, NY 14209* and *The Division of Clinical Pharmacy Science, State University of New York at Buffalo, Amherst, NY 14190.* Accepted for publication July 7, 1983.

Abstract □ A sensitive and simplified high-performance liquid chromatographic procedure was developed for the simultaneous quantification of metoprolol and α-hydroxymetoprolol in human serum, as well as cerebrospinal fluid and urine. Following protein precipitation with trichloroacetic acid, the sample was alkalinized with 1 M NaOH and extracted with dichloromethane. The mobile phase consisted of acetonitrile–water (50:50) containing 0.005 M 1-heptanesulfonic acid in 0.001% acetic acid. Using pronetalol as an internal standard, compounds were quantitated using fluorescence detection at 230 nm with a 300-nm emission filter and 0.02 AUFS. Extraction recovery is ~80% for both compounds. The lower limits of detection are 5 ng/mL and 4 ng/mL for metoprolol and α-hydroxymetoprolol, respectively.

Keyphrases □ Metoprolol—HPLC, α-hydroxymetoprolol, human serum, urine, and cerebrospinal fluid □ α-Hydroxymetoprolol—HPLC, metoprolol, human serum, urine, and cerebrospinal fluid

Metoprolol, a selective β-1-receptor blocker with an active hydroxy metabolite, is widely used in the treatment of several cardiovascular and neurological disorders (1–3). Many patients treated with standard oral doses of β-blockers experience either adverse toxic effects or receive no therapeutic benefit (4). Evaluation of the serum concentration profile of metoprolol may enable optimization of therapy for some patients. Several recent reports suggest that many of the pharmacological actions of metoprolol are paralleled by serum concentrations of metoprolol and/or α-hydroxymetoprolol (5, 6). Although α-hydroxymetoprolol may have relatively weak β-adrenergic blocking potency, its contribution to the other pharmacological actions of metoprolol remain to be determined (1, 2, 7). It is known that α-hydroxymetoprolol accumulates in the serum of patients with certain disease states, such as renal failure (7).

The current assay methods for the analysis of metoprolol include GC–MS (8), GC–EC detection (9), as well as high-performance liquid chromatography (HPLC) (10, 11). Most were designed primarily for quantification of only the parent drug. The assay procedure reported here is sensitive and specific for both metoprolol and the active hydroxy metabolite. Additionally, this procedure is useful for quantification of both compounds from serum and cerebrospinal fluid (CSF).

EXPERIMENTAL SECTION

Reagents—All chemicals and reagents were analytical grade unless otherwise indicated. Metoprolol tartrate[1], α-hydroxymetoprolol[2], and pronetalol[3] were all received as powders; stock solutions were prepared in methanol. Dichloromethane, acetonitrile[4], 30% trichloroacetic acid solution, sodium hydroxide[5], and sodium-1-heptanesulfonate[6] were used as received.

The HPLC system consisted of a delivery system[7], universal injector data module[7], and a variable-wavelength fluorescence detector[8]. Separation was conducted on a reverse-phase C_{18} column, 3.9 mm × 30 cm[9]. The mobile phase consisted of 25 mL of 0.005 M sodium-1-heptanesulfonate in 1.0% acetic acid diluted to 1 L with distilled deionized water (solvent A). The same amount of heptanesulfonic acid solution (25 mL) was diluted to 1 L with acetonitrile (solvent B). The mobile phase was a mixture of solvents A and B (50:50). A flow rate of 2 mL/min was maintained. The effluent was monitored at an excitation wavelength of 230 nm with a 300-nm UV interference filter, to set the emission wavelength, with an attenuation of 0.02.

Extraction Procedure—To 1 mL of serum (in a glass tube) was added 10 μL of a 3.0-μg/mL solution of the internal standard (pronetalol) and 200 μl of 30% trichloroacetic acid solution. This mixture was vortexed and then centrifuged[10] at 5000 rpm for 10 min. The clear supernatant (750 μL) was transferred and 375 μL of 1 M NaOH and 4.0 mL of dichloromethane were added. The mixture was vortexed for 30 s, then centrifuged for 10 min at 5000 rpm. The upper aqueous phase was aspirated and discarded; the lower organic phase was transferred, evaporated to dryness under a stream of nitrogen at 30°C, and reconstituted in 100 μL of the mobile phase. The extraction procedure for urine and (CSF) is exactly the same as described for serum.

Recovery Studies—Human serum and methanol samples were each spiked with two different concentrations of metoprolol and α-hydroxymetoprolol. The methanol samples were evaporated under a stream of nitrogen at 30°C, with internal standard added just prior to injection. The serum samples were extracted as described, with the exception that internal standard was again added prior to injection. Percent recovery was determined by comparison of peak height ratios between extracted samples and methanol samples. Five replicate determinations were made at each concentration. Similar studies were conducted using blank urine and CSF. To determine the within-day

variation, a serum sample with known amounts of metoprolol and α-hydroxymetoprolol was assayed five times. To assess the between-day variation, another serum sample with known amounts was assayed six times over a period of 10 d.

Human Study—A patient diagnosed as having essential tremor was treated for 1 week with a regimen of 75 mg of metoprolol b.i.d. On the day 7, blood samples were collected at various times after the morning dose. The serum was stored at −30°C prior to analysis.

Stability Study—To determine the effects of temperature on the stability of metoprolol and α-hydroxymetoprolol, 1.0-mL aliquots of spiked serum were incubated at −30°C, 5°C, 25°C, and 37°C. Samples were assayed periodically over 30 d.

RESULTS

Chromatography—Figure 1 illustrates the chromatogram obtained after extracting 1.0 mL of blank serum as described. There were no additional peaks eluting that interfered with the determination of metoprolol or α-hydroxymetoprolol. A serum sample spiked with 44.4 ng/mL of metoprolol and 35.2 ng/mL of α-hydroxymetoprolol was extracted, and the resulting chromatograph is shown in Fig. 2. The retention times of metoprolol, α-hydroxymetoprolol, and the internal standard were 9.3, 5.9, and 12.0 min, respectively. A typical chromatogram of serum obtained from a patient receiving metoprolol is shown in Fig. 3.

Table II—Recovery of Metoprolol and α-Hydroxymetoprolol from Human Serum [a]

	Drug conc., ng/mL	Mean Recovery, %	*CV*, %
Metoprolol	22.2	79.0	9.7
	266.4	78.2	7.9
α-Hydroxymetoprolol	17.6	80.0	9.1
	211.1	80.0	7.9

[a] $n = 5$.

Calibration curves, were prepared daily by plotting peak height ratios (drug or metabolite/internal standard) *versus* concentrations of spiked serum samples. These plots were linear over a 5–600-ng/mL concentration range. The mean ±*SD* slope value and intercept values are given in Table I. The lower limits of detection for metoprolol and the α-hydroxy metabolite were 4.9 and 3.8 ng/mL, respectively. Linearity was also demonstrated for metoprolol and α-hydroxymetoprolol when extracted from CSF and urine in the 15–150-ng/mL concentration range (Table I). Chromatograms of samples extracted from urine and CSF showed no additional peaks that interfere with quantification of the drug, metabolite, or internal standard (Fig. 4).

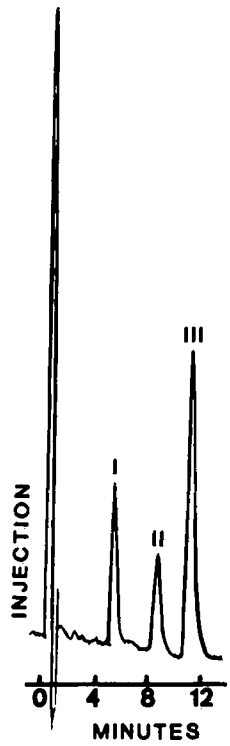

Figure 3—*Chromatogram of extracted serum from a patient receiving metoprolol. Key: (I) α-hydroxymetoprolol; (II) metoprolol; (III) internal standard.*

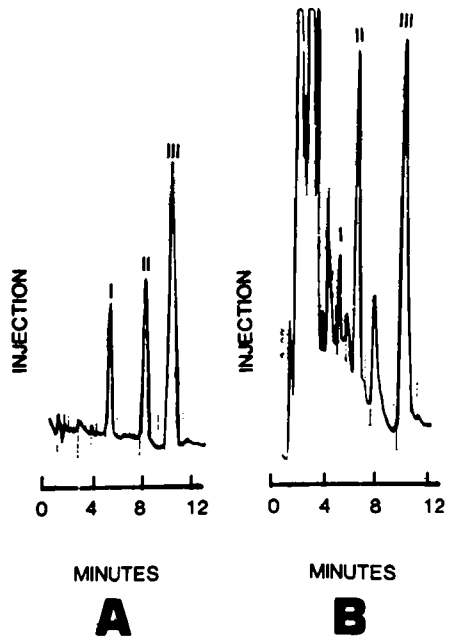

Figure 4—*Chromatograms of extracted CSF (A) and urine (B) containing α-hydroxymetoprolol (I), metoprolol (II), and internal standard (III).*

Recovery Experiments—The results of the recovery experiments are illustrated in Table II for both high and low concentrations. The overall recovery of metoprolol and α-hydroxymetoprolol ranged from 78.2 to 80.0% in serum, urine, and CSF over a 10-fold concentration range. Both metoprolol and α-hydroxymetoprolol also demonstrated similar within-day and between-day variations, as illustrated in Table III. The coefficient of variation ranged from 5.4 to 6.0% for within-day variation experiments, while the between-day studies ranged from 8.6 to 9.3%.

Human Serum Concentration Analysis—Figure 5 illustrates a serum concentration *versus* time profile for metoprolol and α-hydroxymetoprolol in the tremor patient following a 75-mg oral dose of metoprolol. After 2 h, peak concentrations were seen for the drug and its metabolite, 53.8 ng/mL and 88.1 ng/mL, respectively. After 7 h, both metoprolol and α-hydroxymetabolite decreased monoexponentially to 13.1 and 50.5 ng/mL, respectively.

Stability Study—To assess proper handling and storage conditions for

metoprolol and α-hydroxymetoprolol, the effect of temperature on the degradation rate was monitored. Over the 30-d test period, the samples frozen at −30°C remained stable. At 37°C, 25°C, and 5°C there was degradation within 14 d.

DISCUSSION

The metoprolol assay described in this report is specific, selective, and reproducible. Both drug and active metabolite can be specifically and reproducibly quantitated in urine, serum, and CSF in concentrations that are achieved by standard doses of metoprolol.

The procedure reported here is a modification of other previously reported metoprolol assays (10, 11). Modifications in the extraction process circumvents the need to distill reagents daily. These modifications also reduce background interference peaks in blood samples and prevent emulsification of reagents during the extraction. Modification in the mobile phase enables excellent separation of the drug, metabolite, and internal standard within a 15-min time period.

This procedure quantitates drug and metabolite concentrations from urine and CSF using the same experimental procedure used for serum. This procedure has been tested in patients concomitantly taking several medications. Drugs such as thiazide, benzodiazepines, digoxin, and thyroid hormone produced no interference; however, other β-blockers such as alprenolol, atenolol, naldolol, propranolol, sotalol, and timolol did interfere. In summary, this method provides a simplified and clinically comprehensive procedure for the analysis of metoprolol and α-hydroxymetoprolol.

Present addresses: §Analytical R and D Subdivision, Wyeth Laboratories, P.O. Box 8299, Philadelphia, PA 19101, and ¶Department of Drug Metabolism and Pharmacokinetics, Warner Lambert Co., Ann Arbor, MI 48105.

Abstract □ The relative bioavailability of hydrocortisone was determined from four different 20-mg tablet formulations and one suspension in 15 healthy male volunteers; results were compared with *in vitro* dissolution rates. Plasma levels of hydrocortisone were determined by a liquid chromatography method developed in this laboratory. Dissolution of the tablet formulations, using the official USP test, varied from 7.8 to 93.8% in 30 min. Similar plasma profiles were obtained from all tablet products, and there were no differences among tablets in the cumulative percentage of drug absorbed. There were no clear trends in any pharmacokinetic parameter values among the tablet dosages, and the four products were considered bioequivalent. The suspension dosage yielded significantly higher plasma levels compared with some of the tablet formulations during the initial 30-min postdose, significantly higher cumulative absorption at 0.5 and 1.0 h compared with one tablet formulation, and significantly higher k_a and C_{max}, and shorter t_{max} values, compared with some of the tablets.

Keyphrases □ Hydrocortisone—bioavailability, commercial 20-mg tablets, dissolution □ Bioavailability—hydrocortisone, commercial 20-mg tablets, dissolution □ Dissolution—bioavailability of hydrocortisone, commercial 20-mg tablets

Hydrocortisone was designated by the U.S. Food and Drug Administration as a drug whose different brands and dosage forms should be examined for bioequivalence (1). Previous studies in this laboratory have described optimum conditions for hydrocortisone pharmacokinetic studies (2, 3). Circulating hydrocortisone levels have been shown to be linearly related to dose size of oral suspensions (4) and also of intravenous hydrocortisone doses that give rise to plasma levels that are within the range observed with conventional oral doses (5).

This study was designed to examine the relative *in vivo* bioavailability and pharmacokinetics of hydrocortisone from commercial 20-mg tablets that have divergent *in vitro* dissolution characteristics, and to compare these with an oral suspension.

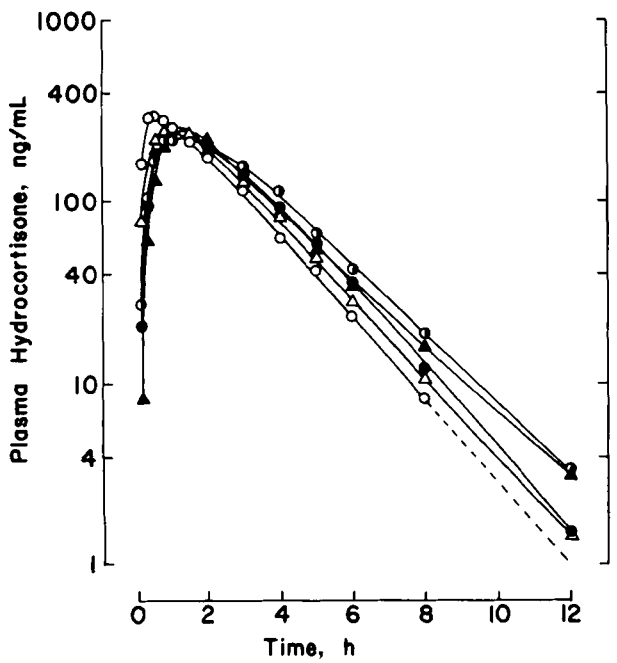

Figure 1— *Mean plasma levels of hydrocortisone in 15 healthy male volunteers following single 20-mg suspension and tablet doses. Key: (○) suspension A; (◑) tablet B; (●) tablet C; (△) tablet D; (▲) tablet E.*

EXPERIMENTAL SECTION

Products—The suspension[1] (treatment A) and the four tablet[2] formulations (treatments B–E) were purchased commercially.

Materials—Chemical standard hydrocortisone[3] and internal standard Δ^4-pregnen-17α,20β,21-triol-3,11-dione[3] were analytical grade. All other solvents and chemicals were reagent grade and were used as supplied. Plasma for construction of standard curves was obtained from healthy volunteers between 7 a.m. and 9 a.m. subsequent to administration of 2 mg of dexamethasone at 11 p.m. the previous day.

***In Vitro* Dissolution**—The *in vitro* dissolution rates of the tablets were determined in 900 mL of distilled water at 37°C using the USP rotating paddle method at 50 rpm (6).

Subjects—Fifteen male volunteers, 22–39 years old, underwent complete physical examinations, including urine and blood analyses, after giving informed consent. Vital signs and laboratory values for all subjects were normal. The subjects weighed 67–84 kg, and their heights ranged from 165 to 186 cm.

Protocol—Subjects were instructed to take no drugs for at least 1 week before, and no drugs other than the required doses of dexamethasone and hydrocortisone during the study. No caffeine-containing beverages were permitted for 1 d before or during the plasma sampling period following each dose of hydrocortisone. Each hydrocortisone dose was administered after an overnight fast, and no food was permitted until 4 h postdose.

The 15 subjects were randomly assigned to one of five groups, each consisting of three subjects. The five dosages (one suspension and four tablets) were administered to the groups according to a 5 × 5 crossover design. Dose size was 20 mg, and all dosages were separated by a 14-d interval.

At 11 p.m. on the day before hydrocortisone administration, subjects received 20 mL (2 mg) of dexamethasone elixir[4] orally together with 180 mL of water. Dexamethasone suppresses plasma levels of endogenous hydrocortisone (2). Hydrocortisone was administered the next morning at 8 a.m. The suspension was given in 20 mL of orange juice with additional water to 180 mL. Tablets were given with 180 mL of water and were swallowed whole. Heparinized blood samples (~8 mL) were taken from a forearm vein at 0, 10, 20, 30, 45 min, 1, 1.5, 2, 3, 4, 5, 6, 8, and 12 h postdose. Plasma was stored at −20°C until assayed.

Analytical Procedure—The HPLC-UV assay used to measure hydrocortisone in plasma was described previously (3, 4). The assay is linearly sensitive to plasma hydrocortisone concentrations between 5 and 700 ng/mL. The reproducibility of the assay is within 4% at the higher concentrations and within 8% at the lower concentrations. Suppressed hydrocortisone concentrations obtained immediately prior to drug administration were subtracted from all measured postdose levels.

Table I—Percentage of Drug Dissolved from Tablets in 30 min in Distilled Water at 37°C Using the USP Rotating Paddle Method at 50 rpm [a]

Tablet	Percentage Dissolved in 30 min [b]
B	93.8 ± 1.9
C	40.2 ± 7.4
D	68.7 ± 7.9
E	7.8 ± 1.1

[a] See Ref. 6. [b] Mean ± *SD*, $n = 12$.

Pharmacokinetic and Statistical Analyses—Individual plasma hydrocortisone profiles were interpreted in terms of Eq. 1 (7):

$$C = \frac{FD}{V}\left(\frac{k_a}{k_a - k_{el}}\right)(e^{-k_{el}(t-t_0)} - e^{-k_a(t-t_0)}) \qquad \text{(Eq. 1)}$$

where C is the concentration of exogenous hydrocortisone in plasma at time t, t_0 is the lag time between drug administration and appearance of exogenous drug in plasma, F is the fraction of the dose (D) that is absorbed, V is the apparent distribution volume of hydrocortisone in the body, and k_a and k_{el} are first-order rate constants for drug appearance in and elimination from plasma, respectively. Cumulative drug absorption profiles were constructed from individual data sets by the method of Wagner and Nelson (8). Model-independent estimates of areas under plasma drug concentration curves from zero to infinite time (AUC) were calculated by the trapezoidal rule, with end correction where necessary (9). Concentrations of hydrocortisone in plasma at each sampling time and all pharmacokinetic values were compared with treatments by analysis of variance for crossover design (10). Differences between individual treatments were examined using Tukey's test (11).

RESULTS

***In Vitro* Dissolution**—The mean percentage dissolution of the four tablet formulations is given in Table I. Tablet B dissolved rapidly, dissolution of this product being virtually complete in 30 min. Dissolution of tablets C and D was somewhat slower than tablet B, while tablet E dissolved even more slowly, over 90% of this product being still intact at 30 min.

***In Vivo* Bioavailability**—The mean plasma levels of exogenous hydrocortisone from the suspension and tablet dosages are given, together with standard deviations, in Table II. The mean plasma profiles are summarized on a semilogarithmic scale in Fig. 1. The results of pharmacokinetic analysis are given in Table III.

Following the suspension dose, plasma hydrocortisone levels reached a mean peak concentration of 311 ng/mL at 0.5 h. Absorption was somewhat slower following the tablet dosages and mean peak levels ranging from 225 to 285 ng/mL were obtained at 1.0–1.5 h postdose. After peak levels had been achieved, plasma levels from all dosages declined monoexponentially to reach mean values of 1.5–3.5 ng/mL at 12 h following the tablet doses, and baseline values following the suspension dose. The suspension dose tended to yield higher plasma hydrocortisone levels compared with the tablets during the initial 30-min postdose period. However there were only minor differences in plasma levels between all dosage forms at times subsequent to this.

The mean cumulative percentage of doses absorbed during 4 h postdose are summarized in Fig. 2 (8). Ninety percent of systemically available drug was absorbed by 1 h following the suspension dose and by 2–3 h from the tablets. The suspension gave rise to significantly higher cumulative absorption compared with tablet E at 0.5 and 1 h, but there were no other significant treatment effects at any other sampling time.

There was considerable variation in some pharmacokinetic parameter values, both within and between treatments (Table III). For example, the mean value of k_a ranged from 0.9 ± 0.4 (*SD*) to 7.2 ± 5.4 h^{-1} for treatments E and A, respectively, with other treatments yielding intermediate values, but significant differences ($p < 0.05$) were observed only between the suspension dose and three of the tablet doses. Interpretation of the k_a values is difficult as they are influenced by the computer-generated values of t_0, which had to be arbitrarily fixed while fitting data from treatment E in order to obtain satisfactory convergence. An additional complication is that hydrocortisone has been shown to obey two-compartment kinetics following intravenous administration (5), so that the numerical value of k_a after oral doses is simultaneously influenced by both distribution and absorption phenomena. The various treatments did not significantly influence the hydrocortisone elimination rate.

Faster absorption of hydrocortisone from the suspension compared with tablets is reflected in high C_{max} and low t_{max} values from treatment A compared with some of the tablet dosages. The higher C_{max} from treatment D compared with treatment E was the only significant difference among tablets for the parameters C_{max} and t_{max}. Tablet E gave rise to somewhat slower

[g] Coefficient of determination, $r^2 = (\Sigma obs^2 - \Sigma dev^2)/\Sigma dev^2$, obtained by fitting individual data to Eq. 1. [h] Deviation sums of squares.

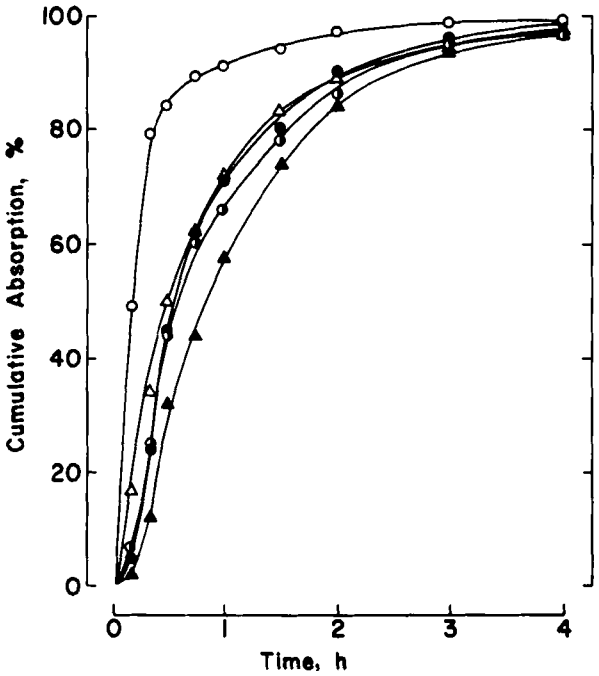

Figure 2—*Mean cumulative percentage of available hydrocortisone dose absorbed by 4 h postdose. Key: (○) suspension A; (◑) tablet B; (●) tablet C; (△) tablet D; (▲) tablet E.*

absorption compared with both the suspension and Tablet D, but the parameter *FD/V*, which is equivalent to the AUC normalized for variations in k_{el}, was significantly higher from treatment E compared with treatments A and C.

The high coefficients of determination for treatments A–D, and also similar deviation sums of squares for these treatments, indicate that individual plasma data sets were adequately described by Eq. 1. Plasma profiles tended to be somewhat more variable from tablet E, and this is reflected in the lower coefficient of determination and greater deviation sums of squares for this tablet formulation. Numerical values for pharmacokinetic values in this study are generally similar to those reported earlier (4, 5).

The HSD values in Table III indicate the difference between parameter values that this study was capable of detecting at the 95% confidence level (10). Comparison of the HSD and parameter values indicates that the study was capable of detecting a 25% difference between treatments at the 95% confidence level for all pharmacokinetic parameters except t_{max}, where a 29% difference could be detected, and k_a and t_0, for which the study was relatively insensitive.

DISCUSSION

Previous studies in this laboratory have suggested that hydrocortisone is ~50–60% available to the systemic circulation following 10–20-mg tablet or suspension doses (4, 5). The results of the present study show that incomplete absorption of hydrocortisone is probably due to intrinsic absorption effects, first-pass hepatic clearance, or both. The similar plasma profiles obtained among tablet dosages, despite a 12-fold range in their dissolution rates, and also similar overall absorption efficiency from the tablet and suspension formulations suggest that dissolution does not play a dominant role in oral hydrocortisone absorption. Our observations with hydrocortisone are similar to those reported earlier for prednisolone and prednisone (12, 13). In those studies, similar plasma profiles for prednisolone were obtained from oral tablet formulations with widely divergent dissolution characteristics in water.

Apart from the discrepancies between products C and E in the value of *FD/V*, and between products D and E in the value of C_{max}, the four tablet products examined here can be considered bioequivalent. However, two of the products (C and E) did not meet the official dissolution requirements for hydrocortisone tablets, *i.e.*, 70% dissolution in 30 min (6). Since completion of the *in vitro* dissolution studies, these products have been reformulated to meet the official requirements[5].

In conclusion, the four hydrocortisone tablet products studied here were bioequivalent. We conclude that other hydrocortisone products meeting the official dissolution test requirement will also be bioequivalent.

Properties of Carbonate-Containing Aluminum Hydroxide Produced by Precipitation at Constant pH

EDWARD C. SCHOLTZ *, JOSEPH R. FELDKAMP ‡, JOE L. WHITE ‡, and STANLEY L. HEM *x

Received May 2, 1983, from the *Departments of *Industrial and Physical Pharmacy and ‡Agronomy, Purdue University, West Lafayette, IN 47907. Accepted for publication July 19, 1983.

Abstract □ Carbonate-containing aluminum hydroxide was precipitated at constant pH at intervals of 0.5 pH units from pH 6 to 10 by pumping 0.5 M $AlCl_3$ into the reaction vessel at a constant rate of 2 mL/min and infusing 2 M Na_2CO_3 at a rate necessary to maintain the desired pH. The pH of precipitation affected both the particle size and the composition of the precipitate. The particle size of the precipitate decreased as the pH of precipitation was increased from 6 to 10. The precipitates formed between pH 7.5 and 9.5 contained crystalline sodium aluminum hydroxycarbonate (dawsonite) in addition to amorphous carbonate-containing aluminum hydroxide.

Keyphrases □ pH—precipitation, carbonate-containing aluminum hydroxide □ Aluminum hydroxide—carbonate containing, production by precipitation at constant pH

Many processes for the preparation of aluminum hydroxide have been reported (1). Examples of these processes include (*a*) slowly cooling a concentrated sodium aluminate solution (2, 3); (*b*) bubbling CO_2 through a concentrated sodium aluminate solution (4–6); (*c*) hydrolysis of aluminum alcoholates (7, 8) or amalgamated aluminum foil (8); and (*d*) neutralization of an aluminum salt solution with a base (9–11). Aluminum hydroxide for pharmaceutical use is often prepared by the neutralization of an aluminum salt solution with a base. Some of the important variables associated with this method include temperature, pH, agitation, method of addition, reactants, reactant concentration, and addition rate (6, 12–18).

Three methods have been utilized for neutralizing an aluminum salt with a base. The first method involves the addition of the aluminum salt to the base (15, 17–20) and is limited to batch processes. The high pH of the base is decreased by the addition of the aluminum salt until a specific pH end point is reached. The second method is the opposite of the first, *i.e.*, base is added to the aluminum salt solution (12–14, 16–18, 21–23). The second method is also a batch process, as base is added until a specific pH end point is reached. In the third method, an aluminum salt solution and a base are simultaneously mixed (8, 17, 24). This method can be either a batch or a continuous process.

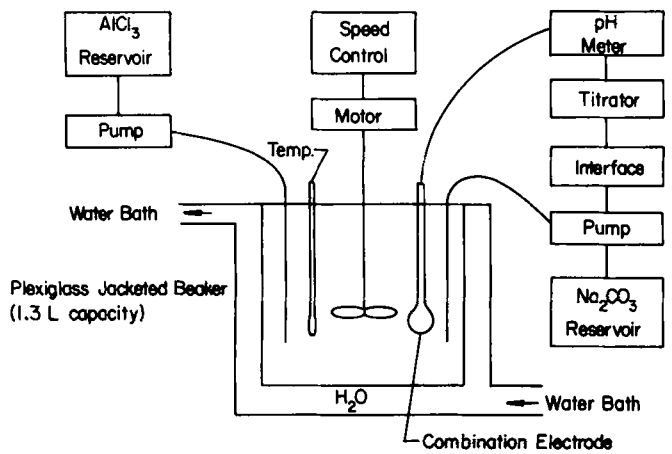

Figure 1—*Schematic of the apparatus used for constant pH precipitation of carbonate-containing aluminum hydroxide.*

Although far less common than other methods, the method of simultaneous mixing of reactants permits the precise control of pH. Since the solubility of aluminum hydroxide is very sensitive to pH, fixing this variable during the precipitation reaction should have a strong influence on the properties of the precipitate.

The objective of the present study was to examine aluminum hydroxide precipitates prepared under the constraint of constant pH. Precipitation reactions were carried out over the pH range of 6 to 10 with an automated apparatus which controls the pH within ±0.03 pH units of the desired value. Since carbonate-containing aluminum hydroxide is of considerable pharmaceutical importance (15), sodium carbonate was used as the base that was treated with aluminum chloride. After the precipitates were prepared, their physical and chemical properties were examined.

EXPERIMENTAL SECTION

Experimental laboratory gels were precipitated at 25°C from pH 6 to 10 at intervals of 0.5 pH units. The apparatus employed for the constant pH precipitations is shown in Fig. 1. The reaction vessel was a jacketed polymethyl methacrylate[1] beaker (10.2 cm i.d., 16.1 cm depth) with a capacity of 1.3 L. The vessel was fitted with four equally spaced polymethyl methacrylate baffles to provide efficient mixing.

The 0.5 M $AlCl_3$ and 2.0 M Na_2CO_3 solutions were injected into the reaction medium through submerged polytef tubes (0.1 mm i.d.). The aluminum chloride solution was pumped continuously into the reaction vessel at a constant rate of 2 mL/min. The sodium carbonate solution was infused into the system as needed to maintain the pH within 0.03 pH units of the predetermined value. The pH was constantly monitored and automatically controlled through the use of a titrator[2] linked between the pH meter and the sodium carbonate injection pump. The titrator was interfaced to the sodium carbonate pump with an opto-coupler chip.

A precipitation reaction was initiated by first placing 250 mL of 0.75 M $NaHCO_3$ into the reaction vessel. Since the pH was ~8.0, either 0.5 M $AlCl_3$ or 2.0 M Na_2CO_3 was infused until the desired pH was reached. When aluminum chloride was used, precipitation occurred during this period of pH adjustment, but the amount of precipitate formed was always insignificant when compared with the total amount of precipitate. Due to the large volume change occurring during the precipitation reaction (250 to 1300 mL), it was

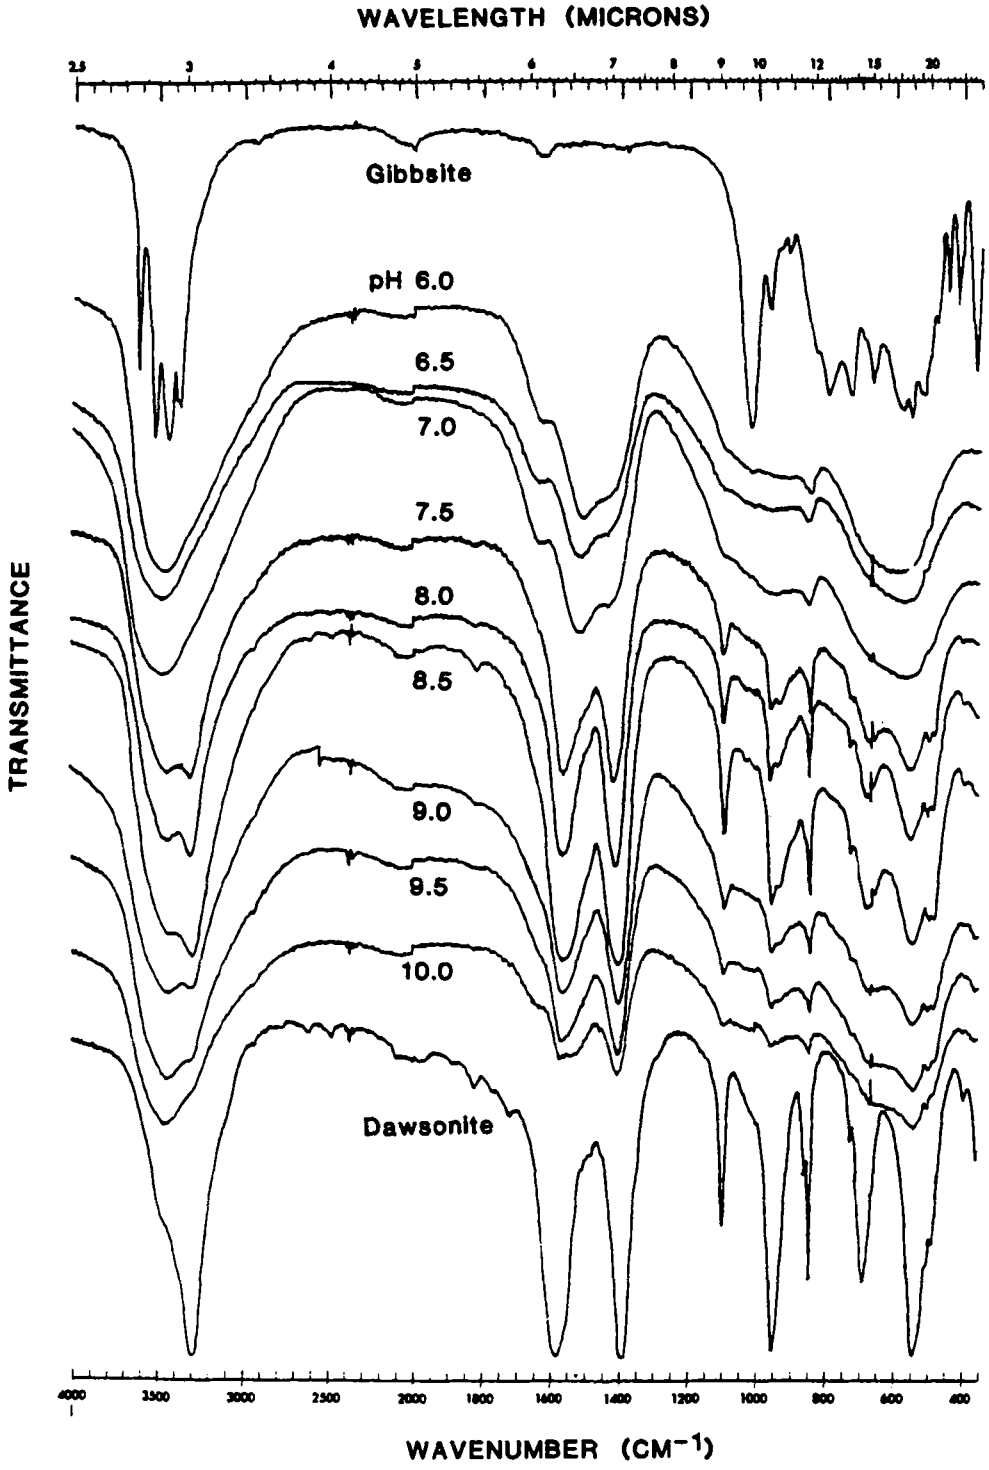

Figure 3—*IR spectra of precipitates formed at various pH_p.*

necessary to vary the stirring rate from 600 to 1200 rpm as needed. A marine propeller (diameter, 6.4 cm) was used to provide uniform mixing.

On completion of the precipitation reaction, the precipitate was washed by centrifugation with deionized water until the chloride content of the supernatant, as determined by a silver nitrate test, was $<6.2 \times 10^{-7}$ M. The washing step was always completed within 24 h of the termination of the precipitation reaction. The final suspension concentration was adjusted to fall within the range of 2–8% (w/w) equivalent Al_2O_3.

The equivalent aluminum oxide content was determined by chelatometric titration (25). IR analysis[3] was performed on air-dried samples as potassium bromide pellets (0.75 mg/300 mg of KBr). Carbonate was determined by a gasometric displacement technique (26, 27) with the Chittick apparatus[4]. The sodium ion content was measured by atomic absorption spectrometry[5]. The ability of magnesium cation to replace sodium cation in the pH 8.5 precipitate was determined by washing 600 mL of the precipitate with 600 mL of 1 M $MgCl_2$. The solids were washed four times with 1 M $MgCl_2$ by centrifugation and were then further washed with deionized water until the chloride content of the supernatant, as determined by a silver nitrate test, was $<6.2 \times 10^{-7}$ M. The point of zero charge (PZC) was determined for each sample by a continuous titration procedure (28).

To provide a qualitative measurement of particle size, the following sedimentation experiment was carried out. One hundred milliliters of sample was adjusted to the following conditions: 1% (w/v) equivalent Al_2O_3; ionic strength, 0.4; and pH = PZC. The sedimentation height in a sealed, undisturbed 100-mL graduated cylinder was monitored for 48 h. Two parameters

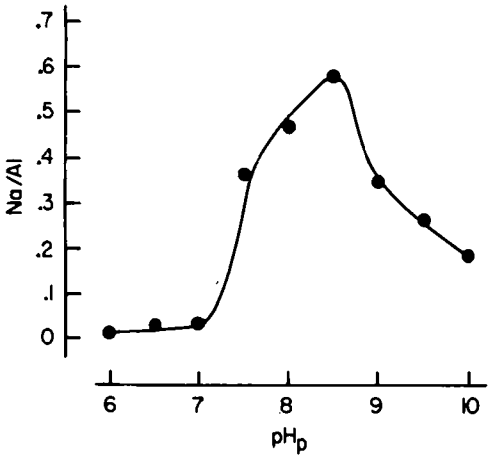

Figure 4—*Effect of pH_p on the sodium-aluminum molar ratio.*

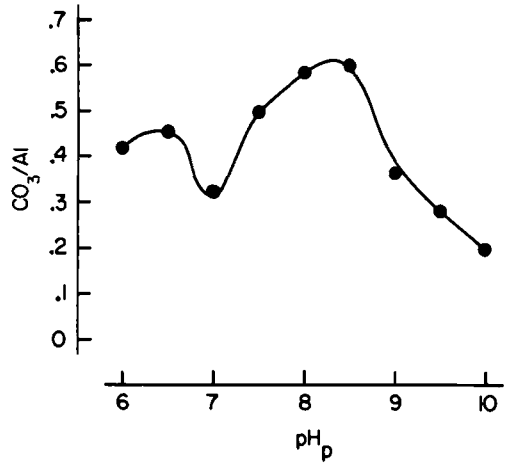

Figure 5—*Effect of pH_p on the carbonate-aluminum molar ratio.*

were used to summarize the sedimentation data: V_{48}, the sediment volume of the flocculated material at the end of the sedimentation period; and τ_{50}, the time required for the sediment volume to reach $(100 + V_{48})/2$. The values of both parameters are inversely related to particle size.

An additional qualitative measurement of particle size was the rate of acid neutralization as measured by pH-stat titration at pH 3.0 and 25°C (29). The time required to neutralize 50% of the sample, t_{50}, was used to characterize the rate of acid neutralization. A smaller value for t_{50} was assumed to infer a larger effective surface area and, hence, a smaller particle size. Particle size was directly measured for samples precipitated at pH 7.0 and 9.5 with a particle counter[6] and a fiber optic Doppler anemometer[7] (30), respectively.

RESULTS AND DISCUSSION

Chemical Structure—In a carbonate-containing system, X-ray and IR analyses have shown that aluminum hydroxide typically forms as an amorphous precipitate consisting of small, two-dimensional crystallites (primary particles) which vary widely in size (15, 31, 32). The crystallites have been identified as precursors of the various crystalline forms of aluminum hydroxide, such as gibbsite (32–34). The edges of the planar crystallites (Fig. 2) serve as sites for specific adsorption of carbonate, which likely takes place immediately after the crystallites have formed (15, 28, 31, 35).

The IR spectra of the precipitates formed at a pH of precipitation (pH_p) of 6.0, 6.5, and 7.0 (Fig. 3, Table I) are typical of amorphous aluminum hydroxide containing specifically adsorbed carbonate (15, 31) and indicate the presence of only an amorphous component. The precipitates formed between pH_p 7.5 and 9.5 exhibit a number of absorption bands in addition to the carbonate-containing aluminum hydroxide bands (Fig. 3). The new absorption bands correspond with the mineral dawsonite, a crystalline sodium aluminum hydroxycarbonate [$NaAl(OH)_2CO_3$] (Table I). The IR analysis indicates that the precipitate formed at pH_p 8.5 contained the largest fraction of dawsonite. This was confirmed by chemical analysis. The theoretical sodium-aluminum molar ratio for dawsonite is 1 and is typically near 0 for carbonate-containing aluminum hydroxide. The theoretical carbonate-aluminum molar ratio of dawsonite is 1, whereas the maximum carbonate-aluminum molar ratio of carbonate-containing aluminum hydroxide has been reported to be 0.5 (15). The maximum sodium-aluminum molar ratio (Fig. 4) and the maximum carbonate-aluminum molar ratio (Fig. 5) occurred at pH_p 8.5 and are attributed to dawsonite formation. Caution is required when interpreting the chemical analysis data since the sodium and carbonate ions do not reside exclusively in the dawsonite crystal lattice. Carbonate may be specifically adsorbed to the amorphous aluminum hydroxide component, and sodium can be bound in substantial quantities as a double-layer ion.

To more accurately determine the dawsonite content of the precipitate formed at pH_p 8.5, a portion of the precipitate was washed with 1 M $MgCl_2$ so that a magnesium-sodium cation exchange reaction might take place. Since the sodium in the dawsonite crystal lattice is not exchangeable, any nonexchangeable sodium is assumed to be associated with dawsonite. The sodium-aluminum molar ratio in carbonate-containing aluminum hydroxide-dawsonite systems can range from 0 in the absence of dawsonite to 1 in the absence of carbonate-containing aluminum hydroxide. The sodium-aluminum molar ratio of the precipitate at pH_p 8.5 decreased from 0.50 to 0.42 after magnesium exchange. The nonexchangeable sodium content indicates that dawsonite accounts for ~42% of the precipitate formed at pH_p 8.5.

The dawsonite content of the precipitate dropped sharply when the pH_p was above or below 8.5 (Figs. 3–5). For example, only trace levels of dawsonite were seen in the IR spectra at pH_p 10, and no indication of dawsonite was seen in the IR spectrum of precipitates at or below pH_p 7.0. Apparently, the requirements for the nucleation of dawsonite were best met at pH_p 8.5.

Particle Size—The rate of acid neutralization and sedimentation measurements can only be used to provide a qualitative measurement of particle size. However, since it was readily apparent from visual observation that the particle size was very sensitive to the pH_p, acid reactivity and sedimentation data were viewed as adequate for determining particle size trends as a function of pH_p. None of the three parameters was able to reflect the change in particle size over the entire pH_p range because of the substantial variation in particle size of the precipitates and the limitations of each technique. The rate of acid neutralization (Fig. 6) indicates a decrease in particle size from pH_p 6.0 to 7.5, whereas both sedimentation parameters, τ_{50} (Fig. 7) and V_{48} (Fig. 8), indicate a decrease in particle size from pH_p 7.0 to 10.0. However, when the t_{50}, τ_{50}, and V_{48} values are analyzed together, it is clear that the particle size decreases as the pH_p increases from 6 to 10.

Particle counter and fiber optic Doppler anemometer measurements were obtained for precipitates formed at pH_p 7.0 and 9.5 to confirm the conclusions drawn from the rate of acid neutralization and sedimentation studies. Particle size variation was quite large, so that measurements were made only for those samples precipitated at pH_p 7.0 and 9.5. The results indicated mean particle diameters of 12.0 and 0.20 μm at pH_p 7.0 and 9.5, respectively. Thus, over the pH_p range of 6.0 to 10.0, there is at least a 50-fold decrease in particle size.

Mechanism of Particle Size Variation—Although dawsonite was formed in significant quantities near pH_p 8.5, amorphous aluminum hydroxide formed the major component in all precipitates. Those precipitates formed at pH_p

9.0			3430			3290	1818		1560			1400	1093
9.5			3440			3290			1560			1400	1092
10.0			3440						1560			1403	1090

6.0, 6.5, 7.0, and 10.0 were found to be essentially free of dawsonite. Thus, the inverse relationship observed between pH_p and particle size is primarily related to the particle size variation of the amorphous component.

The lack of specific diffraction bands in the X-ray diffraction patterns of precipitates containing amorphous aluminum hydroxide establishes that there is no long-range atomic order in these systems (15, 31, 32, 40). The IR spectra (Fig. 3), which are much more sensitive to the presence of ordering, show broad hydroxyl-stretching bands centered at ~3440 cm^{-1}, which indicate the absence of specific proton environments. Thus, the observed large particles of amorphous carbonate-containing aluminum hydroxide (much larger than unit cell dimensions) must be composed of substantially smaller crystallites with dimensions not much larger than that of a unit cell, *i.e.*, primary particles.

The effect of the pH on the primary particle size is described by the von Weimarn law (41):

$$1/d = k(S/S_0) \qquad \text{(Eq. 1)}$$

where d is the diameter of the primary particle, k is a constant, S is the concentration of monomeric aluminum, and S_0 is the solubility, *i.e.*, the concentration of monomeric aluminum in equilibrium with infinitely large aluminum hydroxide particles, *e.g.*, highly crystalline gibbsite. The variable S is related to the concentration and infusion rate of the aluminum chloride solution. Since a 0.5 M $AlCl_3$ solution was infused into the reaction vessel at a rate of 2 mL/min for all precipitations, S is constant for all precipitates. The solubility of aluminum hydroxide (Fig. 9) is strongly influenced by pH (40, 42, 43), and therefore, S_0 varies considerably with pH_p. Since a 0.5 M $AlCl_3$ solution is infused into the reaction vessel, S/S_0 is always $\gg 1$. Therefore, precipitation is expected at all pH_p conditions.

The solubility of aluminum hydroxide is lowest at pH 5.5 to 6.0 and increases sharply as the pH is increased to 10. The ratio, S/S_0, is largest between pH 5.5 and 6.0 and decreases as the pH_p is increased. Therefore, the von Weimarn law predicts that the primary particle size is smallest near pH_p 6.0 and increases markedly as pH_p 10 is approached.

The von Weimarn law describes the size of the primary particles but does not provide any information about the subsequent formation of coagulates. However, based on the preceding conclusions concerning the primary crystallite size, DLVO theory may be used to predict the size of the coagulates. DLVO theory states that interparticle forces are a function of particle size (44, 45). In the case of electric double-layer repulsion between spherical particles of radius r, the following equation relates potential energy, V, to the separation distance, x, between two particles:

$$V = \epsilon\psi_0^2[r^2/(2r + x)]e^{-\kappa x} \qquad \text{(Eq. 2)}$$

where ϵ is the dielectric constant, ψ_0 is the surface electrical potential, and κ^{-1} is the Debye length. Clearly, the repulsive potential energy is increased for particles of larger radius. For large separation between particles, the potential energy is proportional to the square of the radius of the particles, so that the potential energy increases sharply as the particle size increases. The van der Waals attractive force, however, shows the same dependence on particle size, thereby compensating for the effect of particle size on the repulsive force (46).

Although particle size does not affect coagulation, the magnitude of the surface potential has a considerable effect which is independent of the van der Waals force. According to Eq. 2, the coulombic interaction energy varies with the square of the surface potential. For variable charge surfaces such as carbonate-containing aluminum hydroxide, ψ_0 is approximately proportional to PZC − pH (28, 47). Figure 10 shows that the difference between the PZC and the pH_p increases as the pH_p increases. The surface potential is therefore quite small for the precipitate formed at pH_p 6, but the surface potential becomes increasingly negative as the pH_p increases. Thus, the effect of surface potential on electric double-layer repulsion indicates that the probability of coagulation decreases as the pH_p increases from 6 to 10.

Once a coagulate has formed, its continued existence depends on its cohesive strength, which is a function of primary particle size. If only spherical particles are considered and the van der Waals attractive force is assumed to be the only interparticle force, then the following equation describes the relationship between coagulate cohesive strength, σ, the coagulate void volume fraction, ϕ, and the diameter of the primary particle, d:

$$\sigma = \frac{3(1-\phi)A}{64\phi a^2 d} \qquad \text{(Eq. 3)}$$

where A is a constant and a is the shortest interparticle separation distance (44). Equation 3 indicates that as ϕ, a, and d decrease (each decreases as the particle size decreases), the coagulate cohesive strength increases. The interparticle separation distance, a, is expected to be smaller for smaller particles due to a diminished absolute surface roughness. The coagulate void volume fraction, ϕ, decreases as the particle size, d, decreases due to packing considerations. Consequently, smaller primary particles are more likely to form survivable coagulates which are not easily destroyed when exposed to shear.

On consideration of the preceding factors, it is reasonable to conclude that the coagulate number (defined as the number of primary particles per coagulate) is largest for precipitates formed at pH_p 6 and considerably smaller for precipitates formed at pH_p 10. It is not certain, based solely on theoretical grounds, that there exists a sufficiently large variation in coagulate number to account for the greater than 50-fold variation in particle size observed by particle counter and fiber optic Doppler anemometry. However, the electric double-layer and coagulate cohesive strength considerations are of sufficient magnitude to account for the observed decrease in particle size as the pH_p is increased from 6 to 10.

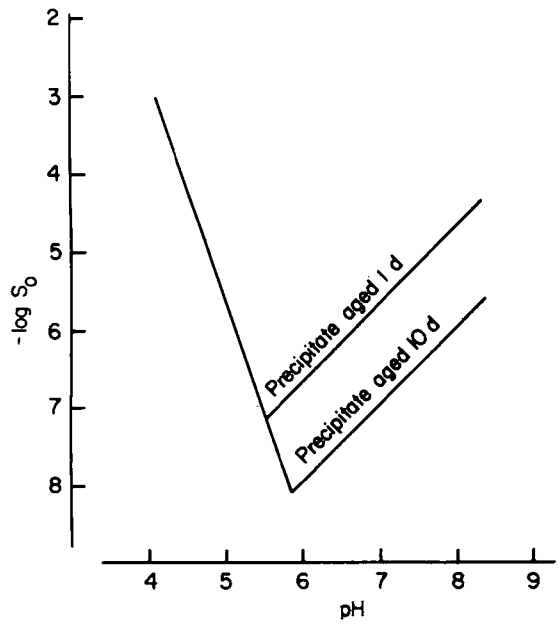

Figure 9—*Effect of pH on the solubility (S_0) of aluminum hydroxide (40).*

An excellent indication of the magnitude of the variation in coagulate number is provided by the pH-stat titrigrams for the precipitates formed at pH_p 6.0, 6.5, and 7.0 (Fig. 11). The titrigrams represent the cumulative amount of acid neutralized at pH 3 as a function of time. A very dramatic displacement of the titrigrams toward shorter reaction times is observed as the pH_p increases. If the von Weimarn law (Eq. 1) has correctly predicted that the primary particle size increases with increasing pH_p (which would tend to increase the t_{50}), then the observed increase in the rate of acid neutralization of the precipitate formed at pH_p 7.0 indicates a substantially lower coagulate number than the precipitate formed at pH_p 6.0.

Although speculative, the arrangement of primary particles within the secondary particles (coagulates) in carbonate-containing aluminum hydroxide might be comparable with the coagulate structures postulated for other materials composed of two-dimensional crystallites. The coagulate structure indicated in Fig. 12 has been proposed for carbon black (48). The edge-to-edge alignment of crystallites within the coagulates is in accord with the effects of van der Waals forces (49). The rectangular blocks represent the particles shown in Fig. 2 viewed from the edge. The results of this study suggest that such models might also describe the carbonate-containing aluminum hydroxide system.

Application to Commercial Precipitation of Carbonate-Containing Aluminum Hydroxide—The physical and chemical properties of carbonate-containing aluminum hydroxide are critically dependent on the pH_p. The property most sensitive to pH_p is particle size. The effect of pH_p on particle size is believed to be a result of variations in primary particle size as predicted by the von Weimarn law and the effects of double-layer repulsion and van der Waals attraction on coagulate formation (secondary particles). In addition to particle size effects, a crystalline phase identified as dawsonite, $NaAl(OH)_2CO_3$, was observed to form along with amorphous carbonate-containing aluminum hydroxide when the pH_p was between 7.5 and 9.5.

For most commercial aluminum hydroxide production, batch processes are utilized and, therefore, either lack pH control altogether or provide for very

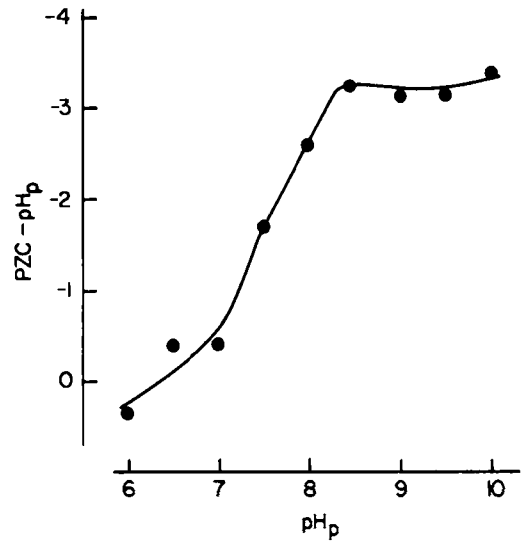

Figure 10—*Effect of pH_p on the difference between the point of zero charge (PZC) and pH_p.*

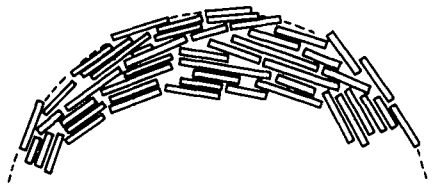

Figure 12—*Cross-sectional schematic for a coagulate (secondary particle) composed of planar primary crystallites (primary particles.)*

little control during the precipitation process. The product, therefore, is highly polydisperse and variable in composition. Consequently, considerable variation and uncertainty exist in the physical and chemical properties of carbonate-containing aluminum hydroxide precipitated by a batch process.

Certain properties may be desirable for specific applications of carbonate-containing aluminum hydroxide. The understanding gained from this study on the effect of the pH_p on the particle size and composition of the precipitate can be applied to aid in the design of precipitation processes which yield carbonate-containing aluminum hydroxides with desired properties. For example, a high surface area (small particle size) may be desired when aluminum hydroxide is used as an adsorbent. Thus, precipitation at a high pH is desired, as the smallest particle size was produced at pH_p 10.

In other situations, a low-viscosity suspension with a high solids content may be desired. To produce this property, a large particle size is necessary, and a pH_p of 6.0 is desirable. The precipitate at pH_p 6.0 formed a free-flowing suspension until a concentration of 18–20% (w/w) equivalent Al_2O_3 was reached, whereas the precipitate formed at pH_p 10 underwent gelation at only 2–3% (w/w) equivalent Al_2O_3. This behavior is readily recognized as a particle size effect since smaller particles are able to form a more extensive network or array (50).

It may also be desirable to produce carbonate-containing aluminum hydroxide which is free of sodium. The results of this study show that the precipitates formed between pH_p 7.5 and 9.5 contained appreciable amounts of dawsonite and, therefore, have a significant sodium content. The sodium in dawsonite cannot be removed through either washing or cation exchange since sodium is part of the crystal structure. Thus, batch precipitations which sweep through the pH_p range of 9.5 to 7.5 will produce precipitates which contain sodium as a permanent component.

Hypolipidemic Activity of Tetrakis-μ-(trimethylamine-boranecarboxylato)-*bis*(trimethylamine-carboxyborane)-dicopper(II) in Rodents and Its Effect on Lipid Metabolism

I. H. HALL *[x], W. L. WILLIAMS, Jr.*, COLLEEN J. GILBERT*, A. T. Mc PHAIL [‡], and B. F. SPIELVOGEL [‡]

Received April 25, 1983, from the **School of Pharmacy, University of North Carolina at Chapel Hill, Chapel Hill, 27514* and [‡]*Paul M. Gross Chemical Laboratory, Duke University, Durham, NC 27706.* Accepted for publication June 8, 1983.

Abstract □ A binuclear copper(II) complex was shown to have potent hypolipidemic activity in rats and mice at low doses, *i.e.*, 2.5-10 mg/kg/d. The agent moderately lowered liver ATP-dependent citrate lyase, acetyl CoA synthetase, and phosphatidate phosphohydrolase activities *in vivo*. The appetite of the animal was reduced by drug treatment, and orally administered cholesterol absorption from the intestine was markedly lowered. Higher lipid levels were found in the chyme and the feces, indicating accelerated excretion of lipids by the drug, probably *via* the biliary route. Organs, *e.g.*, liver and small intestine, as well as serum lipoprotein levels, demonstrated lower lipid content after drug administration. Thus, this chemical class of agents may have potential as a hypolipidemic agent in humans.

Keyphrases □ Binuclear copper(II) complex—antihyperlipidemic activity in rodents, effect on lipid metabolism □ Antihyperlipidemic agents—binuclear copper(II) complex, activity in rodents, effect on lipid metabolism □ Cholesterol—antihyperlipidemic effect of binuclear copper(II) complex

Recently, a series of amine-cyanoboranes and amine-carboxyboranes were observed to be hypolipidemic in mice between 5 and 20 mg/kg ip (1). From *in vitro* studies of these series, the ability to lower serum cholesterol appeared to correlate positively with the inhibition of the liver regulatory enzyme β-hydroxy-β-methyl glutaryl CoA (HMG CoA reductase) reductase activity, and the reduction of serum triglyceride was correlated with inhibition of fatty acid synthetase activity (1). Subsequently, a binuclear copper(II) complex derived from trimethylamine-carboxyborane, *viz.*, tetrakis-μ-(trimethylamine-boranecarboxylato)-*bis*(trimethylamine-carboxyborane)dicopper(II) was synthesized, and its effects on lipid metabolism is reported.

EXPERIMENTAL SECTION

Preparation of Tetrakis-μ-(trimethylamine-boranecarboxylato)-*bis*(trimethylamine-carboxyborane)dicopper(II)—Cupric chloride was purchased commercially[1]. Trimethylamine-carboxyborane was prepared as described previously (2). Trimethylamine-carboxyborane (1.8703 g, 15.9 mmol) was dissolved in 1 M NaOH (16 mL) and water (20 mL). Dropwise addition of 23 mL of a solution of $CuCl_2 \cdot 2H_2O$ (1.36 g, 8 mmol) in water (40 mL) produced a dark green solution which was allowed to stand overnight. Subsequent filtration through a fine-fritted funnel removed a greenish-brown sludge and left a dark-green filtrate, which was allowed to evaporate in the atmosphere. After 6 d, the solution evaporated, leaving many small green crystals in a clear liquor. These crystals were filtered and washed with chloroform (40°C); no $(CH_3)_3N \cdot BH_2COOH$ crystals were evident. The green crystals were then splashed with a minimal amount of cold water to ensure removal of any trace of sodium chloride and dried *in vacuo*. The yield was 0.49 g (23%), mp 165°C (dec.); IR: ν_{BH}, 2350, $\nu_{C=O}$ 1665 cm^{-1}.

Anal.—Calc. for $C_{24}H_{68}B_6Cu_2N_6O_{12}$: C, 34.95; H, 8.31; N, 10.19. Found: C, 35.00; H, 8.49; N, 10.15. The structure was determined by single-crystal X-ray analysis (3).

Antihyperlipidemic Screens in Normal Rodents—Compounds to be tested were suspended in 1% aqueous carboxymethylcellulose and administered to male CF_1 mice (~25 g) intraperitoneally for 16 d or male Holtzman rats (~350 g) orally by an intubation needle for 14 d. On days 9 and 14 or 16, blood was obtained by tail vein bleeding, and the serum was separated by centrifugation for 3 min. The serum cholesterol levels were determined by a modification of the Liebermann-Burchard reaction (4). Serum triglyceride levels were determined with a commercial kit[2] for a different group of animals bled on day 14 or 16.

Testing in Induced Hyperlipidemic Mice—Male CF_1 mice (~25 g) were

Received April 25, 1983, from the **School of Pharmacy, University of North Carolina at Chapel Hill, Chapel Hill, 27514* and [‡]*Paul M. Gross Chemical Laboratory, Duke University, Durham, NC 27706.* Accepted for publication June 8, 1983.

Abstract □ A binuclear copper(II) complex was shown to have potent hypolipidemic activity in rats and mice at low doses, *i.e.*, 2.5-10 mg/kg/d. The agent moderately lowered liver ATP-dependent citrate lyase, acetyl CoA synthetase, and phosphatidate phosphohydrolase activities *in vivo*. The appetite of the animal was reduced by drug treatment, and orally administered cholesterol absorption from the intestine was markedly lowered. Higher lipid levels were found in the chyme and the feces, indicating accelerated excretion of lipids by the drug, probably *via* the biliary route. Organs, *e.g.*, liver and small intestine, as well as serum lipoprotein levels, demonstrated lower lipid content after drug administration. Thus, this chemical class of agents may have potential as a hypolipidemic agent in humans.

Keyphrases □ Binuclear copper(II) complex—antihyperlipidemic activity in rodents, effect on lipid metabolism □ Antihyperlipidemic agents—binuclear copper(II) complex, activity in rodents, effect on lipid metabolism □ Cholesterol—antihyperlipidemic effect of binuclear copper(II) complex

Recently, a series of amine-cyanoboranes and amine-carboxyboranes were observed to be hypolipidemic in mice between 5 and 20 mg/kg ip (1). From *in vitro* studies of these series, the ability to lower serum cholesterol appeared to correlate positively with the inhibition of the liver regulatory enzyme β-hydroxy-β-methyl glutaryl CoA (HMG CoA reductase) reductase activity, and the reduction of serum triglyceride was correlated with inhibition of fatty acid synthetase activity (1). Subsequently, a binuclear copper(II) complex derived from trimethylamine-carboxyborane, *viz.*, tetrakis-μ-(trimethylamine-boranecarboxylato)-*bis*(trimethylamine-carboxyborane)dicopper(II) was synthesized, and its effects on lipid metabolism is reported.

EXPERIMENTAL SECTION

Preparation of Tetrakis-μ-(trimethylamine-boranecarboxylato)-*bis*(trimethylamine-carboxyborane)dicopper(II)—Cupric chloride was purchased commercially[1]. Trimethylamine-carboxyborane was prepared as described previously (2). Trimethylamine-carboxyborane (1.8703 g, 15.9 mmol) was dissolved in 1 M NaOH (16 mL) and water (20 mL). Dropwise addition of 23 mL of a solution of $CuCl_2 \cdot 2H_2O$ (1.36 g, 8 mmol) in water (40 mL) produced a dark green solution which was allowed to stand overnight. Subsequent filtration through a fine-fritted funnel removed a greenish-brown sludge and left a dark-green filtrate, which was allowed to evaporate in the atmosphere. After 6 d, the solution evaporated, leaving many small green crystals in a clear liquor. These crystals were filtered and washed with chloroform (40°C); no $(CH_3)_3N \cdot BH_2COOH$ crystals were evident. The green crystals were then splashed with a minimal amount of cold water to ensure removal of any trace of sodium chloride and dried *in vacuo*. The yield was 0.49 g (23%), mp 165°C (dec.); IR: ν_{BH}, 2350, $\nu_{C=O}$ 1665 cm^{-1}.

Anal.—Calc. for $C_{24}H_{68}B_6Cu_2N_6O_{12}$: C, 34.95; H, 8.31; N, 10.19. Found: C, 35.00; H, 8.49; N, 10.15. The structure was determined by single-crystal X-ray analysis (3).

Antihyperlipidemic Screens in Normal Rodents—Compounds to be tested were suspended in 1% aqueous carboxymethylcellulose and administered to male CF_1 mice (~25 g) intraperitoneally for 16 d or male Holtzman rats (~350 g) orally by an intubation needle for 14 d. On days 9 and 14 or 16, blood was obtained by tail vein bleeding, and the serum was separated by centrifugation for 3 min. The serum cholesterol levels were determined by a modification of the Liebermann-Burchard reaction (4). Serum triglyceride levels were determined with a commercial kit[2] for a different group of animals bled on day 14 or 16.

Testing in Induced Hyperlipidemic Mice—Male CF_1 mice (~25 g) were

placed on a commercial diet[3] which contained butterfat (400 g), cellulose[4] (60 g), cholesterol (53 g), choline dihydrogen citrate (4 g), salt-mixture oil[5] (40 g), sodium cholate (20 g), sucrose (223 g), vitamin-free casein (200 g), and total vitamin supplement for 10 d. After the cholesterol and triglyceride levels were assayed and observed to be elevated, the mice were administered test drugs at 10 mg/kg/d ip for an additional 12-d period. Serum cholesterol and triglyceride levels were measured after 12 d of drug administration.

Toxicity Studies—Animals weights were obtained periodically during the experiments and expressed as a percentage of the weight of the animal on day 0. After dosing for 14 d with test drugs, selected organs were excised, trimmed of fat, and weighed. The organ weights were expressed as a percentage of the total body weight of the animal. Food consumption was assessed daily[6].

The acute toxicity (LD_{50} value) (5) was determined in male CF_1 mice by administering test drugs intraperitoneally from 5 to 50 mg/kg as a single dose. The number of deaths recorded over 7 d in the group was determined for each dosage.

Enzymatic Studies—*In vitro* enzymatic studies were determined with 10% homogenates of male CF_1 mouse liver with 50–200 μM of test drugs. *In vivo* enzymatic studies were determined with 10% homogenates of liver from male CF_1 mice obtained after administering the agents for 16 d at a dose ranging from 2.5 to 20 mg/kg/d ip. The liver homogenates for both *in vitro* and *in vivo* studies were prepared in 0.25 M sucrose and 0.001 M EDTA.

Acetyl CoA synthetase (6) and ATP-dependent citrate lyase (7) activities were determined spectrophotometrically at 540 nm as the hydroxyamate of acetyl CoA formed after 30 min at 37°C. Mitochondrial citrate exchange was determined by the procedure of Robinson *et al.* (8, 9) with sodium [^{14}C]bicarbonate (41 mCi/mmol) incorporated into mitochondrial [^{14}C]citrate after isolating rat mitochondria (9000×*g* for 10 min) from the homogenates. The exchanges of the [^{14}C]citrate were determined after incubating the mitochondrial fraction, which was loaded with labeled citrate and test drugs, for 10 min. The radioactivity was then measured in the mitochondrial and supernatant fractions in scintillation fluid[7] and expressed as a percentage. Cholesterol side-chain oxidation was determined by the method of Kritchevsky and Tepper (10) using [26-^{14}C]cholesterol (50 mCi/mmol) and mitochondria isolated from rat liver homogenates. After 18 h of incubation at 37°C with test drugs, the generated $^{14}CO_2$ was trapped in the center well in [2-[2-(*p*-1,1,3,3,-tetramethylbutylcresoxy)ethoxy]ethyl]dimethylbenzylammonium hydroxide[8] and counted[7]. HMG CoA reductase activity was measured with [1-^{14}C]acetate (56 mCi/mmol) and a postmitochondrial supernatant (9000×*g* for 20 min) incubated for 60 min at 37°C (11). The digitonide derivative of cholesterol was isolated and counted (12). Acetyl CoA carboxylase activity was measured by the method of Greenspan and Lowenstein (13). Initially, the enzyme had to be polymerized for 30 min at 37°C, and then the assay mixture containing sodium [^{14}C]bicarbonate (41.0 mCi/mmol) was added and incubated for 30 min at 37°C with test drugs. Fatty acid synthetase activity was determined by the method of Brady *et al.* (14) with [2-^{14}C]malonyl CoA (37.5 mCi/mmol), which was incorporated into newly synthesized fatty acids that were extracted with ether and counted[7]. Acyl transferase activity was determined with L-[2-^{3}H]glycerol-3-phosphate (7.1 Ci/mmol) and the microsomal fraction of the liver homogenates (15). The reaction was terminated after 10 min, and the lipids were extracted with chloroform–methanol (1:2) containing 1% concentrated HCl and counted. Phosphatidate phosphohydrolase activity was measured as the inorganic phosphate released after 30 min from phosphatidic acid by the method of Mavis *et al.* (16). The inorganic phosphate released after development with ascorbic acid and ammonium molybdate was determined at 820 nm.

Liver, Small Intestine, and Fecal Lipid Extraction—In male CF_1 mice that were administered test drugs for 16 d, the liver, small intestine, and fecal materials (24-h collection) were removed, and a 10% homogenate in 0.25 M sucrose–0.001 M EDTA was prepared. An aliquot (2 mL) of the homogenate was extracted by the methods of Floch *et al.* (17) and Bligh and Dyer (18), and the number of milligrams of lipid was determined. The lipid was taken up in dichloromethane, and the cholesterol level (3), triglyceride levels[9], neutral lipid content (19), and phospholipid content (20) were determined.

[^{3}H]Cholesterol Distribution in Rats—Male Holtzman rats (350 g) were administered the test agent for 14 d orally. On day 13, 10 μCi of [^{3}H]cholesterol (40.7 mCi/mmol) was administered intraperitoneally in mice and orally in rats, and feces were collected for the next 24 h. Twenty-four hours after cholesterol administration, the major organs were excised, and samples of blood, chyme, and urine were obtained. Homogenates (10%) of the tissues were prepared, combusted[10], and counted[7]. Some tissue samples were plated on filter paper[11], dried, digested for 24 h in base[8] at 40°C, and counted[7]. Results are expressed as dpm/mg of wet tissue and dpm/total organ.

Cholesterol Absorption Study—Male Holtzman rats (~400 g) were administered the test drug orally for 14 d at 10 mg/kg/d. On day 13, 10 μCi of [1,2-^{3}H]cholesterol (40.7 Ci/mmol) was administered to the rats orally. After 24 h, the blood was collected, and the serum was separated by centrifugation (21). Both the serum and the precipitate were counted[7].

Bile Cannulation Study—Male Holtzman rats (~400 g) were treated with

Binuclear Copper(II) Complex				
2.5 mg/kg	103 ± 6	102 ± 7	95 ± 6	55 ± 5[b]
5.0 mg/kg	95 ± 5	90 ± 6	95 ± 7	53 ± 5[b]
10.0 mg/kg	120 ± 7	94 ± 5	119 ± 7	18 ± 3[b]

[a] Expressed as percent of control (mean ± *SD*); $n = 6$. [b] $p \leq 0.001$.

test drugs at 10 mg/kg/d orally for 14 d. The rats were anesthetized with chlorpromazine[12] (25 mg/kg) followed 30 min later by pentobarbital[13] (22 mg/kg ip). The duodenum was isolated from the small intestine, and ligatures were placed around the pyloric sphincter and distally to a site approximately one-third of the way down the duodenum. Sterile isotonic saline was injected into the sectioned-off duodenal segment. The saline expanded the duodenum and the common bile duct. Once the bile duct was identified, a loose ligature was placed around it, an incision was made, and plastic tubing[14] was introduced into the duct. Once past the ligature, the tubing was tied in place, and the ligatures around the duodenum were removed. Once bile was freely moving down the cannulated tube [1,2-^{3}H]cholesterol (40.7 Ci/mmol) was injected intravenously into the rats. The bile was collected over the next 6 h and measured (in milliliters). Aliquots were counted[7] and analyzed for cholesterol content (4).

Plasma Lioprotein Fractions—Male Holtzman rats (~400 g) were administered test drugs at 20 mg/kg/d for 14 d. On day 14, blood was collected from the abdominal aorta. Serum was separated from whole blood by centrifugation at 3500 rpm. Aliquots (3 mL) were separated by density gradient ultracentrifugation by the methods of Hatch and Lees (22) and Havel *et al.* (23) into the chylomicrons, very low-density lipoproteins, high-density lipoproteins, and low-density lipoproteins. Each of the fractions was analyzed for cholesterol (4), triglycerides[9], neutral lipids (19), phospholipids (20), and protein levels (24).

RESULTS

Data are expressed in the tables as percent of control ± *SD*. The probable significant level (p) between each test group and the control group was determined by the Student's t test.

The binuclear copper(II) complex proved to be a potent hypolipidemic agent after intraperitoneal administration in mice and oral administration in rats (Table I). The reduction of serum cholesterol in normal mice was dose dependent, with 20 mg/kg/d resulting in the maximal effect of 47%. Serum triglyceride levels were reduced by >50% at 2.5 and 10 mg/kg/d. In rats administered 10 mg/kg/d, a similar reduction in serum cholesterol levels was observed as in mice, *i.e.*, 37%. However, in rats administered 10 mg/kg/d, serum triglyceride levels were reduced 64%, which was greater than the 53% reduction in mice at this dose. In hyperlipidemic-induced mice, serum cholesterol levels were elevated 183% (354 mg%) above normal values (125 mg%), which were reduced 59% to 148 mg% by drug administration over 12 d. Hyperlipidemic mice serum triglyceride levels, which were elevated 168% (367 mg/dL) above control values (137 mg/dL), were lowered 67% by drug administration to 122 mg/dL.

Examination of the *in vitro* liver enzyme studies (Table II) demonstrated that enzymes involved in the generation of the key intermediate, acetyl CoA which is required for cholesterol and fatty acid synthesis as well as cholesterol synthesis, were not affected by the presence of the drug. The degradation of cholesterol by oxidation of the side chain was accelerated significantly (52%) in the presence of drug. Fatty acid synthesis enzyme activities and *sn*-glycerol-3-phosphate acyl transferase (one of the regulatory enzymes of triglyceride synthesis) activities were not affected by the agents; however, the other regulatory enzyme of triglyceride synthesis, phosphatidate phosphohydrolase activity, was suppressed with increasing concentration of the drug.

Studies *in vivo* after dosing for 16 d in mice (Table III) showed that there was a moderate suppression of ATP-dependent citrate lyase and acetyl CoA synthetase activity at 2.5 mg/kg/d. Phosphatidate phosphohydrolase activity was reduced in a dose-dependent manner, with 10 mg/kg/d causing 82% reduction.

Lipid concentrations in the rat liver and small intestine were reduced significantly by drug treatment (Table IV). The cholesterol, triglyceride, and neutral lipid levels were reduced in both organs, and phospholipids were reduced in the small intestine. The lipid content in the livers of mice treated with the drug at 2.5–10 mg/kg/d for 16 d demonstrated similar changes (Table V); however, more dramatic effects were observed in the ability of the drug to lower triglyceride levels more than cholesterol levels. Higher lipid levels were observed in fecal samples of rats after administration of drugs for 2 weeks, particularly in the triglyceride, neutral lipid, and phospholipid levels (Table IV).

After separation of the rat serum lipoprotein fractions (Table IV), it became evident that the cholesterol, neutral lipids, and triglyceride content of each fraction was reduced. The phospholipid and protein content of the fractions were not markedly affected by drug treatment.

In rats after 14 d of treatment, the organ weights (Table VI) had not significantly altered, although in general, the treated animals had lower organ weights. In the control rats over the 2-week period, there was a 9.8% increase in body weight, and for the treated rats, there was only a 0.2% increase. The drug therapy did interfere with appetite, reducing (26%) the grams of food per day per rat from 30.35 to 22.39.

The absorption of [^{3}H]cholesterol after oral administration (Table VI) was reduced 85% over a 24-h period in rats treated for 14 d. [^{3}H]cholesterol distribution in major organs after drug therapy generally showed reductions in dpm/organ compared with the control, *e.g.*, [^{3}H]cholesterol was reduced 42% in the liver, 18% in the heart, 46% in the brain, and 91% in the kidney. There were higher contents of cholesterol in the stomach (198%), chyme (113%), large intestine (27%), small intestine (81%), and urine (336%). The LD_{50} in CF_1 mice by the intraperitoneal administration route was 39.2 mg/kg.

DISCUSSION

Tetrakis-μ-(trimethylamine-boranecarboxylato)-*bis*(trimethylamine-carboxyborane)dicopper(II) was found to be a potent hypolipidemic agent in mice and rats. However, its mode of action seemed to be somewhat different from previously reported amine-cyanoborane and amine-carboxyborane analogues in that HMG CoA reductase and fatty acid synthetase activities were essentially unaltered both in the *in vivo* and *in vitro* studies (1). The binuclear copper(II) complex was active in the dosage range previously reported for borane derivatives as hypolipidemic agents (1); nevertheless, it was more potent than commercially available clofibrate, which at doses of 150–200 mg/kg lowers serum cholesterol 6–15% and serum triglyceride levels 25% (25). Not only is the binuclear copper(II) complex active orally and intraperitoneally, it is effective in hyperlipidemic mice, lowering serum cholesterol to near normal levels and serum triglycerides below normal levels after administration for 12 d. The mode of action of this agent appeared to be by interference with cholesterol absorption from the GI tract and accelerated excretion of cholesterol *via* the fecal route. Triglyceride levels appear to be reduced due to suspension of activity of the regulatory enzyme of *de novo* triglyceride synthesis. Lamb *et al.* (15) have shown a positive correlation between lowering of serum triglyceride levels and the inhibition of hepatic and intestinal phosphatidate phosphohydrolase activity with 1-methyl-4-piperidyl-bis(*p*-chlorophenoxy)acetate and 1,3-bis(*p*-methylphenoxy)-2-propane. have also been made with phthalamide (26), saccharin (27), and 1,8-naphthalamide (28), cyclic imide derivatives, with mouse liver. These compounds, as well as clofibrate, also suppressed *sn*-glycerol-3-phosphate acyl transferase activity, whereas the binuclear copper complex(II) did not. Clofibrate accelerates cholesterol excretion *via* the biliary route (29); however, its effects on liver metabolism include inhibition of HMG CoA reductase. Thus, the copper complex appears to be different in its mode of action than standard therapeutic agents on the market today, *e.g.*, clofibrate and the resin cholestyramine.

The serum lipoprotein fractions after 14 d of dosing at 10 mg/kg/d demonstrated consistent reductions in cholesterol, triglyceride, and neutral lipid content. Supposedly, the chylomicron and very low-density fractions contain the highest triglyceride levels, which the binuclear complex(II) reduced significantly. The low- and high-density lipoprotein fractions contain the majority of the cholesterol and its esters under normal conditions. The cholesterol content of the low-density fraction is important in controlling the amount of cholesterol being deposited in atherogenic plaques. Supposedly, the high-density fraction returns the cholesterol from peripheral tissue to the liver. The binuclear copper(II) complex reduces cholesterol approximately equally in both the low- and high-density lipoprotein fractions. Thus, the ratio of cholesterol content of low-density to high-density lipoprotein fractions probably was not altered by drug therapy; however, the absolute content of each fraction was reduced significantly.

Table VI—Effects of the Binuclear Copper(II) Complex on Rat Organ Weights and Orally Administered [^{3}H]Cholesterol after Dosing for 14 d [a]

Organ[a]	Organ Weight, g		dpm/Total Organ	
	Control	Treated	Control	Treated
Brain	1.866	1.666	29,115	15,783
Lung	1.766	1.933	15,350	17,106
Heart	1.333	1.021	24,582	20,060
Liver	12.000	10.600	47,429	27,695
Kidney	2.900	2.167	5,875	565
Spleen	0.566	0.501	19,388	13,241
Adrenal	0.036	0.031	—	—
Stomach	2.066	1.766	11,375	33,901
Small intestine	8.333	6.433	15,291	16,514
Large intestine	4.100	4.233	47,109	59,665
Chyme	5.866	5.9333	102,772	218,742
Feces	5.702	8.633	320,454	294,644

[a] At 10 mg/kg/d; $n = 6$.

Lipids removed from the serum were not deposited in the organs as demonstrated by reduced lipid content in the liver and small intestine, [^{3}H]cholesterol content in the major organs, and the weights of the organs. Adrenal weights were not altered by drug administration, indicating that there was no compensatory hyperplasia of the adrenal cortex due to stimulation of steroidogenesis because of low serum levels. The appetites of the animals were reduced by the drug; however, the magnitude of the effects of binuclear copper(II) complex on lipid metabolism and blood levels is unknown. Thus, tetrakis-μ-(trimethylamine-boranecarboxylato)-*bis*(trimethylamine-carboxyborane)dicopper(II) appears to be a potent hypolipidemic agent at low doses, lowering both cholesterol and triglyceride levels. Further chemical derivatives of this type and mechanisitic studies need to be investigated in the future.

NOTES

Choline Magnesium Trisalicylate: Comparative Pharmacokinetic Study of Once-Daily and Twice-Daily Dosages

MONTE J. LEVITT ˣ and JULES KANN

Received December 13, 1982, from *Biodecision Laboratories, Inc., Pittsburgh, PA 15213.* Accepted for publication April 5, 1983.

Abstract □ This randomized crossover study compared the pharmacokinetics of choline magnesium trisalicylate tablets administered once daily (3000 mg of salicylate) or twice daily (1500 mg of salicylate) for six d. Serum salicylate levels were measured by HPLC. Mean "trough" concentrations fell within the therapeutic range (5–30 mg/dL) with either regimen and were relatively constant, indicating that the steady state had been reached. The 24-h area under the salicylate curve ($AUC_{0-24\ h}$) after the final 3000-mg salicylate dose averaged about twice the mean 12-h AUC after the last 1500-mg dose, indicating that the two dosing regimens were equally bioavailable. Clinical observations and results of laboratory safety studies indicate that both dosage schedules of the drug are well tolerated. The present findings support the once-daily therapeutic use of choline magnesium trisalicylate.

Keyphrases □ Choline magnesium trisalicylate—pharmacokinetic comparison of once-daily and twice-daily dosages, humans □ Bioavailability—choline magnesium trisalicylate, once-daily and twice-daily dosage schedules, humans □ Pharmacokinetics—choline magnesium trisalicylate bioavailability after once-daily and twice-daily dosages, humans

Complexity of dosage schedule may cause nonadherence to self-administered drug regimens (1, 2), particularly among ambulatory, fully active patients. Conversely, simplicity of treatment, as reflected in a single daily drug dose, is desirable from the standpoint of compliance (2, 3). In terms of this criterion, conventional salicylates, though widely regarded as first-line antiarthritic drugs, are not highly conducive to patient cooperation. These substances, notably aspirin, must often be taken at frequent intervals during the day, primarily to minimize GI irritation; daily quantities high enough to yield sustained therapeutic blood levels may be expected to cause prohibitive side effects when given as only one or two doses. Paradoxically, however, the inadequate compliance such a complex drug regimen might entail could undermine maintenance of therapeutic blood salicylate levels (4).

Published data indicate the feasibility of reducing the frequency of salicylate doses in arthritis. A recently developed nonacetylated drug of this class, choline magnesium trisalicylate (I) has been successfully used on a twice-daily basis in patients with rheumatoid arthritis or osteoarthritis (5–8). It was of interest to determine whether pharmacokinetic data would support even less frequent administration of this drug. We therefore conducted the present crossover bioavailability study in healthy volunteers to compare once-daily and twice-daily treatment schedules of I.

EXPERIMENTAL SECTION

Protocol—Twenty-four healthy males, 19–34 years old (mean, 28 years), whose weights were within 10% of ideal (58.6–96.1 kg; mean, 74.7 kg), took part in the study, which was conducted in accordance with a protocol approved by an institutional review board. The subjects had given written informed consent and were judged to be in good health on the basis of physical findings and the results of blood chemistry determinations, hematological work-up, routine urinalysis, and tests for fecal occult blood. None had a history of sensitivity to salicylates or of serious GI, hepatic, renal, or hematological

Table I—Steady-State 24-h Serum Salicylate Levels in a Crossover Comparison of Once- and Twice-Daily Administration of I

Salicylate Dosage	Baseline[b]	Serum Salicylate Values, mg/dL[a] 1	2	4	8	12	18	23.5
1500 mg twice daily	13.5 ± 5.1	16.5 ± 5.7	18.9 ± 5.1	18.1 ± 4.4	14.7 ± 4.4	12.3 ± 4.6	7.0 ± 4.2	3.4 ± 3.5
3000 mg once daily	9.1 ± 4.8	17.8 ± 6.7	22.2 ± 6.4	22.9 ± 4.1	20.6 ± 3.4	17.1 ± 4.5	12.1 ± 4.4	7.0 ± 4.5

[a] Mean ± *SD*; $n = 24$. [b] "Trough" value.

Table II—Selected Steady-State Pharmacokinetic Values in a Crossover Study of Serum Salicylate Levels after Administration of I

Salicylate Regimen (6 d)	Observation Period, h	Pharmacokinetic Values After Last Dose of Regimen[a] AUC, mg·dL/h	C_{max}, mg/dL	t_{max}[b], h	$t_{1/2\ (el)}$, h	k_{el}, h^{-1}
1500 mg, twice daily	12	174.0 ± 47.7	20.0 ± 5.1	2.5 ± 1.1	7.2 ± 3.6	0.11 ± 0.04
3000 mg, once daily	24	367.3 ± 82.8	24.9 ± 4.1	4.2 ± 3.2	8.2 ± 3.5	0.10 ± 0.04

[a] Mean ± *SD*; $n = 24$. [b] Calculated assuming first-order pharmacokinetics.

disorders. The volunteers had been instructed to take no antibiotics for at least 15 d and no other drugs for at least 7 d before the start of the study; no additional medication was allowed during the trial.

Two groups, approximately comparable in terms of the body weights, were formed by random assignment; the trial proceeded in two phases, the second involving reversal of the initial dosage schedules. For phase 1, 12 subjects received four tablets of I[1] (equivalent to 3000 mg of salicylate) daily as two equal fractions, 12 h apart, for 6 consecutive days. The remaining 12 volunteers were given a single daily four-tablet dose in the evening, also for a 6-d period. The subjects reported to the research facility to receive each supervised dose, and all doses were ingested after a 1-h fast, with 180 mL of water. After a 1-week wash-out period, the treatment schedules were reversed (phase 2). Subjects treated on a twice-daily basis in phase 1 now received the single daily dose, and *vice versa*. All other experimental conditions remained unchanged.

Blood samples were obtained for the determination of "trough" serum salicylate levels just before drug administration on the evenings of study days 4–6 and 18–20. Blood specimens were also drawn at 1, 2, 4, 8, 12, 18, and 23.5 h after the final doses, *i.e.*, those doses ingested in the evenings of day 6 and day 20. The subjects were confined to the facility for sampling. The serum salicylate values obtained at these time points were used to elucidate the pharmacokinetics associated with each dosage schedule. The subjects were questioned at least once daily concerning their well-being, and the clinical and laboratory evaluations performed at the start (physical examination, blood chemistry profile, hematological work-up, urinalysis, and test for fecal occult blood) were repeated at its conclusion.

Assay Method—Serum salicylate concentrations were measured by a modification of the HPLC method described by Peng *et al* (9). After the addition of a known amount of phthalic acid as an internal standard, the serum was acidified with 85% phosphoric acid. Salicylate and internal standard were extracted into a 50:50 (by volume) mixture of benzene–ethyl acetate by vigorous mixing. After centrifugation, the organic phase was transferred to a clean tube, made alkaline by the addition of ammonium hydroxide, and evaporated to dryness at room temperature under a stream of nitrogen. The residue was dissolved in a small volume of mobile phase, acetonitrile–0.1 M phosphoric acid (40:60, v/v). An aliquot was injected onto a reverse-phase C_{18} high-pressure liquid chromatographic column. The effluent from the column was monitored continuously at a wavelength of 237 nm. Average retention times were 3.0 min for the internal standard and 7.5 min for salicylic acid when the mobile phase was pumped at a rate of 1.3 mL/min. The assay was linear over the range of salicylate concentrations from 1.5 to 50 mg/dL. As little as 1.5 mg/dL of salicylate could be measured quantitatively; lower concentrations were reported as zero. The day-to-day coefficient of variation of the assay was 10.6% at a concentration of 7.5 mg/dL.

RESULTS

There was no indication that any of the subjects violated the protocol or took drugs other than the assigned tablets. None of the volunteers left the trial before its conclusion.

Blood samples obtained just before drug ingestion on days 4–6 and 18–20 of treatment yielded consistent "trough" levels. These data indicated that the volunteers had reached steady-state concentrations by the time of the dose administered on the evening of the sixth day of each phase of the study, before sampling for the 24-h curves. Mean serum "trough" levels were within the therapeutic range of 5.0–30.0 mg/dL of salicylate.

The mean ± 1 *SD* values for the b.i.d. schedule were 13.4 ± 5.1, 12.4 ± 5.0, and 13.5 ± 5.1 mg/dL for the final 3 d of dosing in sequence. The corresponding values for the once-a-day dosage regime were 8.4 ± 4.9, 8.5 ± 4.6, and 9.1 ± 4.8 mg/dL. The 24-h serum salicylate curves showed sustained anti-inflammatory blood levels with both schedules (Table I; Fig. 1). Seventeen subjects still exhibited substantial concentrations (>10 mg/dL) 18 h after the once-daily 3000-mg dose.

The measured areas under the curves (AUC) at steady state (Table II) were proportional to the dose of I administered; the mean area computed over the 12-h interval after the subjects received 1500 mg of salicylate was about half the mean area calculated over the 24-h period after one 3000-mg dose was ingested at steady state.

The bioavailability of the single dose relative to that of the divided dose was 1.06. This value respresented the ratio of the AUC values (0–24 h/0–12 h) divided by the ratio of the respective doses (3000/1500) and did not differ significantly from the theoretical value of 1.0. Due to the very complex nonlinear pharmacokinetics of salicylate, the ratio of 1.06 can not be used as absolute evidence for equal absorption *via* the two dosage regimens. However, the data do suggest that the relative bioavailability from the two dosage regimens is probably very similar.

Two-way analyses of variance yielded the following significant differences between treatments in comparisons involving 24-h and 12-h observation periods for single 3000-mg and 1500-mg doses of salicylate, respectively: mean values for serum salicylate peak levels (C_{max}) and time to peak (t_{max}) were significantly higher ($p < 0.001$ and $p = 0.02$, respectively) with once-daily administration. No significant differences in elimination half-life ($t_{1/2\ (el)}$) or the elimination rate constant (k_{el}) was noted (Table I).

The incidence of apparently drug-related complaints was similar with both dosage schedules (Table III). They involved a total of eight subjects, three affected during the once-daily regimen only and four during the twice-daily schedule only; one volunteer experienced undesirable symptoms with both regimens (tinnitus with once-daily treatment and "stomach ache" with b.i.d. administration). The side effects were those generally expected to occur with salicylate use. They were usually transient despite continued treatment, in

Table III—Side Effects Associated with Repeated Administration of I

Salicylate Dosage Schedule[a]	Period	Subject	Side Effects
A	1	13	tinnitus
	1	18	tinnitus
	1	20	tinnitus
	2	22	tinnitus
	2	22	"stomach ache"
B	1	2	tinnitus
	1	6	"stomach pain"
	1	7	"upset stomach"
	2	18	"stomach ache"
	1	19	tinnitus

[a] A 7-d wash-out period intervened between dosage schedules. Schedule A is 3000 mg once daily for 6 d; Schedule B is 1500 mg twice daily for 6 d.

[1] Trilisate 750 tablets, lot no. P-55; The Purdue Frederick Co., Norwalk, Conn.

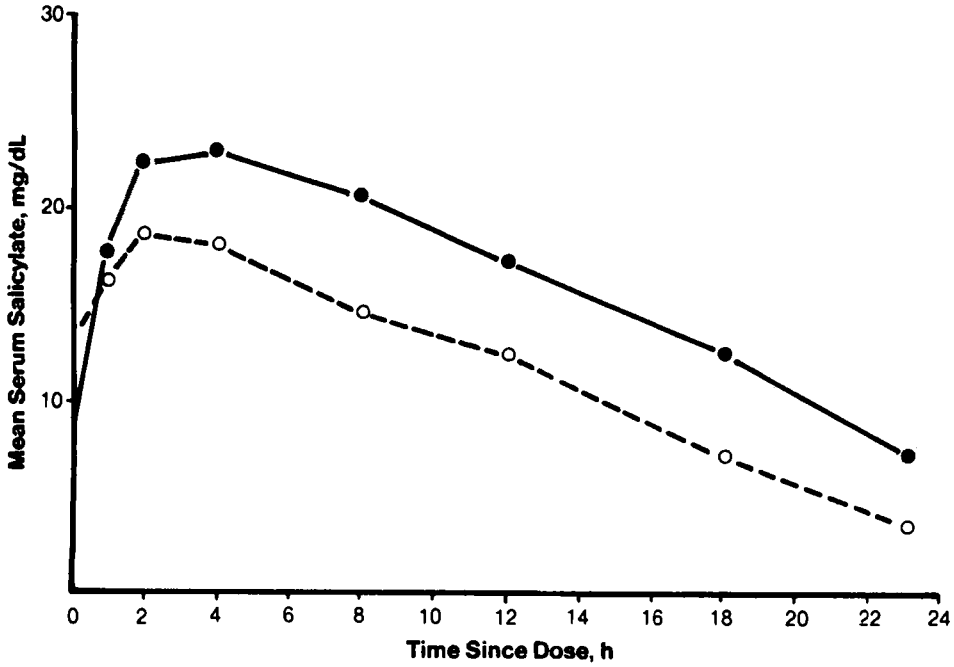

Figure 1—*Steady-state serum salicylate levels in 24 healthy subjects after final doses of two 6-d regimens of I administration. Key: (●) at the end of once-daily treatment with 3000 mg of salicylate; (○) at the end of twice-daily treatment with 1500 mg of salicylate.*

most cases occurred on a single day only, and did not require any of the subjects to leave the study. The complaints were more frequently voiced during the first phase of the study than during the second, regardless of treatment schedule.

DISCUSSION

Our results indicate the equal bioavailability of single daily and b.i.d. doses of I under the conditions of this trial and support the feasibility of once-daily treatment with this drug. They further show that daily ingestion of four-tablet doses yields mean "trough" and peak serum salicylate levels within the therapeutic range. However, since the pharmacokinetics of salicylate vary substantially from individual to individual, the choice of antiarthritic regimen should probably be individualized on the basis of blood concentrations and clinical response.

Once-daily use by arthritic patients is not known to be feasible with other salicylates now available, and hence, within this class of drugs, appears to be limited to choline magnesium trisalicylate (I). Obviously, drug safety is a major consideration in this respect. In the present study, physical examination and laboratory investigations, as well as analysis of reported side effects, indicated comparable safety of both dosage schedules of I in the healthy young males studied. While tinnitus appeared to be the predominating side effect during the once-daily regimen and GI symptoms occurred mainly with b.i.d. administration, the numbers of subjects involved were too small to indicate any trends in this regard.

In Vivo Uptake of Polyisobutyl Cyanoacrylate Nanoparticles by Rat Liver Kupffer, Endothelial, and Parenchymal Cells

V. LENAERTS *, J. F. NAGELKERKE ‡, T. J. C. VAN BERKEL ‡, P. COUVREUR *x, L. GRISLAIN *, M. ROLAND *, and P. SPEISER §

Received November 10, 1982, from the *Laboratoire de Pharmacie Galénique, Université Catholique de Louvain, B-1200 Brussels, Belgium, the ‡Department Biochemistry 1, Erasmus University, 3000-DR Rotterdam, The Netherlands, and the §School of Pharmacy, Federal Institute of Technology, Zürich, Switzerland. Accepted for publication June 23, 1983.

Abstract □ Polyalkyl cyanoacrylate nanoparticles were previously developed as a biodegradable, ultrafine, solid drug carrier. Distribution studies in the rat showed an intense and rapid hepatic uptake. This liver accumulation appears to represent, to a certain extent, extracellularly bound nanoparticles. During liver perfusion, 15–20% of the liver-associated nanoparticles were washed out. The cellular distribution of strongly cell-associated nanoparticles was determined. At different intervals after injection of radioactive nanoparticles to rats, the cells were isolated according to a recently developed, low-temperature procedure during which processing of the carrier was inhibited. At all tested times, a relatively intense capture by Kupffer cells in comparison with endothelial and especially parenchymal cells was observed. This distribution pattern was not influenced by the size of the nanoparticles (0.08–0.215-μm diameter). This specific interaction of nanoparticles with Kupffer cells opens possibilities for the treatment of some parasitic diseases involving this cell type.

Keyphrases □ Nanoparticles—polyisobutyl cyanoacrylate, *in vivo* uptake, rat liver Kupffer, endothelial, and parenchymal cells □ Polyisobutyl cyanoacrylate—*in vivo* uptake of nanoparticles, rat liver Kupffer, endothelial, and parenchymal cells □ Distribution—*in vivo* uptake of polyisobutyl cyanoacrylate nanoparticles, rat liver Kupffer, endothelial, and parenchymal cells

The incorporation of a drug into a carrier such as liposomes, macromolecules, or solid colloidal nanoparticles modifies the body distribution of the drug (1–3). This change in the distribution pattern can be used to direct a drug specifically to the target tissue or to protect a tissue from the toxic effects of a drug. For this purpose a carrier consisting of polyalkyl cyanoacrylate nanoparticles was developed (4, 5). These submicroscopic spheres, <0.3 μm in diameter, are degraded under physiological conditions (6, 7). Associated with a cytostatic drug, they provoke an enhancement of the therapeutic activity (8) or a reduction of the toxicity (9). The body distribution of these carriers was studied, and, as for most carriers, an intense and rapid capture by the organs rich in reticuloendothelial cells was observed (10, 11).

Since the majority of nanoparticles were captured by the liver, the intrahepatic distribution of the carriers as a function of time is important. Whether the interaction between nanoparticles and parenchymal cells could be affected by administration of nanoparticles smaller than the fenestrated lining of the liver sinusoids (0.1 μm) was studied.

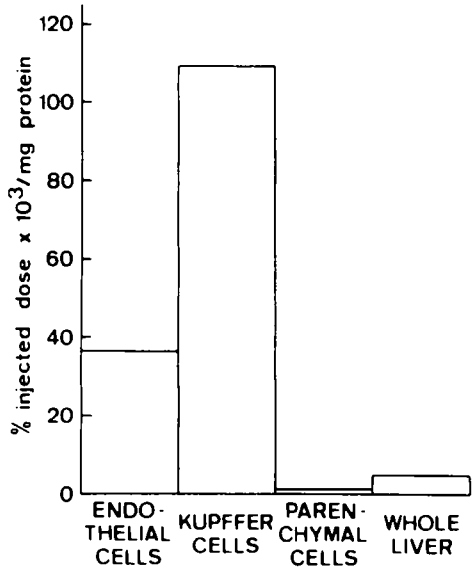

Figure 1—*Distribution of [^{14}C]polyisobutyl cyanoacrylate nanoparticles (0.215-μm diameter) in the rat liver Kupffer, endothelial, and parenchymal cells 30 min after intravenous administration.*

EXPERIMENTAL SECTION

Preparation of Radioactive Nanoparticles—Radioactive monomer was prepared according to a previously published method (12). [^{14}C]Formaldehyde was used in the synthesis; as a result, the monomer was tagged on the C-3 atom. The specific activity of the radioactive monomer[1] was 1.4 mCi/mL.

To a 10-mL solution of 1% dextran 70 and 0.05 M H_3PO_4 was added 0.1 mL of the radioactive monomer, with stirring. After 2 h of polymerization, the suspension was made isotonic with glucose and neutralized with 0.5 M NaOH. Smaller nanoparticles were prepared in a similar way, except the polymerization medium was a 5% glucose in 10^{-5} M HCl solution. The nanoparticles size was measured using a particle counter[2], based on laser beam scattering.

Isolation and Separation of Rat Liver Parenchymal, Kupffer, and Endothelial Cells—After intravenous administration of radioactive nanoparticles to rats (Wistar R1)[3], at different intervals, cell isolation was started by a liver perfusion, first with Ca^{2+}-free Hank's buffer at 8°C and then with 1 mM $CaCl_2$ Hank's buffer at 8°C containing either 0.5% (w/v) collagenase[4] for parenchymal cell isolation or 0.25% protease[5] for Kupffer and endothelial cell isolation. Further isolation was performed at 0°C to minimize degradation and redistribution of the internalized nanoparticles. Further purification of the Kupffer and endothelial cells was performed according to a modified version of a published method (13), which is described in detail elsewhere together with the parenchymal cells isolation technique (14). Kupffer and endothelial cells were obtained by, successively, 400×*g* centrifugation, metrizamide[6] density cushion centrifugation, and centrifugal elutriation[7].

The absence of parenchymal cell remnants was indicated by the absence of L-type pyruvate kinase (15, 16). The characterization of Kupffer and endothelial cell preparations was realized by light microscopic examination after staining for peroxidase activity with diaminobenzaldehyde (17) followed by a Papanicolaou counter-staining (18). After this treatment Kupffer cells were easily recognized by their brown appearance, while endothelial cells were blue. The purity of the endothelial cells preparations was >95%, while the purity of the Kupffer cells preparations was between 70 and 90%, the remainder being endothelial cells.

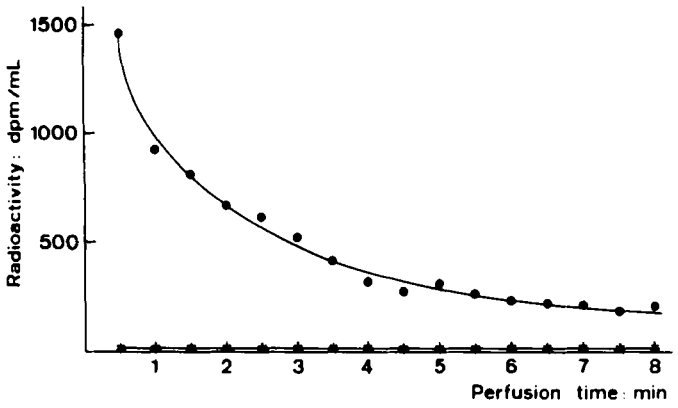

Figure 2—*Radioactivity present in fractions of the liquid collected from the rat liver during a perfusion with Hank's medium at 8°C started 30 min after intravenous administration of [^{14}C]polyisobutyl cyanoacrylate nanoparticles. Radioactivity was measured in the pellets (*) and supernatants (●) of the fractions after a 5-min centrifugation at 600×g.*

Parenchymal cells were isolated by repeated low-speed centrifugations, essentially in the same way as reported previously (19). The parenchymal cell preparations were free of other cell types, as checked by light microscopy.

The total liver value was calculated from the radioactivity present in a liver lobe which was tied off after an 8-min perfusion with Ca^{2+}-free Hank's buffer, just prior to perfusion with proteolytic enzymes. The liver lobe, isolated cells, and samples of the nanoparticle preparation were oxidized[8] and radioactivity was counted by liquid scintillation[9]. The protein content in the samples was determined according to the method of Lowry (20), using bovine serum albumin[10] as a standard.

To determine the amount of loosely bound nanoparticles, radioactivity was measured in the postperfusion medium during an 8-min perfusion with Hank's Ca^{2+}-free medium at 8°C. This perfusion was started 30 min after the injection of nanoparticles and just after a liver lobe had been tied-off and excised to serve as a nonperfusion control. Furthermore, the different samples were centrifuged at 600×*g* for 5 min to check whether the radioactivity was due to nonsediment nanoparticles or to nanoparticle-carrying cells. All these samples were then counted for radioactivity.

RESULTS AND DISCUSSION

Intrahepatic Distribution of Nanoparticles—Figure 1 shows the distribution of the 0.215-nm ^{14}C-labeled polyisobutyl cyanoacrylate nanoparticles between the different liver cell types 30 min after intravenous administration. Nanoparticles were recovered mainly in the Kupffer cells. The association of nanoparticles to Kupffer cells (expressed per milligram of cell protein) was

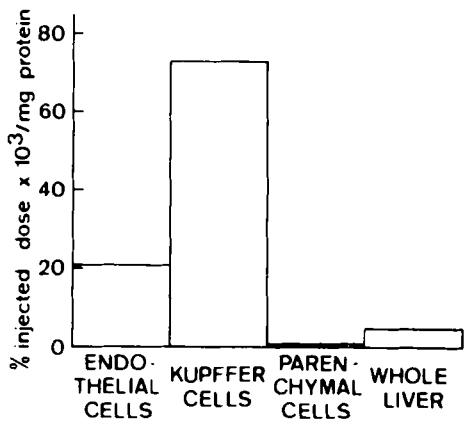

Figure 4—*Distribution of [^{14}C]polyisobutyl cyanoacrylate nanoparticles (0.08-μm diameter) in the rat liver Kupffer, endothelial, and parenchymal cells 30 min after intravenous administration.*

100-fold higher than with the major liver cell type (parenchymal cells). An intermediate cell accumulation value was observed for endothelial cell preparations.

Based on the relative contribution of Kupffer, endothelial, and parenchymal cells to total liver, the recovery of the radioactivity in the isolated cells as compared with that originally present in the whole liver can be calculated. This calculation indicates that the nanoparticles, present in the liver just before the perfusion with proteolytic enzymes, were quantitatively recovered in the isolated cells. This high recovery is only possible if the nanoparticles were either internalized or strongly associated with the liver cells. However, it was observed that during the Ca^{2+}-free perfusion, the loosely bound nanoparticles were removed (15–20% of the initial liver-associated radioactivity).

The total rat liver accumulation of radioactivity after an 8-min perfusion at 8°C was 13% of the injected dose. This value is somewhat lower than for the nonperfused liver (17% of the injected dose). This difference can only be explained by the release of loosely bound nanoparticles. Indeed, when the postperfusion medium was centrifuged at 600×*g* for 5 min, practically all radioactivity was found in the supernatant (Fig. 2). This result excludes the hypothesis of radioactive nanoparticle-containing cell release during the perfusion.

Liver Distribution as a Function of Time—Figure 3 shows the time course of the accumulation of nanoparticles into the different rat liver cell types. The association to Kupffer cells occurs very rapidly, while the maximal association to endothelial cells is clearly slower. However, at all time intervals tested, nanoparticles were always recovered mainly in the Kupffer cells. The radioactivity ratios of Kupffer to parenchymal cells were 173, 101, and 119, respectively, for intervals of 5, 30, and 120 min. For the same intervals, the ratios of Kupffer to endothelial cells were 21.2, 4.9, and 5.9.

Influence of Nanoparticle Size on Liver Distribution—The endothelial lining of the rat liver sinusoid contains fenestrae arranged in "sieve plates;" the pores of the fenestrae are ~0.1 μm in diameter (21). It can be argued that the low *in vivo* uptake of nanoparticles by the parenchymal cells is caused by this morphological barrier. If this is true, a drop in the particle size would enable an interaction with the parenchymal cells. For this purpose, the cellular distribution of particles with a mean diameter of 0.08 μm was studied 30 min after intravenous administration (Fig. 4). The uptake ratios of Kupffer to parenchymal cells and of Kupffer to endothelial cells were 92 and 3.6 for the 0.08-μm particles as compared with 101 and 4.2 for the 0.215-μm particles. These data indicate clearly that the interaction of nanoparticles with the different liver cells is not influenced by the size difference of the carrier.

CONCLUSIONS

After intravenous administration to rats, nanoparticles are localized in various compartments inside the liver. The data show that Kupffer cells are the major liver site for cell accumulation of the nanoparticles. This specific interaction is independent of the particle size in the range studied (0.08–0.215-μ diameter). Endothelial and especially parenchymal cells show a very low cell association with the nanoparticles. It is important to note that part of the nanoparticles remain loosely attached to the cells and can be released from their site by perfusion.

The interaction of nanoparticles with Kupffer cells should lead to specific drug delivery from this colloidal carrier. For the treatment of Kupffer cell-associated diseases, use of nanoparticles could be significant in achieving appropriate drug targeting.

Synthesis and Antimicrobial Activity of Novel Quinazolone Derivatives

N. S. HABIB * and M. A. KHALIL ‡x

Received February 14, 1983, from the **Pharmaceutical Chemistry Department, Faculty of Pharmacy, University of Alexandria, Egypt* and the ‡*College of Pharmacy, Florida A&M University, Tallahassee, FL 32307.* Accepted for publication May 11, 1983.

Abstract □ Three novel series of 4-oxoquinazoline derivatives were prepared and evaluated as potential antimicrobial agents. Evaluation of the antimicrobial activity of a variety of 4-substituted-1-thiosemicarbazides, 3,4-disubstituted thiazolines, and 3-substituted-5-thiazolidones reveals that the majority possess significant *in vitro* activity against Gram-positive organisms. Some derivatives also exhibited antifungal activity.

Keyphrases □ 4-Oxoquinazoline analogues—synthesis, antimicrobial activity, *in vitro* screen □ Antimicrobial agents—potential, 4-oxoquinazoline analogues, synthesis

There has been considerable interest in various 4-oxoquinazoline analogues. Some have shown a wide spectrum of biological effects (1–5) including antitubercular (6), antibacterial (7), and antifungal (8) activities. Thiazoline analogues were also reported to exhibit antitubercular (9) and antibacterial (10) activities. These observations prompted us to synthesize a variety of compounds containing the thiazoline nucleus and examine them for antimicrobial activity (11). Recently, the antimicrobial activities of some 4-oxoquinazoline thiosemicarbazides and thiazoline derivatives were investigated (12).

In a continuing effort to develop new antimicrobial agents, 1- [4- (2-methyl-4-oxoquinazoline-3-yl)benzoyl] -4-alkyl-, -aryl-, and -aralkyl-3-thiosemicarbazides (VII–X), 3,4-disubstituted thiazoline-2-oxo[4-(2-methyl-4-oxoquinazoline-3-yl)benzoyl]hydrazones (XI–XIV), and 3-substituted 5-thiazolidone-2-oxo-[4-(2-methyl-4-oxoquinazoline-3-yl)-benzoyl]hydrazones (XV–XVIII) were synthesized and evaluated as potential antimicrobial agents.

RESULTS AND DISCUSSION

Chemistry—Treatment of 2-substituted-4-oxoquinazolines, with hydrazine hydrate results in hydrazinolysis of the quinazolone ring to give 3-amino-2-substituted-4-oxoquinazolines (13). In the present investigation, as shown in Scheme I, heating 3-(4-carbethoxyphenyl)-2-methyl-4-oxoquinazolone (I) with hydrazine hydrate resulted in the formation of three products: *p*-aminobenzoic acid hydrazide (II), 4-(2-methyl-4-oxoquinazoline-3-yl)benzoic acid hydrazide (III) (as a minor product), and 3-amino-2-methyl-4-oxoquinazoline (IV). Compounds II and IV were identified by TLC, IR, and mixed melting point comparisons with authentic samples prepared by the previously reported methods (14, 15), while III was identified by IR spectrometry and elemental analysis. The formation of these three different products might indicate that hydrazine attacks first the ester side chain of I, then the quinazolone nucleus. This appears to be true since the treatment of III with hydrazine, resulted in the formation of II and IV. More evidence was obtained when we found that the hydrazine hydrate can replace substituted hydrazine from the quinazolone nucleus. This was shown by the hydrazinolysis of 3-(4-carbethoxyphenylamino)-2-methyl-4-oxoquinazoline (V) into IV and *p*-hydrazinobenzoic acid hydrazide (VI) (Scheme I).

In the present work, the intermediate 4-(2-methyl-4-oxoquinazoline-3-yl)benzoic acid hydrazide (III) was prepared in a higher yield, under carefully controlled reaction conditions by treating hydrazine hydrate with I at room temperature for 1 h. As outlined in Scheme II, treatment of III with the selected alkyl-, aryl-, or aralkylisothiocyanate in refluxing ethanol afforded the desired thiosemicarbazides (VII–X) (Table I). Reaction of the formed thiosemicarbazides with phenacyl bromide or ethyl bromoacetate gave the thiazoline (XI–XIV) or thiazolidone (XV–XVIII) derivatives, as shown in Table II and Table III, respectively. The products were identified by elemental

Synthesis and Antimicrobial Activity of Novel Quinazolone Derivatives

N. S. HABIB * and M. A. KHALIL ‡x

Received February 14, 1983, from the **Pharmaceutical Chemistry Department, Faculty of Pharmacy, University of Alexandria, Egypt* and the ‡*College of Pharmacy, Florida A&M University, Tallahassee, FL 32307.* Accepted for publication May 11, 1983.

Abstract □ Three novel series of 4-oxoquinazoline derivatives were prepared and evaluated as potential antimicrobial agents. Evaluation of the antimicrobial activity of a variety of 4-substituted-1-thiosemicarbazides, 3,4-disubstituted thiazolines, and 3-substituted-5-thiazolidones reveals that the majority possess significant *in vitro* activity against Gram-positive organisms. Some derivatives also exhibited antifungal activity.

Keyphrases □ 4-Oxoquinazoline analogues—synthesis, antimicrobial activity, *in vitro* screen □ Antimicrobial agents—potential, 4-oxoquinazoline analogues, synthesis

There has been considerable interest in various 4-oxoquinazoline analogues. Some have shown a wide spectrum of biological effects (1–5) including antitubercular (6), antibacterial (7), and antifungal (8) activities. Thiazoline analogues were also reported to exhibit antitubercular (9) and antibacterial (10) activities. These observations prompted us to synthesize a variety of compounds containing the thiazoline nucleus and examine them for antimicrobial activity (11). Recently, the antimicrobial activities of some 4-oxoquinazoline thiosemicarbazides and thiazoline derivatives were investigated (12).

In a continuing effort to develop new antimicrobial agents, 1- [4- (2-methyl-4-oxoquinazoline-3-yl)benzoyl] -4-alkyl-, -aryl-, and -aralkyl-3-thiosemicarbazides (VII–X), 3,4-disubstituted thiazoline-2-oxo[4-(2-methyl-4-oxoquinazoline-3-yl)benzoyl]hydrazones (XI–XIV), and 3-substituted 5-thiazolidone-2-oxo-[4-(2-methyl-4-oxoquinazoline-3-yl)-benzoyl]hydrazones (XV–XVIII) were synthesized and evaluated as potential antimicrobial agents.

RESULTS AND DISCUSSION

Chemistry—Treatment of 2-substituted-4-oxoquinazolines, with hydrazine hydrate results in hydrazinolysis of the quinazolone ring to give 3-amino-2-substituted-4-oxoquinazolines (13). In the present investigation, as shown in Scheme I, heating 3-(4-carbethoxyphenyl)-2-methyl-4-oxoquinazolone (I) with hydrazine hydrate resulted in the formation of three products: *p*-aminobenzoic acid hydrazide (II), 4-(2-methyl-4-oxoquinazoline-3-yl)benzoic acid hydrazide (III) (as a minor product), and 3-amino-2-methyl-4-oxoquinazoline (IV). Compounds II and IV were identified by TLC, IR, and mixed melting point comparisons with authentic samples prepared by the previously reported methods (14, 15), while III was identified by IR spectrometry and elemental analysis. The formation of these three different products might indicate that hydrazine attacks first the ester side chain of I, then the quinazolone nucleus. This appears to be true since the treatment of III with hydrazine, resulted in the formation of II and IV. More evidence was obtained when we found that the hydrazine hydrate can replace substituted hydrazine from the quinazolone nucleus. This was shown by the hydrazinolysis of 3-(4-carbethoxyphenylamino)-2-methyl-4-oxoquinazoline (V) into IV and *p*-hydrazinobenzoic acid hydrazide (VI) (Scheme I).

In the present work, the intermediate 4-(2-methyl-4-oxoquinazoline-3-yl)benzoic acid hydrazide (III) was prepared in a higher yield, under carefully controlled reaction conditions by treating hydrazine hydrate with I at room temperature for 1 h. As outlined in Scheme II, treatment of III with the selected alkyl-, aryl-, or aralkylisothiocyanate in refluxing ethanol afforded the desired thiosemicarbazides (VII–X) (Table I). Reaction of the formed thiosemicarbazides with phenacyl bromide or ethyl bromoacetate gave the thiazoline (XI–XIV) or thiazolidone (XV–XVIII) derivatives, as shown in Table II and Table III, respectively. The products were identified by elemental

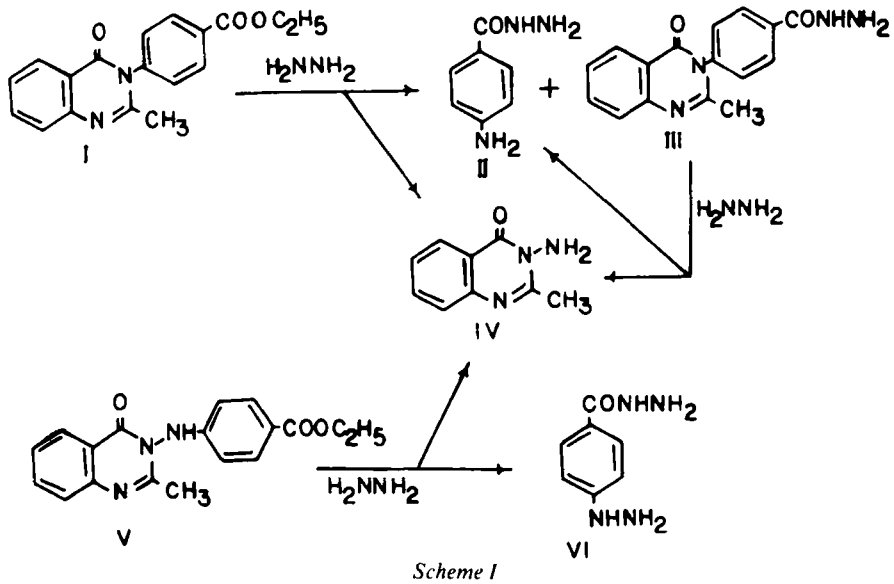

Scheme I

analyses, IR, and for some representative examples by H^1-NMR and MS. The H^1-NMR spectrum for thiazoline derivative XIV showed a singlet at δ 5.7 ppm characteristic for the thiazoline proton, while the spectrum for XVIII showed a singlet at δ 3.85 ppm characteristic of the thiazolidone protons. The mass spectra of both derivatives XIV and XVIII showed molecular ion, at *m/z* 543 and 483, respectively, and a base peak at *m/z* 91 corresponding to the tropylium ion.

Antimicrobial Activity—Compounds VII–XVIII were tested for antimicrobial activity by the agar diffusion method (16). The test organisms used were *Staphylococcus aureus* NCTC 4163, *Escherichia coli* NCTC 5933, and *Candida albicans* 3501[1]. The preliminary results obtained (Tables I–III) indicate that most of the tested compounds possess considerable antimicrobial activity against Gram-positive bacteria (*S. aureus*) and showed no activity against Gram-negative bacteria (*E. coli*). In addition, many of the tested compounds showed inhibitory activity against *C. albicans*.

EXPERIMENTAL SECTION[2]

3-(4-Carbethoxyphenyl)-2-methyl-4-oxoquinazoline (I) and 3-(4-Carbethoxyphenylamino)-2-methyl-4-oxoquinazoline (V)—Compounds I and V were prepared according to a previously reported method (17); I (80% yield), mp 169–170°C [lit. (17) mp 169–170°C]; V (72% yield) mp 149–150°C [lit. (17) mp 149–150°C].

Reaction of Hydrazine Hydrate with 2-(4-Carbethoxyphenyl)-2-methyl-4-oxoquinazoline (I)—A mixture of hydrazine hydrate (5 mL) and I (0.92 g, 3 mmol) in ethanol (15 mL) was refluxed for 30 min, diluted with water, and extracted with ethyl acetate. The organic phase was washed with water then dried over anhydrous sodium sulfate. The residue obtained after evaporation of the solvent to dryness, showed three spots on TLC. This mixture was chromatographed on a silica gel column [chloroform–ethanol (9:1)]. The first fraction afforded 3-amino-2-methyl-4-oxoquinazoline (IV) as white needle crystals from aqueous ethanol in 53% yield mp 149–151°C [lit. (15) mp 151–152°C]. The second fraction furnished *p*-aminobenzoic acid hydrazide (II) as white needles from ethanol in 35% yield, mp 221–223°C [lit. (14) mp 222°C]. The third fraction gave 4-(2-methyl-4-oxoquinazoline-3-yl)benzoic acid hydrazide (III) as white prisms from chloroform–benzene (10% yield), mp 220–221°C; IR: 3380–3350 (NH), 1670, and 1650 cm^{-1} (C=O).

Anal.—Calc. for $C_{16}H_{14}N_4O_2$: C, 65.31; H, 4.76; N, 19.05. Found: C, 65.20; H, 4.80; N, 19.30.

Reaction of Hydrazine Hydrate with III—A mixture of III (0.29 g, 0.001 mol) and hydrazine hydrate (2 mL) in ethanol (5 mL) was heated under reflux for 30 min, diluted with water, and extracted with ethyl acetate. The organic phase was washed with water, dried over anhydrous sodium sulfate, and the solvent was evaporated to dryness. The residue was chromatographed on silica gel [chloroform–ethanol (9:1)]. The initial fraction afforded IV, while the later fractions afforded II, identical in all respects with the aforementioned specimens.

Reaction of Hydrazine Hydrate with 3-(4-Carbethoxyphenylamino)-2-methyl-4-oxoquinazoline (V)—A mixture of V (0.32 g, 0.001 mol), hydrazine hydrate (2 mL), and ethanol (10 mL) was refluxed for 30 min. The mixture was treated in a manner similar to that above. The initial fraction afforded IV as white needles from aqueous ethanol (65% yield), mp 150–152°C [lit. (15) 151–152°C]. The later eluate furnished *p*-hydrazinobenzoic acid hydrazide (VI) as white needles from methanol (30% yield), mp 163–165°C [lit. (18) mp 165°C].

4-(2-Methyl-4-oxoquinazoline-3-yl)benzoic Acid Hydrazide (III)—Hydrazine hydrate (5 mL) was added to a solution of 3-(4-carbethoxyphenyl)-2-methyl-4-oxoquinazoline (I) (0.92 g, 3 mmol) in benzene (9 mL) and ethanol (1 mL). The mixture was stirred for 1 h at room temperature, then diluted with water. The remaining ester I was removed by extraction with benzene. The aqueous layer was then adjusted pH 6 with HCl and then extracted with chloroform. The extract was washed with water, dried over anhydrous sodium sulfate, and the solvent was evaporated *in vacuo* at room temperature. The residue was crystallized from chloroform–benzene to give III as white prisms; (33% yield), mp 220–221°C; IR: 3380–3350 (NH), 1670, and 1650 cm^{-1} (C=O).

Anal.—Calc. for $C_{16}H_{14}N_4O_2$: C, 65.31; H, 4.76; N, 19.05. Found: C, 65.20; H, 4.80; N, 19.30.

1-[4-(2-Methyl-4-oxoquinazoline-3-yl)benzoyl]-4-alkyl-, aryl-, or -aralkyl-3-thiosemicarbazides (VII–X)—A solution of equimolecular amounts of an alkyl-, aryl-, or aralkylisothiocyanate (2 mmol) and 4-(2-methyl-4-oxoquinazoline-3-yl)benzoic acid hydrazide (III) (0.58 g, 2 mmol) in ethanol (20 mL) was heated under reflux for 15 min. The mixture was concentrated, cooled, and left overnight at room temperature. The precipitate was removed by filtration and recrystallized from ethanol (only VII was recrystallized from aqueous ethanol). The yields and physical constants of the products are listed in Table I; IR: 3270–3140 (NH), 1700–1670 (C=O and C=N), and 1550–1520, 1340–1330, 1070–1050, and 870–830 cm^{-1} [—N—C=S I, II, III, and IV mixed-vibration bands, respectively (19)].

3,4-Disubstituted Thiazoline-2-oxo[4-(2-methyl-4-oxoquinazoline-3-yl)-benzoyl]hydrazones (XI–XIV)—A mixture of the appropriate thiosemicarbazides (VII–X) (0.01 mol), phenacyl bromide (0.01 mol), and anhydrous sodium acetate (0.04 mol) in absolute ethanol (40 mL) was refluxed for 2 h.

Table I—Properties and Antimicrobial Activity of 1-[4-(2-Methyl-4-oxoquinazoline-3-yl)benzoyl]-4-alkyl-, -aryl- or -aralkyl-3-thiosemicarbazides[a]

Compound	Yield, %	mp, °C	Molecular Formula	Antimicrobial Activity[b] *S. aureus*	*E. coli*	*C. albicans*
VII	70	141–142	$C_{21}H_{23}N_5O_2S$[c]	11	(–)	11
VIII	85	214–215	$C_{23}H_{19}N_5O_2S$	11	(–)	13
IX	85	225–226	$C_{24}H_{21}N_5O_2S$	12	(–)	14
X	75	145–146	$C_{24}H_{21}N_5O_2S$	11	(–)	12

[a] Compounds VII–X were analyzed for C, H, N, and S; unless otherwise noted, all results were within ±0.4% of the theoretical values. [b] Expressed in terms of *in vitro* inhibition zones in millimeters. [c] Calc. for S, 7.82; found, 7.40.

[1] The standard strain was obtained from the Institut of Microbiology, Göttingen, West Germany.

[2] All melting points were determined in open glass capillary tubes and are reported uncorrected. IR spectra were measured in Nujol mulls on a Beckman 4210 spectrophotometer. H^1-NMR spectra were obtained on a Bruker HX-270, and the chemical shift was expressed in ppm downfield from an internal tetramethylsilane standard. Mass spectra were recorded on a Finnigan 4510 GCMS at an electron energy of 70 eV.

XVIII	91	benzene	139-40	$C_{26}H_{21}N_5O_3S$	15	(−)	10

[a] Compounds XV-XVIII were analyzed for C, H, N, and S; unless otherwise noted, all results were within ±0.4% of the theoretical values. [b] Expressed in terms of *in vitro* inhibition zones in millimeters. [c] Calc. for N, 14.49; found, 16.00.

The mixture was cooled, diluted with water, and allowed to stand. The solid material was removed by filtration and recrystallized from the appropriate solvent. The yields and physical constants of the products are summarized in Table II; IR: 3300-3200 (NH), 1680-1650 (C=O), 1543-1530 (NH), and 1330-1300 cm^{-1} (C—N); H^1-NMR for XIV ($CDCl_3$): δ 2.24 (s, 3, CH_3), 4.6 (s, 2, benzyl), 5.75 (s, 1, thiazoline proton), 7.39, 7.75, and 8.1 (3m, 19, ArH), and 8.3 ppm (br s, 1, N—H); MS for XIV, *m/z* (relative intensities): M^+ at 543 (0.06), 500 (0.02), 409 (38), 326 (0.29), 279 (2), 263 (12), 143 (24), 131 (2), 105 (13), 91 (100), and 76 (8).

2-Substituted 5-Thiazolidone-2-oxo[4-(2-methyl-4-oxoquinazoline-3-yl)-benzoyl]hydrazones (XV-XVIII)—These compounds were prepared by applying the same molar amounts and solvent volumes as in the preparation of XI-XIV, but using ethyl bromoacetate instead of phenacyl bromide. The yields and physical data of the products are recorded in Table III; IR: 3250-3200 (NH), 1740-1720 (C=O of thiazolidone), 1680-1650 (C=O), 1543-1530 (NH), and 1370-1320 cm^{-1} (C—N); H^1-NMR for XVIII ($CDCl_3$): δ 2.25 (s, 3, CH_3), 3.85 (s. 2, thiazolidone protons), 5.0 (s, 2 benzyl), 7.33, 7.76, and 8.05 (3 m, 13, ArH), and 8.49 ppm (br s, 1, N—H); MS for XVIII, *m/z* (%): M^+ at 483 (13), 409 (7), 279 (4), 263 (59), 236 (4), 143 (50), 121 (6), 116 (4), 105 (3), 91 (100), and 76 (14).

Antimicrobial Testing—Antimicrobial testing was performed by the agar diffusion method (16). The prepared compounds were dissolved in propylene glycol (2 mg/mL). Sterile nutrient agar (oxoid) was incubated with the test organisms (*S. aureus*, *E. coli*, and *C. albicans*). Each 100 mL of the medium received 1 mL of 24-hr broth culture, and 3 drops of the tested compound were placed separately in cups (8-mm diameter) cut in the agar. The plates were incubated at 37°C for 24 h and the resulting inhibition zones were measured (Tables I-III).

Determination of Acetazolamide in Biological Fluids by Reverse-Phase High-Performance Liquid Chromatography

DENNIS J. CHAPRON *‡× and LORRAINE B. WHITE *

Received February 24, 1983, from the **School of Pharmacy, University of Connecticut, Storrs, CT 06268* and the *‡Clinical Pharmacokinetics Laboratory, University of Connecticut Health Center, Farmington, CT 06032.* Accepted for publication May 23, 1983.

Abstract □ A high-performance liquid chromatographic method for the determination of acetazolamide in whole blood, plasma, and urine was developed. Samples of biological fluids containing various concentrations of acetazolamide were spiked with the internal standard, sulfadiazine. Samples were then mixed with a 50% ammonium sulfamate solution. Whole blood samples were heated for 25 s in boiling water. All samples were extracted with ethyl acetate; a phosphate buffer (pH 8.0) was used to wash the extracts. Acetazolamide was back-extracted into a glycine buffer (pH 10.0), which was then washed with ether. Separation of acetazolamide and internal standard from other biological constituents was achieved on a 10-μm C_{18} reverse-phase column using an acetonitrile–methanol–acetate buffer (pH 4.0). The eluant was monitored at 254 nm. All calibration curves were linear, and the results from reproducibility studies were excellent. Application of the method to human pharmacokinetic studies was demonstrated.

Keyphrases □ Acetazolamide—biological fluids, reverse-phase HPLC, pharmacokinetics □ HPLC-acetazolamide, biological fluids, pharmacokinetics

Acetazolamide, a carbonic anhydrase inhibitor widely used in the medical management of glaucoma, lowers intraocular pressure by reducing the rate of aqueous humor formation. Acetazolamide is also used as an antiepileptic drug, where its effect is thought to result from inhibition of brain carbonic anhydrase. There is evidence that effective intraocular hypotensive and anticonvulsant actions are seen at plasma concentrations of 5–20 and 10 μg/mL, respectively (1–4). The drug is concentrated in erythrocytes, a site of action which has received little attention in the clinical literature. In humans, high erythrocyte levels have recently been associated with significant toxicity (4, 5). This is attributed to carbon dioxide retention resulting from inhibition of erythrocyte carbonic anhydrase, an important enzyme that greatly facilitates carbon dioxide exchange and transport in the capillary beds (6). Acetazolamide is completely eliminated unchanged *via* the kidney; determination of its clearance by this organ may prove useful for adjusting acetazolamide plasma concentrations.

Several high-performance liquid chromatographic (HPLC) assays have been published for determining acetazolamide levels in plasma or serum (7–9), and they have been an improvement on the older, less sensitive enzymatic assays (10, 11). A sensitive GC method is available, but it requires an electron-capture detector (12). Some of the recent HPLC procedures require repeated and/or successive extractions and dry-down procedures. None of the HPLC methods can quantitate acetazolamide in whole blood [erythrocytes indirectly (12)] or urine, fluids from which clinically important information may be ascertained.

The present report describes an HPLC method that (*a*) obviates time-consuming solvent evaporation steps, (*b*) displays excellent sensitivity and reproducibility, and (*c*) can be applied to several different biological fluids.

EXPERIMENTAL SECTION

Reagents and Materials—Acetazolamide[1] and sulfadiazine[2] were used as supplied. The solvents used for extraction and chromatography were all HPLC grade[3]. All chemicals were analytical reagent grade[4].

Standards—Separate stock solutions containing 1.0 mg/mL of acetazolamide and sulfadiazine (internal standard) were prepared weekly by dissolving these agents in 0.005 and 0.01 M NaOH, respectively. Aqueous solutions of lower concentrations (*i.e.*, 0.01–0.5 mg/mL) were prepared extemporaneously as needed from the stock solutions. Buffer solutions of 0.032 M glycine (pH 10.0) and 0.1 M phosphate buffer (pH 8.0) were prepared monthly. All solutions were stored at 4°C when not in use.

Extraction—Urine and heparinized whole blood were obtained from drug-free, normal, human volunteers. Plasma was obtained from an aliquot of whole blood using heparin as anticoagulant. Two hundred-microliter aliquots of plasma, whole blood, or urine (diluted 1:10) were added to 13 × 100-mm borosilicate glass tubes.

Determination of Acetazolamide in Biological Fluids by Reverse-Phase High-Performance Liquid Chromatography

DENNIS J. CHAPRON *‡× and LORRAINE B. WHITE *

Received February 24, 1983, from the **School of Pharmacy, University of Connecticut, Storrs, CT 06268* and the *‡Clinical Pharmacokinetics Laboratory, University of Connecticut Health Center, Farmington, CT 06032.* Accepted for publication May 23, 1983.

Abstract □ A high-performance liquid chromatographic method for the determination of acetazolamide in whole blood, plasma, and urine was developed. Samples of biological fluids containing various concentrations of acetazolamide were spiked with the internal standard, sulfadiazine. Samples were then mixed with a 50% ammonium sulfamate solution. Whole blood samples were heated for 25 s in boiling water. All samples were extracted with ethyl acetate; a phosphate buffer (pH 8.0) was used to wash the extracts. Acetazolamide was back-extracted into a glycine buffer (pH 10.0), which was then washed with ether. Separation of acetazolamide and internal standard from other biological constituents was achieved on a 10-μm C_{18} reverse-phase column using an acetonitrile–methanol–acetate buffer (pH 4.0). The eluant was monitored at 254 nm. All calibration curves were linear, and the results from reproducibility studies were excellent. Application of the method to human pharmacokinetic studies was demonstrated.

Keyphrases □ Acetazolamide—biological fluids, reverse-phase HPLC, pharmacokinetics □ HPLC-acetazolamide, biological fluids, pharmacokinetics

Acetazolamide, a carbonic anhydrase inhibitor widely used in the medical management of glaucoma, lowers intraocular pressure by reducing the rate of aqueous humor formation. Acetazolamide is also used as an antiepileptic drug, where its effect is thought to result from inhibition of brain carbonic anhydrase. There is evidence that effective intraocular hypotensive and anticonvulsant actions are seen at plasma concentrations of 5–20 and 10 μg/mL, respectively (1–4). The drug is concentrated in erythrocytes, a site of action which has received little attention in the clinical literature. In humans, high erythrocyte levels have recently been associated with significant toxicity (4, 5). This is attributed to carbon dioxide retention resulting from inhibition of erythrocyte carbonic anhydrase, an important enzyme that greatly facilitates carbon dioxide exchange and transport in the capillary beds (6). Acetazolamide is completely eliminated unchanged *via* the kidney; determination of its clearance by this organ may prove useful for adjusting acetazolamide plasma concentrations.

Several high-performance liquid chromatographic (HPLC) assays have been published for determining acetazolamide levels in plasma or serum (7–9), and they have been an improvement on the older, less sensitive enzymatic assays (10, 11). A sensitive GC method is available, but it requires an electron-capture detector (12). Some of the recent HPLC procedures require repeated and/or successive extractions and dry-down procedures. None of the HPLC methods can quantitate acetazolamide in whole blood [erythrocytes indirectly (12)] or urine, fluids from which clinically important information may be ascertained.

The present report describes an HPLC method that (*a*) obviates time-consuming solvent evaporation steps, (*b*) displays excellent sensitivity and reproducibility, and (*c*) can be applied to several different biological fluids.

EXPERIMENTAL SECTION

Reagents and Materials—Acetazolamide[1] and sulfadiazine[2] were used as supplied. The solvents used for extraction and chromatography were all HPLC grade[3]. All chemicals were analytical reagent grade[4].

Standards—Separate stock solutions containing 1.0 mg/mL of acetazolamide and sulfadiazine (internal standard) were prepared weekly by dissolving these agents in 0.005 and 0.01 M NaOH, respectively. Aqueous solutions of lower concentrations (*i.e.*, 0.01–0.5 mg/mL) were prepared extemporaneously as needed from the stock solutions. Buffer solutions of 0.032 M glycine (pH 10.0) and 0.1 M phosphate buffer (pH 8.0) were prepared monthly. All solutions were stored at 4°C when not in use.

Extraction—Urine and heparinized whole blood were obtained from drug-free, normal, human volunteers. Plasma was obtained from an aliquot of whole blood using heparin as anticoagulant. Two hundred-microliter aliquots of plasma, whole blood, or urine (diluted 1:10) were added to 13 × 100-mm borosilicate glass tubes.

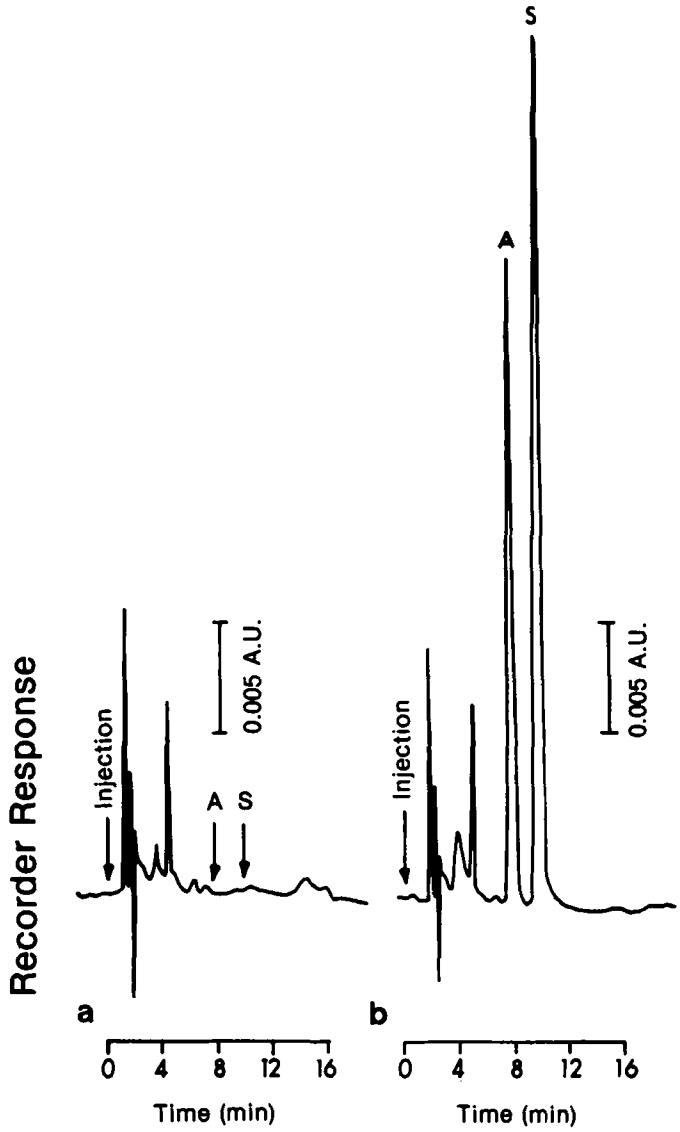

Figure 2—*Chromatograms of an extract of (a) blank plasma and (b) an extract of plasma containing 6.0 and 10.5 μg/mL of acetazolamide (A) and sulfadiazine (S), respectively.*

The tubes containing whole blood underwent two freeze-thaw cycles. Internal standard was then added (1–20 μL), the amount dependent on the range of concentrations expected in the unknown samples. One milliliter of a 50% solution of ammonium sulfamate was added, and the tubes were vortexed for a few seconds. The tubes containing whole blood were then placed in boiling water for 25 s, removed, and then quickly placed in cool water. One-half milliliter of water was added to the whole blood samples, and the tubes were vortexed for a few seconds.

Three milliliters of ethyl acetate was added to all tubes. The tubes were sealed with an extraction-tube plug[5] and shaken (200 oscillations/min) for 15 min. The phases were separated by centrifugation at 444×*g* for 5 min. The ethyl acetate layer was transferred to an identical tube containing 1.5 mL of pH 8.0 phosphate buffer (3.0 mL was used for urine workup). The tubes were then plugged and shaken, and the phases were separated by centrifugation as previously described. The organic phase was then transferred to tapered tubes[6] containing 200 μL of glycine buffer (pH 10.0), capped, and vortexed for 3 min. The phases were separated by centrifugation (444×*g*, 5 min), and the ethyl acetate layer was removed and discarded. To the remaining glycine layer, was added 1.0 mL of ether. The tubes were capped, vortexed for 2 min, the ether layer was removed and discarded, and the tubes were allowed to vent the ether vapors for ~15 min. An aliquot of the glycine phase (25–50 μL) was sampled from the tube and injected into the chromatograph.

Chromatography—The HPLC system consisted of a constant-flow pump[7], a variable-volume sampling valve[8], and a fixed-wavelength detector[9]. A 3.9 mm × 30-cm reverse-phase column[10] was used with a 2.3 × 3.9 mm guard column[11], which was packed with a commercially available bulk packing material[12]. The output from the detector was monitored on a 10-mV recorder[13].

Analyses were performed using a mobile phase of acetonitrile–methanol–0.05 M sodium acetate (3:2:95), the pH adjusted to 4.0 with glacial acetic acid. The mobile phase was deaerated before use. The system was operated at ambient temperature at a flow rate of 2.0 mL/min. The UV detector was fixed at a wavelength of 254 nm.

Calibration and Reproducibility—Known quantities of acetazolamide were added to blank plasma and whole blood. Samples (0.2 mL) were then assayed for acetazolamide. Calibration curves were constructed by plotting peak height ratio (acetazolamide-internal standard) *versus* the concentration of acetazolamide. Acetazolamide is rapidly eliminated from plasma; in order to accommodate a broad range of concentrations, two different standard curves

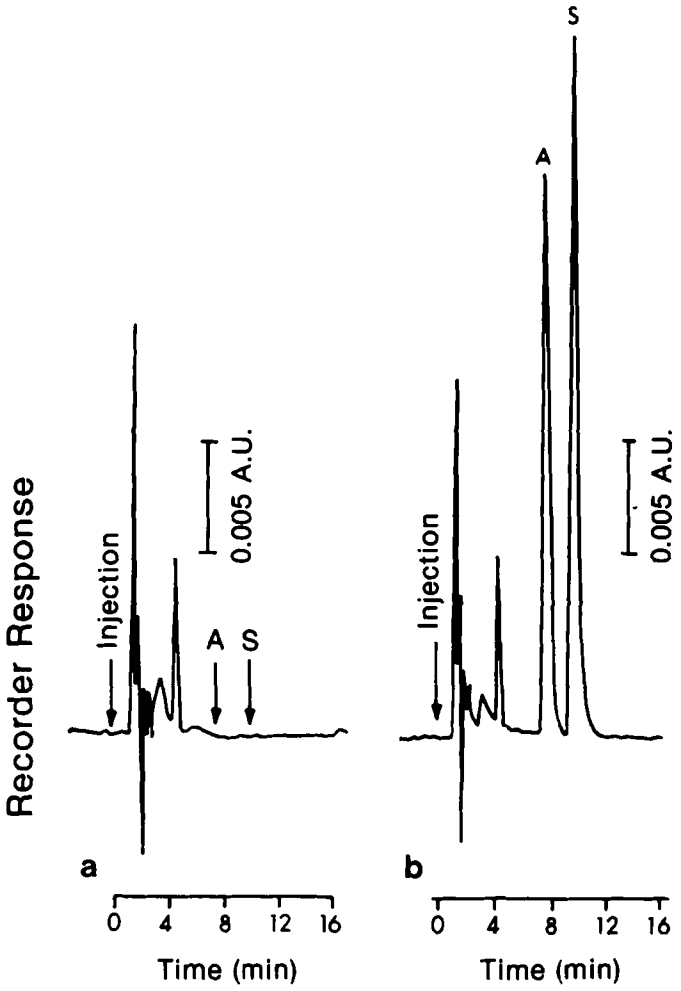

Figure 3—*Chromatograms of extracts of (a) blank urine and (b) urine containing acetazolamide (A) and sulfadiazine (S). Prior to extraction, each urine sample was diluted 1:10 with distilled water to yield final concentrations of 4.0 and 6.4 μg/mL for acetazolamide and sulfadiazine, respectively.*

were prepared. For plasma, standard calibration curve ranges were 0.05–1.5 μg/mL and 2.0–50.0 μg/mL. Because of significant accumulation and persistence of acetazolamide in erythrocytes, only a single calibration curve was needed for whole blood (*i.e.*, 1–50 μg/mL). Standard curves for urine were prepared in diluted urine (1:10) over the concentration range of 1–12 μg/mL. Day-to-day reproducibility and within-run precision of the analytical procedures were examined by processing spiked samples of plasma, whole blood, and urine.

Stability and Recovery—The stability of acetazolamide as a refrigerated aqueous solution (1 mg/mL), a frozen glycine extract, and frozen plasma and whole blood samples was assessed periodically by HPLC assay. Recovery of acetazolamide was calculated by comparing the peak height ratio of drug added to the biological fluid against the peak height ratio of drug added to the final glycine phase. In both treatments, the internal standard was added to the final glycine phase.

RESULTS AND DISCUSSION

Acetazolamide is a relatively polar drug [chloroform–water partition coefficient at pH 7.0 ≅ 0.001 (13)] which coextracts with endogenous blood and urinary constituents that create detection and quantification difficulties. The present results showed that a phosphate buffer washing step, which removes a moderate amount of acetazolamide, dramatically eliminates interfering endogenous substances. Blank urine, whole blood, and plasma (Figs. 1–3) do not show any endogenous interfering peaks. The retention times for acetazolamide and sulfadiazine were 7.6 and 9.8 min, respectively. Extraction of acetazolamide from whole blood was markedly improved by heating in boiling water for 25 s prior to processing. Perhaps heating irreversibly inactivates carbonic anhydrase and liberates the bound acetazolamide. Degradation of either acetazolamide or sulfadiazine does not occur during this heating step.

Table I—Calibration Curves for Acetazolamide in Various Biological Fluids

Fluid[a]	Concentration, μg/mL	r^2 [b]
Plasma	0.05–1.5	0.9984 ± 0.0025
	2.0–50	0.9988 ± 0.0022
Whole blood	1.0–50	0.9997 ± 0.0004
Urine	1.0–12	0.9996 ± 0.0004

[a] Based on five calibration curves. [b] Mean ± *SD*.

Calibration curves for all the biological fluids were linear over the concentrations described, and the intercepts were essentially zero. The mean coefficient of determination (r^2) for five successive calibration curves for urine, whole blood, and plasma are shown in Table I. Table II shows the coefficient of variation (*CV*) for the reproducibility studies. These data indicate the overall variability of the assay to be excellent, with all *CV* values <5.0%. With a 200-μL sample, the lowest quantifiable concentration providing reasonable reproducibility (*CV* ≤10%) was 0.05 μg/mL.

Absolute recoveries from plasma, whole blood, and urine were found to be 36, 33, and 20%, respectively. The significant loss of acetazolamide during processing was expected (acetazolamide has a pK_a of 7.4 and would be significantly ion-trapped in the phosphate buffer during the washing step) and considered very acceptable, because endogenous interfering substances were completely eliminated, sensitivity was adequate for human pharmacokinetic studies, and reproducibility of the assay was excellent. Absolute recovery can be increased by increasing the volume of ethyl acetate used for the initial extraction (*e.g.*, 4.0- and 5.0-mL ethyl acetate extraction of plasma provided absolute recoveries of 45 and 50%, respectively). We found it more convenient, however, to work with smaller extraction volumes. During sample processing the net loss of sulfadiazine was found to exceed that of acetazolamide. Across the biological matrices examined, sulfadiazine loss was found to parallel that of acetazolamide. A processed sample will produce a peak height ratio ~1 when initially spiked with a concentration of sulfadiazine 30% greater than that of acetazolamide.

Several stability studies were conducted. The aqueous refrigerated solution of acetazolamide (1 mg/mL) was found to be stable for ≤30 d. Frozen (−20°C) glycine extracts of acetazolamide and sulfadiazine were stable for ≤7 d. Acetazolamide in frozen plasma and whole blood was stable ≤180 d.

The HPLC procedures described have been successfully applied to pharmacokinetic studies of acetazolamide disposition in humans after intravenous administration. Figure 4 shows typical acetazolamide concentration–time curves following intravenous administration to a young female volunteer. Because urinary concentrations of the drug were expected to vary considerably, being very high initially and then rapidly declining thereafter, the following formula was used to estimate acetazolamide urinary concentrations:

$$\text{Estimated urinary acetazolamide concentration} = \frac{\text{AUC}\ (\mu\text{g}\cdot\text{min/mL}) \times CL\ (\text{mL/min})}{\text{Urine Volume (mL)}}$$

where AUC is the area under the acetazolamide plasma concentration–time curve and *CL* is its estimated clearance from plasma. Estimated urinary acetazolamide concentrations were then diluted to produce concentrations that would fall at the midpoint of the standard curve for urine (*i.e.*, 1–12 μg/mL). Cumulative urinary and excretion rate plots are shown in Fig. 5 for the same subject. It is noteworthy that 98.8% of the injected dose (320 mg) was recovered during a 72-h urine collection period. Studies designed to better define

Table II—Summary of Data for Reproducibility

Within-Run Precision[a]		Day-to-Day Reproducibility[b]	
Conc., μg/mL	*CV*, %	Conc., μg/mL	*CV*, %
	Plasma		
0.1	2.8	0.5	4.2
1.0	3.6	10.0	1.1
10.0	1.5		
20.0	2.0		
	Whole Blood		
1.0	1.3	10.0	3.7
10.0	1.6		
20.0	2.6		
	Urine		
5.0	1.2	6.0	1.3
10.0	1.5

Amperometric Determination of Hydralazine Hydrochloride in a Flowing Stream at the Glassy Carbon Electrode

MUMTAZ H. SHAH and JAMES T. STEWART ˣ

Received March 11, 1983, from the *Department of Medicinal Chemistry, College of Pharmacy, The University of Georgia, Athens, GA 30602.* Accepted for publication May 25, 1983.

Abstract □ A flow-injection method for the determination of hydralazine hydrochloride based on electrochemical oxidation at the glassy carbon electrode is presented. The amperometric method is highly specific and may be used to determine hydralazine hydrochloride in the presence of other drugs commonly found in its pharmaceutical dosage forms or administered concurrently in therapeutic situations. By using an electrode potential of +650 mV *versus* an Ag/AgCl reference electrode, a calibration curve was found to be linear in the 1–50-μg/mL concentration range, with minimum detectability at 10 ng (signal-to-noise ratio, 2). When the method was applied to the analysis of hydralazine hydrochloride in selected pharmaceutical dosage forms, it showed good accuracy and precision. Although automation was not used in this study, the method could readily be incorporated in automated systems because it employs the technique of continuous analysis in a flowing stream.

Keyphrases □ Hydralazine hydrochloride—amperometric determination in a flowing stream, glassy carbon electrode □ Flow-injection method—amperometric determination, hydralazine hydrochloride, glassy carbon electrode □ Electrochemical oxidation—glassy carbon electrode, flow-injection method, determination of hydralazine hydrochloride

Hydralazine hydrochloride, a widely prescribed antihypertensive agent, has been analyzed by diverse methodologies, including titrimetry (1, 2), spectrophotometry (3, 4), fluorometry (5), GC, and HPLC (6–10). Interest in this laboratory in the development of new continuous assay methods for drugs in flowing streams led us to investigate the oxidation of hydralazine at the glassy carbon electrode. There is almost no information in the literature concerning the electrochemistry of hydralazine. One report has indicated that the drug can be reduced at the dropping mercury electrode to give two half-wave potentials of −700 and −950 mV *versus* the standard calomel electrode (11). The reduction occurs in a solution containing 1 M HCl as a supporting electrolyte and gelatin as a surfactant. The report did not comment on the sensitivity, accuracy, precision, and specificity of the method. There appears to be no data in the literature on the electrochemical oxidation of the drug.

This laboratory has reported previously on continuous analysis in flowing streams by oxidation of drugs such as ascorbic acid and methyldopa at the tubular carbon electrode (12, 13). The glassy carbon electrode has supplanted the tubular carbon electrode and has shown general usefulness as a sensitive tool for the determination of oxidizable drugs in flowing stream systems such as HPLC (14–16). These kinds of electrodes can be easily incorporated into automated or semiautomated systems such as would be used in dosage form analysis.

In this report, amperometric determination of hydralazine hydrochloride in a flowing stream utilizing oxidation at the glassy carbon electrode is reported. The flow-injection method

detects the drug in the 1-50-μg/mL range with good accuracy, precision, and specificity. The procedure was shown to be applicable to the analysis of hydralazine hydrochloride in pharmaceutical dosage forms.

EXPERIMENTAL SECTION

Apparatus—Voltammograms and cyclic voltammetry measurements were made with a conventional three-electrode system[1] consisting of a glassy carbon working electrode, a platinum auxiliary electrode, and a silver-silver chloride reference electrode. A wall-jet-type methyl methacrylate electrochemical cell[2] and associated electronics[2] were used for the flowing stream analysis. The cell contained a glassy carbon working electrode, a silver-silver chloride reference electrode, and a second glassy carbon auxiliary electrode. The mobile phase was pumped through the cell at a fixed flow rate with a reciprocating pump[3]. Samples were manually injected into the sample injection system[4] with a microsyringe[5]. The pump, injector, and electrochemical cell were connected with standard HPLC stainless steel tubing (0.02 cm) and fittings. Cell currents were recorded at ambient temperature with a strip-chart recorder[6].

Chemicals—Hydralazine hydrochloride[7] powder was obtained for use in the analytical study. All other chemicals were commercially available and were used as received. A stock solution containing 0.1 mg/mL of hydralazine hydrochloride was prepared in Walpole acetate buffer, pH 4.2 (17). Further dilutions of the solution were made to provide working standards in the 1-50-μg/mL range.

Procedures—A 40:60 mixture of Walpole acetate buffer (pH 4.2)-absolute methanol was pumped through the electrochemical cell[2] at a flow rate of 1.0 mL/min. Aliquots (50 μL) of hydralazine hydrochloride solutions in acetate buffer were injected into the flowing stream, and the current was measured with an applied potential of +650 mV *versus* an Ag/AgCl reference electrode.

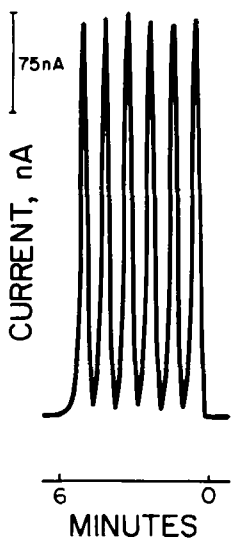

Figure 2—*Replicate injections of hydralazine hydrochloride (16 μg/mL) into the flowing stream system at a rate of 60 samples/h.*

To determine whether other antihypertensive drugs or compounds commonly found in dosage forms with hydralazine hydrochloride interfered with the assay by altering the current flow of the drug or were oxidized at the glassy carbon electrode, the following studies were performed. Individual solutions (0.1 mg/mL) of guanethidine monosulfate, reserpine, hydrochlorothiazide, chlorothiazide, triamterene, methyldopa, propranolol hydrochloride, and chlorthalidone were prepared in acetate buffer (pH 4.2)-methanol (40:60). Accurately pipetted aliquots of these solutions were then used to prepare various mixtures containing the individual drugs at the 8-100-μg/mL range, with the hydralazine concentration maintained at 16 μg/mL. Each mixture was then assayed for hydralazine content. The data obtained from each mixture were then compared with those of a pure solution of hydralazine hydrochloride to calculate the degree of interference, if any, at the various concentration levels of the added drugs.

Analysis of solid dosage form—Tablets and/or capsules containing hydralazine hydrochloride were sonicated in Walpole acetate buffer (pH 4.2). The resulting solution was then filtered, if necessary, and diluted to the 1-50-μg/mL range. An aliquot of the diluted solution was then assayed for hydralazine hydrochloride as described above.

RESULTS AND DISCUSSION

Figure 1 shows a hydrodynamic voltammogram of hydralazine hydrochloride (50 μg/mL) when subjected to electrochemical oxidation at the glassy carbon electrode in acetate buffer (pH 4.2)-methanol (40:60). A half-wave potential of +510 mV was observed. A potential of +650 mV was selected for the amperometric determination since it represented the point on the wave at which maximum drug sensitivity could be obtained.

By using the optimum electrode potential of +650 mV, a hydralazine hydrochloride calibration curve was obtained in the 1-50-μg/mL range. Linear regression analysis of the calibration data gave typical slope, intercept, and r values of 19.82, 8.79, and 0.9990 (n = 18), respectively.

To estimate the reproducibility of the electrode response by the amperometric method, eight replicate injections at hydralazine hydrochloride concentrations of 4-, 16-, and 40-μg/mL were run. Mean peak currents of 51 ± 1.15, 165.63 ± 1.25, and 367.50 ± 1.25 nA, respectively, were obtained. The

Table II—Analysis of Hydralazine Hydrochloride in Pharmaceutical Dosage Forms

Product Components	Hydralazine Declared/Sample, mg	Hydralazine Found/Sample, mg[a]	Recovery, %
Hydralazine hydrochloride	25	25.55 ± 0.25	102.10
Hydralazine hydrochloride Hydrochlorothiazide	25	24.98 ± 0.10	99.90
Hydralazine hydrochloride Reserpine	50	50.85 ± 0.52	101.70
Hydralazine hydrochloride Hydrochlorothiazide Reserpine	25	24.90 ± 0.42	99.35

[a] Values represent mean ± *SD* based on quadruplicate determinations of each sample.

precision of these measurements is expressed by relative standard deviations of 2.30, 0.75, and 0.34% for the 4-, 16-, and 40-μg/mL levels, respectively.

Interference studies were performed to establish the specificity of the method for hydralazine hydrochloride in the presence of other drugs that might be found in its combination dosage forms. There was little or no interference from these miscellaneous compounds, except for hydrochlorothiazide, chlorothiazide, and reserpine, in which appreciable interference was noted when their concentrations were six- to sevenfold greater than the hydralazine level (Table I).

Applications of the method to the assay of hydralazine hydrochloride in commercial dosage forms was then studied. After sample preparation and dilution to the 1–50-μg/mL calibration range, the drug solutions were analyzed, and the concentration in each dosage form was calculated using the slope and intercept values generated from linear regression analysis of the hydralazine calibration data. The results of the assay shown in Table II indicate that hydralazine content in dosage forms can be conveniently determined by the amperometric method described herein with good accuracy and precision.

By using the parameters established for the assay, hydralazine samples can be injected into the flowing stream system at the rate of 60 samples/h (Fig. 2). The sensitivity of the assay, based on a signal-to-noise ratio of two, is 10 ng of drug.

Rapid Gas Chromatographic Assay for Monitoring Valproic Acid and Valpromide in Plasma

MEIR BIALER ˣ, MICHAEL FRIEDMAN, and ABRAHAM RUBINSTEIN

Received July 1, 1982, from the *Department of Pharmacy, School of Pharmacy, Hebrew University, P.O. Box 12065, Jerusalem 91120, Israel.* Accepted for publication May 23, 1983.

Abstract □ A gas chromatographic (GC) method for monitoring valproic acid and valpromide in plasma was developed. The procedure involved a single solvent extraction of drugs from acidified plasma samples, followed by a GC injection of the organic phase. This rapid, sensitive, specific, and reproducible method is a key factor in pharmacokinetic and stability studies of valpromide. Pharmacokinetic application of the new GC method is presented by a simultaneous plasma monitoring of valpromide and valproic acid levels obtained after intravenous administration of valpromide to a dog.

Keyphrases □ Valproic acid—GC, plasma, valpromide □ Valpromide—GC, plasma, valproic acid

Valpromide (2-propylvaleramide), commonly used in clinical practice as an antiepileptic and antipsychotic drug (1–6), is a primary amide of the more widely known valproic acid, which is used to treat different types of epilepsy, particularly petit mal epilepsy (7, 8). Recent reports claimed that valpromide is biotransformed to valproic acid before reaching the systemic circulation. Only traces of valproic acid have been observed in patients who were on chronic oral treatment of valpromide (1, 4, 5); after treatment with valpromide (600 mg t.i.d.) to 42 epileptic patients, the therapeutic plasma concentrations of valproic acid ranged from 50 to 60 μg/mL with minimal fluctuations in plasma level (4). This is within the therapeutic range of valproic acid (8). After single oral administration of valpromide (600 mg) to humans, the plasma levels of valproic acid ranged from 7 to 20 μg/mL for >30 h after the valpromide administration (4, 5).

During the last decade various methods for analyzing valproic acid in biological fluids have been published (9, 10). Recently a gas chromatographic (GC) method for monitoring valpromide in plasma was reported (11). The aim of this work was to develop a rapid GC method for a routine valproic acid and valpromide assay in plasma. This assay is fundamental in pharmacokinetic and stability studies of valpromide, since valpromide may serve as a prodrug for valproic acid (1, 2).

EXPERIMENTAL SECTION

Reagents—Organic stock solutions of valproic acid[1] and valpromide[2] were prepared by dissolving the drugs separately in chloroform. Aqueous stock solutions were prepared by dissolving sodium valproate[1] and valpromide separately in water. The concentration of all stock solutions was 1 mg/mL. Caprylic acid[2] was used as an internal standard and was dissolved in chloroform at a concentration of 1 mg/mL. Stock solutions were stored at 4°C.

Apparatus—The gas chromatograph[3] was equipped with a flame-ionization detector and a recorder[4]. The glass column, 180 cm × 2 mm i.d., was packed with 5% free fatty acid phase[5] on 80–100 mesh Chrom Q. Flow rates were as follows: hydrogen, 40 mL/min; air, 400 mL/min; carrier gas (nitrogen), 40 mL/min. The system temperatures were: column, 175°C; injector, 180°C; detector, 220°C.

Extraction Procedure—To 1.0 mL of plasma spiked with the appropriate aliquots of valproic acid and valpromide aqueous solutions were added 480

60	104.21	6.85	6.57	99.81	7.64	7.66

[a] Mean of 10 determinations.

μL of chloroform, 20 μL of internal standard solution, and 0.5 mL of 1 M HCl. The sample was vortexed for 15 s, shaken for 15 min, and centrifuged at 4000 rpm for 15 min. Three microliters of the organic phase was injected into the gas chromatograph.

To determine the precision of the assay, 12 mL of human plasma was spiked with appropriate aliquots of the aqueous valproic acid and valpromide stock solutions and was stored at −20°C during the 3-month study. On different days 1-mL aliquots were taken from the various stored samples and analyzed against a fresh calibration curve made according to the extraction procedure on the same day.

RESULTS AND DISCUSSION

Typical chromatograms of extracts from plasma with reference to drug-free plasma samples is presented in Fig. 1. Under the assay conditions the following retention times were obtained: valproic acid, 0.96 min; internal standard, 1.8 min; and valpromide, 2.23 min. There was no interference from endogeneous plasma components.

Calibration curves from plasma extracts showed a linear correlation between peak height ratio (y) of valpromide or valproic acid against the internal standard and plasma concentration of the drugs (x). The linear calibration equation was $y = 0.0968x - 0.044$ ($r = 0.997$) for valproic acid and $y = 0.0713x + 0.0018$ ($r = 0.997$) for valpromide. A least-squares linear regression method was used to calculate these curves. The minimal detectable concentration was ~1-2 μg/mL in plasma.

Analytical recoveries of substances were established as follows. Various amounts (5, 10, 20, 30, 40, 50, and 60 μg taken from the aqueous stock solutions) of valproic acid and valpromide were dissolved in 1 mL of drug-free plasma. After acidification, plasma samples were extracted into 0.5 mL of chloroform which contained 20 μL of the internal standard solution. A series of external standards were prepared by adding 20 μL of the internal standard solution to 0.48 mL of chloroform which contained the various amounts taken from the organic stock solution (5, 10, 20, 30, 40, 50, and 60 μg) of valproic acid and valpromide. Recoveries were calculated by comparing peak height ratios of the extracted standard to the ratios of the external standards (Table I). The standard deviation of the analytical recoveries can serve as a good estimate for reproducibility.

Precision or accuracy of the assay was determined by performing 10 replicate analyses of five control samples containing 20, 30, 40, 50, and 60 μg/mL of both drugs on different days over a 3-month period (Table II). The recovery percentage of valpromide and valproic acid, as presented in Table I, does not have a statistically significant difference from 100% ($p > 0.05$). The observed values of the various valpromide and valproic acid concentrations (Table II) were not different statistically from the added concentrations ($p > 0.05$) (12).

In a preliminary pharmacokinetic study, valpromide (400 mg) was administered intravenously to a mongrel dog (20 kg). This 20-mg/kg dose was of the same order of magnitude as the therapeutic dose in humans, which is 900-1800 mg (13-26 mg/kg) in divided doses (6). The plasma levels of valpromide and valproic acid obtained in this study are presented in Fig. 2 (mean ± *SD* of three replicates). The curves presented in Fig. 2 were obtained after a computer fitting of the observed data using the NONLIN computer program (13). Valpromide was partly biotransformed to valproic acid, and the plasma levels of these two compounds were assayed by the proposed method throughout the duration of the 12-h study. The *CV* among the three replicates of each data point of valproic acid and valpromide was <10%. As in previous studies of valpromide, plasma levels of valpromide and valproic acid were

Pharmacokinetics of Iohexol, a New Nonionic Radiocontrast Agent, in Humans

JEROME EDELSON ˣ, DAVID SHAW, and GERARD PALACE

Received Feburary 17, 1983, from *Sterling-Winthrop Research Institute, Rensselaer, NY 12144.* Accepted for publication May 20, 1983.

Abstract □ Sixteen healthy men received iohexol intravenously at a concentration of 346 mg of iodine/mL. Doses of 500, 750, 1000, and 1500 mg of iodine/kg of body weight were administered to four volunteers each. Neither clearance nor percent of dose excreted in the urine showed any significant correlation with size of the dose. The overall mean (±*SD*) renal and total body clearances were 120 ± 18.6 and 131 ± 18.6 mL/min, respectively. The overall mean apparent volume of distribution was 165 (±30.7) mL/kg. Urine contained 92.3 ± 4.4% of the dose. Most of the drug (89.9%) was excreted within the first 12 h. An open three-compartment body model gave the best fit to the experimental data. The mean apparent first-order terminal elimination (γ-phase) half-life was 12.6 h.

Keyphrases □ Iohexol—pharmacokinetics, intravenous administration, humans □ Pharmacokinetics—iohexol intravenous administration, humans □ Radiocontrast agents—iohexol, plasma and urine levels, intravenous administration, pharmacokinetics, humans

Ionic contrast media that are approved for human use are hyperosmolar to plasma. Administration of the large volumes necessary for visualization can result in large detrimental fluid shifts within the body. Prior to conducting intensive clinical trials with a new contrast medium, the route and rate of excretion must be adequately assessed. Previous studies with ionic contrast media have suggested that excretion occurs almost exclusively *via* the kidney at a rate that is consistent with passive handling by glomerular filtration (1).

Iohexol[1], 5-[acetyl(2,3-dihydroxypropyl)-amino]-*N*,*N*′-bis(2,3-dihydroxypropyl)-2,4,6-triiodo-1,3-benzenedicarboxamide, is a new nonionic radiographic contrast agent which is intended for vascular and intrathecal use in humans. The biological properties of iohexol (2) are similar to those of metrizamide, the first nonionic contrast medium approved for clinical use (3). A significant advantage of iohexol is its stability in solution to terminal heat sterilization, and its preparation as a ready-to-use solution.

This report describes the results of our investigations into the excretion of iohexol, and includes a nonlinear least-squares estimate of the pharmacokinetic parameters of iohexol following intravenous administration.

Pharmacokinetics of Iohexol, a New Nonionic Radiocontrast Agent, in Humans

JEROME EDELSON ˣ, DAVID SHAW, and GERARD PALACE

Received Feburary 17, 1983, from *Sterling-Winthrop Research Institute, Rensselaer, NY 12144.* Accepted for publication May 20, 1983.

Abstract □ Sixteen healthy men received iohexol intravenously at a concentration of 346 mg of iodine/mL. Doses of 500, 750, 1000, and 1500 mg of iodine/kg of body weight were administered to four volunteers each. Neither clearance nor percent of dose excreted in the urine showed any significant correlation with size of the dose. The overall mean (±*SD*) renal and total body clearances were 120 ± 18.6 and 131 ± 18.6 mL/min, respectively. The overall mean apparent volume of distribution was 165 (±30.7) mL/kg. of 500, 750, 1000, and 1500 mg of iodine/kg. Iohexol was administered at a concentration of 346 mg of iodine/mL of solution at a temperature of 37°C. The injection was made into an antecubital vein at a rate that delivered the total dose in 3 min. Time zero ($t = 0$) is defined as the time at which the injection was completed. Blood samples were drawn from the contralateral antecubital vein. Plasma and urine samples were collected at appropriate intervals and stored frozen until analyzed.

[a] Expressed as iohexol.

Appropriate institutional review and approval were obtained. No subject had a clinical history or laboratory findings that were suggestive of renal or hepatic dysfunction.

Assay Procedure—The analysis of plasma and urine for iohexol concentration was dependent on separation by HPLC. The mobile phase was a mixture of 0.01 M phosphate buffer, pH 7.4, and methanol; the column was a 5-μm Spherisorb ODS[2] column, 25 cm × 4.6 mm i.d. The UV detector was set at 254 nm. Details of the HPLC procedure will be reported elsewhere (4). Plasma and urine standards, which were prepared in normal human biological fluids, were processed and anlayzed with each set of samples from the subjects in the study. The concentrations of iohexol were determined by inverse prediction (5), using the linear regression of the peak height ratios of the standards. The minimum quantifiable level of iohexol was estimated as the concentration whose lower 80% confidence limit just encompassed zero (6).

Pharmacokinetic Calculations—The data obtained from the analysis of the plasma samples was described by an open three-compartment body model by means of a weighted nonlinear regression (NLIN) procedure using the Marquardt algorithm (7); the weighting factor was the reciprocal of the square of the concentration. The model was defined with the following equation:

$$C_p = Ae^{-\alpha t} + Be^{-\beta t} + Ce^{-\gamma t}$$

where C_p is the plasma concentration; A, B, and C are constants; and α, β, and γ are the hybrid rate constants for the three-compartment model.

In addition to the regression-dependent parameters, the plasma concentration data were used to calculate the area under the plasma concentration *versus* time curve during the 96-h study period (AUC_0^{96}). Both total body clearance and renal clearance were estimated by dividing the dose administered and the amount of drug excreted into the urine during 96 h, respectively, by the AUC_0^{96}.

RESULTS AND DISCUSSION

The concentrations of iohexol in the plasma samples from each of the volunteers were determined. After intravenous administration, the plasma concentrations declined triexponentially with time, suggesting that a three-compartment body model would be appropriate. Pharamacokinetic parameters were estimated for each subject after computer-fitting of the plasma data by

[2] Excalibar, Applied Science, State College, Pa.

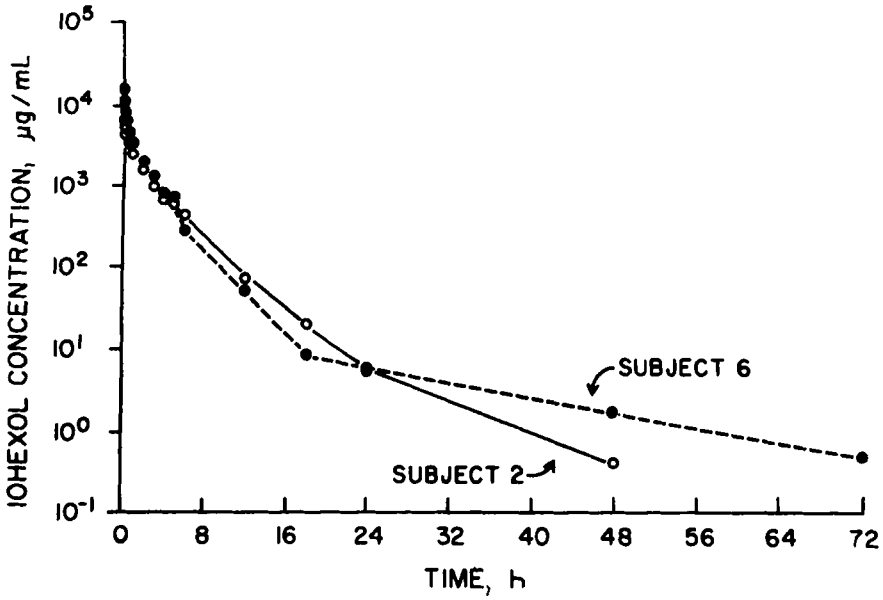

Figure 1—*Plasma concentration of iohexol in human volunteers after intravenous administration. Plasma concentrations were observed in subject 2 (○), and in subject 6 (●), with widely divergent renal clearance rates and concentrations predicted by the open three-compartment body model (lines).*

an iterative nonlinear least-squares regression technique (7). Despite the threefold range in both the total dose administered and the infusion rate, the same model was fitted to the plasma concentration data of each subject, with satisfactory results (Table I).

The mean apparent first-order terminal (γ-phase) elimination half-life for iohexol was ~12.6 h. The mean value for α, 1.92 h^{-1}, corresponds to a half-life of 22 min; the mean value for β, 0.331 h^{-1}, corresponds to a half-life of 2.1 h. The mean ($\pm SD$) apparent volume of distribution was 165 (±30.7) mL/kg of body weight. This value suggests that iohexol distributes into extracellular water.

The AUC during the 96-h study period was estimated by the trapezoidal method (Table I); linear regression analysis indicated a good correlation between the amount of drug injected and the AUC_0^{96} ($r = 0.94$; $p < 0.001$).

From the amount of drug excreted into the urine and the regression-independent AUC, the renal clearances were calculated (Table I). Although there is almost a twofold difference between the highest (subject 6) and lowest (subject 2) renal clearances, the observed concentration data were adequately described by the open three-compartment body model for both of these subjects. A comparison of the observed and predicted concentrations is shown in Fig. 1; the agreement between the observed values and those predicted by the pharmacokinetic model is apparent.

The urinary excretion of intact iohexol is summarized in Table II. The overall mean ($\pm SD$) percent of dose excreted into urine was 92.3 ± 4.4%; the recovery was not significantly different across doses ($p < 0.158$). Most of the drug was excreted into the urine within the first 12 h[3] with a mean of 89.9 ± 7.0%. As can be determined from the clearances presented in Table I, renal clearance accounts for 95% of the total body clearance; obviously, iohexol is not metabolized appreciably.

Iohexol was well tolerated in these subjects, in doses up to 1500 mg of iodine/kg of body weight. No drug-related adverse reactions were reported, although, in a few cases, a sensation of heat was recorded following injection of iohexol.

High-Performance Liquid Chromatographic Assay for *N*-Acetylcysteine in Plasma and Urine

P. A. LEWIS ˣ, A. J. WOODWARD, and J. MADDOCK

Received February 22, 1983, from *Simbec Research Ltd, Merthyr Tydfil Industrial Park, Merthyr Tydfil, Mid Glamorgan, Wales, U.K.* Accepted for publication July 29, 1983.

Abstract □ A sensitive high-performance liquid chromatographic (HPLC) assay for *N*-acetylcysteine in human plasma and urine has been developed. The method employs a prechromatographic stage to produce the dinitrophenyl derivative of *N*-acetylcysteine, which is chromatographed on a 5-μm C_{18} bonded reverse-phase column using an external standard method. The derivatized *N*-acetylcysteine molecule has a retention time of ≃13 min at a flow rate of 1.0 mL/min for a mobile phase of methanol–aqueous 0.05 M citrate–0.001 M EDTA buffer pH 7.0 (30:70). In a multistep extraction procedure, which is slightly modified for the *N*-acetylcysteine assay in urine, the limits of sensitivity for the plasma and urine assays were found to be ≃60 ng/mL and ≃200 μg/mL, respectively. Preliminary data from pilot studies in human subjects are presented.

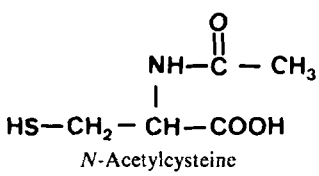
Keyphrases □ *N*-Acetylcysteine—HPLC, plasma and urine □ HPLC-*N*-acetylcysteine, plasma and urine

N-Acetylcysteine, when administered intravenously, has been shown to be effective as an antidote for the treatment of acetaminophen poisoning, giving protection against liver damage (1), and to influence the consistency and volume of sputum when administered orally to patients with chronic obstructive bronchitis (2). A further potential use of *N*-acetylcysteine is the inhibition of cyclophosphamide-induced bladder toxicity in rodents without adversely affecting the beneficial immunosuppressive action of cyclophosphamide (3).

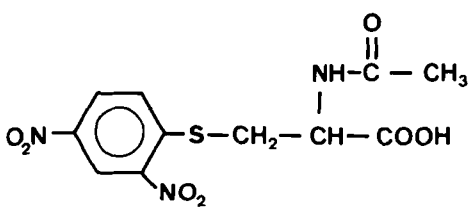
Pharmacokinetic studies with *N*-acetylcysteine are confined to studies (4) employing material labeled with sulfur-35 which measured total radioactivity. Studies with unlabeled *N*-acetylcysteine have been hampered by the lack of a suitable analytical procedure to determine the compound in plasma and urine.

A GC procedure (5) has been reported but is unsuitable for determinations in plasma. A high-performance liquid chromatographic (HPLC) method for determining the compound in plasma ultrafiltrates has been published (6), but this method failed to detect *N*-acetylcysteine on every occasion and was unable to determine total plasma levels. *N*-Acetylcysteine has been determined (7) as *N*-(1-pyrene)maleimide and *N*-(7-dimethylamino-4-methyl-3-coumarinyl)maleimide derivatives, but the procedure can only be used for urinary measurements.

This paper describes a reliable and sensitive procedure for determining *N*-acetylcysteine in plasma and urine which is suitable for the study of the pharmacokinetics of the drug.



N-Acetylcysteine



2,4-Dinitrophenyl Derivative

EXPERIMENTAL SECTION

Materials—Pure authentic *N*-acetylcysteine[1] was used as received without purification, as a standard. All chemicals used were of "Analar" [2] grade. All solvents used were of glass-distilled[3] or HPLC[3] grade. The ultrafiltration cones[4] used were of a membrane type.

Apparatus—The high-performance liquid chromatographic pump[5] was fitted with a loop injector[6] with a 50-μL loop and a variable-wavelength detector[7] set at 360 nm, attenuated at 0.02 AUFS for plasma and 0.5 AUFS for urine. The signal was recorded on a 10-mV recorder[8]. An "in-house" packed 25 cm × 0.46-mm i.d. column containing a reverse-phase (C_{18}) chemically bonded to 5-μm silica[9] was employed at ambient temperature.

Mobile Phase—The mobile phase was prepared by mixing an aqueous solution of 0.05 M trisodium citrate and 0.001 M EDTA, adjusted to pH 7.0 with a citric acid solution, with HPLC-grade methanol in a ratio of 70:30. (When performing the assay on urine samples, this solution may be modified by mixing the aqueous buffer with methanol in a 65:35 ratio.) This solution was filtered through a membrane filter[10] and deaerated by sonication in an ultrasonic bath[11]. Immediately prior to use the solution was purged with pure helium. The mobile phase was pumped isocratically through the column at ambient temperature with a flow rate of 1.0 mL/min, giving a back-pressure of ≃1000 psi.

Standard Solutions—Aqueous stock solutions of *N*-acetylcysteine were prepared daily and stored at 4°C. Plasma standard solution was prepared by dissolving authentic *N*-acetylcysteine in the mobile phase solution (25 mg/100 mL). Urine standard solution was prepared by dissolving authentic *N*-acetylcysteine in 2.0% sodium hydrogen carbonate solution (2.0 g/100 mL).

Plasma standards were produced by spiking 3.0-mL aliquots of fresh human plasma to give a range of calibrators with concentrations of *N*-acetylcysteine as follows: 0, 0.25, 0.50, 0.75, 1.0, 1.25, 1.50, 2.0, and 2.5 μg/mL. These standards were vortex-mixed for 30 s and then allowed to stand at ambient temperature for 15 min to equilibrate. Similarly, urine calibration standards were produced by spiking 100-μL aliquots of fresh human urine to give a range of concentrations of *N*-acetylcysteine as follows: 0, 0.25, 0.50, 0.75, 1.0, 1.25, and 1.50 mg/mL.

Each range of calibrators were taken through the appropriate complete extraction procedure as described below. In each instance, calibration curves were constructed by plotting the integrated peak area against the corresponding *N*-acetylcysteine standard concentration. Plasma and urine samples were similarly treated, and the measured peak areas (referred to the appropriate calibration curve) were used to determine the concentration of *N*-acetylcysteine present.

Chromatographic Method—Aliquots of plasma (3.0 mL) or urine (100 μL) diluted in 1 mL of glass-distilled water were pipetted into 10-mL polytef-lined screw-capped glass tubes. A 500-μL aliquot of 5-mg/mL dithiothreitol solution was added; the tubes were vortex-mixed for 10 sec, capped, and incu-

Assay	Calibration Range	*n*	Slope	Intercept	*r*
Plasma	0.25–2.5 μg/mL	4	8.07	0.82	0.996
Urine	0.25–1.5 mg/mL	5	152.7	11.5	0.997

bated for 30 min at 37°C in a water bath. Following incubation 1.0 mL of 2% sodium hydrogen carbonate in water and 350 μL of 5.0% 2,4-dinitro-1-fluorobenzene in ethanol, which had been recrystallized from ether, was added to all tubes. The tubes were vortex-mixed for 10 s and incubated for 30 min at 60°C in a water bath.

The contents of each tube were then transferred to the membrane centrifuge cones, conditioned before use by immersion in double-glass-distilled water for 60 min and centrifuging for 5 min at 1000×*g* to remove excess water. The samples in the ultrafiltration cones were placed in labeled 20-mL glass vials and centrifuged at 1000×*g* for 20 min at 20°C. Aliquots (1.0 mL) of the ultrafiltrates were transferred to 25-mL extraction tubes, and 5 mL of water was added. The ultrafiltration step was omitted for the urine sample assays. Ether (10 mL) was added to all tubes, which were then capped and shaken mechanically[12] at 250 cpm for 5 min in the dark. Following centrifugation at 1000×*g* for 5 min at 10°C, the ether layers were transferred to clean glass vials and the solvent was evaporated to dryness under a gentle stream of nitrogen at room temperature. The dried residues were stored in capped vials at −20°C until just prior to chromatography, when the plasma and urine residues were reconstituted with 75 μL and 1.0 mL of mobile phase, respectively.

RESULTS AND DISCUSSION

The chromatographic conditions described were implemented in order to provide the best compromise between chromatographic resolution and peak symmetry and relatively short retention times, permitting the analysis of a large number of samples with good accuracy and precision. Under these HPLC conditions, the *N*-acetylcysteine derivative gives a retention time of ≃13 min, with a run time between injections of 20 min.

Figures 1 and 2 illustrate typical plasma and urine chromatograms, respectively, of spiked material, drug-free control material, and of material following dosing of the compound. Standard calibration lines were constructed by plotting the peak areas of *N*-acetylcysteine against the concentration of the compound in spiked standards. Typical calibration curve data is presented in Table I, showing linearity over the ranges employed with coefficients of variation of 12.6% at 0.25 mg/mL and 3.8% at 1.5 mg/mL for the urinary range and 11.9% at 0.25 μg/mL and 9.7% at 2.5 μg/mL for the plasma calibrations. These data show good precision despite the lack of an internal standard. A number of candidate substances were investigated for suitability as an internal standard, but none were acceptable for a variety of reasons.

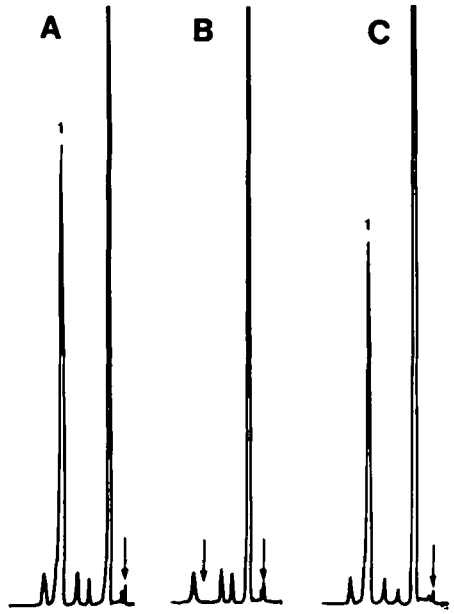

Figure 1—*Typical chromatograms of* N-*acetylcysteine in human plasma. Key: (A) a spiked plasma extract containing 2.0 μg/mL of* N-*acetylcysteine (1); (B) a drug-free control plasma extract; (C) a plasma extract from a subject receiving oral* N-*acetylcysteine.*

[12] Braun Lab-Shaker LSL; FT Scientific Ltd., Tewkesbury, England.

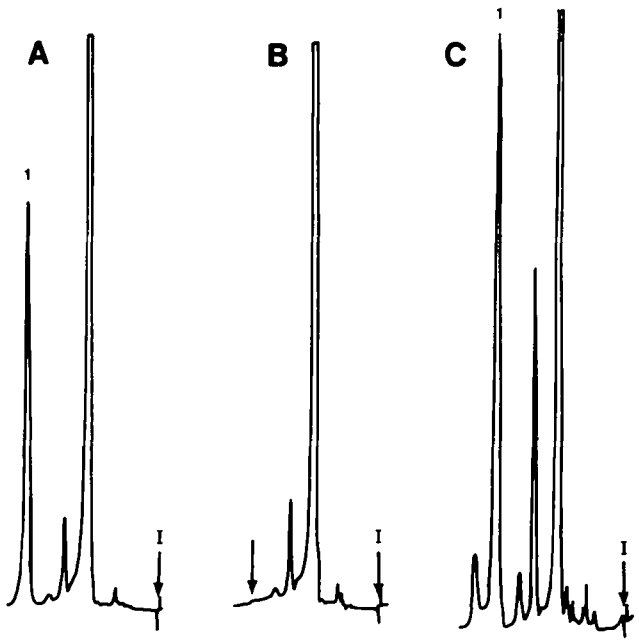

Figure 2—*Typical chromatograms of* N-*acetylcysteine in human urine. Key: (A) a spiked urine extract containing 1.5 mg/mL of* N-*acetylcysteine (1); (B) a control drug-free urine extract; (C) a test urinary collection 4–6 h following intravenous administration of* N-*acetylcysteine.*

Within- and between-batch data showed generally very favorable reproducibility. Ten replicate plasma controls each at 0.4, 1.1 and 1.9 μg/mL assayed the same day gave mean values of 0.43 ± 0.07 (*SD*), 0.99 ± 0.06 (*SD*), and 1.95 ± 0.22 (*SD*) μg/mL, respectively. Between-batch reproducibility ranged from 0.6 to 17.3% (mean 7.9%) for a series of seven control samples; however, occasional outliers were encountered, *e.g.*, a control spiked at 0.83 μg/mL gave a result of 1.15 μg/mL, a 38% error. Investigations of the stability of *N*-acetylcysteine in plasma on storage at −20°C lend further evidence of good overall reproducibility for the procedure. Plasma from a subject in receipt of a 1.0-g iv dose of *N*-acetylcysteine was assayed freshly and at 4, 5, 6, and 11 d of storage at −20°C. Samples withdrawn at 0.5, 1, 1.5, and 2.0 h postdose gave concentrations of 58.9, 25.0, 15.4, and 12.0 μg/mL when analyzed freshly, and the levels did not deteriorate on storage, giving *SD* values of 2.41, 2.48, 1.46, and 1.52, respectively, over the period.

Levels as low as 50 ng/mL can be seen over a baseline signal-to-noise ratio of 2.1. Although accurate detection limits have not been determined, sensitivity for the plasma and urine levels encountered were not a problem.

The measurement of free levels of *N*-acetylcysteine in plasma was investigated by omitting the dithiothreitol stage in order to produce ultrafiltrates containing free, unbound compound. Following derivatization and HPLC, no discernible free levels could be detected, even after oral doses of 800 mg of *N*-acetylcysteine. These data call into question that published by other workers who have reported free *N*-acetylcysteine in plasma. Our investigations demonstrate that a reduction employing dithiothreitol is essential to release *N*-acetylcysteine from binding sites on protein and to release the compound from disulfides, *e.g.*, bis-*N*-acetylcysteine. There is evidence to suggest that the latter is present, since our investigation of urinary *N*-acetylcysteine levels shows that very much lower levels of the compound are found when omitting the dithiothreitol stage. An ultrafiltration stage is incorporated in the plasma assay to remove excess 2,4-dinitro-1-fluorobenzene, which binds to plasma proteins and interferes with the chromatography.

The procedure described herein is being used to investigate the pharmacokinetics of *N*-acetylcysteine in adult healthy human subjects in receipt of intravenous and oral dosage forms. Preliminary data indicate that a rapid, specific, and precise procedure for determining *N*-acetylcysteine in biological fluids has been developed.

Comparative Aspirin Absorption Kinetics after Administration of Sodium- and Potassium-Containing Buffered Solutions

WILLIAM D. MASON

Received March 28, 1983, from the *Pharmacokinetics Laboratory, University of Missouri-Kansas City, Schools of Pharmacy & Medicine, Kansas City, MO 64108.* Accepted for publication June 29, 1983.

Abstract □ Twelve fasting normal volunteers received three aspirin dosage forms in a single 325-mg dose in a complete crossover study; the plasma aspirin and salicylic acid levels and the urine salicylic acid and salicyluric acid levels were measured over 10 h. The three dosage forms included an unbuffered tablet and two effervescent solutions, one with sodium bicarbonate-citrate buffer and the other with potassium bicarbonate-citrate buffer. A significantly faster absorption rate was observed with the sodium bicarbonate-citrate buffer, when compared with the potassium bicarbonate-citrate buffer and the unbuffered tablets, which were equivalent. These differences were attributed primarily to gastric emptying rate differences. Urine pH and salicylate renal clearance were significantly affected by the single dose of antacid buffer. The area under the curve and urine accumulation comparisons suggested that ~25% more aspirin reaches the general circulation intact after administration of the unbuffered tablet than the two solutions, but that the total salicylate absorbed is equivalent for all three dosage forms. This difference in aspirin bioavailability is probably due to the fact that the two buffered solutions are predominantly absorbed through the intestine, in which presystemic hydrolysis occurs, whereas a significant portion of the tablet dose is absorbed through the gastric mucosa.

Keyphrases □ Aspirin—absorption kinetics after administration of sodium- and potassium-containing buffered solutions □ Salicylic acid—absorption kinetics after administration of sodium- and potassium-containing buffered solutions □ Absorption kinetics—aspirin after administration of sodium- and potassium-containing buffered solutions

Aspirin is the drug of choice when a mild analgesic-antipyretic effect is required. It is also a primary agent used in the chronic management of rheumatoid arthritis and osteoarthritis. After oral administration for pain, rapid absorption is desirable to provide the rapid onset of effects and to reduce contact time with the gastric mucosa. The potential influence of potassium ion *versus* sodium ion on the absorption kinetics of aspirin from two different effervescent solutions is the subject of this report.

BACKGROUND

A recent report (1) from this laboratory compared the absorption kinetics of aspirin from three commercially available dosage forms. Two of the dosage forms were extemporaneously prepared effervescent solutions containing either 1.825 or 3.808 g of sodium bicarbonate as a component of the buffer. It was concluded that a primary mechanism for the more rapid absorption of the solutions than the unbuffered tablet was more rapid gastric emptying. Also, the lower area under the aspirin curve for the solutions was attributed to a greater portion of the aspirin being absorbed through the intestine (*i.e.*, rather than through the stomach wall) and thus being subjected to a greater presystemic hydrolysis.

Patients on sodium-restricted diets may wish to take aspirin as a buffered effervescent solution. Absorption kinetics of the commercially available buffered effervescent solution was compared with that of a solution in which the sodium was replaced with potassium. A commercially available unbuffered tablet was also studied for comparison.

EXPERIMENTAL SECTION

Dosage Forms—Three dosage forms were used to provide equal doses of aspirin: a plain tablet containing 325 mg of aspirin[1]; an effervescent tablet containing 324 mg of aspirin, 1,904 g of sodium bicarbonate, and 1 g of citric acid[2]; and a prepared effervescent tablet containing 324 mg of aspirin, 2.26 g of potassium bicarbonate, and 1 g of citric acid.

Subjects—Twelve healthy volunteers (eight males and four females; ages 21–37 years; weight, 53.6–94.5 kg) were evaluated by a comprehensive physical examination, blood chemistry profile (including blood count and differential), and complete urinalysis. None of the subjects had a history of gastrointestinal disease or surgery. All subjects were free of any active disease process, and none had used any medication for 14 d before the study.

Method—A Latin-square design for three treatments in 12 subjects was employed. A 10-h fast preceded dosing and continued for 4 h postdose. At ~7 a.m., predose urine and blood samples were obtained, and a single dose of aspirin with 240 mL of water was administered. The effervescent tablets were dissolved in 140 mL of water 3 min before dosing and the mixture was then swallowed. The glass was rinsed with 100 mL of water, which also was swallowed. After dosing, 100 mL of water was administered at 1, 2, and 3 h, and a uniform meal was served after the 4-h sample was obtained, after which water was allowed *ad libitum*. Subjects remained standing or sitting through the day, and exercise was limited to walking about the room.

Blood was drawn into chilled vacuum containers[3] *via* an indwelling catheter at 5, 10, 15, 20, 30, and 45 min and 1, 1.5, 2, 3, 4, 6, 8, and 10 h. Plasma was separated by centrifugation at 1764×*g* at 4°C within 20 min of collection. All urine was collected at 2-h intervals over 10 h, the pH and volume were measured, and an acidified aliquot was saved for analysis. All samples were frozen at −30°C and assayed within 2 weeks of collection by the HPLC method described previously (2).

RESULTS

As shown in Tables I and II, both plasma aspirin and salicylic acid levels rise more rapidly after administration of the solution with sodium than the potassium solution or the tablet. This rank order and profile reflect the values for 11 of the 12 subjects and is statistically significant ($p < 0.05$). Plasma aspirin levels rise rapidly to a mean peak of 7.20 μg/mL at 17.5 min with the single 324-mg dose in a sodium-containing effervescent solution, whereas the potassium-substituted solution reaches only 5.26 μg/mL at 30.4 min, which is not significantly higher ($p < 0.05$) than for the tablet. Table I—Mean Plasma Aspirin Levels and Kinetic Parameters [a]

Parameter	Na^+ solution	K^+ solution	Tablet
Mean conc, μg/mL			
5 min	1.04	0.71	0.94
10 min	4.17	1.84	2.17
15 min	6.43	2.97	3.42
20 min	6.27	3.56	3.98
30 min	4.41	4.34	4.22
45 min	1.99	2.65	3.34
60 min	1.10	1.56	2.70
90 min	0.36	0.52	1.28
120 min	0.30	0.30	0.80
Maximum conc., μg/mL	7.20*	5.27†	4.76†
Time of maximum conc., min	17.5*	30.4†	36.7†
Area under curve to 120 min, (μg·min/mL)	228.1*	211.4*	276.3†
to infinity, (μg·min/mL)	231.7*	216.6*	290.8†
$t_{1/2}$, min	19.6*	18.7*	24.7†

[a] A common symbol beside the mean indicates no significant difference ($p < 0.05$) by three-way analysis of variance and least significant difference.

to aspirin, as indicated by the area under the curve to infinity, is higher by ~25% for the tablet than for the two buffered solutions, which are equivalent.

Parameters that indicate the rate of absorption, maximum concentration, and time to maximum concentration for salicylic acid show the sodium-containing solution to be faster, with the potassium-containing solution being intermediate, and the tablet slowest. For salicylic acid, however, only the maximum concentration differs significantly ($p < 0.05$), whereas the renal clearance of salicylate is higher for the two buffered solutions (Table III). The overall contribution to total clearance is not sufficient to lower the area under the salicylate plasma curve over 10 h (Table II).

In Table III, the data obtained from urine samples are summarized, and the small differences in urine pH and salicylate renal clearance resulting from the buffered solutions are shown. Although urine pH was measured for 10 h, only during the first 2 h was there a significant difference between buffered and unbuffered dosages. Over a 10-h period, ~70% of the 325-mg dose was recovered in urine as salicylurate and salicylate, which demonstrates the equivalence of the extent of aspirin and/or salicylate absorption for all three dosage forms.

Table II—Mean Plasma Salicylic Acid Levels and Kinetic Parameter [a]

Parameter	Na^+ solution	K^+ solution	Tablet
Mean conc., μg/mL			
0.08 h	1.03	0.71	0.73
0.16 h	6.17	3.13	2.04
0.25 h	12.3	6.18	4.39
0.33 h	18.1	9.87	6.62
0.50 h	20.8	16.6	10.6
0.75 h	20.2	19.5	13.9
1.0 h	19.0	19.1	14.8
1.5 h	17.1	16.8	15.6
2 h	15.3	15.7	16.1
3 h	12.0	12.5	13.4

10 h	1.86	2.06	2.28
Maximum conc., μg/mL	21.8*	20.2*	17.2†
Time of maximum conc., h	0.59*	0.75*	1.50†
Area under curve to infinity, μg·h/mL	94.9*	95.6*	98.1*
$t_{1/2}$, h	2.42*	2.60*	2.91*

[a] A common symbol beside the mean indicates no significant difference ($p < 0.05$) for three-way analysis of variance and least significant difference.

Table III—Mean Urine Salicylate and Salicylurate Levels [a]

Parameter	Na^+ solution	K^+ solution	Tablet
Urine volume (0 → 2 h), L	0.131*	0.186*	0.170*
Urine pH (0 → 2 h)	6.63*	6.87*	6.11†
Salicylic acid renal clearance (0 → 2 h), L/h	0.31*	0.43*	0.14†
Urine volume (0 → 10 h), L	0.845*	0.918*	0.874*
Salicylic acid renal clearance (0 → 10 h), L/h	0.334*	0.353*	0.204†
Accumulation of salicylic acid (0 → 10 h), mg	28.7*	29.2*	17.1†
Accumulation of salicyluric acid (0 → 10 h), mg	214*	206*	221*
Percent aspirin dose (equivalent) recovered as salicylic acid and salicylurate to 10 h, %	72.3*	70.4*	69.9*

[a] A common symbol beside the mean indicates no significant difference ($p < 0.05$) for three-way analysis of variance and least significant difference.

DISCUSSION

Two significant results were obtained from this study. First, the rapid absorption rate of aspirin from a buffered solution is, in part, related to the sodium content, and potassium is not equivalent to sodium in this regard. This observed difference in absorption rate is most probably from the comparative effects of these two ions on gastric emptying kinetics. Before mixing with gastric secretion, the solutions are each ~100 mM in sodium or potassium ion with a total milliosmolarity of ~120[4]. In this concentration range, sodium has been shown to accelerate gastric emptying, whereas potassium inhibits gastric emptying (3, 4). Thus, although both solutions can raise gastric pH, which would speed gastric emptying, the inhibitory effect of potassium nullifies the pH effect, and the potassium-containing solution is emptied at about the same rate as the unbuffered tablet.

A second and more subtle observation is the extent to which aspirin reaches the general circulation unhydrolyzed, which is the same for both the sodium- and potassium-containing buffered solutions. Both are ~25% less bioavailable than the unbuffered tablet. This is consistent with the previously stated hypothesis (1) that the aspirin administered in a buffered solution is ionized in the stomach and little or no absorption occurs until it is emptied into the intestine. Intestinal absorption is associated with greater presystemic hydrolysis and, thus, a lower portion is bioavailable. These observations are consistent with the hypothesis that the potassium-containing solution is retained longer in the stomach and the antacid buffering is sufficient to reduce or inhibit gastric absorption.

It would appear that the replacement of sodium in extemporaneously prepared effervescent solutions of aspirin may slow absorption to equal that of a conventional tablet. However, the protection afforded the gastric mucosa by the elevated pH may be the same for both the sodium and potassium buffers.

Plasma Protein Binding of Warfarin: Methodological Considerations

DENNIS MUNGALL *, YAN YAN WONG ‡, ROBERT L. TALBERT *, MICHAEL H. CRAWFORD §, JAMES MARSHALL ¶, DAVID W. HAWKINS *, and THOMAS M. LUDDEN *x

Received January 24, 1983, from the *College of Pharmacy, The University of Texas at Austin, Austin, Texas, and The University of Texas Health Science Center at San Antonio, San Antonio, TX 78284; ‡Department of Pharmaceutical Services, University of Chicago Hospital and Clinics, Chicago, IL 60637; §Department of Medicine, Division of Cardiology, The University of Texas Health Center and Veterans Administration Hospital, San Antonio, TX 78284; and ¶Veterans Administration Medical Center, Department of Clinical Pharmacy, Birmingham, AL 35209. Accepted for publication June 7, 1983.

Abstract □ Recent theoretical work has suggested that radiochemical impurities can significantly alter the binding results for highly protein-bound drugs. We compared protein binding of warfarin by ultrafiltration and equilibrium dialysis with 98% radiochemically pure [^{14}C]warfarin. Ultrafiltration and equilibrium dialysis were performed at 37°C and pH 7.45 on the plasma of patients receiving chronic warfarin therapy. Binding to plasma from seven patients was measured in duplicate by both a nonspecific radioisotopic technique and a specific HPLC technique. The nonspecific technique gave percentage of free warfarin values of 1.84 ± 0.11 (mean ± *SD*) and 1.59 ± 0.14 for ultrafiltration and equilibrium dialysis, respectively. The HPLC procedure yielded a percentage of free warfarin by ultrafiltration of 0.969 ± 0.203 and a value of 0.690 ± 0.095 by equilibrium dialysis ($p < 0.05$). The HPLC procedure for protein binding was performed on plasma samples from 12 additional patients and yielded a percentage of free warfarin of 1.01 ± 0.69 by ultrafiltration and 0.44 ± 0.34 by equilibrium dialysis ($p < 0.05$). It can be concluded that radiochemical impurities may lead to significant overestimation of the percentage of free warfarin. Ultrafiltration yielded a higher percentage of free warfarin than did equilibrium dialysis, but the ability to distinguish binding differences among patients was similar.

Keyphrases □ Warfarin—methodological considerations, plasma protein binding □ Plasma protein binding—methodological considerations, warfarin, radiochemical impurities □ Radiochemical impurities—methodological considerations, plasma protein binding of warfarin

A number of factors may affect the results of protein binding studies. These factors include the administration of heparin, the type of blood collection tubes, the system used for determining binding (equilibrium dialysis, ultrafiltration), and the radiochemical purity of the radiolabeled compound. Bjornsson *et al.* (1) have recently emphasized the importance of radiochemical purity of radiolabeled drugs used for determining plasma protein binding. Theoretically, radiochemical impurities that are poorly bound to plasma proteins could lead to significant overestimations of the free concentration of drugs that are highly bound. Warfarin is an agent which is highly protein bound, and its binding could be susceptible to measurement errors related to the presence of radiochemical impurities. [^{14}C]Warfarin is ~98.5% radiochemically pure. Studies with [^{14}C]warfarin for binding without a purification procedure (2–4) have reported a significantly higher percentage of free warfarin than studies in which a TLC assay procedure was utilized (5, 6). Yacobi and Levy (7) have found that a twofold error in the estimation of the percentage of free warfarin was made when radiochemically impure warfarin was used to determine protein binding in rats. No data on human plasma are available concerning this issue.

The majority of studies evaluating warfarin binding have utilized equilibrium dialysis, and no information is available comparing ultrafiltration with equilibrium dialysis. In the present study, the influence of radiochemical impurity on warfarin binding in human plasma is evaluated, and plasma binding as determined by ultrafiltration and equilibrium dialysis is compared.

Table I—Comparison of Ultrafiltration and Equilibrium Dialysis Methods for Measuring Warfarin Protein Binding [a]

Procedure	Mean Unbound ± *SD*, %
Ultrafiltration	1.010 ± 0.69
Equilibrium dialysis	0.44 ± 0.34

[a] Free and total concentrations were determined by the chromatographic procedure described in the text ($n = 12$).

EXPERIMENTAL SECTION

Initial attempts were made to purify racemic [^{14}C]warfarin[1] (specific activity, 50 mCi/mmol) before binding studies were performed. The major impurity could be separated by HPLC. Collection and assay of sequential fractions of the eluant revealed that 98.5% of the eluted radioactivity corresponded to warfarin, and ~1.5% corresponded to a chromatographic peak with a somewhat longer retention time. However, an overall recovery of only 20–25% could be obtained by collecting the eluant fraction corresponding to warfarin and extracting into ether. A second method with a sample preparation column[2] did not separate the impurity from the parent compound. Thus, it was necessary to perform the binding studies with the 98.5% pure [^{14}C]warfarin. However, the radioactive warfarin was measured in plasma, ultrafiltrate, or dialysate by the specific chromatographic procedure described below.

Preliminary studies were performed to assess binding of [^{14}C]warfarin to the ultrafiltration device[3] and the effect of *in vitro* heparin on the binding of warfarin. Binding of [^{14}C]warfarin to the ultrafiltration device was tested between the concentrations of 0.02 μg/mL and 2 mg/mL. Less than 10% binding to the device was found with these concentrations. No difference in binding was found between heparinized (*in vitro*) and nonheparinized samples. The time to reach equilibrium with the equilibrium dialysis system[4] was 4 h.

Plasma samples from 19 outpatients treated chronically with warfarin were collected in evacuated blood collection tubes[5] containing 143 U of lithium heparin per tube. Total warfarin concentrations ranged from ~1.0 to 4.3 μg/mL. The coefficient of variation of the HPLC assay was 10.0%. All plasma samples were stored at −20°C until assayed.

Equilibrium dialysis—Aliquots of plasma (1 mL) were dialyzed against 1 mL of 0.1 M phosphate buffer (pH 7.45) with polytef cells separated by dialysis membranes[3]. Radiolabeled [^{14}C]warfarin (0.5 μCi) was added to each plasma sample. The cells were rotated in a water bath at 37°C for 4 h.

Ultrafiltration—[^{14}C]Warfarin (1 μCi) was added to 1-mL plasma samples placed in the reservoir of the ultrafiltration device[3]. An initial 100-μL plasma sample was obtained for measurement of total radioactivity. The samples were placed in a centrifuge in an incubator maintained at 37°C. Samples were allowed to equilibrate for 15 min and were then centrifuged for 15 min at 1000×*g*.

Sample Analysis—For the dialysis experiments, 0.4 μg of phenprocoumon (the internal standard) and 10 μg of unlabeled warfarin (the carrier) were added to 250-μL samples of plasma and dialysate. For the ultrafiltration experiments, similar quantities of internal standard and carrier were added to 100-μL samples of plasma and ultrafiltrate. Each sample was then processed

and described by Fasco *et al.* (8). Each sample was extracted with 5 mL of ether, and the ether was evaporated to dryness at room temperature under a stream of nitrogen. The residue was diluted in 100 μL of mobile phase and injected onto a reverse-phase HPLC column[6]. The mobile phase was 40% acetonitrile in 1.5% acetic acid and was adjusted to pH 4.7 with ammonium hydroxide. The flow rate was 2 mL/min[7], and detection was at 309 nm[8].

The effluent which corresponded to the warfarin peak was collected in a liquid scintillation vial, mixed with 15 mL of scintillation fluid[9], and counted for 10 min in a liquid scintillation counter[10]. The percentage of [^{14}C]warfarin that was unbound was calculated as follows:

$$\% \text{ unbound} = (0.93A/B)100\% \qquad \text{(Eq. 1)}$$

where A is the net counts in dialysate or ultrafiltrate per internal standard peak height for dialysate or ultrafiltrate and B is the net counts in plasma per internal standard peak height for plasma. The correction factor of 0.93 was used to correct for the fact that plasma is ~93% water, and only this portion was available for the distribution of free drug.

Plasma samples of 7 of the 19 patients were used to determine the apparent percentage of free warfarin if the extraction and chromatography procedures were omitted. Aliquots of plasma and dialysate or filtrate were directly placed in scintillation fluid and counted. The percent unbound was calculated as follows:

$$\% \text{ unbound} = 100\% \frac{0.93 \text{ (net counts in dialysate or filtrate)}}{\text{net counts in plasma}} \qquad \text{(Eq. 2)}$$

For these seven patients, all procedures were performed in duplicate.

RESULTS AND DISCUSSION

Table I shows the mean binding values by ultrafiltration and equilibrium dialysis when the HPLC procedure was used. Ultrafiltration yielded a higher percentage of unbound warfarin than did equilibrium dialysis ($p < 0.05$).

Table II demonstrates the effect of the radiochemical impurities on warfarin plasma protein binding and compares the results obtained between ultrafiltration and equilibrium dialysis in seven additional patients. A significant difference in the percentage of unbound warfarin was found between the direct counting and the chromatographic procedures ($p < 0.05$). The samples counted directly yielded unbound values approximately twice those given by the more specific chromatographic procedure. These results are similar to those found by Yacobi and Levy (7) in rat plasma.

An important consideration in evaluating binding procedures is the relative ability of each to assess differences in the percentage of unbound warfarin between patients. This was evaluated in the present study by using the Spearman rank correlation coefficient (Rs). In the 12 patients in which equilibrium dialysis and ultrafiltration were performed singly and samples were assayed chromatographically, the Rs was 0.7 ($p < 0.05$). For the seven patients in which binding was determined in duplicate, these procedures yielded an Rs value of 0.81 ($p < 0.05$). An Rs of 0.63 ($p < 0.05$) was found between unchromatographed and chromatographed samples from the ultrafiltration procedure, and an Rs of 0.929 ($p < 0.05$) was found between unchromatographed and chromatographed samples from the equilibrium dialysis procedure. These results suggest that the same relative binding results may be obtained for equilibrium dialysis whether or not a cleanup procedure is used. Further study of a group of patients with greater differences in warfarin binding is needed.

This study demonstrates that radiochemical impurities can significantly alter the percentage of unbound warfarin as determined by ultrafiltration or equilibrium dialysis, and that equilibrium dialysis and ultrafiltration are similar in their ability to discriminate warfarin binding differences between patients.

Table II—Effect of Radiochemical Impurity on Protein Binding of Warfarin [a]

Procedure	Mean Unbound ± *SD*, %
Ultrafiltration (counted directly)	1.84 ± 0.11
Equilibrium dialysis (counted directly)	1.59 ± 0.14
Ultrafiltration (extracted, chromatographed)	0.97 ± 0.20
Equilibrium dialysis (extracted, chromatographed)	0.69 ± 0.10

Penetration of Trolamine Salicylate into the Skeletal Muscle of the Pig

J. R. BALDWIN ˣ, R. A. CARRANO, and A. R. IMONDI

Received January 7, 1983, from *Adria Laboratories, Inc., Columbus, OH 43216.* Accepted for publication May 26, 1983.

Abstract □ Studies to determine the extent of local tissue penetration of topically applied trolamine [^{14}C]salicylate were conducted in domestic pigs. The preparation was applied onto a 100-cm^2 shaved area of skin overlying the biceps femoris at a concentration of 0.7 mg of salicylate/cm^2 to closely approximate the actual use in humans. At least 82% of the topically applied trolamine salicylate was absorbed over a 2-h period. Based on blood and muscle salicylate levels, a localization of the absorbed drug occurred in muscle underlying the treated area within 120 min. Muscle from the treated area had a concentration of salicylate that was 13 times that of blood and 49 times that of muscle taken from untreated areas. Blood samples taken from the treated area at 10, 20, and 30 min showed that salicylate levels ranged from 15.8 to 5.3 μg/g. Less than 0.5% of the applied drug was excreted in the urine during the 2-h period.

Keyphrases □ Trolamine salicylate—percutaneous absorption, local tissue penetration, domestic pigs □ Percutaneous absorption—trolamine salicylate, domestic pigs, local tissue penetration □ Tissue penetration—local, percutaneous absorption of trolamine salicylate, domestic pigs

Trolamine salicylate is the active ingredient in a number of topical analgesic creams that are used for sore muscles, joint stiffness, and strains. The creams are also used as a topical adjunct for arthritis and rheumatism therapy. Although the percutaneous absorption of salicylate is well known, only one published report on the penetration of salicylate into canine knee joints has shown that preferential uptake and localization of salicylate occurs in tissue and fluids beneath the area of salicylate application (1). This study was carried out to determine whether localization of trolamine salicylate could be demonstrated in the muscle of the domestic pig after topical administration.

The most commonly used laboratory species have loose-fitting skin, a heavy hair coat, and dermal vasculature that does not resemble that found in humans (2). The pig, on the other hand, has a sparse hair coat, close-fitting skin, a thick epidermis with a well-differentiated lower limit, a dermis with a distinct papillary body, a highly elastic tissue content (3, 4), and vascularization similar to that of humans (2, 5). These findings have been confirmed ultrastructurally by Karasek and Oehlert (6, 7). In addition, the thickness of the dermis and epidermis (8), the distributed enzymes (9), the keratinous proteins (10), and the permeability characteristics of pig skin closely resemble those of humans (11, 12).

EXPERIMENTAL SECTION

Materials—The [7-^{14}C]salicylic acid[1] had a specific activity of 0.37 mCi/mg. Scintillation fluid[2], carbon dioxide trapping agent[2], cellulose cups[2], powdered cellulose[3], ^{14}C-recovery standards[3], and scintillation fluid[4] were commercially obtained. All other materials were reagent grade, obtained from commercial sources, and used without further purification.

Animals—Six healthy female Yorkshire swine (weighing 23–40 kg), maintained on a commercial swine diet[5], were used.

Dosage Preparation—A trolamine [^{14}C]salicylate formulation based on a commercial topical cream[6] was prepared. The trolamine [^{14}C]salicylate was incorporated into a white hydrophilic cream base by dissolving [^{14}C]salicylate (1 μCi/mg) and trolamine in stoichiometric proportions in the aqueous phase of the cream. The oil phase of the cream was then added and thoroughly mixed. The final concentration of trolamine [^{14}C]salicylate was 10% (w/w).

Drug Treatment and Sample Collection—Before the experiment, each pig was dosed with acepromazine (1.1 mg/kg im) followed 30 min later by administration of pentobarbital[7] (30 mg/kg ip). Phenobarbital was administered intravenously as required during the experimental period. The animals were quickly washed with water and dried, and their hind quarters were clipped and carefully shaved. Shaving was performed with a safety razor and warm water. The trolamine [^{14}C]salicylate formulation was not applied until 45–60 min after shaving. During the 45–60-min pretreatment, the urinary bladder was catheterized with a polypropylene catheter, and a 10- × 10-cm area was marked over the biceps femoris. The radiolabeled cream was applied to this area with a syringe fitted with a 16-gauge blunt needle and spread evenly over the area by gentle rubbing. The syringe was calibrated to deliver 1.5 g of the preparation, which contained the equivalent of 72 mg of salicylic acid. This application closely approximates the amounts and conditions of application of trolamine salicylate applied in actual practice by humans.

In pigs 1 through 4, 30 min after the application of the dose, one-half of the 100-cm^2 area was washed with a damp paper towel until the cream was no longer visible. An incision of ~4 cm was then made in the center of the washed area with a scalpel. The scalpel blade was changed often during the cutting of the skin. The subcutaneous fat (when present) was then removed with scissors to expose the underlying muscle. Three samples of the exposed muscle (0.4–0.6 g) were then removed with scissors and pressed firmly between gauze to remove blood. Muscle was also taken from the contralateral side (control) by the same procedure. At the same time, blood samples were collected from the orbital sinus. The procedures were repeated at 120 min postdose. Skin wipes taken at 120 min were retained for analysis of carbon-14. Skin removed from the total area of application (10 × 10 cm) was assayed for carbon-14 in pigs 1 and 4.

The concentration of salicylate in blood at the site of application was determined in pigs 5 and 6. The area of drug application was cleaned as described above, and blood samples were taken from shallow incisions (1–1.5 mm) at 10, 20, and 30 min postdose.

All samples were placed in cellulose cups and allowed to air-dry for 48 h before combustion in an oxidizer[8]. The amount of radioactivity on the paper towel wipes was determined by placing the wipes into a 500-mL beaker containing a magnetic stirring bar and by adding 300 mL of toluene. The beaker was covered and placed on a magnetic stirrer to stir overnight. Duplicate 1-mL samples were removed the next morning and added to 10 mL of scintillation fluid[4]. The carbon-14 was quantitated by liquid scintillation counting.

RESULTS AND DISCUSSION

Skin wipes taken at 120 min after application of the dose indicated 7.9 ± 0.5% (mean ± *SEM*) of the dose remaining on the skin, whereas assays of skin tissue showed 9.3 ± 0.7% remaining in the skin. These figures were calculated from data obtained at the 120-min sampling time and multiplied by a factor of two, since one-half of the area remained at this time. Thus, at least 82% of the dose was found to be absorbed within 120 min after application. The excellent absorption of trolamine salicylate shown by the data was not a result of incomplete extraction of the paper towels. Extraction of paper towels containing a known amount of cream indicated that 49.1, 78.1, 90.7, 93.7, 97.7, 101.0, and 100% of the applied carbon-14 could be recovered at 30, 60, and 90 min and 2, 3, 4, and 7 h, respectively. The literature indicates that the absorption of salicylate after topical administration to humans varies considerably. Feldmann and Maibach have found that only 13% of the applied salicylate was absorbed in a 24-h period (13), whereas Taylor and Halprin have

Control muscle/blood	0.5	0.1	0.2	0.6	0.4 ± 0.1
Treated muscle/control muscle	22.1	67.7	83.2	23.5	49.1 ± 15.5

[a] [^{14}C]Salicylate trolamine was applied topically (0.6–0.7 mg/cm^2) over biceps femoris (treated muscle). Biopsy from treated muscle and contralateral (control) muscle assayed for total carbon-14. Blood was taken from orbital sinus. [b] Concentration of drug is expressed as free salicylic acid equivalents. [c] Number in parentheses represents the time of biopsy (30 or 120 min) when concentration was higher. [d] Only data at 30 min were obtained. Animal died from anesthesia before 120-min sampling time.

shown that 60% of the dose was absorbed within a 24-h period (14). In the latter study, the peak plasma level occurred at 5 h. The extreme differences shown in the percentage of the dose absorbed between these two studies are probably due to the vehicle and the treatment of the dose after application. Feldmann and Maibach applied salicylate to the skin dissolved in a small volume of acetone, whereas Taylor and Halprin used 60% propylene glycol and 19.4% alcohol as a vehicle and occluded the areas for 10 h. However, not only the vehicle, but also the salt form of salicylate affect the rate of its percutaneous absorption. Gaudin has demonstrated that the percutaneous absorption of the trolamine salt of salicylate after 24 h is 1.7 times greater than that of the sodium salt form (15). The fact that the dose of salicylate applied to the skin of the pig in the present study was the trolamine salt in a hydrophilic cream base most likely accounts for the rapid absorption of the dose.

Although the dose was well absorbed, urinary excretion of carbon-14 was found to be minimal. Urine collected during the first 30 min postdose contained 0.13 ± 0.12% of the dose, and 0.45 ± 0.07% (mean ± *SEM*) of the dose was excreted after 2 h.

Data obtained from the blood and tissue samples taken at 30 and 120 min are shown in Table I. Greater concentrations of carbon-14 were observed in the treated area at 30 min of pigs 1 and 3, whereas pigs 2 and 4 were found to have a greater concentration of carbon-14 at 120 min. Pig 3 died from the anesthesia after the 30-min muscle biopsy, but the data obtained at that time were similar to those in pigs 1, 2, and 4, which had greater concentrations of carbon-14.

A summary of those data representing the greater concentration of salicylate in muscle is presented in Table II. Whether these data represent the highest concentrations of carbon-14 achieved during the experimental period is not known since samples were only obtained at 30 and 120 min to minimize the possible effects of local trauma.

Table II shows that [^{14}C]salicylate was detectable in muscle underlying the site of application in greater concentrations (49 times) than that taken from the contralateral (control) muscle. Gross differences in skin thickness were observed not only from pig to pig, but also from areas as close as 3.5 cm within the same pig. This may have influenced the differences in the time of detection of the greater concentration from pig to pig. Table II also shows the ratios of [^{14}C]salicylate levels in muscle to [^{14}C]salicylate levels in blood taken from the orbital sinus. The data show that the carbon-14 concentration was ~13 times greater in the muscle underlying the site of drug application than in the blood. The concentration of salicylate in pig muscle was low compared with that obtained in the dog (1). This difference may be attributed to the application of a much lower dose in the pig (1.5 *versus* 10 g) without massaging the preparation into the skin, as was done in the dog. However, despite methodological differences, preferential uptake and localization of salicylate in tissues underlying the area of drug application were found in both studies.

Analysis of blood taken from the applied area also indicated that the penetration of salicylate through the dermis to underlying muscle occurs fairly rapidly. Whether partitioning of the salicylate between the local vasculature and the muscle tissue accounts for the high concentration of salicylate in the muscle beneath the area treated with trolamine salicylate is not known. However, blood collected from shallow incisions in the dermis of pigs 5 and 6 had carbon-14 concentrations equivalent to 15.8 ± 4.6, 6.2 ± 3.3, and 5.3 ± 1.8 μg of salicylate/g (mean ± *SEM*) at 10, 20, and 30 min, respectively. Data obtained from control muscle demonstrate that salicylate has a muscle-blood partition coefficient of 0.1. If this coefficient is applicable in the tissues underlying the point of trolamine salicylate application, then the local blood salicylate concentrations of 5–16 μg/g would be expected to result in salicylate concentrations of 500–1600 ng/g in the treated muscle. This agrees with the mean value of 625 ng/g that was actually found.

Several studies have demonstrated the percutaneous absorption of salicylic acid and its ultimate excretion from the body. However, the significance of this absorption with regard to a local pharmacological effect on muscles or other tissues beneath the area of application has not been fully investigated. The present studies, as well as an earlier study (1), have indicated that salicylic acid does, indeed, penetrate the skin and is taken up by muscle tissue beneath the treated area. Although these studies shed little light on the pharmacological significance of the concentration of salicylic acid present in the muscle of the treated area, the fact that significant amounts of salicylate were transported through the local area and permeated the musculature provides a basis for the possible efficacy of topically applied trolamine salicylate.

Simultaneous Determination of Nitrate and Nitrite in Toothpastes by High-Performance Liquid Chromatography

H. LULLA, S. S. CHEN ˣ, and F. J. SENA

Received February 24, 1983, from *R & D Laboratories, Block Drug Co. Inc., Jersey City, NJ 07302.* Accepted for publication May 25, 1983.

Abstract □ A stability-indicating analytical method is described for the simultaneous determination of nitrate, and if present, its reductive degradation product, nitrite, in toothpastes. Nitrate and nitrite were extracted from the toothpaste using distilled water and separated from other water-soluble excipients by two RP-8 columns (250 mm × 4 mm i.d.) using a mobile phase containing 0.2% (w/v) sodium acetate and 2.5% (v/v) glacial acetic acid in distilled water. A UV detector set at 313 nm was used for quantitation. The method was applied to commercial toothpastes containing 5% potassium nitrate and yielded an average recovery of 100.1% with a relative standard deviation of 1.43%. Average recovery of nitrate and nitrite from spiked samples were 100.6% and 96.4%, respectively. The minimum detectable concentration for nitrite was 50 μg/g of toothpaste.

Keyphrases □ Nitrate—simultaneous determination with nitrite, toothpastes, HPLC □ Nitrite—simultaneous determination with nitrate, toothpastes, HPLC □ Dentifrices—simultaneous determination of nitrate and nitrite, HPLC

Potassium nitrate, reportedly a tooth desensitizing agent (1-3), is the active ingredient in commercial dentrifrices for the treatment of dental hypersensitivity. As nitrate ion can be converted to nitrite by reducing agents or bacteria, a simple, specific, and sensitive method for simultaneous determination of intact nitrate and its reductive degradation product is desirable for routine quality control and stability evaluation.

The widely used colorimetric procedures for nitrate (4, 5) and nitrite (6-12) are subject to interference by other ions and generally require tedious sample treatment. In addition, those methods involving the cadmium reduction of nitrate to nitrite (6, 7) prior to color development often suffer from nonstoichiometric conversion.

Methods involving derivatization followed by HPLC (13) or GC (14, 15) are lengthy. The potentiometric method with a nitrate ion-selective electrode (16-18), differential pulse polarography (19), and enthalpimetric analysis for nitrate (20) are specific, but they measure only one ion (nitrate or nitrite). The newly developed ion chromatography (21) and its variations (22-27) are selective, sensitive, and suitable for one-step differentiation and determination of nitrate and nitrite. However, the need for additional expensive instrumentation (an ion chromatography system with conductivity or electrochemical detector and ion-exchange columns) hinders the use of this technique.

Recently, Skelly (28) reported the use of an eluant containing the octylamine salt of a mineral acid to separate inorganic anions on a conventional reverse-phase column, with detection at 205 nm. Leuenberger *et al.* (29) and Cortes (30), using phosphate buffer as an eluant, have described the resolution of nitrate from nitrite on an amino normal-phase column. The separation mechanism of the former is dynamic ion-exchange, while the second is weak base ion-exchange. Both methods, which directly determined nitrate and nitrite by conventional HPLC with low-wavelength detection, are simple and sensitive, but they have not been applied to the toothpaste matrix.

The purpose of this paper is to report the separation and simultaneous determination of nitrate and nitrite by high-performance liquid chromatography (HPLC) using two RP-8 columns with acetate buffer as mobile phase. The separated nitrate and nitrite were monitored by a UV detector set at 313 nm. No sample treatment or cleanup was required, and the method was found to be simple, rapid, precise, and selective for the measurement of nitrate and nitrite in a complex toothpaste matrix.

EXPERIMENTAL SECTION

Chemicals and Reagents—Potassium nitrate[1] and sodium acetate[2] were used without further purification. Glacial acetic acid[3] and 0.1 M sodium nitrite solution[4] were used as received.

Apparatus—The liquid chromatograph[5] was fitted with a manual septumless injector[6], a fixed-wavelength UV detector (313 nm)[7], and a strip-chart recorder[8]. The recorder was connected to a laboratory data system[9] through an A/D converter[10]. Two 250 mm × 4.0-mm i.d. columns containing 10-μm Lichrosorb RP-8 packing[11] and one precolumn containing 37-40-μm octadecylsilane packing[12] were used.

Chromatographic Conditions—The chromatographic solvent was 0.2% (w/v) sodium acetate in distilled water containing 2.5% (v/v) glacial acetic acid, adjusted to pH 3.0 ± 0.1 with glacial acetic acid or sodium hydroxide. This solvent was vacuum-filtered[13] through a 0.45-μm filter[13] and deaerated

Simultaneous Determination of Nitrate and Nitrite in Toothpastes by High-Performance Liquid Chromatography

H. LULLA, S. S. CHEN ˣ, and F. J. SENA

Received February 24, 1983, from *R & D Laboratories, Block Drug Co. Inc., Jersey City, NJ 07302.* Accepted for publication May 25, 1983.

Abstract □ A stability-indicating analytical method is described for the simultaneous determination of nitrate, and if present, its reductive degradation product, nitrite, in toothpastes. Nitrate and nitrite were extracted from the toothpaste using distilled water and separated from other water-soluble excipients by two RP-8 columns (250 mm × 4 mm i.d.) using a mobile phase containing 0.2% (w/v) sodium acetate and 2.5% (v/v) glacial acetic acid in distilled water. A UV detector set at 313 nm was used for quantitation. The method was applied to commercial toothpastes containing 5% potassium nitrate and yielded an average recovery of 100.1% with a relative standard deviation of 1.43%. Average recovery of nitrate and nitrite from spiked samples were 100.6% and 96.4%, respectively. The minimum detectable concentration for nitrite was 50 μg/g of toothpaste.

Keyphrases □ Nitrate—simultaneous determination with nitrite, toothpastes, HPLC □ Nitrite—simultaneous determination with nitrate, toothpastes, HPLC □ Dentifrices—simultaneous determination of nitrate and nitrite, HPLC

Potassium nitrate, reportedly a tooth desensitizing agent (1-3), is the active ingredient in commercial dentrifrices for the treatment of dental hypersensitivity. As nitrate ion can be converted to nitrite by reducing agents or bacteria, a simple, specific, and sensitive method for simultaneous determination of intact nitrate and its reductive degradation product is desirable for routine quality control and stability evaluation.

The widely used colorimetric procedures for nitrate (4, 5) and nitrite (6-12) are subject to interference by other ions and generally require tedious sample treatment. In addition, those methods involving the cadmium reduction of nitrate to nitrite (6, 7) prior to color development often suffer from nonstoichiometric conversion.

Methods involving derivatization followed by HPLC (13) or GC (14, 15) are lengthy. The potentiometric method with a nitrate ion-selective electrode (16-18), differential pulse polarography (19), and enthalpimetric analysis for nitrate (20) are specific, but they measure only one ion (nitrate or nitrite). The newly developed ion chromatography (21) and its variations (22-27) are selective, sensitive, and suitable for one-step differentiation and determination of nitrate and nitrite. However, the need for additional expensive instrumentation (an ion chromatography system with conductivity or electrochemical detector and ion-exchange columns) hinders the use of this technique.

Recently, Skelly (28) reported the use of an eluant containing the octylamine salt of a mineral acid to separate inorganic anions on a conventional reverse-phase column, with detection at 205 nm. Leuenberger *et al.* (29) and Cortes (30), using phosphate buffer as an eluant, have described the resolution of nitrate from nitrite on an amino normal-phase column. The separation mechanism of the former is dynamic ion-exchange, while the second is weak base ion-exchange. Both methods, which directly determined nitrate and nitrite by conventional HPLC with low-wavelength detection, are simple and sensitive, but they have not been applied to the toothpaste matrix.

The purpose of this paper is to report the separation and simultaneous determination of nitrate and nitrite by high-performance liquid chromatography (HPLC) using two RP-8 columns with acetate buffer as mobile phase. The separated nitrate and nitrite were monitored by a UV detector set at 313 nm. No sample treatment or cleanup was required, and the method was found to be simple, rapid, precise, and selective for the measurement of nitrate and nitrite in a complex toothpaste matrix.

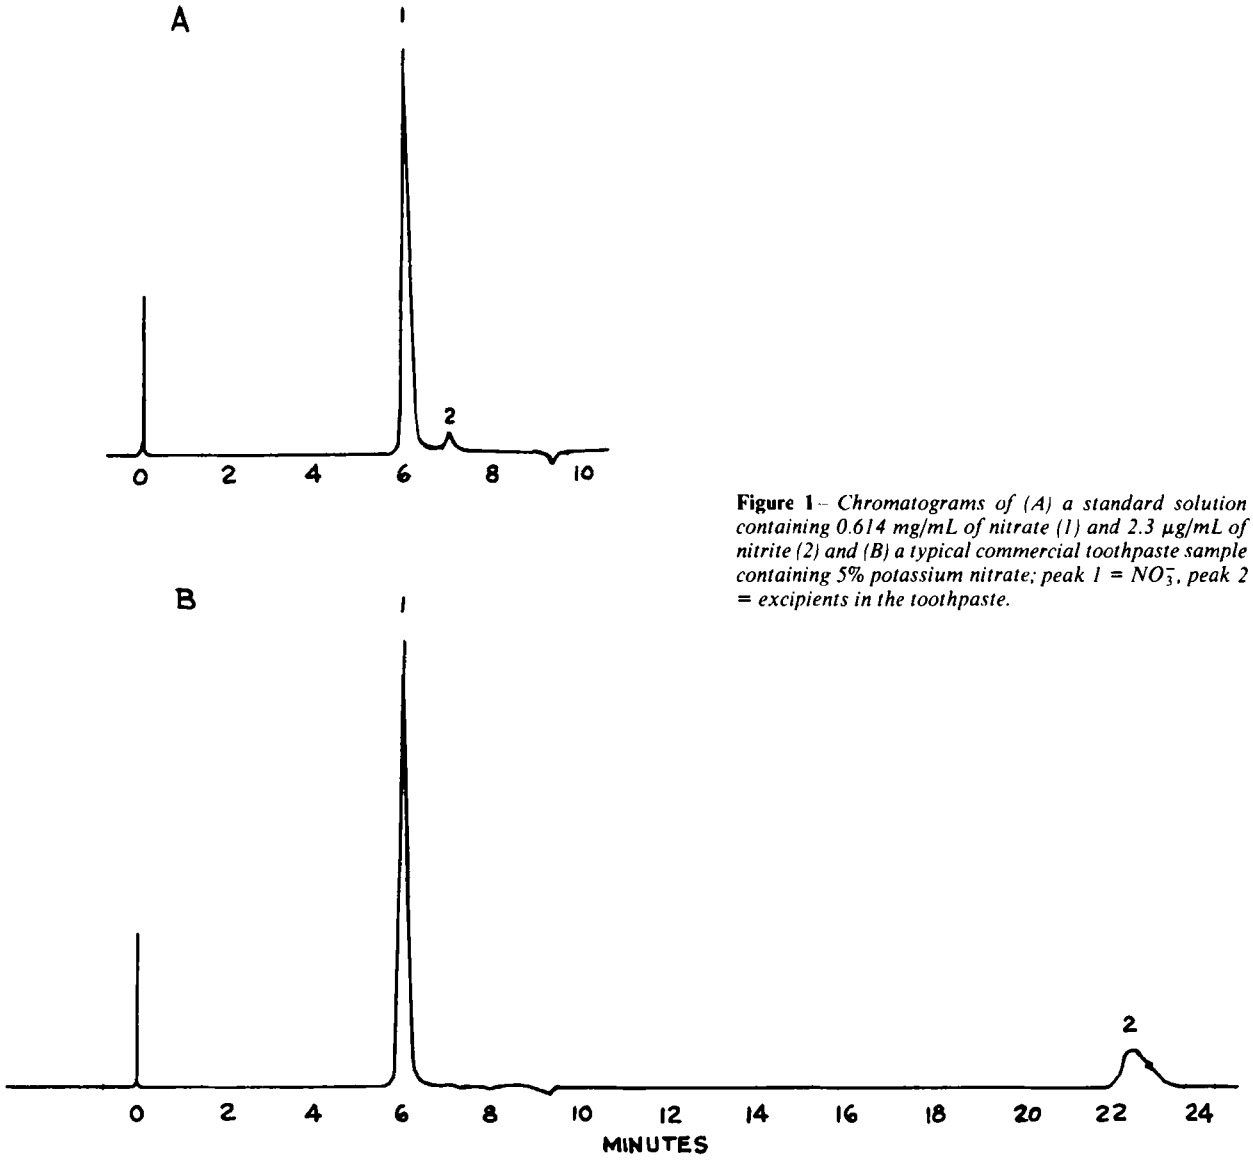

Figure 1—*Chromatograms of (A) a standard solution containing 0.614 mg/mL of nitrate (1) and 2.3 μg/mL of nitrite (2) and (B) a typical commercial toothpaste sample containing 5% potassium nitrate; peak 1 = NO_3^-, peak 2 = excipients in the toothpaste.*

for 5 min with stirring before use. The temperature was ambient, the solvent flow rate was 1.0 mL/min, and the inlet pressure was 1800 psi. The detector sensitivity was 0.1 AUFS, and the chart speed was 1.0 cm/min.

Standard Solutions—Three standard solutions containing 30.7, 61.4, and 92.1 mg of nitrate and, respectively, 115, 230, and 460 μg of nitrite per 100 mL were prepared in distilled water and filtered as described above prior to injection.

Assay for Commercial Products—An accurately weighed 2.0-g portion of the toothpaste was transferred to a 100-mL beaker, 20 mL of distilled water was added, and the contents were mixed with a spatula to complete dispersion. The dispersion was then quantitatively transfered to a 100-mL volumetric flask, diluted to volume with distilled water, and mixed well. A portion of this solution was centrifuged at 3000 rpm for 5 min and filtered through a 0.45-μm filter before injection.

Spiked Samples—Accurately measured quantities of nitrate and nitrite were admixed with a placebo portion of toothpaste. These mixtures were formulated to contain 30.7, 61.4, and 92.1 mg of NO_3 and 115, 230, and 460 μg of NO_2, respectively, per 2.0-g sample. These samples were assayed as described above for commercial products.

Quantitation—Since peak areas of nitrate and nitrite were found to be directly proportional to their concentrations, all results were calculated by interpolation from standard curves of peak areas *versus* concentrations.

Table I—Recovery Data for Nitrate from Spiked Samples

Amount Added, mg	Amount Found, mg	Recovery, %
0.5062	0.5167 (*RSD* = 0.69%, *n* = 3)	102.07
1.0124	1.0199 (*RSD* = 1.11%, *n* = 4)	100.75
1.5186	1.5045 (*RSD* = 1.72%, *n* = 3)	99.07
Mean *N* = 10		100.6
SD		1.63
RSD		1.62

RESULTS AND DISCUSSION

Linearity responses for nitrate and nitrite were observed, respectively, over the range of 0.307–0.921 mg/mL with a correlation coefficient of 0.999 and 1.15–9.2 μg/mL with a correlation coefficient of 0.999. The relationship of peak area to concentration can be presented by the linear regression equations

Table II—Assay Results for Toothpaste Containing 5% Potassium Nitrate

Sample	Potassium Nitrate Found, %	Percent of Label Claim
1	5.09	101.8
2	4.99	99.8
3	5.07	101.4
4	5.00	100.0
5	4.90	98.0
6	5.02	100.4
7	5.02	100.4
8	4.89	97.8
9	5.07	101.4
Mean		100.1
SD		1.43
RSD		1.43

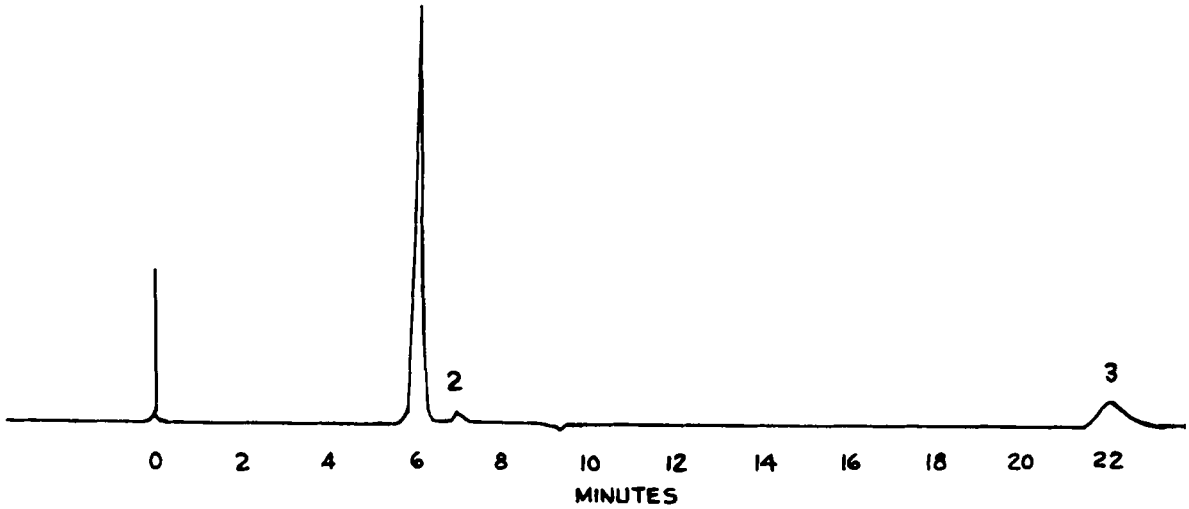

Figure 2—*Chromatogram of a toothpaste placebo spiked with both nitrate (1) and nitrite (2). The spiked placebo was prepared by adding 100 mg of potassium nitrate and 2 mL of 5.0 mM sodium nitrite solution into 2 g of toothpaste placebo; peak 3 = excipients in the toothpaste.*

$y = 35789.8x + 1127.5$ for nitrate and $y = 668322x + 312$ for nitrite, where y is the peak area obtained by the laboratory data system and x is the concentration in mg/mL.

Chromatograms obtained for a standard solution of nitrate and nitrite and for a typical commercial toothpaste containing 5% potassium nitrate are presented in Fig. 1A and B, respectively. The nitrate ion was well resolved from the other excipients, and the recovery data for nitrate from spiked samples of toothpaste (Table I) illustrate the validity of the method for these formulations. Average recovery for placebo dentifrices spiked with three concentration levels (50, 100, and 150% of label concentration) of nitrate was 100.6% with a standard deviation of 1.63%. This method has been used routinely in a product stability program and found to be accurate and precise with a relative standard deviation of 1.43% ($n = 9$). Representative data are summarized in Table II.

Although nitrite was not detected in any commercial toothpaste samples, it was necessary to demonstrate the selectivity of the method for nitrate in the presence of nitrite; therefore, spiked toothpaste samples containing both nitrate and nitrite were prepared and assayed. A representative chromatogram of a spiked sample containing 61.4 mg of nitrate and 115 μg of nitrite per 100 mL is reproduced in Fig. 2. Excellent resolution of nitrite from nitrate, an essential requirement for a stability-indicating assay, was obtained. Average recovery at the 2.3–9.2-μg/mL nitrite level was 96.4%, with a relative standard deviation of 6.7% ($n = 8$). The minimum detectable concentration of nitrite was 50 μg/g of toothpaste sample.

The retention of nitrate and nitrite on a reverse-phase column may be attributed to the interaction of these anions with the protonated silanol backbone of stationary phase at the acidic condition (pH 3.0 ± 0.1) employed in this experiment. In addition to this electrostatic attractive force, solute anions may also experience the steric exclusion provided by the hydrophobic long-chain octyl substituents of the stationary phase. The balance between these two opposing forces could determine the retention of anions on the column and the separation of one anion from the others. The unsatisfactory results obtained with an RP-18 column may be due to the overwhelming steric exclusion provided by the more hydrophobic octadecyl substituents of the stationary phase.

Exchange of Sodium by Magnesium in Aluminum Hydroxycarbonate Gel

EDWARD C. SCHOLTZ *, JOSEPH R. FELDKAMP ‡, JOE L. WHITE ‡, and STANLEY L. HEM *x

Received April 11, 1983, from the *Departments of *Industrial and Physical Pharmacy and ‡Agronomy, Purdue University, West Lafayette, IN 47907. Accepted for publication June 5, 1983.

Abstract □ Approximately 90% of the sodium present in a washed aluminum hydroxycarbonate gel was removed by exchange with magnesium. This behavior supports recent structural studies which have suggested that cations such as sodium serve as counterions in aluminum hydroxycarbonate gel. However, sodium could not be removed from dihydroxyaluminum sodium carbonate by exchange with magnesium because sodium is part of the crystal structure. It is hypothesized that aluminum hydroxycarbonate gels which resist removal of sodium are actually mixtures containing dihydroxyaluminum sodium carbonate in addition to aluminum hydroxycarbonate.

Keyphrases □ Aluminum hydroxycarbonate gel—removal of sodium by magnesium □ Counterions—removal of sodium by magnesium in aluminum hydroxycarbonate gel

Structural studies have suggested (1, 2) that the acid-reactive aluminum hydroxide gel used in antacids has a planar structure in which the basic unit is a six-membered ring of aluminum atoms joined by double hydroxide bridges. Carbonate is specifically adsorbed at aluminum sites along the edge (3-5). This structure suggests that other cations which may be present simply function as counterions. To further test the structural model of aluminum hydroxycarbonate gel, the ability of magnesium ions to replace sodium ions was studied.

EXPERIMENTAL SECTION

The aluminum hydroxycarbonate gel was precipitated by reacting solutions of 0.5 M aluminum chloride and 2.0 M sodium carbonate at a constant pH of 7.0 (6). A gel composed of a mixture of aluminum hydroxycarbonate and dihydroxyaluminum sodium carbonate was precipitated from the same system at a constant pH of 8.5 (6).

Each gel was divided into two equal portions. One portion, designated as the control, was washed with distilled water by adding a volume of distilled water equal to the volume of the gel, mixing for 15 min, and centrifuging to produce a clear supernatant. The supernatant was tested for chloride by the silver nitrate test (7). The washing procedure was repeated until the supernatant was free of chloride as indicated by the silver nitrate test. The second portion was washed four times with a volume of 1 M $MgCl_2$, which was equal to the volume of the gel before washing with distilled water as described above, and is called the magnesium-exchanged portion.

The chloride-containing aluminum hydroxide gel was prepared by treating 0.5 M $AlCl_3$ with 1 M KOH (8). The equivalent aluminum oxide and magnesium content were determined by chelatometric titration (9).

The sodium content was determined by atomic absorption spectrometry[1]. A sample containing a 0.4-g equivalent of aluminum oxide was dissolved by adding 4 mL of 12 M HCl. Potassium chloride (95 mg) was added, and the final volume was adjusted to 25 mL with distilled water. Standards and blanks for the magnesium-exchanged samples contained the same quantity of magnesium ion as was present in the sample.

IR spectra[2] were recorded on air-dried samples with potassium bromide pellets (0.75-mg sample and 300 mg of KBr). X-ray diffractograms were obtained with air-dried samples in powder mounts (McCreery mounts). Diffractograms were recorded from 6 to 40° (2θ) under the following conditions[3]: CuK_α radiation, 30 kV, 28 mA, 2°/min. The acid neutralization reaction was monitored by an automated[4] pH-stat titration (10). The point of zero charge was determined by a continuous titration procedure (8).

RESULTS AND DISCUSSION

The control and magnesium-exchanged portions of the aluminum hydroxycarbonate gel each required four washings with distilled water to produce a negative test for chloride. The control contained 0.82 M (8.4%) equivalent aluminum oxide and 2.5×10^{-2} M (0.057%) sodium, which is equivalent to a sodium-aluminum molar ratio of 1.5×10^{-2}. The magnesium-exchanged portion contained 0.78 M (8.0%) equivalent aluminum oxide and 2.7×10^{-3} M (0.0062%) sodium, which is equivalent to a sodium-aluminum molar ratio of 1.7×10^{-3}. Thus, ~90% of the sodium present in the control was removed by the magnesium-exchange procedure.

The IR spectrum and X-ray diffraction pattern of the magnesium-exchanged portion were typical of aluminum hydroxycarbonate gel (11) and were identical with the control (Fig. 1A and B), indicating that no structural changes occurred due to the magnesium-exchange procedure.

The control aluminum hydroxycarbonate gel was free of magnesium, whereas the magnesium-exchanged portion contained 6.9×10^{-2} M (0.17%) magnesium, which is equivalent to a magnesium-aluminum molar ratio of 0.044. Thus, as suggested by recent structural studies (1-5), sodium appears to be a counterion in aluminum hydroxycarbonate gel and not a structural component.

It should be noted that the sodium content of the control was low in terms of the clinical use of aluminum hydroxycarbonate gel as an antacid. For example, if the control were used at a dosage regimen of 40 mEq/dose for seven daily doses, as occurs in high-intensity antacid therapy (12, 13), the aluminum hydroxycarbonate gel would contribute 32 mg of sodium/d to the sodium intake of the patient. This represents only 6.4% of the 500 mg (22 mmol) of sodium allowed in a strict sodium-restricted diet (14). The magnesium-exchanged aluminum hydroxycarbonate gel would only contribute 3.7 mg of sodium/d for the same dosage regimen (<1% of the sodium allowed in a strict sodium-restricted diet).

The ratio of milliequivalents of magnesium adsorbed to milliequivalents of sodium desorbed was 6.2. This ratio exceeds the expected value of 1. It is hypothesized that magnesium displaced some other cation, such as a proton, in addition to sodium. Magnesium ions could displace protons in the diffuse portion of the electrical double layer or perhaps from the Stern layer.

The hypothesis that magnesium exchanges for protons in addition to sodium was tested by titrating a chloride-containing aluminum hydroxide suspension with magnesium nitrate. The pH of the chloride-containing aluminum hydroxide suspension and the 6×10^{-4} M $Mg(NO_3)_2$ was adjusted to 9.6, which is the point of zero charge for the chloride-containing aluminum hydroxide. This was necessary to eliminate pH shifts in the suspension on addition of titrant, which could be attributed to a simple ionic strength effect (8). The pH of the chloride-containing aluminum hydroxide suspension decreased from pH 9.6 to 8.76 as a result of titration with 3 mL of 6×10^{-4} M $Mg(NO_3)_2$ (Table I). Titration with 3 mL of water adjusted to pH 9.6 only caused a pH change of 0.08. The decrease in pH on addition of $Mg(NO_3)_2$ is believed to be due to the exchange of magnesium for protons at the aluminum hydroxide surface. Normally, the pH of the aluminum hydroxide at its point of zero charge would be unaffected by an ionic strength change since the background salt usually behaves as an indifferent electrolyte. This suggests that magnesium specifically adsorbs as a Stern layer ion and displaces protons in the process.

The antacid properties of the magnesium-exchanged aluminum hydroxycarbonate gel are very similar to the control. Both portions reacted completely within 15 min, with the neutralization of three protons per aluminum ion. Thus, the presence of sodium as a counterion in aluminum hydroxycarbonate

gel is unimportant in terms of antacid properties since the rate of acid neutralization is independent of sodium content (15).

The hypothesis that sodium is a counterion in aluminum hydroxycarbonate gel was further tested by attempting to exchange magnesium for sodium in a gel which is known to be a mixture of aluminum hydroxycarbonate and dihydroxyaluminum sodium carbonate. Dihydroxyaluminum sodium carbonate has the formula $NaAl(OH)_2CO_3$ and is known mineralogically as dawsonite (16). The precipitation conditions were altered to produce the desired mixture (6). The IR spectrum of the mixture (Fig. 1C) shows a wider split of the ν_3 mode of carbonate (1560 and 1410 cm^{-1}) than aluminum hydroxycarbonate (Fig. 1A). The IR spectrum of the mixture also contains bands which are characteristic of dawsonite at 3290, 1818, 955, 935, 846, and 550 cm^{-1} (17), in addition to the bands associated with aluminum hydroxycarbonate.

Table I—Titration of Aluminum Hydroxide [a] with 6×10^{-4} M Magnesium Nitrate

Sample[b]		Blank[b]	
pH	Titrant, mL	pH	Water, mL
9.60	0	9.63	0
9.52	0.1	9.61	0.1
9.44	0.2	9.60	0.5
9.36	0.3	9.58	1.0
9.30	0.4	9.56	2.0
9.21	0.6	9.55	3.0
9.12	0.8		
9.05	1.0		
8.96	1.4		
8.86	2.0		
8.76	3.0		

[a] At pH equal to the point of zero charge (9.6). [b] Aluminum hydroxide gel (100 mL) containing 1% equivalent aluminum oxide.

The sodium to aluminum molar ratio of the mixture was 0.50 after washing with water. The high sodium to aluminum molar ratio is due to the presence of dawsonite, which has a sodium-aluminum molar ratio of 1. The sodium-aluminum molar ratio of the mixture only decreased to 0.42 after magnesium exchange. It is believed that the sodium associated with aluminum hydroxycarbonate was exchanged with magnesium, but the sodium in dawsonite is part of the crystal structure and was not exchanged with magnesium.

In conclusion, cations such as sodium which are present in aluminum hydroxycarbonate gel function as counterions and can be removed by cation exchange. However, sodium cannot be removed by cation exchange from dihydroxyaluminum sodium carbonate. Thus, aluminum hydroxycarbonate gels which resist the removal of sodium by cation exchange may also contain dihydroxyaluminum sodium carbonate (dawsonite).

Rapid Quantitative Liquid Chromatographic Determination of Caffeine Levels in Plasma after Oral Dosing

S. E. O'CONNELL ˣ **and F. J. ZURZOLA**

Received May 6, 1983, from *Bristol-Myers Products, Hillside, NJ 07207.* Accepted for publication July 11, 1983.

Abstract □ A simple method is described for the rapid, quantitative analysis of caffeine in human plasma. Caffeine levels present in plasma following drug administration were determined by high-performance liquid chromatography with UV detection at 273 nm after plasma protein precipitation. Caffeine was detectable at levels as low as 0.1 μg/mL. Mean recoveries of 98% with a coefficient of variation of 3% were obtained for plasma standards, in which concentrations ranged from 0.1 to 8 μg/mL. Interassay variability of the slope of the standard curve had a coefficient of variation of 3%. Application of this method during human bioavailability studies is described.

Keyphrases □ Caffeine—HPLC, human plasma, bioavailability □ Bioavailability—caffeine, HPLC, human plasma, oral dosing

Caffeine is a commonly ingested drug that is present in foods, beverages, and medicaments. Its widespread use has stimulated an interest in the development of a simple and rapid plasma determination for caffeine suitable for analyzing multiple samples.

Although GC (1-3) and spectrophotometric (4) methods exist for caffeine determination in biological fluids, high-performance liquid chromatographic (HPLC) methods are relatively few, and those available suffer from the disadvantages of inadequate sensitivity (5), time-consuming extraction steps (5-7), dedicated equipment (8), inadequate sample cleanup, inadequate sensitivity for pharmacokinetic studies (9-11), and insufficient testing in human plasma (11).

The method described herein involves a single plasma protein precipitation followed by liquid chromatographic determination of caffeine in the clear supernatant. The plasma proteins were denatured and precipitated with 0.15 M $Ba(OH)_2$ and 5% $ZnSO_4$ solutions, as described previously (12). The use of this combination of reagents results in a supernatant with a neutral pH and a clean chromatographic profile due to efficient coprecipitation of both plasma proteins and excess reagents. The method is capable of detecting at least 0.1 μg/mL of caffeine, and the reproducibility eliminates the need for an internal standard. Furthermore, the ease and rapidity of sample workup make this method ideal for multiple-sample analyses.

This method has been used routinely on long-term human bioavailability studies, resulting in clean predose plasma chromatograms with no interference and no column deterioration after several hundred analyses, and has been found to be precise and accurate.

EXPERIMENTAL SECTION

Reagents—Standard solutions were prepared in distilled water. The 0.15 M $Ba(OH)_2$ and 5% $ZnSO_4$ solutions were obtained commercially[1].

Instrumentation and Operating Conditions—The analysis was performed with a high-performance liquid chromatograph[2] with a variable-wavelength UV detector[3] set at 273 nm, an automated injection system[4] fitted with a 75-μL loop, and a 30 cm × 4-mm i.d. reverse-phase, high-efficiency C_{18} col-

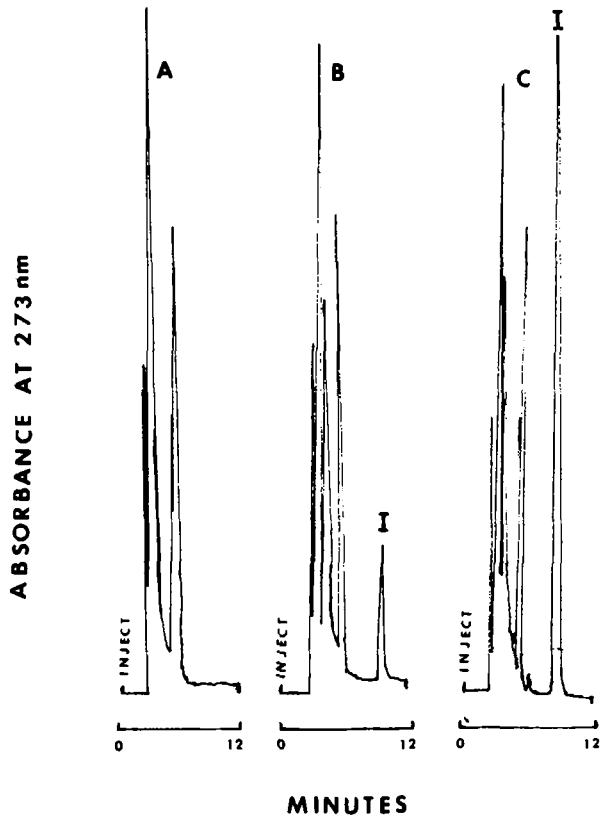

Figure 1—*Chromatograms for a typical subject. Key: (A) taken prior to caffeine (I) administration; (B) taken 10 min after oral administration of two 65-mg tablets; (C) taken 20 min postdose.*

umn[5]. The mobile phase was methanol-water (30:70), which was filtered through a 0.45-μm pore-size filter[6] and was deaerated before use. The flow rate was 1.0 mL/min. The column was fitted with a precolumn packed with C_{18} Corasil, 37–50 μm[7]. This precolumn was repacked once a week during panel use, since particulate matter accumulated on the precolumn frit and started to increase the column pressure after a weekly load of 300–400 injections. The detector was set at a sensitivity of 0.02 AUFS.

Plasma Caffeine Study in Humans—Because the described method was so sensitive to low levels of caffeine, it became necessary to insist that panelists abstain from caffeine-containing food, drugs, and beverages for at least 72 h before dosing. The panelists were fasted overnight and then received a 130-mg oral dose of caffeine in the form of two multicomponent tablets[8] taken with 100 mL of water. It had been determined in earlier panels that coadministration of aspirin and acetaminophen do not result in drug or metabolite peaks which interfere with the caffeine peak. Venous blood specimens were withdrawn by syringe and discharged into centrifuge tubes containing heparin as an anticoagulant. Specimens were taken before and at specified times after drug administration through 4 h. Collected specimens were centrifuged immediately for 15 min at 3500 rpm in a bench-top centrifuge. Plasma was separated and analyzed for caffeine by the proposed method.

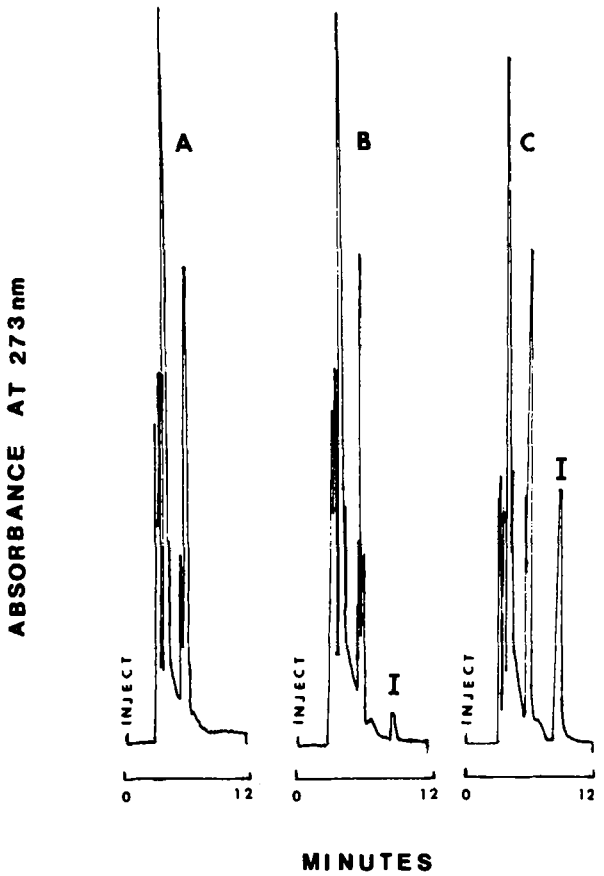

Figure 2—*Chromatograms of a 1-mL human plasma sample processed by the described precipitation method. The mobile phase was 30% methanol at a flow rate of 1.0 mL/min, and the chart speed was 15 cm/h. Key: (A) unspiked plasma; (B) plasma spiked with 0.1 μg of caffeine (I); (C) plasma spiked with 1 μg of I.*

Analysis—One milliliter of freshly drawn plasma was added to a screw-top culture tube (16 × 100 mm). To each tube was added 1 mL of the saturated 0.15 M $Ba(OH)_2$ solution. The tubes were vortexed for 2 min at sufficient speed on a multiple tube vortex mixer[9] to allow thorough mixing and sufficient reaction time. The addition of 1 mL of the 5% $ZnSO_4$ solution was made only after each sample became opaque in appearance. Each tube was then capped and vortexed at high speed for 1 min. The tubes were then centrifuged in a bench-top centrifuge at high speed for 10 min. The resulting clear, water-like supernatant was separated from the precipitate and filtered directly into an autoinjector vial with a Pasteur pipet plugged with glass wool. This ensured a minimal volume loss and a particulate-free sample.

Standard Curves—Calculations were carried out with standard curves constructed by analyzing 1-mL samples of the pooled predose plasma spiked with 0.1–8 μg of caffeine and by plotting the peak height *versus* the corresponding concentration. The standard curve data were subjected to least-squares linear regression analyses, and the resulting equation was utilized for the calculation of the drug concentration in the unknown samples.

RESULTS AND DISCUSSION

Typical chromatograms of a predose plasma sample (Fig. 1A) and the 10- and 20-min postdose plasma samples (Fig. 1B and C, respectively) obtained for a typical subject demonstrate the specificity of this method by the absence of interfering peaks. With 30% methanol in water as the eluant at a flow rate of 1.0 mL/min, the retention time for caffeine was 9 min.

Figure 2 represents the chromatograms of a 1-mL plasma blank, a 1-mL plasma sample spiked with 0.10 μg of caffeine, and a 1-mL plasma sample spiked with 1 μg of caffeine. The standards and samples are chromatographically clean to the extent that caffeine concentrations <0.1 μg/mL can be detected by this procedure. The adequate peak size and clean baseline resolution for a 75-μL sample injection containing 0.10 μg/mL of caffeine indicates the potential for detecting caffeine at concentrations of <0.1 μg/mL *via* an increased injection volume or more sensitive detector setting. Since the lowest caffeine level normally encountered in our therapeutic drug monitoring was ~0.25 μg/mL, the present sensitivity of this method is more than adequate for use in blood level and pharmacokinetic studies.

Recovery—The recovery of caffeine from plasma relative to its recovery from water, as measured by the ratio of the slopes of the standard curves in plasma and water, respectively, was 0.98 ± 0.03, with a coefficient of variation

[a] $n = 36$.

of 3%. Interassay variability of the slope of the standard curves generated during the bioavailability study had a coefficient of variation of <5%. A typical calibration regression line is $y = 44.33x - 0.37$, where x is concentration and y is peak height; this is linear over a concentration range of 0.1–8 μg/mL. The good linearity between the peak height and caffeine concentration in plasma is indicated by the correlation coefficient of >0.999.

Accuracy—Table I shows the actual amounts with which 1-mL blank plasma samples were spiked and the amounts found when the plasma was analyzed by the described method. The experiment was performed in duplicate on each of 5 d. The percent error for each unknown sample was calculated according to (13):

$$\text{percent error} = \left(\frac{\text{amount added} - \text{amount found}}{\text{amount added}}\right) \times 100$$

The average percent error was 3%. In no case did it exceed 10%.

Plasma Levels of Caffeine—A comparison was made of caffeine levels produced by two different caffeine-containing tablet formulations. The total caffeine dose administered was 130 mg. Table II shows the caffeine levels for one of the formulations for 36 subjects in a two-way crossover study with samples taken at 10, 20, 40, 60,120, 180, and 240 min postdose. The 10-min plasma levels indicate a slower absorption by male panelists, with the lowest detectable level of caffeine being slightly less than 0.2 μg/mL. A further inspection of the data reveals that caffeine was rapidly absorbed from the oral dose, reaching a peak plasma level of 3.6 μg/mL in <40 min.

The proposed method is extremely simple, inexpensive, and sensitive for the rapid determination of caffeine in plasma or blood at levels likely to be encountered after a usual 65- or 130-mg total dose. Plasma proteins are denatured by the addition of a saturated $Ba(OH)_2$ solution and then precipitated with a 5% $ZnSO_4$ solution. The resulting colorless clear supernatant is analyzed by HPLC with conventional 3.9-mm i.d. columns. The reproducibility, sensitivity, and selectivity of the method make the use of an internal standard unnecessary. The reproducibility and reliability of this method have been demonstrated in >500 determinations of plasma concentrations of caffeine.

Antimicrobial Activity of Triethylammonium Chloride–*N*-Substituted *N'*-Cyano-*O*-(triphenylstannyl)-isourea Complexes

EUGENE J. KUPCHIK *[x], MICHAEL A. PISANO [‡], DILIPKUMAR K. PARIKH *, CAROLYN KREJCI [‡], and JONATHAN TAYLOR [‡]

Received January 31, 1983, from the **Department of Chemistry* and the [‡]*Department of Biological Sciences, St. John's University, New York, NY 11439.* Accepted for publication May 20, 1983.

Abstract □ The triethylammonium chloride complexes of *N*-substituted *N'*-cyano-*O*-(triphenylstannyl)isoureas were generally found to be better antifungal and antibacterial agents than the uncomplexed compounds.

Keyphrases □ *N*-Substituted *N'*-cyano-*O*-(triphenylstannyl)isoureas—complexes with triethylammonium chloride, antibacterial and antifungal activities □ Antimicrobial agents—*N*-substituted *N'*-cyano-*O*-(triphenylstannyl)isourea-triethylammonium chloride complexes, bacterial and fungal screens

Many biocidal applications have been found or suggested for organotin compounds (1, 2). Their use in agriculture as fungicides and pesticides (3–5) is of special interest because they degrade to nontoxic inorganic compounds and, therefore, appear to pose little threat to the environment (6–10). Recently, some diorganotin dihalide and di-pseudohalide complexes were shown to exhibit antitumor activity (11, 12).

It was previously found that triethylammonium (organocyanoamino)chlorotriphenylstannates (I), which are the triethylammonium chloride complexes of *N*-substituted *N*-(triphenylstannyl)cyanamides (II), exhibit higher antifungal activity than the II compounds (13). It was of interest to determine if the triethylammonium chloride complexes (III) (14) of some previously tested *N*-substituted *N'*-cyano-*O*-(triphenylstannyl)isourea compounds (IV) (15) would likewise exhibit higher antifungal activity than the IV compounds. It was also of interest to compare the antibacterial activity of the III and IV compounds.

RESULTS AND DISCUSSION

The data in Table I show that each of the series III compounds behaved essentially identically toward each of the 10 test fungi. All of the series III compounds were inactive towards *Rhizopus stolonifer* and *Trichoderma viride* at all concentrations. In this regard they were inferior to the previously tested series IV compounds, which partially inhibited *R. stolonifer* at 10 μg/mL and *T. viride* at 100 μg/mL (15). With the exception of IIIe, the series III compounds partially inhibited the growth of the other eight test fungi at a concentration of 1 μg/mL. Employment of higher concentrations did not improve the antifungal activity. Compound IIIe differed from the other series III compounds only in that it was inactive towards *Chaetomium globosum* and *Cladosporium carpophilum* at 1 μg/mL. In comparison with the series III compounds, IVa was inactive towards *Aspergillus niger*, *Ch. globosum*, *Cl. carpophilum*, *Fusarium monoliforme*, *Penicillium notatum*, and *Saccharomyces cerevisiae* at 1 μg/mL. Compound IVb was also inferior to the series III compounds in that it was inactive towards *A. niger*, *Ch. globosum*, *F. monoliforme*, *Myrothecium verrucaria*, *P. notatum*, and *S. cerevisiae* at 1 μg/mL. Furthermore, the series IV compounds were inactive towards *S. cerevisiae* even at 10 μg/mL. Thus, the series III compounds generally exhibited higher antifungal activity than the series IV compounds.

The data in Table II show that all of the series III compounds were inactive towards the Gram-negative bacterium *Escherichia coli* at all concentrations. In this regard they resembled the previously tested IVa (15). All of the series III compounds behaved identically towards the two Gram-positive bacteria *Micrococcus agilis* and *Bacillus subtilis*, totally inhibiting the growth of these bacteria at a concentration of 1 μg/mL. In this regard they were somewhat better than IVa, which only partially inhibited *B. subtilis* at 1 μg/mL. The most effective series III compound against *Staphylococcus aureus* was IIIe, which totally inhibited the growth of this bacterium at 1 μg/mL. In contrast, IVa was inactive towards *St. aureus* at 1 μg/mL. Thus, the series III compounds generally exhibited higher antibacterial activity than IVa.

Acylation of Hemoglobin by Aspirin-Like Diacyl Esters

SOLOMON E. MASSIL, GUEY-YUEH SHI, and IRVING M. KLOTZ ˣ

Received April 5, 1983 from the *Department of Chemistry, Northwestern University, Evanston, IL 60201.* Accepted for publication May 19, 1983.

Abstract □ Aspirin-like diacyl esters of different steric disposition have been prepared and compared with acetylsalicylate in their abilities to modify hemoglobin.

Keyphrases □ Diacyl esters—aspirin derivatives, acylation of hemoglobin □ Hemoglobin—acylation by aspirin-like diacyl esters, sickle cell anemia

In a previous paper (1), it has been shown that aspirin can acylate hemoglobin and thereby provide a novel approach to the alteration of sickle hemoglobin. Acetylsalicylate is the prototype of a general class of monoacyl esters of salicylic acid. Consequently, a variety of such esters have been synthesized (2) and examined for their effectiveness in modifying hemoglobin S and in inhibiting the aggregation process leading to sickling.

Among variants in aspirin-like derivatives are the diacyl esters of dihydroxybenzoic acids. These seem attractive because they would present two active acyl groups to the protein when it forms a reaction complex with a reagent molecule. We have prepared, therefore, a series of such diacyl ester compounds of different steric structure and compared their abilities to modify hemoglobin.

EXPERIMENTAL SECTION

A variety of hydroxybenzoic acids were purchased from commercial sources[1]. Their mono- and diacyl esters were synthesized by methods described in the literature (3-7). The derivatives prepared are listed in Table I.

[1] Aldrich Chemical Co., for example.

Of the compounds obtained, only 3,5-diacetoxybenzoic acetic anhydride (XI) has not been reported in the literature. It appeared as a by-product in the mother liquor (chloroform–petroleum ether) from the preparation of the diacetoxybenzoic anhydride (X). The fine white precipitate which appeared in the mother liquor after standing for several hours was removed by filtration, washed with petroleum ether, and dried without heat, mp 71–72°C. This product, insoluble in aqueous $NaHCO_3$ at room temperature, bubbled on heating. It did not give a positive $FeCl_3$ test for free phenol. ^{1}H-NMR and

The preparation of hemoglobin and procedures for following its chemical modification by aspirin-like reagents have been described previously (2).

RESULTS AND DISCUSSION

In Table I, the efficacies of the diacyl esters in modifying hemoglobin are compared with those of corresponding monoacyl compounds. The following features are worthy of note.

Compound II, the *para* analogue of aspirin, is about as effective as I in acylating hemoglobin. Likewise the two positional monoacyl isomers of hydroxysalicylic acid, III and IV, are comparable in activity to each other and to aspirin (I). In contrast, the diacetoxy salicylic acid, V, is significantly more reactive, but the isomer VI is less so. By far the most effective of the diacyl hydroxysalicylic esters is VII, in which both acetyl groups are close to the anionic $-COO^-$ moiety. Alternative isomers of dihydroxybenzoic acids gave diacyl esters VIII and IX that did not compare in efficacy with VII, although VIII was significantly better than aspirin itself. Compound X, the anhydride of IX, was not better than aspirin, but the mixed anhydride XI was significantly better. In this series, therefore, the double *ortho* derivative VII is the most interesting compound and merits further investigation.

Previous studies (1, 8) have shown that aspirin-like reagents acylate sickle hemoglobin S just as extensively as they do hemoglobin A. Consequently effective compounds, such as 6-acetoxyacetylsalicylic acid (VII) of the present series, have potential as antisickling agents.

Liquid Chromatographic Analysis of Cimetidine with Procainamide as Internal Standard

Keyphrases □ Cimetidine—HPLC analysis in plasma and urine □ Liquid chromatography—analysis of cimetidine in plasma and urine

To the Editor:

We recently reported in this journal a simple and sensitive liquid chromatographic assay for cimetidine in plasma and urine (1). Chromatographic separation was performed on a radially compressed column[1], which allowed much faster and more efficient chromatography than previously described assays (1). However, since burimamide (the internal standard) is no longer manufactured, this has rendered our assay inapplicable by other investigators. We have therefore examined the chromatography of a wide variety of other compounds, including many other H_2-antagonist analogues, and found procainamide to be the most suitable alternative internal standard to burimamide. This results in minimal modification of our originally published assay.

In the analysis of plasma, procainamide hydrochloride[2] (20 μg/mL, 100 μL, in a 0.09% sodium metabisulfite solution), sodium hydroxide (2 M, 0.5 mL), and dichloromethane (20 mL) were added to 1.0 mL of plasma in a 30-mL glass tube. In the analysis of urine, procainamide hydrochloride[2] (1 mg/mL, 25 μL, in a 0.09% sodium metabisulfite solution), sodium hydroxide (2 M, 100 μL), and dichloromethane (5 mL) were added to 250 μL of urine in a 30-mL glass tube. Thereafter, the method of extraction and reconstitution of both plasma and urine samples was identical to that previously reported (1). The mobile phase, radial compression column[1], chromatographic conditions, and instrumentation were as reported previously (1). Procainamide (2.6-min retention) and cimetidine (3.8-min retention) were completely resolved. Cimetidine sulfoxide (1.5-min retention), the major metabolite of cimetidine (2), did not interfere with the assay. The analytical recoveries of cimetidine and procainamide were 60 and 59%, respectively. The coefficient of variation for within-day assays of plasma cimetidine levels was 1.8% at 1000 ng/mL (n = 6); for urine it was 0.53% at 50 μg/mL (n = 6). The coefficient of variation of between-day assays of plasma cimetidine levels over 4 weeks was 5.2% at 901 ng/mL (n = 7); for urine over 4 weeks the value was 5.4% at 51.0 μg/mL (n = 5).

The assay was applied to the measurement of plasma and urine samples obtained from a patient who underwent intravenous and oral cimetidine therapy in pharmacokinetic studies according to the protocol reported previously (1). The same samples were also analyzed for cimetidine by our original liquid chromatographic method (1) with burimamide as internal standard. There was good correlation between the two methods (r = 0.991), and the cimetidine levels did not significantly differ (paired t test, $p \geq 0.20$, df = 20) between the assays.

Thus, with a change in internal standard from burimamide to procainamide, this method can still be applied to the assay of cimetidine in biological fluids, without a major change in methodology.

BOOKS

A Textbook of Pharmaceutical Analysis, 3rd Ed. By KENNETH A. CONNORS. Wiley-Interscience, 605 Third Avenue, New York, NY 10016. 1982. 664 pp. 15 × 23 cm. Price $55.00.

This book is the latest revision in what is by now a classic text in pharmaceutical analysis for the undergraduate pharmacy curriculum. The first and second editions were issued in 1967 and 1975. The field of "pharmaceutical analysis" has undergone enormous changes over the 15 years this text has been used. Whether the sample be raw materials, dosage forms, or biological fluids, the methodology is more selective, more precise, and more accurate. As a reflection of modern developments, the latest edition includes a chapter on immunoassay and a substantially expanded chapter on liquid chromatography. Both of these subjects scarcely existed in 1967 (especially with respect to determination of pharmaceuticals), and now they are prominent in virtually every issue of this journal.

As was the case with previous editions, this book meets its objectives very well. I especially like Connor's focus on chemical reactions and his liberal use of examples, practice problems, and laboratory experiments. He is at his best when describing the interface between fundamental chemistry and instrumentation. It is delightful to see organic reaction mechanisms and stereochemistry taken into consideration. So many analytical chemistry texts are stuck on inorganic things and gadgets and thus miss the needs of many students.

The only fault I find with this book is that it is too much material for the undergraduate level and not quite enough to be useful as a graduate text for junior researchers. It just misses these audiences by dropping in between, a problem that can be solved by selective assignments and supplementary material. Overall, a job well done!

Liquid Chromatographic Analysis of Cimetidine with Procainamide as Internal Standard

Keyphrases □ Cimetidine—HPLC analysis in plasma and urine □ Liquid chromatography—analysis of cimetidine in plasma and urine

To the Editor:

We recently reported in this journal a simple and sensitive liquid chromatographic assay for cimetidine in plasma and urine (1). Chromatographic separation was performed on a radially compressed column[1], which allowed much faster and more efficient chromatography than previously described assays (1). However, since burimamide (the internal standard) is no longer manufactured, this has rendered our assay inapplicable by other investigators. We have therefore examined the chromatography of a wide variety of other compounds, including many other H_2-antagonist analogues, and found procainamide to be the most suitable alternative internal standard to burimamide. This results in minimal modification of our originally published assay.

In the analysis of plasma, procainamide hydrochloride[2] (20 μg/mL, 100 μL, in a 0.09% sodium metabisulfite solution), sodium hydroxide (2 M, 0.5 mL), and dichloromethane (20 mL) were added to 1.0 mL of plasma in a 30-mL glass tube. In the analysis of urine, procainamide hydrochloride[2] (1 mg/mL, 25 μL, in a 0.09% sodium metabisulfite solution), sodium hydroxide (2 M, 100 μL), and dichloromethane (5 mL) were added to 250 μL of urine in a 30-mL glass tube. Thereafter, the method of extraction and reconstitution of both plasma and urine samples was identical to that previously reported (1). The mobile phase, radial compression column[1], chromatographic conditions, and instrumentation were as reported previously (1). Procainamide (2.6-min retention) and cimetidine (3.8-min retention) were completely resolved. Cimetidine sulfoxide (1.5-min retention), the major metabolite of cimetidine (2), did not interfere with the assay. The analytical recoveries of cimetidine and procainamide were 60 and 59%, respectively. The coefficient of variation for within-day assays of plasma cimetidine levels was 1.8% at 1000 ng/mL (n = 6); for urine it was 0.53% at 50 μg/mL (n = 6). The coefficient of variation of between-day assays of plasma cimetidine levels over 4 weeks was 5.2% at 901 ng/mL (n = 7); for urine over 4 weeks the value was 5.4% at 51.0 μg/mL (n = 5).

The assay was applied to the measurement of plasma and urine samples obtained from a patient who underwent intravenous and oral cimetidine therapy in pharmacokinetic studies according to the protocol reported previously (1). The same samples were also analyzed for cimetidine by our original liquid chromatographic method (1) with burimamide as internal standard. There was good correlation between the two methods (r = 0.991), and the cimetidine levels did not significantly differ (paired t test, $p \geq 0.20$, df = 20) between the assays.

Thus, with a change in internal standard from burimamide to procainamide, this method can still be applied to the assay of cimetidine in biological fluids, without a major change in methodology.

Drugs and Therapy: A Handbook of Psychotropic Drugs, 2nd Ed. By ALVIN SWONGER and LARRY CONSTANTINE. Little, Brown and Company, 34 Beacon Street, Boston, MA 02106 1983. 431 pp. 15.5 × 23.5 cm. Price $18.95 (paperback).

This book is unusual in that it is directed to nonmedical personnel. The "therapy" of the title refers not to those modalities that medical people generally consider therapy, but more specifically to psychosocial approaches to treatment. The authors are a faculty member of a school of pharmacy and a family therapist. The intended audience might be nurses, social workers, psychologists, or others not primarily concerned with the use of drugs in treatment, but who may need to know what types of drugs their clients are taking and what effects these drugs may have on them.

This second edition has been expanded to include new sections not in the first. It is organized around eight general topics, each of which is covered in a few short chapters: drugs in therapeutic perspective (again, meaning from the perspective of the psychotherapist); foundations of drug action (a review of basic neuropharmacology); drug use and abuse; drugs and the arousal state (referring to sedative-hypnotics, alcohol, stimulants, and psychedelics); psychiatric disorders and drugs (psychosis, anxiety, depression, and mania); motor functions and drugs; pain and its drug management; and drugs and consciousness (which includes anticonvulsants). Each section is headed by a short introduction indicating the aims of the several chapters that follow.

The book is well illustrated with figures and tables. Most of these have appeared in either the same or slightly different form in other books. Virtually all the references are also to books or book chapters. Thus, it appears that the authors have attempted a synthesis of much that has already been published, tailoring it to the needs of the prospective audience. Relatively little emphasis has been placed on how specific drugs are used, but each chapter that discusses a class of drugs finishes with a brief synopsis providing the generic and trade names of the drug, the class to which they belong, their usual indications, and the usual range of daily doses. The major emphases are on how the drugs work in the nervous system and how they may affect the behavior of interest to the psychotherapist.

The book is well written and generally free of errors. It should certainly meet the needs of its intended audience, but would probably be inadequate for pharmacists or physicians. The only other book that I can remember that addressed a similar audience was one that Honigfeld wrote many years ago. Thus, the present volume services a useful need. It would be well worth having as a reference handbook for those who need to know how drugs affect their clients.

Calcium Antagonism in Heart and Smooth Muscle: Experimental Facts and Therapeutic Perspectives. By ALBRECHT FLECKENSTEIN. John Wiley and Sons, Inc., One Wiley Drive, Somerset, NJ 08873. 1983. 399 pp. 17 × 24 cm. Price $60.00.

Calcium antagonists have generated considerable interest in the pharmaceutical sciences since nifedipine was reported to be effective in the treatment of Printzmetal angina. This book constitutes a major tool for understanding the role of calcium and calcium antagonism in the heart and smooth muscle. The reader will find important information about the pharmacological properties of verapamil and its derivative, nifedipine and its derivatives, and diltiazem. It is not the first book published on this subject; however, the author makes this one very original.

Dr. Albrecht Fleckenstein investigated this field for more than 20 years. He is recognized as one of the most important contributors to the advancement accomplished in this field. This book provides indispensable knowledge related to the role of calcium in myocardial and vascular smooth muscle contractions, the pacemaker activity in physiological and pathological conditions, allowing a much better understanding of the cardiovascular indications of this very attractive group of drugs. Finally, it is of special interest to find a classification of these drugs in relation to their specificity in affecting the calcium channel. Dr. Fleckenstein proposed classifying the calcium antagonists in three groups: Group A, specific calcium antagonists including verapamil, nifedipine, their derivatives, and diltiazem; Group B, calcium antagonists also affecting the movement of sodium including prenylamine, terodiline, fendiline, perhexiline, and caroverine; Group C, substances with calcium antagonistic side effects, including nitroglycerin, barbituric acid, etc. Such classification is based on a number of pharmacological criteria. There are so many drugs claimed to be specific calcium antagonists, but also interfere with movements of other ions.

This book is recommended as a major source of information concerning the pharmacological properties of calcium antagonists.

Nicotinic Acid: Nutrient–Cofactor–Drug. (Clinical Pharmacology Series, Vol. 1). By MURRAY WEINER and JAN VAN EYS. Marcel Dekker, 270 Madison Avenue, New York, NY 10016. 1983. 308 pp. 16 × 24 cm. Price $55.00 (20% higher outside the U.S. and Canada).

This monograph provides a synthesis of existing knowledge from a wide variety of sources into a single, concise volume. Topics are not examined in excessive detail, but that was not a purpose of the book. Rather, it emerges as a strength in that it permits the diverse audience addressed to be informed readily in areas beyond particular disciplinary constraints. An index and extensive references facilitate acquisition of detailed information on the topics covered for interested readers. The book succeeds well in crossing disciplinary boundaries, and it frequently reveals provocative possibilities for future research. Exposition, organized by sections according to the title, is acceptably comprehensive and includes such newer developments as the nicotinamide coenzymes as donors in transribosylation reactions and in regulation of DNA repair and synthesis, use of nicotinic acid in cardiovascular and hyperlipidemic diseases (including pharmacokinetics and pharmacodynamics), and reexamination of the tryptophan-nicotinic acid relationship in a world in which protein hunger is a global problem of growing concern. For example, nonspecialists who identify pellagra with a simple niacin-tryptophan deficiency will be enlightened by the very first chapter.

The roles of nicotinic acid at the metabolic level are manifold. The most vital function of living material—the capacity to abstract and utilize energy from complex molecules—requires controlled oxidations linked to the nicotinic acid-derived coenzymes. Moreover, NAD participates in the generation of adenosine diphosphate robose polymers, which have a role in DNA metabolism and function. Indeed, in its coenzyme forms the physiological roles of nicotinic acid are pervasive and pivotal in the subcellular compartments of cytoplasm, nucleus, mitochondrion, and endoplasmic reticulum. The authors aver that "there are few areas of biochemistry in which pharmacology, nutritional biochemistry, and molecular biology are interwoven in such a coherent whole." Their monograph amply illuminates that statement. This overview of nicotinic acid and its variety of chemical and metabolic derivatives includes important biochemical, nutritional, pharmacological, and clinical aspects. In addition to life scientists and practitioners in those fields, the book should appeal to dieticians, pharmacists, and others interested in a concise and authoritative exposition of the functions and relationships of this critical cog in the metabolic machinery. It is an excellent contemporary reference for courses in all these disciplines, and it will be at home on laboratory benches due to its durable, stain-resistant binding.

There are relatively few printing errors and oversights for a first printing. Minor misspellings and errors in figures, such as the entry of the symbol for oxygen for that of coenzyme Q and a misplaced arrow (p. 219) and an exotically appended CO_2 on the NAM molecule (p. 19), are neither overly distracting nor misleading. Of somewhat more concern are the use of "niacin" in the second paragraph of p. 9 when "niacytin" is intended and strange displacements such as "substitutes" for "substrates" (p. 217).

This monograph is the first volume in a projected series in clinical pharmacology under the general editorial direction of Dr. Weiner. Three decades of distinguished research in many of the aspects of the metabolic roles of these compounds by Professor van Eys are evident in the clarity and insightful coverage which characterize this volume. If succeeding volumes maintain those qualities we will have much to look forward to and a wide audience stands much to gain.

Nicotinic Acid: Nutrient–Cofactor–Drug. (Clinical Pharmacology Series, Vol. 1). By MURRAY WEINER and JAN VAN EYS. Marcel Dekker, 270 Madison Avenue, New York, NY 10016. 1983. 308 pp. 16 × 24 cm. Price $55.00 (20% higher outside the U.S. and Canada).

This monograph provides a synthesis of existing knowledge from a wide variety of sources into a single, concise volume. Topics are not examined in excessive detail, but that was not a purpose of the book. Rather, it emerges as a strength in that it permits the diverse audience addressed to be informed readily in areas beyond particular disciplinary constraints. An index and extensive references facilitate acquisition of detailed information on the topics covered for interested readers. The book succeeds well in crossing disciplinary boundaries, and it frequently reveals provocative possibilities for future research. Exposition, organized by sections according to the title, is acceptably comprehensive and includes such newer developments as the nicotinamide coenzymes as donors in transribosylation reactions and in regulation of DNA repair and synthesis, use of nicotinic acid in cardiovascular and hyperlipidemic diseases (including pharmacokinetics and pharmacodynamics), and reexamination of the tryptophan-nicotinic acid relationship in a world in which protein hunger is a global problem of growing concern. For example, nonspecialists who identify pellagra with a simple niacin-tryptophan deficiency will be enlightened by the very first chapter.

The roles of nicotinic acid at the metabolic level are manifold. The most vital function of living material—the capacity to abstract and utilize energy from complex molecules—requires controlled oxidations linked to the nicotinic acid-derived coenzymes. Moreover, NAD participates in the generation of adenosine diphosphate robose polymers, which have a role in DNA metabolism and function. Indeed, in its coenzyme forms the physiological roles of nicotinic acid are pervasive and pivotal in the subcellular compartments of cytoplasm, nucleus, mitochondrion, and endoplasmic reticulum. The authors aver that "there are few areas of biochemistry in which pharmacology, nutritional biochemistry, and molecular biology are interwoven in such a coherent whole." Their monograph amply illuminates that statement. This overview of nicotinic acid and its variety of chemical and metabolic derivatives includes important biochemical, nutritional, pharmacological, and clinical aspects. In addition to life scientists and practitioners in those fields, the book should appeal to dieticians, pharmacists, and others interested in a concise and authoritative exposition of the functions and relationships of this critical cog in the metabolic machinery. It is an excellent contemporary reference for courses in all these disciplines, and it will be at home on laboratory benches due to its durable, stain-resistant binding.

There are relatively few printing errors and oversights for a first printing. Minor misspellings and errors in figures, such as the entry of the symbol for oxygen for that of coenzyme Q and a misplaced arrow (p. 219) and an exotically appended CO_2 on the NAM molecule (p. 19), are neither overly distracting nor misleading. Of somewhat more concern are the use of "niacin" in the second paragraph of p. 9 when "niacytin" is intended and strange displacements such as "substitutes" for "substrates" (p. 217).

This monograph is the first volume in a projected series in clinical pharmacology under the general editorial direction of Dr. Weiner. Three decades of distinguished research in many of the aspects of the metabolic roles of these compounds by Professor van Eys are evident in the clarity and insightful coverage which characterize this volume. If succeeding volumes maintain those qualities we will have much to look forward to and a wide audience stands much to gain.

Pain, Analgesia, and Addiction: The Pharmacologic Treatment of Pain. By BARRY STIMMEL. Raven Press, 1140 Avenue of the Americas, New York, NY 10036. 1983. 312 pp. 16 × 24 cm. Price $45.00.

This is an interesting volume presenting a multifaceted discussion of pain and its pharmacological management. The book appears to be written primarily with a pedagogic perspective and intent, presenting a rather broad survey of factors involved in the phenomenon of pain and of drugs used for relief of pain. It seems most useful for someone who is interested in pain and wishes to learn more about its various aspects, rather than for one who already has some expertise in the study or treatment of pain.

This book is organized into three distinct sections. The first deals with fundamental components of pain and analgesia, including the description and discussion of the anatomical pathways, neurochemical species, and psychological factors believed to be involved, as well as discussion of drug tolerance, dependence, and withdrawal. The second section deals with the clinical pharmacology of drugs used to relieve pain. Included in this are discussions of some unconventional agents such as stimulants, antidepressants, antipsychotic drugs, sedative-hypnotic-antianxiety agents, and marijuana. The discussions of pharmacological properties of the drug classes are broad, including description of effects on a number of organ systems, biodisposition, adverse effects, and drug interactions, rather than being confined to matters relating to pain and analgesia. This approach seems to diffuse the focus of the book somewhat, but may make it more useful for the clinician considering the use of these agents in a patient or encountering a patient already taking them. The third section offers a discussion of practical management of pain. It addresses such issues as the differences in management of acute *versus* chronic pain, management in "problem" populations such as the elderly, patients with malignancy, and drug-dependent patients, and the problem of iatrogenic drug dependence.

Included with each chapter is an ample list of references, but for some chapters more recent references are noticeably lacking. It also seems that the pharmacology section would have benefitted from more basic science references, especially some dealing with cellular actions and mechanisms of drugs, which would contribute to a better understanding of drug effects.

One strength of the volume, in spite of the preceding statement, is its combination and integration of basic and clinical sciences. The first section is done best in this regard. Another strength is the breadth of topics covered, including some not usually considered in texts dealing with pain or analgesic drugs. The author also applies his practical experience in discussion of the topics, which probably enhances the usefulness of the book for less experienced practitioners. The opinions of the author are expressed rather strongly in some of the "practical" sections of the book, and this expression could be viewed as being both a strength and weakness of the work. Weaknesses of the volume include a rather large number of typographical errors and some factual errors. While these are rather trivial relative to the content of the book as a whole, they are still somewhat bothersome. Other weaknesses, referred to earlier, include lack of currency in discussion of some topics and a paucity of basic science data in some discussions.

In summary, this volume deals with pain, analgesia, and related phenomena in considerable breadth and in sufficient depth to make it a useful source of information for both health scientists and clinicians who are interested in basic concepts concerning the nature of pain and analgesia and in the practical treatment of pain.

Antibiotics: Assessment of Antimicrobial Activity and Resistance. (Society for Applied Bacteriology, Technical Series No. 18.) Edited by A. DENVER RUSSELL and LOUIS B. QUENSEL. Academic Press, Inc., 111 Fifth Avenue, New York, NY 10003. 1983. 384 pp. 15 × 23 cm. Price $48.00 (£29.00).

This volume, the 18th in the Society for Applied Bacteriology technical series, includes 23 lectures with contributions from 50 microbiologists presented at a Demonstration Meeting of the Society held at the Welsh School of Pharmacy, University of Science and Technology, Cardiff, in September 1981.

The invaluable medicinal properties of antibiotics are universally recognized, but the ability of many organisms to develop resistance to certain of these antibiotics is sometimes underestimated or ignored. One of the greatest challenges in drug development is the continued need to discover and develop new chemotherapeutic agents to which microorganisms are initially, and continue to be, highly sensitive. This volume discusses many of the details of microbial sensitivity and resistance to antibiotics.

An introductory chapter in the book briefly describes the various types of antibiotics, their mode(s) of action, and methods of assay for these compounds. Other topics considered include: sensitivity testing; effects of media composition on MIC values of antibiotics; sensitivity determination by the measurement of conductance; the effects of cell envelope composition on antibiotic activity; the use of ionophoric antibiotics as experiment tools in microbiology; the extraction, purification, detection, and identification of β-lactamases; methods for determining the stability of β-lactam antibiotics to β-lactamase extracts; the biochemical evaluation of β-lactamase inhibitors; detection methods for bacterial penicillin-binding proteins; means of detecting aminoglycoside-modifying strains of bacteria; assay methods for aminoglycosides; methods of studying plasmid-determined tetracycline resistance; methods of studying bacterial folate metabolism inhibition; *in vitro* methods for determining transferable resistance to antibiotics; phage typing and plasmid characterization in studying the epidemiology of multiresistant *Salmonella typhimurium;* measurement of combined antibiotic action; use of a biophotometer in determining the effects of antibiotics; use of high-voltage electrophoresis in the identification of antibiotics; testing antibiotics for sterility; and the detection of antibiotic residues in milk and animal tissues.

The volume contains both theoretical and practical information on a variety of analytical techniques, and many valuable tables, figures, and schemes are included. The articles presented are well referenced and are current up to 1982. This is an excellent publication which contains an enormous amount of information and is highly recommended as a reference book. The price, along with its incomplete coverage of all aspects of antibiotics, would limit its usefulness as a textbook.

The Alkaloids: Chemistry and Pharmacology. Vol. 21. Edited by ARNOLD BROSSI. Academic Press, Inc., 111 Fifth Avenue, New York, NY 10003. 1983. 368 pp. 16 × 23.5 cm. Price $49.50.

This new volume in *The Alkaloids* series, the first to be edited by Arnold Brossi, is truly an exciting book. There is a sense of urgency and intensity about it which is hard to miss. It includes seven chapters, and in three of these the authors involved have deemed it necessary to add (at the end of their respective chapters) an addendum to bring the material presented completely up-to-date. In another chapter, a last minute change was made to round off the material presented.

In every instance, emphasis has been placed not only on occurrence, structural elucidation, and synthesis, but also on the most recent pharmacological results. One is thus led to realize that the justification for endeavors in natural products chemistry lies in the intrinsic interest and challenge of the chemical subject matter, as well as in the biological activity of natural products, particularly alkaloids.

Another characteristic of this volume of *The Alkaloids* is that the term "alkaloid" has been interpreted in broad terms, so that cyclic nitrogenous compounds produced by plants, micro-organisms, sponges, amphibians, and mammals are all discussed in detail.

Each of the presentations for the seven chapters is authoritative, precise, thorough, and above all permeated with enthusiasm. The authors who brought about this impressive *tour de force* in their chapters are: K. Gerzon and G. H. Svoboda: "Acridone Alkaloids"; J. Bergman: "Quinazolinocarboline Alkaloids"; T. Arai and A. Kubo: "Isoquinolinequinones"; J.-C. Cai and C. R. Hutchinson: "Camptothecin"; B. Witkop and E. Gossinger: "Amphibian Alkaloids"; J. Lundstrom: "Simple Isoquinolines"; and M. A. Collins: "Mammalian Alkaloids."

Incidentally, one of the twelve authors is supposed to be retired and has only a private address. Yet, he has shared in the writing of an excellent chapter.

Incidentally, one of the twelve authors is supposed to be retired and has only a private address. Yet, he has shared in the writing of an excellent chapter.

The choice of Dr. Brossi as editor of *The Alkaloids* is particularly felicitous since he brings to his position an extensive and impressive background in natural products chemistry as well as pharmacology.

To minimize costs, the publishers have seen fit to let each group of authors draw their own chemical diagrams. This has worked out very satisfactorily, since the structures are well drawn and clearly layed out. The result is that this book of almost 400 pages, with a very large number of tables, charts and structures, is offered for a relatively modest $49.50. Not a bad deal!

Compartmental Models and Their Application. By KEITH GODFREY. Academic Press Inc., 24-28 Oval Road, London NW1 7Dx, England. 1983. 293 pp. 15.5 × 23.5 Price $50.00 (£32.00).

The use of compartmental models to describe the disposition of drugs *in vivo* is a widely practiced art in the pharmaceutical sciences. These models very often provide a reasonable phenomenological description of the complex set of events and processes that determine the pharmacokinetics of a drug in mammalian systems. Less often, they also provide a means to interpret or discern what mechanisms are responsible for the observed performance. It is surprising, then, that the current texts on pharmacokinetics do not address the properties and problems associated with the models themselves. Godfrey's text attempts to do just that.

This book provides a comprehensive overview of compartmental models. The subjects can be roughly divided into three general areas (not corresponding to the individual chapters): the performance of linear systems; the problem of identifiability and parameter estimation; and the properties of more complex systems which display nonlinear, time variant, and stochastic behavior. The general layout includes a mathematical description of the various systems, comments concerning their performances, and many examples to illustrate applications. Two cautions must be voiced. First, while proofs have been eliminated, the vocabulary and notation are that of an applied mathematics-engineering approach. This, however, should not be a problem since the author carefully provides good descriptions throughout the text. Second, this is definitely not a pharmacokinetics text. While many of the examples are taken from that area, the emphasis is on the mathematical system and not on the phenomena being modeled. In this respect, the author provides a welcome service to the pharmacokinetics community.

In the first four chapters many linear compartmental systems are presented. The descriptions are straightforward and present an excellent overview. The various models are shown mathematically, their performances are illustrated by numerous calculations and graphical illustrations, and literature examples of actual applications are provided. The third section on nonlinear and time variant systems is similarly well described, to a depth not found elsewhere. The second section on identifiability and parameter estimation is by far the most important contribution of this book. Here, Dr. Godfrey provides an excellent analysis of whether particular models actually can be used to describe real data. Often we decide that a particular model effectively represents a set of data. Is the model unique? In most cases the answer is a resounding no. That fact is amply demonstrated by the use of Laplacian analysis as well as consideration of numerical problems. My only complaint is that the author does not go far enough; the emphasis is on the estimation of microconstants, not on integrated parameter estimation. The problem of correlation between parameters is barely considered; no mention of reparameterization is provided. Yet, this is a minor fault compared with the large assortment of warnings provided.

In summary, this book is an excellent reference document concerning the power and problems of lumped parameter systems composed of first-order differential equations. It is probably the best book on that subject available. The appropriateness of these models is up to us.

Formaldehyde: Toxicology—Epidemiology—Mechanisms. Edited by JOHN J. CLARY, JAMES E. GIBSON, and RICHARD S. WARITZ. Marcel Dekker, 270 Madison Avenue, New York, NY 10016. 1983. 296 pp. 15 × 23 cm. Price $45.00 (20% higher outside the U.S. and Canada).

The Chemical Industry Institute of Toxicology (CIIT), Research Triangle Park, NC, sponsored conferences on formaldehyde toxicity in November 1980 and, with funding from the Formaldehyde Institute, on November 3, 1982. The papers and discussions of the latter conference are presented in this book.

There are eleven chapters by 26 contributors, of which half are from CIIT. Chapter titles are as follows: "Occupational Exposure to Formaldehyde—Recent NIOSH Involvement," "Mathematical Cancer Risk Assessment for Formaldehyde," "Case Control Study of Cancer Deaths in DuPont Workers with Potential Exposure to Formaldehyde," "Mortality of Ontario Undertakers: A First Report," "Skin Initiation/Promotion Study with Formaldehyde in Sencar Mice," "Skin Initiation/Promotion Study with Formaldehyde in CD-1 Mice," "Mutagenic Effects of Formaldehyde in Bacterial and Human Cells," "Formaldehyde and the Nasal Mucociliary Apparatus," "Reaction of Formaldehyde in the Rat Nasal Mucosa," "The Effect of Formaldehyde Exposure in Cytotoxicity and Cell Proliferation," and "Mechanisms of Formaldehyde Toxicity and Risk Evaluation."

In general these topics are well written, and the summaries of the discussions that follow the actual presentations are of interest. Literature is cited up to the time of publication including 1983 references and citations to manuscripts in press.

In summary of the information presented at this second CIIT conference—it is now well accepted that airborne formaldehyde leads to cancer in rats and mice, that formaldehyde has the potential to cause genetic toxicity, and that formaldehyde will bind to DNA *in vitro*. Clarification, however, is still required regarding the importance of binding *in vitro*, especially as related to detoxification pathways and repair mechanisms. Of prime importance was the need for the results of additional epidemiological studies. While this volume is of restricted interest in the pharmaceutical sciences, it should be of value to those in contact with formaldehyde and its products as well as to toxicologists.

Methods in Industrial Microbiology. By B. SIKYTA. John Wiley & Sons, Inc. One Wiley Drive, Somerset, NJ 08873. 1983. 349 pp. 16 × 24 cm. Price $79.95.

This short textbook is aimed primarily at the microbiologist who is seeking a very broad and simplified introduction to industrial fermentation processes. The chapter headings: "Introduction," "Culture Equipment," "Sterilization of Media and Air," "Aeration and Mixing," "Substrates for Microbial Processes," "Kinetics of Microbial Processes," "Genetics of Industrial Microorganisms," "Development of Microbial Processes," "Measurement and Control of Microbial Processes," and "Isolation of Microbial Products" indicate that the author has attempted to condense a broad spectrum of biotechnology in a limited space. As a result, the subject matter is treated too superficially to make this a truly valuable reference source (*e.g.*, mass transfer scale-up in two and one-half pages).

The potentially useful aspects of this book might be the listing of the composition of various natural substances (*e.g.* cornsteep liquor) for material balance purposes and, possibly, the reference sources for their historical significance. Otherwise, the book should be of value to the layman interested in a broad view of the fermentation industry.

The choice of Dr. Brossi as editor of *The Alkaloids* is particularly felicitous since he brings to his position an extensive and impressive background in natural products chemistry as well as pharmacology.

To minimize costs, the publishers have seen fit to let each group of authors draw their own chemical diagrams. This has worked out very satisfactorily, since the structures are well drawn and clearly layed out. The result is that this book of almost 400 pages, with a very large number of tables, charts and structures, is offered for a relatively modest $49.50. Not a bad deal!

Compartmental Models and Their Application. By KEITH GODFREY. Academic Press Inc., 24-28 Oval Road, London NW1 7Dx, England. 1983. 293 pp. 15.5 × 23.5 Price $50.00 (£32.00).

The use of compartmental models to describe the disposition of drugs *in vivo* is a widely practiced art in the pharmaceutical sciences. These models very often provide a reasonable phenomenological description of the complex set of events and processes that determine the pharmacokinetics of a drug in mammalian systems. Less often, they also provide a means to interpret or discern what mechanisms are responsible for the observed performance. It is surprising, then, that the current texts on pharmacokinetics do not address the properties and problems associated with the models themselves. Godfrey's text attempts to do just that.

This book provides a comprehensive overview of compartmental models. The subjects can be roughly divided into three general areas (not corresponding to the individual chapters): the performance of linear systems; the problem of identifiability and parameter estimation; and the properties of more complex systems which display nonlinear, time variant, and stochastic behavior. The general layout includes a mathematical description of the various systems, comments concerning their performances, and many examples to illustrate applications. Two cautions must be voiced. First, while proofs have been eliminated, the vocabulary and notation are that of an applied mathematics-engineering approach. This, however, should not be a problem since the author carefully provides good descriptions throughout the text. Second, this is definitely not a pharmacokinetics text. While many of the examples are taken from that area, the emphasis is on the mathematical system and not on the phenomena being modeled. In this respect, the author provides a welcome service to the pharmacokinetics community.

In the first four chapters many linear compartmental systems are presented. The descriptions are straightforward and present an excellent overview. The various models are shown mathematically, their performances are illustrated by numerous calculations and graphical illustrations, and literature examples of actual applications are provided. The third section on nonlinear and time variant systems is similarly well described, to a depth not found elsewhere. The second section on identifiability and parameter estimation is by far the most important contribution of this book. Here, Dr. Godfrey provides an excellent analysis of whether particular models actually can be used to describe real data. Often we decide that a particular model effectively represents a set of data. Is the model unique? In most cases the answer is a resounding no. That fact is amply demonstrated by the use of Laplacian analysis as well as consideration of numerical problems. My only complaint is that the author does not go far enough; the emphasis is on the estimation of microconstants, not on integrated parameter estimation. The problem of correlation between parameters is barely considered; no mention of reparameterization is provided. Yet, this is a minor fault compared with the large assortment of warnings provided.

In summary, this book is an excellent reference document concerning the power and problems of lumped parameter systems composed of first-order differential equations. It is probably the best book on that subject available. The appropriateness of these models is up to us.

Formaldehyde: Toxicology—Epidemiology—Mechanisms. Edited by JOHN J. CLARY, JAMES E. GIBSON, and RICHARD S. WARITZ. Marcel Dekker, 270 Madison Avenue, New York, NY 10016. 1983. 296 pp. 15 × 23 cm. Price $45.00 (20% higher outside the U.S. and Canada).

The Chemical Industry Institute of Toxicology (CIIT), Research Triangle Park, NC, sponsored conferences on formaldehyde toxicity in November 1980 and, with funding from the Formaldehyde Institute, on November 3, 1982. The papers and discussions of the latter conference are presented in this book.

There are eleven chapters by 26 contributors, of which half are from CIIT. Chapter titles are as follows: "Occupational Exposure to Formaldehyde—Recent NIOSH Involvement," "Mathematical Cancer Risk Assessment for Formaldehyde," "Case Control Study of Cancer Deaths in DuPont Workers with Potential Exposure to Formaldehyde," "Mortality of Ontario Undertakers: A First Report," "Skin Initiation/Promotion Study with Formaldehyde in Sencar Mice," "Skin Initiation/Promotion Study with Formaldehyde in CD-1 Mice," "Mutagenic Effects of Formaldehyde in Bacterial and Human Cells," "Formaldehyde and the Nasal Mucociliary Apparatus," "Reaction of Formaldehyde in the Rat Nasal Mucosa," "The Effect of Formaldehyde Exposure in Cytotoxicity and Cell Proliferation," and "Mechanisms of Formaldehyde Toxicity and Risk Evaluation."

In general these topics are well written, and the summaries of the discussions that follow the actual presentations are of interest. Literature is cited up to the time of publication including 1983 references and citations to manuscripts in press.

In summary of the information presented at this second CIIT conference—it is now well accepted that airborne formaldehyde leads to cancer in rats and mice, that formaldehyde has the potential to cause genetic toxicity, and that formaldehyde will bind to DNA *in vitro*. Clarification, however, is still required regarding the importance of binding *in vitro*, especially as related to detoxification pathways and repair mechanisms. Of prime importance was the need for the results of additional epidemiological studies. While this volume is of restricted interest in the pharmaceutical sciences, it should be of value to those in contact with formaldehyde and its products as well as to toxicologists.

Good Public Policy Requires Good Science

Everyone knows that there are many different languages spoken around the world—a phenomenon that the Old Testament tells us was God's punishment to Noah's descendents who embarked on building the Tower of Babel after surviving the great flood.

But even though we all acknowledge the differences *between* languages—English, French, German, Russian, and so on—we seldom recognize, much less acknowledge, the difference *within* a language. And yet, there are differences and at times those differences can be highly significant.

For example, the vast majority of our readers are over 30 years of age. And those who are over 30 probably have encountered the difficulty in conversing with someone under 20 although they are both from the same country, and presumably speak the same native tongue; in fact, they may even be family members from the same household!

Similarly, there is a major difference between the language of the scientist and the language of the layperson—even though both claim to speak the same tongue or native language.

However, the language of scientists is really unique to them; it is very carefully precise and qualified; it often focuses on the exceptions—their occurrence, their frequency, their seriousness, etc. On the other hand, the layperson or the general public speaks another language—one that deals in simple absolutes, and also involves instincts, intuition, psychology, and moods.

The public asks whether a drug is effective or not; whether it is safe or not. The idea that it may be judged "effective" when it only works in three out of four patients, or 75% of the time, is incomprehensible. And the concept that a drug is classified as "safe" when it causes minor side effects in one out of five patients, major side effects in one out of a thousand patients, and death in one out of a hundred thousand patients, is mind-boggling to virtually everyone outside of the field of science.

We were recently reminded of this vast communication gap, as we read reports relating to the issuance of revised cancer guidelines from the White House Office of Science and Technology Policy (OSTP). The June 1 issue of the *Washington Post* headlined its article "Drastic Revision from 1982 Draft." The story itself then started out by describing the background to this report:

"The Reagan Administration has issued dramatically revised draft principles to guide federal policy-makers in cancer regulation, stating that cancer-causing substances can be dangerous even at extremely low levels.

"The massive White House science office document also says that materials that cause cancer in animals are 'suspected human carcinogens.'

"The report reverses many of the positions laid out in a draft issued 18 months ago, according to experts in the field. Designed as the basis for setting cancer policy across the federal government, it appears to have succeeded in creating consensus out of the chaos caused by earlier efforts."

The "earlier efforts" referred to was the former approach to the regulation of potential carcinogens as promoted most vigorously by the Environmental Protection Agency (EPA) during the very early days of the Reagan Administration.

Efforts were then felt necessary to overcome the "doomsday" interpretation that the public had come to associate with the theory that "everything and anything can be harmful and cause cancer if given in a large enough dose, for a long enough period of time, and via certain peculiar conditions of exposure" that was then being espoused by many scientists. The EPA responded by discounting the value of animal tests in determining the risk of cancer in humans; it criticized the way high doses given to animals were being used to predict human reactions; and it stated that a threshold probably existed below which doses of a suspected carcinogen would not cause cancer.

This approach calmed public fears and anxiety, but was roundly criticized by the scientific community at large.

The chief toxicologist for the Environmental Defense Fund is quoted as saying that the original policy draft "got blasted across the board because people were appalled at the bad science in it." A spokesman for the industry-supported American Industrial Health Council commented that the former policy draft "just wasn't accurate scientifically. It has to be defensible scientifically."

In contrast, the current draft comes close to drawing "rave reviews" from the great majority of scientists who have examined it to date. Moreover, those scientists represent the full spectrum of philosophical thinking from the environmental and consumer groups at one end, to the industrial and trade groups on the other end.

Specifically, the current report carefully describes the present state of knowledge as to how cancer is caused and to what degree science can determine whether a given substance is carcinogenic. It also provides a number of guidelines for federal agency use in helping agency officials decide how to regulate suspected carcinogens.

Although the document does not constitute binding policy or regulatory requirements, it does set benchmarks of agreement and understanding for those who regulate and those who are regulated. It also provides a standard of measurement for other interested parties such as consumer groups and environmental coalitions. For these reasons, there is general recognition of the significance of the report, despite its lack of obligatory standing. A key feature of the statement is the listing of 31 separate principles designed to help at least 10 different federal agencies prepare their own guidelines to shape their regulatory programs and activities.

OSTP Director George A. Keyworth II—who also serves as President Reagan's Science Advisor—characterized the document as "one of the most ambitious attempts yet to examine data on cancer causation and their implications for regulatory policy. It responds to society's need for better balance and objectivity in how we regulate man-made and naturally occurring chemicals that may cause cancer."

If there is a lesson to be learned from this experience, it is that good science is a basic need for good public policy. Furthermore, in communicating with the public, efforts must be made to enable the public to understand and comprehend the risks, the benefits, the costs, and so on that may be involved. And in doing so, great efforts must be made to translate the language of science into that which the public can grasp, understand, accept, and place in proper perspective. Finally, and most important, it is essential to maintain the factual accuracy and fundamental integrity of the information itself.

Relationship of Chemical Structure to Corneal Penetration and Influence of Low-Viscosity Solution on Ocular Bioavailability

GEORGE M. GRASS and JOSEPH R. ROBINSON ˣ

Received May 2, 1983, from the *School of Pharmacy, University of Wisconsin, Madison, WI 53706.* Accepted for publication August 12, 1983.

Abstract □ Current understanding of the mechanism of corneal penetration by organic molecules proposes the epithelial layer as the rate-limiting membrane for water-soluble compounds and the stromal layer as rate limiting for lipid-soluble compounds. This suggests that the relationship between corneal permeability and the logarithm of oil/water partition coefficients, for a series of drugs, should not be the typical, single, continuous, parabolic-shaped curve. Corneal penetration studies have been conducted in unanesthetized albino rabbits using various organic compounds, representing five orders of magnitude in partition coefficient, at a constant concentration of 4×10^{-5} M dispensed in either a 1- or 90-centipoise (cps) solution. It has been shown that for non-ionizable compounds, a pair of bell-shaped curves were generated, one for lipid-soluble and one for water-soluble compounds. Small water-soluble species demonstrate very high apparent permeabilities, which may relate to the presence of aqueous pores or other paracellular drug movement. Penetration of ionizable compounds does not appear to correlate well with the structural relationships invoked for un-ionized compounds. Consistent with the proposed mechanisms of corneal penetration, oil-soluble drug substances show no improvement in drug bioavailability when dosed from a 90-cps solution, and water-soluble drugs show a modest improvement in ocular drug bioavailability. Small water-soluble substances demonstrate no improvement due to their already high bioavailability. The importance of nonproductive absorption and precorneal drainage on bioavailability is addressed.

Keyphrases □ Bioavailability, ocular—corneal penetration mechanisms, low-viscosity solutions □ Corneal penetration—ocular bioavailability, low-viscosity solutions

Although numerous studies on the penetration of organic compounds into the eye from topical dosing have been reported, these efforts have been limited in the majority of cases to the simple quantification of the amount of drug reaching the aqueous humor (1-3). None of these *in vivo* studies were designed to explore the relationship between drug structure and corneal penetration rate. On the other hand, there have been several reported *in vitro* studies which were expressly designed to explore corneal penetration rate and properties of the permeating species, especially the partition coefficient of the permeating species (4-6). In each of the *in vitro* studies, only a limited number of compounds and/or partition coefficient ranges was studied, and interpretation of the results generally ignored the mechanism of corneal penetration and precorneal disposition kinetics.

The intent of the present work is to explore corneal drug absorption as a function of drug properties, including the following specific aims: (*a*) an examination of vehicle effects (low-viscosity solutions) on drug bioavailability and the relationship of this effect, if any, to the mechanism(s) of corneal permeability, and (*b*) an investigation of the relationship of corneal penetration to physicochemical properties of the drug entity.

Several investigators (4-7) have postulated that the best predictor of corneal penetration rate of drugs is the oil/water (o/w) partition coefficient, and that an optimum partition coefficient exists for maximal penetration. Furthermore, several sources cite this optimal o/w partition coefficient for corneal penetration at a value of 10:1-1000:1 (4, 6), with the corresponding implication that very water-soluble drugs do not penetrate effectively. It has also been assumed that the charged forms of the drug, *i.e.*, ionized molecules, penetrate the cornea at a low rate that is essentially zero. In general, the studies upon which these assertions/assumptions have been based employed *in vitro* mounted corneas and either a restricted range of drugs (*i.e.*, a restricted range of partition coefficients) or a small number of drugs.

Based on published studies (8, 9) and the known structure of the cornea, a limiting-membrane mechanism for corneal penetration of small organic molecules, as depicted in Fig. 1, is proposed. When a drug with a high o/w partition coefficient is applied to the cornea, it quickly partitions into the "lipid-like" epithelial layers of the cornea. However, for such a drug, the aqueous stroma presents a rate-limiting membrane and, therefore, a small concentration gradient across this barrier is expected. Conversely, when a compound with a low o/w partition coefficient is applied to the corneal surface of high-

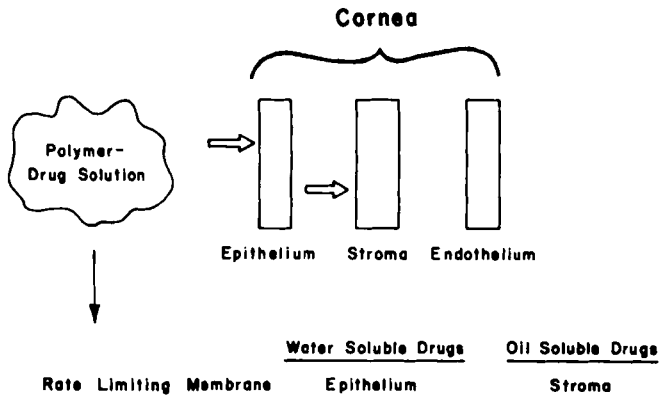

Figure 1—*Diagrammatic representation of proposed limiting-membrane mechanism for corneal penetration of small organic molecules based on oil/water partition coefficient for the penetrating species.*

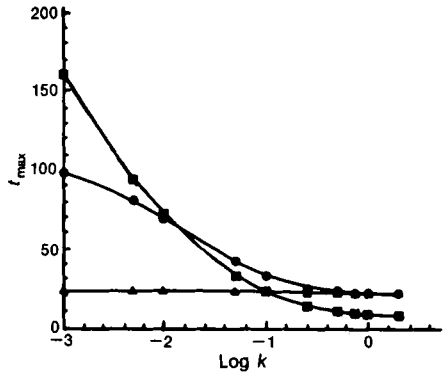

Figure 2—*Representation of the effects of changing rate constants on peak concentration (C_{max}) in the aqueous humor. Key: (●) k_{10}; (▲) k_{12}; (■) k_{23}.*

lipid character, this region serves as the rate-limiting membrane. Once across this barrier, the drug favorably partitions and quickly diffuses across the stroma. At some intermediate partition coefficient, it is likely that both membranes are rate limiting.

Directly related to this model are the anticipated effects of low-viscosity solutions on drug bioavailability. It is known that an increase in solution viscosity from 1 to 100 centipoises (cps) causes a decrease in precorneal drainage and, hence, increases corneal contact time for the drug. The decrease in the drainage rate constant, over this viscosity range, is ~10-fold in albino rabbits (10). For drugs with high o/w partition coefficients, little or no improvement in the bioavailability of the drug in the aqueous humor is expected, since the drug quickly partitions into the epithelium and the limited increase in contact time afforded by this solution should be of little or no benefit. However, water-soluble substances should show increased bioavailability due to the fact that any increase in contact time with the cornea allows continued flux of the drug across the rate-limiting membrane. Evidence of this result in rabbits has already been demonstrated for pilocarpine in low-viscosity polyvinyl alcohol and methylcellulose solutions (10–13).

A prediction of the effect of viscosity on bioavailability for compounds which possess both water and oil solubility (intermediate o/w partition coefficient) is difficult, since these drugs will most likely combine the above mechanisms. Predictions concerning ionizable compounds are equally difficult, since corneal penetration may involve mechanisms which are unrelated to the o/w partition coefficient. Expected corneal penetration mechanisms for the different drug types are summarized in Table I.

THEORETICAL SECTION

Pharmacokinetic Background—Many aspects of drug disposition in the eye have been reported (8, 15–17). Of particular interest is the precorneal fate and the rate of corneal absorption of various compounds. Extensive work in this area has been reported for pilocarpine, and this provides a substantial base from which to make predictions for other drugs (18).

One of the most important developments to come from the kinetic modeling of pilocarpine is the notion of a parallel loss process from the precorneal area. When a drug is placed in the precorneal area, in a simple solution, it experiences very short residence time. All corneal absorption of pilocarpine ceases after 4–5 min in rabbits (15). This, combined with the fact that most drugs demonstrate a relatively short time to reach peak levels in the aqueous humor, led early investigators to believe that the rate of corneal absorption was quite large (0.5 min^{-1}). However, this apparent rate constant and the true rate constant for corneal absorption have been demonstrated to be ~100 times smaller [~0.005 min^{-1} (15)]. The remaining rate of disappearance of drug from the precorneal area (0.495 min^{-1}) can be attributed to several loss processes, collectively referred to as the parallel loss function. This elimination step consists primarily of drainage coupled with tear turnover and nonproductive absorption. Since the rate constant for parallel elimination is ~100 times larger than the absorption rate constant, it is obvious that it is this larger rate constant which will control the time to reach peak drug levels in the cornea and the aqueous humor.

Since this is a parallel first-order process, the fraction of the dose absorbed can be calculated from:

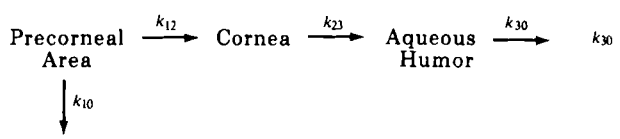
$$(F_t) = \frac{k_{12}}{k_{12} + k_{10}} \qquad \text{(Eq. 1)}$$

where k_{12} is the true rate constant for corneal absorption and k_{10} is the rate constant for precorneal loss. A simple calculation using the determined rate constants for pilocarpine predicts that the fraction absorbed should be ~0.01, and this has been found to be a good estimate (15). Assuming that k_{10} is largely comprised of the drainage rate constant (19), changes in the fraction of dose absorbed should be a direct reflection of changes in k_{12}.

An initial premise of the present work is that the true corneal absorption rate should be related to the o/w partition coefficient of the specific drug. Assuming this is accurate, it should be possible to predict changes in the extent of absorption from changes in the o/w partition coefficient.

Directly related to the above discussion is the expected effect of instilled solution viscosity on the extent of corneal absorption. Previous work with methylcellulose has demonstrated that a 100-cps solution can improve precorneal residence time by a factor of ~10, with a corresponding doubling of the aqueous humor levels of pilocarpine (10). Since an increase in residence time is associated with a decreased drainage loss, with subsequent smaller influence of tear turnover, this allows a calculated estimate of the maximum increase expected for this dosage form. Decreasing k_{10} by a factor of 10 and then calculating Eq. 1 gives a fraction absorbed of 0.09, or about a ninefold increase. It is emphasized that this calculation is for the maximum improvement obtainable and is dependent on the absolute magnitude of the corneal absorption rate. Just as the available time for corneal absorption increases so will that for nonproductive absorption, thus increasing drug loss by this mechanism. Also, drugs which could attain saturation of the epithelial layer would show varying degrees of improvement less than this amount. Since the degree of this saturation should be related to the o/w partition coefficient of the absorbing drug, very oil-soluble drugs should demonstrate little or no improvement, while very water-soluble compounds should approach this maximal increase. A gradation of this effect is expected for compounds with an intermediate o/w partition coefficient.

Theoretical Pharmacokinetic Simulations—As shown in Scheme I, a simplified model of the eye, based on previously published work with pilocarpine, was chosen to assess the importance of the various rate constants on drug levels in the aqueous humor. Drug movement is designated in one direction only, since there is no evidence of significant back-diffusion.



Scheme I—Model used to determine effects of parallel loss on C_{max} and t_{max} in aqueous humor

Table I—Expected Mechanism(s) of Corneal Penetration and Corresponding Viscosity Effects

Drug Type	Apparent Rate-Limiting Membrane	Mechanism	Low-Viscosity Polymer Influence
Water soluble	Epithelium	- Low oil/water partition into epithelium - High partition rate plus rapid diffusion through stroma-endothelium - Leaky channels do exist, *i.e.*, albumin (14) - Solute movement may be intercellular and/or transcellular	Increase in ocular bioavailability
Water and oil soluble	Epithelium–stroma	- Both mechanisms operate	Unknown
Oil soluble	Stroma	-High oil/water partition into epithelium and rapid diffusion through epithelium - Low oil/water partition into stroma	No effect
Ionizable	Epithelium or aqueous channel	- Mechanism not solely dependent on partition coefficient	Variable

The rate equation for appearance of drug in the aqueous humor is presented as:

$$dA/dt = k_{23}C - k_{30}A \qquad \text{(Eq. 2)}$$

where k_{23} is the rate constant for transfer from the cornea to the aqueous humor, k_{30} is the elimination rate constant from the aqueous humor, C is the amount of drug in the cornea, and A is the amount of drug in the aqueous humor at time t. C can be represented by:

$$C = \frac{Dk_{12}}{k_{12} + k_{10} - k_{23}} (e^{-k_{23}t} - e^{-(k_{12}+k_{10})t}) \qquad \text{(Eq. 3)}$$

as earlier derived (18), where D is the dose administered, k_{12} is the rate constant for corneal absorption, and k_{10} is the rate constant for precorneal loss. Equation 3 was integrated to give the amount of drug in the aqueous humor:

$$A = \frac{Dk_{12}k_{23}}{abc} (ae^{-k_{30}t} + be^{-k_{23}t} + ce^{-Kt}) \qquad \text{(Eq. 4)}$$

where a is $k_{23} - K$, b is $K - k_{30}$, C is $k_{30} - k_{23}$, and $K = k_{12} + k_{10}$. It should be noted that when D has a value of unity, A becomes the fraction of the applied dose in the aqueous humor at time t.

Simulations were conducted by solving for the fraction of dose in the aqueous humor at various times up to 60 min. Each rate constant was varied individually with the remaining values held constant, using the experimentally determined values for pilocarpine as starting values. A series of curves delineating the fraction of dose in aqueous humor *versus* time was generated for each rate constant examined. The elimination rate constant (k_{30}) was not varied.

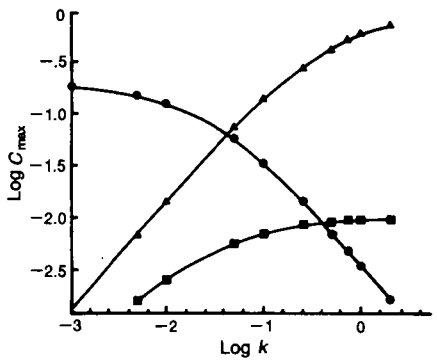


Figure 3—*Representation of the effects of changing rate constants on peak time (t_{max}) in the aqueous humor. Key: (●) k_{10}; (▲) k_{12}; (■) k_{23}.*

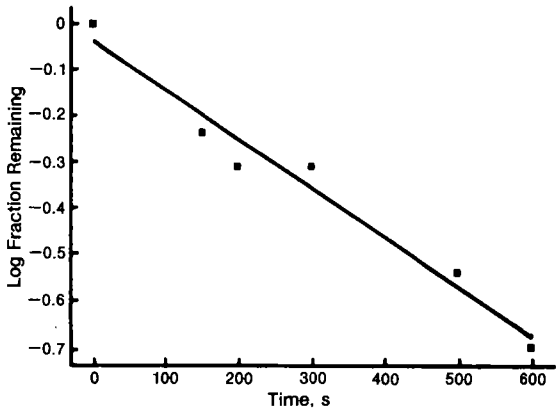

Figure 4—*Results of* in vitro *evaporation experiments for methanol conducted at 34°C. Note that the* SEM *is less than point size.*

In Figs. 2 and 3, the rate constant for parallel loss (k_{10}) is shown to affect both the time of peak concentration (t_{max}) and the magnitude of aqueous humor levels (C_{max}). The effect of decreasing the magnitude of this loss with, for example, a viscous solution or sustained-release system to a factor of 10 less, causes the expected increase in C_{max}. It is important to note that any decrease in k_{10} will be accompanied by a change in t_{max}. In this case, an order-of-magnitude decrease in k_{10} will result in an increase in peak time from the normal time of 20 min to ~40 min.

Results obtained for variations in the true absorption rate constant from its experimentally determined value of 0.005 min^{-1} demonstrate that the fraction of drug reaching the aqueous compartment is increased significantly with an increase in k_{12} (Fig. 3), as was expected from Eq. 1. Another result demonstrated in these simulations (Fig. 2), which would not be intuitively expected, is that t_{max} is minimally affected by increases in the range of values used for this rate constant. This is due to the fact that the changes in k_{12} are minimal when compared with the magnitude of k_{10}, which remains the controlling rate constant for precorneal processes. When k_{12} is increased by two orders of magnitude, this only doubles the sum of k_{10} and k_{12}; hence, the effects on t_{max} in this range of values are minimal. Therefore, it is expected that if changes in partitioning affect only the absorption rate constant, no effect on the time of peak levels in the aqueous humor should be observed. This is consistent with a previously presented theory (15).

The effects of a theoretical change in the rate constant for transfer of drug from the cornea to the aqueous humor (k_{23}) were as anticipated. At values below the experimentally determined value for pilocarpine (0.1 min^{-1}), t_{max} is increased and C_{max} is decreased. Conversely, t_{max} is decreased and C_{max} is increased for values >0.1 min^{-1}.

Summarizing the effects of changes in these rate constants on t_{max} and C_{max}, it may be concluded that an increase of the partition coefficient, which favors an increase in permeability through the corneal epithelium, will increase bioavailability of the compound (C_{max}), but should not influence the time to maximum aqueous humor concentration. This simulation does not allow for changes in nonproductive absorption due to changes in permeability from partitioning.

Table II—Characterization and Applied Concentration of Studied Compounds

Drug Name	Label	Supplier[a]	Specific Activity, Ci/mmol	Actual Applied Conc., $\times 10^{-5}$

Hydrocortisone	Dichloromethane–acetone	1:1	<2.0
Hydrocortisone	Ethyl acetate	—	<1.0
Prednisolone	Ethyl acetate	—	<1.0
Glycerol	1-Butanol–water	9:1	<3.5

Factors which decrease the magnitude of drug loss will have a direct and almost linear effect on aqueous humor concentration and may increase the time to reach peak levels. A 10-fold decrease in k_{10} will result in a change in peak time from 20 min to ~40 min. Another factor of 10 decrease should result in a peak time of 90 min. It can be concluded, therefore, that a viscous solution that reduces the rate of loss from the precorneal area by a factor of 10, and increases C_{max}, should have a small effect on t_{max}. It is also notable that the second factor of 10 decrease in k_{10} (to a value of 0.005 min^{-1}) does not provide the same factor of nine increase in C_{max} decribed earlier, since it appears that for this rate constant an asymptotic value is reached (Fig. 3). This is reasonable and represents the ideal situation where no drug is lost, and k_{12} is the only precorneal rate constant for drug removal.

Due to the overwhelming magnitude of k_{10}, this rate constant has been proposed to control the peak time of drug in the aqueous humor. In cases where k_{10} is constant or decreases, this is valid. However, changes in k_{10} cannot induce a peak time in <20 min as demonstrated in Fig. 2. An increase in k_{23} is required to obtain a shorter peak time. The magnitude of k_{10} reaches an asymptotic value at 20 min. This value is obtained within the normal range of values expected for this rate constant, hence its control over C_{max}, t_{max} values below 20 min appear to be induced by an increase in the rate of transfer from the corneal epithelium to the following compartment. However, it is emphasized that the absolute magnitude of this asymptotic value of k_{10} is dependent on the fixed values of the remaining rate constants (k_{12} and k_{23}).

EXPERIMENTAL SECTION

Materials—Radiolabeled substances were obtained from commercial sources. All compounds were purified by vacuum distillation immediately prior to use. The original supplier, specific activity, and type of radiolabel are indicated in Table II for each compound. All other chemicals were either reagent or analytical grade and were used as received.

Male albino rabbits[2] (weight, 2.5–3.0 kg) were used throughout. Lighting and auditory background were maintained at a constant level in the caging facilities, and the animals were fed a regular diet with no restrictions on the amount of food or water consumed.

Preparation of Solutions—Drug solutions were prepared by the addition of purified, labeled material to a 4.0×10^{-5} M solution of the specific drug. The standard buffer solution was isotonic Sörenson's buffer at a pH of 7.4.

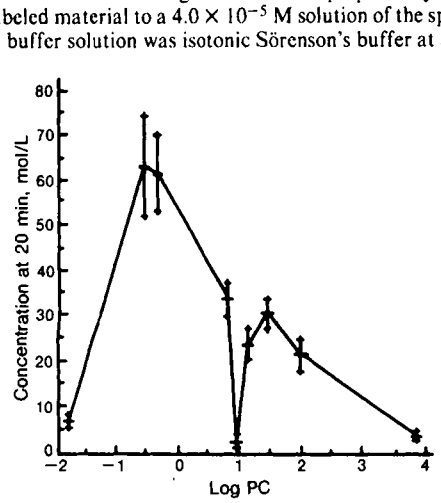

Figure 5– *Plot of molar concentration* versus *log partition coefficient for un-ionized species only.*

Methanol	−0.32	64.69 (10.90)	83.64 (18.90)	0
Glycerol	−1.79	6.84 (1.27)	8.15 (0.79)	0

[a] Numbers in parentheses represent *SEM*. [b] Percent increase was taken to be zero if no statistical difference was found between the means by t test. [c] $p < 0.01$. [d] $p < 0.001$.

Sufficient radioactive material was used to ensure good counting efficiency throughout the studies, *i.e.*, 100,000–400,000 cpm/μL of dosing solution. The actual final molar concentration of the solution was calculated from summation of the amount of unlabeled and labeled drug (Table II). Individual compounds, which resulted in high concentrations (Table II, footnote *b*) due to low specific activity, were also repeated at 20-min time points at another concentration to ensure linearity. All solution concentrations were normalized to 4×10^{-5} M for calculation and comparison purposes.

Ninety-centipoise solutions were prepared by the addition of methylcellulose[3] to a standard buffer solution until a final concentration of 0.8% polymer was reached. The viscosities of the solutions were determined with a viscometer[4].

Partition Coefficient Determinations—Oil/water partition coefficients were determined for all compounds listed in Table II. For lipid-soluble drugs, 4×10^{-5} M solutions of these compounds, with a sufficient amount of radiolabeled material added, were prepared in octanol. One hundred milliliters of this solution was added to an equivalent volume of isotonic Sörenson's buffer (pH 7.4) and allowed to reach equilibrium in a constant-temperature water bath at 34°C for 5–7 d. Both aqueous and octanol layers were sampled at 24-h intervals, and the samples placed in vials with scintillation cocktail for counting. The experimentally determined concentration was compared with the initial concentration in octanol, and an o/w partition coefficient was calculated. For water-soluble compounds, the procedure was the same except that the initial solution was prepared in the aqueous buffer phase.

Aqueous Humor Concentration Determinations—Rabbits were placed in restraining boxes to minimize movement. Doses (25 μL) were administered directly onto the corneas of both eyes with a micropipet. Animals were sacrificed at various times postdose by rapid injection of sodium pentobarbital solution through a marginal ear vein. The corneal surface was rinsed with buffer solution and carefully blotted dry with tissue. Aqueous humor samples were then tapped with a 1-mL syringe fitted with a 27-gauge needle.

Aqueous humor samples were transferred to glass vials, and scintillation cocktail[5] was added. Vials were dark-adapted for 24 h before counting to minimize chemiluminescence. Samples were counted with a liquid scintillation counter[6] and, after appropriate corrections, the final counts were converted to micrograms of drug per milliliter of aqueous humor.

Throughout the study, samples were removed as quickly as possible to minimize error due to redistribution and elimination. This is of particular importance for early time points and for drugs with apparently fast absorption kinetics. Rinsing the cornea prior to sampling and rapid surgery were methods used to minimize potential sources of error.

Metabolism Studies—Four aqueous humor samples were pooled, extracted with 1 mL of chloroform, and then centrifuged. The recovered chloroform was evaporated under nitrogen and then 10 μL of methanol was added. The methanol solution was spotted on silica gel plates[7] and developed in an appropriate solvent system. For water-soluble compounds (glycerol), aqueous humor was spotted directly without extraction. Control solutions were extracted, excepted glycerol, and treated in an identical manner. Dried plates were cut into 0.5-cm sections and then placed in scintillation vials containing 1 mL of methanol or water and mixed for 5 min. Scintillation cocktail was added and the samples counted after 24-h dark adaptation. Results were compared to TLC plates which had been spotted with nonradioactive solutions

and examined under UV light to determine R_f values for each drug in its specific solvent system.

***In Vitro* Evaporation Studies**—A 10.16-cm diameter petri dish was suspended in a water bath maintained at 34°C. Distilled water was added to just cover the inner surface of the dish. A 2.54-cm diameter watch glass was placed onto this arrangement and 25-μL samples of the test solution were placed on the watch glass and allowed to evaporate for ≤20 min. A separate watch glass was used for each determination to avoid contamination. At appropriate times, disks were rinsed with 3 mL of distilled water, and the rinsing solution was retained in a scintillation vial. Determinations of amount of compound remaining with respect to time were computed.

RESULTS

Drug Metabolism—Table III indicates, unexpectedly, that there is little or no metabolism occurring for the drugs examined over the time course of these studies. For example, published results (20) for prednisolone acetate demonstrate 100% metabolism under these conditions, and one would anticipate that fluorometholone acetate would behave similarly. Further comment on metabolism will be presented subsequently.

Viscosity Effects—Table IV gives the results of partition coefficient studies and aqueous humor levels for both 1- and 90-cps solutions. Results of partition coefficient studies correlate well with data available from Leo *et al.* (21). The percent bioavailability increase between 1- and 90-cps solutions was indicated as zero if there was no statistical difference ($p < 0.01$) in the mean values at 20 min as indicated by Student's *t* test. It is notable that a significant increase was demonstrated only for pilocarpine and pyrilamine. Additional studies for glycerol at both 20- and 30-min time points established that a change in t_{max}, expected from an increase in k_{10}, had not obscured the effects of viscosity on C_{max}.

Drug Concentrations in Aqueous Humor—Drug levels in the aqueous humor for the compounds studied are given in Table V. From the data, it appears that there is not a linear relationship between the partition coefficient and the amount of drug in the aqueous humor at 20 min. An order of magnitude increase in the partition coefficient does not coincide with a similar magnitude increase in the aqueous humor drug levels.

The low molecular weight alcohols (methanol, ethanol, and butanol) demonstrated peak times ≥10 min. Methanol and tritiated water data[8] from this laboratory had significantly ($p < 0.005$) higher levels in the aqueous humor at 5 min as compared with the 10-min levels. These compounds also have increased precorneal loss rates. *In vitro* determinations of evaporation rates for these compounds indicate that this is a significant mechanism of drug loss (methanol = 0.21 min^{-1}, water = 0.098 min^{-1}). An example of the evaporation study for methanol is given in Fig. 4. The rate constants of evaporation (k_{ev}) for these compounds were as expected, with the more volatile compound having the greater value. If these values represent an accurate approximation of evaporation rates *in vivo*, then the total rate constant for loss can be calculated as the sum of k_{10} and k_{ev}. For methanol, the total loss rate constant (0.71 min^{-1}) is ~40% higher than for nonvolatile compounds (0.5 min^{-1}).

To verify that methanol was not penetrating at a rapid rate due to toxic destruction of the corneal barrier, fluorometholone acetate was coadministered. Results were identical to fluorometholone acetate levels obtained without methanol.

The plots of C_{max} *versus* the log partition coefficient provide some insight into the relationships of the corneal penetration mechanism and the partition coefficient. Of particular interest is the observation that a clear dual-parabolic shape is demonstrated in the plot which includes only non-ionizable species (Fig. 5). This is consistent with predictions derived from the concept of the corneal epithelium or stroma as rate-limiting membranes depending on the partitioning properties of the absorbing drug. It is also important to note that on a molar basis, small molecular weight (water-soluble) species such as methanol and ethanol have greater corneal permeability than larger molecular weight compounds. This argues against the conclusions of some investigators, who have postulated that water-soluble compounds should show little or no corneal absorption. A similar relationship between partition coefficient and aqueous humor drug levels for ionized species is not clear, as shown in Fig. 6.

DISCUSSION

Vehicle Effects—Increasing vehicle viscosity from 1 to 90 cps did not result in an increase in aqueous humor levels for compounds whose log partition coefficients ranged from 1 to 4. This is consistent with the expectation that these lipid-soluble drugs quickly partition into the corneal epithelium. Thus, the limited increase in contact time afforded by low-viscosity solutions should not and does not improve their bioavailability. Propranolol data are also consistent with this expectation, since this compound has a relatively high partition coefficient. Despite the fact that propranolol is largely ionized at physiological pH, the favorable partition coefficient of the un-ionized species predicts that no effect is expected from an increase in viscosity of administered solution. It is anticipated that the un-ionized species will account for the majority of penetrating drug; therefore, the high degree of ionization also accounts for the decreased bioavailability of propranolol when compared with a steroid with a similar partition coefficient (such as hydrocortisone).

The effects of viscosity on water-soluble compounds indicate that, for these species, the mechanism(s) of corneal penetration are not well understood. Based on the partition coefficient alone, un-ionized water-soluble species such as glycerol or methanol are predicted to show modest increases in bioavail-

[8] Unpublished results.

ability from a viscous solution. Related processes, such as the possible water structuring of glycerol, may account for this discrepancy. Structured water could greatly inhibit transport of even a small molecule through a highly lipid membrane; also, water structuring may not be fully reflected in an equilibrium partition coefficient measurement.

For methanol, the apparently high rate of corneal penetration, in light of its small molecular size, suggests that this compound may be passing through aqueous channels. No significant improvement in bioavailability is demonstrated with a viscous solution. It is obvious that the rate of transfer from the epithelium to the stroma for this compound will be very high (high k_{23}). This explains the very short peak time and, to some extent, the substantial levels of compound in the aqueous humor. The lack of improvement with a low-viscosity solution for methanol suggests several possibilities. The first is that of a saturable mechanism within the epithelium, since a compound which already demonstrates saturable kinetics in the epithelial layer from a 1-cps solution should reflect little improvement from moderately increased precorneal residence time. This proposes that methanol enters the epithelium at a fairly fast rate to a maximum solubility of the compound. Partitioning across this barrier occurs, followed by very fast transfer from the epithelium to the stroma and aqueous humor. The relatively low partition coefficient and linear change in aqueous humor levels with changes in dosing concentration, however, argue against this explanation.

An alternate explanation for the lack of a viscosity effect on methanol bioavailability requires a calculated estimate for k_{12}. Using the peak concentration to give a rough estimate of the fraction of dose absorbed, since an accurate calculation of area under the curve is not possible, methanol demonstrates an ~30-fold increase over pilocarpine. Using Eq. 1, it is possible to calculate an estimate of k_{12}. For methanol, the total loss rate constant, including evaporation, is ~0.71 min^{-1}. This provides an estimate for k_{12} of 0.3 min^{-1}. Decreasing residence time by a factor of 10 and maintaining the evaporation rate constant reduces k_{10} to 0.26 min^{-1}. An estimate of the fraction absorbed from Eq. 1 predicts a value of 0.53 or a maximum increase of ~1.75. As with pilocarpine, this calculation represents the maximum increase expected with a 10-fold increase in precorneal residence time, neglecting all other precorneal factors. In light of the fact that pilocarpine demonstrates only a factor of two increase from a calculated maximum of nine, little increase should be expected with methanol. Close inspection of these calculations reveals that the increase in k_{10} is responsible for the dramatic decrease in the effect of viscosity. Since reduction of residence time should have no effect on the rate constant for evaporation (k_{ev}), the total loss rate constant remains relatively high. For example, if the approximation of the fraction of methanol absorbed has been overestimated by a factor of two (*i.e.*, k_{ev} decreases to 0.15 min^{-1}), this only changes the estimation of maximum benefit from a viscous solution to 2.1.

It is interesting that only pilocarpine and, to some extent, pyrilamine demonstrate vehicle effects in rabbits. Note that as the partition coefficient increases from that of pilocarpine to pyrilamine, the effect from a viscous solution decreases, as expected. Of importance also is the observation that as the percent increase falls below 50%, it becomes more difficult to discern statistical differences in the values between 1- and 90-cps solutions. This indicates that in an ideal situation, where errors in biological data were greatly reduced, the trends demonstrated for prednisolone and hydrocortisone could be the minimal increases in bioavailability expected for compounds with this range of partition coefficients. It should also be kept in mind that the rabbit, as a model for human ocular kinetics, apparently demonstrates much less sensitivity to viscous solutions than the human eye does for vehicles in this viscosity range (22).

Complicating the results for ionizable compounds is the possibility of penetration of ionized species through the cornea. Evidence of possible ionized drug movement through the cornea has been documented for cromolyn sodium[9]. This compound, with a pK_a of 2.0, is almost totally ionized at physiological pH; yet, significant drug levels in aqueous humor from solution dosing have been reported[9] in rabbits and confirmed in this laboratory.

In light of the results with compounds of relatively high log partition coefficients (1.0–4.0), one can visualize the epithelial layer acting in the same manner as a viscous solution for the ionizable water-soluble compounds, maintaining drug concentration at the rate-limiting membrane.

Partition Coefficient Relationships—The plot of aqueous humor drug concentration at 20 min *versus* partition coefficient for un-ionized compounds, Fig. 5, is a dual parabolic shape, consistent with expectations based on the proposed model of corneal penetration. In the high log partition coefficient range (1.0–4.0), a parabolic-shaped curve is indicated, although it is not as well defined as expected. It is obvious that compounds such as prednisolone and hydrocortisone do not penetrate the epithelial layer as well as fluorometholone or fluorometholone acetate, and that progesterone partitions well into the epithelial layer but has extremely poor partitioning characteristics from this layer to the stroma (decrease in k_{23}). The relatively low aqueous humor bioavailability for these drugs may be partially due to an increase in nonproductive absorption, since partitioning through these tissues, *e.g.*, the conjunctiva and nictitating membrane, will increase as partitioning increases into the epithelium.

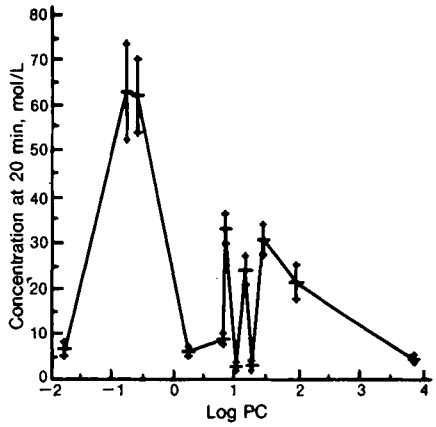

Figure 6—*Plot of molar concentration* versus *log partition coefficient for un-ionized and ionizable species.*

The curve depicted in Fig. 5 shows a much more defined peak than the *in vitro* data presented by Schoenwald and Ward (4). The reasons for this may be twofold. First, the plateau effect seen in the Schoenwald and Ward (4) data may be due to saturation of the system at partition coefficients near the "peak"; therefore, no defined peak is observed. Second, effects from changes in precorneal disposition cannot be accounted for in these *in vitro* studies. With a low partition coefficient, drug is lost to a greater extent by tear turnover and drainage. As the partition coefficient increases, corneal absorption increases in a relative manner, and relative drainage loss decreases. At very high partition coefficient values, nonproductive absorption greatly increases; hence, the sharp peak in the curve of the aqueous humor drug level *versus* the log partition coefficient.

As the o/w partition coefficient increases, the concept of a changing rate-limiting membrane predicts that the peak time should increase, since partitioning into the stroma becomes less favorable. This represents a decrease in k_{23} and should result in an increase in t_{max} and a corresponding decrease in C_{max}. It appears that this expected shift in peak time is obscured by the biological variability of the data. Although the means of the concentrations for the steroid compounds demonstrate a progressive increase in peak time with increasing partition coefficients, this is at a low level of significance ($p > 0.01$). In general, the expected decrease in C_{max} from a decrease in k_{23} appears offset by the increase in corneal absorption (k_{12}) due to favorable partitioning into the epithelium. The change in k_{12}, as previously noted, has no effect on peak time.

In the low log partition coefficient range (−2.0–1.0), a parabolic trend is also observed. This is most likely due to a combination of partitioning effects from the tears to the epithelium and then to the stroma. The peak in this region is due to the fact that compounds here have the best combination of partitioning characteristics in the water-soluble range. At the extreme ranges, drugs with the lowest partition coefficients cannot readily pass the epithelial layer (low k_{12}), and no matter how ideal their partitioning to the stroma (k_{23}), only low levels will be found in the aqueous humor. At the upper end of the water-soluble range, and the lower end of the oil-soluble range, it is probable that these compounds have both the epithelial layer and the stroma as rate-limiting membranes (low k_{12} and k_{23}), and therefore, have poor corneal permeability. The validity of the dual-parabolic shape of these results rests on the significance of the data for prednisolone and hydrocortisone. These data points are in substantial agreement with those of Schoenwald and Ward (4).

Water and Small Molecule Permeation—When low molecular weight alcohols were used, their rate of corneal penetration was much faster than the rate of most other molecules. Since the rate of elimination from the precorneal area by tear turnover should be essentially the same for these compounds as for all others, the shorter peak time observed must be due to an increase in transfer of drug from the epithelium to the stroma (k_{23}). Important to this discussion are results reported by Donn *et al.* (23) from a study utilizing $[^3H]H_2O$ and $[^{18}O]H_2O$. These investigators concluded that the transport for these two molecules was the same, within experimental error, thus ruling out the possibility of hydrogen ion transport as opposed to molecular transport

[9] V. H.-L. Lee, unpublished results.

for tritiated water. Significantly, they concluded that there is no active transport of water and that diffusion of water in the epithelium and endothelium is very close to the rate of diffusion for this molecule in the stroma, which is composed of 70–80% water. Since water and methanol are both compounds of small molecular size, the above comments concerning the possibility of paracellular penetration through the epithelium are strengthened. Such a pathway has been proposed by Kaiser and Maurice for fluorescein (24). This leads to a mechanistic picture of drug movement through the epithelium, where both transcellular and paracellular routes for drug permeation are possible and probable for water-soluble drugs. It is anticipated that transcellular drug penetration would be related to the partition coefficient, whereas paracellular movement would more likely be related to characteristics such as molecular size and aqueous diffusivity.

Ocular Metabolism—The results of metabolism studies in this work clearly indicate that, over the time period of 20–30 min in albino rabbits, the drug entities examined are not subject to appreciable degradation. Previously published work in the area of ocular metabolism must be considered before allowing such a simple conclusion. It is well documented that metabolism of pilocarpine is minimal in albino rabbits but increases in mixed breeds (25); since all work herein has been with albino species, this discussion will be restricted to studies using these animals. Studies in the area of ocular metabolism are limited in number, and the activity of different ocular enzymes appears variable; *i.e.*, pilocarpine undergoes minimal degradation, whereas dipivefrin demonstrates significant corneal metabolism (25, 26). The degradation of atropine is dependent on atropine esterase, which is inherited through an incompletely dominant trait (27). Mydriatic response to atropine is significantly less in a rabbit with positive esterase than one without the enzyme.

The area of steroid metabolism is equally confusing. One study (20) indicates that prednisolone acetate is metabolized completely to the parent alcohol, and one would therefore expect similar results with fluorometholone acetate. However, minimal metabolism was detected despite the fact that two different solvent systems were used which could potentially separate the acetate and alcohol forms. Another study (28) utilizing steroid alcohols and ketones, reports metabolites of $\leq 15\%$ from corneal and iris–ciliary tissue incubates. The results of these investigations agree with the present study for both hydrocortisone and progesterone. The subject of ocular metabolism, its mechanism and location, is one which requires additional research.

Dynamic *versus* Equilibrium Correlation—The original concept relating drug action to the partition coefficients, by Meyer (29) and Overton (30, 31), or to log partition coefficients, by Hansch and co-workers (32, 33), demonstrated relationships between lipophilic character and biological activity. Many of these examples deal with drugs that bind to enzymes, other proteins, or receptor sites. Current attempts to relate the partition coefficient and corneal penetration of compounds must rely on the fact that partitioning into the corneal layers mimics an equilibrium phenomenon: this is in fact difficult to imagine in the eye. Administered drugs have finite contact time with the corneal tissues. The dynamic aspect of corneal penetration is, therefore, being correlated with an equilibrium value of the partition coefficient; thus, one would not expect a good correlation between corneal absorption and the partition coefficient.

A significant rate of loss (k_{10}) controls the amount of drug reaching the target tissue, so steady-state kinetics, which should be accurately reflected by the partition coefficient, are not expected. Compounds with a very high rate of oil or water solubility can be expected to transfer more rapidly to their respective membrane of favorable partitioning. Therefore, some method of correlating the rate of partitioning with corneal penetration is desirable and is currently being pursued in this laboratory.

In summary, the present study has demonstrated that, as anticipated, a low-viscosity solution affords no benefit to compounds with a log partition coefficient >1.0. For these compounds, the rate-limiting membrane for corneal penetration is fairly well defined, although several factors influencing bioavailability, such as metabolism and nonproductive absorption, require further investigation and quantitation. Water-soluble compounds, on the other hand, are not as well understood.

Physical Model Approach in the Study of the Transport of Alkyl Amines Across a Silicone Rubber Membrane in a Two-Chamber Diffusion Cell

DINESH C. PATEL, JEFFREY L. FOX, and WILLIAM I. HIGUCHI *x

Received December 22, 1978, from the *College of Pharmacy, The University of Michigan, Ann Arbor, MI 48109.* Accepted for publication July 26, 1983. *Present address: Department of Pharmaceutics, College of Pharmacy, The University of Utah, Salt Lake City, UT 84112.

Abstract □ The transport of hexylamine and octylamine through a silicone rubber membrane was studied as a function of buffer (phosphate) concentration and pH. The results were interpreted using a physical model which assumed a steady-state rate of transport and which accounted for (*a*) the simultaneous diffusion and rapid equilibrium of all the aqueous species, (*b*) the possible diffusion of both the amine and its protonated form through the membrane, and (*c*) the effect of a stagnant aqueous diffusion layer on each side of the membrane. The following conclusions were reached: (*a*) The thickness of the aqueous diffusion layer is ~100 μm, which is about the same as that previously measured for benzoic acid in this system. Transport of octylamine at pH ≥ 10 is ~90% aqueous diffusion layer controlled, whereas hexylamine is ~50% aqueous diffusion layer controlled at high pH. (*b*) The membrane permeability of octylamine is ~15–20 times that of hexylamine. This gives an incremental π constant for the partition coefficient of ~0.61, as compared with the previously reported value of 0.56. (*c*) At low pH (≤5), the transport of the protonated species becomes important. The membrane permeabilities of these ammonium ions are about four or five orders of magnitude less than the membrane permeabilities of the corresponding amines. The membranes were examined at 30,000× with the scanning electron microscope, and no evidence of holes was found.

Keyphrases □ Diffusion—transport of alkyl amines across a silicone rubber membrane □ Hexylamine—transport across a silicone rubber membrane, octylamine, two-chamber diffusion cell □ Octylamine—transport across a silicone rubber membrane, hexylamine, two-chamber diffusion cell

There is a need for an experimental system in which the transport of weak organic acids and bases across a lipoidal membrane can be studied. There are many situations in biopharmaceutics and therapeutics, including situations involving binding of drugs to macromolecules and micelles, in which such a system would be useful. Stehle and Higuchi (1, 2) have conducted studies on the transport of weak acids and bases across lipoidal membranes; however, these were of a limited nature. They used fiberglass filter disks preloaded with oil-polymer mixtures as lipoidal membranes. These membranes were not entirely satisfactory, as experiments could not be performed in the totally diffusion-controlled region. Also, membrane permeability changes with time were found in some of the experiments which were attributed to changes in the lipid viscosity with time.

Accordingly, this investigation was carried out to develop a rugged experimental system for studying the transport of weak acids and bases across lipoidal membranes and, simultaneously, to develop theoretical methods for analyzing the experimental results on a quantitative basis. We selected a silicone rubber membrane as our model membrane, as several investigators (3–8) have found it suitable for studying drug transport, and employed a standard two-chamber diffusion cell. This membrane may be used in consecutive experiments without significant changes in its permeability characteristics. We modified and adopted the theoretical relationships developed previously by Stehle and Higuchi (1, 2) and Suzuki *et al.* (9, 10) and show how this experimental system and the theoretical relationships can be productively employed in evaluation of pH, buffer concentration, and chain-length effects on the transport of weak bases from aqueous solutions across lipoidal membranes.

It is hoped that the results of these studies can also be used for quantitative determination of macromolecular binding or micellar solubilization of weak acids and bases in aqueous media. It can be argued that, where possible, the use of a lipoidal membrane would be preferred over the cellulose dialysis membrane for studying micellar solubilization of weak acids and bases because of the Donnan membrane effects encountered with cellophane membrane dialysis methods. Also, we hope to use this technique in the study of species distribution and the mechanisms of action of the amine-type cholesterol dissolution rate accelerators (11) in bile.

THEORETICAL SECTION

A physical model approach was utilized to study the transport of hexylamine and octylamine through a silicone rubber membrane as a function of buffer (phosphate) concentration and pH. The model used in this study is very similar to the one developed by Stehle and Higuchi (1, 2), in which a membrane separates two aqueous compartments, with an aqueous diffusion layer on each side of the membrane.

The steady-state model for amine, RN, which is protonated to RNH^+ at lower pH values, is illustrated in Fig. 1. Steady-state diffusion is assumed between donor and receiver compartments, and all relevant equilibria (the various phosphate species, as well as the free and protonated amines) are accounted for. The model allows for diffusion of protonated amine, as well as free amine, through the membrane.

The following equations describe the model under steady-state conditions. G, the total flux of the amine species RN and RNH^+ through each barrier, I–III, is given by:

$$GI = \{D_{RN}[(RN)_L - (RN)_1] + D_{RNH^+}[(RNH^+)_L - (RNH^+)_1]\}/h_1 \quad \text{(Eq. 1)}$$

$$GII = \{P_{RN}[(RN)_1 - (RN)_2] + P_{RNH^+}[(RNH^+)_1 - (RNH^+)_2]\}/h_2 \quad \text{(Eq. 2)}$$

$$GIII = \{D_{RN}[(RN)_2 - (RN)_R)] + D_{RNH^+}[(RNH^+)_2 - (RNH^+)_R]\}/h_3 \quad \text{(Eq. 3)}$$

where the subscripts 1 and 2 indicate the left and right aqueous interfacial locations, respectively, and subscripts L and R refer to the borders of left and right bulk aqueous phases, respectively (Fig. 1). D_{RN} and D_{RNH^+} (cm^2/s) are the aqueous diffusion coefficients of RN and RNH^+, respectively; P_{RN} and P_{RNH^+} are the membrane permeabilities (defined as the product of partition coefficient and diffusion coefficient) of RN and RNH^+, respectively; h_1 and h_3 (cm) are the effective thicknesses of the unstirred aqueous diffusion layers; h_2 is the membrane thickness. G is expressed in $mmol/cm^2 \cdot s$. At steady state, $GI = GII = GIII$.

Since it is assumed that no buffer species can penetrate the lipid phase, the total net flux of the buffer species through each of the two aqueous diffusion layers is zero at steady state. Hence, the equations for J_B, the total net flux of buffer species in the aqueous barriers, can be written as follows:

$$J_{BI} = D_{H_3PO_4}[(H_3PO_4)_L - (H_3PO_4)_1] + D_{H_2PO_4}[(H_2PO_4)_L - (H_2PO_4)_1] + D_{HPO_4}[(HPO_4)_L - (HPO_4)_1] + D_{PO_4}[(PO_4)_L - (PO_4)_1] = 0 \quad \text{(Eq. 4)}$$

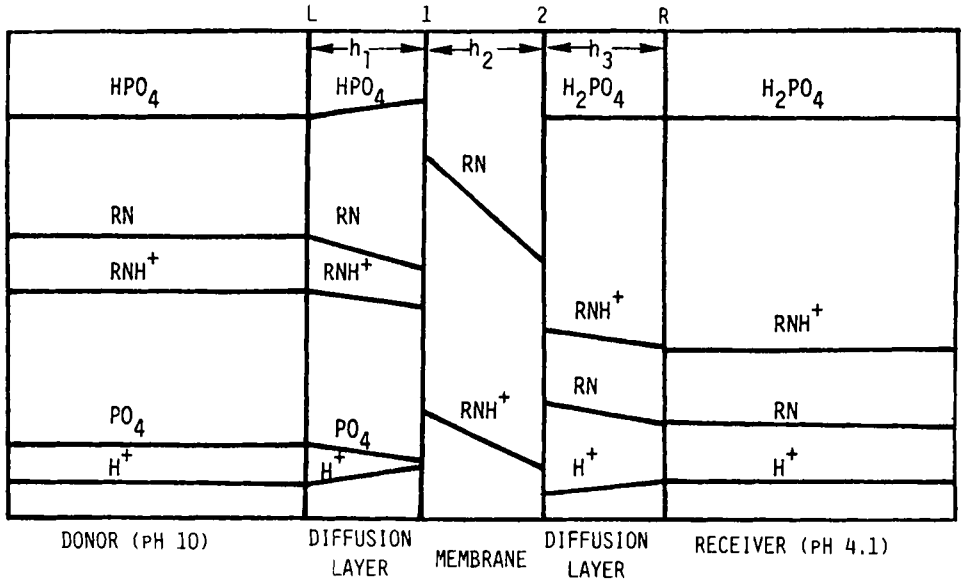

Figure 1—*Three-phase model showing schematic concentration profiles present in steady-state transport of amine, RN. RNH^+ is protonated amine; H_2PO_4, HPO_4, and PO_4 are buffer species (only the predominant species are shown in Fig. 1), and H^+ is hydrogen ion. h_1, h_2, and h_3 are diffusion barrier thicknesses in the three phases.*

$$J_B III = D_{H_3PO_4}[(H_3PO_4)_2 - (H_3PO_4)_R] + D_{H_2PO_4}[(H_2PO_4)_2 - (H_2PO_4)_R] + D_{HPO_4}[(HPO_4)_2 - (HPO_4)_R] + D_{PO_4}[(PO_4)_2 - (PO_4)_R] = 0 \quad \text{(Eq. 5)}$$

J_H, the net flux of H^+ minus the flux of OH^-, occurs *via* the transport of the protonated form of the amine, RNH^+, through the membrane and *via* the transport of all protonated species and also OH^- through the aqueous diffusion layers. The expressions for this quantity are given by:

$$J_{H^+}I = \{D_{RNH^+}[(RNH^+)_L - (RNH^+)_1] + 3D_{H_3PO_4}[(H_3PO_4)_L - (H_3PO_4)_1] + 2D_{H_2PO_4}[(H_2PO_4)_L - (H_2PO_4)_1] + D_{HPO_4}[(HPO_4)_L - (HPO_4)_1] + D_H[(H)_L - (H)_1] - D_{OH}[(OH)_L - (OH)_1]\}/h_1 \quad \text{(Eq. 6)}$$

$$J_{H^+}II = \{P_{RNH^+}[(RNH^+)_1 - (RNH^+)_2]\}/h_2 \quad \text{(Eq. 7)}$$

$$J_{H^+}III = \{D_{RNH^+}[(RNH^+)_2 - (RNH^+)_R] + 3D_{H_3PO_4}[(H_3PO_4)_2 - (H_3PO_4)_R] + 2D_{H_2PO_4}[(H_2PO_4)_2 - (H_2PO_4)_R] + D_{HPO_4}[(HPO_4)_2 - (HPO_4)_R] + D_H[(H)_2 - (H)_R] - D_{OH}[(OH)_2 - (OH)_R]\}/h_3 \quad \text{(Eq. 8)}$$

Analogous to the total amine flux, at steady state $J_HI = J_HII = J_HIII$. In the above equations, $D_{H_3PO_4}$, $D_{H_2PO_4}$, D_{HPO_4}, and D_{PO_4} (cm^2/s) are the aqueous diffusion coefficients of the H_3PO_4, H_2PO_4, HPO_4, and PO_4 buffer species, respectively, and D_H and D_{OH} (cm^2/s) are the aqueous diffusion coefficients of the hydrogen and hydroxyl ions, respectively.

In addition to satisfying the flux relationships expressed in Eqs. 1–8, a valid solution of the model must also satisfy all the chemical equilibrium constraints at each point in the system. These constraints can be written as follows (for n = 1, 2, L, R):

$$(HPO_4)_n = \frac{(H)_n(PO_4)_n}{K_{HPO_4}} \quad \text{(Eq. 9)}$$

$$(H_2PO_4)_n = \frac{(H)_n^2(PO_4)2_n}{K_{H_2PO_4}} \quad \text{(Eq. 10)}$$

$$(H_3PO_4)_n = \frac{(H)_n^3(PO_4)_n}{K_{H_3PO_4}} \quad \text{(Eq. 11)}$$

where $K_{HPO_4} = K_3$, $K_{H_2PO_4} = K_3 \cdot K_2$, and $K_{H_3PO_4} = K_3 \cdot K_2 \cdot K_1$ (K_1, K_2, and K_3 are the dissociation constants of phosphoric acid).

Similarly, for the amine (for n = 1, 2, L, R):

$$K_a = \frac{(RN)_n(H)_n}{(RNH^+)_n} \quad \text{(Eq. 12)}$$

where K_a is the dissociation constant of the protonated amine.

Given these relationships, the model can be used to calculate concentrations and fluxes of all the species at each point in the system when only the compositions of the bulk solutions on each side are given. This calculation is complicated by both the complex equilibria involved and the fact that a solution is sought for a system employing a trilaminar membrane. Nonetheless, the equations can be arranged in such a way that they can be rapidly solved with a digital computer if a program is available for the solution of systems of nonlinear algebraic equations. This particular problem can be reduced to a system of two equations in two unknowns by a number of different approaches. The algebraic approach employed here was to choose pH_1 and pH_2 (the pH values at the membrane surfaces) as the unknowns and, for a given set of values for pH_1 and pH_2, to calculate all the other quantities in such a way that all the problem constraints are satisfied, except for the constraint that $GI = GII = GIII$ at steady state. The nonlinear system solver then determines the values for pH_1 and pH_2 such that the equations $GI = GII$ and $GII = GIII$ are satisfied.

The algebraic procedure for calculating the species concentrations throughout the system for a given trial set of pH_1 and pH_2 values is as follows. First, the concentrations of all the species in the bulk solutions on each side of the membrane are calculated (for n = L, R):

$$(H)_n = 10^{-pH_n} \quad \text{(Eq. 13)}$$

$$(PO_4)_n = P_{tot_n} \Big/ \left(1 + \frac{(H)_n}{K_{HPO_4}} + \frac{(H)_n^2}{K_{H_2PO_4}} + \frac{(H)_n^3}{K_{H_3PO_4}}\right) \quad \text{(Eq. 14)}$$

$$(RN)_n = R_{tot_n} \Big/ \left(1 + \frac{(H)_n}{K_a}\right) \quad \text{(Eq. 15)}$$

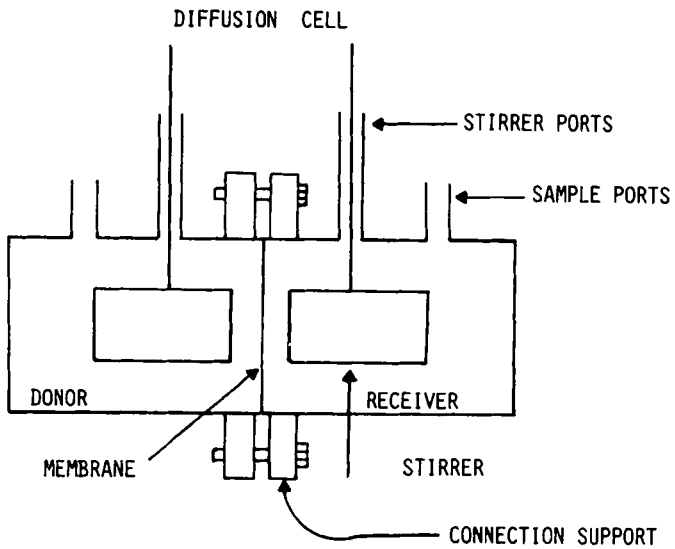

Figure 2—*Two-chamber diffusion cell used in transport studies. At predetermined intervals, donor and receiver solutions were totally replaced for analysis. Cross-sectional transport area was 2.10 cm^2.*

Table I—Typical Permeation Data [a]

Δ Time, h	Concentration, μg/mL Receiver	Donor	Flux, mmol/cm²·s [b]
0	0	546	—
2	9.9	514	5.654×10^{-11}
2	11.5	522	6.606×10^{-11}
2	13.2	519	7.562×10^{-11}
2	12.9	530	7.425×10^{-11}

[a] The system consisted of donor, 5 mM hexylamine, 0.1 M NaCl, and 0.1 M PO_4 (pH 8.5); receiver, 0.1 M NaCl and 0.1 M PO_4 (pH 4.1). [b] From the receiver data.

where P_{tot} and R_{tot} are total concentrations of the phosphate and amine, respectively. The concentrations of the other species can be readily calculated from $(H)_n$, $(PO_4)_n$, and $(RN)_n$ with Eqs. 9-12.

Next, the concentrations of the phosphate species at the membrane interfaces can be calculated by a suitable rearrangement of Eqs. 4 and 5 with appropriate substitutions from Eqs. 9-11. The concentrations of PO_4 at the interfaces are given by:

$$(PO_4)_1 = [D_{H_3PO_4}(H_3PO_4)_L + D_{H_2PO_4}(H_2PO_4)_L + D_{HPO_4}(HPO_4)_L + D_{PO_4}(PO_4)_L] \Big/ \left[D_{H_3PO_4}\frac{(H)_1^3}{K_{H_3PO_4}} + D_{H_2PO_4}\frac{(H)_1^2}{K_{H_2PO_4}} + D_{HPO_4}\frac{(H)_1}{K_{HPO_4}} + D_{PO_4}\right] \quad \text{(Eq. 16)}$$

and:

$$(PO_4)_2 = [D_{H_3PO_4}(H_3PO_4)_R + D_{H_2PO_4}(H_2PO_4)_R + D_{HPO_4}(HPO_4)_R + D_{PO_4}(PO_4)_R] \Big/ \left[D_{H_3PO_4}\frac{(H)_2^3}{K_{H_3PO_4}} + D_{H_2PO_4}\frac{(H)_2^2}{K_{H_2PO_4}} + D_{HPO_4}\frac{(H)_2}{K_{HPO_4}} + D_{PO_4}\right] \quad \text{(Eq. 17)}$$

and the concentrations of HPO_4, H_2PO_4, and H_3PO_4 follow from Eqs. 9-11.

Thus far, for given values of pH_1 and pH_2 we have determined concentrations of the various phosphate species at 1 and 2 so that the net total phosphate flux is zero. The remaining task is to determine the concentrations of RN and RNH^+ at these interfaces that satisfy the equations for total proton flux (Eqs. 6-8). This task is greatly facilitated by defining new variables *RI* and *RIII* such that:

$$RI = J_H I + \frac{D_{RNH^+}}{h_1}(RNH^+)_1 \quad \text{(Eq. 18)}$$

and

$$RIII = J_H III - \frac{D_{RNH^+}}{h_3}(RNH^+)_2 \quad \text{(Eq. 19)}$$

Table II—Model Parameters [a]

Parameter	Known	Computer Fitted
D_{OH}	5×10^{-5} cm²/s	
D_H	9×10^{-5} cm²/s	
D_{RN}, D_{RNH^+} (hexylamine)	1.087×10^{-5} cm²/s	
D_{RN}, D_{RNH^+} (octylamine)	9.880×10^{-6} cm²/s	
$D_{H_3PO_4}$, $D_{H_2PO_4}$, D_{HPO_4}, kD_{PO_4},	10^{-5} cm²/s	
h_1 and h_3	0.009 cm	0.01 cm
h_2	0.0127 cm	
K_1 (H_3PO_4)	7.50×10^{-3}	
K_2 (H_3PO_4)	6.20×10^{-8}	
K_3 (H_3PO_4)	2.10×10^{-13}	
K_a (hexylamine)	2.7542×10^{-11}	
K_a (octylamine)	2.2387×10^{-11}	
P_{RN} (hexylamine)		2.27×10^{-5} cm²/s
P_{RNH^+} (hexylamine)		4.130×10^{-9} cm²/s
P_{RN} (octylamine)		3.88×10^{-4} cm²/s
P_{RNH^+} (octylamine)		3.770×10^{-9} cm²/s

[a] Diffusivities for hexylamine and octylamine were determined experimentally; those for hydrogen and hydroxyl ions were calculated from mobility data. For the phosphate species, we assumed 10^{-5} cm²/s to be a reasonable estimate based on previous experience.

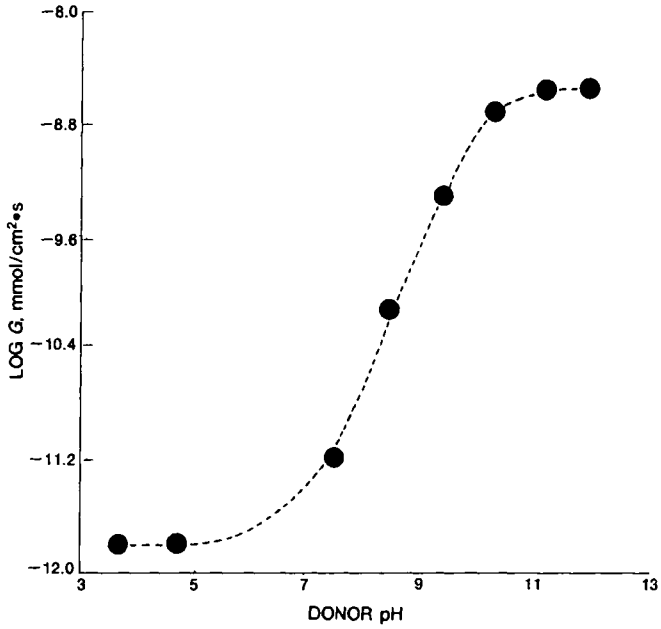

Figure 3—*pH-rate profile for hexylamine diffusing through the silicone rubber membrane into aqueous phase buffered at pH 4.1. The dashed line is a computer-generated line for* $h_1 = h_3 = 100$ *μm,* $h_2 = 127$ *μm,* $P_{RN} = 2.27 \times 10^{-5}$ *cm²/s, and* $P_{RNH^+} = 4.13 \times 10^{-9}$ *cm²/s.*

Numerical values for *RI* and *RIII* are readily obtained by substituting Eqs. 18 and 19 into Eqs. 6 and 8 and rearranging to get:

$$h_1 \cdot RI = D_{RNH^+}(RNH^+)_L + D_H[(H)_L - (H)_1] + D_{HPO_4}\left[(HPO_4)_L - \frac{(H)_1(P)_1}{K_{HPO_4}}\right] + 2D_{H_2PO_4}\left[(H_2PO_4)_L - \frac{(H)_1^2(PO_4)_1}{K_{H_2PO_4}}\right] + 3D_{H_3PO_4}\left[(H_3PO_4)_L - \frac{(H)_1^3(PO_4)_1}{K_{H_3PO_4}}\right] - D_{OH}[(OH)_L - (OH)_1] \quad \text{(Eq. 20)}$$

$$h_3 \cdot RIII = D_{RNH^+}(RNH^+)_R + D_H[(H)_R - (H)_2] + D_{HPO_4}\left[(HPO_4)_R - \frac{(H)_2(PO_4)_2}{K_{HPO_4}}\right] + 2D_{H_2PO_4}\left[(H_2PO_4)_R - \frac{(H)_2^2(PO_4)_2}{K_{H_2PO_4}}\right] + 3D_{H_3PO_4}\left[(H_3PO_4)_R - \frac{(H)_2^3(PO_4)_2}{K_{H_3PO_4}}\right] - D_{OH}[(OH)_R - (OH)_2] \quad \text{(Eq. 21)}$$

Consideration of Eqs. 6, 18, and 19 leads to:

$$h_2 \cdot h_1 \cdot RI = P_{RNH^+} \cdot h_1[(RNH^+)_1 - (RNH^+)_2] + h_2 \cdot D_{RNH^+}[RNH^+]_1 \quad \text{(Eq. 22)}$$

and

$$h_2 \cdot h_3 \cdot RIII = P_{RNH^+} \cdot h_3([RNH^+]_1 - [RNH^+]_2) - h_2 \cdot D_{RNH^+}[RNH^+]_2 \quad \text{(Eq. 23)}$$

or:

$$\begin{pmatrix} h_1 P_{RNH^+} \cdot h_2 D_{RNH^+} & -h_1 P_{RNH^+} \\ h_3 PRNH^+ & -h_3 P_{RNH^+} - h_2 D_{RNH^+} \end{pmatrix} \begin{pmatrix} [RNH^+]_1 \\ [RNH^+]_2 \end{pmatrix} = \begin{pmatrix} h_2 h_1 RI \\ h_2 h_3 RIII \end{pmatrix} \quad \text{(Eq. 24)}$$

Table III—Influence of the Aqueous Diffusion Layer

Donor pH	Receiver pH	Flux, mmol/cm²·s
	Hexylamine	
11.20	11.00	1.987×10^{-9}
11.20	4.10	2.975×10^{-9}
	Octylamine	
11.10	11.00	2.518×10^{-9}
11.10	4.10	4.951×10^{-9}

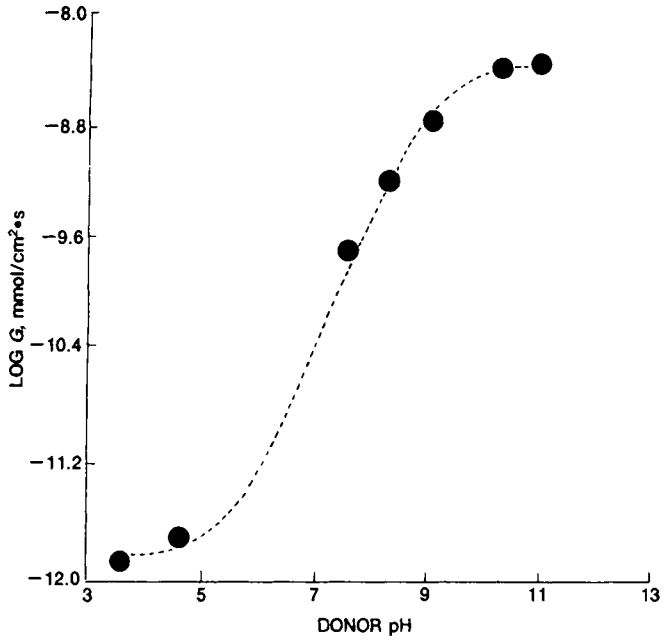

Figure 4—*pH-rate profile for octylamine diffusing through the silicone rubber membrane into aqueous phase buffered at pH 4.1. The dashed line is a computer-generated line for* $h_1 = h_3 = 100\ \mu m$, $h_2 = 127\ \mu m$, $P_{RN} = 3.88 \times 10^{-4}\ cm^2/s$, *and* $P_{RNH^+} = 3.77 \times 10^{-9}\ cm^2/s$.

where every quantity except $(RNH^+)_1$ and $(RNH^+)_2$ has been calculated. This equation is solved for $(RNH^+)_1$ and $(RNH^+)_2$, after which $(RN)_1$ and $(RN)_2$ are calculated from Eq. 12. Finally, *GI*, *GII*, and *GIII* are calculated from Eqs. 1-3 and the functions:

$$f_1 = GI - GII \qquad \text{(Eq. 25)}$$

and:

$$f_2 = GIII - GII \qquad \text{(Eq. 26)}$$

are evaluated. The procedure is repeated, with the nonlinear system solver adjusting the values of pH_1 and pH_2 until f_1 and f_2 are arbitrarily close to zero.

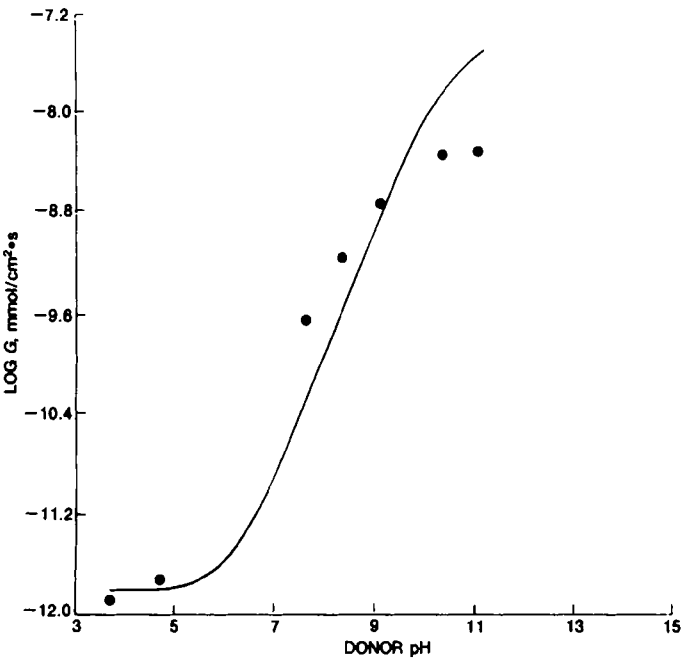

Figure 5—*pH-rate profile for octylamine diffusing through the silicone rubber membrane into aqueous phase buffered at pH 4.1. The solid line is a computer-generated line for* $h_1 = h_3 = 0\ \mu m$, $h_2 = 127\ \mu m$, $P_{RN} = 9.586 \times 10^{-5}\ cm^2/s$, *and* $P_{RNH^+} = 4.017 \times 10^{-9}\ cm^2/s$.

EXPERIMENTAL SECTION

Experimental Design—The overall permeation procedure was designed such that depletion of the donor concentration was negligible during the course of the runs, and the receiver concentration was never an appreciable fraction of the donor concentration. Under these circumstances, the steady-state condition is readily attained.

The presence of the aqueous diffusion layer was studied by conducting studies in which the receiver compartment pH was maintained at pH 11.0 or 4.1. At high pH, the resistance of the aqueous diffusion layer causes a concentration gradient across the aqueous diffusion layer, and permeation of the weak base is reduced. At low pH, the aqueous diffusion layer is "short-circuited," *i.e.*, the aqueous diffusion layer offers no significant resistance to the transport of the weak base. When the aqueous diffusion layers are the main barriers for the weak base transport, elimination of half of the total aqueous diffusion layer resistance should result in ~100% increase in the permeation rate.

To study the influence of pH and buffer concentration on permeation, permeation was measured as a function of donor pH and donor buffer concentration. The pH of the donor compartment was closely monitored. The receiver compartment solution was buffered at pH 4.1 to ensure zero concentration of un-ionized drug; thus, perfect sink conditions were obtained.

Materials—*n*-Octylamine[1], *n*-hexylamine[2], sodium chloride[3], picric acid[4], dichloromethane[5], and sodium phosphate[5] (monobasic and dibasic) were reagent grade and used as received.

Preparation of Membrane—Membranes were cut from sheets of nonreinforced dimethylpolysiloxane[6], reportedly 0.127-cm thick, with a die made especially for the diffusion cell. Initially, they were washed in hot water, thoroughly rinsed with distilled water, and allowed to equilibrate overnight in receiver solution. Fresh membrane was used for each experiment.

Diffusion Cell—The diffusion cell consisted of two cylindrical half-cells, with inside diameters of ~1.5 cm and depths of ~5 cm. This gave a half-cell volume of ~9 mL. The cell halves were assembled, with the membrane between half-cells (Fig. 2), using polytef connection supports. The entire cell was immersed in a constant-temperature bath. The cell contents were stirred with small stirrers on shafts driven at 150 rpm by a constant-speed motor.

Permeation Procedure—Donor solution (9 mL) was placed in one half-cell, and 9 mL of receiver solution was placed in the other half-cell. The receiver solution consisted of 0.1 M NaCl and 0.1 M phosphate buffer. The donor

The dashed line is a computer-generated line for* $h_1 = 0$ *μm,* $h_2 = 127$ *μm,* $h_3 = 100$ *μm,* $P_{RN} = 3.88 \times 10^{-4}$ *cm²/s, and* $P_{RNH^+} = 3.77 \times 10^{-9}$ *cm²/s.*

solution consisted of the amine and 0.1 M NaCl in 0.1 M phosphate buffer. The contents of each half-cell were stirred at 150 rpm. At predetermined intervals, donor and receiver solutions were totally replaced for analysis. The total time involved in the exchange of the solutions was 1–2 min. The experiment was continued until the difference between two consecutive receiver compartment concentrations was <5%. The average of these concentrations was then used to calculate the flux under essentially steady-state conditions.

The amine analysis involved complexation of the amine with picric acid. The concentration of this picrate complex was determined spectrophotometrically. Receiver solution (5 mL) was shaken in a separatory funnel with two successive portions of 10 and 15 mL of a 0.2% solution of picric acid in dichloromethane. The two portions were drawn off, and the absorbance of these solutions was determined spectrophotometrically at a wavelength of 420 nm[7]. Picric acid was used as the reagent here for assaying the amines because it has a strong absorption spectrum and a single strong anionic functional group that has been shown to react quickly and quantitatively with the base (12, 13).

Except at low pH (pH $\lesssim$ 6.0), the typical uncertainty in the flux determination was on the order of 5%. At low pH, because of the extremely low fluxes, the errors were relatively large (~25–50%).

RESULTS AND DISCUSSION

Table I shows typical transport data, from which it can be seen that a 5% error in the donor compartment would result in ~ ±26 μg/mL scatter; this scatter is greater than the amount transported across the membrane. Hence, it was decided to calculate the flux from the receiver compartment data only. Typically, steady-state conditions were attained within 2–4 h.

The initial steady-state flux into the receiver compartment is given by:

$$\text{Flux} = \frac{V}{A} \cdot \frac{dC}{dt} = k \cdot C_0 \text{ mmol/cm}^2 \cdot \text{s} \qquad \text{(Eq. 27)}$$

where V is the donor compartment volume, A is the diffusional area of the membrane, dC/dt is the rate at which drug permeates the membrane under steady-state conditions, C_0 is the concentration differential across the membrane (assumed to be initial donor concentration), and k is the permeability constant. Thus, k can be calculated from the experimental data by:

$$k = \frac{V \cdot \frac{dC}{dt}}{A \cdot C_0} \qquad \text{(Eq. 28)}$$

Variation in flux from run to run was 5–10% when the fluxes were $>10^{-11}$; for fluxes $<10^{-11}$ cm²/s, variation was 25–50%. Table II shows the values of various model parameters. Of the model parameters, the only unknown is the membrane permeability (defined as the partition coefficient multiplied by diffusivity) which is obtained by computer fitting (14).

Using nonlinear least-squares regression, best values were found for the membrane permeabilities and the aqueous diffusion layer thickness by the following technique. Trial values for the unknown parameters were assumed. Then, Eqs. 1–26 were solved, as described above, to calculate flux as a function of solution composition. The calculated values were compared with the experimentally observed fluxes, and the sum of the squares of the relative differences between calculated and observed fluxes was computed. Then, new values were chosen for the unknown parameters, and the procedure was re-

[7] Model 139, Hitachi Perkin-Elmer UV-V15 Spectrophotometer; Hitachi Ltd., Japan.

Table IV—Influence of Buffer Concentration on Hexylamine

Donor pH	Flux, mmol/cm²·s	
	0.1 M PO_4	0.01 M PO_4
12.05	3.334×10^{-9}	3.269×10^{-9}
9.50	5.210×10^{-10}	1.696×10^{-10}
7.50	7.154×10^{-12}	7.200×10^{-12}

peated. This entire cycle was repeated using a nonlinear least-squares fitting program until the sum of squares was minimized.

For both compounds, the diffusion layer thickness was found to be ~100 μm. The membrane permeabilities were as follows (cm²/s): free hexylamine, 2.27×10^{-5}; protonated hexylamine, 4.13×10^{-9}; free octylamine, 3.88×10^{-4}; protonated octylamine, 3.77×10^{-9}. Figures 3 and 4 show the experimental fluxes and theoretical fluxes based on parameter values shown in Table II. Over a range of more than 7 pH units and three orders of magnitude of flux, the model gives an essentially perfect fit to data.

Table III shows the influence of high and low pH in the receiver compartment on permeation. At low pH, the aqueous diffusion layer in the receiver compartment is essentially "short-circuited," *i.e.*, the effective transport resistance is very low. For octylamine under these conditions, this is an ~100% increase in flux, which indicates that the transport is essentially 100% aqueous diffusion layer controlled for this solute. However, for hexylamine, it can be seen that there is only an ~50% increase; this means that the membrane transport resistance is an appreciable part of the overall resistance in the case of hexylamine.

The thickness of the aqueous diffusion layer was independently evaluated by mounting a benzoic acid pellet onto the half-cell. The thickness was calculated from:

$$J/A = \frac{D(C_s - C_b)}{h} \qquad \text{(Eq. 29)}$$

where J is the dissolution rate (flux), A is the surface area of dissolving solid exposed to the solution, C_s is the concentration of the solute in the solution at saturation, C_b is the concentration of the solute in the bulk, D is the diffusion coefficient of the solute in the solvent (1.4×10^{-5} cm²/s at 37°C), and h is the Nernst effective diffusion layer thickness. Under sink conditions, $C_b = 0$; J/A and C_s were experimentally determined, and the value of D has been well documented previously (15). The thickness of the aqueous diffusion layer was found to be 90 μm. Hence, the computer-fit value of 100 μm is reasonable.

To determine whether the experimental data could fit a model in which there were no aqueous diffusion layers, *i.e.*, $h_1 = h_3 = 0$, best values were found for the membrane permeabilities using nonlinear least-squares regression and values listed in Table II, except for the membrane permeabilities and the aqueous diffusion layer thickness. Figure 5 shows the best fit when the aqueous diffusion layers are totally neglected. As can be seen under such circumstances, *i.e.*, when $h_1 = h_3 = 0$, the fit between the experimental values and the values predicted by the model is rather poor.

To assess the importance of the aqueous diffusion layers and the membrane permeabilities of the protonated species on the steady-state flux, computer simulations were made using the model parameters listed in Table II but excluding the parameter of interest. Figures 6 and 7 show that if the aqueous diffusion layer of the donor compartment is left out, the fluxes are significantly greater at the higher pH values. This shows that the aqueous diffusion layer is important, and significant errors in the analysis may result when it is ignored.

Figures 8 and 9 show the expected behavior if no protonated amine species were diffusing through the membrane. The theoretical fluxes were much smaller than the experimental fluxes at lower pH values. This clearly indicates that protonated amines are diffusing through the membrane, although they have much lower apparent membrane permeabilities than the free amines. These membranes were examined *via* scanning electron microscopy at 30,000×, and no evidence of holes was found, which supports the hypothesis of a true diffusion through the membrane of the protonated species.

Table IV shows the influence of buffer concentration on permeation. At pH values at which the buffer capacity is good (pH 12.05 and 7.50), the buffer concentration has no significant influence on permeation. At pH 9.5, at which the buffer capacity is poor, a lower flux was observed when the buffer strength was 0.01 M. This was the result of a drop in the bulk pH of ~1 pH unit at the lower buffer concentration, which was theoretically predicted and experimentally observed.

Figure 10 shows the effect of the alkylamine chain length. The membrane permeability of octylamine is 15–20 times that of hexylamine. If it is assumed that the membrane diffusivities of these two compounds are about equal, this leads to an incremental π constant for the partition coefficient per methylene group of ~0.61, which is in good agreement with the value of 0.56 reported by Flynn and Yalkowsky (16).

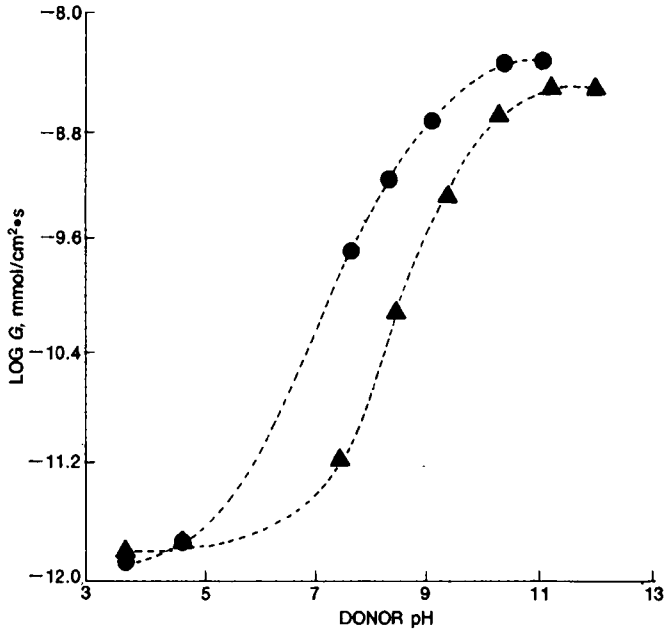

Figure 10—*Influence of chain length on flux. Assuming that the membrane diffusivities of these two compounds are approximately equal, it leads to an incremental π constant for the partition coefficient of ~0.61 per methylene group. Key: (●) octylamine; (▲) hexylamine.*

CONCLUSIONS

We have developed a rugged experimental system for studying the transport of weak acids and bases across a lipoidal membrane and developed theoretical methods for analyzing the experimental results on a quantitative basis. The experimental system consisted of the two aqueous phases separated by silicone rubber membrane. The experimental data were analyzed by utilizing theory, which takes into account the simultaneous diffusion and equilibria among all species (the various buffer species as well as the free and protonated amine), pH, and aqueous diffusion layers on both sides.

These results are conclusive evidence of the existence of aqueous diffusion barriers, as well as their effect on transport rates of solutes under varying conditions in a three-phase model. A true diffusion through the membrane of the protonated species was shown. The incremental π constant for the partition coefficient per methylene group was found to be 0.61, which is in good agreement with the value reported by Flynn and Yalkowsky (16).

Since charged bile acid micelles are not transported across the membrane, it should be possible to evaluate the degree of micellar solubilization of the amines if the study were carried out at pH 7.5–8.5, where aqueous diffusion layer effects are not important. As the un-ionized form of the amine is the major species diffusing through the membrane, the flux is the direct measurement of the thermodynamic activity of the un-ionized species and can be measured accurately, as the Donnan membrane effects encountered with cellophane membrane dialysis methods are absent.

Sintering Technique for the Preparation of Polymer Matrices for the Controlled Release of Macromolecules

JONATHAN COHEN *‡, **RONALD A. SIEGEL** §¶△, **and ROBERT LANGER** *¶‖x

Received September 13, 1982, from the *Department of Nutrition and Food Science, ‡Department of Materials Science and Engineering, §Department of Electrical Engineering and Computer Science, ¶Whitaker College of Health Sciences, Technology, and Management, Massachusetts Institute of Technology, Cambridge, MA 02139; and ‖Department of Surgery, Children's Hospital Medical Center, Boston, MA 02115. Accepted for publication July 28, 1983. △Present address: Department of Pharmaceutics, School of Pharmacy, University of California at San Francisco, San Francisco, CA 94143.

Abstract □ A new method for making polymeric systems for the controlled release of macromolecular drugs is described. The method consists of mixing drug and polymer (ethylene-vinyl acetate copolymer) powders below the glass transition temperature of the polymer and compressing the mixture at a temperature above the glass transition point. The macromolecule is not exposed to organic solvent during the fabrication process. Kinetic studies indicate that there is sustained release, and the bioactivity of macromolecules tested is unchanged throughout the sintering and release processes.

Keyphrases □ Copolymers—ethylene-vinyl acetate, controlled release of macromolecules □ Sustained release—macromolecules, ethylene-vinyl acetate copolymer □ Sintering technique—preparation of ethylene-vinyl acetate copolymer, controlled release of macromolecules

Previous studies (1, 2) have shown that controlled-release systems for macromolecules can be formulated by dissolution of ethylene-vinyl acetate copolymer in an organic solvent (dichloromethane), adding powdered macromolecule, casting the mixture in a mold at low temperature, and vacuum drying. However, the addition of solvent during the casting procedure may cause denaturation of certain macromolecules. In addition, the removal of the casting solvent in the drying step is time consuming and leads to shrinkage with possible shape distortion of the matrix. This report describes a 37°C sintering technique which takes advantage of the low glass transition temperature (−36.5°C) of ethylene-vinyl acetate copolymer and eliminates the need for solvent casting.

EXPERIMENTAL SECTION

Polymer Glass Transition Temperature—The glass transition temperature (T_g) of ethylene-vinyl acetate copolymer was determined with a differential scanning calorimeter[1] (3).

Matrix Preparation—Ethylene-vinyl acetate copolymer[2] was converted into a powder by one of two methods. The first method involved the dissolution of 3 g of ethylene-vinyl acetate copolymer in 20 mL of dichloromethane[3]. The solution was extruded dropwise, with a 50-mL syringe[4] fitted with a hypodermic needle[5], into a 250-mL beaker containing 100 mL of liquid nitrogen. From this point on, all instruments that came into contact with the frozen polymer solution were cooled with liquid nitrogen and, whenever possible, precooled in a freezer to minimize the quantity of liquid nitrogen needed for cooling.

The frozen droplets were ground for 5 min with a mortar and pestle. The powder was then spread evenly over three 20.3 × 20.3-cm glass sheets that were cooled to −10°C. The glass sheets were returned to a −10°C freezer for 2 h. At the end of that time, most of the solvent had evaporated, leaving a stringy powder. This powder was removed with a razor blade, bathed in a 100-mL beaker[6] with 30 mL of liquid nitrogen, and then ground to a fine powder with a mortar and pestle as described above. This powder was placed under vacuum for 2 h. The bulk powder was sieved to specific size ranges with a stack of graduated sieves[7]. Polymer powder prepared by this method is referred to here as powder I.

Powder I was produced under two aging conditions. In one set of experiments, the powder was dried under vacuum for 2 h at room temperature. This is referred to here as "fresh" powder I. In the other set of experiments, the powder was dried under vacuum for 2 h and then left in a covered petri dish for 1 week at room temperature. This is referred to here as "aged" powder I.

In the second method of powder preparation, 20 g of ethylene-vinyl acetate copolymer beads[2] were cooled in 40 mL of liquid nitrogen and placed in an electric mill[8]. The mill was set for 90-s grinding intervals. Between grindings, the polymer beads were cooled with 20-mL portions of liquid nitrogen. During the grinding process, cold nitrogen vapor was circulated around the sample chamber through the cooling ducts of the chamber. The powder collected around the outer edges of the sample chamber and could be extracted with a spatula after the second grinding and after every successive grinding. After the eighth grinding, ~4 g of frozen pellets was added to restore the sample to its original volume. This process was repeated until sufficient powder was collected to prepare the samples. The ground polymer powder was then sieved to specific size ranges with a stack of graduated sieves in an automatic sieve shaker[9] at −40°C. Polymer powder prepared by this second method is referred to here as powder II.

Studies were performed on both powders with either a specific particle size range (90–180 μm) or a mixture of sizes as described in Table I. To formulate the controlled-release system, macromolecular drug powder was sieved to a particle size range of 90–180 μm. Macromolecule and polymer powders, a total of 1.0 g, were placed in a plastic weighing boat[10], which was then

Abstract □ A new method for making polymeric systems for the controlled release of macromolecular drugs is described. The method consists of mixing drug and polymer (ethylene-vinyl acetate copolymer) powders below the glass transition temperature of the polymer and compressing the mixture at a temperature above the glass transition point. The macromolecule is not exposed to organic solvent during the fabrication process. Kinetic studies indicate that there is sustained release, and the bioactivity of macromolecules tested is unchanged throughout the sintering and release processes.

Keyphrases □ Copolymers—ethylene-vinyl acetate, controlled release of macromolecules □ Sustained release—macromolecules, ethylene-vinyl acetate copolymer □ Sintering technique—preparation of ethylene-vinyl acetate copolymer, controlled release of macromolecules

Previous studies (1, 2) have shown that controlled-release systems for macromolecules can be formulated by dissolution of ethylene-vinyl acetate copolymer in an organic solvent (dichloromethane), adding powdered macromolecule, casting the mixture in a mold at low temperature, and vacuum drying. However, the addition of solvent during the casting procedure may cause denaturation of certain macromolecules. In addition, the removal of the casting solvent in the drying step is time consuming and leads to shrinkage with possible shape distortion of the matrix. This report describes a 37°C sintering technique which takes advantage of the low glass transition temperature (−36.5°C) of ethylene-vinyl acetate copolymer and eliminates the need for solvent casting.

EXPERIMENTAL SECTION

Polymer Glass Transition Temperature—The glass transition temperature (T_g) of ethylene-vinyl acetate copolymer was determined with a differential scanning calorimeter[1] (3).

Matrix Preparation—Ethylene-vinyl acetate copolymer[2] was converted into a powder by one of two methods. The first method involved the dissolution of 3 g of ethylene-vinyl acetate copolymer in 20 mL of dichloromethane[3]. The solution was extruded dropwise, with a 50-mL syringe[4] fitted with a hypodermic needle[5], into a 250-mL beaker containing 100 mL of liquid nitrogen. From this point on, all instruments that came into contact with the frozen polymer solution were cooled with liquid nitrogen and, whenever possible, precooled in a freezer to minimize the quantity of liquid nitrogen needed for cooling.

The frozen droplets were ground for 5 min with a mortar and pestle. The powder was then spread evenly over three 20.3 × 20.3-cm glass sheets that were cooled to −10°C. The glass sheets were returned to a −10°C freezer for 2 h. At the end of that time, most of the solvent had evaporated, leaving a stringy powder. This powder was removed with a razor blade, bathed in a 100-mL beaker[6] with 30 mL of liquid nitrogen, and then ground to a fine powder with a mortar and pestle as described above. This powder was placed under vacuum for 2 h. The bulk powder was sieved to specific size ranges with a stack of graduated sieves[7]. Polymer powder prepared by this method is referred to here as powder I.

Powder I was produced under two aging conditions. In one set of experiments, the powder was dried under vacuum for 2 h at room temperature. This is referred to here as "fresh" powder I. In the other set of experiments, the powder was dried under vacuum for 2 h and then left in a covered petri dish for 1 week at room temperature. This is referred to here as "aged" powder I.

In the second method of powder preparation, 20 g of ethylene-vinyl acetate copolymer beads[2] were cooled in 40 mL of liquid nitrogen and placed in an electric mill[8]. The mill was set for 90-s grinding intervals. Between grindings, the polymer beads were cooled with 20-mL portions of liquid nitrogen. During the grinding process, cold nitrogen vapor was circulated around the sample chamber through the cooling ducts of the chamber. The powder collected around the outer edges of the sample chamber and could be extracted with a spatula after the second grinding and after every successive grinding. After the eighth grinding, ~4 g of frozen pellets was added to restore the sample to its original volume. This process was repeated until sufficient powder was collected to prepare the samples. The ground polymer powder was then sieved to specific size ranges with a stack of graduated sieves in an automatic sieve shaker[9] at −40°C. Polymer powder prepared by this second method is referred to here as powder II.

Studies were performed on both powders with either a specific particle size range (90–180 μm) or a mixture of sizes as described in Table I. To formulate the controlled-release system, macromolecular drug powder was sieved to a particle size range of 90–180 μm. Macromolecule and polymer powders, a total of 1.0 g, were placed in a plastic weighing boat[10], which was then

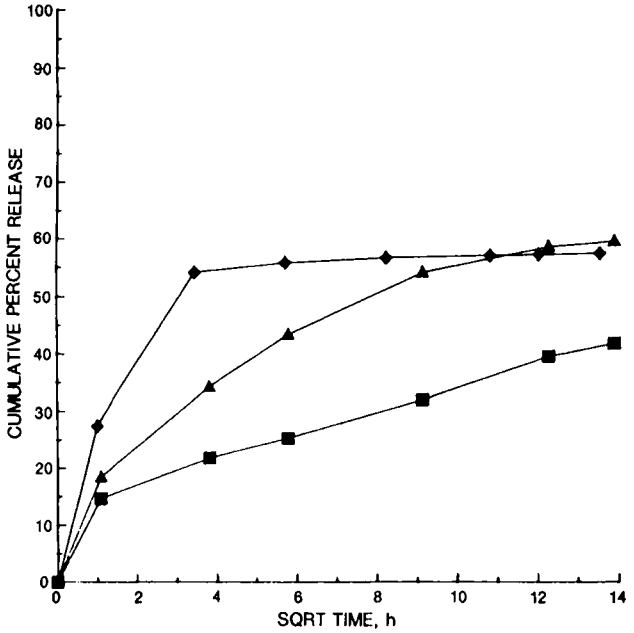

Figure 1—*Release kinetics for 25% (w/w) albumin slabs: effect of polymer powder type. Matrices were cast with a mixed particle size range (Table I) and with a formation pressure of 10.5 MPa. Key: (■) fresh powder I; (▲) aged powder I; (◆) powder II.*

transferred to a baking dish[11] containing liquid nitrogen at a depth of 1 cm. The powders were mixed in the weighing boat for 5 min with a spatula that was chilled with liquid nitrogen. After mixing, the powders were poured into a piston mold[12]. The mold was chilled in a −10°C freezer for 1 h and then chilled with 20 mL of liquid nitrogen immediately before the powder mixture was poured in. After the mixed powder was poured into the piston, the piston mold assembly was warmed to 37°C in an oven[13] for 1 h and then placed in a hydraulic press[14]. The pressure on the mold was increased over a 90-s interval from 0 Pa to the maximum pressure desired. After 30 min, the pressure was released, leaving a cohesive, heterogeneous slab.

The slab was removed from the mold with the aid of a scalpel[15] and forceps. A small amount (<2%) of the fused polymer mixture was extruded into the space between the moving piston and the jacket of the mold. The scalpel was used to trim any of the polymer mixture than may have leaked. The slab was then gently peeled from the mold with forceps.

Slabs were prepared separately at maximum pressures of 3.5, 7, and 10.5 MPa from each powder described above. Macromolecules tested for release were bovine serum albumin[16] and trypsin[17].

Kinetics—Each slab was ~1.4-mm thick. Four pieces, measuring ~7 × 7 × 1 mm each, were cut from each slab with a scalpel and tested for release as follows. Scintillation vials[18] were filled with 10 mL of physiological saline for albumin release studies and 10 mL of Tris[19] buffer for trypsin release studies. The matrix samples were attached to glass loops made from Pasteur pipets[20] that were fitted into scintillation vial caps. The samples were attached by passing a thread of 4/0 silk[21] through the sample in an orthogonal direction to its face. By tying the sample to the rod, it ensured that the sample was always bathed on all sides with fluid and provided an easy way to transfer the samples from vial to vial during the release study. Release kinetics for albumin, based on the amount of protein released, were determined by UV spectrophotometry at 220 nm on 144 samples cut from 36 25% (w/w) loaded slabs.

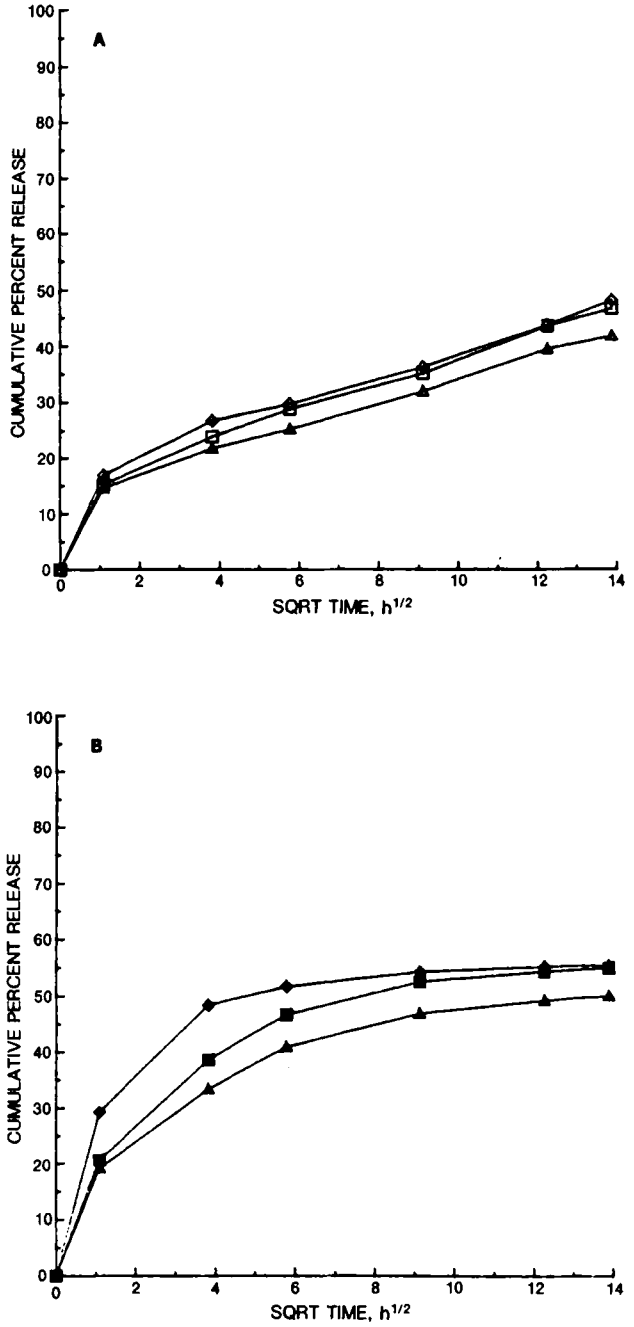

Figure 2—*Release kinetics for 25% (w/w) albumin slabs: effect of formation pressure. Key: (a) matrices cast with fresh powder I, a mixed particle size range (Table I), and with formation pressures of 3.5 (◇), 7.0 (□), and 10.5 MPa (△); (b) matrices cast with aged powder I, a fixed particle size range (90–180 μm), and with formation pressures of 3.5 (◆), 7.0 (■), and 10.5 MPa (▲).*

Trypsin release, also based on protein content, was determined by UV spectrophotometry at 220 nm on 18 samples cut from nine 18% loaded slabs.

Bioactivity—After trypsin release from the 18 samples was assayed (see above), the recovered enzyme was then diluted with Tris buffer to a concentration of 0.11 mg/mL. The enzyme turnover rate of the diluted trypsin solution on a tosyl-arginine methyl ester[22] substrate was then tested at 247 nm (4). The turnover rate of the test solution was compared with the turnover rate of a standard trypsin solution at the same concentration. The bioactivity index was taken to be the ratio of the two turnover rates.

Bioactivity was assessed at nine different times over a 310-h release period for two separate matrices cast with each powder (fresh powder I, aged powder I, and powder II) all at a pressure of 10.5 MPa. Bioactivity was also tested

[22] T4626, catalog number 1022-31; Sigma Chemical Co.

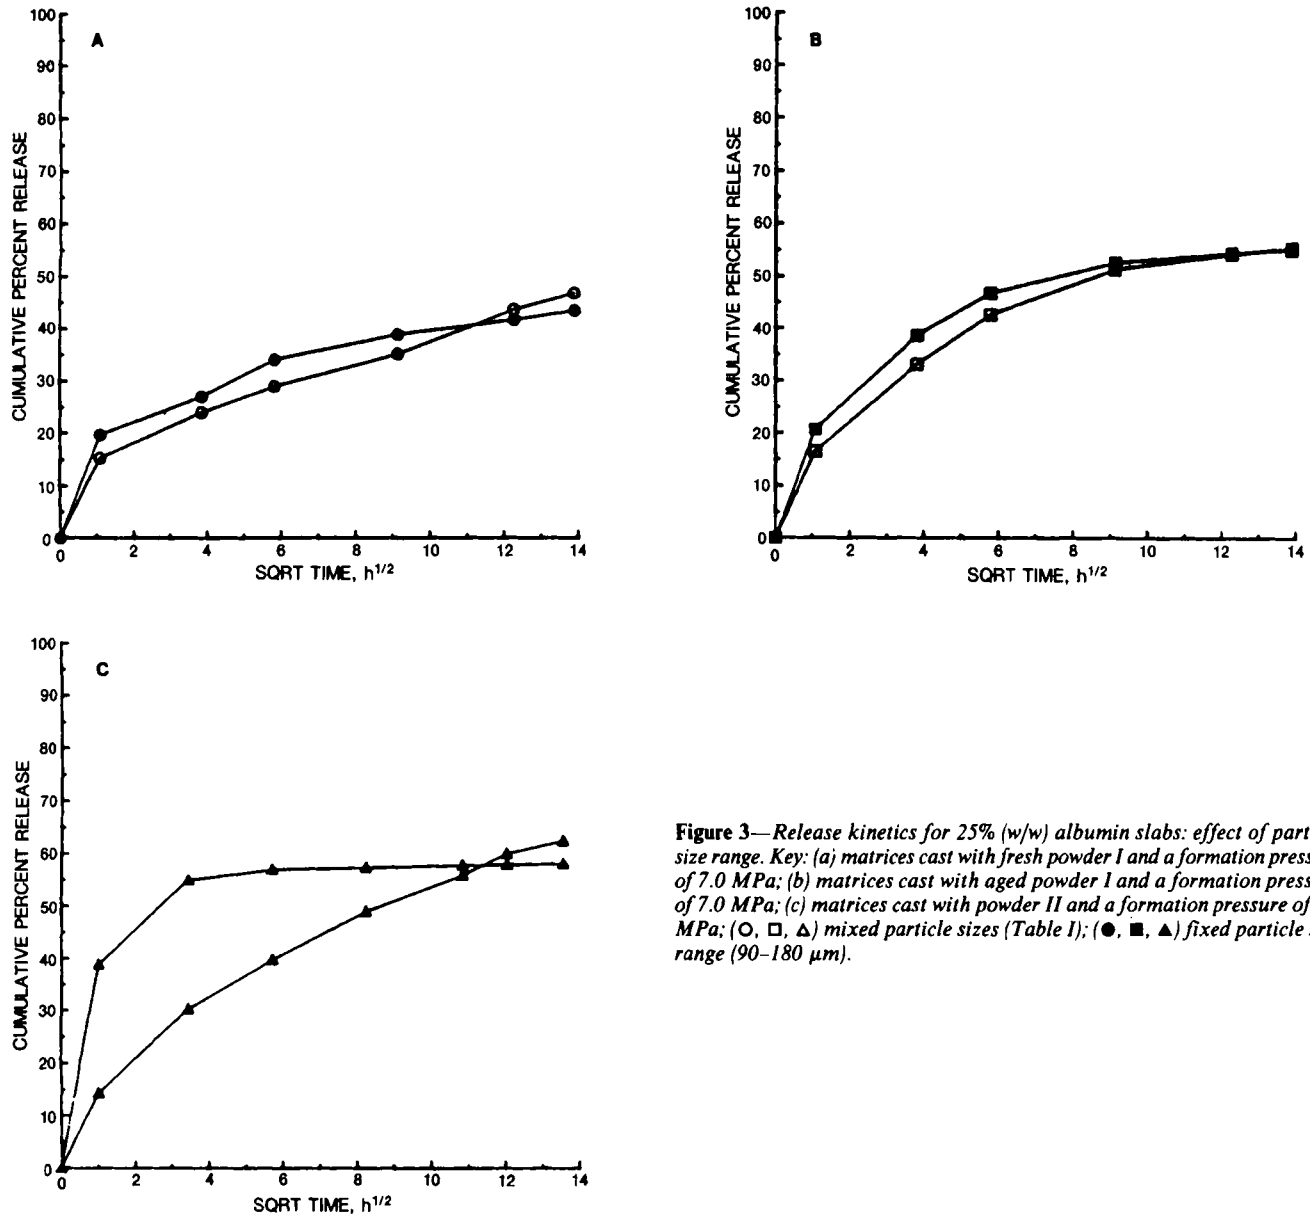

Figure 3—*Release kinetics for 25% (w/w) albumin slabs: effect of particle size range. Key: (a) matrices cast with fresh powder I and a formation pressure of 7.0 MPa; (b) matrices cast with aged powder I and a formation pressure of 7.0 MPa; (c) matrices cast with powder II and a formation pressure of 7.0 MPa; (○, □, △) mixed particle sizes (Table I); (●, ■, ▲) fixed particle size range (90–180 μm).*

for each powder on trypsin matrices cast at 3.5 and 7.0 MPa. For these matrices, bioactivity was assessed at only one time point (with release occurring between 24 and 36 h).

RESULTS

Polymer Glass Transition Temperature—The glass transition temperature was −36.5°C.

Kinetics—Figure 1 shows the release kinetics for slabs cast at 10.5 MPa with polymer powder granules with a mixed size range (Table I). Both the powder type and aging condition affect the rate of drug release. Specifically, powder II matrices release all of their releasable drug rapidly. Aged powder I matrices release drug at an intermediate rate, and fresh powder I matrices release drug at the slowest rate. Fresh powder I still releases at the same $t^{1/2}$ rate after 1 week.

In general, it was found that formation pressure has a small effect on release kinetics. When it does have an effect, it tends to be in the earliest stages of release, *i.e.*, the initial burst. Two examples of formation pressure dependence are shown in Fig. 2. The initial burst decreases with increasing pressure.

Similarly, the polymer powder particle size distribution generally does not dramatically affect release. Typical plots comparing release for the two polymer particle size distributions are shown in Fig. 3a. There is a slight tendency for matrices cast with mixed polymer particles to release more slowly and steadily than matrices cast with polymers cast with polymer particles of a single size range (90–180 μm). One case was observed in which the particle size mix had a pronounced effect (Fig. 3c).

Reproducibility between identically made slabs was within 8%. From samples cut from the same slab, reproducibility was within 6%[23].

Bioactivity—Table II shows the bioactivity index of released trypsin recovered during the time point corresponding to the release occurring between 24 and 36 h as a function of formation pressure and polymer powder type. The bioactivity index in all cases exceeded 96%. There appeared to be no difference between polymer powder types in their effect on enzyme activity. When the bioactivity index of released trypsin was measured for the amount of enzyme released from the matrix at later times, it exceeded 95% in every case.

DISCUSSION

The advantages of the sintering method used in this study, when compared with solvent casting methods used in previous studies, include (*a*) elimination of shrinkage; (*b*) elimination of the need for potentially expensive scale-up steps such as vacuum drying; (*c*) reduction of processing time [slabs were produced in 2 h[24] compared with 4 d required for solvent casting (1)]; and (*d*) lack of the necessity to expose the macromolecule to solvent.

Microscopic examination of the polymer particles of the two powder types reveals that they are similar in shape and are both white and translucent. They range in shape from a spherical form to an oblate spheroid form, in which the

[23] Reproducibility was determined by dividing the range of all points corresponding to a mean value by that mean value.

[24] These studies were performed on test slabs that were produced in 2 h. Since then, slabs have been produced in as little as 24 min.

Table I—Particle Size Distribution for Polymer Powder with a Mixture of Particle Sizes

Particle Size, μm	Weight, %
300-425	33
150-300	7
106-150	33
90-106	10
53-90	17

length is ~1.5 times the width. The only visually discernable differences between the powder types is surface topography. Powder I shows a roughened surface, with occasional folds and depressions. Powder II shows particles that are smoother with neither folds nor depressions. Some of the powder II particles have sharp, well-defined edges.

When stored at room temperature for 2 weeks and reexamined with a microscope, polymer powders produced by both of the methods described above showed the same surface morphology as the respective fresh powders. Neither fabrication procedure nor aging affected the adhesive quality of the polymer powder.

In the sintering method, the powdered drug and polymer were cooled to −200°C at which temperature they lose their adhesive properties. They were then mixed to give a homogenous blend. Warming the powders restored their elastic properties. Pressure applied at temperatures > −36.5°C caused the polymer particles to flow around the drug powder and merge together with other polymer particles. The result was a solid with drug powder locked into it.

Temperatures below T_g are essential for uniform mixing. Ethylene-vinyl acetate with 40% vinyl acetate by weight is a highly adhesive substance. Above T_g there are clumps of polymer powder that cannot be evenly mixed with the macromolecule. When fabrication was undertaken without cold mixing, some of the polymer particles clumped together. Substrate crystals adhered to these lumps in a nonuniform fashion. The mechanical strength of the slabs that were prepared without cold mixing was poor. Samples prepared in this way were fragile, pulled apart easily, and did not have evenly distributed substrates.

The polymer powder type seems to be the most important variable in determining release rates. The difference in the release kinetics for polymers cast with different powder types may be due to the fact that fresh powder I may contain residual solvent which might help fuse the boundaries between the polymer particles. Powder I granules also appear to have a folded surface. The extra surface area of the grains may allow for a more complete fusion to the solid matrix. Similarly, it is likely that aged powder I contains less solvent than fresh powder I, and this might explain why the fresh powder releases drug on a more sustained basis.

Increasing formation pressure often decreases the initial burst of release when both powder I and powder II are used. This is probably due to the requirement of high pressure to ensure fusion of polymer granules. At low formation pressure, the polymer matrix is grainy. The boundaries between polymer grains may provide extra channels (4) through which drug can diffuse.

Table II—Percent Bioactivity for Trypsin Release Averaged over Two Slabs for Each Formation Pressure and Powder Type

Pressure, MPa	Powder I, %		Powder II, %
	Fresh	Aged	
3.5	97.3	100	100
7.0	99.4	98.5	96.4
10.5	98.3	98.8	100

Using a mixture of varying polymer particle sizes can have the effect of prolonging release. This is probably due to the fact that the smaller particles fit into the interstitial spaces between the larger grains. The smaller particles might then help cement the larger polymer particles and thereby foster a more complete fusion. The small particles might also help fill spaces that would otherwise become small pores that would increase the release rate. It was noted, however, that there was only one case in which the particle size mixture had a significant effect on release rates (Fig. 3c). At present, we cannot ascertain whether the results shown in Fig. 3c are anomalous or whether there is some uncontrolled variable that caused the difference between the results shown in Fig. 3c and Fig. 3a and b.

It is well known (5) that diffusive release from slabs shows $t^{1/2}$ kinetics. Our results also follow $t^{1/2}$ kinetics. It has been shown that diffusive release with zero-order release kinetics is obtained from hemispheric drug–polymer pellets that are coated with an impermeable barrier, except for a small cavity in the center face (6). It is possible to form hemispheres by the sintering method presented here. Initial results with such sintered hemispheres have shown near-constant release of polypeptides such as insulin for >70 d (7).

Renal Clearance and Serum Protein Binding of Acetaminophen and Its Major Conjugates in Humans

MARILYN E. MORRIS and GERHARD LEVY ˣ

Received April 4, 1983, from the *Department of Pharmaceutics, School of Pharmacy, State University of New York at Buffalo, Amherst, NY 14260.* Accepted for publication July 29, 1983.

Abstract □ The renal clearances of acetaminophen, acetaminophen glucuronide, and acetaminophen sulfate were determined in eight healthy adults 2 h after administration of 1.5 g of acetaminophen. The renal clearance ratios (relative to creatinine) were 0.058 ± 0.026, 0.890 ± 0.153, and 1.43 ± 0.250 (mean ± *SD*), respectively. The renal clearance of acetaminophen increased with increasing urine flow rate, and that of acetaminophen sulfate decreased with increasing serum concentration of the conjugate. A strong positive correlation was found between the renal clearances of acetaminophen glucuronide and acetaminophen sulfate, possibly due to blood perfusion rate-dependent renal tubular secretion of the two conjugates. The serum protein binding of acetaminophen (≃20%) and acetaminophen glucuronide (<10%) are minor. Acetaminophen sulfate is >50% protein bound, as determined by equilibrium dialysis and ultrafiltration. The results of these studies are (*a*) consistent with previous reports of animal studies, indicating that renal excretion of acetaminophen involves glomerular filtration and passive reabsorption and that acetaminophen sulfate is subject to active renal tubular secretion, and (*b*) compatible with the reported occurrence of renal tubular secretion of acetaminophen glucuronide in animals.

Keyphrases □ Acetaminophen—renal clearance, serum protein binding, glucuronide and sulfate metabolites □ Renal clearance—acetaminophen, serum protein binding glucuronide and sulfate conjugates □ Protein binding—acetaminophen, ligand and albumin concentration

Acetaminophen, the widely used nonnarcotic analgesic and antipyretic agent, is eliminated primarily by formation of the glucuronide and sulfate conjugates (1–3). These metabolites are excreted as such in the urine. While the renal clearance of the acetaminophen conjugates has been studied extensively in experimental animals (4–6), only limited information is available concerning their renal clearance in humans (7, 8). We have, therefore, determined the renal clearances of acetaminophen, acetaminophen glucuronide, and acetaminophen sulfate in normal humans of both sexes and examined the concentration dependence of, and the interrelationship between, these processes. Since proper interpretation of renal clearance data requires knowledge of the plasma or serum protein binding characteristics of the cleared substance, we have also determined the serum protein binding of acetaminophen and its two major metabolites, and the effect of ligand and albumin concentration, respectively, on the protein binding of these compounds.

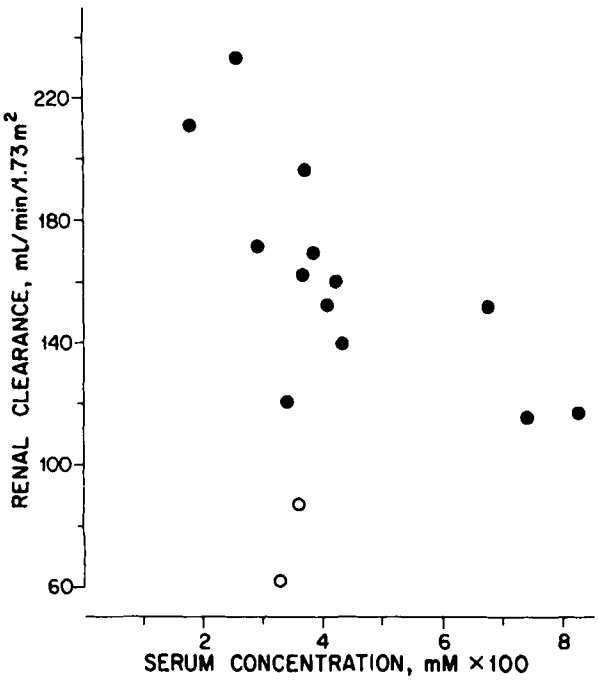

Figure 1—*Relationship between the apparent renal clearance of acetaminophen sulfate (normalized to a body surface area of 1.73 m²) and the serum concentration of acetaminophen sulfate; r = 0.718, p < 0.01. The open symbols are the data points of one outlier, which were not included in the statistical analysis; 0.01 mM acetaminophen = 1.51 μg/mL.*

EXPERIMENTAL SECTION

Eight adults in apparent good health (two females and six males, weighing 46–98 kg, 26–35 years old), received 1.5 g of acetaminophen in solution[1] orally, after an overnight fast. Seven of these subjects received acetaminophen a second time, 8 months later, after a light, low-fat breakfast (as part of another study). The subjects were drug-free for at least 4 d prior to the study. Urine was collected from 1 to 3 h after administration of the drug, and a blood sample was obtained at the midpoint of the urine collection period. Urine and serum samples were stored at −20°C until assayed. The concentrations of acetaminophen and its conjugates were determined by a slightly modified version of the HPLC assay of Adriaenssen and Prescott (9). A C_{18} column[2] with a mobile phase of 10% methanol and 1% acetic acid in 0.1 M potassium dihydrogen phosphate solution was used. The assay has a sensitivity limit of ~0.1 μg/mL (in terms of acetaminophen) for acetaminophen, acetaminophen sulfate, and acetaminophen glucuronide. Serum and urine were also assayed for creatinine by a modified picrate method[3].

Renal clearance values were determined by dividing the urinary excretion rate of acetaminophen, its conjugates, or creatinine by the midpoint serum concentration of the respective compound. Clearance ratios were calculated by dividing the clearance of acetaminophen or its conjugates by the creatinine clearance. Body surface area was estimated by means of a nomogram (10) based on body weight and height.

Multiple regression analysis was used to determine the relationships between the renal clearances of acetaminophen, or its conjugates, and urine flow rate, creatinine clearance, and serum concentration (11). Bivariate linear regression equations were determined by the perpendicular least-squares method, in which it is assumed that both variables are subject to error (12).

Serum protein binding measurements were made by equilibrium dialysis at 37°C against an equal volume, 0.3 mL, of 0.13 M phosphate buffer (pH 7.4) and by ultrafiltration. In the equilibrium dialysis studies, acetaminophen and its conjugates were added to the buffer phase in amounts designed to produce serum concentrations similar to those found in the study samples. The buffer solutions were dialyzed against pooled blank human serum or solutions of crystalline human albumin[4]; also, blank buffer was dialyzed against samples of pooled serum obtained in this study. Preliminary experiments showed that the optimal equilibration time for acetaminophen, acetaminophen glucuronide, and acetaminophen sulfate was 6–8 h. The protein binding of acetaminophen, acetaminophen glucuronide, and acetaminophen sulfate over the concentration ranges of 0.10–1.15 mM, 0.04–0.52 mM, and 0.11–1.22 mM, respectively, in human albumin solutions of varying concentrations (1.57–4.79 g/dL) was determined. Tris buffer (0.16 M) was used instead of phosphate buffer in some of these experiments.

Table I—Renal Clearance of Acetaminophen, Acetaminophen Glucuronide, and Acetaminophen Sulfate in Normal Adults [a]

Excretion Product	Renal Clearance, mL/min/1.73 m²	Clearance Ratio[b]
Acetaminophen	6.32 ± 1.93 (3.26-8.92)	0.058 ± .026 (0.030-.103)
Acetaminophen glucuronide	100 ± 13.6 (80.9-120)	0.890 ± .153 (0.770 ± 1.16)
Acetaminophen sulfate	161 ± 30.6[c] (116-200)	1.43 ± .250[c] (1.05-1.86)

[a] Results expressed as mean ± *SD* (range), $n = 8$, based on clearance values for each subject, which are the average of two determinations made on separate occasions. The average renal clearance of creatinine ranged from 75.5 to 135 mL/min/1.73 m², and average urine flow rates ranged from 15 to 75 mL/h/1.73 m². [b] Relative to creatinine. [c] One outlier with an average renal clearance of 74.9 mL/min/1.73 m² and an average clearance ratio of 0.628 was excluded.

Ultrafiltration studies were performed with solutions of acetaminophen and its conjugates in pH 7.4 isotonic phosphate buffer (to examine the possibility of membrane binding) and with serum obtained following the administration of acetaminophen. Approximately 2 mL of buffer solution or serum was placed in cellulose tubing[5] (0.83 mm o.d., molecular exclusion limit of 12,000–14,000 Da) which was mounted in stoppered plastic centrifuge tubes. The tubes were centrifuged at 750×*g* for 30 min at 37°C, and 0.10–0.15 mL of ultrafiltrate was collected (13).

Acetaminophen sulfate was synthesized in our laboratory[6] by the method of Feigenbaum and Neuberg (14), and acetaminophen glucuronide was supplied[7] (15). Total protein concentrations were determined by the biuret method (16), and the albumin fraction was determined by electrophoresis[8].

RESULTS

The creatinine clearance values of the subjects in this study ranged from 74 to 139 mL/min/1.73 m². Urine flow rates ranged[9] from 15 to 110 mL/h/1.73 m². The renal clearance values for acetaminophen, acetaminophen glucuronide, and acetaminophen sulfate and the corresponding renal clearance ratios relative to creatinine are summarized in Table I[10]. The renal clearance ratio of acetaminophen sulfate was consistently larger than unity, indicative of net renal tubular secretion. The renal clearance ratio of acetaminophen was quite small, reflecting extensive renal tubular reabsorption since (as will be shown) the serum protein binding of the drug is very limited. The body surface area-normalized renal clearance of acetaminophen increased with increasing normalized urine flow rate ($r = 0.577$, $p < 0.05$), but the urine flow rate had no apparent effect on the renal clearances of acetaminophen glucuronide or acetaminophen sulfate.

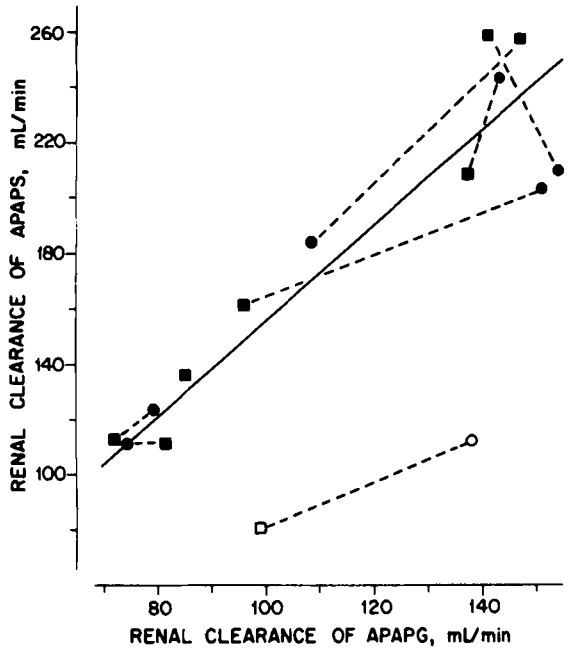

Figure 2—*Relationship between the apparent renal clearances of acetaminophen sulfate (APAPS) and acetaminophen glucuronide (APAPG); r = 0.928, p < 0.001. Seven of the eight subjects received acetaminophen on two separate occasions [first dose (■), second dose (●)], and the two data points for any one subject are connected by a dashed line. The open symbols are the data points for one outlier, which were not included in the statistical analysis.*

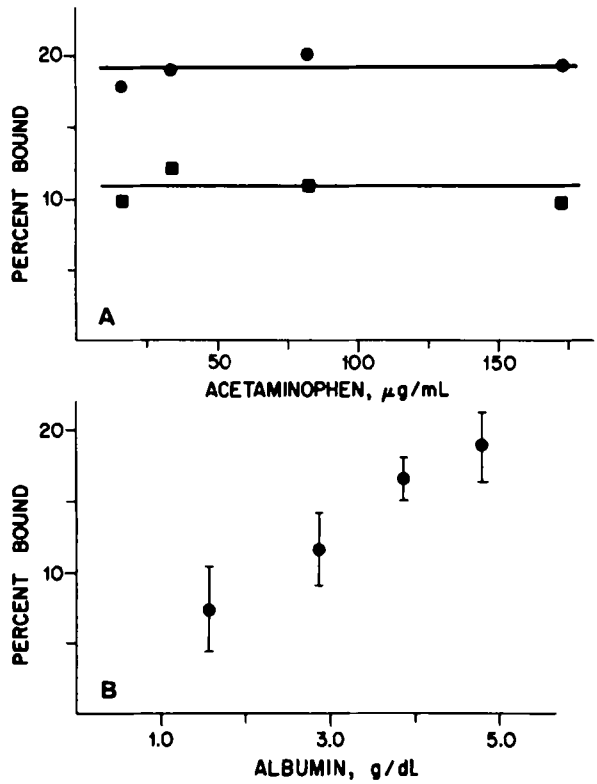

Figure 3—*Protein binding of acetaminophen in human albumin solution, determined by equilibrium dialysis. (A) Binding of acetaminophen over the concentration range of 15–174 μg/mL in 4.79 g/dL (●) and 2.88 g/dL (■) albumin solution. (B) Binding (mean ± SD, n = 9) of acetaminophen over the same drug concentration range in albumin solutions of 1.57, 2.88, 3.88, and 4.79 g/dL.*

The normalized renal clearance of acetaminophen sulfate decreased with increasing serum concentration of this conjugate (Table II and Fig. 1). A similar negative correlation ($r = -0.771$, $p < 0.01$) was found with respect to the acetaminophen sulfate-to-creatinine clearance ratio and acetaminophen sulfate serum concentration for concentrations <0.06 mM (this excludes a total of three sets of data from two subjects), but the correlation was not statistically significant when all data were included. There was no apparent correlation between normalized renal clearance and serum concentration in the cases of acetaminophen and acetaminophen glucuronide, respectively (Table II). Also, there was no statistically significant correlation between the normalized renal clearance of either conjugate and the serum concentration of acetaminophen.

The absolute renal clearances of acetaminophen glucuronide and acetaminophen sulfate for individual subjects (except one outlier) were strongly correlated (Fig. 2). A statistically significant correlation was found also with respect to normalized clearance values for the individual subjects ($r = 0.876$, $p < 0.001$), again excluding the one outlier. The latter individual yielded, on two occasions, significantly lower renal clearance values for acetaminophen sulfate than any of the other subjects in the study, but renal clearance values for acetaminophen glucuronide (Fig. 2) and the serum-free fraction of acetaminophen sulfate (≃0.4) for this subject were in the normal range.

Neither acetaminophen nor acetaminophen glucuronide was significantly protein bound in the serum of subjects who had taken acetaminophen or in human albumin solution and blank serum to which these compounds had been added *in vitro* (Table III). On the other hand, acetaminophen sulfate was

Table II—Concentration Dependence of the Renal Clearance and Clearance Ratio of Acetaminophen, Acetaminophen Glucuronide, and Acetaminophen Sulfate [a]

	Range of Serum Conc., mM	Range of Clearance, mL/min/1.73 m²	Range of Clearance Ratio[c]	Correlation Coefficient	
				Clearance	Clearance Ratio
Acetaminophen	0.070–0.200	3.26–11.3	0.030–0.127	0.095	0.229
Acetaminophen glucuronide	0.052–0.134	71.7–132	0.530–1.169	−0.104	−0.086
Acetaminophen sulfate[b]	0.018–0.083	115–233	0.889–2.12	−0.718[d]	−0.145

[a] Ranges and correlation analyses based on 15 individual sets of values from eight subjects (all but one subject participated in two studies). One mM of acetaminophen glucuronide and acetaminophen sulfate is equal to 327 mg/L and 231 mg/L, respectively. [b] One outlier (see footnote c in Table I) was excluded. [c] Relative to creatinine. [d] $p < 0.01$.

appreciably (>50%) protein bound in all of these fluids. These results, obtained by equilibrium dialysis, were confirmed by ultrafiltration experiments. For example, the serum free fraction value (mean ±*SD*, $n = 3$ or 4) of acetaminophen sulfate was 0.460 ± 0.021 by equilibrium dialysis and 0.425 ± 0.021 by ultrafiltration. Preliminary ultrafiltration experiments with protein-free aqueous solutions of acetaminophen and its two conjugates yielded average "free fraction" values consistently near unity (0.988–1.07), indicative of negligible binding to the cellophane membrane. Freezing and thawing of serum (one or two times) had no apparent effect on the protein binding of acetaminophen and its conjugates.

The albumin binding of acetaminophen was independent of drug concentration over a wide range, but increased with increasing albumin concentration (Fig. 3). On the other hand, the albumin binding of acetaminophen sulfate decreased with increasing concentration of the conjugate and increased with increasing albumin concentration (Fig. 4). The protein binding of acetaminophen glucuronide was very low (<10%) and not significantly affected by its concentration or by the concentration of albumin[11].

DISCUSSION

Acetaminophen, in nontoxic doses, has no apparent effect on renal creatinine clearance in humans (17) and on glomerular filtration rate and other indices of renal function in experimental animals (18–20). Consistent with previous reports (7, 8), the renal clearance of unmetabolized acetaminophen is quite low despite its negligible serum protein binding and is positively correlated with urine flow rate (7). It is also independent of acetaminophen concentration in the serum, at least under the conditions of this investigation. These observations confirm studies in dogs which have shown that acetaminophen undergoes glomerular filtration and renal tubular reabsorption by simple diffusion (4). The mean renal clearance of acetaminophen obtained in this investigation, 6.32 ± 1.93 mL/min/1.73 m², is somewhat lower than that reported by Prescott *et al.* (8) for 12 normal subjects (11.9 ± 4.9 mL/min/67 kg average body weight). This may be due to different urine flow rates in the two studies. In general, small differences in the average renal clearances of acetaminophen and its major metabolites, observed in this investigation and in that by Prescott *et al.* (8), may be due to the fact that the data reported here are based on a single serum concentration determination at the midpoint of a 2-h urine collection period while Prescott *et al.* employed the usually preferable area-under-the-curve method. However, the latter method would not reveal concentration dependence of renal clearance if the determinations are based on the total area under the plasma concentration–time curve and total urinary excretion. The conditions of the present study (*i.e.*, a constant absolute dose given to subjects of widely differing body weight) facilitated assessment of the possible serum concentration dependence of the renal clearances.

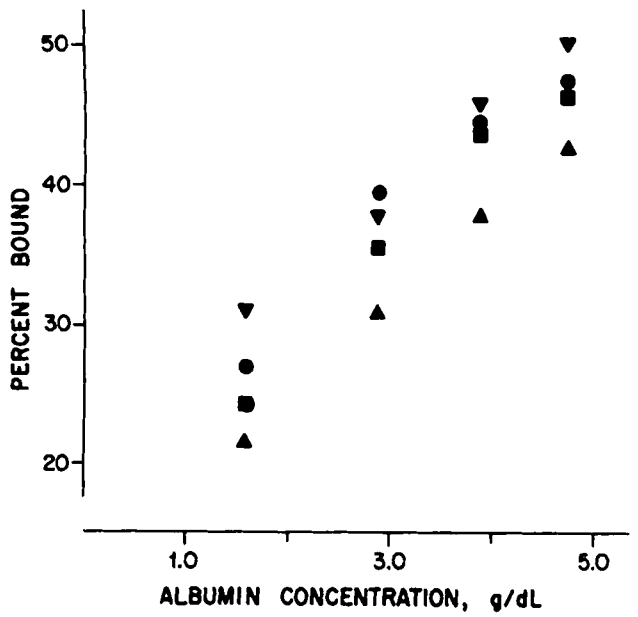

Figure 4—*Protein binding of acetaminophen sulfate in human albumin solutions (1.57, 2.88, 3.88, and 4.79 g/dL), determined by equilibrium dialysis, at acetaminophen sulfate concentrations of 1.22 ± 0.040 mM (mean ± SD) (▲), 0.564 ± 0.038 mM (■), 0.252 ± 0.021 mM (●), and 0.107 ± 0.007 mM (▼).*

[11] Unpublished results.

Renal clearance values for the acetaminophen glucuronide and sulfate conjugates determined following administration of acetaminophen, rather than of the conjugates themselves, must be considered, in principle, as estimates of apparent renal clearances. This is because studies on isolated perfused rat kidneys (18–20) and isolated rat kidney cells (21) have shown that renal tissues form acetaminophen glucuronide and sulfate conjugates, albeit at very low rates. These conjugates do not appear in the perfusate of isolated kidneys, but are immediately excreted in the urine. It is likely that the renal contribution to acetaminophen conjugation is also quantitatively negligible in humans since the elimination of acetaminophen by biotransformation is not impaired in anephric patients (22).

Previous studies by Duggin and Mudge in dogs (4) and by Lin and Levy in rats (6) have shown that the renal clearance of acetaminophen sulfate is substantially higher than glomerular filtration rate at low serum concentrations of the conjugate and that the renal clearance decreases with increasing serum concentration. The present study in humans also yielded renal clearance ratios, relative to creatinine, appreciably higher than unity. This demonstrates that acetaminophen sulfate is subject to renal tubular secretion. While, in theory, similar results may be obtained if the conjugate was excreted only by glomerular filtration and formed at a high rate in the renal tissues, that possibility is unlikely in view of the evidence reviewed in the preceding paragraph. Moreover, there was no relationship between the normalized apparent renal clearance of acetaminophen sulfate and the serum concentration of acetaminophen. A relationship would be expected had there been appreciable renal synthesis of the conjugate. The renal clearance value obtained in this study (161 ± 30.6 mL/min/1.73 m²) is in good agreement with that of Prescott *et al.* (166 ● 29 mL/min) in 12 healthy volunteers, with an average body weight of 67 kg, who received a single dose of acetaminophen, 20 mg/kg (8). More direct comparison is not possible since Prescott *et al.* did not report individual or normalized average values or glomerular filtration rates.

The apparent renal clearance of acetaminophen glucuronide determined in this study, 100 ± 13.6 mL/min/1.73 m², is also in reasonable agreement

Table III—Serum Protein Binding of Acetaminophen, Acetaminophen Glucuronide, and Acetaminophen Sulfate [a]

	Free Fraction		
	Acetaminophen	Acetaminophen Glucuronide	Acetaminophen Sulfate
Serum after administration of acetaminophen	0.819 ± 0.018	0.923 ± 0.009	0.460 ± 0.021
Human albumin, 5%	0.818 ± 0.013	0.928 ± 0.012	0.469 ± 0.019
Blank serum	0.780 ± 0.020	0.916 ± 0.019	0.391 ± 0.016
	0.844 ± 0.017[b]	0.954 ± 0.019[b]	0.387 ± 0.015[b]

[a] Results expressed as mean ±*SD* ($n = 3$). Serum was dialyzed for 6–8 h at 37°C against isotonic phosphate buffer, pH 7.4. The approximate concentrations of acetaminophen, acetaminophen glucuronide, and acetaminophen sulfate at equilibrium were 0.09, 0.06, and 0.05 mM, respectively, in serum from medicated subjects, and 0.2, 0.1, and 0.05 mM in albumin solution and blank serum. [b] Determined by 6-h dialysis against Tris buffer instead of phosphate buffer.

with that of Prescott *et al.* (8), 131 ± 22 mL/min, but did not, on the average, exceed creatinine clearance. However, there were four individual renal clearance ratio values (of two subjects) above unity: the highest of these was 1.17. Thus, the results of the present study do not provide strong evidence for renal tubular secretion of acetaminophen glucuronide, perhaps because of the opposing effects of tubular secretion and reabsorption. Duggin and Mudge (4) found that acetaminophen glucuronide is subject to both processes in the dog.

This investigation revealed a striking positive correlation between the renal clearances of acetaminophen glucuronide and acetaminophen sulfate in normal human subjects. Such correlation could reflect the existence of a common renal tubular secretory (transport) process for the two conjugates. Alternatively, the secretion rate of both conjugates could be blood flow rate dependent, either in terms of overall renal blood flow or with respect to the blood perfusion of the secretory region of the kidneys. We favor the second of these alternatives because of evidence suggesting separate renal transport processes for the two conjugates. First, probenecid has been found to inhibit the net renal tubular secretion of acetaminophen sulfate, but not that of the glucuronide, in dogs (4). Second, the present investigation identified one apparently healthy male subject, with normal creatinine, inorganic sulfate (17), and acetaminophen glucuronide renal clearances, but markedly subnormal renal clearance of acetaminophen sulfate during two experiments ~8 months apart. Such selectivity suggests a dissociation of the secretory processes for acetaminophen glucuronide and sulfate or, alternatively, the existence of separate specialized reabsorption processes together with a common or separate process(es) for renal tubular secretion of the two conjugates.

The serum protein binding of acetaminophen and acetaminophen glucuronide is very limited, so that correction of the renal clearance values of these compounds for protein binding will have only a quantitatively small effect. On the other hand, acetaminophen sulfate was found to be appreciably bound to serum proteins, so that its renal clearance referenced to the unbound metabolite would be more than double the value reported in Table III. While the limited protein binding of acetaminophen and acetominophen glucuronide is consistent with the results of previous studies (4, 22, 23), one of these studies had also indicated that acetaminophen sulfate binding to serum proteins is similarly negligible. Consequently, the protein binding of acetaminophen sulfate was examined in considerable detail in this investigation. Appreciable (>50%) binding was found by equilibrium dialysis and ultrafiltration, with good agreement between the results of the two methods. These binding experiments were performed on serum obtained from acetaminophen-treated subjects, blank serum with acetaminophen and its two major conjugates added *in vitro*, and human albumin solution with added acetaminophen and conjugates. All of these fluids yielded similar free fraction estimates. Moreover, protein binding was also determined in serum from rats pretreated with acetaminophen, with the following average results (percent binding, concentration): acetaminophen 23%, 0.55 mM; acetaminophen glucuronide 5%, 0.15 mM; acetaminophen sulfate 65%, 0.28 mM. Several studies by other investigators have shown that various organic sulfate esters are extensively bound to plasma proteins (24–26).

Acetaminophen is almost entirely metabolized to the glucuronide and sulfate conjugates under ordinary conditions, and these conjugates are excreted in the urine. Renal failure results, therefore, in substantial accumulation of these metabolites in plasma (22). The present study provides information relevant to the elimination of these metabolites by human subjects with normal renal function under conditions yielding serum concentrations of acetaminophen and its glucuronide and sulfate conjugates in the usual therapeutic range.

Kinetics of Partitioning and Binding of Digoxin and Its Analogues in the Subcompartments of Blood

PETER H. HINDERLING

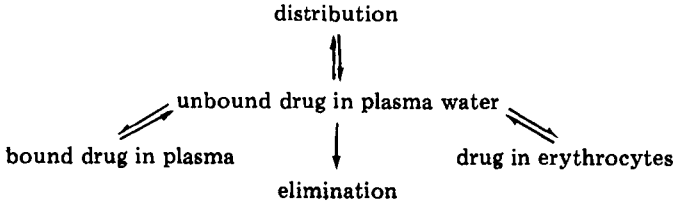
Received April 12, 1982, from the *Department of Pharmacology, Biocenter, University of Basle, 4056 Basle, Switzerland.* Accepted for publication March 10, 1983. Present address: F. Hoffmann-La Roche & Co., Grenzacherstrasse 124, Basle CH-4002, Switzerland.

Abstract □ The kinetics of digoxin and analogues (metabolites) in the subcompartments of blood, erythrocytes and plasma, were first order and concentration independent. The rate and extent of red blood cell partitioning of the tested compounds were, according to first-order kinetics, identical in the presence and absence of structurally related compounds and dependent on lipophilicity and temperature; red blood cell penetration was a reversible process. Erythrocyte partitioning of digoxin and its analogues was postulated to be by passive diffusion. There was significant intracellular binding of the compounds, and hemoglobin was the major ligand. The kinetics of red blood cell partitioning of the individual compounds were fitted according to a closed two- or three-compartment model. The latter indicated the existence of two kinetically separable compartments within the red blood cells. Model-independent mean transit times of red blood cell–plasma water partitioning of the compounds depended largely on the lipophilicity and were a thousand times greater for the least lipophilic analogues than for the most lipophilic derivatives. Red blood cell partitioning of digoxin and its metabolites under *in vivo* and *in vitro* conditions, were equivalent. Plasma protein binding of the tested compounds was concentration independent, unaltered in the presence of the analogues, and temperature independent between 24°C and 37°C. Binding to albumin in buffer solution was significantly larger than to albumin in plasma for all the compounds. Binding of digoxin and its analogues to albumin in buffer solution increased with increasing lipophilicity of the compounds.

Keyphrases □ Digoxin—kinetics of red blood cell partitioning, plasma protein binding, analogues □ Red blood cell partitioning—digoxin and analogues, kinetics, plasma protein binding □ Plasma protein binding—digoxin and analogues, kinetics of red blood cell partitioning □ Kinetics—digoxin and analogues in blood, plasma protein binding, red blood cell partitioning

The overall goal of the present study was the further (1) elucidation of the kinetics of digoxin (I) and its analogues (*i.e.*, metabolites) in the subcompartments of blood, plasma and red blood cells (Scheme I). The individual goals were to (*a*) delineate the kinetics of red blood cell partitioning, (*b*) investigate the influence of temperature and drug lipophilicity on cellular uptake, (*c*) assess the gross intracellular distribution of the compounds, and (*d*) make a comparative study of the binding of the compounds to albumin and plasma protein.

Special emphasis was put on the delineation of the kinetics of red blood cell partitioning of the tested compounds. A review of the pharmacokinetic literature on this subject indicated that the significance of the kinetics of drugs in this subcompartment of blood has not been adequately appreciated by pharmacokineticists. The extent of red blood cell uptake has been determined for drugs in some studies; the rate of such uptake has been studied only exceptionally (2). Often tacit assumptions have been made that either red blood cell partitioning of the drug is negligible or equilibration between plasma and cells is instantaneous if drug uptake into the erythrocytes is significant. Concentrations of drugs usually have been assessed in plasma, not whole blood, in pharmacokinetic studies. Obviously, temperature-independent red blood cell partitioning has been presumed for the drugs in most of the studies, since no effort appears to have been made to maintain the temperature of the blood samples after their withdrawal until separation of plasma and erythrocytes. This paper will show conclusively that these *a priori* assumptions are unwarranted and may lead to biased values of pharmacokinetic parameters.



Scheme I—Drug in the blood compartments.

EXPERIMENTAL SECTION

Materials—The following unlabeled and labeled compounds were used: digoxin[1] (I), digitoxin[1] (II), β-methyldigoxin[1] (III), dihydrodigoxin[1] (IV), digoxigenin bis(digitoxoside)[1] (V), digoxigenin digitoxoside[1] (VI), epidigoxigenin[1], digitoxigenin bis(digitoxoside)[1], digitoxigenin digitoxoside[1], digoxin-16′-glucuronide[2] (VII), [12α-^{3}H]digoxin[1], β-methyl[12α-^{3}H]digoxin[1], [12α-^{3}H]digoxigenin bis(digitoxoside)[1], [12α-^{3}H]digoxigenin digitoxoside[1], [21,22-^{3}H]digitoxin[2], dihydro[12α-^{3}H]digoxin[2], and [12α-^{3}H]digoxin-16′-glucuronide[2]. The compounds with the label in the α-position were synthesized according to the method of von Wartburg *et al.* (3) and had the following specific activities: [^{3}H]I, 1460 μCi/mg; [^{3}H]III, 910 μCi/mg; [^{3}H]IV, 12,772 μCi/mg; [^{3}H]V, 552 μCi/mg; [^{3}H]VI, 457 μCi/mg; [^{3}H]VII, 1570 μCi/mg. [^{3}H]II was synthesized according to the method of Haberland and Merten (4) and had a specific activity of 509 μCi/mg. The radiochemical purities of the labeled compounds were investigated using different TLC systems, as described elsewhere (5, 6), and were: [^{3}H]I, >94.5%; [^{3}H]II, 100%; [^{3}H]III, >95.9%; [^{3}H]IV, 100%; [^{3}H]V, >92.5%; [^{3}H]VI, >95.9%; [^{3}H]VII, >98.0%.

n-Octanol was obtained commercially[3]; heparinized (5 USP U/mL) or citrated (3.69 mg/mL sodium citrate and 0.46 mg/mL citric acid) blood and plasma samples were obtained from healthy volunteers who had no prior drug intake[4] for 168 h. Human albumin (fraction V, fatty acid free) (AB_1[5] AB_2[6]) and hemoglobin (HB)[5] (type IV, crystalized twice) were purchased. Three different buffers were used: (*a*) 0.067 M KH_2PO_4, 0.067 M Na_2HPO_4, and 0.113 M NaCl (pH 7.4, 0.300 Osmol, ionic strength: 0.23) (7), (*b*) 0.001 M KH_2PO_4, 0.001 M Na_2HPO_4, 0.157 M NaCl, 0.006 M glucose, 0.004 M KCl, 0.003 M $CaCl_2$, and 0.002 M $MgCl_2$ (pH 7.2, 0.356 Osmol, ionic strength: 0.18), and (*c*) 0.05 M Tris, 0.042 M HCl, and 0.060 M NaCl (pH 7.4, 0.304 Osmol, ionic strength: 0.15). Buffers b and c represented a slight modification of the original buffers employed previously (8, 9).

Determination of Apparent Octanol–Water Partition Coefficients of Digoxin and Analogues—Partition coefficients were determined for [^{3}H]I–[^{3}H]VII at 24°C using twice-distilled water ([^{3}H]I–[^{3}H]VI) or phosphate buffer *a* ([^{3}H]VII). The octanol was allowed to equilibrate with water with gentle shaking for 24 h. Only water-saturated octanol and octanol-saturated water were used in the partitioning experiments. The experiments were performed in 15-mL tubes equipped with glass stoppers. The compounds were added to tubes containing, initially, only the water phase (2.5 mL) spiked with drug concentrations of 40 ng/mL ([^{3}H]I, [^{3}H]III–[^{3}H]VI), 100 ng/mL ([^{3}H]II), and 200 ng/mL ([^{3}H]VII); the octanol phases were added subsequently. The stoppered tubes were then shaken vigorously for 45 min. Preliminary experiments had indicated that this time permitted the compounds to reach equilibrium. After centrifugation, the phases were separated and aliquots (200 μL) were taken from both phases for determination of radioactivity. Two experiments were performed with each of the compounds tested.

[a] Mean ± *SD*; individual values are reported in parentheses. The upper value is P_{e/c_u}; the lower value is $P_{e/c}$. [b] In order of decreasing lipophilicity. [c] Number of mean values considered; averages of 3–5 individual determinations in blood of 1–7 donors.

Erythrocyte Partitioning of Digoxin and Analogues—The goals of these experiments were to investigate the red blood cell–buffer or –plasma distribution of the compounds prior to and at partition equilibrium, and to determine whether the partitioning was temperature dependent. The experiments used erythrocytes obtained from different donors (n = 2–8) for the partitioning of each individual compound.

Erythrocyte suspensions in buffer *a* or in plasma, with physiological hematocrits of 40% (10), were employed. The procedure used for the determination of drug partitioning into red blood cells was the centrifugal method, which has previously been described in detail (7). Briefly, the suspensions had volumes of 10 mL and were kept in 15-mL glass-stoppered tubes. Immediately after drug addition, the tubes containing the suspensions were shaken vigorously for 15 s and were then rotated for the duration of the experiments. Samples of the suspensions were taken as early as possible following drug addition (≥0.3 min) and at appropriate intervals thereafter. The samples were immediately centrifuged for intervals ranging from 0.5 (early samples) to 5 min (later samples). The time of removal of the separated buffer or plasma phases was taken as the sampling time. The concentrated erythrocyte phases had hematocrits ranging between 50 and 95%. Aliquots (100–500 μL) were taken from the separated erythrocyte, buffer, or plasma phases, and the radioactivity was determined.

Erythrocyte buffer partitioning studies were conducted at 37°C, 24°C, and 4°C with all the labeled compounds; additional experiments at 14°C were performed with [^{3}H]II and [^{3}H]VI. Erythrocyte plasma partitioning was investigated at 37°C and 24°C with all the labeled compounds. The temperatures were maintained throughout the experiments, including the final centrifugation of the red blood cell suspensions. The pH was in the 7.35–7.45 range. Only fresh erythrocyte suspensions were used. For a delineation of the type of kinetics involved, the partitioning of all the compounds with the exception of [^{3}H]VII was investigated systematically at 24°C at drug concentrations of 5, 10, and 100 ng/mL. Additional experiments at 24°C studied the red blood cell partitioning of the (labeled) compounds (10 ng/mL) in the presence of the (unlabeled) analogues (100 ng/mL each). Reversibility of red blood cell partitioning was checked at 24°C by resuspending drug-containing erythrocytes in fresh buffer *a* (11).

The stability of the compounds during their incubation with erythrocytes in buffer or plasma at 37°C was checked for all compounds except [^{3}H]II. Plasma and buffer aliquots taken at different times after incubation were analyzed by specific column chromatography or TLC, as described previously (6). The results showed that the compounds were stable under these experimental conditions. Estimates for the precision of the red blood cell partitioning values were obtained by repetitive determination of the ratios of the erythrocytes to buffer or plasma concentrations in suspensions with red blood cells from a particular donor. The coefficient of variation (CV) values ranged between 1 and 8% for the compounds, except [^{3}H]II. Considerably larger CV values (20–80%) were obtained for this compound with red blood cell plasma suspensions. This was due to the comparatively low erythrocyte concentrations of this drug in the plasma suspensions.

The possible influence of buffer composition on red blood cell partitioning of [^{3}H]I and its analogues was also studied. Red blood cells from different donors were divided up in equal parts and suspended either in buffer *a* or buffer *c*. Red blood cell partitioning from the two buffers at 37°C was then studied with all the compounds except [^{3}H]VII. The results of these experiments showed that red blood cell partitioning from buffer *a* was significantly larger than from buffer *c* for all the compounds tested, although the respective mean red blood cell-to-buffer concentration ratios differed by only 1–15%. These results indicated that red blood cell partitionings of the nonelectrolytic [^{3}H]I–[^{3}H]VI were influenced by buffer composition. Differences in ionic strength, pH, and molecular composition of the two buffers used may have been responsible for the observed discrepancy.

Only buffer *a* was used in the definitive partitioning experiments with [^{3}H]I and its analogues. Buffer *a* was preferred because it had been used successfully in the past (7, 12) in equivalent experiments with other compounds and guaranteed a pH equivalent to that in plasma water (13).

***In Vivo* Erythrocyte Partitioning of Digoxin and Metabolites**—Tritiated digoxin (0.6 and 1.2 mg) was administered intravenously (bolus) and orally to three healthy volunteers aged 21–25 years. Blood was obtained over a period of 144 h after administration of the drug. After blood withdrawal, there was a lapse of 30 min before separation of the plasma and erythrocytes. During this interval the samples were kept at a temperature of 24°C. Plasma of the samples was then divided into two parts. In one part [^{3}H]I and its separable, known, apolar metabolites ([^{3}H]IV–[^{3}H]VI) and unknown polar metabolites were assayed by specific methods (6); in the other part, total radioactivity was measured. Total radioactivity was also determined in the separated erythrocytes of the samples.

Binding of Digoxin and Analogues to Hemolysate, Hemoglobin, Albumin, and Plasma Protein—Details of the equilibrium dialysis method employed in these investigations have been reported previously (1). The experiments were performed at 37°C or 24°C and within a pH range of 7.30–7.50. The hemolysate suspensions and the protein solutions were dialyzed against buffer for 6.5 h. Equilibrium between the free drug concentrations in plasma and buffer was established within this time interval. Aliquots (100–500 μL) were then taken from both chambers of the dialysis apparatus, and the radioactivity was determined.

The binding to hemolysate and albumin was investigated for all the compounds. The binding to hemoglobin was studied with [^{3}H]I and [^{3}H]II. Plasma protein binding was investigated with [^{3}H]II, [^{3}H]III, and [^{3}H]VII. The results obtained with [^{3}H]I and [^{3}H]IV–[^{3}H]VI have been reported previously (1).

Hemolysate Binding—Red blood cells from one donor were separated from

Table II—Linearity of the Red Blood Cell Partitioning Kinetics of Digoxin and Analogues at 24°C

Compound[a]	P_{e/c_u}[b]			
	5 ng/mL	10 ng/mL	10 ng/mL[c]	100 ng/mL
[^{3}H]II	1.82 (1.75, 1.87)	2.03 (2.01, 2.06)	1.93 (1.88, 1.97)	2.06 (2.01, 2.10)
[^{3}H]III	1.10 (1.05, 1.14)	1.13 (1.13, 1.13)	1.19 (1.07, 1.30)	1.13 (1.13, 1.13)
[^{3}H]IV	1.39 (1.38, 1.39)	1.36 (1.33, 1.39)	1.31 (1.30, 1.33)	1.35 (1.32, 1.39)
[^{3}H]I	1.29 (1.22, 1.36)	1.35 (1.33, 1.37)	1.26 (1.24, 1.28)	1.31 (1.24, 1.37)
[^{3}H]V	1.15 (1.08, 1.22)	1.14 (1.13, 1.15)	1.17 (1.10, 1.24)	1.19 (1.16, 1.21)
[^{3}H]VI	1.19 (1.13, 1.25)	1.20 (1.18, 1.22)	1.23 (1.22, 1.24)	1.23 (1.22, 1.23)

[a] In the order of decreasing lipophilicity. [b] n (Number of individual values considered) = 2, obtained from one donor. Individual values are in parentheses. [c] Molar ratio of labeled drug to each of the unlabeled analogues = 0.1.

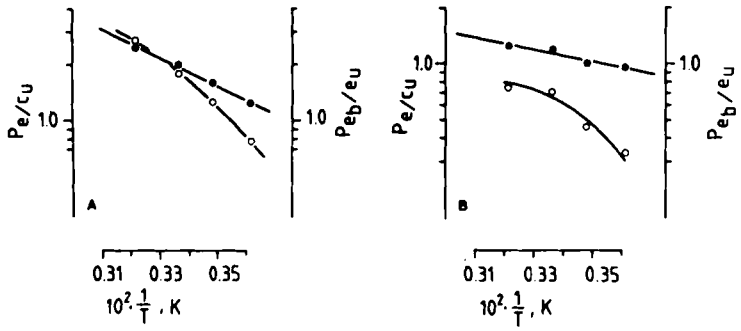

Figure 1—*Semilogarithmic plot of the averaged apparent red blood cell-buffer partition coefficient, P_{e/c_u} (●), and the averaged true red blood cell partition coefficient, P_{e_b/e_u} (○) against the reciprocal of the absolute temperature 1/T for [^{3}H]II (A) and [^{3}H]VI (B). There was an apparent linear dependency of P_{e/c_u} on 1/T in contrast to a nonlinear relationship between P_{e_b/e_u} and 1/T.*

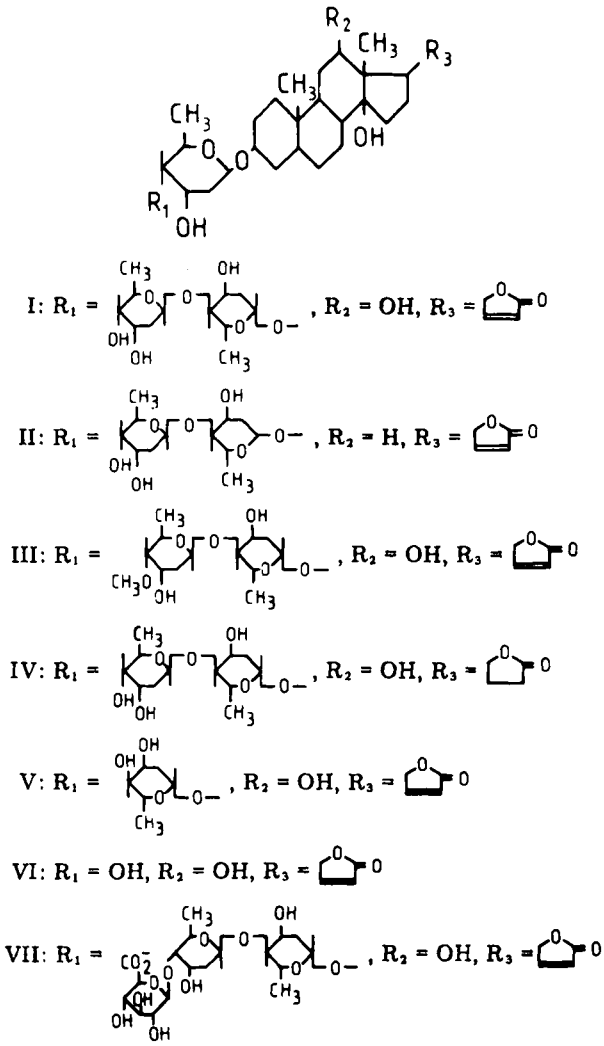
plasma by centrifugation. After removal of the buffy coat, the cells were washed five times and suspended in buffer *a*. Lysis was then induced by exposing the red cells to a temperature of −20°C for 2 h. Membrane-free hemolysates (hemoglobin concentration 140 g/L) were then obtained by ultracentrifugation[7] at 20,000 rpm for 20 min. Binding and/or partitioning to hemolysate was determined for [^{3}H]II (20, 50, and 100 ng/mL) and [^{3}H]I and [^{3}H]III-[^{3}H]VII (20 ng/mL) at 37°C. There was significant net transport of fluid during dialysis, leading to a 10–20% decrease of the initial hemoglobin concentrations in the hemolysates. From 2 to 6 dialysis experiments were run in parallel with the hemolysates for each compound.

Hemoglobin Binding—The binding to hemoglobin was investigated with [^{3}H]I and [^{3}H]II (20 ng/mL) by dialysis against buffer *a* at 37°C. There was significant net transport of fluid during dialysis leading to a 10–20% decrease of the initial hemoglobin concentrations of 140 g/L. The binding to diluted hemoglobin (7 g/L) was also investigated. There was no net transport of fluid in these experiments. Two dialysis experiments were run in parallel.

Albumin Binding—Albumin binding was studied with all the compounds



[7] Sorvall Ultracentrifuge, RC-2B; Ivan Sorvall Inc., USA.

(20 ng/mL) at a physiological concentration of the protein (45 g/L) (14). Buffer *a* was used, and the experiments were conducted at 37°C. Albumin AB_1 and AB_2 were employed in these studies: the binding of [^{3}H]II was with both albumins, the binding of [^{3}H]I and [^{3}H]IV-[^{3}H]VI with albumin AB_1, and the binding of [^{3}H]III and [^{3}H]VII with albumin AB_2. Between 2 and 10 dialysis experiments were run with albumin for each compound. The *CV* values of replicate albumin binding determinations were 1% for [^{3}H]II and 3–7% for the rest of the compounds.

Preliminary experiments had shown that binding of [^{3}H]I (20 ng/mL) to albumin was not influenced by the buffer used. [^{3}H]I was 34.2 ± 2.67% (n = 10) and 35.9% (35.2, 36.6; n = 2) bound to albumin when buffers *a* and *c* were used, respectively. This suggested that the [^{3}H]I-albumin interaction was not influenced by the phosphate ion concentration of buffer *a*.

Plasma Protein Binding—Plasma with physiological albumin content (42–54 g/L) (14) obtained from different donors was used. The binding of [^{3}H]III and [^{3}H]VII was studied at concentrations of 5, 10, and 100 ng/mL (initial concentrations after spiking plasma prior to initiation of dialysis) with the plasma of two donors. [^{3}H]II was investigated at concentrations of 100 and 1000 ng/mL with the plasma of seven donors. In addition, the plasma binding of these three labeled compounds in the presence of unlabeled analogues was studied. The plasma binding of [^{3}H]III and [^{3}H]VII (5 ng/mL) was studied in the presence of all the other analogues (unlabeled I–VII, 100 ng/mL each), and the plasma binding of [^{3}H]II (5 and 100 ng/mL) was determined in the presence of unlabeled digitoxigenin bis(digitoxoside) and digitoxigenin digitoxoside (100 ng/mL each). From 4 to 8 dialysis experiments were run in parallel with the plasma of a particular donor for each compound. The *CV* values for replicate determinations of the plasma protein binding were 1% for [^{3}H]II and 7–15% for the rest of the compounds.

Analytical Procedures—The details of the liquid scintillation method used have been given previously (10). Briefly, 100–500-μL aliquots from plasma buffers *a*, *b*, and *c* and octanol were analyzed in duplicate, either directly[8] or after combustion[9]. The radioactivity in erythrocytes, hemoglobin solutions, and hemolysates was measured only after combustion. The red blood cells were lysed prior to combustion. The hemoglobin concentrations in the hemoglobin and hemolysate binding studies were measured spectrophotometrically after transformation to hemoglobin cyanide (15).

RESULTS

The ± values given in the text and in the Tables refer to the standard deviation, *SD*, of the means, and n is the number of observations considered. Values for *SD* and n are only given in the text for mean values which are not listed in the Tables.

Octanol–Water Partition Coefficients of Digoxin and Analogues—Apparent octanol–water partition coefficients at 24°C (P) of [^{3}H]I and its analogues were calculated from the ratio of the concentration in the organic phase to the concentration in the aqueous phase at equilibrium. The mean P values for the individual compounds were (n = 2): [^{3}H]I, 16.6 (16.5, 16.7); [^{3}H]II, 98.2 (96.8, 99.5); [^{3}H]III, 38.6 (38.3, 38.8); [^{3}H]IV, 17.6 (17.5, 17.6); [^{3}H]V, 15.6 (15.2, 16.0); [^{3}H]VI, 11.6 (11.4, 11.8); [^{3}H]VII, 0.024 (0.023, 0.024).

Erythrocyte Partitioning of Digoxin and Analogues—*Equilibrium Kinetics*—Red blood cell–buffer and red blood cell–plasma partition coefficients, P_{e/c_u} and $P_{e/c}$, respectively, were obtained for the compounds under different experimental conditions and are listed in Tables I, II, and III as mean values for erythrocytes from different donors. Red blood cell partitioning of all the tested compounds was linear and concentration independent (Table II), indicating that first-order kinetics were operative. The values for P_{e/c_u} of the individual compounds were identical in the presence and absence of large concentrations of the respective analogues (Table II). This implied the exis-

tence of binding and/or partitioning sites of large capacity within the red blood cells. The equivalency of P_{e/c_u} for the individual compounds in suspension and resuspension experiments (Table III) suggested reversibility of the red blood cell partitioning kinetics. For all the compounds tested, P_{e/c_u} is greater than P_{e/c_l}, indicating significant plasma protein binding of the compounds.

There was no clear-cut relationship between the magnitude of P_{e/c_u} and lipophilicity (P) of the compounds (Table I). Red cell partitioning from buffer or plasma was clearly temperature dependent and decreased with decreasing temperature (Table I). Semilogarithmic plots of P_{e/c_u} against $1/T$, the reciprocal of the absolute temperature, yielded apparent straight lines for all the compounds tested (Fig. 1). The P_{e/c_u} values of [^{3}H]I and its analogues in the experiments conducted at 4°C were >0.70 (Table I), the partition coefficient value predicted for compounds solely distributed within the intracellular water phase of the red blood cells (2, 16). This implied binding and/or partitioning of the compounds in nonaqueous phases within the red blood cells, even at this low temperature.

However, P_{e/c_u}, as defined, did not characterize the distribution of the compounds between a nonaqueous and an aqueous phase as required (17), but defined equilibrium conditions existing in mixed nonaqueous-aqueous (cellular) and aqueous (extracellular) phases. In conceiving the red blood cells as a two-phase (nonaqueous-aqueous) system, a true partition coefficient, P_{e_b/e_u}, was defined as the ratio of the bound/partitioned concentration in the nonaqueous phase to the unbound concentration in the aqueous phase of the cells. Values for P_{e_b/e_u} were calculated (see *Appendix I*). Similarly, the percentage of drug truly bound/partitioned within the nonaqueous phase of the red cells, β_E, was computed (see *Appendix I*) for the different compounds. The values obtained for P_{e_b/e_u} and β_E are listed in Table IV.

When P_{e_b/e_u} was plotted semilogarithmically against $1/T$, curves were obtained with all the compounds (Fig. 1). This was in contrast to the apparent linear relationship obtained previously with semilogarithmic plots of P_{e/c_u} against $1/T$ (Fig. 1).

Nonequilibrium Kinetics—Time-dependent concentration curves were not obtained for the compounds under all the experimental conditions. With the most hydrophilic compound of the series, [^{3}H]VII, erythrocyte partitionings at temperatures of 4°C and 24°C were such slow processes that substantial hemolysis occurred long before the red blood cell partitionings were at equilibrium. With the more lipophilic compounds, however, red blood cell uptake was so fast that partition equilibrium was nearly or completely reached within the interval needed for centrifuging the very first sample taken after admixing the compounds ([^{3}H]I-[^{3}H]V at 37°C, [^{3}H]II and [^{3}H]III at 24°C).

Semilogarithmic plots against time of $(B - B_{eq})/(B_0 - B_{eq})$ and of $(E_{eq} - E)/E_{eq}$, derived respectively from the experimental data obtained in erythrocytes and buffer (see *Appendix II*), gave equivalent results and could be fitted by the same line (Figs. 2 and 3). Red blood cell partitioning of the compounds was characterized by a single distribution phase in most of the experimental settings. However, two distribution phases were clearly distinguishable with [^{3}H]I and [^{3}H]IV-[^{3}H]VI (Fig. 3) at 4°C and with [^{3}H]VII at 37°C. The respective concentration-time data in the erythrocytes, e, in buffer, c_u, and in plasma, c, of all the experiments were fitted using the non-

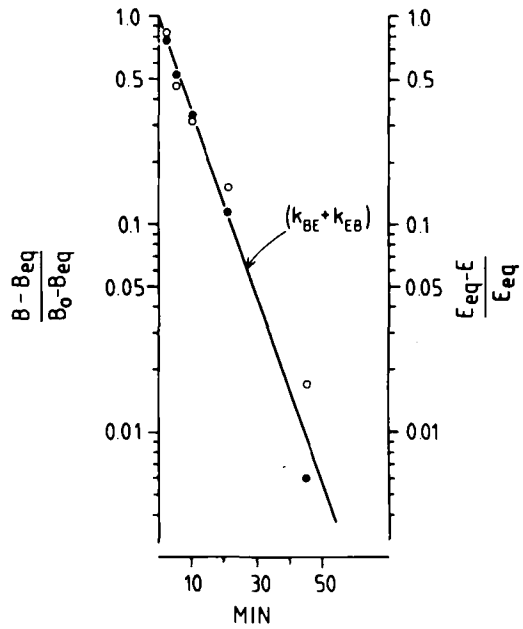

Figure 2—*Semilogarithmic plots of* $(B - B_{eq})/(B_0 - B_{eq})$ *and* $(E_{eq} - E)/E_{eq}$, *calculated from the experimental data for buffer and erythrocytes, respectively, for [^{3}H]III at 4°C. A red blood cell suspension in buffer was spiked with drug, and a single distribution phase was observed. The erythrocyte and buffer data could be fitted to the same line.*

linear least-squares estimation program TOPFIT (18). The program yielded values for the microscopic rate constants (Figs. 4–7) and equilibrium concentrations in erythrocytes, buffer, or plasma. The respective volumes of the red blood cell and buffer/plasma phases, hematocrit (Hc) and "plasmacrit" (1 − Hc), which were known in all the experiments, were fixed and not iterated.

Except for [^{3}H]VII, all data sets from the experiments were fitted individually and the fitting of the concentrations in erythrocytes, buffer, or plasma was simultaneous. The data sets obtained for [^{3}H]VII showed larger variability. The respective results of the two experiments performed with this compound in suspensions of red blood cells in buffer or in plasma were averaged and then fitted. Equal weights were given to all the erythrocyte, buffer, or plasma data. This was justified since the concentration range of all the experimental data was rather small. Attempts were made to fit all the data sets to a closed two-compartment model (Figs. 5–7); however, systematically deviating fits were obtained in those cases where two distribution phases had been seen previously in the graphic analysis of the data (Fig. 3). Adequate fits resulted when these data were fitted to a closed three-compartment model (Fig. 4).

A detailed analysis was performed with the data that had been fitted to the three-compartment model. Attempts were made to interpret, physiologically, the two erythrocyte compartments, E_1 and E_2, which were separable in these experiments (see the Scheme in Fig. 4). Plasma membrane, cellular water, and hemoglobin were expected to contain significant amounts/concentrations of the compounds (9, 19) and, thus, could be the physiological equivalents of the two erythrocyte compartments. However, it must be clearly realized that compartments E_1 and E_2 and the corresponding rate constants obtained in the kinetic analysis were interchangeable; these two compartments could be attributed to the cellular constituents and barriers as follows: (*a*) E_1 = plasma membrane + water, E_2 = hemoglobin; (*b*) E_1 = plasma membrane, E_2 =

[a] $e_{1,eq}$, $e_{2,eq}$, $e_{eq}[(e_1 + e_2)_{eq}]$, and $c_{u,eq}$, respectively the drug concentrations in the erythrocyte compartments (E_1, E_2, E) and plasma water (buffer) (B) at equilibrium, were obtained from fitting suitable data to the closed three-compartment model (see Fig. 4, *Appendix II*). The values for P_{e_b/e_u} and $\beta_E(e_b/e)_{eq}$ were predicted from P_{e/c_u}, depicting the red blood cells as consistingg of a nonaqueous and an aqueous phase of fractional volume 0.7. The values of $(e_1/e)_{eq}$ and $(e_1/e_2)_{eq}$ of the individual compounds should be compared, respectively, to P_{e_b/e_u} and β_E. The values are mean ± *SD*, with individual values in parentheses. [b] In order of decreasing lipophilicity. [c] Number of experiments performed in blood of different donors. [d] Number of mean values considered; averages of 3–5 individual determinations in blood of 3–7 donors.

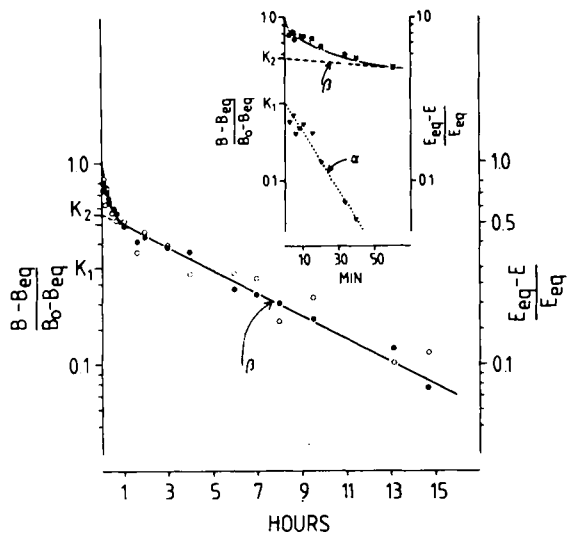

Figure 3 —*Semilogarithmic plot for [^{3}H]VI under same conditions as in Fig. 2. The inset is for the initial data on an expanded time scale. Two distribution phases were separable. The erythrocyte and buffer data could be fitted to the same line.*

water + hemoglobin; (*c*) E_1 = hemoglobin, E_2 = plasma membrane + water; and (*d*) E_1 = water + hemoglobin, E_2 = plasma membrane.

The respective concentrations in the red blood cell compartments, relative to the concentration in buffer [$(e_1/c_u)_{eq}$ and $(e_2/c_u)_{eq}$], were calculated from the microscopic rate constants obtained from the fits (see *Appendix II*). Similarly, the respective compartmental concentrations in the erythrocytes at equilibrium, as a percentage of the total concentration in the red blood cells, $10^2(e_1/e)_{eq}$ and $10^2(e_2/e)_{eq}$, and the ratio of the compartmental concentrations at equilibrium, $(e_1/e_2)_{eq}$, were computed (Table IV). It is interesting to note that, on average, $(e_2/c_u)_{eq}$ was 0.65 ± 0.05 for the tested compounds (Table IV), which is close to 0.7 (2, 16), the value predicted for the ratio of $(e_u/c_u)_{eq}$. In addition, $10^2(e_1/e)_{eq}$ of the individual compounds were similar to the predicted individual values for β_E (Table IV). Furthermore, the $(e_1/e_2)_{eq}$ values for the individual analogues agreed with the individually predicted P_{e_b/e_u} values (Table IV). This suggested that $(e_1)_{eq}$ and $(e_2)_{eq}$ obtained from the kinetic analysis on the assumption of a three-compartment model were equivalent, respectively, to e_b and e_u calculated on consideration of the physiology of erythrocytes and the P_{e/c_u} for the compounds. Hence, the most probable physiological equivalents of compartments E_1 and E_2 were, respectively, hemoglobin and cellular water + plasma membrane (alternative *c* above), on the assumption that the plasma membrane did not contain significant amounts of the drugs.

It became necessary to compare the partitioning kinetics of all the compounds under all the different experimental conditions. Hence, there was a need for a model-independent parameter. Mean transit time, $\bar{t}$, which has been used repeatedly in pharmacokinetic data analysis (20, 21), appeared to be most appropriate for this purpose. The $\bar{t}$ values for the individual experiments were calculated from the ratio of the area under the first moment curve ($AUMC_\infty$) to the area under the plasma concentration time curve (AUC_∞) (21) or from the microscopic rate constants obtained in the fits (see *Appendix II*). The values so obtained for $\bar{t}$ are listed in Table V. An upper limit for $\bar{t}$ was estimated in experiments where red blood cell partition equilibrium of the compounds was reached very quickly. There was wide variation among the $\bar{t}$ values obtained for the compounds in the different experimental settings; $\bar{t}$ ranged between <0.5 and 3800 min. Mean transit time clearly decreased with increasing lipophilicity (*P*) of the compounds (Table V, Fig. 8). For the experiments conducted at 4°C and 24°C, plots of log $(1/\bar{t})$ against log *P* yielded straight lines for the tested compounds (Fig. 8). Mean transit times of [^{3}H]I and its analogues were also highly dependent on absolute temperature. The quantitative evaluation of this dependency, using the data obtained with [^{3}H]VI and plotting log $(1/\bar{t})$ against $1/T$, showed that the relationship was nonlinear (Fig. 9).

The values obtained for $\bar{t}$ with erythrocyte buffer suspensions were significantly larger than with erythrocyte plasma suspensions for all the compounds tested; the differences ranged between 10–25% (Table IV). This implies that plasma protein binding and unbinding were not rate limiting and were much faster processes than red blood cell partitioning and repartitioning. Attempts were made to predict $(\bar{t})$, k_{PE}, and k_{EP} in red blood cell plasma suspension experiments at 24°C for [^{3}H]I and [^{3}H]IV–[^{3}H]VI from $\bar{t}$, k_{BE}, and k_{EB} in red blood cell buffer suspensions, which had been previously obtained in experiments conducted at an equivalent temperature (see *Appendix III*). There was good agreement between predicted and experimentally measured parameters for the tested compounds in the red blood cell plasma suspensions [$(\bar{t})_{pred}$ = 96.9 (±8.50)%·$(\bar{t})_{exp}$, $k_{PE,pred}$ = 103.1 (±10.4)%·$k_{PE,exp}$, and $k_{EP,pred}$ = 104.4 (±10.2)%·$k_{EP,exp}$ (n = 4)].

The similarity of the respectively obtained mean transit time values on partitioning of [^{3}H]VI from buffer into red blood cells ($\bar{t}$ = 5.1 min) and on repartitioning of the compound from erythrocytes into buffer ($\bar{t}$ = 4.9 min) (Fig. 6) suggested complete reversibility of the kinetics. Attempts were made to estimate mean transit times of repartitioning from red blood cells into buffer and plasma at 37°C for the compounds that reached partition equilibrium very quickly ([^{3}H]I–[^{3}H]V: $\bar{t}$ < 1.5 min, Table V). It was assumed that the temperature dependency of $\bar{t}$ for [^{3}H]VI in the range of 4°–37°C was also representative for the other analogues and that the equilibrium of the plasma protein interaction with the compounds was instantaneous. The estimated $\bar{t}$ values for the analogues in the red blood cell buffer suspensions at 37°C were: 0.008 min for [^{3}H]II; 0.036 min for [^{3}H]III; 0.307 min for [^{3}H]IV; 0.536 min for [^{3}H]I; and 1.39 min for [^{3}H]V (*Appendix III*). The corresponding values in the red blood cell plasma suspensions were smaller, on average 80% of the estimates obtained in the red blood cell buffer suspensions, for the slowly plasma-bound compounds ([^{3}H]I and [^{3}H]III–[^{3}H]V). In contrast, the estimated mean transit times in the two suspensions differed widely for the highly plasma-bound [^{3}H]II. The value in suspensions in plasma was clearly smaller [$(\bar{t})$ = 0.001 min] than in suspensions in buffer [$\bar{t}$ = 0.008].

Mean transit times for blood flowing through the sinusoids of the liver and the capillaries of the proximal tubules of the kidney were reported to be 10 and 2.5 s, respectively (22, 23). This suggested that, for the most lipophilic analogues ([^{3}H]II and [^{3}H]III), all of the amounts in the red blood cells could repartition during a single pass through the eliminating organs and, hence, could become available for extraction. For the least lipophilic analogues ([^{3}H]V–[^{3}H]VII), only small fractions of the amounts residing in the red blood cells could repartition and were available for extraction.

***In Vivo* Red Cell Partitioning of Digoxin and Metabolites**—Mean *in vivo*

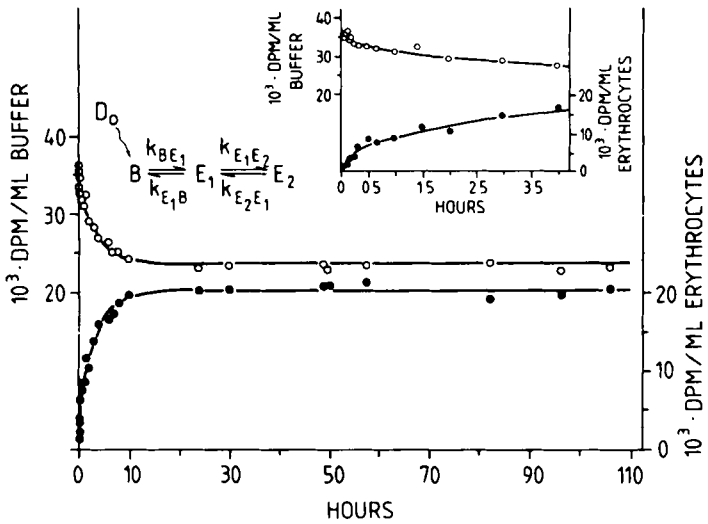

Figure 4—*Typical linear plot of the respective concentrations in erythrocytes (e) (●) and in buffer (c_u) (○) against time for [^{3}H]V at 4°C. A red blood cell suspension in buffer was spiked; the erythrocyte and buffer data were fitted simultaneously to the closed three-compartment model shown. The inset is a plot of the initial data on an expanded time scale.*

Table V—Mean Transit Time of Red Blood Cell Partitioning of Digoxin and Analogues from Buffer or Plasma at Different Temperatures

Compound[a]	$\bar{t}$ in Buffer or ($\bar{t}$) in Plasma, min[b] 4°C	n[c]	24°C	n[c]	37°C	n[c]
[^{3}H]II	1.65 ± 0.32	5	<0.50	2	<0.50	2

[a] In the order of decreasing lipophilicity. [b] Mean ± *SD*; individual values in parentheses. When multiple values are given, the upper value is in buffer, the lower value in plasma; all single values are in buffer. [c] Number of experiments performed in blood of different donors.

red blood cell-plasma partition coefficients, $\bar{P}_{e/c}^{in\ vivo}$, were determined from the ratio of the total radioactivity in erythrocytes to total radioactivity in plasma in all the blood samples obtained in the pharmacokinetic studies. The $\bar{P}_{e/c}^{in\ vivo}$ values found were dose independent, but showed a clear time dependency: they were only constant for periods of ~2 h after intravenous and oral administration of the drug and increased significantly at later times. This was most probably due to a slow red blood cell partitioning of polar derivatives of [^{3}H]I, which were consistently measurable in the plasma samples of the volunteers. $\bar{P}_{e/c}^{in\ vivo}$ values obtained within the initial 2 h after drug administration were considered for a comparison with *in vitro* red blood cell partitioning values. Estimates for $\bar{P}_{e/c}^{in\ vitro}$ were made from the individual red cell partitioning values of [^{3}H]I and its apolar metabolites ([^{3}H]IV-[^{3}H]VI), previously obtained under *in vitro* conditions at 24°C ($P_{e/c,i}^{in\ vitro}$) and the concentrations of the individual compounds measured in plasma of the volunteers ($c_{eq}^{in\ vivo}$) in accordance with:

$$\bar{P}_{e/c}^{in\ vitro} = \frac{\sum_{i=1}^{4} (P_{e/c,i}^{in\ vitro}) \cdot c_{eq,i}}{\sum_{i=1}^{4} (c_{eq,i})}$$

It was assumed that $P_{e/c} \simeq 0$ for the measured polar derivatives of [^{3}H]I. This was in accordance with the insignificant red blood cell partitioning found for the polar [^{3}H]VII within comparable time intervals at 37°C.

Mean red blood cell partitioning *in vivo* and *in vitro* at 24°C were found to be similar in the intravenous experiments [$\bar{P}_{e/c}^{in\ vivo} = 0.943 \pm 0.154$ ($n = 6$), $\bar{P}_{e/c}^{in\ vitro} = 0.971 \pm 0.012$ ($n = 6$)] and oral experiments [$\bar{P}_{e/c}^{in\ vivo} = 0.975 \pm 0.148$ ($n = 6$), $\bar{P}_{e/c}^{in\ vitro} = 0.955 \pm 0.023$ ($n = 6$)]. This suggested that results on the kinetics of red blood cell partitioning obtained under *in vitro* conditions are valid and allow conclusions regarding *in vivo* conditions.

Binding of Digoxin and Analogues to Hemolysate, Hemoglobin, Albumin, and Plasma Protein—The percentage of drug bound to hemolysate ($\beta_{HB'}$), to hemoglobin (β_{HB}), to albumin (β_{AB}), and to plasma protein (β_{PB}) were obtained with the equilibrium dialysis method. The respective values are given in Table VI (see *Appendix I*). Estimates for β_{PB} of the compounds were also obtained by the red blood cell partitioning method and are included in Table VI (see *Appendix I*).

Binding to Hemolysate—Except for [^{3}H]VII, all the compounds showed significant binding to hemolysate (hemoglobin concentration, 110 g/L) at 37°C (Table VI). The $\beta_{HB'}$ values obtained for [^{3}H]I and its analogues ranged between 47.1% ([^{3}H]II) and −5.1% ([^{3}H]VII). The apparent negative value observed with [^{3}H]VII indicated that this compound was completely unbound and, hence, was excluded from volumes where binding of the other analogues occurred (12, 24). The binding of [^{3}H]II to hemolysate was concentration independent over the range studied (20–100 ng/mL). Estimates of $\beta_{HB'}$ in hemolysates (hemoglobin concentration, 110 g/L) were significantly and consistently smaller than β_E in intact cells (hemoglobin concentration, 330 g/L) (25) (Fig. 10), indicating a diminished binding capacity of the former. This was either due to the much lower hemoglobin concentration in the hemolysates or suggested additional binding/partitioning to constituents other than hemoglobin in the intact cells. There existed a significant positive linear correlation between the values obtained for β_E and $\beta_{HB'}$ [$\beta_E = 27.4\ (\pm 4.71) + 1.11\ (\pm 0.214) \cdot \beta_{HB'}$, $r = 0.919$ (Fig. 10)].

Binding to Hemoglobin—The respective values for the binding of [^{3}H]I and [^{3}H]II to hemoglobin (110 g/L) were $\beta_{HB} = 22.0$ and 71.4% (Table VI). The former value was in agreement with the value previously obtained for the binding of [^{3}H]I to hemolysate ($\beta_{HB'} = 19.7\%$). In contrast, binding of [^{3}H]II was much greater with hemoglobin ($\beta_{HB} = 71.4\%$) than with hemolysate ($\beta_{HB'} = 47.1\%$) (Table VI). It is possible that existing differences in conformation or aggregation of hemoglobin in the two preparations affect the highly bound [^{3}H]II more than the lesser-bound [^{3}H]I. The binding of [^{3}H]II to diluted hemoglobin (7 g/L) was significant [$\beta_{HB} = 19.0$ (15.6 and 22.3; $n = 2$)] and suggested that results on the membrane binding of compounds reported in the literature (19), which had been obtained with red cell ghosts not freed from hemoglobin (14 g/L), must be interpreted with due caution.

Binding to Albumin—The values for the binding of [^{3}H]I and its analogues to albumin are listed in Table VI. The bindings of [^{3}H]II to albumins AB_1 and AB_2 were $\beta_{AB_1} = 97.0\%$ and $\beta_{AB_2} = 97.9\%$. The similarity of these results implied equivalence of the two albumins. Binding of the compounds tested ranged between $\beta_{AB} = 97\%$ ([^{3}H]II) and $\beta_{AB} = 27\%$ ([^{3}H]VII). Albumin binding increased with increasing lipophilicity (P) of the compounds [$\beta_{AB} = 24.3\ (\pm 1.78) + 0.748\ (\pm 0.043) \cdot P$, $r = 0.992$].

Binding to Plasma Protein—The mean values obtained for the plasma protein binding of [^{3}H]II, [^{3}H]III, and [^{3}H]VII together with the previously reported (1) values for [^{3}H]I and [^{3}H]IV-[^{3}H]VI are given in Table VI. All the values were obtained with the equilibrium dialysis method. Plasma protein binding of [^{3}H]II, [^{3}H]III, and [^{3}H]VII was concentration independent over the range studied and was unaltered in the presence of large concentrations of analogues. This was in accordance with the binding characteristics previously found with [^{3}H]I and [^{3}H]IV-[^{3}H]VI (1). Plasma protein bindings of

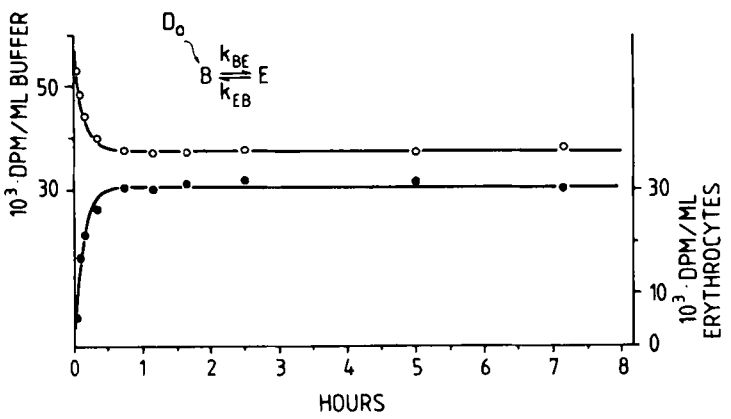

Figure 5—*Linear plot of the respective concentrations in erythrocytes (e) (●) and in buffer (c_u) (○) against time for [^{3}H]III at 24°C. A red blood cell suspension in buffer was spiked; the erythrocyte and buffer data were fitted simultaneously to the closed two-compartment model shown.*

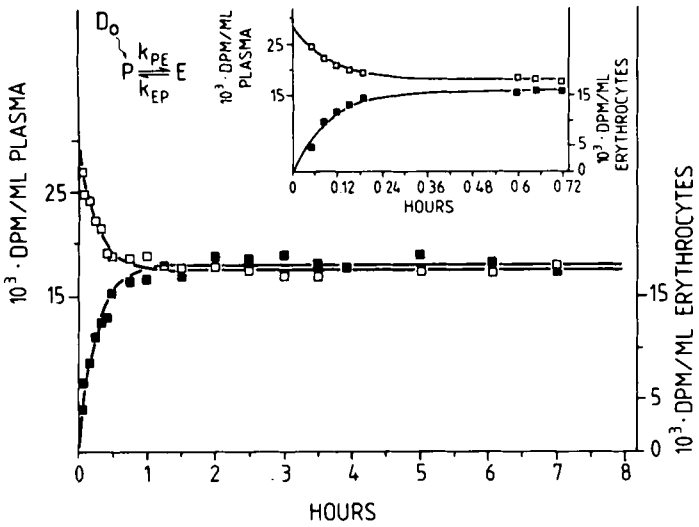

Figure 6—*Linear plot of the respective concentrations in erythrocytes (e) (■) and in plasma (c) (□) against time for [³H]V at 24°C. A red blood cell suspension in plasma was spiked; the data were fitted to the two-compartment model shown. The inset is a plot of the initial data on an expanded time scale.*

[³H]II at experimental temperatures of 24°C [β_{BP} = 96.7 ± 0.38% (n = 11)] and 37°C [β_{PB} = 95.1 ± 1.90% (n = 5)] were similar.

The binding to plasma protein was consistently smaller than to albumin for [³H]I and all the analogues tested (Table VI). A highly significant positive correlation existed between binding to albumin and to plasma protein for the compounds [$\beta_{AB} = -15.9\ (\pm 8.36) + 1.07\ (\pm 0.164)\ \beta_{PB}$, r = 0.894]. There was excellent agreement between the respective plasma protein binding estimates of the compounds obtained from the red blood cell partitioning procedure and the equilibrium dialysis method (Table VI). Plasma protein binding of [³H]I and its analogues using the red blood cell partitioning method was temperature independent within the tested range of 24–37°C (Table VI).

DISCUSSION

Octanol–Water Partition Coefficient of Digoxin and Its Analogues—The partition coefficient values obtained for [³H]I and its analogues in the present study were—except for [³H]II—in agreement with those reported previously by Cohnen *et al.* (26); a significantly higher P value was found for [³H]II in the present study. The reason for this discrepancy was not apparent, since equivalent experimental methods were used in both studies. A significant linear correlation existed between the R_m values by partition chromatography reported by Cohnen *et al.* (26) and the log P values obtained in the present study [$R_{m(30)} = 1.36\ (\pm 0.069) \cdot x - 1.47\ (\pm 0.091) \cdot \log P$, r = 0.995].

Erythrocyte Partitioning of Digoxin and Its Analogues—Red blood cell partitioning kinetics of [³H]I and its analogues were first order over a considerable concentration range, unaltered in the presence of large concentrations of analogues (Table II) and clearly temperature dependent (Table I). This suggested that red blood cell uptake of the compounds was a passive process. Its temperature dependency indicated that partitioning into the plasma membrane, diffusion through unstirred water layers, and/or interaction with hemoglobin could be rate limiting. Membrane diffusion through pores (27) was excluded for [³H]I and its analogues on consideration of the molecular weights of the compounds and the pore radius (4 Å) of the red blood cell plasma membrane (28–32).

The three-compartment model kinetics found for the less lipophilic analogues [³H]V and [³H]VI at 4°C (Figs. 3 and 4) and [³H]VII at 37°C indicated that two rate-limiting steps—one faster, one slower—were operative in these cases. Clearly the processes could be composite. In accordance with the previous physiological interpretation of the erythrocyte compartments, the slower process represented partitioning into the plasma membrane and/or diffusion through intracellular water; the faster process was equivalent to binding to hemoglobin. However, in considering the degree of acceleration of the kinetics of red blood cell partitioning of the compounds found on elevating the temperature, it was concluded that diffusion through water was most probably not a rate-limiting process (31). The three-compartment model collapsed into a two-compartment model with the more lipophilic analogues at the lowest temperature ([³H]II–[³H]III; Figs. 2 and 5) and with all the analogues except [³H]VII at the higher temperatures. This finding suggested that the slower of the two processes was accelerated by an increase in temperature or lipophilicity of the compounds and approached the rate of the faster process, so that apparently two-compartment kinetics with a single rate-limiting process evolved in these cases.

Equilibrium Kinetics—Red blood cell partition coefficients for [³H]-IV–[³H]VII have not been reported thus far in the literature; however, values for [³H]I–[³H]III have been published. Mean P_{e/c_u} and $P_{e/c}$ values of 0.97 (0.93, 1.01; n = 2) and 0.89 ± 0.030 (n = 3), respectively, had been obtained previously by Hinderling *et al.* (5). The latter value was confirmed by the results of the present study [$P_{e/c}$ = 0.88 (0.842, 0.922; n = 2)]; however, the former value was significantly smaller than the corresponding value of the present study [$P_{e/c_u} = 1.11 \pm 0.027$ (n = 3)]. Although it cannot be excluded that the discrepancy was caused by the use of plasma water instead of buffer a in the previous study, there was indications that the value of the former study was biased. Abshagen *et al.* (19), using radiolabeled compounds, reported mean red blood cell partitioning values of six donors for [³H]I and [³H]II at 37°C. The values were obtained on consideration of one drug concentration only ([³H]I: 51 ng/mL; [³H]II: 69 ng/mL). Their respective P_{e/c_u} and $P_{e/c}$ values were 0.90 and 0.90 for [³H]I and 1.37 and 0.09 for [³H]II. The former three values were significantly smaller than those found in the present study ([³H]I: P_{e/c_u} = 1.49, $P_{e/c}$ = 1.13; [³H]II: P_{e/c_u} = 2.51); there was agreement regarding the last value. Attempts to compute estimates for the plasma protein binding of the two compounds using the respective P_{e/c_u} and $P_{e/c}$ values (see *Appendix I*) of Abshagen *et al.* (19) yielded β_{PB} = 0% for [³H]I and β_{PB} = 93.1% for [³H]II. The former value was clearly lower than the values given in the literature for the plasma binding of [³H]I [β_{PB} = 23–29% (equilibrium dialysis, 37°C, normal human serum–plasma) (33–37)] and there was no ready explanation for this bias. The latter value was within the range of the

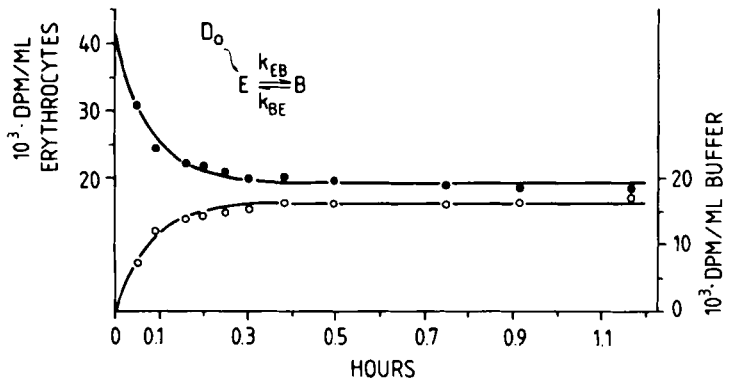

Figure 7—*Linear plot of the respective concentrations in buffer (c_u) (○) and in erythrocyte (e) (●) against time for [³H]VI at 24°C. Red blood cells suspended in buffer and spiked with the compound were separated centrifugally and then resuspended in fresh buffer. The data were fitted according to the two-compartment model shown.*

values reported in the literature for the plasma binding of [^{3}H]II [β_{PB} = 92–97% (equilibrium dialysis, 37°C, normal human serum–plasma) (33–35, 38)].

Nonequilibrium Kinetics—Gardner *et al.* (9) reported mean data on the kinetics of red blood cell partitioning for [^{3}H]I (9–94 ng/mL) at 37°C. An apparent $\bar{t}$ value of 13 min could be calculated from those results. This value was much larger than the corresponding estimate of $\bar{t} < 0.5$ min obtained in the present study. The discrepancy was possibly due to differences in the methods employed. The procedure of Gardner *et al.* used a different buffer and the red blood cell suspensions had much lower hematocrits (5–10%); the incubated red blood cell suspensions were repeatedly washed (at nonspecified temperatures) prior to the final ultracentrifugal separation of the cells and buffer. The surprisingly low values for P_{c/c_u} of 0.65 and 0.40 at concentrations of 9 and 94 ng/mL of the drug, respectively, calculated from their data, indicated that the washing procedure used may have led to a substantial loss of drug from the cells.

Binding of Digoxin and Its Analogues to Hemolysate, Hemoglobin, and Plasma Protein—Hemoglobin (*per se* and in hemolysate preparations) was shown to bind significantly all the compounds tested with the exception of [^{3}H]VII (Table VI). A statistically significant linear correlation existed between binding to hemolysate and binding to intact cells for [^{3}H]I–[^{3}H]VI (Fig. 10). These results suggested that hemoglobin was the major red blood cell constituent that interacted with the compounds. An important binding of the analogues to constituents other than hemoglobin could not be excluded; however, the finding that low concentrations of hemoglobin (7 g/L) bound substantial amounts of [^{3}H]II suggested that reported plasma membrane binding values (9, 19) could be overestimations, since the membrane preparations used in these studies were not free of hemoglobin.

The differences in the binding of [^{3}H]I and its analogues to hemolysate, hemoglobin, and suspensions of intact cells observed in the present study could be explained by the nonequivalence of the three preparations. The cell suspensions had larger hemoglobin concentrations and included additional constituents with binding potential. In addition, conformation and aggregation of hemoglobin in the different preparations were possibly not identical.

The binding of [^{3}H]I and its analogues in albumin preparations was consistently larger than in plasma. Albumin was reported to be the sole protein in plasma to interact with [^{3}H]I and [^{3}H]II (38, 39). The different binding performance observed could be due to a nonidentical conformation or aggregation of the commercially available albumin in buffer *a* and of the "natural" albumin in plasma water. Alternatively, and more likely, this discrepancy was due to a difference in the concentrations of free fatty acids in the albumin preparations and in the plasma used. Free fatty acids at physiological concentrations in plasma were shown to interfere with the binding of drugs to albumin (40). Elevated concentrations of free fatty acids were reported to decrease, significantly, the binding of [^{3}H]I and [^{3}H]II in plasma (41).

Data on the binding of [^{3}H]I and [^{3}H]II to albumin at 37°C, obtained with equilibrium dialysis methods, are reported in the literature. Lukas and de Martino (38) reported β_{AB} = 23% for [^{3}H]I, employing an albumin with a significant free fatty acid content. This value was clearly smaller than β_{AB} = 34.2% for [^{3}H]I found in the present study, which used a fatty acid-free albumin preparation (Table VI). Brock (39) reported a value of β_{AB} = 96.6% for [^{3}H]II with no specification as to the fatty acid content of the albumin used. This value was close to the β_{AB} = 97.2% obtained in the present study (Table VI).

Widely varying plasma protein binding values were reported for [^{3}H]I and [^{3}H]II in the literature (35). The discrepancies were most likely due to differences in the methodologies and experimental conditions used in the studies. For a discussion of the results of the present study, only those data reported in the literature that had been obtained on application of equivalent procedures (equilibrium dialysis, individual plasma of healthy volunteers, temperature 37°C, pH 7.4) were considered. The average percent plasma protein binding found for [^{3}H]II (β_{PB} = 95.6%, Table VI) in the present study was within the

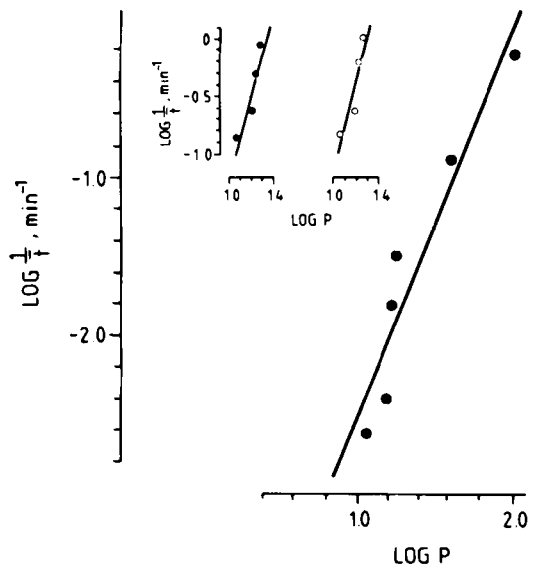

Figure 8—*Logarithmic plot of the reciprocal of the averaged mean transit time, $1/\bar{t}$, against the octanol–water partition coefficient, P, for [^{3}H]I–[^{3}H]VI at an experimental temperature of 4°C. Red blood cell suspensions in buffer were spiked with the compounds. There was an apparent linear dependency of log ($1/\bar{t}$) on log P [log ($1/\bar{t}$) = −5.00 (±0.608) + 2.49 (±0.0428) · log P, r = 0.995]. Corresponding plots are given in the inset for [^{3}H]I and [^{3}H]-IV–[^{3}H]VI in red blood cell–buffer suspensions (●) and in red blood cell–plasma suspensions (○) at an experimental temperature of 24°C.*

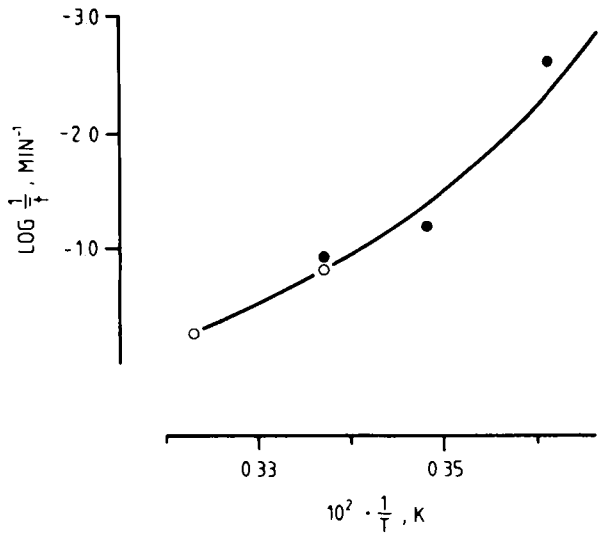

Figure 9—*Linear plot of the logarithm of the reciprocal of the averaged mean transit time, $1/\bar{t}$, against the reciprocal of the absolute temperature, 1/T, for [^{3}H]VI at 4°C, 14°C, 24°C, and 37°C. The relationship between log ($1/\bar{t}$) and 1/T was nonlinear. Key: (●) red blood cell–buffer suspensions; (○) red blood cell–plasma suspensions.*

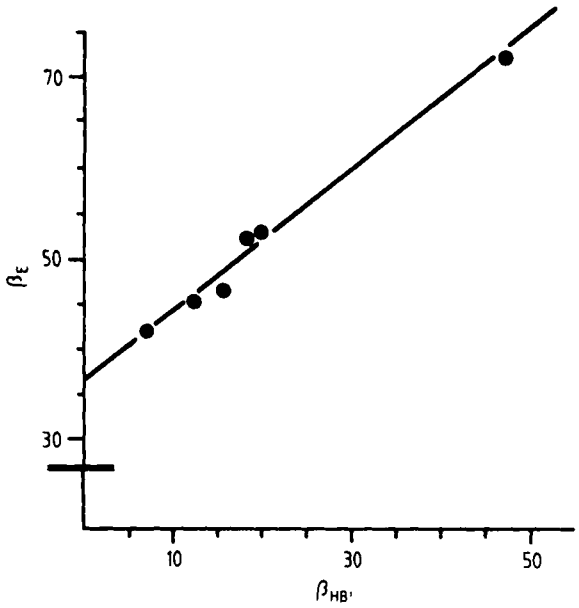

Figure 10—*Linear plot of the percentage bound in intact erythrocytes, β_E, against the percentage bound in hemolysate, $\beta_{HB'}$, for [^{3}H]I–[^{3}H]VI at 37°C. There was an apparent linear relationship between β_E and $\beta_{HB'}$ [β_E: 36.7 (±1.19) + 0.762 (±0.0502) · $\beta_{HB'}$, r = 0.992].*

range of the values given in the literature [92.3–97.3% (33–35, 38)]. The corresponding value for [^{3}H]III, β_{PB} = 25.1%, in the present study was close to the β_{PB} = 25.8% reported by Kramer *et al.* (34), but exceeded the value reported by Dengler *et al.* (42) (β_{PB} = 14%) for this drug. The plasma binding of [^{3}H]VII (β_{PB} = 13.9%) in the present study was similar to the sole value reported in the literature [β_{PB} = 16% (43)] for this drug. The temperature independence of the plasma binding of [^{3}H]I and its analogues for the range of 24–37°C observed in the present study was in agreement with equivalent findings of earlier studies with [^{3}H]II (35, 39).

CONCLUSIONS

The present study showed that red blood cell partitioning under *in vivo* and *in vitro* conditions gave equivalent results. The rate and extent of the red blood cell partitioning of [^{3}H]I and its analogues were according to first-order kinetics, identical in the presence and absence of structurally related compounds, and dependent on lipophilicity and temperature. The kinetics of red blood cell partitioning were reversible. Except for the rather strong temperature dependence found, the results were in accordance with passive diffusion as the underlying process (44, 45). The kinetics of red blood cell partitioning of the compounds from plasma could be predicted from the results obtained in analogous experiments with red blood cell buffer suspensions. The rate constants of red blood cell partitioning and repartitioning were much smaller than the rate constants of plasma protein binding and unbinding for the compounds tested.

Mean transit times of partitioning between red blood cells and plasma water were largely different for the compounds tested and varied at 37°C more than 1000-fold. Similarly, large differences in the kinetics of red blood cell partitioning were reported by Schanker *et al.* (2) for a series of basic compounds which differed in lipophilicity. Measured and estimated values for the mean transit time of the compounds at 37°C indicated that there could be significant repartitioning from red blood cells into plasma during a single passage of blood through the eliminatory organs with the more lipophilic analogues. In contrast, only insignificant red blood cell repartitioning occurred with the less lipophilic analogues.

Plasma membrane partitioning appeared to be the rate-limiting step in the red blood cell penetration of the compounds. All the compounds tested—with the exception of [^{3}H]VII—exerted significant binding/partitioning in a "nonaqueous" phase of the red blood cells. Hemoglobin was the major ligate among the erythrocyte constituents.

Plasma protein bindings of [^{3}H]I and its analogues were concentration independent and unaltered in the presence of structurally related compounds. Binding of [^{3}H]I and the analogues to plasma did not simply reflect the interaction between the individual compounds and albumin, but included the interfering action of fatty acids. Albumin binding of the compounds increased with increasing lipophilicity.

In contrast to plasma protein binding, erythrocyte partitioning of the tested compounds was temperature dependent within the range of 24–37°C. Temperature-dependent repartitioning of the compounds from the red blood cells into plasma on lowering the temperature from 37°C to 24°C was low for the tested compounds, leading to an increase in the plasma concentrations of 2–6%. However, it is entirely feasible that for drugs with more extensive red blood cell partitioning, temperature-dependent red blood cell repartitioning could lead to important artifactual changes in the plasma concentration.

The study demonstrated that the delineation of the kinetics of digoxin and analogues in the subcompartments of blood (erthrocytes and plasma) was mandatory and that *a priori* assumptions regarding the rate and extent of red blood cell partitioning of drugs are unwarranted. In defining clearance in the well-stirred (46) or parallel-tube models (47), it was assumed that drug repartitioning from red blood cells into plasma water was instantaneous, so that the unbound fraction was maintained during the passage of blood through the eliminatory organs. However, the results of this study suggest that this may not generally be true. Hence, in the reported literature, clearance values of drugs estimated without experimentally testing the kinetics of red blood cell partitioning may be biased.

APPENDIX I: Calculations for Partition Coefficients and Percentages Bound

Apparent Red Blood Cell–Buffer (P_{e/c_u}) and Red Blood Cell–Plasma Partition Coefficients ($P_{e/c}$)—Red blood cell–buffer and red blood cell–plasma partition coefficients of drugs have been defined previously (48):

$$P_{e/c_u} = \left(\frac{e}{c_u}\right)_{eq} \quad \text{(Eq. 1A)}$$

$$P_{e/c} = \left(\frac{e}{c}\right)_{eq} \quad \text{(Eq. 2A)}$$

where $c_{u,eq}$, c_{eq} [*i.e.*, $(c_u + c_b)_{eq}$], and e_{eq} [*i.e.*, $(e_u + e_b)_{eq}$] represent, respectively, the unbound concentration of a drug in plasma water (buffer), the total (bound + unbound) concentration in plasma, and the total (bound + unbound) concentration in red blood cells at equilibrium.

True Red Blood Cell Partition Coefficient—The red blood cell partition coefficient, P_{e_b/e_u}, may be defined as the ratio of the unbound to bound red blood cell concentration of a drug at equilibrium:

$$P_{e_b/e_u} = (e_b/e_u)_{eq} \quad \text{(Eq. 3A)}$$

On the assumption that the concentration of a nonelectrolytic drug in the aqueous phase of the red blood cells at equilibrium is equal to the known concentration in the surrounding plasma water (buffer), $c_{u,eq}$, and by setting the fractional volume of the red cell water phase equal to 0.7 (2, 16), e_u can be calculated:

$$e_{u,eq} = 0.7 \cdot c_{u,eq} \quad \text{(Eq. 4A)}$$

In substituting $e_{b,eq}$ with $(e - e_u)_{eq}$ and $e_{u,eq}$ with $0.7 \cdot c_{u,eq}$, an expression for P_{e_b/e_u} is obtained:

$$P_{e_b/e_u} = \frac{P_{e/c_u}}{0.7} - 1 \quad \text{(Eq. 5A)}$$

Percentage of Drug Bound and/or Partitioned in Red Blood Cells—The percentage of a compound bound to and/or partitioned into the nonaqueous phase of red cells, β_E, was defined according to:

$$\beta_E = 10^2 \cdot \left(\frac{e_b}{e}\right)_{eq} = 10^2\left[1 - \left(\frac{e_u}{e}\right)_{eq}\right] \quad \text{(Eq. 6A)}$$

On substitution of Eq. 4A into Eq. 6A an expression for β_E is obtained:

$$\beta_E = 10^2[1 - (0.7/P_{e/c_u})] \quad \text{(Eq. 7A)}$$

Respective Percentages of Drug Bound to Hemolysate, Hemoglobin, Albumin, and Plasma Protein—In the studies which employed the equilibrium dialysis method, the percentage of bound drug, β, was obtained from:

$$\beta = 10^2(c_b/c)_{eq} = 10^2[(c - c_u)/c]_{eq} \quad \text{(Eq. 8A)}$$

In the studies which used the red blood cell partitioning method to estimate plasma protein binding, β_{PB} was calculated from Eq. 9A as reported previously (7):

$$\beta_{PB} = 10^2[1 - (P_{e/c}/P_{e/c_u})] \quad \text{(Eq. 9A)}$$

APPENDIX II: Compartmental Models

Closed Two-Compartment Model (Figs. 4–6)—The integrated equations for this model and the initial conditions, $B = B_0$ and $E = 0$, are in accordance with (49):

$$B = \frac{B_0}{k_{BE} + k_{EB}} [k_{EB} + k_{BE} \cdot e^{-(k_{BE}+k_{EB})t}] \quad \text{(Eq. 10A)}$$

$$E = \frac{k_{BE}B_0}{k_{BE} + k_{EB}} [1 - e^{-(k_{BE}+k_{EB})t}] \quad \text{(Eq. 11A)}$$

where $B_0(D_0)$, B, and E represent the dose and the amounts of drug in the plasma water (buffer) and red blood cells, respectively. Equation 10A can be transformed into:

$$\frac{B(k_{BE} + k_{EB}) - k_{EB} \cdot B_0}{k_{BE} \cdot B_0} = e^{-(k_{BE}+k_{EB})t} \quad \text{(Eq. 12A)}$$

Solving Eqs. 10A and 11A for $t = \infty$ (at equilibrium) yields respectively:

$$k_{BE} + k_{EB} = \frac{k_{EB} \cdot B_0}{B_{eq}} \quad \text{(Eq. 13A)}$$

$$k_{BE} + k_{EB} = \frac{k_{BE} \cdot B_0}{E_{eq}} \quad \text{(Eq. 14A)}$$

where B_{eq} and E_{eq} are, respectively, the amounts in plasma water (buffer) and red blood cells at equilibrium. Substituting Eq. 13A into Eq. 12A and rearranging gives:

$$\frac{B - B_{eq}}{B_0 - B_{eq}} = e^{-(k_{BE}+k_{EB})t} \quad \text{(Eq. 15A)}$$

Equation 15A can be formulated in terms of the amounts of drug in the red blood cells:

$$\frac{E_{eq} - E}{E_{eq}} = e^{-(k_{BE}+k_{EB})t} \quad \text{(Eq. 16A)}$$

Plots of $\ln [(B - B_{eq})/(B_0 - B_{eq})]$ or $\ln [(E_{eq} - E)/E_{eq}]$ against time yield identical negative slopes of $(k_{BE} + k_{EB})$ and intercepts of 1.0 (see Fig. 2).

The mean transit time, $\bar{t}$, for the closed two-compartment model is obtained in accordance with (21):

$$\bar{t} = \frac{AUMC_\infty}{AUC_\infty} = \frac{[(B_0 - B_{eq})/(1 - Hc)]/(k_{BE} + k_{EB})^2}{[(B_0 - B_{eq})/(1 - Hc)]/(k_{BE} + k_{EB})} = \frac{1}{k_{BE} + k_{EB}} \quad \text{(Eq. 17A)}$$

Closed Three-Compartment Model (Fig. 4)—The integrated equations for this model and the initial conditions, $B = B_0$ and $E_1 = E_2 = 0$, are in accordance with (49):

$$B = B_0 \left\{ \frac{k_{E_1B} \cdot k_{E_2E_1}}{\alpha \cdot \beta} + \left[\frac{\alpha^2 - \alpha(k_{E_1B} + k_{E_1E_2} + k_{E_2E_1}) + k_{E_1B} \cdot k_{E_2E_1}}{\alpha(\alpha - \beta)} \right] \cdot e^{-\alpha t} + \left[\frac{\beta^2 - \beta(k_{E_1B} + k_{E_1E_2} + k_{E_2E_1}) + k_{E_1B} \cdot k_{E_2E_1}}{\beta(\beta - \alpha)} \right] \cdot e^{-\beta t} \right\} \quad \text{(Eq. 18A)}$$

$$E = E_1 + E_2 = k_{BE_1}B_0 \left\{ \frac{k_{E_2E_1} + k_{E_1E_2}}{\alpha \cdot \beta} + \left[\frac{k_{E_2E_1} + k_{E_1E_2} - \alpha}{\alpha(\alpha - \beta)} \right] \cdot e^{-\alpha t} + \left[\frac{k_{E_2E_1} + k_{E_1E_2} - \beta}{\beta(\beta - \alpha)} \right] \cdot e^{-\beta t} \right\} \quad \text{(Eq. 19A)}$$

where:

$$\alpha,\beta = \frac{1}{2} [k_{BE_1} + k_{E_1B} + k_{E_1E_2} + k_{E_2E_1} \pm \sqrt{(k_{BE_1} + k_{E_1B} + k_{E_1E_2} + k_{E_2E_1})^2 - 4k_{BE_1} \cdot k_{E_1E_2} + k_{E_1B} \cdot k_{E_2E_1} + k_{BE_1} \cdot k_{E_2E_1}}] \quad \text{(Eq. 20A)}$$

Equation 18A can be transformed and written in a form which is equivalent to Eqs. 15A and 16A of the two-compartment model:

$$\frac{B - B_{eq}}{B_0 \cdot B_{eq}} = \frac{E_{eq} - E}{E_{eq}} = K_1 \cdot e^{-\alpha t} + K_2 \cdot e^{-\beta t} \quad \text{(Eq. 21A)}$$

Similarly plots of $\ln [(B - B_{eq})/(B_0 - B_{eq})]$ or $\ln [(E_{eq} - E)/E_{eq}]$ against time have an intercept of 1.0 and a terminal logarithmic linear phase with a negative slope of β. By, respectively, extrapolating and using peeling-off techniques, the intercepts, K_2, K_1, and the slope α of the faster exponential term can be obtained (see Fig. 3).

The mean transit time for the closed three-compartment model with measurements in compartment B, $\bar{t}_B$, can be computed in accordance with (21):

$$\bar{t}_B = \frac{AUMC_{\infty,B}}{AUC_{\infty,B}} = \frac{[(B_0 - B_{eq})/(1 - Hc)]/(k_1/\alpha^2 + k_2/\beta^2)}{[(B_0 - B_{eq})/(1 - Hc)]/(k_1/\alpha + k_2/\beta)} = \frac{k_1/\alpha + k_2/\beta}{k_1/\alpha^2 + k_2/\beta^2} \quad \text{(Eq. 22A)}$$

Alternatively, $\bar{t}_B$, can be calculated and expressed in terms of the microscopic rate constants in accordance with:

$$\bar{t}_B = \frac{1}{k_{E_1B} + k_{E_1E_2} + k_{E_2E_1}} \cdot \left[\frac{(k_{E_1B} + k_{E_1E_2} + k_{E_2E_1})^2 - k_{E_1B} \cdot k_{E_2E_1} + k_{E_1B} \cdot k_{BE_1}}{k_{BE_1}(k_{E_1E_2} + k_{E_2E_1}) + k_{E_1B} \cdot k_{F_2E_1}} - \frac{k_{E_1B} \cdot k_{E_2E_1}}{(k_{E_1F_2} + k_{E_2E_1})^2 + k_{E_1B} \cdot k_{E_1E_2}} \right] \quad \text{(Eq. 23A)}$$

This alternative way of calculating $\bar{t}$ from the microscopic rate constants of compartmental systems will be presented in a forthcoming paper[10].

Calculation of Equilibrium Concentrations of Drugs in Erythrocytes ($e_{1,eq}$, $e_{2,eq}$, and e_{eq}) and Plasma Water/Buffer ($c_{u,eq}$) Using the Microscopic Rate Constants Obtained from the Fits (Table IV)—*Two-Compartment Model:*

$$e_{eq} = \frac{E_{eq}}{Hc} = \frac{k_{BE}}{k_{EB}} \cdot \frac{B_{eq}}{Hc} \quad \text{(Eq. 24A)}$$

$$c_{u,eq} = \frac{B_{eq}}{1 - Hc} = \frac{k_{EB}}{k_{BE}} \cdot \frac{E_{eq}}{1 - Hc} \quad \text{(Eq. 25A)}$$

$$P_{e/c_u} = \frac{k_{BE}}{k_{EB}} \cdot \frac{1 - Hc}{Hc} \quad \text{(Eq. 26A)}$$

Three-Compartment Model:

$$e_{1,eq} = \frac{E_{1,eq}}{Hc} = \left(\frac{k_{BE_1} \cdot k_{E_2E_1} \cdot B_0}{\alpha \cdot \beta} \right) \cdot \frac{1}{Hc} \quad \text{(Eq. 27A)}$$

$$e_{2,eq} = \frac{E_{2,eq}}{Hc} = \left(\frac{k_{BE_1} \cdot k_{E_1E_2} \cdot B_0}{\alpha \cdot \beta} \right) \cdot \frac{1}{Hc} \quad \text{(Eq. 28A)}$$

$$c_{u,eq} = \frac{B_{eq}}{1 - Hc} = \left(\frac{k_{E_1B} \cdot k_{E_2E_1} \cdot B_0}{\alpha \cdot \beta} \right) \cdot \frac{1}{1 - Hc} \quad \text{(Eq. 29A)}$$

$$(e_1/c_u)_{eq} = \frac{k_{BE_1}}{k_{E_1B}} \cdot \frac{1 - Hc}{Hc} \quad \text{(Eq. 30A)}$$

$$(e_2/c_u)_{eq} = \left(\frac{k_{BE_1} \cdot k_{E_1E_2}}{k_{E_1B} \cdot k_{F_2E_1}} \right) \left(\frac{1 - Hc}{Hc} \right) \quad \text{(Eq. 31A)}$$

$$P_{e/c_u} = (e/c_u)_{eq} = \left(\frac{k_{BE_1} \cdot k_{E_1E_2}}{k_{E_1B} \cdot k_{F_2E_1}} + \frac{k_{BE_1}}{k_{E_1B}} \right) \left(\frac{1 - Hc}{Hc} \right) \quad \text{(Eq. 32A)}$$

APPENDIX III: Prediction of Apparent Mean Transit Time and Rate Constants of a Drug in a Erythrocyte Plasma Suspension from Its True Mean Transit Time and Rate Constants in an Erythrocyte Buffer Suspension Assuming a Two-Compartment Model

The values of the apparent $(\bar{t})$, k_{PE}, and k_{EP} for a drug in a red blood cell plasma suspension are expected to be different from the values of the true $\bar{t}$, k_{BE}, and k_{EB} for the same drug in a red blood cell buffer suspension. Plasma protein binding affects extent and rate of drug partitioning into red blood cells in a suspension in plasma. On the assumption that drug binding to and unbinding from plasma protein is much faster than drug partitioning into and repartitioning from red blood cells, predictions of $(\bar{t})$, k_{PE}, and k_{EP} from $\bar{t}$, k_{BE}, and k_{EB}, respectively, are possible.

The plasma binding-induced alteration of the equilibrium conditions and its impact on the magnitude of the parameters in a red blood cell suspension in plasma relative to a red blood cell suspension in buffer is considered first. Equation 16A can be reformulated:

$$\frac{E_{eq}}{E_{eq} - E} = e^{t/\bar{t}} \quad \text{(Eq. 33A)}$$

for a red blood cell buffer suspension experiment and:

$$\frac{(E_{eq})}{(E_{eq}) - (E)} = e^{t/(\bar{t})} \quad \text{(Eq. 34A)}$$

for a red cell plasma suspension experiment. Solving Eqs. 33A and 34A for $t = \bar{t}$ and $t = (\bar{t})$, respectively, yields:

$$E_{t=\bar{t}}/E_{eq} = (1 - e^{-t/\bar{t}}) = 0.632 \quad \text{(Eq. 35A)}$$

$$(E_t)_{=(\bar{t})}/(E_{eq}) = (1 - e^{-t=(\bar{t})}) = 0.632 \quad \text{(Eq. 36A)}$$

[10] R. Sperb and P. H. Hinderling, unpublished results.

Equations 35A and 36A indicate that after a lapse of $\bar{t}$ after drug administration to buffer or of $(\bar{t})$ after administration of drug to plasma, 63.2% of the amounts, respectively, residing in the erythrocytes at partition equilibrium have reached the cells. (Analogously for a drug "administration" into red blood cells, after a lapse of $\bar{t}$ following drug administration, 63.2% of the amounts, respectively, residing in plasma at partition equilibrium have reached the plasma.)

In the following fractional equilibria $[E_{t=\gamma\bar{t}} = (1 - e^{-\gamma})\cdot E_{eq}, (E_t)_{=\gamma\cdot(\bar{t})} = (1 - e^{-\gamma})\cdot(E_{eq})]$ of a drug and the respective times for their attainment in red blood cell suspensions, $t = \gamma\cdot\bar{t}$ and $(t) = \gamma\cdot(\bar{t})$, where γ is a dimensionless fraction ($0 < \gamma \leq 1$), will be considered. The respective fractional equilibria in a red blood cell suspension in plasma and in buffer are not equivalent for a plasma protein-bound drug. The shift in the equilibrium toward the plasma site in the former suspension affects the magnitude of the parameters. This effect can, however, be assessed theoretically in an erythrocyte buffer suspension. Fractional equilibrium conditions equivalent to those in an erythrocyte plasma suspension are reached at some time, $t = \gamma\cdot\bar{t}'$, after addition of drug to a red blood cell buffer suspension $[E_{t=\gamma\bar{t}'} = (1 - e^{-\gamma})E'_{eq}]$. Intuitively, the corresponding new mean transit time, $\bar{t}'$, should be smaller than $\bar{t}$ (and accordingly k'_{BE}, and k'_{EB} should be larger than k_{BE} and k_{EB}) since the new fractional equilibrium is reached earlier than the true fractional equilibrium in a red blood cell in buffer suspension.

The ratio of $\gamma\cdot\bar{t}$ to $\bar{t}'$, r, can be calculated from:

$$r = \gamma\frac{\bar{t}}{\bar{t}'} = -\ln\left[\frac{E'_{eq} - E_{t=\gamma\cdot\bar{t}}}{E'_{eq}}\right] \qquad \text{(Eq. 37A)}$$

After substituting Eqs. 1A, 2A, 9A, 24A, 25A, and 35A and rearranging, Eq. 37A can be reformulated:

$$r = \gamma\frac{\bar{t}}{\bar{t}'} = -\ln\left\{1 - \left[(1 - e^{-\gamma}) \cdot \frac{[(1 - \beta_{PB}/10^2)\cdot P_{e/c_u}\cdot Hc] + (1 - Hc)}{(1 - \beta_{PB}/10^2)\cdot[P_{e/c_u}\cdot Hc + (1 - Hc)]}\right]\right\} \qquad \text{(Eq. 38A)}$$

and k'_{BE} and k'_{EB} are then obtained from:

$$k'_{BE} = k_{BE}\cdot\frac{r}{\gamma} \qquad \text{(Eq. 39A)}$$

$$k'_{EB} = k_{EB}\cdot\frac{r}{\gamma} \qquad \text{(Eq. 40A)}$$

The plasma binding-induced reduction of the amounts of drug that can partition into the red blood cells is now considered. In a red blood cell plasma suspension only the unbound drug fraction in plasma is available for cell partitioning. The magnitude of the apparent partitioning constant, k_{PE}, referenced to the total (bound + unbound) drug concentration in plasma, will be affected in accordance with:

$$k_{PE} = k'_{BE}\cdot\left(1 - \frac{\beta_{PB}}{10^2}\right) = k_{BE}\cdot\frac{r}{\gamma}\left(1 - \frac{\beta_{PB}}{10^2}\right) \qquad \text{(Eq. 41A)}$$

Hence, if plasma protein binding and red blood cell buffer partitioning of a drug are known, the apparent parameters $(\bar{t})$, k_{PE}, and k_{EP} in an erythrocyte plasma suspension can be predicted from the true parameters ($\bar{t}$, k_{BE}, and k_{EB}) obtained for the drug in an erythrocyte buffer suspension according to:

$$(\bar{t}) = \frac{1}{k_{PE} + k_{EP}} = \frac{1}{\frac{r}{\gamma}[k_{BE}(100 - \beta_{PB}) + k_{EB}]} \qquad \text{(Eq. 42A)}$$

$$k_{PE} = \frac{r}{\gamma}[k_{BE}(100 - \beta_{PB})] \qquad \text{(Eq. 43A)}$$

$$k_{EP} = \frac{r}{\gamma}\cdot k_{EB} \qquad \text{(Eq. 44A)}$$

Absorption and Disposition of Ethambutol in Rabbits

M. M. CHEN *, C. S. LEE ‡x, and J. H. PERRIN *

Received May 9, 1983, from the **Department of Pharmacy, University of Florida, Gainesville, FL 32610* and the ‡*Department of Pharmaceutics, University of Houston, Houston, TX 77030.* Accepted for publication July 13, 1983.

Abstract □ The absorption and disposition of ethambutol was examined in six rabbits in a three-way crossover study. Each rabbit received 45-mg/kg doses of ethambutol in three treatments: one intravenous injection, and two oral solutions, ethambutol alone and ethambutol in the presence of aluminum hydroxide (40 mg/kg). Half-lives of ethambutol ranged from 2.26 to 5.20 h when administered alone and 2.18 to 4.00 h when coadministered with the antacid; the difference was not significant ($p > 0.3$). Mean clearance after the oral administrations (189.2 mL/min/kg) was significantly greater than the mean intravenous clearance (43.7 mL/min/kg) ($p < 0.01$), suggesting a first-pass metabolism of ethambutol when administered nonparenterally to rabbits. The volume of distribution ranged from 5.5 to 17.8 L/kg, suggesting an extensive distribution of ethambutol outside the central compartment and, possibly, a localized deposit within the body tissues. Mean bioavailability of ethambutol was ~28% and was not affected by the presence of aluminum hydroxide. The rate of ethambutol absorption, however, was slightly delayed by the antacid.

Keyphrases □ Ethambutol—pharmacokinetics in rabbits, coadministration with aluminum hydroxide □ Aluminum hydroxide—effect on ethambutol absorption in rabbits □ Bioavailability—absorption of ethambutol in rabbits, coadministration with aluminum hydroxide

Ethambutol (I), an antitubercular agent, is prescribed alone or in combination with other drugs for the treatment of tuberculosis. The absorption and excretion of I has been studied in rats and mice (1), dogs (2, 3), and humans (4–6). The median lethal dose (LD_{50}) of racemic I in noninfected adult mice was 12,800 mg/kg when administered orally, 1600 mg/kg when administered subcutaneously, 800–1600 mg/kg when administered intraperitoneally, and 200–400 mg/kg when administered intravenously (1). Since I is well absorbed in mice and the drug metabolites are pharmacologically inactive (3), the remarkable discrepancies in LD_{50} following different administration routes suggest a first-pass metabolism of the drug when taken nonparenterally. A part of this study was thus designed to investigate the effect of first-pass metabolism on the availability of I in rabbits.

Pharmacokinetic studies comparing the intravenous and oral administrations of I to humans have demonstrated rapid and adequate absorption, with bioavailabilities of 70–80% (6, 7). The oral solution and tablets of I were equally well absorbed in humans (6), suggesting a gastric emptying rate- rather than dissolution rate-limited absorption of the drug. Aluminum ion is a known inhibitor of gastric emptying, and its effect on drug absorption has been documented (8). Mattila *et al.* (9) have investigated the effect of aluminum hydroxide on the absorption of I in humans; the results were erratic. Since the results of Matilla *et al.* (9) were inconclusive, this study also seeks to clarify the effect of aluminum hydroxide on the absorption of I using the rabbit model.

EXPERIMENTAL SECTION

Materials—All materials used in this study were the same as those used in a previous investigation (10).

Animal Experiments—Six male New Zealand White rabbits (weight, 2.8–4.1 kg) were studied in a three-way crossover manner. Each rabbit received 45-mg/kg doses of I in three separate treatments: as an intravenous injection, as an oral solution, and as an oral solution in the presence of aluminum hydroxide (40 mg/kg). Gastric emptying of solid food residues was induced by fasting for 38–42 h before drug administration. Water was allowed *ad libitum* during fasting; food and water were withheld over the experimental period. A 2-week washout interval was implemented between the crossover studies.

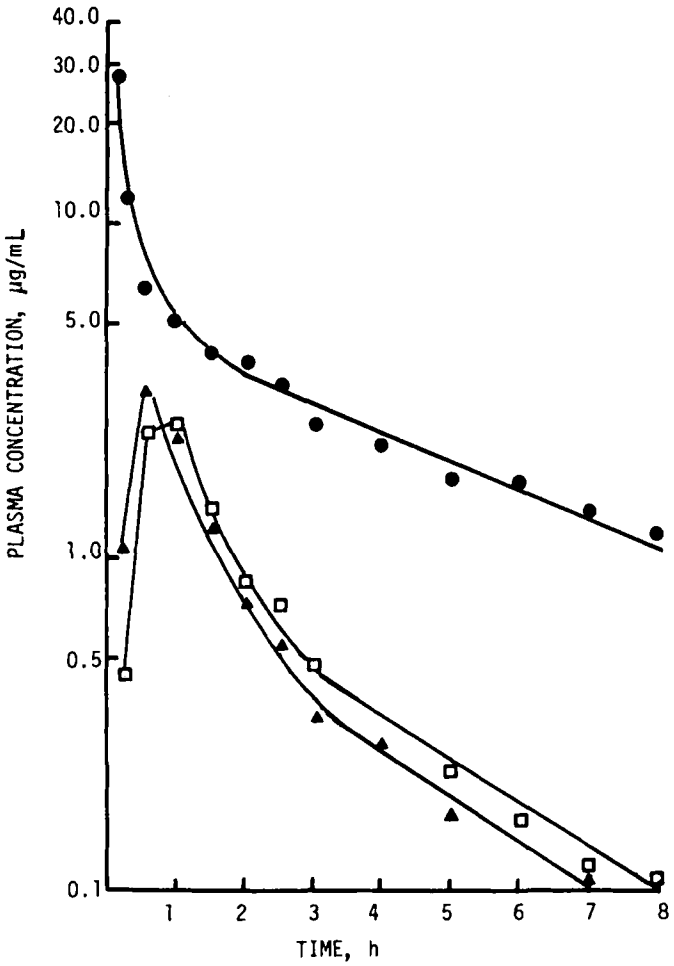

Figure 1—*Semilogarithmic plasma concentration* versus *time plots for rabbit 6 administered ethambutol (45 mg/kg) intravenously (●) and orally (▲, without aluminum hydroxide; □, with the antacid).*

Absorption and Disposition of Ethambutol in Rabbits

M. M. CHEN *, C. S. LEE ‡x, and J. H. PERRIN *

Received May 9, 1983, from the **Department of Pharmacy, University of Florida, Gainesville, FL 32610* and the ‡*Department of Pharmaceutics, University of Houston, Houston, TX 77030.* Accepted for publication July 13, 1983.

Abstract □ The absorption and disposition of ethambutol was examined in six rabbits in a three-way crossover study. Each rabbit received 45-mg/kg doses of ethambutol in three treatments: one intravenous injection, and two oral solutions, ethambutol alone and ethambutol in the presence of aluminum hydroxide (40 mg/kg). Half-lives of ethambutol ranged from 2.26 to 5.20 h when administered alone and 2.18 to 4.00 h when coadministered with the antacid; the difference was not significant ($p > 0.3$). Mean clearance after the oral administrations (189.2 mL/min/kg) was significantly greater than the mean intravenous clearance (43.7 mL/min/kg) ($p < 0.01$), suggesting a first-pass metabolism of ethambutol when administered nonparenterally to rabbits. The volume of distribution ranged from 5.5 to 17.8 L/kg, suggesting an extensive distribution of ethambutol outside the central compartment and, possibly, a localized deposit within the body tissues. Mean bioavailability of ethambutol was ~28% and was not affected by the presence of aluminum hydroxide. The rate of ethambutol absorption, however, was slightly delayed by the antacid.

Keyphrases □ Ethambutol—pharmacokinetics in rabbits, coadministration with aluminum hydroxide □ Aluminum hydroxide—effect on ethambutol absorption in rabbits □ Bioavailability—absorption of ethambutol in rabbits, coadministration with aluminum hydroxide

Ethambutol (I), an antitubercular agent, is prescribed alone or in combination with other drugs for the treatment of tuberculosis. The absorption and excretion of I has been studied in rats and mice (1), dogs (2, 3), and humans (4–6). The median lethal dose (LD_{50}) of racemic I in noninfected adult mice was 12,800 mg/kg when administered orally, 1600 mg/kg when administered subcutaneously, 800–1600 mg/kg when administered intraperitoneally, and 200–400 mg/kg when administered intravenously (1). Since I is well absorbed in mice and the drug metabolites are pharmacologically inactive (3), the remarkable discrepancies in LD_{50} following different administration routes suggest a first-pass metabolism of the drug when taken nonparenterally. A part of this study was thus designed to investigate the effect of first-pass metabolism on the availability of I in rabbits.

Pharmacokinetic studies comparing the intravenous and oral administrations of I to humans have demonstrated rapid and adequate absorption, with bioavailabilities of 70–80% (6, 7). The oral solution and tablets of I were equally well absorbed in humans (6), suggesting a gastric emptying rate- rather than dissolution rate-limited absorption of the drug. Aluminum ion is a known inhibitor of gastric emptying, and its effect on drug absorption has been documented (8). Mattila *et al.* (9) have investigated the effect of aluminum hydroxide on the absorption of I in humans; the results were erratic. Since the results of Matilla *et al.* (9) were inconclusive, this study also seeks to clarify the effect of aluminum hydroxide on the absorption of I using the rabbit model.

[a] Treatments: (A) intravenous injection; (B) oral solution with I alone; (C) oral solution with I and aluminum hydroxide; $n = 6$.

In the case of the intravenous injection, I was administered *via* the ear vein by a slow push over 5 min. As oral solutions, I was prepared in 70 mL of warm, deionized water and administered *via* the mouth by intubation. The intubation line was flushed with 30 mL of warm water to ensure that the complete dose was deposited into the stomach. Blood samples were collected from the ear vein at 0 (blank), 0.15 (injection only), 0.25, 0.5, 1.0, 1.5, 2, 2.5, 3, 4, 5, 6, 7, and 8 h. Hourly urine aliquots were collected from two rabbits by urethral catheter for the first 8 h; thereafter, cumulative 16-h urine samples were collected by natural voiding while rabbits were housed in the metabolism cage.

Blood Cell-to-Plasma Partition Ratio—Aliquots (1 mL) of heparinized whole blood were incubated with I (concentrations of 0.5, 1, and 2 μg/mL) at 37°C for 30 min. Immediately after incubation, plasma was separated by centrifugation and stored at −20°C until analysis. The blood cell-to-plasma partition ratio was calculated as $[C_b/C_p - (1 - H)]/H$, where H is the hematocrit.

Analytical Procedure—A GC procedure, as previously described, was used for sample analysis (10). The GC procedure normally provides a lower detection limit of 0.25 μg/mL. Since plasma levels of I after administration of the oral solutions were usually low, the procedure was manipulated to accommodate the concentration of 0.1 μg/mL.

Pharmacokinetic Analysis—The β-phase half-life ($t_{1/2\beta}$) was obtained by fitting the plasma data to a two-compartment model by the NONLIN program (11). Total body clearance (CL_t) and the noncompartmental steady-state volume of distribution (Vd_{ss}) were determined as:

$$CL_t = \text{dose}/\text{AUC}_\infty \qquad \text{(Eq. 1)}$$

$$Vd_{ss} = \text{dose}(\text{AUMC}_\infty)/(\text{AUC}_\infty)^2 \qquad \text{(Eq. 2)}$$

where AUC is the area under the plasma concentration *versus* time curve, and AUMC is the area under the first moment of the plasma curve (12). Both areas were calculated by the trapezoidal rule in conjunction with an area extrapolation method. The first plasma datum was assumed to be zero in the case of the oral administrations; the first plasma datum after intravenous administration was a NONLIN-generated initial concentration.

Bioavailability was determined by the AUC method, taking into account the half-life change due to alternate routes of drug administration:

$$F = \left(\frac{\text{AUC}_{po}}{\text{AUC}_{iv}}\right) \times \left(\frac{t_{1/2iv}}{t_{1/2po}}\right) \qquad \text{(Eq. 3)}$$

where iv indicates the intravenous administration route, and po indicates the oral administration route. In the two rabbits for which urine was collected at 24 h, bioavailability was also determined by the urinary recovery method:

$$F = \frac{(Ae,24 + CL_r \cdot \text{AUC}_{24\to\infty})_{po}}{(Ae,24 + CL_r \cdot \text{AUC}_{24\to\infty})_{iv}} \qquad \text{(Eq. 4)}$$

Table II—Half-lives of I after Single Doses of I (45 mg/kg) as Three Treatments [a]

Rabbit	Half-life, h		
	Treatment A	Treatment B	Treatment C
1	4.67	5.20	3.77
2	4.08	3.58	3.37
3	4.49	3.66	4.00
4	3.42	2.65	2.18
5	1.96	2.26	2.58
6	4.59	2.83	2.62
Mean ± *SD*	3.87 ± 1.03[b]	3.36 ± 1.05[b]	3.09 ± 0.73[b]

[a] Treatments: (A) intravenous injection; (B) oral solution with I alone; (C) oral solution with I and aluminum hydroxide. [b] Half-lives of I after treatments A, B, and C are not significantly different ($p > 0.3$); $n = 6$.

where $Ae,24$ is the amount of drug excreted in the 24-h urine sample, and CL_r is the average renal clearance as determined from the drug excretion rates during the first 8 h. The extrapolated area ($\text{AUC}_{24\to\infty}$) was calculated as $C_{p,24}/\beta$, where the 24-h plasma concentration was extrapolated from $C_{p,8}$ using the elimination rate constant, β.

Statistical Analysis—Mean pharmacokinetic parameters between any two treatments were tested for significance of difference by paired *t* test statistics.

RESULTS AND DISCUSSION

Table I describes the mean plasma data for rabbits that received I after treatment protocols A, B, and C. At the end of the 8-h sampling period, the residual level of I after intravenous injection was six times that after administration of the oral solutions. Figure 1 depicts a representative plasma profile in rabbit 6. During the first hour of intravenous injection, plasma concentrations of I dropped rapidly, indicating a fast distribution of the drug into the peripheral tissue compartment. Overall, the log-linear phase began at 1–3 h after drug injection and exhibited a half-life range of 1.96–4.67 h. After the oral administrations of I, a rapid distribution of the drug was also observed in all rabbits. Peak plasma concentrations were reached within 1 h, and a slightly delayed peak time was observed for I in combination with aluminum hydroxide. The log-linear phase did not begin until 1.5 h after oral solution administration, and the time to reach distribution equilibrium was as late as 3 h in some rabbits. It should be noted that the delayed stomach emptying as induced by fasting might lead to prolonged absorption and overestimation of half-life measurements (13). In the presence of aluminum hydroxide, I exhibited half-lives of 2.18–4.00 h, as compared with 2.26–5.20 h for I administered alone. The mean half-life of I was not significantly altered by the coadministration of aluminum hydroxide (3.36 ± 1.05 *versus* 3.09 ± 0.73 h; $p > 0.3$). In Table II, the mean half-lives of I in the three treatments are compared; all rabbits exhibited similar half-lives, irrespective of the route of administration and the presence of aluminum hydroxide.

Values for the steady-state volume of distribution of I, derived on the basis of venous data after intravenous administration, are shown in Table III. A wide range was observed for the volume of distribution of I (5.5–17.8 L/kg; mean, 8.5 ± 1.9 L/kg). Chiou (14) has reported that Vd_{ss} estimated with venous data could be 20–120% higher than that derived on the basis of arterial concentration. By taking into consideration the arteriovenous difference, the volume obtained is still several times the body weight of the rabbit (assuming a density of 1 g/mL). This indicates that in addition to the extensive distribution, I was probably deposited locally in the rabbit body tissues. Ethambutol has been known to be extensively distributed into the viscera and tissues of animals and humans. Pujet and Pujet (15) have reported a preferential distribution of I in the deep layers of the lung. Furthermore, *in vivo* and *in vitro*

Table III—Total Body Clearance and Volume of Distribution of I after Single Doses of I (45 mg/kg) as Three Treatments [a]

Rabbit	CL_t, mL/min/kg			Vd_{ss}, L/kg
	Treatment A	Treatment B	Treatment C	Treatment A
1	70.4	120.6	139.4	17.8
2	35.3	196.3	199.5	7.8
3	28.6	175.6	182.5	6.4
4	29.8	261.3	272.7	5.5
5	76.1	178.9	249.2	8.1
6	22.3	148.2	145.8	5.6
Mean ± *SD*	43.7 ± 23.2[b]	180.2 ± 46.0[b]	198.2 ± 54.0[b]	8.5 ± 4.6

[a] Treatments: (A) intravenous injection; (B) oral solution with I alone; (C) oral solution with I and aluminum hydroxide. [b] Oral clearances are not significantly different ($p > 0.1$); however, oral clearance and intravenous clearance are statistically different ($p < 0.01$); $n = 6$.

studies have demonstrated a favorable partition of I into erythrocytes in humans (4, 6). The blood-cell-to plasma partition ratio averaged 1.25 in all rabbits for the concenration range thus investigated.

Values for total body clearance of I after the three treatments are summarized in Table III. Two oral studies, I alone and I in combination with aluminum hydroxide, yielded virtually the same clearance (180.2 ± 47.9 *versus* 198.2 ± 54.0 mL/min/kg), indicating that aluminum hydroxide had no effect on the elimination of I. However, the total clearance after oral administration was significantly greater than the intravenous clearance (189.2 *versus* 43.7 mL/min/kg; $p < 0.01$), suggesting a first-pass metabolism for I. Previous studies with mice, rats, and dogs did not document first-pass metabolism of I since intravenous and oral studies were not carried out in a crossover manner (2, 3). The difference in LD_{50} among various routes of administration in mice could be due partly to the rate of absorption into the circulatory system. However, the magnitude of difference in LD_{50} observed (1) between oral and intravenous administrations (12,800 *versus* 400 mg/kg) supported our proposition of first-pass metabolism in rabbits. Poor absorption of I in rabbits could be an alternative argument; however, we found <15% of orally administered I in rabbit feces.

Renal excretion of I was studied in two rabbits after intravenous and oral administrations. Renal clearances, computed as $Ae,8/AUC_{0\to8}$, averaged 2.5 mL/min/kg. There was no significant change in renal clearance between studies utilizing the oral and intravenous administration routes. The fraction of I dose excreted unchanged after intravenous studies averaged 5.2%, which is considerably lower than the corresponding figures of 30 and 70% in dogs and humans, respectively (10).

The bioavailability data for I, alone and in combination with aluminum hydroxide, were calculated with Eq. 3 and are shown in Table IV. It should be noted that the validity of Eq. 3 is based on the assumption that $Vd_\beta(CL_t/\beta)$ remains the same, in spite of a change in β (16). Although the AUC method was used in all rabbits for bioavailability determination, the urinary recovery method was simultaneously applied to two rabbits for cross-examination. For rabbit 1, the urinary recovery method yielded a somewhat higher bioavailability than the AUC method (62.9 *versus* 57.5%), whereas for rabbit 5, both methods yielded virtually the same results (30.1 *versus* 30.0%). On the average, 28% of the oral I dose was bioavailable to the circulatory system. Without correction for half-life change with Eq. 3, the mean bioavailability was somewhat lower (25%). The low bioavailability also supported the hypothesis of first-pass metabolism of I in rabbits, as previously suggested on the basis of clearance measurements (Table III). As the hepatic blood flow (Q_b) in rabbits has been reported to be 60 mL/min/kg (17), the extent of hepatic first-pass effect for I was approximated as CL_t/Q_b where CL_t is the mean plasma clearance after intravenous administration. A mean of 73% (43.7 of 60) of the dose of I was estimated to undergo first-pass metabolism. This is consistent with the bioavailability of 25–28% in rabbits reported here.

The aluminum hydroxide dose of 40 mg/kg, as used in this study, was three times the therapeutic dose of the antacid used in humans on a weight basis. In the study of Mattila *et al.* (9), a 60-mg/kg dose was used. *In vitro*, aluminum ion at 5×10^{-4} M inhibits the contractile response of human and rat gastric strips to acetylcholine by >50% (18). The *in vitro* effect of aluminum ion on the contractile response of rabbit gastric strips has not been investigated. The aluminum concentration achieved *in vivo* in the stomach of rabbits receiving aluminum hydroxide (2×10^{-2} M) was much higher than that used *in vitro*. It was felt that such a concentration would be sufficient to significantly delay gastric emptying in rabbits.

With regard to the absorption of I, the rabbit may not be an ideal model for comparison with human data; however, rabbits demonstrated a consistent, although insignificant, response to aluminum hydroxide. On the contrary, humans responded to aluminum hydroxide erratically, making it difficult to make a conclusion on the effect of the antacid on the bioavailability of I. In summary, the concomitant administration of aluminum hydroxide appeared to have slightly delayed the absorption of I in some rabbits, as reflected by a prolonged peak time; the extent of absorption, however, was insignificantly altered by the presence of the antacid.

Table IV—Bioavailability of I after Two Oral Treatments [a]

Rabbit	Bioavailability, % of Intravenous Dose	
	Treatment B	Treatment C
1	52.40 (67.57)[b]	62.52 (58.30)[b]
2	20.48	21.38
3	19.97	17.58
4	14.71	17.12
5	36.87 (30.28)[b]	23.17 (29.98)[b]
6	24.44	26.82
Mean ± *SD*[c]	28.15 ± 14.01	28.10 ± 17.24

[a] Treatments: (B) solution with I alone; (C) solution with I and aluminum hydroxide. [b] Numbers in parentheses denote bioavailability determined by the urinary recovery method. [c] $n = 6$.

In Vitro Interaction of Neuroleptics and Tricylic Antidepressants with Coffee, Tea, and Gallotannic Acid

WILLIAM L. LASSWELL, JR. ˣ, STANLEY S. WEBER, and JOHN M. WILKINS

Received March 16, 1983, from the *College of Pharmacy, University of Rhode Island, Kingston, RI 02881.* Accepted for publication September 4, 1983.

Abstract □ The *in vitro* interaction of selected drugs with coffee, tea, gallic acid, and gallotannic acid was examined by mixing solutions of drug with each of these four preparations. Results of these experiments indicate that significant precipitation occurs for a variety of agents, including several phenothiazines, amitriptyline, haloperidol, imipramine, and loxapine. The strong complex which is formed between these drugs and tannins is probably the basis of the interaction of these drugs with coffee and tea. Although precipitates did occur with a number of neuroleptics, two members of this drug class, thiothixene and molindone, failed to interact with the solutions used.

Keyphrases □ Tricyclic antidepressants—*in vitro* interaction with coffee, tea, gallotannic acid, and gallic acid □ Neuroleptics—*in vitro* interaction with coffee, tea, gallotannic acid, and gallic acid

The interaction of certain antipsychotic agents with tea and coffee has received some attention in recent years. Mikkelsen (1) first reported that increased consumption of coffee may reduce the effectiveness of phenothiazines. Soon after, Hirsch (2) and Kulhaneck *et al.* (3) reported that *in vitro* mixing of a number of neuroleptics, including chlorpromazine, haloperidol, and fluphenazine (but not trifluoperazine), with coffee or tea led to the formation of a precipitate. Cheeseman and Neal (4) have studied the interaction of chlorpromazine with coffee and tea in more detail and have found that simultaneous oral administration of tea with chlorpromazine completely abolished the cataleptic effects of this drug in rats. Concern about the possible effects which precipitation of antipsychotics could have on their bioavailability in humans led Bowen *et al.* (5) to study the possible interaction of coffee and tea with these four drugs in female patients. Using a dopamine receptor assay (6), plasma drug concentrations were measured during sequential weekly periods of normal coffee and tea intake, abstinence from these beverages, and finally resumption of intake. On the basis of plasma drug levels and behavioral scores (7), they concluded that withdrawal of coffee and tea did not increase drug bioavailability. However, neither the amounts of coffee and tea used in this study nor the timing of beverage intake with respect to drug administration were specified. Furthermore, the time intervals used in the overall design of this experiment were questionable.

In the present study, we report results on the *in vitro* interaction of coffee, tea, gallotannic acid, and gallic acid with a variety of neuroleptic agents, as well as amitriptyline and imipramine.

EXPERIMENTAL SECTION

The drugs used in this study included amitriptyline hydrochloride[1], chlorpromazine hydrochloride[2], haloperidol[3], imipramine hydrochloride[2], loxapine hydrochloride[4], molindone hydrochloride[5], prochlorperazine hydrochloride[6], thioridazine hydrochloride[7], thiothixene hydrochloride[8], and trifluoperazine hydrochloride[2]. Gallotannic acid[9] and gallic acid[2] were commercially obtained. The buffer solutions used in these studies were McIlvaine's buffer (0.1 M citric acid–0.2 M sodium dihydrogen phosphate, pH 2–8) and Clark and Lub's buffer (0.1 M potassium chloride–0.1 M hydrochloric acid, pH 1).

pH Variability Studies—Portions (1 mL) of an aqueous solution of drug (20 mg/mL) were diluted with 1 mL of buffer. This solution was then added to a mixture of aqueous gallotannic acid (1 mL, 20 mg/mL) and buffer (3 mL) to achieve final concentrations of drug and gallotannic acid of 3.3 mg/mL each. The resulting precipitate was removed by filtration[10]. A portion of the filtrate (2 mL) was acidified by the addition of 2 M HCl in a dropwise manner and adjusted to pH 2 by addition of 2 mL of buffer. A saturated solution of lead acetate (2 mL) was added to the acidified filtrate, and the resulting precipitate was removed by filtration. The concentration of free drug in the filtrate was determined by comparing the UV absorbance of appropriately diluted samples with a standard curve of absorbance *versus* concentration. Experiments designed to study the interaction of gallotannic acid with various drugs at specific pH values were carried out in an identical manner. Studies assessing the effects of reduced drug concentration on precipitation were also carried out in an identical fashion with drug concentrations of 2 mg/mL (for a 1:10 dilution). Samples containing drug at a 1:10 dilution required an additional extraction step because of the high concentration of tannin relative to drug. During this step, 2 mL of the lead acetate filtrate was adjusted to pH 10 by addition of 1 M NaOH in a dropwise manner. This solution was then extracted three times with 2-mL portions of distilled ethyl acetate. The combined ethyl acetate fractions were washed with water, dried with anhydrous sodium sulfate, filtered, and evaporated. The remaining residue was dissolved in 4 mL of buffer (pH 2) before dilution and UV absorption measurement.

Studies to estimate the effects of mutual dilution of drug and tannin were conducted by using buffered solutions of drug and gallotannic acid which were diluted 1:5 with distilled water before mixing and filtration. The filtrate (2 mL) was then mixed with 2 mL of buffer (pH 2), treated with 2 mL of lead acetate, and filtered before UV absorption measurements.

Experiments with Coffee and Tea—Measurements of the interaction of coffee and tea with neuroleptic agents were carried out by mixing aqueous solutions of drugs with these beverages in the following proportions: for amitriptyline, haloperidol, and loxapine, 1 mL of drug solution (10 mg/mL) with 2.5 mL of beverage; for thiothixene, 1 mL of drug solution (5 mg/mL) with 0.65 mL of beverage. All other studies were conducted with 1 mL of drug solution (20 mg/mL) and 5 mL of beverage. Coffee was prepared by dissolving 2 g of instant coffee in 150 mL of boiling distilled water. Tea infusions were prepared by steeping one tea bag containing 2.5 g of black tea in 150 mL of boiling water for 5 min. The pH resulting from addition of drug to tea or coffee varied between 4.5 and 5.0. In the experiments with tea, the resulting precipitates were filtered, and 2-mL portions of the filtrate were diluted with buffer, treated with lead acetate, and filtered as described above. In the experiments with coffee, the drug precipitates and lead–tannin precipitates were removed by centrifugation at 4000 rpm for 8 min. Extractions and UV absorption measurements were then carried out as described above.

Other Studies—Studies designed to examine the reversibility of the interaction between chlorpromazine and gallotannic acid in an aqueous medium were conducted by mixing buffered (pH 5) solutions of drug and gallotannic acid as described above. The resulting suspension was placed in a dialysis bag made from benzoylated dialysis tubing[2] (exclusion range, 1200–2000). The bag was immersed in four volumes of buffer and stirred at room temperature for 24 h. The suspension within the dialysis bag was then filtered. Portions of this filtrate, as well as the dialysate, were then treated with lead acetate, filtered, and diluted in preparation for the UV absorption measurement. The

[a] Values listed are averages of triplicate determinations taken at drug concentrations of 20 and 2 mg/mL. [b] Numbers in parentheses indicate wavelengths at which measurements were made. [c] Numbers in parentheses indicate pH vaues at which these determinations were made. The pH values represent the highest pH which could be used without precipitating the free base forms of these drugs. [d] All determinations were made with pH 5 buffer. [e] nd—Percent drug precipitated was not determined due to weak drug absorptions and interfering absorptions due to constituents in coffee and tea. In the case of loxapine, measurements were not made due to inability to extract drug into the organic phase. [f] nr—No precipitate was formed on mixture of these substances. [g] Duplicate experiments indicated that 67% drug precipitation occurred when the same brand of decaffeinated coffee was mixed with thioridazine.

resulting absorbances for these fractions were compared with those obtained from a dialysis experiment using chlorpromazine alone, which was dissolved in buffer (pH 5). A similar procedure was used to examine the reversibility of the interaction between chlorpromazine and the condensed tannins present in tea. A solution of drug and tea were mixed as described above, and this mixture was placed in a dialysis bag which was immersed in water for 24 h with stirring.

In a separate experiment, a buffered solution of chlorpromazine was mixed with tea or gallotannic acid. A portion of the resulting suspension was centrifuged at 4000 rpm for 8 min. The supernatant was decanted, and the remaining pellet was washed by resuspending in distilled water and centrifuging. After decanting the resulting supernatant, the drug precipitate was washed once more and then dissolved in 6 mL of a 1:1 methanol-water. Several drops of this solution were treated with 3% ferric chloride in 0.5 M HCl. Another portion of this solution was spotted on a TLC plate[11], which was developed in methanol and visualized under short-wavelength UV light.

RESULTS AND DISCUSSION

In Table I the interactions which occurred between the various drugs and the solutions are listed. Although drug precipitation was most pronounced with phenothiazines, it also occurred with other drugs as well. The observation of precipitate formation between trifluoperazine and coffee or tea is contrary to the results reported by Hirsch (2).

It is not surprising that tannins interact with many of the drugs examined in this study. Both hydrolyzable tannins (*e.g.*, gallotannic acid) and condensed tannins, such as those present in tea and coffee, are known for their ability to precipitate metals, proteins, and certain organic compounds (8–10). The historic use of gallotannic acid as an antidote for alkaloid poisoning is based on its ability to form precipitates with many such natural products (11). Gallotannic acid complexes with morphine and cyanocobalamin have been examined as possible sustained dosage forms (12, 13). The effects of tannins on the absorption of iron and thiamine have also been studied. Roy and Mukherjee (14) have studied the effects of food tannins on iron metabolism. Morck *et al.* (15) have recently demonstrated that both coffee and tea can inhibit iron absorption in humans. In studies of the interaction between gallotannic acid and thiamine (16), it has been suggested that excessive intake of tea can contribute to thiamine deficiency, possibly because the phenolic groups of the tannins found in tea participate in ring opening and oxidation reactions of thiamine (17).

The phenothiazines used in these studies formed a precipitate with gallic acid, which is a constituent of both condensed and hydrolyzable tannins. Cheeseman and Neal have reported precipitation of chlorpromazine with solutions of sodium benzoate and sodium salicylate (4). They have suggested that these agents could account for the observed interactions of neuroleptics with coffee and tea. However, the concentrations of the aromatic acids used in the studies of Cheeseman and Neal, as well as the gallic acid solutions used in this study, are much higher than those which could exist in coffee and tea. On the other hand, the concentrations of tannins found in tea are high enough to account for the degree of drug precipitation seen in Table I. The differences in the amounts of drug precipitated by coffee and tea reflect the differences in tannin content (tea, 10–15%; coffee, 3–5%). In addition, ferric chloride treatment of a washed chlorpromazine–tea precipitate resulted in the production of a dark-green color, which is indicative of polyphenolic compounds, such as the condensed tannins present in tea. Furthermore, tea which was pretreated with lead acetate to remove tannins failed to produce a precipitate when mixed with chlorpromazine.

Experiments were carried out by using thioridazine with regular and decaffeinated coffee to test the possible effects of caffeine on drug precipitation. The results show very little difference in the amount of drug precipitated with the two varieties of coffee. Thus, any competition which may exist between caffeine and drug in complexing with tannins results in a minimal decline in drug precipitation. Although caffeine may not alter drug precipitation in tea or coffee, it could exert significant influence on the therapeutic effects of phenothiazines by producing pharmacokinetic or pharmacodynamic interactions. Such interactions may result from effects of caffeine on microsomal metabolism of antipsychotics (18) or from possible pharmacological antagonism (19). Evidence for a pharmacological effect is conflicting. Morpurgo (20) has reported that caffeine citrate (10 mg/kg) totally inhibited the cataleptic effects of phenothiazines in rats within 1 h after administration. On the other hand, Cheeseman and Neal have found that the caffeine content in tea did not account for the total loss of chlorpromazine-induced catalepsy in rats when tea was administered simultaneously (4). The doses of chlorpromazine and caffeine used in this experiment were 8 and 15 mg/kg, respectively.

The effects of pH and dilution on drug precipitation were studied in some detail to learn more of the drug-tannin interaction. The results shown in Fig. 1 indicate that the percent precipitation of imipramine, loxapine, and thioridazine increases as the pH increases from 1 to 6. A similar trend holds for all other drugs listed in Table I when mixed with either gallotannic acid or tea. Furthermore, dilution studies indicate that a significant amount of chlorpromazine (59%) is precipitated, even when drug and gallotannic acid are both diluted 1:5 before mixing. Experiments with tea and chlorpromazine diluted 1:5 resulted in a 36% drug precipitation. As indicated in Table I, a 10-fold dilution of drug alone also had little effect on total drug precipitation. Such increases in drug precipitation which occur with dilution are consistent with the results of Cheeseman and Neal (4), who have reported increases in percent chlorpromazine precipitation as the chlorpromazine–tea ratio is reduced.

Additional experiments have indicated that the drug-tannin complex is strong in the sense that the majority of drug remains complexed with tannin after prolonged dialysis. Dialysis of the chlorpromazine–gallotannic acid precipitate at pH 5 for 24 h showed that 90% of total drug remained complexed. Dialysis of a chlorpromazine–tea precipitate showed that 62% of the drug remained complexed after 24 h. However, although the complex between chlorpromazine and tannins is strong, it is not irreversible, and it does not produce a modification of the drug molecule. Dissolution of the precipitate in methanol–water (1:1), followed by TLC showed the presence of chlorpromazine. This result is in agreement with the findings of Kulhaneck *et al.* (3), who have reported that fluophenazine and haloperidol were liberated unchanged by dissolving drug–tea precipitates in water.

CONCLUSIONS

The present studies identify tannins as the major contributory factor in the precipitation of various neuroleptics and tricyclic antidepressants by coffee and tea. They also indicate that tea and coffee can precipitate significant

[11] Silica gel 60 F-254.

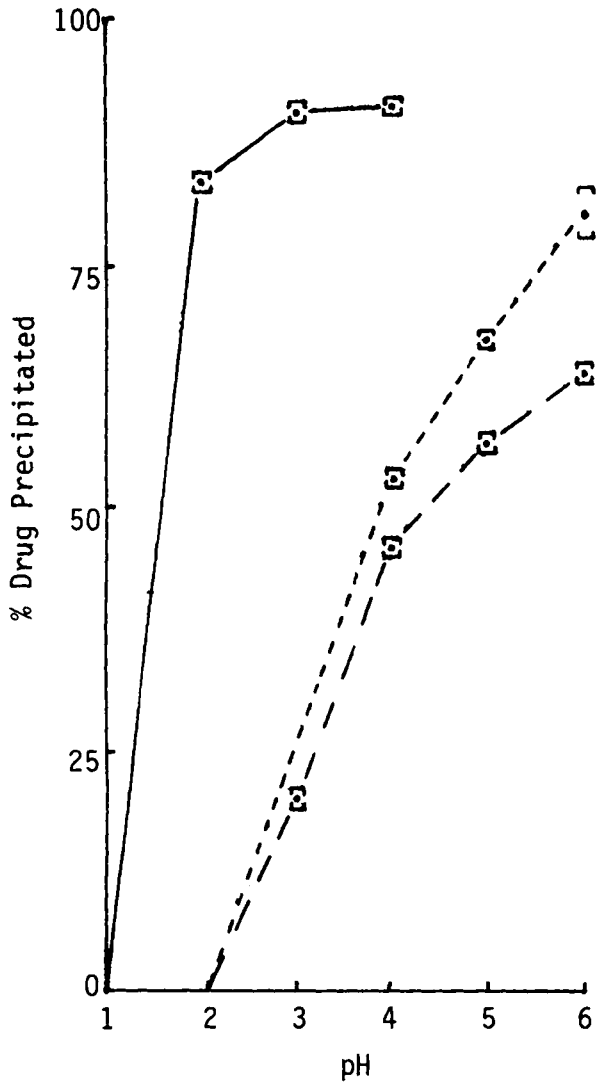

Figure 1—*pH variability of drug-gallotannic acid interaction. Plots represent results with thioridazine (—), loxapine (- - - -), and imipramine (— —). Each point represents the average of three determinations. At pH 3, loxapine produced a fine precipitate which could not be isolated by filtration or centrifugation. However, no precipitate was formed with this drug at pH 2.*

amounts of these drugs, especially phenothiazines. It is possible that the effects of gastric acidity, along with GI secretions and motility, may drastically reduce the amount of drug complexed in the intestine. However, studies on the effects of pH and dilution indicate that any drug-tannin complexation which may occur in the GI tract should be maximal in the intestine, where most drug absorption occurs. Furthermore, dilution studies indicate that gallotannic acid and tea precipitate significant amounts of drug even at somewhat diluted concentrations, suggesting that dilution in the intestine may not completely eliminate drug-tannin interactions. Finally, dialysis experiments show that the chlorpromazine-gallotannic acid complex is quite stable at nearly neutral pH. Thus, once formed, the drug-tannin precipitate may not be readily soluble in the intestine.

Studies in rats have shown that simultaneous administration of tea can abolish the cataleptic effects of chlorpromazine. Whether this effect is due to caffeine or other components in tea is open to question. Bowen *et al.* (5) have reported that abstinence from tea or coffee had no effect on the bioavailability of several neuroleptics studied. However, the time and amounts of coffee and tea intake in this study were not specified. It is interesting to note that Bogner and Walsh (21) have compared the absorption of a sustained-release complex of gallotannic acid and radiolabeled phenylephrine hydrochloride with that of phenylephrine hydrochloride alone in human volunteers. The results indicated that use of the drug-tannin complex prolonged the time at which peak radioactivity was observed in the blood and reduced levels of peak radioactivity. A reduction in total radioactivity *versus* time (~25%) also occurred during the 24-h period in which measurements were taken. Prolonged absorption such as that observed in this study may have an especially significant role in affecting blood and tissue levels of drugs, such as chlorpromazine, which undergo significant metabolism in the intestine (22, 23). More detailed studies need to be carried out on the possible *in vivo* interaction of coffee and tea with neuroleptics and tricyclic antidepressants.

Solid–Solid Reaction Between Sulfacetamide and Phthalic Anhydride

HO-LUN WENG and EUGENE L. PARROTT ˣ

Received May 23, 1983, from the *College of Pharmacy, The University of Iowa, Iowa City, IA 52240.* Accepted for publication September 30, 1983.

Abstract □ Thermal and kinetic data for the solid-state addition reaction of sulfacetamide and phthalic anhydride are presented. A compaction method was used so that the influence of some pharmaceutical parameters (compressional pressure, particle size, concentration, and temperature) on the reaction kinetics could be observed.

Keyphrases □ Sulfacetamide—solid-solid reaction with phthalic anhydride □ Phthalic anhydride—solid-solid reaction with sulfacetamide □ Solid-solid reactions—sulfacetamide and phthalic anhydride, thermal and kinetic analyses

The stability of a medicinal compound in a solid dosage form is routinely investigated in terms of the percentage of the medicinal compound that is unchanged after exposure to various temperatures (1–4). Although thermal decomposition is an important consideration in the processing, testing, and storage of solid dosage forms, only a limited number of reports in the pharmaceutical literature have been concerned with the physicochemical mechanism and kinetics of solid-state reactions (5–13). In general, the chemistry of solids has been presented in several texts (14–18). This study was initiated to present a simple model of a solid-state addition reaction so that some pharmaceutical factors (compressional pressure, concentration, particle size, and temperature) could be viewed in relation to their influence on the reaction.

EXPERIMENTAL SECTION

Samples of sulfacetamide[1] and phthalic anhydride[2] were individually separated into a 100/140-mesh-size fraction by means of U.S. standard sieves and a shaker[3]. Blends of the sulfacetamide and phthalic anhydride were prepared at 2:1, 1:1, and 1:2 molar ratios and were passed through a 200-mesh sieve. The thermal analytical data of the components and the blends were determined with a thermogravimetric analyzer[4] and a differential thermal analyzer[5]. Typical thermograms are given in Figs. 1 and 2.

For the study concerned with the effect of molar ratio on the reaction kinetics of sulfacetamide and phthalic anhydride, compacts with molar ratios of 1:1, 1:2, and 1:3 were used. An appropriate weight (400 mg) of a 100/140-mesh fraction of the blend was compressed for 1 min at a pressure of 3580 kg/cm^2 with an hydraulic press[6] fitted with a 1.27-cm punch and die set. Each compact was sealed under nitrogen in a glass vial and then immersed in a thermostated oil bath at 95 ± 0.5°C. At a given time, the reaction was quenched by immersion of the vial in ice, and the compact was then assayed. The reaction was conducted in triplicate. Typical data of the percent conversion of sulfacetamide to phthalylsulfacetamide are given in Table I.

For the study of the effect of particle size on the reaction kinetics, sulfacetamide was recrystallized from distilled water and then dried in a vacuum oven at 60°C. The purity of the sulfacetamide, as analyzed by differential scanning calorimetry[7], was 99.63%. With sieves and a shaker, the sulfacetamide was classified into 40/45-, 45/60-, 60/80-, 80/100-, and 100/140-mesh fractions. Blends with a 1:2 molar ratio of sulfacetamide and phthalic anhydride were prepared with phthalic anhydride of a 100–140-mesh fraction and the five sizes of sulfacetamide. An appropriate weight (2025 mg) of the blends was compressed for 1 min at a pressure of 35 kg/cm^2 with a hydraulic press fitted with a 2.857-cm punch and die set. Each compact, which corresponded to a specific particle size of sulfacetamide, was manually divided diametrically into six parts with a razor blade. Three parts were assayed for initial content, and the other parts were used for the kinetic study at 95°C. The percent conversion of sulfacetamide to phthalylsulfacetamide is shown in Table II.

For the study concerned with the effect of compressional pressure on reaction kinetics, a blend of an equimolar ratio of sulfacetamide and phthalic anhydride with a 100/140-mesh fraction was compressed for 1 min with a hydraulic press fitted with a 2.857-cm punch and die set at 35, 106, 283, 601, 1003, 2005, 3580, and 5371 kg/cm^2. The percent conversion is shown in Table III.

For the study concerned with the influence of temperature on the reaction kinetics, a blend of an equimolar ratio of sulfacetamide and phthalic anhydride with a 100/140-mesh fraction was compressed for 1 min in an hydraulic press fitted with a 1.27-cm punch and die set at a pressure of 3580 kg/cm^2. Each compact weighed 400 mg. The reaction was conducted at 85°C, 90°C, 95°C, 100°C, 105°C, and 110°C. Typical data are given in Table IV.

The unreacted sulfacetamide was colorimetrically analyzed by diazotization and a coupling reaction with *N*-naphthylethylenediamine dihydrochloride (19, 20). A standard concentration–absorbance curve was determined by transferring 0.5-, 1.0-, 2.0-, 3.0-, and 4.0-mL aliquots of a stock solution

	14.88[b]	

[a] At 95°C as a function of time for a 1:2 molar ratio of sulfacetamide and phthalic anhydride. [b] Corrected to include sublimed phthalic anhydride (0.51 and 1.10% of total compact weight for 180 and 300 min, respectively).

(prepared by dissolving 125.6 mg of sulfacetamide in 50 mL of 0.5 M NaOH and adjusting with distilled water to 250 mL in a volumetric flask) into sufficient distilled water to make 50 mL. From each dilution, 5.0 mL was transferred into a 50-mL volumetric flask and neutralized with 0.02 M HCl. Then, 5.0 mL of 0.5 M HCl and 5.0 mL of a 0.1% aqueous sodium nitrite solution were added to the flask. After 3 min, 5.0 mL of 0.5% ammonium sulfamate solution was added, and the volume was adjusted to 50 mL by the addition of distilled water. The absorbance was measured against a blank at 536 nm. A plot of absorbance against concentration showed a Beer's law relationship.

At each time period, the compact was triturated in a mortar, and the appropriate amount of powdered compact corresponding to 125 mg of sulfacetamide was accurately weighed and transferred to a 250-mL volumetric flask. The subsequent addition of reagents and the procedure have been described above. By means of the standard curve, the measured absorbance was used to determine the concentration of unreacted sulfacetamide. When sublimation occurred, a correction was made in the calculation of the percent conversion.

RESULTS AND DISCUSSION

Physicochemical Characteristics—As reports (14–18) have been published for single-solid decompositions, the reaction of sulfacetamide and phthalic anhydride was selected as an example of a solid–solid addition reaction for the simple model: A + B → AB. Samples of sulfacetamide maintained at 50°C, 90°C, and 110°C for 24 and 16 d and 5 h, respectively, showed no degradation within the variability (0.6%) of the analytical method.

[a] After 3 h at 95°C. [b] Corrected to include sublimed phthalic anhydride.

It has been demonstrated that the solid-state reaction of sulfathiazole and phthalic anhydride is an addition reaction with a 1:1 stoichiometry (21). Preliminary differential thermal analysis (DTA) of an equimolar ratio of sulfacetamide and phthalic anhydride showed that (*a*) the stoichiometry was 1:1, (*b*) the reaction product melted at 195°C [lit. mp of phthalylsulfacetamide (22) 196°C] and (*c*) decomposition occurred as the temperature exceeded 196°C. The anhydrous state of each reactant was determined by thermogravimetry. The weight loss of phthalic anhydride is due to sublimation, as the slope (*dW/dT*) (Fig. 1) is negatively increasing without discontinuity. The melting points of sulfacetamide and phthalic anhydride, as shown on the thermograms, were 185°C and 132.1°C, respectively [lit. mp (22) 182–184°C and 130.8°C, respectively].

Figure 2 is a typical thermogram of those determined on the blends of various molar ratios. The endothermic peak at 107°C is probably caused by fusion of the sulfacetamide and phthalic anhydride eutectic because a large exothermic peak ensues immediately. The exothermic peak at 117°C is due to the liquid-state addition reaction. At 131°C, the unreacted anhydride is completely melted and penetrates into the surface fissures of any solid sulfacetamide undergoing the addition reaction, as indicated by the broad exothermic peak between 135°C and 156°C. The endothermic peak at 172.5°C is likely caused by the melting of the sulfacetamide-phthalylsulfacetamide eutectic. After melting, a small exothermic peak occurs at 178.5°C and may be due to the liquid-state addition between sulfacetamide and the residual anhydride. Finally, the endothermic peak at 187°C may be caused by fusion of phthalylsulfacetamide (depressed by impurity).

At molar ratios of 1:1 and 1:2 sulfacetamide and phthalic anhydride, the thermograms (not shown to conserve space) are essentially the same as those for the 2:1 molar ratio at temperatures <160°C. The relatively small quantity of sulfacetamide in the 1:2 molar ratio has undergone addition, so there is no endothermic peak corresponding to the melting of sulfacetamide at 172.5°C. The final endothermic peaks are caused by the melting of impure phthalysulfacetamide; however, the quantity of impurity is different in the three ratios.

Influence of Concentration on Reaction Kinetics—Molar ratios of sulfacetamide to phthalic anhydride from 1:1 to 1:3 provide excess phthalic anhydride so that the initial contact area between the reactants is varied as the concentration of sulfacetamide is changed. The conversion (milligrams sulfacetamide per gram of anhydride) is shown as a function of time in Fig. 3.

[a] Corrected to include sublimed phthalic anhydride (0.53% of weight of compact).

The conversion (milligrams of sulfacetamide per gram of anhydride) is greater for a high concentration of sulfacetamide than for a lower concentration as the reaction time is increased (Fig. 4). For example, a comparison of the 60- and 180-min curves shows that for the 1:1 molar ratio, an additional 33.7 mg of sulfacetamide/g of anhydride was converted during the 120-min interval, whereas for the same interval of time, only an additional 16.5 mg of sulfacetamide/g of anhydride was converted at the 1:3 molar ratio.

Influence of Particle Size on Reaction Kinetics—By using a 1:2 molar ratio of sulfacetamide to phthalic anhydride, compacts were prepared with several sizes of sulfacetamide. A low compressional pressure (35 kg/cm²) was used to retain the integrity of the particles. The percent conversion of sulfacetamide after 3 h at 95°C is given for the various sizes in Table II. It appears that a reduction of particle size increases the percent conversion.

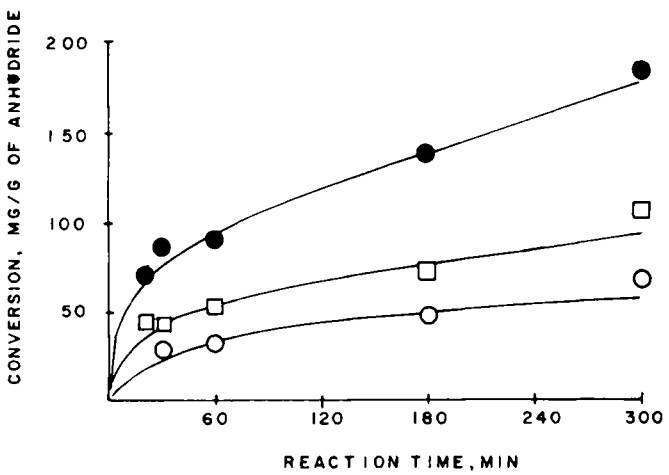

Figure 3—*Influence of concentration on the reaction at 95°C of sulfacetamide and phthalic anhydride prepared from 100/140-mesh fraction compressed at 3581 kg/cm². Key: (○) 1:3; (□) 1:2; (●) 1:1.*

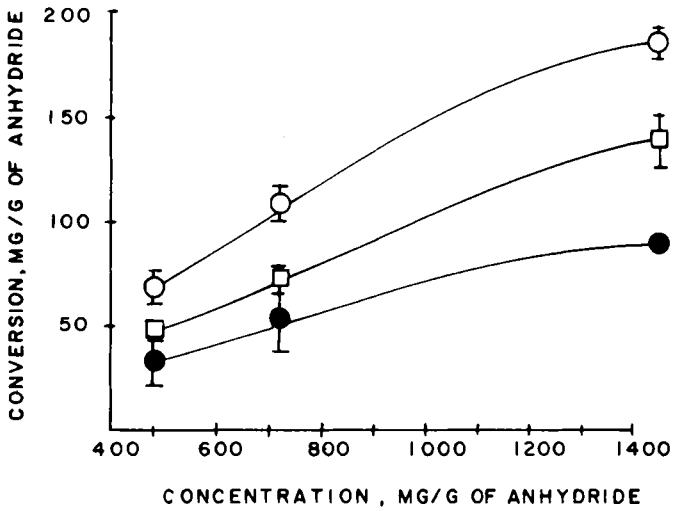

Figure 4—*Influence of concentration of sulfacetamide on weight conversion at various times at 95°C. Key: (●) 60 min; (□) 180 min; (○) 300 min. Bars represent* SD.

Although the conversion rate of sulfacetamide has been shown to be proportional to its concentration, it may be more meaningful to describe the kinetics of solid-solid reactions in terms of interfacial area of contact between the reactants (18, 23); however, the determination of actual area of contact is questionable. Since the actual area of contact is unknown but is probably proportional to the total surface area, reaction kinetics of a solid-solid system could be considered in terms of the total surface area of the sulfacetamide, because phthalic anhydride is the only mobile phase (21, 24) and is transported to the surface of the sulfacetamide by surface migration (21) and/or sublimation. Assuming that the particles of sulfacetamide are spherical, the total surface area per gram of blend was calculated and plotted against the percent conversion (Fig. 5).

Influence of Pressure on Reaction Kinetics—Compacts of an equimolar blend of sulfacetamide and phthalic anhydride were prepared at pressures up to 5380 kg/cm² and were maintained for 3 h at 95°C. The percent conversion of sulfacetamide increases to a maximum value (17%) as the compressional pressure is increased to 283 kg/cm² (Fig. 6), and then, with further increases in compressional pressure, the percent conversion decreases.

As the compressional pressure is increased, packing of the particles is more dense, and as bonding occurs, the porosity is decreased (25, 26). As consolidation occurs, the area of contact between the reactants is increased by fragmentation or deformation (27) until a maximum specific surface area, which provides more reaction sites between the sulfacetamide and phthalic anhydride, is attained. Additional increases in compressional pressure result in consolidation with a progressive decrease in specific surface area, which

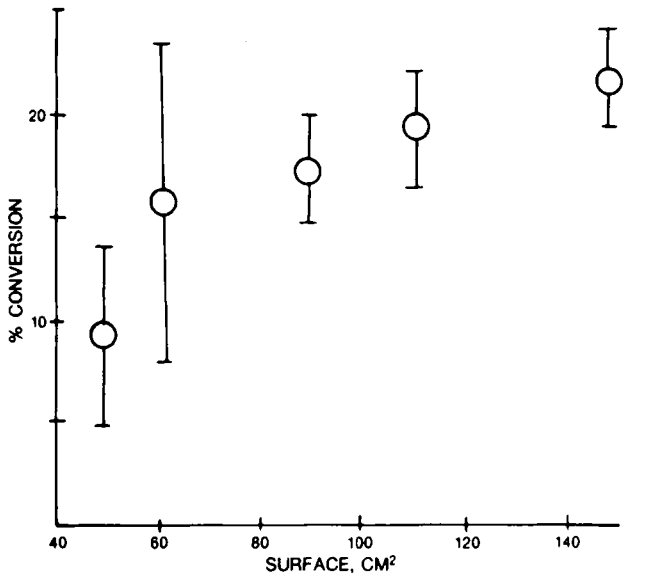

Figure 5—*Influence of total surface area of sulfacetamide on conversion after 3 h at 95°C. Bars represent* SD.

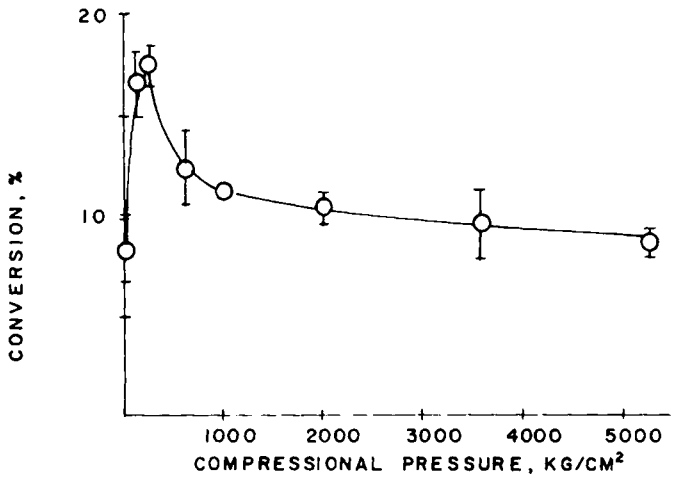

Figure 6—*Influence of compressional pressure on the conversion of sulfacetamide after 3 h at 95°C. Bars represent* SD.

provides fewer reaction sites. In addition, the transport rate of the anhydride by diffusion through the phthalylsulfacetamide layer (24), surface migration (21), and/or sublimation will be decreased. Both effects operate to decrease the percent conversion.

Influence of Temperature on Reaction Kinetics—Compacts compressed at a pressure of 3581 kg/cm² from an equimolar blend of sulfacetamide and phthalic anhydride of a 100/140-mesh fraction were exposed to six temperatures from 85°C to 110°C. The percent conversion of sulfacetamide at these temperatures is shown as a function of time in Fig. 7. At 100°C, 105°C, and 110°C, the curve attains a plateau in a very brief time because of the fast reaction. Based on the thermogram (Fig. 2), it is likely that the initial phase-boundary reaction proceeds mainly in the liquid state, in which a more vigorous chemical reaction would be expected according to the lever rule (28), which infers that the fraction of the melt at the interface between the reactants is approximately proportional to the reaction temperature. At 85°C, 90°C, and 95°C, there is a slowing of the reaction rate, possibly due to the fact that the reaction occurs primarily in the solid state, which requires more energy and is more restrictive of molecular movement than in the liquid-solid reaction.

In addition to the solid-solid interaction at the phase boundary, mass transport of the anhydride to the free sulfacetamide surface occurs simultaneously (21). Diffusion through a solid is slow, and after the phase-boundary reaction is completed, the conversion curve asymptotically approaches a plateau. Since the percent conversion at 85°C, 90°C, and 95°C significantly increases, although at a slower rate, it could be considered as phase-boundary reaction and treated mathematically (see *Appendix*). The reaction rate constants for given conditions at 85°C, 90°C, and 95°C were calculated by starting with an A value, which was set equal to the percent conversion at 300 min, and then sequentially, reaction rate constants were calculated by continuous increments of 0.5 to the previous A value. The value of the derived constant, A, was selected which best fit the experimental data.

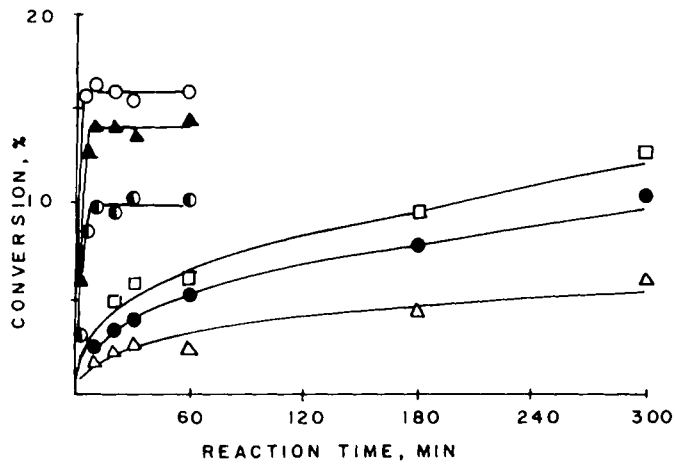

Figure 7—*Influence of temperature on the reaction kinetics of equimolar sulfacetamide and phthalic anhydride compacts prepared at 3581 kg/cm². Key: (△) 85°C; (●) 90°C; (□) 95°C; (◐) 100°C; (▲) 105°C; (○) 110°C.*

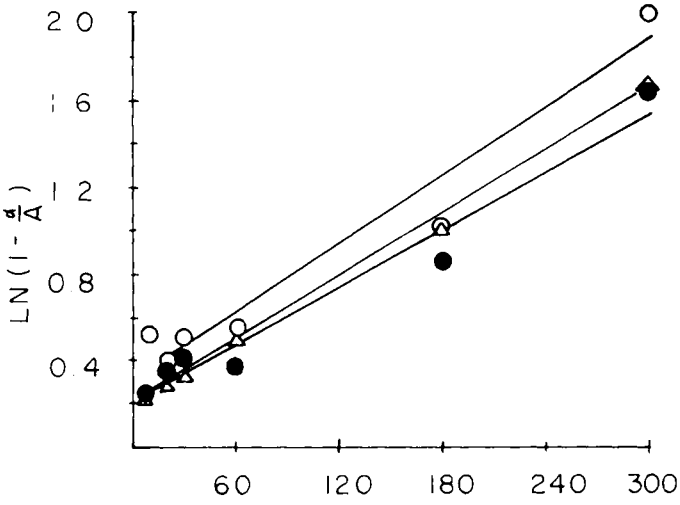

Figure 8—*Linear plot of $-\ln(1 - \alpha/A)$ against reaction time at various temperatures. Key: (●) 85°C; (△) 90°C; (○) 95°C.*

The best plot ($r = 0.9758$) of $-\ln[1 - (\alpha/A)]$ against time at 85°C is shown in Fig. 8 ($A = 7.75\%$; $k = 0.004704\ \text{min}^{-1}$). The experimental percent conversion at 85°C is compared in Fig. 9 with that calculated with the best set of values of A and k and Eq. 14 (see *Appendix*). The greatest deviation in the plot occurs at short reaction times and is obviously due to the omission in case 2 (see *Appendix*) of the second term of Eq. 12. Similar results occur if the data at 90°C ($A = 13.14\%$; $k = 0.004912\ \text{min}^{-1}$; $r = 0.9875$) and at 95°C ($A = 14.72\%$; $k = 0.005272\ \text{min}^{-1}$, $r = 0.9437$) are plotted.

As shown in Fig. 10, a plot of ln k against reciprocal temperature is linear with a slope of $-1502\ \text{K}^{-1}$. From the plot of ln k against reciprocal temperature over the range from 85°C to 95°C, it could be inferred that the reaction rate constants could be estimated at various temperatures; however, this concept has its limitations and may not be extended to other temperatures at which different physical parameters and mechanisms of transport and reaction occur (18).

APPENDIX

By assuming that the solid-solid reaction rate, $d\alpha/dt$, is proportional to the area of contact, X, between the reactants at time, t:

$$\frac{d\alpha}{dt} = \frac{k}{c}X \qquad \text{(Eq. 1)}$$

where k is the reaction rate constant and c is the proportionality constant. If the rate of generation of new contact area between the reactants is proportional to the free sulfacetamide surface, X_f, at time, t:

$$\frac{dX}{dt} = -kX + k_1X_f \qquad \text{(Eq. 2)}$$

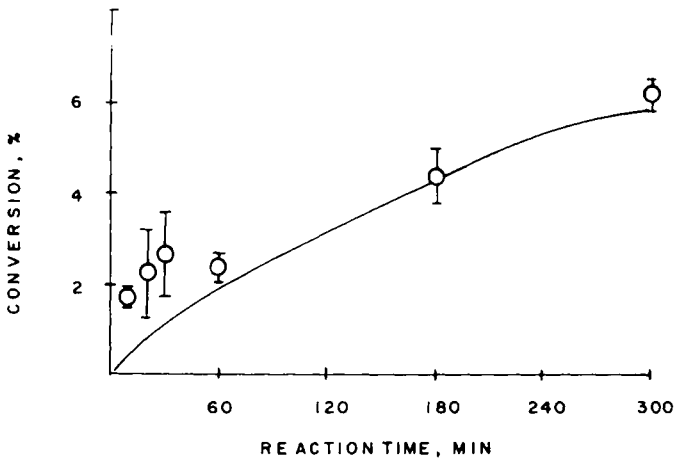

Figure 9—*Conversion curve at 85°C of equimolar sulfacetamide and phthalic anhydride compacts compressed at 3581 kg/cm². Solid curve represents theoretical values according to Eq. 14. Points are experimental values; bars represent* SD.

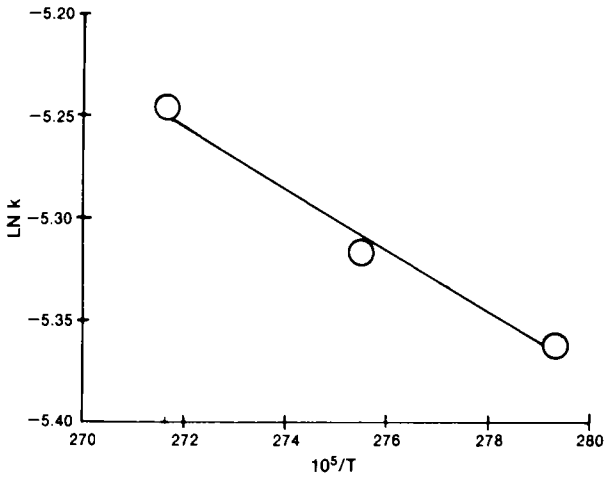

Figure 10—*Arrhenius plot of reaction rate constants and temperatures (T).*

where k_1 is the rate constant for the generation of new area of contact and is related to the mass transport of the anhydride. The changing rate of free sulfacetamide surface may be expressed as:

$$\frac{dX_f}{dt} = -k_1 X_f \qquad \text{(Eq. 3)}$$

The Laplace transformations of Eqs. 1–3 are:

$$s\bar{\alpha} = (k/c)\bar{X} \qquad \text{(Eq. 4)}$$

$$s\bar{X} - k_2X_0 = -k\bar{X} + k_1\bar{X}_f \qquad \text{(Eq. 5)}$$

$$s\bar{X}_f - k_2k_3X_{f,0} = -k_1\bar{X}_f \qquad \text{(Eq. 6)}$$

where s is the Laplace parameter, X_0 is the initial contact area between the reactants, $X_{f,0}$ is the initial free sulfacetamide area of contact, k_2 is the fraction of ultimately reacted area of contact, k_3 is the fraction of ultimately covered free sulfacetamide surface area, and $\bar{\alpha}$ is the Laplace transform of α. After combining the same terms in Eqs. 5 and 6:

$$\bar{X} = \frac{k_2X_0 + k_1\bar{X}_f}{s + k} \qquad \text{(Eq. 7)}$$

$$\bar{X}_f = \frac{k_4X_{f,0}}{s + k_1} \qquad \text{(Eq. 8)}$$

where $k_4 = k_2k_3$. By combining Eqs. 7 and 8 and substituting $\bar{X}$ into Eq. 4:

$$\bar{\alpha} = \frac{(k/c)k_2X_0s + (k/c)k_1k_2X_0 + (k/c)k_1k_4X_{f,0}}{s(s + k)(s + k_1)} \qquad \text{(Eq. 9)}$$

In Case 1, assume that $k \gg k_1$, and then the anti-Laplace transformation of $\bar{\alpha}$ in Eq. 4 would be:

$$\alpha = \frac{(kk_1k_2X_0 + kk_1k_4X_{f,0})/c}{kk_1} - \frac{(k^2k_2X_0 - kk_1k_2X_0 - kk_1k_4X_{f,0})/c}{k(k - k_1)} \cdot \exp(-kt) - \frac{(kk_1k_2X_0 - kk_1k_2X_0 - kk_1k_4X_{f,0})/c}{k_1(k - k_1)} \cdot \exp(-k_1t) \qquad \text{(Eq. 10)}$$

Because $k \gg k_1$, the second term on the right side of the equation rapidly becomes negligible, and in a short reaction time, Eq. 10 reduces to:

$$\alpha = (k_2X_0 + k_4X_{f,0})/c - (k_4X_{f,0}/c) \cdot \exp(-k_1t) \qquad \text{(Eq. 11)}$$

and at $t = 0$ and $\alpha = 0$, $k_2X_0/c = 0$. Since X_0 and c cannot be zero, the inference is that $k_2 = 0$ (no reaction occurred). Thus, the simplified form (Eq. 11) does not meet the initial condition, although it may apply when the reaction time is long enough to neglect the second term of Eq. 10. In addition, at a molar ratio of 1:3 sulfacetamide to phthalic anhydride, the sulfacetamide would be completely covered by the anhydride, and the third term of Eq. 10 would be operative. As shown in Fig. 9, the conversion is continuing. The value of k is relatively small, so the second term in Eq. 10 is not negligible throughout the 5-h reaction time.

In Case 2, assume that $k_1 \gg k$ and then:

$$\alpha = \frac{(kk_1k_2X_0 + kk_1k_4X_{f,0})/c}{kk_1} - \frac{(kk_1k_2X_0 - kk_1k_4X_{f,0} - kk_1k_2X_0)/c}{k_1(k_1 - k)} \cdot \exp(-k_1t) - \frac{(k^2k_2X_0 - kk_1k_2X_0 - kk_1k_4X_{f,0})/c}{k(k_1 - k)} \cdot \exp(-kt) \qquad \text{(Eq. 12)}$$

Because $k_1 \gg k$, the second term on the right side of the equation rapidly becomes negligible, so in a very short reaction time:

$$\alpha = (1/c)(k_2X_0 + k_4X_{f,0})[1 - \exp(-kt)] \qquad \text{(Eq. 13)}$$

or:

$$\alpha = A[1 - \exp(-kt)] \qquad \text{(Eq. 14)}$$

$$A = (1/c)(k_2X_0 + k_4X_{f,0}) \qquad \text{(Eq. 15)}$$

Thus, a plot of $-\ln[1 - (\alpha/A)]$ against time will produce a straight line with the slope equal to k.

Long-Term Controlled Navel Administration of Testosterone

YIE W. CHIEN

Received September 28, 1982, from the *Controlled Drug Delivery Research Center, Rutgers University, College of Pharmacy, Busch Campus, Piscataway, NJ 08854.* Accepted for publication June 29, 1983.

Abstract □ Male fertility has reportedly been regulated by the long-term, continuous administration of testosterone. To deliver the testosterone at a controlled rate for a month or longer, a bandage-type, testosterone-releasing, disk-shaped device was developed. *In vitro* drug elution studies demonstrated that a constant release profile of testosterone was achieved. *In vivo* studies in rhesus monkeys with the medicated device directly overlaying the navel for 46 d, yielded a fairly steady plasma level and also a constant urinary excretion rate for 32 d. A greater systemic bioavailability (more than twofold) was achieved as compared with drug disposition directly onto the navel or *via* the polacebo device (*i.e.*, drug is deposited onto the prefabricated placebo device). A fairly constant cumulative urinary recovery profile was achieved for longer than 1 month, in which >90% of the dose was administered. The *in vitro* and *in vivo* relationship was analyzed and discussed.

Keyphrases □ Testosterone—long-term controlled administration, navel, rhesus monkeys, bioavailability □ Controlled administration, navel—long-term, testosterone, rhesus monkeys, bioavailability □ Bioavailability—long-term controlled administration, navel, testosterone

It is known that the spermatogenesis is an androgen-dependent process which can be maintained in hypophysectomized rats by continuous administration of testosterone (1). Also, it was reported that male fertility can be regulated by the long-term, continuous administration of testosterone or testosterone derivatives (2–4).

Recently, several medicated bandages were successfully developed and approved by the FDA for marketing to provide a continuous transdermal administration of systemically active drugs through the intact skin (5–7). Following the development of a scopolamine-releasing system for 3-d prevention of motion sickness, four nitroglycerin-releasing transdermal therapeutic systems (system A[1], system B[2], system C[3], and system D[4]) were also developed to provide 24-h continuous protection against anginal attack (6, 7).

It was recently observed in this laboratory that the transdermal absorption of testosterone in six rhesus monkeys *via* the navel area produces a substantially greater systemic bioavailability than by forearm administration (79.9 *versus* 49.9%). Bioavailability of testosterone by intravenous administration was used as the control (22). In the present investigation, we evaluated the feasibility of using the navel as the site for a long-term application of a bandage-type controlled-release drug delivery system developed to provide a continuous transdermal administration of testosterone at a controlled rate.

EXPERIMENTAL SECTION

Preparation of the Testosterone-Releasing Transdermal Bandage—To deliver the testosterone at a controlled rate for a month or longer, a disk-shaped testosterone-releasing device was fabricated, using the methodology and process outlined for the preparation of microsealed drug delivery (MDD) systems (9–11), to contain a combination of 0.041% w/w of [^{14}C]testosterone and 0.252% w/w of nonradioactive testosterone in the medicated liquid compartments. The testosterone-saturated liquid compartments were dispersed homogeneously as discrete microscopic spheres in the cross-linked polymer matrix (Fig. 1).

For the *in vivo* studies, medicated MDD disks with a surface area closely resembling that of the navel of a rhesus monkey (with an apparent surface area of 0.2 cm^2 each) were fabricated to contain 4.41 ± 0.25 μCi of [^{14}C]-testosterone. Each of the disks was then glued onto the center of a piece of commercially available plastic adhesive[5] to form a testosterone-releasing transdermal bandage.

***In Vitro* Release Studies**—The *in vitro* drug elution system, used to characterize the mechanism and rates of testosterone release from each of the MDD disks, was essentially the same as that reported previously (12), except that the medicated MDD disk was mounted in a specially designed acrylic holder (Fig. 2). The whole assembly was then rotated at a constant angular rotation speed of 81 rpm, to achieve a constant hydrodynamic condition, in a perfect sink aqueous medium (with a constant volume of 150 mL) at 37°C. The medium contains 75% v/v of polyethylene glycol 400 to enhance the aqueous solubility of testosterone and to maintain a perfect sink, which simulates the biological sink achieved by blood perfusion. The amount of testosterone released daily was determined spectrophotometrically at the λ_{max} of 241 nm.

***In Vivo* Navel Absorption Studies**—Rhesus monkeys (4.85–5.0 kg) were immobilized by the injection of 1 mg/kg of phencyclidine hydrochloride[6]

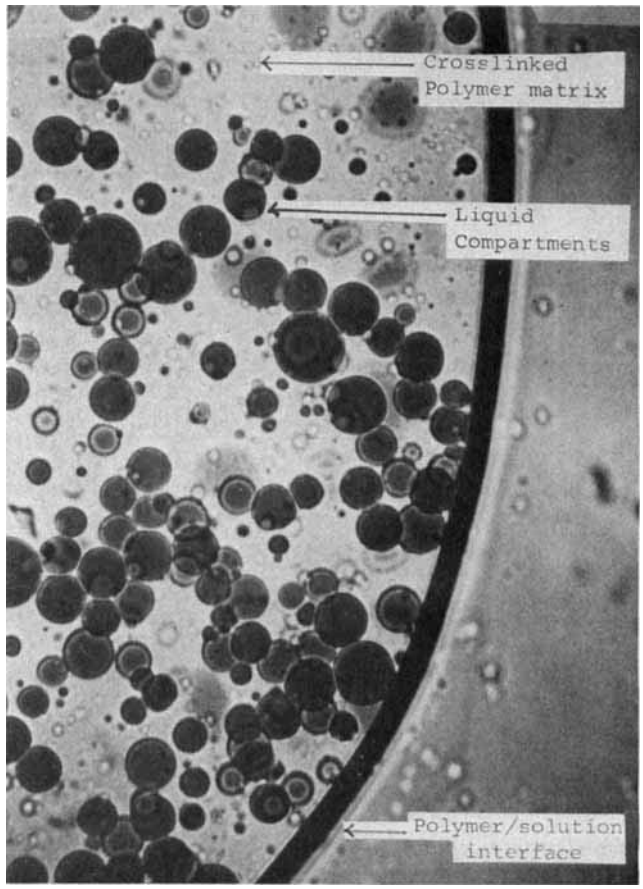

Figure 1 —*Photomicrograph (1300×) of the cross-sectional view of an MDD system. The microscopic liquid compartments (dark areas), which encapsulate drug particles, are homogenously dispersed as discrete, immobilized, unleachable spheres (with diameter <50 μm) in a cross-linked polymer matrix (light background area).*

solution. Testosterone was then administered to the navel area by the following methods.

Drug Disposition—Five microcuries (25 μg) of [^{14}C]testosterone[7] in 100 μL of acetone was applied dropwise to the navel, with the area of application controlled at 0.2 cm^2 by a template (an aluminum plate with a 0.2-cm^2 circular hole at the center). After all the drug solution was applied and quickly dried, a piece of plastic adhesive was placed over the application site and further reinforced with another plastic adhesive strip.

MDD Disk Application—One hundred microliters of drug-free acetone[8] was applied dropwise to the navel (this was done to correct for any possible effect of acetone on percutaneous absorption). After the solvent had dried, a unit of testosterone-releasing transdermal bandage was applied directly with the medicated MDD disk centered on the navel. It was then reinforced with another strip of plastic adhesive.

Placebo Disk Application—A placebo disk containing no testosterone was prepared in the same manner as described earlier for the MDD disk. After placing the placebo disk over the acetone-treated navel, 6 μCi (30 μg) of [^{14}C]testosterone in 10 μL of acetone was applied dropwise on the 0.2-cm^2 placebo disk. After drug solution was dried rapidly, a piece of plastic adhesive was placed over the placebo disk and further reinforced with another strip of plastic adhesive.

Each of the treated monkeys was placed into a jacket[9] and then secured in a metabolism chair. A 20-gauge catheter needle[10] was secured to the leg of the monkey to collect blood samples from the saphenous vein. Meanwhile, saline solution[11] was continuously infused through another catheter at a rate of 14 mL/h. Two-milliliter aliquots of blood were collected at 0.5, 1, 2, 3, 4, 5, 6, and 24 h and then every 24 h thereafter until the completion of a study. Urine was also collected on a daily basis.

At the end of each study, the plastic adhesive strips and MDD or placebo disks were removed and thoroughly extracted with methanol[8]. The area of drug application was also carefully washed to remove the residual, unabsorbed testosterone (both radioactive and nonradioactive). The extractions and washings were then combined for the analysis and determination of the fraction of dose not absorbed.

The blood samples were collected in heparinized tubes. After centrifugation, 200 μL of plasma were transferred from each sample and mixed with 5 mL of scintillation fluid[12]. Duplicate samples were prepared and their radioactivity was determined[13]. Conversion of counts per minute (cpm) to disintegrations per minute (dpm) was accomplished by the external standard channels ratio method. Data measured as dpm was recorded and converted to the corresponding total radioactivity in 100 mL of plasma (μCi/100 mL) at each sampling interval.

Samples (500 μL–1 mL) were taken in duplicate from a daily urine collection and mixed with 10 mL of scintillation fluid[12]. Total radioactivity in each sample was determined and calculated in the same manner as described earlier for plasma samples.

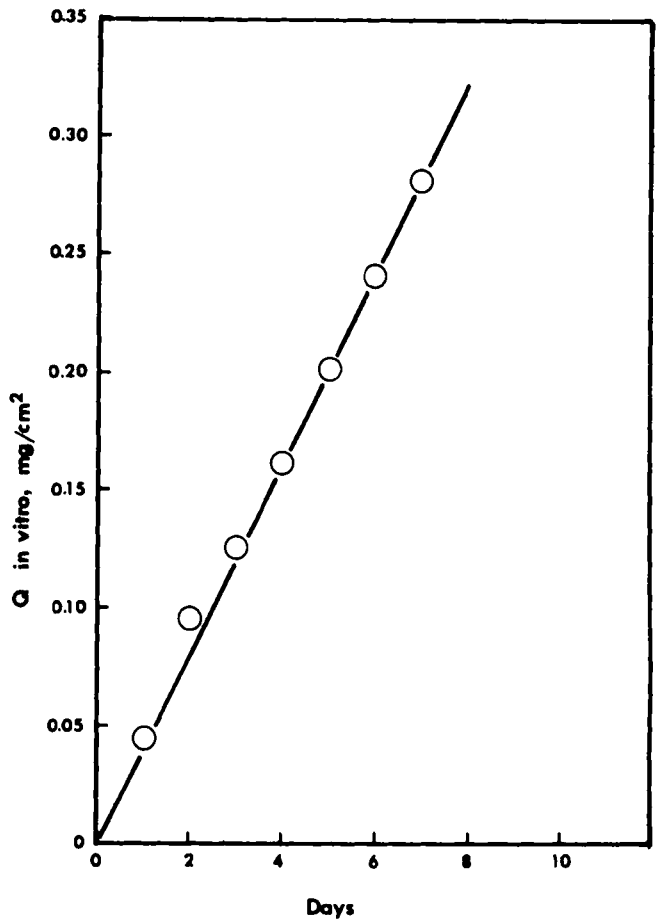

Figure 3—*Seven-day* in vitro *release of testosterone from the disk-shaped MDD system under a perfect sink condition at 37°C. The rate of release (Q/t) was determined to be 40.25 ± 0.64 μg/cm^2/d (mean ± SD).*

RESULTS AND DISCUSSION

***In Vitro* Release of Testosterone from MDD Disks**—A typical set of data on the *in vitro* release of testosterone from an MDD disk is illustrated in Fig. 3. The cumulated amount, Q, of testosterone released from a unit surface area of the MDD disk was found to be linearly proportional to the duration (in days) of elution in the elution solution. Apparently, a constant (zero-order) release profile was achieved. The observation is in good agreement with the controlled release of deoxycorticosterone acetate from the same type of MDD system (12). From the slope of the linear Q *versus* t plot, the rate of release, Q/t, of testosterone from the MDD disk was calculated to be 40.25 (±0.64) μg/cm^2/d (average of triplicate experiments with a coefficient of variation of 1.6%). The theoretical basis for the observed Q *versus* t relationship was analyzed previously (13).

Long-Term Navel Absorption of Testosterone—For the *in vivo* studies, a unit of testosterone-releasing transdermal bandage was applied to each of two rhesus monkeys with the medicated MDD disk (0.2 cm^2) directly overlaying the navel. Blood and urine samples were collected according to the protocol outlined earlier (*Experimental Section*) until all the testosterone dose incorporated was totally released (~46 d).

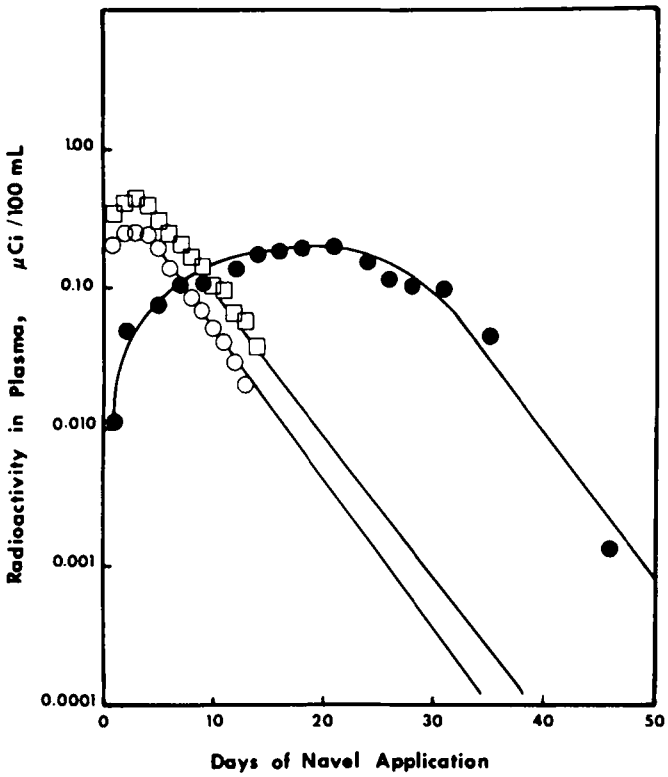

Figure 4—*Mean plasma radioactivity levels following the navel administration of [^{14}C]testosterone in two rhesus monkeys. Key: (○) drug alone (5.03 μCi); (□) disposition on a placebo disk (6.02 μCi), (●) microseal in an MDD disk (4.41 μCi). The first-order rate constants for elimination (β) were 0.0104, 0.0098, and 0.0101 h^{-1}, respectively.*

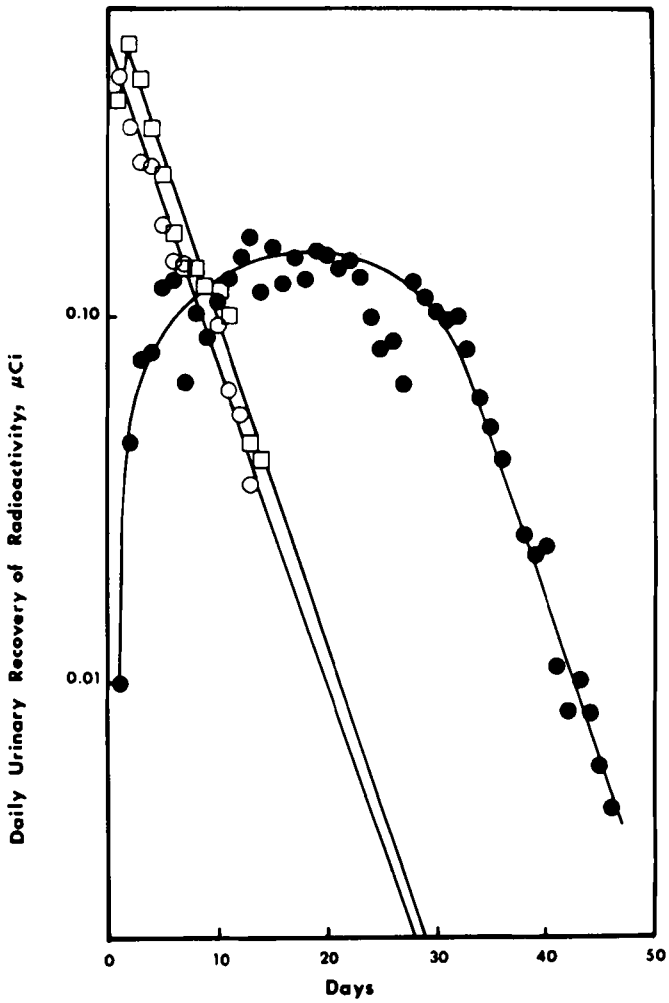

Figure 5—*Mean daily urinary recovery of radioactivity following the navel administration of [^{14}C]testosterone in two rhesus monkeys. Key: (○) drug alone (5.03 μCi); (□) disposition on a placebo disk (6.02 μCi); (●) microseal in an MDD disk (4.41 μCi). The first-order constants for urinary excretion (k_e) were 0.0085, 0.0087, and 0.0085 h^{-1}, respectively.*

Both plasma profiles (Fig. 4) and daily urinary recovery data (Fig. 5) demonstrated that the 46-d application of the MDD disk on the navel of the monkey maintained a fairly steady plasma radioactivity level at ~0.10 μCi/100 mL for a duration of slightly over 1 month and also a fairly constant urinary excretion rate of 0.10 μCi/d in the same period.

On the other hand, application of [^{14}C]testosterone directly onto the navel by the solution disposition technique or disposition of drug on a placebo MDD disk (without microsealed drug inside the device) at the time of navel application could not achieve or maintain either a steady plasma level or a constant daily urinary excretion rate of [^{14}C]testosterone (Figs. 4 and 5). The results suggested that the MDD system provides the controlled-release mechanisms to meter the release of a constant amount of [^{14}C]testosterone available for navel absorption.

The data in Figs. 4 and 5 also indicated that the rate constants for elimination (β) and for urinary excretion (k_e) of [^{14}C]testosterone were not altered by the controlled drug administration of the MDD system. These observations are expected since the β and k_e values are the intrinsic pharmacokinetic profiles of the drug and should not be modified in any way by the method of administration. Both with and without microsealed [^{14}C]testosterone in the device, the testosterone and its metabolites were eliminated and excreted basically at the same rates as those for drug alone. Testosterone and its metabolites were eliminated at a mean β value of 0.0101 ± 0.0003 h^{-1} and excreted at a mean k_e value of 0.0085 ± 0.0001 h^{-1}.

To determine the *in vivo* release rate of testosterone at the navel site, the cumulative urinary total radioactivity recovery data (expressed as percent of the administered dose) was plotted as a function of time (Fig. 6). As seen in the short-term (7-d) *in vitro* drug release studies (Fig. 3), a fairly constant urinary recovery profile was also observed in the navel absorption of testosterone when the combination of radioactive and nonradioactive testosterone was delivered by an MDD disk, for a period of ≤32 d. It was also noted that >90% of the administered dose of the radioactive testosterone was recovered in the urine during the 32-d zero-order transdermal controlled drug administration (Fig. 6).

On the other hand, it was observed that only one-half (~46%) of the administered dose was recovered from the urinary excretion when [^{14}C]testosterone was administered either by direct disposition on the navel or by depositing a placebo MDD disk (without microsealed compound in the liquid compartments) on the navel. The balance of the administered dose was recovered from the washings of the skin surface and from the extractions of the covering materials. The reasons for the low transdermal bioavailability observed are still not clear and require further study. In any case, a better systemic bioavailability of testosterone was achieved by use of the controlled-release MDD system, which released testosterone at the molecular level and controlled the amount of testosterone available for continuous transdermal administration through the navel.

As previously stated, each MDD disk contained a combination of 0.041% w/w [^{14}C]testosterone and 0.252% w/w nonradioactive testosterone. By calculation, the 32-d cumulative urinary radioactivity recovery data in Fig. 6 can be translated into the cumulative total amount (Q) of testosterone (radioactive and nonradioactive) absorbed by each of the rhesus monkeys investigated. Again, a fairly linear Q *versus* t relationship was achieved (Fig. 7), as seen in the *in vitro* drug release studies (Fig. 3). From the slope of this linearity, it was determined that the testosterone was released and absorbed from the MDD disk at an *in vivo* rate (Q/t) of 27.66 μg/cm^2/d.

***In Vitro–In Vivo* Relationships**—Comparison of this *in vivo* release rate (27.66 μg/cm^2/d) with the *in vitro* release rate (40.25 μg/cm^2/d) determined in Fig. 3 yields an *in vitro–in vivo* correlation coefficient of 0.69. The observation of a nonunity correlation coefficient, *e.g.*, 0.69, could be attributed to the existence of skin tissues in the *in vivo* situation, which act as an additional diffusion barrier for the permeation of drug molecules released from the medicated MDD disk. Drug molecules have to diffuse through this barrier before they can reach the biological sink for transport to a target organ[4]. The dissimilarity between *in vitro* and *in vivo* conditions may also contribute to the *in vitro–in vivo* correlation coefficient lower than unity. The sink condition established in the *in vitro* situation by the enhancement in saturation solubility may not simulate the interfacial partitioning of the drug from the drug delivery device toward the stratum corneum, which is a nonsink medium in nature.

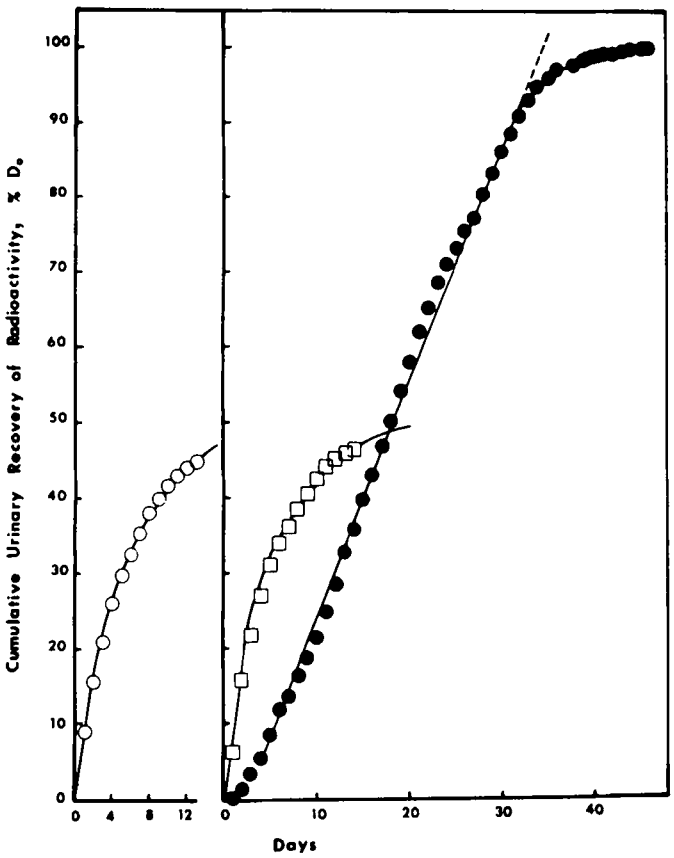

Figure 6—*Comparison of the time course for the cumulative urinary total recovery of radioactivity following the navel administration of [^{14}C]testosterone. Key: (○) drug only; (□) disposition on a placebo disk; (●) microseal in an MDD disk. The total urinary recovery is 44.8, 46.5, and 93.4%, respectively, of the administered dose (D_0).*

In a separate study with subcutaneously controlled administration of deoxycorticosterone acetate delivered by an identical MDD-type drug delivery system, an almost unity (1.09) *in vitro–in vivo* correlation coefficient was obtained (13), in which the stratum corneum does not exist between the drug delivery system and the biological sink.

However, the *in vitro–in vivo* correlation coefficient (0.69) obtained can be utilized as a working factor in the determination and projection of the long-term *in vivo* release rates from a short-term *in vitro* drug release study (13–17). This coefficient can be very useful in the development of a long-acting drug delivery system in that it can minimize the expense involved in the amount of testing required and the use of costly animals.

In conclusion, the bioavailability data generated in this investigation have clearly demonstrated that the navel can be a useful site for long-term transdermal administration of drugs, such as testosterone, *via* a bandage-type controlled-release drug delivery system [such as a microsealed drug delivery (MDD) system] to provide a prolonged plasma drug level for at least 1 month. The systemic bioavailability of the drug can also be enhanced substantially by the controlled drug-release mechanisms of the MDD system. The same conclusion was reached in the controlled subcutaneous administration of deoxycorticosterone acetate by a subdermal implant-type MDD system (13).

Phenytoin Prodrugs III: Water-Soluble Prodrugs for Oral and/or Parenteral Use

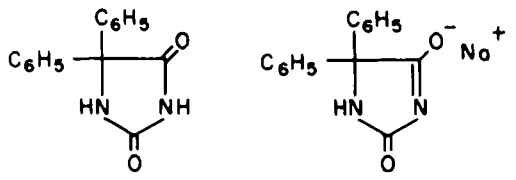
S. A. VARIA *, S. SCHULLER, K. B. SLOAN ‡, and V. J. STELLA ˣ

Received December 22, 1982, from the *Department of Pharmaceutical Chemisty, School of Pharmacy, The University of Kansas, Lawrence, KS 66045.* Accepted for publication September 6, 1983. Present addresses: *Squibb Institute for Medical Research, New Brunswick, NJ 08903; ‡College of Pharmacy, University of Florida, Gainesville, FL 32610.

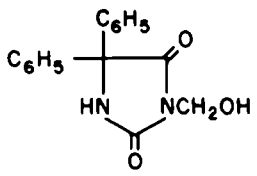
Abstract □ Various bioreversible derivatives of phenytoin, a poorly water soluble and erratically absorbed drug after both oral and parenteral dosing, were synthesized. Initial evaluation of these expected prodrugs, *i.e.*, their aqueous solubility, cleavage in the presence of various animal tissues, and anticonvulsant activity in mice, confirmed that a number of the derivatives did indeed behave as prodrugs. The more promising prodrugs were the disodium phosphate ester and various amino groups containing acyl esters of 3-(hydroxymethyl)-5,5-diphenylhydantoin.

Keyphrases □ Prodrugs—phenytoin, water-soluble, hydroxymethylation, anticonvulsants □ Anticonvulsants—phenytoin prodrugs, water-soluble, hydroxymethylation □ Phenytoin—water-soluble prodrug, hydroxymethylation

Phenytoin (I) is a high melting (293°C), weakly acidic (1, 2) drug exhibiting poor solubility (3–5) in water. These properties lead to erratic absorption after oral dosing with both the free acid and the sodium salt (Ia) (3, 6–19). For parenteral use, sodium phenytoin is formulated in an aqueous alkaline medium of pH ~12 containing 40% propylene glycol and 10% ethanol. The parenteral dosage form is hazardous if the intravenous injection is rapid (20, 21), and the free acid appears to precipitate at intramuscular injection sites (22–25). The parenteral dosage form has also presented handling problems, especially if admixing or dilution was desired (26, 27).

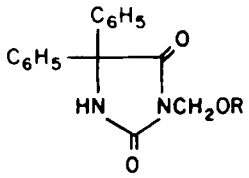


I Ia



II

One solution to these problems was to develop prodrugs of phenytoin with more desirable physicochemical properties[1]. The overall goal of this study, therefore, was to synthesize various water-soluble phenytoin prodrugs and to evaluate their potential oral and parenteral use. Recently, interest has arisen in *N*-hydroxymethyl derivatives of hydantoins, amides, and imides (4, 5, 28–31). In the present study 3-(hydroxymethyl)-5,5-diphenylhydantoin or 3-(hydroxymethyl)phenytoin (II) was synthesized with the expressed purpose of providing a "synthetic handle" in the molecule to which various other potential bioreversible water-solubilizing functional groups could be added (esters III–X).



III: R = $COCH_3$
IV: R = $COCH_2\overset{+}{N}H(CH_3)_2\ CH_3SO_3^-$
V: R = $CO(CH_2)_2\overset{+}{N}H(C_2H_5)_2$ (2-naphthalenesulfonate)
VI: R = $CO_2(CH_2)_2\overset{+}{N}H(CH_3)_2\ CH_3SO_3^-$
VII: R = $PO_3^{2-}Na_2^+$
VIII: R = $SO_3^-Na^+$
IX: R = $CO(CH_2)_2CO_2^-Na^+$
X: R = $CO(CH_2)_3CO_2^-Na^+$

All the esters except III have an ionizable group in the ester moiety, and the salt forms of esters would be expected to have an increased aqueous solubility over that of phenytoin. Compounds IV–VI, IX, and X would be expected to be cleaved *in vivo* by esterases to II, which will be shown in this study to break down further to phenytoin and formaldehyde with a half-life of ~2 s at 37°C and pH 7.4, an observation consistent with an earlier study (5). Similarly, VII and VIII were expected to be catalytically hydrolyzed by phosphatase and sulfatase enzymes, respectively.

The evaluation of VIII as a potential prodrug of phenytoin has been presented elsewhere (32); VIII was found not to behave as a prodrug of phenytoin. The syntheses and preliminary evaluations of compounds IV–VII, IX, and X are presented herein.

EXPERIMENTAL SECTION

All compounds were synthesized by standard techniques. The specific details for the synthesis of each compound are presented below.

3-(Hydroxymethyl)phenytoin [II, 3-(Hydroxymethyl)-5,5-diphenylhydantoin]—A suspension of 20 g (0.08 mol) of phenytoin, 80 mL of formalin (1.07 mol, 37% formaldehyde in water), 1 g (0.007 mol) of potassium carbonate, and 720 mL of water were stirred at room temperature for 24 h. The mixture was filtered and the resulting white solid was washed with 3% aqueous formaldehyde, air dried for 24 h to give 21.5 g of II (92% yield), mp 187–189°C. ^{1}H-NMR (Me_2SO-d_6): δ 4.85 (d, CH_2), 6.4 (t, OH), 7.4 (s, 10), and 9.6 ppm (s, NH).

Anal.—Calc. for $C_{16}H_{14}N_2O_3$: C, 68.08; H, 5.00; N, 9.92. Found: C, 68.15; H, 4.93; N, 9.97.

3-(Hydroxymethyl)-5,5-diphenylhydantoin Acetate (Ester III)—A solution of 1.5 g (0.0058 mol) of II, 1 mL of acetic anhydride, and 10–20 μL of sulfuric acid was allowed to stand for 10 min. The solid precipitate was suspended in 10 mL of ether, filtered, washed with 30 mL of ether, and then recrystallized from ethanol to give 1.69 g of ester III (90% yield), mp 154–157°C. ^{1}H-NMR ($CDCl_3$): δ 2.0 (s, CH_3), 5.55 (s, CH_2), 7.4 (s, 10), and 7.7 ppm (s, NH).

Anal.—Calc. for $C_{18}H_{16}N_2O_4$: C, 66.65; H, 4.97; N, 8.64. Found: C, 66.66; H, 5.01; N, 8.61.

3-(Hydroxymethyl)-5,5-diphenylhydantoin Ester with *N,N*-Dimethylglycine, Monomethanesulfonate (IV)—A suspension of 3.65 g (0.035 mol) of *N,N*-dimethylglycine, 7.3 g (0.035 mol) of dicyclohexylcarbodiimide, and 10 g (0.035 mol) of II in 50 mL of dry pyridine was stirred at room temperature for 24 h. After evaporation under reduced pressure at 50°C, the syrupy contents were triturated with 100 mL of dichloromethane and the dicyclohexylurea was removed by filtration. The dichloromethane was removed under reduced pressure, and the trituration was repeated twice to produce a syrup, to which was added 50 mL of ether. After standing, the resulting precipitate was removed by filtration and washed with 25 mL of ether and dried *in vacuo* to give 11.3 g of IVa (88% yield), mp 133–137°C. ^{1}H-NMR and elemental analysis confirm the structure of the product as 3-(hydroxymethyl)-5,5-diphenylhydantoin ester with *N,N*-dimethylglycine (IVa). A solution of 1.92 g (0.005 mol) of IVa, 0.5 g (0.005 mol) of methanesulfonic acid, and 25 mL of dichloromethane was stirred, and the resulting precipitate was removed by filtration and recrystallized from ethanol–acetone–ether to give 2.15 g of IV (93% yield), mp 173–175°C. ^{1}H-NMR (D_2O): δ 3.05 (s, CH_3), 3.2 (s, 2, CH_3), 4.4 (s, CH_2), 5.85 (s, CH_2), and 7.5 ppm (s, 10).

Anal.—Calc. for $C_{21}H_{25}N_3O_7S$: C, 54.42; H, 5.44; N, 9.07. Found: C, 54.22; H, 5.40; N, 8.92.

3-(Hydroxymethyl)-5,5-diphenylhydantoin Ester with *N,N*-Diethyl-β-alanine, Mono-2-naphthalenesulfonate (V)—A suspension of 3.54 g (0.0195 mol) of 3-*N,N*-diethylaminopropionic acid hydrochloride, 4.02 g (0.0195 mol) of dicyclohexylcarbodiimide, and 5 g (0.0177 mol) of II in 20 mL of dry pyridine was stirred at room temperature for 20 h and filtered. The glassy residue was triturated with 100 mL of dichloromethane, and the suspended dicyclohexyl urea was removed by filtration. The dichloromethane was removed under reduced pressure and the trituration was repeated twice. The syrup was dissolved in 100 mL of water, the pH was lowered to 3 with dilute HCl, and the mixture was extracted twice with 100 mL of ether. The pH of the aqueous layer was raised to 9 with solid potassium carbonate, and the mixture was extracted with 100 mL of ether. The organic phase was dried (magnesium sulfate), and the solvent was removed under reduced pressure to yield 3-(hydroxymethyl)-5,5-diphenylhydantoin ester with *N,N*-diethyl-β-alanine (Va). A solution of 4.35 g (0.0106 mol) of Va and 2.6 g (0.0106 mol) of 2-naphthalenesulfonic acid, dissolved in a minimum amount of methanol, in 80 mL of dry ether was stirred until the precipitation of a white solid. The precipitate was removed by filtration, washed with 50 mL of ether, and dried in a vacuum desiccator to give 4.0 g of V (44.5% yield), mp 174–176°C. ^{1}H-NMR (Me_2SO-d_6): δ 1.15 (t, $2CH_3$), 3.1 (m, 8), 5.55 (s, CH_2), 7.4 (m, 17), and 9.9 ppm (s, NH).

Anal.—Calc. for $C_{33}H_{35}N_3O_7S$: C, 64.17; H, 5.17; N, 6.80. Found: C, 63.90; H, 5.72; N, 6.62.

3-(Hydroxymethyl)-5,5-diphenylhydantoin Ester with 2-(Dimethylamino)-ethyl Carbonate, Monomethanesulfonate (VI) *Via* 3-(Hydroxymethyl)-5,5-diphenylhydantoin, *p*-Nitrophenyl Carbonate (XI)—A solution of 6.78 g (0.033 mol) of *p*-nitrophenylchloroformate and 9.5 g (0.033 mol) of II in 30 mL of dry pyridine was stirred at room temperature for 5 h, poured with vigorous stirring into ice water, and acidified with 0.38 mol of sulfuric acid. The pale yellow solid was removed by filtration and dried in a vacuum oven at 40°C overnight to give 12.9 g of XI (88% yield), mp 191–193°C.

A solution of 4 mL of 2-(*N,N*-dimethylamino)ethanol, previously dried by distillation, and 4.5 g (0.01 mol) of XI in 25 mL of acetonitrile was stirred at room temperature for 5 h, poured into ice water, and extracted with 100 mL of dichloromethane. The organic layer was extracted twice with 25 mL of 5% aqueous potassium carbonate solution, dried over anhydrous magnesium sulfate, filtered, and evaporated under reduced pressure to give 1.42 g of a white glassy solid, (35% yield), mp 88–90°C (VIa).

The methanesulfonate salt of VIa (VI) was prepared in the same manner as IV from IVa, except that on filtration from dichloromethane, the salt was refluxed in acetone to remove phenytoin contamination (46% yield), mp 186–189°C. ^{1}H-NMR (D_2O): δ 3.05 (s, CH_3), 3.2 (s, $2CH_3$), 3.7 (t, CH_2), 4.75 (t, CH_2), 5.8 (s, CH_2), and 7.55 ppm (s, 10).

Anal.—Calc. for $C_{22}H_{27}N_3O_8S$: C, 53.57; H, 5.47; N, 8.51. Found: C, 53.2; H, 5.5; N, 8.3.

3-(Hydroxymethyl)-5,5-diphenylhydantoin Disodium Phosphate Ester (VII)—Sodium dibenzylphosphate and silver dibenzylphosphate were synthesized according to the method of Clark and Todd (33) from dibenzylphosphite[2].

3-(Chloromethyl)-5,5-diphenylhydantoin (XII)—A solution of 20 g (0.071 mol) of II and 6.2 mL of phosphorous trichloride in 100 mL of dichloromethane was stirred at room temperature for 24 h, diluted with a further 50 mL of dichloromethane, and extracted once with 100 mL of water and twice with 250 mL of 5% w/v aqueous sodium carbonate solution. The separated dichloromethane was dried over anhydrous magnesium sulfate, filtered, and evaporated under reduced pressure to give 13.1 g of a white solid (61% yield), mp 155.0–156.5°C.

[2] Aldrich Chemical Co., Milwaukee, Wis.

Table I—Aqueous Solubilities and pH Values of the Saturated Solutions of Phenytoin, II (in 1 M Aqueous Formaldehyde), and IV–VII at 25°C

Compound	pH	Solubility (Phenytoin Equivalent), mg/mL	Solubility Relative to Phenytoin
I	Neutral	0.02[a] (0.02)	1
II	Neutral	0.19[b] (0.17)	8.5
IV	~2	140 (76.2)	3810
V	~4	1.9 (0.78)	39
VI	~2	185 (94.6)	4730
VII	~9	142 (88.17)	4408.5

[a] Literature values vary from 0.01–0.04 mg/mL (1, 26). A value of 0.02 mg/mL was found in our studies. [b] The solubility was determined in aqueous formaldehyde (1 M).

3-(Hydroxymethyl)-5,5-diphenylhydantoin Dibenzyl Phosphate Ester (XIII)—A suspension of 13.13 g (0.034 mol) of silver dibenzylphosphate and 10 g (0.033 mol) of XII in 300 mL of benzene was refluxed for 2 h, hot-filtered under reduced pressure, extracted with 250 mL of 5% aqueous potassium carbonate, dried over magnesium sulfate, filtered, and evaporated under reduced pressure. The remaining syrup was triturated with 60 mL of ether and allowed to stand overnight; the white precipitate (XIII) which formed was removed by filtration, washed with 60 mL of ether, and dried in a vacuum oven to give 12 g of XIII (67% yield), mp 116–118°C.

Phosphate Ester of II (VIIa) and Its Disodium Salt (VII)—A suspension of 1 g of palladium (5%) on activated carbon[2] and 2 g (0.0037 mol) of XIII in 100 mL of ethyl acetate was subjected to hydrogenation[3] at 60 psi for 25 min (34). The suspension was filtered and the filtrate was evaporated under reduced pressure to give 0.7 g of a white solid (VIIa) which readily recrystallized from acetone (54.5% yield), mp 173–176.5°C.

Anal.—Calc. for $C_{16}H_{15}N_2O_6P$: C, 53.05; H, 4.17; N, 7.73. Found: C, 52.88; H, 4.02; N, 7.60.

A solution of 1.8 g (0.005 mol) of VIIa in 100 mL of methanol was titrated with 1 M NaOH to the second end point as determined by pH monitoring. The solution was filtered, evaporated under reduced pressure, and the white solid recrystallized from water–ethanol–acetone to give 1.1 g of VII (56% yield), mp 220°C (softens). ^{1}H-NMR (D_2O): δ 5.3 (d, CH_2) and 7.45 ppm (s, 10).

Anal.—Calc. for $C_{16}H_{13}N_2O_6PNa_2{\cdot}2H_2O$: C, 43.4; H, 3.87; N, 6.33. Found: C, 43.25; H, 3.82; N, 6.31.

3-(Hydroxymethyl)-5,5-diphenylhydantoin Sodium Succinate (Ester IX)—A solution of 10 g (0.035 mol) of II in 100 mL of dry pyridine was stirred at room temperature for 5 d with the gradual addition of 4.85 g (0.043 mol) of succinic anhydride. The solution was poured into 400 mL of 5% w/v aqueous sodium bicarbonate and immediately extracted with 250 mL of chloroform. The aqueous layer was isolated and the pH was lowered to 2 with hydrochloric acid; the aqueous layer was then rapidly extracted with 400 mL of chloroform. The chloroform layer was dried over anhydrous magnesium sulfate, filtered, and evaporated under reduced pressure; the resulting white solid (IXa) was triturated with ether and removed by filtration, mp 144.5–147.5°C. ^{1}H-NMR ($CDCl_3$): δ 2.6 (s, $2CH_2$), 5.55 (s, CH_2), 6.2 (s, 1), 7.4 (s, 10), and 7.6 ppm (s, 1).

Anal.—Calc. for $C_{20}H_{18}N_2O_6$: C, 62.83; H, 4.75; N, 7.33. Found: C, 62.74; H, 4.71; N, 7.20.

The sodium salt of IXa was prepared by titrating IXa with an equimolar solution of sodium methoxide in anhydrous methanol to give 8.8 g (62% yield), mp 141.5–146°C.

Anal.—Calc. for $C_{20}H_{17}N_2O_6Na{\cdot}0.5\ H_2O$: C, 58.13; H, 4.36; N, 6.78. Found: C, 57.87; H, 4.18; N, 6.57.

3-(Hydroxymethyl)-5,5-diphenylhydantoin Sodium Gluturate (Ester X)—Compound X was synthesized by allowing glutaric acid anhydride to react with II in dry pyridine and isolated by a method identical to that described for the synthesis of IX (30% yield), mp 137.5–144°C. ^{1}H-NMR of Xa ($CDCl_3$): 2.8 (m, 3 CH_3), 5.55 (s, CH_2), 6.6 (s, 1), 7.4 (s, 10), and 7.7 ppm (s, 1).

Anal.—Calc. for $C_{21}H_{20}N_2O_6$ (Xa): C, 63.6; H, 5.09; N, 7.07. Found: C, 62.87; H, 5.07; N, 6.91.

Anal.—Calc. for $C_{21}H_{19}N_2O_6Na{\cdot}H_2O$ (X): C, 57.81; H, 4.81; N, 6.41. Found: C, 57.71; H, 4.77; N, 5.47.

Aqueous Solubility of II and IV–VII—The aqueous solubility of II was determined by adding an excess of II to a solution of formaldehyde (1 M) in vials maintained at 25 ± 0.1°C in a constant-temperature water bath. The solubility was determined in 1 M formaldehyde solution in order to prevent

[3] Parr Instrument Co., Moline, Ill.

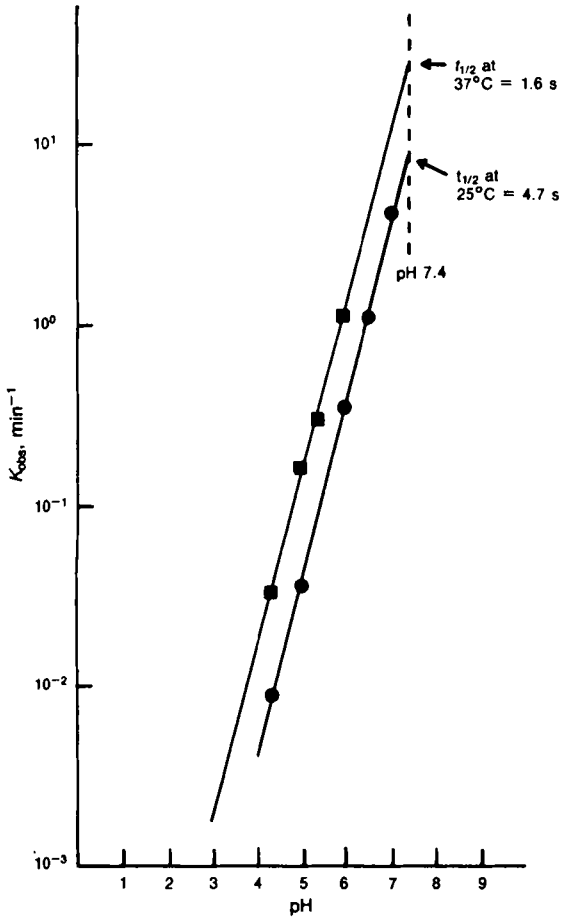

Figure 1—*pH-rate profile for the conversion of II to phenytoin at 25°C (●) and 37°C (■), μ = 0.5.*

the decomposition of II to phenytoin. The vials were shaken for 24 h so that equilibrium solubility was attained. The contents of the vials were then filtered. Appropriate dilutions of the filtrate with 1 M formaldehyde were made, and the absorbances of the diluted solutions at 260 nm were measured. The concentration of II was calculated from the measured absorbances by reference to standard curves. The aqueous solubilities of IV–VII were estimated at 25 ± 0.1°C by shaking an excess of the compound with a known volume of water, over a limited time period of 3–6 h to minimize the extent of degradation of the esters to phenytoin. The saturated solutions were filtered, diluted, and the concentrations of the esters were calculated from measured UV absorbances of the diluted solutions by reference to standard curves. The pH values of the saturated solutions were also measured.

Cleavage of IV–VII to Phenytoin in Biological Tissues—Conversion of IV–VII to phenytoin was carried out at 25°C and 37°C in plasma or whole blood obtained from rats[4], beagle dogs[5], and human subjects[6]. Blood was treated with EDTA to prevent coagulation. Plasma was obtained by centrifuging[7] blood for 15–20 min at 1000×*g*.

The conversion of VII to phenytoin was also studied in rat and dog tissue homogenates at 37°C. Sörensen's isotonic phosphate buffer (pH 7.4) was used to prepare the tissue homogenates and also to dilute plasma in cases where the reversion of the esters to phenytoin was too fast to follow in undiluted plasma. Reaction was initiated by injecting an appropriate amount of a stock solution of the ester in an appropriate solvent into temperature-equilibrated plasma, whole blood, or tissue homogenates. Samples obtained for the hydrolysis of IV–VI were quenched with *m*-phosphoric acid and assayed for phenytoin by the GC[8] method of Stella (35). In the case of the hydrolysis of VII, 100 μL of blood, plasma, or tissue homogenate samples were extracted directly into toluene containing the gas chromatography internal standard, 5-(*p*-methylphenyl)-5-phenylhydantoin, 0.7 μg/mL. The rest of the procedure

Table II—Half-Lives for the Conversion of IV–VII to Phenytoin in Rat, Dog, and Human Plasma at 25°C and 37°C

Compound	Temperature, °C	Half-Life Rat	Dog	Human
IV	25	1.3 min	19.5 min	1.1 min
	37	16 s	10.7 min	23 s
V	25	27 s[a]	20.3 min	24.0 min
	37	—[c]	8.3 min	6.8 min
VI	25	1.1 min[b]	28.6 min	9.3 min
	37	33 s[b]	14.1 min	1.7 min

[a] In 10% rat plasma diluted with isotonic Sörenson's phosphate buffer, pH 7.4. [b] In 0.5% rat plasma diluted with isotonic Sörenson's phosphate buffer, pH 7.4. [c] Not determined.

was as described by Stella (35). Apparent first-order kinetics over 2–4 half-lives for the appearance of phenytoin were observed in all instances. Quantitative recovery (or conversion) of all the prodrugs were observed.

The tissue homogenates studied were rat and dog liver and rat intestinal homogenates prepared in pH 7.4, isotonic Sörensen's phosphate buffer (one part tissue to four parts buffer). The tissue was homogenized for 10 min using a 100-mL glass homogenizer with a polytef pestle having radial serrations[9]. The homogenizer was mechanically driven using a 3/8-hp variable-speed drill. The homogenates were centrifuged[10] for 90 min at 100,000×*g* at 5°C. The temperature was maintained between 5–10°C during the preparation of the tissue homogenate to prevent inactivation of the enzymes.

Hydrolysis of II to Phenytoin—The rates of decomposition of II in buffer solutions at 25°C and 37°C were studied spectrophotometrically[15] by recording the decrease[11] in absorbance at 255 nm. A 10-cm thermostated quartz cuvette was filled (30 mL) with pre-equilibrated buffer solutions [0.1 M acetate buffer (pH 3.0–5.0), 0.1 M phosphate buffer (pH 5.0–7.05), ionic strength 0.5], and the reaction was initiated by injecting a 25-μL aliquot of a stock solution of II in acetonitrile to yield a final concentration of II of 8×10^{-5} M. All reactions followed apparent first-order kinetics as determined from plots of log $(A_t - A_\infty)$ *versus* time, where A_t and A_∞ are the absorbance readings at time t and at completion of the reaction, respectively. In all cases the final spectrum corresponded to that of phenytoin. In a few studies, the effects of varying buffer concentrations at constant pH were evaluated. Since no buffer catalysis was noted at any pH value, no further studies on the effect of buffers were attempted.

Anticonvulsant Activity and Toxicological Evaluation of IV–VII—Compounds IV–VII were evaluated using the anticonvulsant drug screening program (36) conducted by the National Institute of Neurological and Communicative Disorders and Stroke at the National Institutes of Health, Bethesda, Md. All four compounds underwent the primary evaluation (phase I); in a minimal number of animals, the anticonvulsant activity of each compound was evaluated by the maximal electroshock test (MES) and the subcutaneous pentylenetetrazol test (ScMET); the CNS toxicity of each compound was evaluated by the rotorod test using mice[12] (36). After this initial evaluation, any potentially useful derivatives may be subjected to further comprehensive screening for activity and toxicity. Specifically, this consists of the phase II and phase IV studies. The phase II study requires administering the drug intraperitoneally to mice and determining the time of peak effect (activity and toxicity) by the MES and the rotorod test. From this, the effective dose 50% (ED_{50}) and toxic dose 50% (TD_{50}) for the prodrugs could be determined. The phase IV study is similar to the phase II study except that the drug is administered orally.

For specific details of the procedures used in the screening, the reader is directed to Ref. 36. With the current compounds, IV–VII underwent the initial screening (Phase I), VI underwent phase II, while IV and VII underwent both phase II and phase IV evaluations.

RESULTS AND DISCUSSION

Compounds IV–X were synthesized by standard procedures as indicated in the *Experimental Section*. All compounds were found to conform to the proposed structures and showed only one spot on TLC. Compounds IX and X showed less than theoretical values for carbon and nitrogen analyses. Recrystallization attempts did not improve the results. The precursors IXa and Xa gave reasonable C, H, N analyses, so it appears that during the formation

of the sodium salts in methanol a certain amount of degradation took place and the final product may have been contaminated with small quantities of phenytoin.

The solubility of II in aqueous formaldehyde (1 M) and the solubilities of I and IV–VII in water at 25°C are shown in Table I. The increase in solubility of II over I of 8.5-fold may partly be attributed to the decreased intermolecular hydrogen bonding in the crystal lattice of II. This is reflected by the decrease in the melting point from 293°C for phenytoin (I) to 187–189°C for II. The reported solubilities of IV–VII are only approximate, as the prodrugs did begin to revert to phenytoin to some extent during the course of the solubility determinations, *i.e.*, the solid state is a mixture of prodrug and precipitated phenytoin. The methanesulfonate salts of IV, VI, and VII were prepared preferentially to the hydrochloride salts to prevent any common ion solubility problems on oral dosing with the prodrugs. Also, the hydrochloride salt of IV was very hygroscopic. The hydrochloride and methanesulfonate salts of V were prepared but were also found to be very hygroscopic; therefore, only the 2-naphthalenesulfonate salt was evaluated.

The solubilities of IX and X in water could not be determined because initial clear solutions rapidly began precipitating phenytoin acid, which was easily characterized on filtration by its melting behavior. This rapid precipitation of phenytoin from IX and X precluded the use of IX and X as parenteral forms of phenytoin and, therefore, IX and X were discarded as potentially useful prodrugs of I.

Compounds IV–VII were more soluble in water than phenytoin (Table I, last column). Based on this initial observation, IV, VI, and VII were considered possible candidates for parenteral and oral forms of phenytoin, while V was considered as a possible oral prodrug form of phenytoin.

For IV–VII to behave as true prodrugs of phenytoin, they must undergo cleavage to phenytoin under *in vivo* conditions. Therefore, the cleavage rates of IV–VII were studied in various rat, dog, and human tissues to give indications as to their *in vivo* behavior. The hydrolysis of esters IV–VI, 2×10^{-5} M, monitored by following the formation of phenytoin, exhibited pseudo-first-order kinetics in rat, dog, and human plasma. The half-lives are given in Table II. Esters IV–VI were quantitatively hydrolyzed to phenytoin in the plasma of all species studied. The hydrolysis of V and VI was determined in 10 and 0.5% rat plasma, respectively, because their cleavage rates were too fast to follow at higher plasma concentrations. Under comparable conditions in the absence of plasma, IV–VI hydrolyzed slowly to phenytoin; however, no attempts were made at this stage to unambiguously discriminate as to whether the acceleration in the cleavage rates in the presence of plasma was truly enzymatic in nature. Overall, the cleavage of the esters was slowest in dog plasma, consistent with findings of low overall esterase activity in various dog tissues relative to other animal species (37–39). The differences in the relative cleavage rates indicate that the spectrum of esterases present in plasma varies between the animal species.

An attempt was made to determine the hydrolysis of VII in the plasma of rats, dogs, and humans. No detectable cleavage was observed over a 3-h period. Since phosphatases are known to exist in red blood cells (40, 41), cleavage of

Table III—ED_{50} and TD_{50} of Phenytoin, IV, VI, and VII after Intraperitoneal and/or Oral Administration to Mice

Compound	Intraperitoneal Administration		Oral Administration

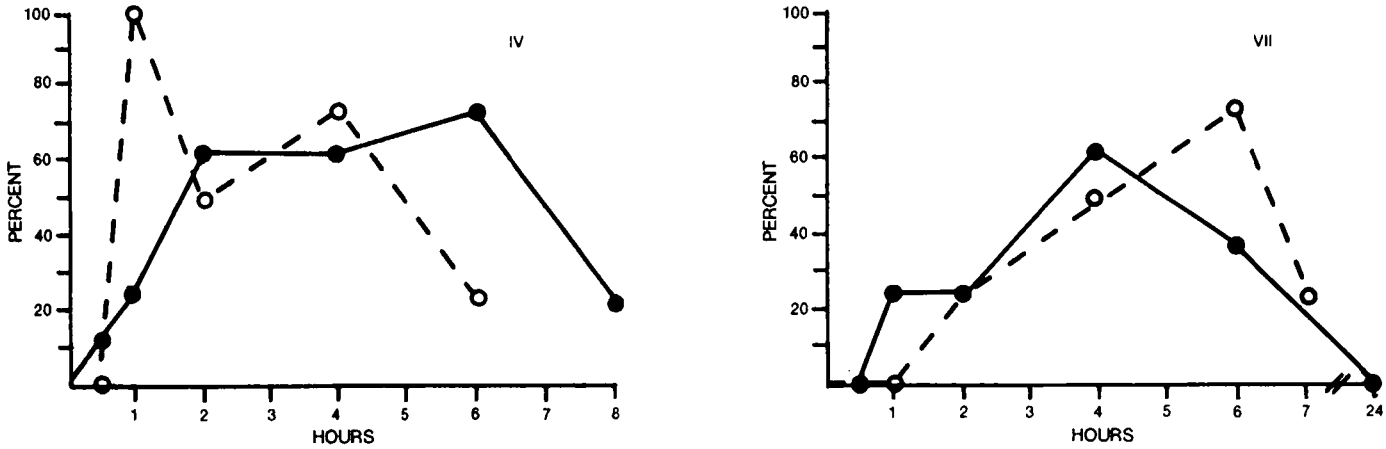

Figure 3—*Plots of the percent of the total population found toxic (●) by the rotorod test or the percent of the total population protected (○) against the MES test* versus *time after oral administration of IV and VII to mice.*

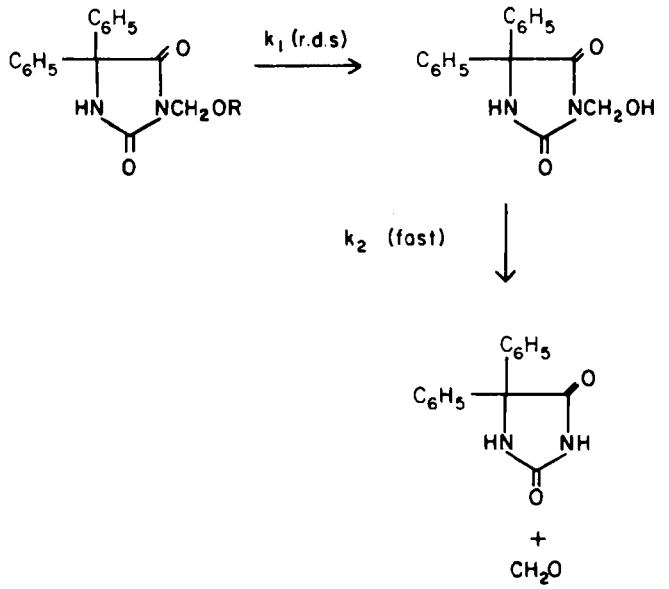
VII in rat, dog, and human whole blood was evaluated. Cleavage in rat whole blood was observed ($t_{1/2}$ = 2 h and 30 min at 25°C and 37°C, respectively). Slow cleavage in dog whole blood ($t_{1/2}$ > 24 h) was observed, but no significant cleavage was seen in human whole blood. These results tend to suggest that either the activity of the phosphatase enzymes was low in dog and human whole blood or that VII had poor accessibility to red blood cell phosphatases. The catalytic conversion of VII to phenytoin in the rat liver ($t_{1/2}$ < 30 s) and intestinal homogenates ($t_{1/2}$ < 30 s) and dog liver homogenate ($t_{1/2}$ = 57.5 min) were observed at 37°C.

It appears from these tissue studies that esters IV–VII would behave as prodrugs of phenytoin *in vivo* based on their reasonably facile cleavage *in vitro* in rat, dog, and human tissues. The only questionable candidate for quantitative conversion might be the phosphate ester VII, although there is adequate precedence in the literature for phosphate esters of various alcohols as prodrugs (42–50).

Mechanistically, the cleavage of esters IV–VII is expected to follow Scheme I, where k_1 represents the *in vitro* or *in vivo* cleavage of esters IV–X to II, which should then hydrolyze releasing formaldehyde[13]. The dehydroxymethylation of II to phenytoin was, therefore, studied in the pH range 4–7 at both 25°C and 37°C (μ = 0.5). As stated earlier, the hydrolysis followed pseudo-first-order kinetics, and no buffer catalysis was observed. Figure 1 shows the pH–rate profiles for the hydrolyses of II to phenytoin at 25°C and 37°C. The half-lives for the dehydroxymethylation extrapolated to pH 7.4 are also indicated in the figure. These data are quantitatively and qualitatively similar to those observed by Bundgaard and Johansen (5) who proposed a



Scheme I

mechanism involving an initial fast ionization of the hydroxyl group (p*Ka* > 12) followed by a slower nitrogen–carbon bond cleavage step producing phenytoin and formaldehyde. The very rapid breakdown of II to phenytoin ($t_{1/2}$ < 2 s at pH 7.4 and 37°C) precludes the accumulation of II when esters IV–VII are cleaved *in vitro* or *in vivo*.

Compounds IV–VII underwent pharmacological evaluation in the anticonvulsant drug screening program operated by National Institute of Neurological and Communicative Disorders and Stroke (36). In the phase I (initial screen) study all compounds showed good anticonvulsant (antiseizure) activity after intraperitoneal administration in the MES evaluation, but (as expected) showed no activity in the ScMET test[14]. The least active prodrug was V, which showed no protection in the MES test at 30 mg/kg; all the other compounds were active at 30 mg/kg. From the results of this initial screen, IV, VI, and VII were subjected to phase II analysis, where the anticonvulsant activity, MES, and rotorod toxicity were evaluated after intraperitoneal administration of the prodrugs in a larger number of animals. Compounds IV and VII were also evaluated in a phase IV study, which involves administering the prodrugs orally. Table III summarizes the ED_{50} and TD_{50} data for IV, VI, and VII after intraperitoneal and oral administrations to mice.

As can be seen in Table III, all the prodrugs had equivalent activity when compared with phenytoin, but all displayed slightly higher toxicity (lower TD_{50} values). This may be consistent with the more rapid absorption of phenytoin in the form of the prodrugs or an elevated intrinsic toxicity by the prodrugs exacerbated by their expected more rapid absorption relative to phenytoin, *i.e.*, the TD_{50} values probably should be compared with the TD_{50} of intravenous phenytoin. Figures 2 and 3 are plots of the percent of the total mice population studied found to be toxic by the rotorod test (toxicity–time profile) and the percent of the total population protected against the MES (activity–time profile) *versus* time after intraperitoneal and oral administrations, respectively. In Fig. 2 (intraperitoneal data) prodrugs VI and VII show an early peaking in the activity- and toxicity-time profile, suggesting rapid release of phenytoin, providing that the anticonvulsant activity is attributable to phenytoin. Ester IV, however, shows maximum activity at 2 h and the toxicity peaking at 0.5 h postdose. This tends to suggest that IV may be undergoing slow hydrolysis, compared with VI and VII, and that the early toxicity peaking may be due to the intact ester IV.

The lack of early toxicity in the oral study (Fig. 3) for IV compared with its activity suggests that after oral dosing, IV may be hydrolyzed during the absorption process. The delayed peaking of both toxicity and activity for VII after oral dosing (compared with the intraperitoneal data), suggests that the activity and toxicity of VII are probably due to phenytoin and that VII is only slowly absorbed from the intestine; alternatively, VII may be cleaved slowly in the GI tract, releasing phenytoin which was subsequently absorbed.

Based on the findings presented in this paper, IV, VI, and VII were evaluated further with respect to other physicochemical properties (51) and their pharmacokinetic behavior after oral and intravenous administration to dogs compared with phenytoin (52). Compound VII was also evaluated after intramuscular and intravenous administration to rats (53).

Phenytoin Prodrugs IV: Hydrolysis of Various 3-(Hydroxymethyl)phenytoin Esters

S. A. VARIA *, S. SCHULLER, and V. J. STELLA ˣ

Received December 22, 1982, from the *Department of Pharmaceutical Chemistry, The University of Kansas, Lawrence, KS 66045.* Accepted for publication July 6, 1983. *Present address: Squibb Institute for Medical Research, New Brunswick, NJ 08903.

Abstract □ The aqueous chemical stability of various bioreversible derivatives or prodrugs of phenytoin, a poorly water-soluble and erratically absorbed drug after both oral and intramuscular parenteral dosing, were evaluated. This study, together with assessments of other physicochemical properties including cleavage in the presence of various animal tissues and anticonvulsant activity in mice, helped identify a number of promising candidate prodrugs. Various amino groups containing acyl esters of 3-(hydroxymethyl)phenytoin [3-(hydroxymethyl)-5,5-diphenylhydantoin] were identified as potential orally and perhaps parenterally useful prodrugs, while the disodium phosphate ester of 3-(hydroxymethyl)phenytoin appears to be ideally suited as a parenteral form of phenytoin.

Keyphrases □ Prodrugs—water-soluble, phenytoin stability, pH profiles □ Phenytoin—water-soluble prodrugs, stability, pH profiles □ Anticonvulsants—phenytoin, water-soluble prodrugs, stability, pH profiles

The aqueous chemical stabilities of various selected prodrugs and model compounds of phenytoin (I), *i.e.*, various esters (III–VII) of 3-(hydroxymethyl)phenytoin [II, 3-(hydroxymethyl)-5,5-diphenylhydantoin], are presented in this paper. The synthesis and a preliminary evaluation (including aqueous solubility determination, cleavage rates in the presence of various animal tissues, the chemical degradation of II to I under simulated physiological conditions, and, in some cases, the anticonvulsant activity in mice) of II–VII and other potential prodrugs of phenytoin were presented in the previous paper (1).

VII: R = $PO_3^{2-}Na_2^+$

The overall goal of this series of studies was to identify orally bioavailable phenytoin prodrugs with delivery characteristics superior to phenytoin itself, and parenterally useful prodrugs of phenytoin with good aqueous solubility and stability at a physiologically acceptable pH, a goal that was only partially achieved in a previous study (2).

Since any prodrug, to be useful as either an oral or parenteral form of phenytoin, must display adequate chemical stability, a study of the aqueous stability pH profiles for III–VII was undertaken. Because phenytoin has poor aqueous solubility (1, 3–6), the stability-limiting factor for a potential parenteral prodrug form of phenytoin was not considered to be maintenance of some percentage of the labeled amount of prodrug, but rather, the time that it takes for the poorly water-soluble phenytoin to begin precipitating from an aqueous solution of the prodrug on chemical degradation (2). This question will also be addressed briefly in this paper.

EXPERIMENTAL SECTION

Materials—Unless otherwise stated, all reagents used were analytical grade. Phenytoin was obtained from a commercial source[1]; the prodrugs were synthesized previously and were analytically pure (1). The water used in the stability studies was deionized (≤1-mho conductance) and charcoal-filtered prior to use or freshly distilled from an all-glass still. All buffers were prepared in carbonate-free (freshly boiled) deoxygenated (nitrogen-purge) water.

Kinetic Studies—Stock solutions of III in dry acetonitrile, IV–VII in water, and V in methanol–water were prepared immediately before use. An appropriate aliquot of the stock solution was mixed with the aqueous buffers to initiate kinetic runs. The final concentration of methanol in the case of V was <0.2% v/v and that of acetonitrile for III was <0.01% v/v.

All kinetic studies were carried out at a constant temperature maintained by a circulating-water bath[2]. The kinetics of conversion of IV–VI in the pH range of 3–5 and VII at all pH values were studied in aqueous buffers by the

initial rate method (7) since the half-lives of the esters under these conditions were long. The prodrugs in their stock solutions were mixed with the temperature-equilibrated buffer solution, and phenytoin production was followed until ~5% of the reaction was complete. All other kinetic studies were followed to completion by monitoring the appearance of phenytoin.

The chemical stability of III–VI was assessed in aqueous buffer solutions at 25 ± 0.1°C, and VII was studied at 70 ± 0.1°C (and at 50°C and 90°C at pH 7.4). A list of the buffers used at the various pH values is shown in Table I. The ionic strength was adjusted to 0.5 by the addition of potassium chloride. The stability studies were carried out at different buffer concentrations to allow for the determination of the rate constant at zero buffer concentration. Unless otherwise specified, all rate constants used in the pH–rate profiles were obtained by extrapolation to zero buffer concentration. The hydrolysis of III was monitored by UV spectroscopy[3], and the stability of VI–VII was studied by following the formation of phenytoin as a function of time using GC[4] as described previously by Stella (8).

Specifically, the rate of hydrolysis of III was studied at 25°C by following the decrease in absorbance at 256 nm. The initial concentration of the ester was 2×10^{-5} M. The reaction followed pseudo-first-order kinetics, and apparent first-order rate constants were determined from plots of log $(A_t - A_\infty)$ *versus* time, where A_t and A_∞ are the absorbance readings at time t and at the completion of the reaction, respectively. In all cases, the final spectrum corresponded to that of phenytoin. Conversion to phenytoin was also confirmed by TLC and GC.

The stability of IV–VII was studied by observing the appearance of phenytoin as a function of time using GC analysis (1, 8). In the case of esters possessing an amino group in the ester moiety (IV–VI), 100-μL samples were removed from the temperature-equilibrated reaction vessels at regular intervals and added to 100 μL of 10% metaphosphoric acid solution. The metaphosphoric acid helped quench the reaction due to the increased stability of these compounds under acidic conditions and also protonated the amino group of the ester, which prevented its extraction into toluene, the next step required for the work-up for the GC analysis (8).

For conversion of VII to phenytoin at elevated temperatures in aqueous buffer solutions, aliquots (100 μL) were removed from the reaction vessel at various intervals and transferred to tubes immersed in dry ice in order to quench the reaction. The samples were then assayed by the same technique used for following the hydrolysis of VII in tissue samples (1).

The conversion of the esters to phenytoin followed first-order kinetics. Apparent first-order rate constants for the production of phenytoin from the various prodrugs were determined from plots of log $(D_\infty - D_t)$ *versus* time where D_t and D_∞ are the concentrations of phenytoin at time t and infinity, respectively. The apparent first-order rate constants for the decompositions of IV–VI in the pH range of 3–5 and VII were determined by the initial rate method, in which <5% of the reaction was followed (7).

Precipitation Time Study—This study was carried out to determine the time for precipitation of phenytoin from aqueous solutions of IV and VII. Various aqueous solutions of IV, *i.e.*, 1, 10, and 100 mg/mL, were prepared and filtered, and the pH values of the solutions were measured. Visual observations and spectral determinations of the precipitation times were recorded by the following technique. Three-milliliter aliquots of the solutions were placed in cylindrical 1-cm quartz spectrophotometer cells. These cells were then placed in a constant-temperature shaking water bath[5] and maintained at 25 ± 0.1°C. The absorbance of these solutions as a function of time was followed at 500 nm, a wavelength at which there was no absorbance due to the compounds, and the light absorption due to precipitate formation could be easily assessed. Plots of absorbance *versus* time were made and the precipitation time determined when a significant break occurred in the plot.

To determine the time for precipitation of phenytoin from a 61-mg/mL aqueous filtered solution of VII, visual observations were made. The solution was stored in sealed vials, and these were kept at ambient temperature (23-26°C). The vials were not subjected to any agitation during storage. The vials were inspected at regular intervals for the presence of any turbidity, in order to get an estimate of the time for phenytoin to precipitate from solution.

RESULTS AND DISCUSSION

Esters III-VII would be expected to revert to phenytoin in aqueous solution according to Scheme I, with the cleavage of the ester being the rate-determining step. The pH-rate profile for the cleavage of II to I was presented in the previous paper in this series (1), as well as by Bundgaard and Johansen (5). The log k_{obs} *versus* pH profile is reproduced in Fig. 1 (pH profiles at 25°C for II and IV-VI) to show that for all the esters at all the pH values studied, k_2 was indeed fast relative to k_1.

The observed pseudo-first-order rate constants (k_{obs}) for the hydrolysis of III to phenytoin at alkaline pH (μ = 0.5, 25°C) is given in Table II, and a plot of log k_{obs} *versus* pH was linear with a slope of 0.92, indicating a hydroxide ion-catalyzed reaction. The observed pseudo-first-order constant follows the form of:

$$k_{obs} = k_{OH}a_{OH} \qquad \text{(Eq. 1)}$$

where a_{OH} is the hydroxide ion activity (calculated from k_w/a_H) and k_{OH} is the second-order hydroxide ion-catalyzed rate constant for the hydrolysis of III. A value of 50.8 M^{-1} min^{-1} was calculated for k_{OH} at 25°C, which was consistent with similar findings by Bundgaard and Johansen (5) for the hydrolysis of III at 37°C.

The purpose of studying the hydrolysis of III was twofold: (*a*) to observe the hydrolysis rate of III as a standard for the accelerative effect of amino groups in the acyl function, *e.g.*, how much faster does IV cleave relative to III, and (*b*) the determination of k_{OH} for III allows an estimate of the pK_a' of the hydroxyl group of II. For example, Bruice *et al.* (9) have shown that a linear relationship exists between the logarithm of the second-order rate constants for the alkaline hydrolysis of various acetyl esters and the pK_a' for the corresponding leaving-group alcohol. This relationship is given by:

$$\log k_{OH} = -0.253 \cdot pK_a' + 4.9 \qquad \text{(Eq. 2)}$$

Substituting the k_{OH} value for III into this equation gives a pK_a' = 12.6, a

[a] μ = 0.5, 70°C. [b] No buffer catalysis.

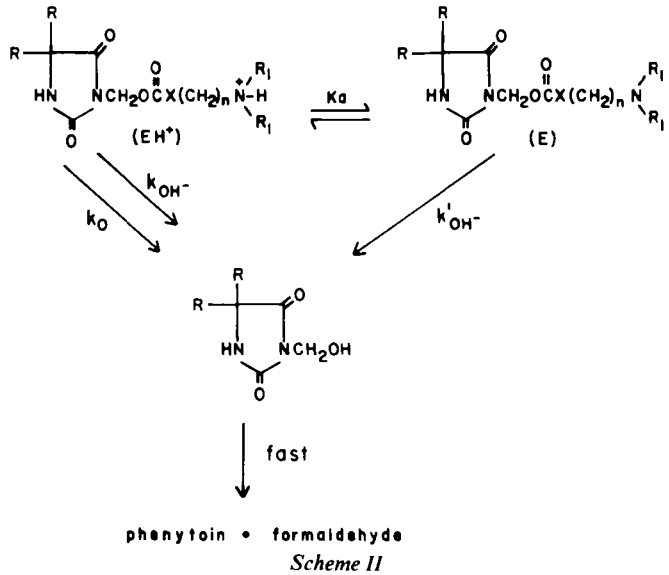
value comparable to the apparent pK_a' of 13.1 at 37°C previously reported for *N*-(hydroxymethyl)benzamide (4).

In aqueous solution, IV–VI hydrolyzed to yield phenytoin quantitatively. The effect of pH and buffer concentration on the apparent first-order rate constants for the hydrolyses of IV–VI are shown in Tables III–V, respectively. The buffer-free apparent first-order rate constants (k_{obs}) at various pH values were obtained from intercepts of linear plots of the apparent first-order rate constants against the total buffer concentration (see Fig. 2). The slopes of these plots are the catalytic constants for buffer catalysis, k_{cat}. Figure 1 is a plot of the logarithm of k_{obs} *versus* pH for the hydrolysis of II and IV–VI to phenytoin at 25°C, μ = 0.5.

The pH–rate profiles for IV–VI are consistent with Scheme II, where R_1 = —CH_3 or —C_2H_5, n = 0–2, x = —CH_2— or —O— and can be adequately described by[6]:

$$k_{obs} = \frac{k_0 a_H}{K_a + a_H} + \frac{k_{OH} a_H}{K_a + a_H}[OH^-] + \frac{k'_{OH} K_a}{K_a + a_H}[OH^-] \qquad \text{(Eq. 3)}$$

where k_0 is the pseudo-first-order rate constant for the pH-independent hydrolysis of the protonated form of the ester (pH < 4), and k_{OH} and k'_{OH} are the second-order rate constants for the apparent attack of the hydroxide ion on the protonated and unprotonated form of the esters, respectively. K_a is the dissociation constant of the protonated amino group. Equation 3 predicts a break in the pH profile at around the pK_a if k_{OH} is significantly different from k'_{OH} (as expected). Breaks can be seen at pH values close to the expected pK_a' values of the amino group for IV and VI. Ester V did not show a break up to pH 9.0, suggesting its pK_a may be >9.0. The lines drawn for the pH–rate profiles for IV–VI in Fig. 1 were constructed from Eq. 3 and the appropriate rate constants given in Table VI. These pH profiles were similar to the pH–rate profile of phenyl-3-dimethylaminopropionate reported by Kirby and Lloyd (10), as well as other amino side-chain esters (11–15).



Scheme II

[6] It is recognized in this and subsequent cases that kinetically equivalent terms may be equally correct and indistinguishable.

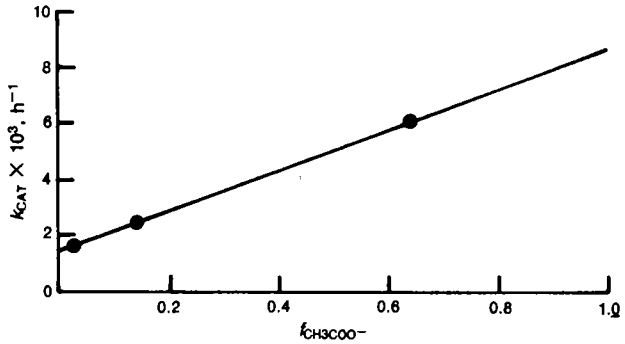


Figure 5—*Dependence of the catalytic constant, k_{cat}, on the fraction of acetate ion, $f_{CH_3COO^-}$, for the hydrolysis of V.*

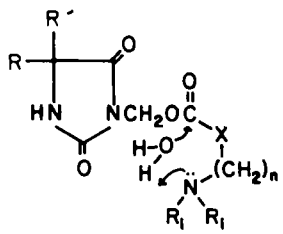
Based on the pH profiles alone, it is difficult to assign mechanisms for these reactions. For example, the reaction term defined by k_{OH} in Scheme II and Eq. 3 is kinetically equivalent (mathematically equivalent) to the water-catalyzed hydrolysis of the unprotonated ester, perhaps facilitated intramolecularly through a general-base mechanism by the unprotonated tertiary amino group; alternatively, the possibility of an intramolecular nucleophilic attack by the tertiary amine on the acyl function displacing the alcohol has to be considered. A clue as to the possible mechanisms can be seen from an analysis of the buffer catalysis. The hydrolysis of IV exhibited buffer catalysis in the presence of acetate and phosphate buffers (see Figs. 2 and 3). Plots of k_{cat} *versus* the fraction of acetate ion $f_{CH_3COO^-}$ for each pH (Fig. 4) shows that the only catalytic species is the acetate ion. Similarly, reference to Fig. 3 shows that HPO_4^{2-} is a better catalyst than $H_2PO_4^-$. All these results are consistent with a general-base catalysis mechanism for these buffers, where the buffers are facilitating the attack by a water molecule on the acyl function or stabilizing a transition state.

In the case of V and VI, little or no buffer catalysis was observed, except in the case of acetate buffer for V. A plot of k_{cat} *versus* $f_{CH_3COO^-}$ (Fig. 5) for the cleavage of V again showed that general-base catalysis by the acetate anion was the primary catalyst; however, $k_{CH_3COO^-}$ for IV is 1.5×10^{-1} $M^{-1}h^{-1}$, while $k_{CH_3COO^-}$ for V is 8.5×10^{-3} $M^{-1}h^{-1}$, *i.e.*, acetate anion is a 17.6-fold better catalyst of IV hydrolysis compared with V. No significant buffer catalysis was seen for the hydrolysis of VI. It would appear from these results that the following mechanisms for the hydrolysis of IV–VI are operative:

1. At pH values <4, the primary reaction, k_0, involves water attack on the protonated ester, facilitated by general bases such as acetate and phosphate.

2. At pH values >5 but <pK_a, the primary reaction (defined mathematically in Eq. 3 as k_{OH}) is probably hydroxide ion attack on the protonated amine or attack of water on the unprotonated amine. The reason it is difficult to distinguish between these two mechanisms is that if the first mechanism is operative, no catalysis by buffers should be seen provided the rate-determining step is the actual attack on the acyl function by the hydroxide ion. This is usually seen with esters that have good leaving groups, *e.g.*, esters of activated phenols. Compound II should show behavior intermediate between a phenol and an aliphatic alcohol (a conclusion based on a pK_a of 12.6). Water



Scheme III

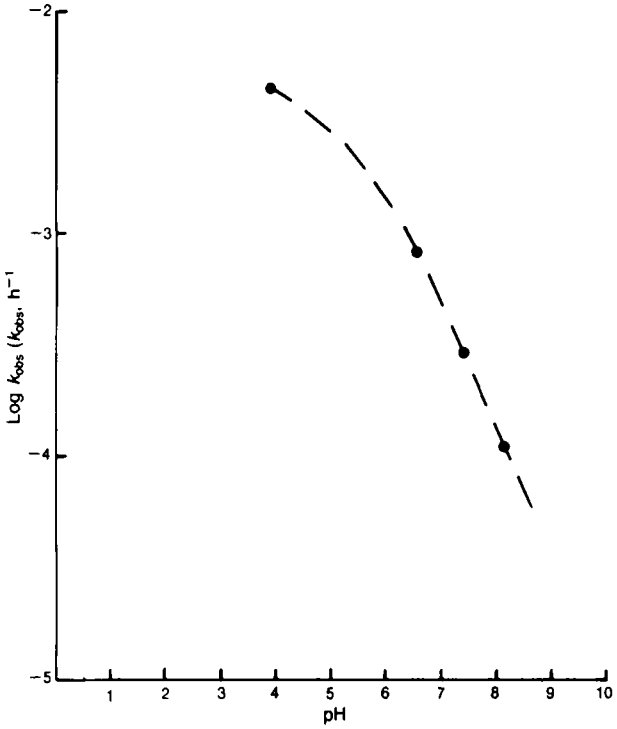


Figure 6—*pH-rate profile for the hydrolysis of VII at 70°C, μ = 0.5.*

attack on the unprotonated ester should be subject to general-base catalysis, but as seen in Scheme III intramolecular general-base catalysis by the dialkylamino group may be operative.

Such a mechanism is unfavorable for IV because a *five*-membered ring including a hydrogen bond would be required. Hydrogen-bonded systems favor a linear hydrogen bond (16) which, therefore, is not favored in a five-membered ring. Compounds V and VI form six- and seven-membered rings, respectively. Such cyclic structures are favorable for hydrogen-bond formation (16, 17). This type of intramolecular general-base catalysis has been shown by Kirby and Lloyd (10) to occur in the hydrolysis of other 3-dimethylaminopropionates. To fully differentiate between the two mechanisms, techniques such as proton inventory solvent isotope effects will have to be employed. Alternatively, ionic strength and solvent polarity changes could be used. However, interpretation of results obtained from such studies are complicated by changes in pK_a values, *etc.*

3. More than likely at pH > pK_a (*e.g.*, pH > 9 for IV), the major reaction is probably hydroxide attack on the unprotonated amine. Consistent with this is the lack of buffer catalysis by carbonate or borate[7] in the hydrolysis of IV.

Phosphate esters such as VII are of interest pharmaceutically because their polar nature provides a means of making water-soluble derivatives of sparingly soluble compounds such as those containing a hydroxyl group. In addition phosphate esters have been found to be chemically stable at neutral to slightly alkaline pH (18–22). The hydrolysis of such esters follow pseudo-first-order kinetics; it is assumed that VII would behave similarly.

Table VII contains the data on the rates of hydrolysis of VII to phenytoin at 70°C and various pH values and buffer concentrations, while Fig. 6 shows the pH–rate profile for the hydrolysis of VII at 70°C.

To determine the apparent energy of activation and the half-life for the hydrolysis of VII at 25°C and pH 7.4, rate constants were determined at various temperatures. Figure 7 shows the Arrhenius plot for the hydrolysis of VII, obtained by plotting the apparent first-order rate constants, determined at pH 7.4 and in 0.04 M phosphate buffer, *versus* the reciprocal of the absolute temperatures. From the slope of the Arrhenius plot, the apparent energy of activation and the half-life for the hydrolysis of VII at 25°C were calculated.

The data on the hydrolysis of VII suggests that it is catalyzed by acetate and phosphate buffers at pH 3.9 and 6.5. The pH–rate profile for VII is similar to the pH–rate profiles reported for the hydrolysis of various other phosphate monoesters (18–22). The rate of hydrolysis increases with decreasing pH suggesting that the monoanionic form of VII is the reactive species. The concentration of the monoanion would be at a maximum at pH ~4.0, as the

[7] This was also not unexpected, as borate is a poor general-base catalyst.

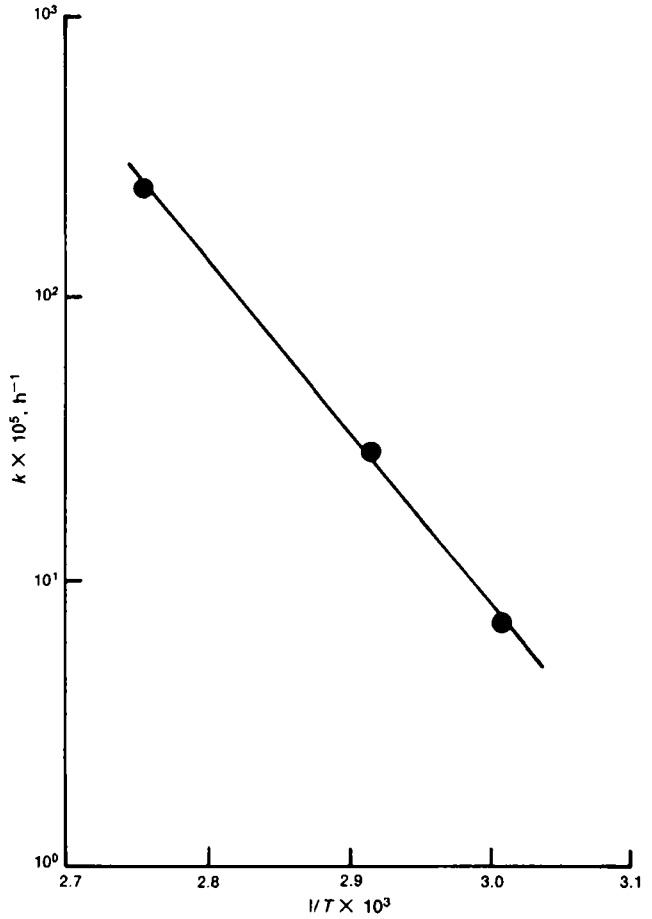

Figure 7—*Arrhenius plot for the hydrolysis of VII to phenytoin in 0.04 M phosphate buffer, pH 7.4, μ = 0.5.*

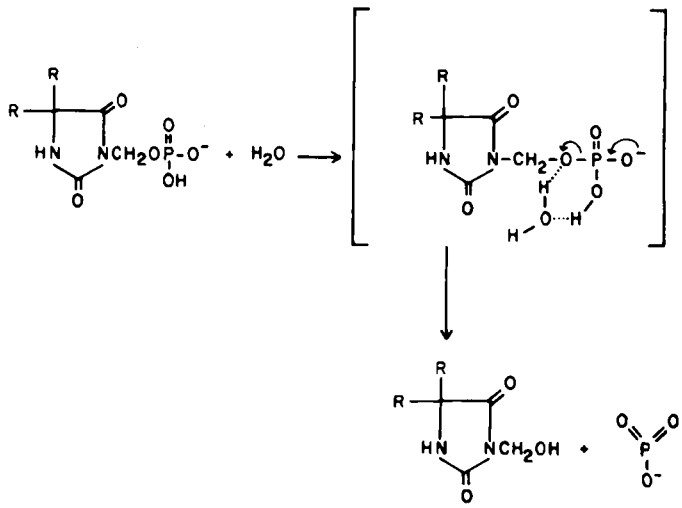
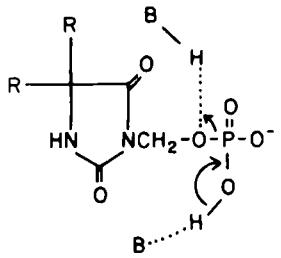
second pK_a of most phosphate esters is 6.0–6.5 (18–21) at this ionic strength. The pK_{a_2} of VII in water at 25°C was determined to be 6.2 by titration with hydrochloric acid. Thus, the pH–rate profile for VII began to plateau at pH 4.0; however, the rate of degradation of VII below pH 4.0 was not studied. The hydrolysis of other phosphate esters at pH <4.0 has been shown to increase (20) or decrease (23, 24) depending on the reactivity of the neutral species. The neutral species may undergo degradation, with carbon–oxygen bond cleavage. The mechanism for the hydrolysis of VII in the pH range 3.9–8.1 is probably similar to that proposed for the hydrolysis of other phosphate monoesters (20–22). The probable reaction mechanism is shown in Scheme IV. The mechanism involves the negative charge on the phosphate oxygen acting as the driving force for the reaction. Proton transfer to the alkoxide group occurs by formation of a six-membered ring through hydrogen



Scheme IV



Scheme V

bonding with a single water molecule. This would be consistent with the dianion being less susceptible to hydrolysis, as observed in the pH-rate profile.

Another concerted mechanism can be proposed to explain the buffer catalysis observed at pH 3.9 and 6.5 (Scheme V). The mechanism involves the buffer acting as both a proton donor and a proton acceptor.

The apparent energy of activation of 20.5 kcal·mol^{-1} obtained for the hydrolysis of VII was consistent with the activation energies reported for other phosphate esters (18). Ester VII had a long half-life of ~6800 d at 25°C and pH 7.4, which is characteristic of most phosphate esters.

Based on the pH profiles (Figs. 1 and 7) and the data presented in the rest of this study, esters IV–VII hydrolyze to phenytoin *via* pseudo-first-order kinetics at fixed pH values with no accumulation of the decomposition intermediate, II. The amino acyl esters exhibit maximum stability in the pH range 3–4 (Table VIII), which is within the physiologically acceptable range for parenteral dosage forms. The superior stability of VII over IV–VI makes it an attractive prodrug candidate for parenteral administration provided it is nontoxic and rapidly and quantitatively reverts to phenytoin *in vivo*.

Table VIII points out the $t_{90\%}$ (time for 90% of the ester remaining at the indicated pH values), perhaps suggesting that this may be the determining factor controlling the shelf life of a reconstituted dosage form of these prodrugs if they were to be formulated as reconstituted parenteral dosage forms (sterile powder or freeze-dried powder). However, as pointed out earlier, the $t_{90\%}$ will probably not be the stability-limiting factor for these products, since hydrolysis of the esters produces the sparingly soluble parent drug, phenytoin. For example, if a 50-mg/mL solution (phenytoin equivalents) of IV is prepared, then theoretically, when 0.02 mg/mL of phenytoin is produced, phenytoin should begin precipitating from solution; *i.e.*, the reaction would only have to proceed to the extent of 0.04% before problems could occur. For this reason, and because IV and VII (25, 26) were considered to be the two most likely candidates as oral/parenteral and parenteral prodrugs, respectively, a limited study[8] on the theoretical and observed precipitation times for phenytoin was undertaken

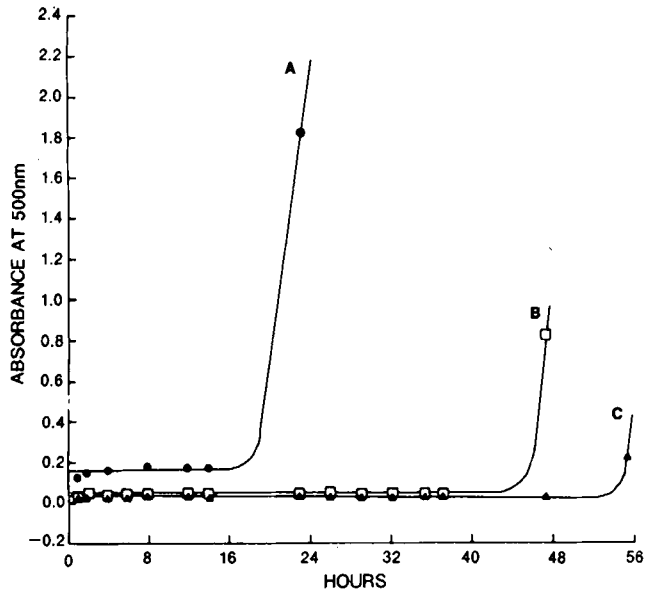


Figure 8—*Plot of change in the absorbance at 500 nm of aqueous solutions of IV due to precipitation of phenytoin. Solutions are 100 (A), 10 (B), and 1 mg/mL (C) of IV.*

[8] A more comprehensive study of this problem of precipitation is currently underway in our laboratory. Results will be formally presented in a later paper.

Table VIII—Time for 10% Hydrolysis ($t_{90\%}$) of IV–VI at pH Values of Maximum Stability and of VII at pH 7.4 [a]

Compound	pH	$t_{90\%}$, h
IV	3.2	17.4
V	3.2	138.1
VI	4.0	107.1
VII	7.4	24,769.0 (2.8 years)

[a] μ = 0.5, 25°C.

Table IX—Theoretical ($t_{ppt,calc}$) and Experimental ($t_{ppt,obs}$) Precipitation Times for the Formation of Phenytoin from Aqueous Solutions of IV and VII, Determined at 25°C

Compound	Initial Conc. of Ester (Phenytoin equivalent), mg/mL	pH of Solution	$t_{ppt,calc}$	$t_{ppt,obs}$
IV	1 (0.54)	3.86	6 h[a]	~55 h
IV	10 (5.44)	2.85	0.6 h[a]	~43 h
IV	100 (54.43)	1.94	0.06 h[a]	~19 h
VII	61.3 (38.1)	8.5	13.7 d[b]	>114 d[c]

[a] The half-life for the degradation of IV to phenytoin was taken as 115.0 h at pH 3.2 and 25°C. [b] The apparent first-order rate constant for the degradation of VII to phenytoin was taken as 68.9 × 10^{-8} h^{-1} at pH 8.5 and 25°C. [c] No precipitation was observed at the end of the 114-d period.

using aqueous solutions of 1–100 mg/mL of IV at 25 ± 0.1°C and a 61.3-mg/mL aqueous solution of VII at pH ~8.5 and ambient room temperature.

In the case of IV, 1-, 10-, and 100-mg/mL solutions of IV were prepared and the presence of a precipitate was detected by following absorbance changes at 500 nm (Fig. 8). The break in the absorbance *versus* time plots was due to the light absorption by the solid phenytoin when it began to precipitate from solution. In the case of VII, only periodic visual inspection over a 114-d period was attempted. Table IX summarizes the calculated and observed times for phenytoin to precipitate from aqueous solutions of esters IV and VII. The calculated times were based on the assumption that the rate constant for hydrolysis was independent of initial concentration and that precipitation would occur when a 7.9 × 10^{-5} M (20-μg/mL) solution of phenytoin was produced at 25°C. It was also assumed that the prodrug solutions contained no phenytoin as an initial impurity.

The results shown in Table IX show no correlation between the calculated (theoretical) and observed precipitation times. Possible explanations for this behavior have appeared in the literature (2). In an extension of the results presented in Table IX, we have tentatively shown[8] that the following processes contribute to this lack of correlation.

1. In the case of IV, associated solutions (probably micellar) occur at ~3–5 mg/mL of IV, resulting in a slowing of the rate of phenytoin production at concentrations >3–5 mg/mL than would be predicted by the dilute solution kinetics. This contributes approximately a factor of two to the discrepancy between $t_{ppt,calc}$ and $t_{ppt,obs}$.

2. Phenytoin is significantly solubilized by IV at concentrations >3–5 mg/mL, *e.g.*, a 50-mg/mL solution of IV has been shown to dissolve ~1.6 mg/mL of phenytoin[8], an increase in aqueous solubility of phenytoin of ~80-fold over water alone. This increased solubility by the prodrug, along with the processes mentioned above, can account for all but about a factor of three in the discrepancy between the theoretical and observed precipitation times. A similar study with VII showed that in the presence of 74 mg/mL of VII, the solubility of phenytoin was approximately double that in water[8].

3. Therefore, it appears from our preliminary results that there may also be a contribution from supersaturation (a factor of two to five).

Based on the data presented in this paper and the solubility data on IV–VII presented in the previous paper (1), it seems that all the compounds should be sufficiently stable for oral usage, especially in solid dosage forms; *i.e.*, the compounds do not appear to be excessively unstable in aqueous solution. It also seems likely that any injectable form of IV, VI[9], and VII would have to be of the reconstitutable type, although there may be a chance that VII maintained at pH ~9–9.5 would be sufficiently stable as a constituted injectable[10]. Based on stability considerations alone, the best candidate for an injectable form of phenytoin appears to be the phosphate ester, VII.

[9] Compound VI will be rejected later due to toxicity concerns. Compound V had already been rejected as a parenteral form due to its low aqueous solubility.

[10] Such studies on VII are ongoing.

Phenytoin Prodrugs V: *In Vivo* Evaluation of Some Water-Soluble Phenytoin Prodrugs in Dogs

S. A. VARIA * and V. J. STELLA ˣ

Received December 22, 1982, from the *Department of Pharmaceutical Chemistry, School of Pharmacy, The University of Kansas, Lawrence, KS 66045.* Accepted for publication September 6, 1983. *Present address: Squibb Institute for Medical Research, New Brunswick, NJ 08903.

Abstract □ Phenytoin bioavailability was evaluated in beagle dogs after oral and intravenous administrations of sodium phenytoin and two amino acyl esters and a disodium phosphate ester of 3-(hydroxymethyl)phenytoin (three prodrugs of phenytoin). Phenytoin displayed nonlinear pharmacokinetics in the dogs, complicating the determination of the absolute bioavailability of phenytoin from sodium phenytoin and the prodrugs. All three prodrugs essentially released phenytoin after intravenous administration in a quantitative manner, and all gave plasma levels of phenytoin after oral administration greater than those found after administration of sodium phenytoin. Based on the behavior in dogs and the earlier determination of the physicochemical properties of the prodrugs, it was concluded that one of the amino acyl esters, 3-(hydroxymethyl)-5,5-diphenylhydantoin *N,N*-dimethylglycine ester methanesulfonate, would be the most useful prodrug for oral administration, while 3-(hydroxymethyl)-5,5-diphenylhydantoin disodium phosphate ester would be the most useful for parenteral administration.

Keyphrases □ Prodrugs—phenytoin, bioavailability, dogs □ Phenytoin—hydroxymethyl esters, prodrugs, bioavailability, dogs □ Bioavailability—phenytoin prodrugs, dogs

Phenytoin (I), because of its weakly acid nature (1–4) and poor aqueous solubility (3–5), shows erratic absorption patterns after oral administration of either the sodium salt (Ia) or the free acid in both humans (6–19) and dogs (20, 21). Sodium phenytoin (Ia) in the parenteral dosage form is hazardous if rapidly injected intravenously (22, 23), and the free acid appears to precipitate at intramuscular injection sites (24–29), leading to prolonged and marginal phenytoin release.

In the previous papers in this series (5, 30), a number of water-soluble prodrugs of phenytoin were evaluated with respect to their physicochemical properties (*e.g.*, solubility and stability), their cleavage to phenytoin in animal tissues, and their anticonvulsant activity in mice. Based on those studies, three of the prodrugs, 3-(hydroxymethyl)-5,5-diphenylhydantoin *N,N*-dimethylglycine ester methanesulfonate (II)[1], 3-(hydroxymethyl)-5,5-diphenylhydantoin *N,N*-dimethylaminoethyl carbonate methanesulfonate (III)[1], and 3-(hydroxymethyl)-5,5-diphenylhydantoin disodium phosphate

ester (IV)[1] were chosen for further evaluation in the beagle dog.

Compounds II and III were evaluated as possible oral-delivery forms of phenytoin because of their aqueous solubility (~150 mg/mL), pK_a values (6.60 and 8.20, respectively), and because they are readily cleaved enzymatically to phenytoin. However, the chemical stability of II and III indicated that there could be some difficulty in preparing suitably stable injectable dosage forms (30). Ester IV was chosen primarily as a parenteral candidate but was also evaluated for oral delivery of phenytoin, since recent evidence has suggested that dexamethasone phosphate quantitatively releases dexamethasone after oral dosing (31). Beagle dogs were chosen for this study because of their ease of handling and because phenytoin has been shown to be marginally bioavailable in dogs (20, 21), probably because of their short GI transit times (20). Dogs, therefore, may be a good model for pediatric patients, where phenytoin absorption has been shown to be particularly erratic (10, 19).

EXPERIMENTAL SECTION

Prodrugs II–IV were analytically pure and were prepared as previously described (5). Phenytoin and sodium phenytoin were obtained from a commercial source[2].

Gas Chromatographic Analysis of Phenytoin—Venous whole blood obtained from dogs was immediately centrifuged for 15–20 min at 1000×*g* and plasma was collected. In the case of II and III, a 100-μL plasma sample was immediately treated with 100 μL of a 10% metaphosphoric acid solution and assayed for phenytoin by GC according to the method of Stella (32). A second plasma sample was allowed to stand at 37°C for >1–2 h and then was assayed as described above. Any II or III in dog plasma is cleaved to phenytoin during this period (5). This procedure allowed for the analysis of phenytoin (first sample) and phenytoin plus prodrug (second sample), whereby prodrug concentration could be determined by difference. None of the samples (after both oral and parenteral dosings), contained any significant levels of II or III.

The procedure for IV was modified. The first plasma sample was not quenched with metaphosphoric acid, but was extracted into toluene, the first step in preparation for the GC assay. The second plasma sample was diluted with 100 μL of 10% amylase[3], maintained at 37°C overnight, and then assayed for phenytoin as described above. Only in the case of the 5–15-min samples were any levels of IV detectable after intravenous administration of IV; IV could not be detected after oral dosing.

Oral and Intravenous Evaluation Studies in Dogs—Four adult female beagle dogs, ranging in weight from 8 to 13 kg, were used for two crossover studies employing a Latin-square design. The intravenous and oral studies were carried out according to Table I. Each dog received 15-mg/kg (phenytoin equivalent) doses of sodium phenytoin, II, III, and IV orally and intravenously. The dogs were fasted overnight prior to drug administration, but were allowed water *ad libitum*. The dogs were rested for at least 1 week between studies.

For the intravenous study, fresh aqueous solutions of II, III, and IV were used. Phenytoin was administered intravenously as the sodium salt in a solvent system of propylene glycol–alcohol–water (4:1:5). The pH of this solution was adjusted to ~11.5–12.0 with sodium hydroxide. The injection volumes ranged from 2–3.5 mL and were administered into the leg vein over a period of 1–2 min.

In the oral study the compounds were administered in hard gelatin capsules without any excipients. After administering the compound, sufficient water to guarantee that the capsule had been swallowed (100–200 mL) was administered. The dogs were then returned to their respective cages.

After administration of the drug, serial venous blood samples were taken at appropriate times from the neck vein. The samples were withdrawn into 2-ml containers[4] containing 3 mg of EDTA. The blood samples were immediately centrifuged, and the separated plasma samples were analyzed for phenytoin and prodrug as described earlier.

Dose-Dependent Pharmacokinetics in Dogs—The evaluation of plasma concentration time curves of phenytoin, after administration of sodium phenytoin and the prodrugs of phenytoin at 15 mg/kg (phenytoin equivalents), suggested that phenytoin at a dose of 15 mg/kg displayed nonlinear pharmacokinetics. To confirm this, dogs 20 and 21, used in the 15-mg/kg study, were each administered 10-mg/kg and 6.6- or 5.5-mg/kg (phenytoin equivalent) doses of sodium phenytoin intravenously; plasma samples were assayed for phenytoin as described earlier.

RESULTS AND DISCUSSION

Figure 1 is a representative plot of the plasma phenytoin concentration *versus* time obtained after oral administrations of 15-mg/kg (phenytoin equivalent) doses of sodium phenytoin (Ia) and II–IV to dog 20. Dog 22 consistently rejected III, and hence, data for III for that particular dog could not be obtained. The areas under the plasma phenytoin concentration *versus* time curves (AUC_0^∞) after oral administration of Ia and II–IV were evaluated by the trapezoidal method (33) (Table II). Statistical analysis by one-way ANOVA showed that there was significant difference ($p < 0.05$) between the mean AUC_0^∞ values obtained after oral administration of the prodrugs and the mean AUC_0^∞ obtained after oral administration of sodium phenytoin (Ia). However, there was no significant difference ($p > 0.05$) in the mean AUC_0^∞ values between the prodrugs. Figures 2 and 3 show two representative plots of the plasma phenytoin concentration *versus* time after intravenous administration of the prodrugs and sodium phenytoin to dogs 19 and 20. Dogs 21 and 22 were not administered the intravenous injection of III, since the compound was observed to cause pain and toxic manifestations in dogs 19 and 20. Intravenous administration of III to dog 20 appeared to be incomplete, since pain and swelling around the injection site suggested that some of the dose may not have been placed directly in the vein.

Prodrugs II–IV, on oral administration, produced higher plasma phenytoin levels than the levels obtained after oral administration of Ia. The poor availability of phenytoin from Ia was probably due to the precipitation of phenytoin acid in the acidic environment of the stomach as well as the poor dosage form used, *i.e.*, sodium phenytoin in a hard gelatin capsule. Phenytoin has a low aqueous solubility and, thus, the slow and incomplete redissolution probably results in low plasma levels of phenytoin.

The primary purpose of the intravenous and oral administration of the prodrugs to the beagle dogs was to determine (*a*) if the prodrugs quantitatively released phenytoin and (*b*) the extent of absorption of phenytoin from the prodrugs on oral administration. Such an evaluation of the prodrugs of phenytoin is difficult since the elimination kinetics of phenytoin may be

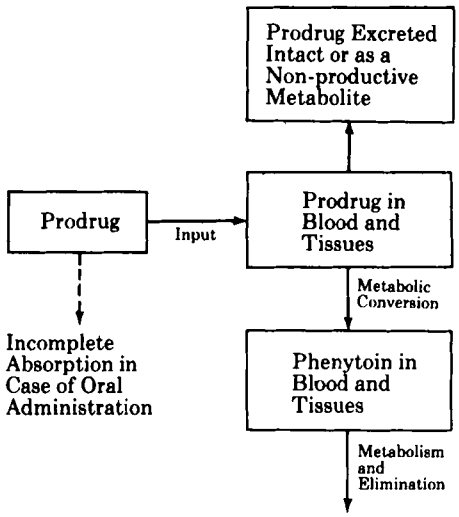
5	Ia	II	IV	III[d]
6	III	Ia	II	IV
7	IV	III	Ia	II
8	II	IV	III	Ia

[a] Produced severe toxic reactions in the dog including salivation, dilatation of the pupils, and hypotension. [b] Appeared to cause severe pain on administration, thus resulting in incomplete administration of the dose. [c] Not administered due to toxicity seen in Experiments 1 and 2. [d] Dog 22 rejected III three times. Further attempts to administer III orally to dog 22 were therefore terminated.

nonlinear (34, 35), probably due to the saturation of the enzyme system responsible for the metabolism of phenytoin to 5-*p*-hydroxyphenyl-5-phenylhydantoin (36). Dayton *et al.* (34) and Frey and Loseher (35) have shown that phenytoin exhibits dose-dependent kinetics in the dog. It was reported (35) that after intravenous administration of 20, 10, and 5 mg/kg (phenytoin equivalents) of Ia to dogs, the apparent elimination half-life of phenytoin decreased from 11.2 to 6.1 to 4.3 h, respectively. A plot of the logarithm of the plasma phenytoin concentration *versus* time was curvilinear at the three doses studied. Such a curvilinear plot is typical of drugs with Michaelis–Menten kinetics with a capacity-limited pathway of elimination or for drugs exhibiting product inhibition (37–41). In the present study, the nonlinear behavior of phenytoin in the beagle dog is apparent from the curvilinear shape observed in the plot of the logarithm of the plasma phenytoin concentration *versus* time obtained after intravenous administration of a 15-mg/kg (phenytoin equivalent) dose of Ia (Fig. 4).

In its simplest form, the pharmacokinetic model in Scheme I can be proposed for phenytoin and its prodrugs. Since phenytoin seems to exhibit nonlinear elimination kinetics in the dog (34, 35) at a dose of 15 mg/kg (phenytoin equivalents) of either Ia or the prodrug, quantitation of the extent of conversion of the prodrugs to phenytoin is difficult. This is because the elimination rate and the clearance of phenytoin (and thus the area under the plasma phenytoin concentration *versus* time profiles) depends on its input rate. This, in turn, depends on either the absorption rate of the prodrug after oral dosing and/or the metabolic conversion rate of the prodrug to phenytoin.

To confirm the nonlinear behavior of phenytoin in the beagle dog, a pharmacokinetic study involving variation of the dose of Ia was carried out in dogs 20 and 21. Dog 20 was administered 15-, 10-, and 6.6-mg/kg (phenytoin equivalent) doses of Ia intravenously and dog 21 was administered 15-, 10-, and 5.5-mg/kg (phenytoin equivalent) doses of Ia intravenously. The AUC_0^∞ values obtained after intravenous administration of the different doses of Ia were determined by the trapezoidal method. A plot of the AUC_0^∞ values *versus* the dose is shown in Fig. 5. The plot shows that the relationship between AUC_0^∞ and the dose is nonlinear. In the case of drugs obeying linear pharmacokinetics,



Scheme I

the AUC_0^∞ obtained after intravenous administration of the drug is directly proportional to the intravenous dose:

$$AUC_0^\infty = \frac{D_{iv}}{CL} \qquad \text{(Eq. 1)}$$

where D_{iv} is the intravenous dose and CL is the total body clearance of the drug. Thus, the AUC_0^∞ would increase proportionately with dose if the clearance remains constant. The elimination half-life of the drug should also be independent of the dose for drugs obeying linear pharmacokinetics. Hence, the nonlinear relationship between AUC_0^∞ *versus* dose and the increase in the apparent elimination half-life with increasing dose observed in this study (Table III) confirms the dose dependency and nonlinear behavior of phenytoin in the current study.

The absolute bioavailability of drugs (or prodrugs) exhibiting linear pharmacokinetics is normally determined by calculating the ratio of the AUC_0^∞ of the parent drug obtained after oral administration of the drug (or prodrug) and the AUC_0^∞ obtained after intravenous administration of the parent drug (33). Also, the availability of the parent drug after intravenous administration of a prodrug could be determined by calculating the ratio of the AUC_0^∞ values obtained after intravenous administration of the prodrug and those obtained after intravenous administration of an equivalent dose of the parent drug. Table IV summarizes the AUC_0^∞ values, calculated by the trapezoidal method, of the plasma phenytoin concentration *versus* time profiles obtained after intravenous administration of molar equivalent doses of Ia and II–IV. If phenytoin did exhibit linear pharmacokinetics, then the ratio of the AUC_0^∞ obtained after intravenous administration of the prodrugs and the AUC_0^∞ obtained after intravenous administration of Ia (Table V) would give the extent of conversion of the prodrugs to phenytoin. Similarly, the ratio of the AUC_0^∞ values obtained after oral administration of the prodrug and those obtained

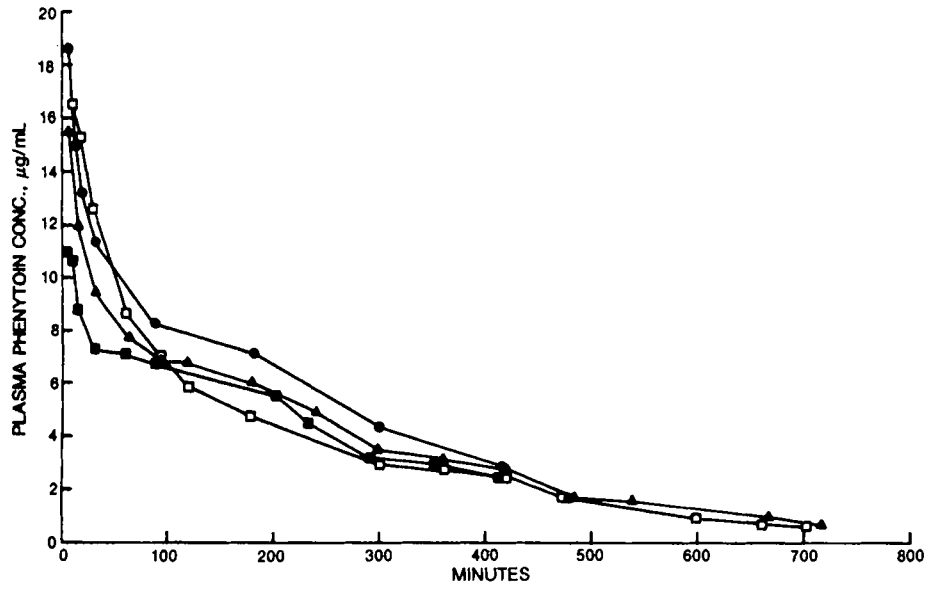


Figure 2—*Plots of the plasma phenytoin concentrations* versus *time obtained after intravenous administration of Ia (●), II (■), III (□), and IV (▲) to dog 19. Doses (phenytoin equivalents) were 15 mg/kg.*

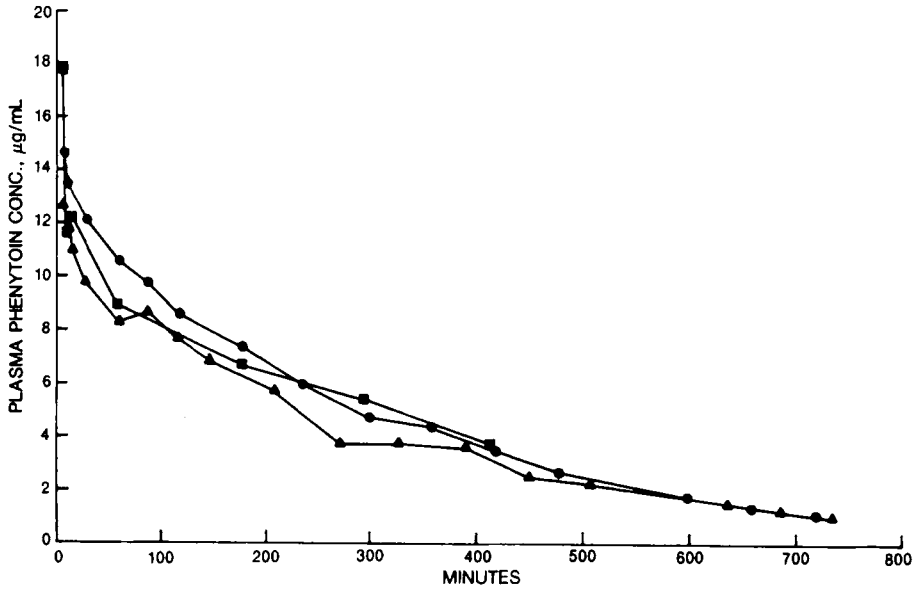

Figure 3—*Plots of the plasma phenytoin concentrations* versus *time obtained after intravenous administration of Ia (●), II (■), and IV (▲) to dog 20. Doses (phenytoin equivalents) were 15 mg/kg.*

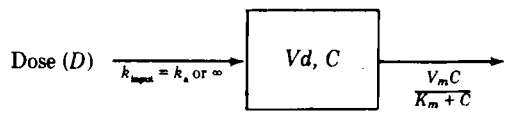
after intravenous administration of Ia (Table VI) would give the absolute bioavailability of the prodrugs. However, since phenytoin exhibits nonlinear behavior, the ratios summarized in Tables V and VI are only apparent values of the bioavailabilities of the prodrugs compared with Ia.

To determine the bioavailabilities of the prodrugs, the model shown in Scheme II is proposed, representing a one-compartment model. Although phenytoin does exhibit two-compartmental behavior, the distribution phase in the dog is insignificant; most authors[5] (35, 42, 43), therefore, describe the kinetics of phenytoin according to a one-compartment model[6]. According to the model, elimination of phenytoin, after an intravenous or oral dose D, is assumed to occur by a capacity-limited process. It will be assumed that the capacity-limited process, described by the Michaelis–Menten equation for a one-enzyme reaction, is applicable to phenytoin elimination in the dog.



Scheme II

Following intravenous administration of a dose (D_{iv}) of phenytoin, the differential equation describing the concentration of phenytoin at any time t in the body is:

$$\frac{-dC}{dt} = \frac{V_m C}{K_m + C} \qquad \text{(Eq. 2)}$$

where V_m is the theoretical maximum velocity per unit volume of distribution of the capacity-limited process (and in the present case has the units of μg/mL/min) and K_m represents the Michaelis–Menten constant (and has the units of concentration, μg/mL). Numerical values of V_m and K_m for dogs 20 and 21 were obtained by nonlinear least-squares iteration of the integrated form of Eq. 2, *i.e.*:

$$C_1 - C + K_m \cdot \ln (C_1/C) = V_m(t - t_1) \qquad \text{(Eq. 3)}$$

using the SIMPLEX program; data was obtained at three different intravenous doses of sodium phenytoin. C_1 is the first plasma phenytoin concentration point chosen by inspection in the elimination phase at time t_1.

The volume of distribution, Vd (really Vd extrapolated) was obtained from:

$$Vd = \frac{D_{iv}}{C_0} \qquad \text{(Eq. 4)}$$

where C_0 is the time zero plasma phenytoin concentration, determined by back extrapolation of the elimination phase of the plasma phenytoin concentration *versus* time profile obtained after intravenous administration of Ia.

The values of V_m, K_m, and Vd obtained are shown in Table VII. Figures 6 and 7 show the semilogarithmic plots of the plasma phenytoin concentration *versus* time in dogs 20 and 21, respectively, after administration of the three different doses of Ia; the solid lines were computer-generated from Eq. 2 using the individual V_m and K_m values determined at the different doses. The solid lines in Fig. 4 are the theoretical lines obtained using Eq. 3 and the mean V_m and K_m values shown in Table VII.

To determine the true bioavailability of the prodrugs in dogs 20 and 21, the method described by Martis and Levy (39) and Jusko *et al.* (38) for calculating the bioavailability of drugs exhibiting dose-dependent elimination due to enzyme saturation was employed. The method assumes a one-compartment pharmacokinetic system with a constant volume of distribution and a capacity-limited pathway of elimination. The volume of distribution of phenytoin, shown in Table VII, is practically constant. Following oral administration of

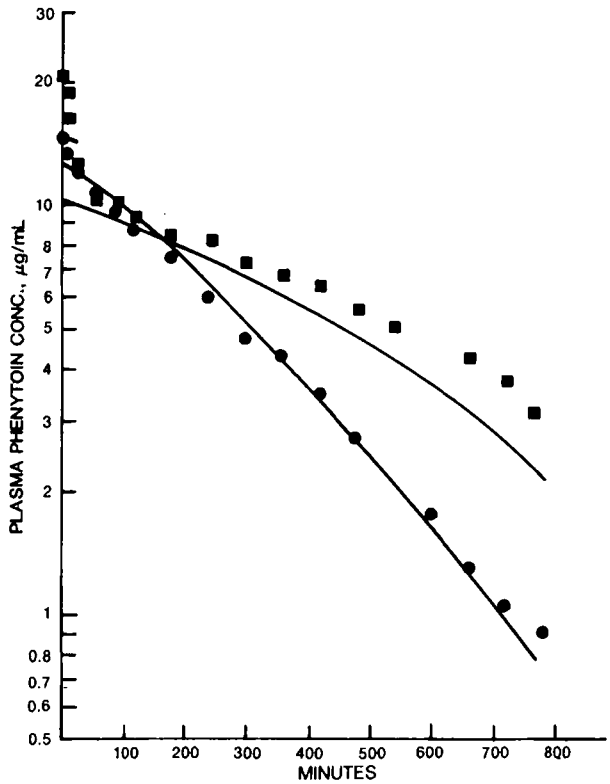


Figure 4—*Semilogarithmic plots of plasma phenytoin concentrations* versus *time after an intravenous dose of 15 mg/kg (phenytoin equivalents) of sodium phenytoin to dog 20 (●) and dog 21 (■). (——) theoretical line using mean* V_m *and* K_m *values.*

[5] D. F. Kowalczyk, unpublished results.

[6] The differences in AUC^{∞}_0 values between assuming a distribution phase and disregarding the distribution phase is only 0.5 and 3.8% in dogs 20 and 21, respectively, for the 15-mg/kg data.

Table II—Area under the Plasma Phenytoin Concentration *versus* Time Curve After Oral Administration of a Dose Equivalent to 15 mg/kg of Phenytoin

Compound	AUC_0^∞, μg·min/mL[a]				
	Dog 19	Dog 20	Dog 21	Dog 22	Mean ± *SD*
Ia	376	668	921	659	656 ± 222
II	2569	3724	2975	2576	2961 ± 543
III	3306	4438	1869	—[b]	3204 ± 1287[c]
IV	1714	2065	4190	2151	2530 ± 1123

the prodrugs and Ia, the rate of change of phenytoin concentration in the body can be expressed by:

$$\frac{dC}{dt} = \frac{k_a F D_{iv} e^{-K_a t}}{Vd} - \frac{V_m C}{K_m + C} \qquad \text{(Eq. 5)}$$

where k_a is the first-order absorption rate constant and F represents the fraction of the dose absorbed. D_{iv} is the intravenous dose, and this is equal to the oral dose, *i.e.*, 15 mg/kg. The rate of elimination of phenytoin from the body after oral administration is given by:

$$\frac{1}{Vd} \times \frac{dA_e}{dt} = \frac{V_m C}{K_m + C} \qquad \text{(Eq. 6)}$$

where A_e is the amount of phenytoin eliminated at any time t. If the total amount of drug eliminated is equal to the amount absorbed, then:

$$\int_0^\infty \frac{dA_e}{dt} dt = F D_{oral} \qquad \text{(Eq. 7)}$$

where D_{oral} is the oral dose. However, from Eq. 6:

$$\int_0^\infty \frac{dA_e}{dt} dt = Vd \int_0^\infty \frac{V_m C}{K_m + C} dt \qquad \text{(Eq. 8)}$$

Combining Eqs. 7 and 8, the following equality is obtained:

$$Vd \int_0^\infty \frac{V_m C}{K_m + C} dt = F D_{oral} \qquad \text{(Eq. 9)}$$

Dividing Eq. 9 by the intravenous dose, D_{iv}, gives:

$$\frac{\int_0^\infty \frac{V_m C}{K_m + C} dt}{D_{iv}/Vd} = \frac{F D_{oral}}{D_{iv}} \qquad \text{(Eq. 10)}$$

Since equivalent doses are administered intravenously and orally, Eq. 10 reduces to:

$$\frac{\int_0^\infty \frac{V_m C}{K_m + C} dt}{D_{iv}/Vd} = F \qquad \text{(Eq. 11)}$$

where F is the corrected bioavailability. Equation 11 can also be used to determine the availability of phenytoin after an intravenous dose of the prodrug relative to an equivalent intravenous dose of Ia.

To obtain the numerator of Eq. 11, the area under the plot of $V_m C/(K_m + C)$ *versus* time from zero to the last time point (t_L) was determined by the trapezoidal method (33). The concentration at the last time point in the plasma phenytoin concentration *versus* time profile after oral and intravenous administration of the prodrugs was very low. The contribution of the $AUC_{t_L}^\infty$ of a plot of $V_m C/(K_m + C)$ *versus* time would, therefore, be very small. Thus, $AUC_0^{t_L}$ would be approximately equal to AUC_0^∞, which is equal to the numerator of Eq. 11.

The results of the determination of the corrected true bioavailability of intravenously administered prodrugs II and IV in dogs 20 and 21 relative to intravenously administered Ia are summarized in Table VIII, and corrected bioavailabilities of prodrugs II–IV in dogs 20 and 21 after oral dosing are shown in Table IX. Similar calculations could be done to determine the corrected bioavailabilities of oral and intravenously administered prodrugs, respectively, in dogs 19 and 22 if the V_m and K_m values could have been accurately estimated.

Comparison of the AUC_0^∞ values to determine the availability of phenytoin after intravenous administration of its prodrugs relative to Ia can result in an underestimation in the case of drugs like phenytoin, which exhibit nonlinear pharmacokinetics. The extent of underestimation will depend on the rate of conversion of the prodrugs to phenytoin. If the rate of hydrolysis of the prodrugs is slow, the input rate of phenytoin will be slow. This in turn will show a decreased degree of saturation of the enzyme system responsible for metabolism of phenytoin compared with the saturation that would be exhibited by an equivalent intravenous dose of Ia. Similarly, the bioavailability of the prodrugs calculated by determining the ratio of AUC_0^∞ obtained after oral administration of the prodrugs and the AUC_0^∞ obtained after intravenous administration of an equivalent dose of Ia can result in an underestimation. If the input rate of phenytoin (*i.e.*, the absorption and conversion of the prodrug) is slow, the apparent absolute bioavailability is considerably underes-

timated. This is apparent from the results summarized in Tables VIII and IX. The corrected bioavailabilities show that in dog 21, the apparent bioavailabilities are drastic underestimations. This is consistent with the larger change in the AUC^{∞}_{0} and the apparent elimination half-life of phenytoin with dose observed in dog 21 compared with the change observed in dog 20 (Table III),

suggesting that dog 21 is more susceptible to enzyme saturation than is dog 20 (lower K_m value observed for dog 21).

The corrected bioavailability of both orally and intravenously administered II in dog 20 is ~100%; in dog 21, it is ~60%. This suggests that in dog 20, II undergoes quantitative hydrolysis to phenytoin and is completely absorbed from the GI tract. However, in dog 21, it seems that the complete oral dose of II may be absorbed from the GI tract, but the prodrug may not undergo quantitative conversion to phenytoin, *i.e.*, the ester may be undergoing a nonproductive metabolic pathway such as hydroxylation of the hydantoin phenyl ring followed then by the cleavage of the ester. This pathway may be

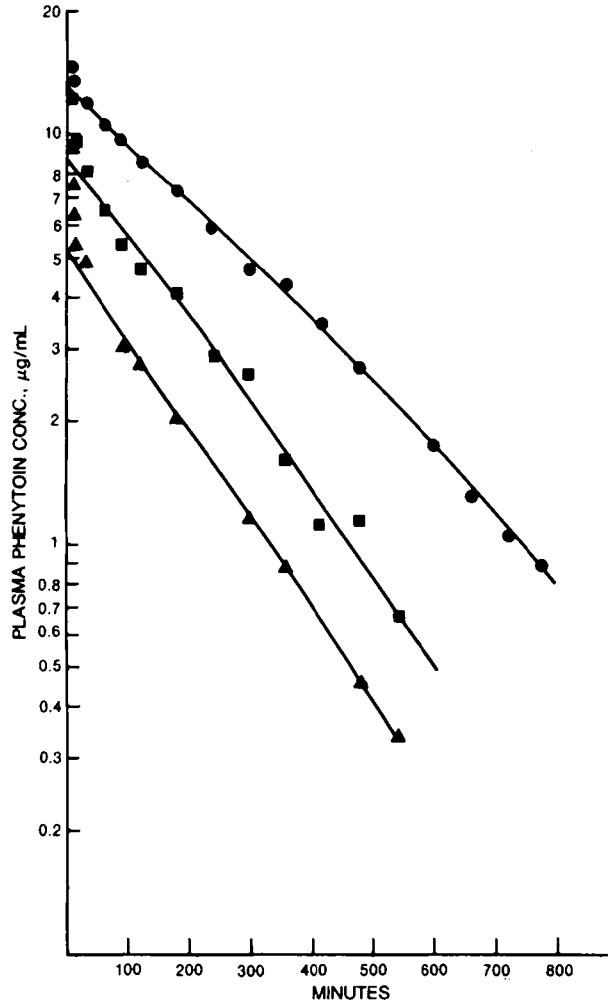

Figure 6—*Semilogarithmic plots of plasma phenytoin concentrations* versus *time following intravenous administration of 15 (●), 10 (■), and 6.6 (▲) mg/kg (phenytoin equivalents) of sodium phenytoin to dog 20; (—) computer-fitted lines.*

competing with the hydrolysis of the ester to phenytoin. Another possibility is that the esterase activity in dog 21 may be low. Prodrug III also seems to show a bioavailability of only ~45% in dog 21, whereas, in dog 20, the corrected bioavailability of III is ~100%.

The results in Table VIII suggest that IV is quantitatively hydrolyzed to phenytoin on intravenous dosing to dogs 20 and 21. However, the corrected bioavailability of IV on oral dosing in dogs 20 and 21 was ~65 and ~90%, respectively. This suggests that the ester may be incompletely absorbed from the GI tract, probably because of its polar nature.

In all the calculations and discussions to date, it was assumed that phenytoin does not exhibit presystemic clearance in the dog and that orally or intravenously administered prodrugs do not exhibit a sequential first-pass effect (44); *i.e.*, if the prodrugs are cleaved to phenytoin prior to reaching systemic circulation, then the formed phenytoin may be further metabolized prior to release to systemic circulation. For dogs 20 and 21, presaturation clearances could be calculated from:

$$CL = \frac{VdV_m}{K_m} \qquad \text{(Eq. 12)}$$

For dog 20, the approximate phenytoin clearance is 5.6 mL/min/kg, while for dog 21 a clearance of ~6.9 mL/min/kg is calculated. If it is assumed that phenytoin readily equilibrates between red blood cells and plasma, that the metabolism of phenytoin occurs only in the liver, and that liver blood flow in dogs is 40–45 mL/min/kg (45), then it can be estimated that phenytoin at presaturation doses may exhibit a first-pass effect of ~12–14% and 15–17% in dogs 20 and 21, respectively. Obviously, this is not sufficient to account for the poor oral performance of Ia, but it may account for the <100% availability of phenytoin from the prodrugs, even correcting for the nonlinear kinetics.

It can be concluded that II would be a better oral-delivery form of phenytoin than Ia. Compound III caused nausea, vomiting on oral dosing, and pain and hematoma on intravenous dosing. This would make it less favorable as a prodrug candidate for either oral or parenteral use. Compound II would probably be quantitatively hydrolyzed to phenytoin on oral administration to humans, since the esterase activity of the intestinal mucosa of dogs is poor relative to other mammalian species (46). Oral administration of II would help in overcoming the problem of low and erratic bioavailability of phenytoin associated with the oral administration of Ia.

The long shelf life of IV (30) and its high aqueous solubility at physiological pH (5) would render it useful as a parenteral dosage form for the delivery of phenytoin in humans, provided it is quantitatively hydrolyzed to phenytoin (as was observed in the dog). This would aid in overcoming the hazards associated with intravenous administration of sodium phenytoin.

Phenytoin Prodrugs VI: *In Vivo* Evaluation of a Phosphate Ester Prodrug of Phenytoin after Parenteral Administration to Rats

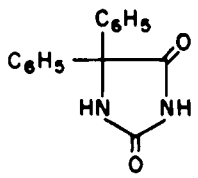
S. A. VARIA * and V. J. STELLA ˣ

Received December 22, 1982, from the *Department of Pharmaceutical Chemistry, School of Pharmacy, The University of Kansas, Lawrence, Kansas 66045.* Accepted for publication September 6, 1983. *Present address: Squibb Institute for Medical Research, New Brunswick, NJ 08903.

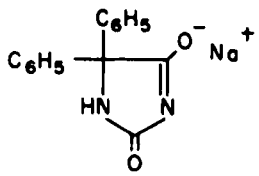
Abstract □ Tissue damage caused by subcutaneous and intramuscular administration of three phenytoin prodrugs to rats was assessed. Since two of the prodrugs caused significant irritation, only 3-(hydroxymethyl)-5,5-diphenylhydantoin disodium phosphate ester might be useful as a nonirritant phenytoin prodrug suitable for parenteral administration. To confirm the release of phenytoin from this prodrug, phenytoin availability after intramuscular and intravenous administrations of the phosphate prodrug was evaluated in rats and compared with sodium phenytoin. The prodrug quantitatively released phenytoin after intravenous administration, and phenytoin levels from intramuscular administration of the prodrug were far superior to those generated from similarly administered sodium phenytoin. Based on this and earlier studies, it was concluded that this prodrug should be further assessed as a parenteral form of phenytoin.

Keyphrases □ Phenytoin—phosphate prodrug, parenteral administration, rats □ Prodrugs—phenytoin, phosphate ester, parenteral administration, rats □ Anticonvulsants—phenytoin, phosphate prodrug, parenteral administration, rats

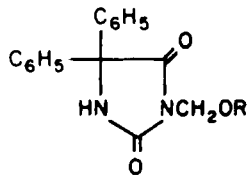
The parenteral form of the anticonvulsant drug phenytoin (I), *i.e.*, sodium phenytoin (Ia) dissolved in a vehicle consisting of 40% propylene glycol and 10% alcohol at pH ~12, is hazardous if too rapidly injected intravenously (1, 2); intramuscular injection results in delayed release of phenytoin from the precipitated phenytoin acid at the injection site (3–8). We recently evaluated the potential usefulness of a series of phenytoin prodrugs (9–11). Based on those studies, II–IV were thought to be possible parenteral forms of phenytoin because of their superior solubility properties compared with phenytoin (9). In a dog study, these prodrugs quantitatively released phenytoin after intravenous injection (11), although III was observed to cause significant acute toxicity in the dog and II had only marginal chemical stability (10). It was concluded that IV would be the best candidate among prodrugs II–IV (11) for parenteral administration.



I



Ia



II: R = $-COCH_2\overset{+}{N}H(CH_3)_2\ CH_3SO_3^-$
III: R = $-CO_2(CH_2)_2\overset{+}{N}H(CH_3)_2\ CH_3SO_3^-$
IV: R = $-PO_3^{2-}\ Na_2^+$

Presented here are two further studies, designed to evaluate the possible utility of II–IV as parenteral forms of phenytoin. First, an evaluation of the tissue damage after subcutaneous and intramuscular injection of prodrugs II–IV to rats was initiated. Based on these findings (significant irritation seen with both II and III but not IV) a second study, the intravenous and intramuscular availability of phenytoin from IV in rats, was addressed. The results of the two studies are presented in this paper.

EXPERIMENTAL SECTION

Evaluation of the Tissue Damage Caused by Subcutaneous and Intramuscular Administration of II–IV—Male Sprague-Dawley rats[1], weighing between 250–275 g, were used; twelve rats were used for each ester studied. Fresh aqueous solutions of esters II–IV (9), 25 mg/kg (phenytoin equivalents), were prepared, and each of six groups of six rats received an ester injected intramuscularly in the thigh muscle or an ester injected subcutaneously under the thigh skin. The injection volume did not exceed 200 μL. After administration, the rats were placed in metabolism cages with access to food and water. At 24 h postdose, three rats administered drug intramuscularly and three rats administered drug subcutaneously for each ester were sacrificed, and the extent of tissue damage was evaluated. The extent of tissue damage in the remaining six rats was evaluated after 7 d postdose. Visual observations were made to determine the extent of tissue damage. The rats were observed externally to check for any skin damage after the subcutaneous injection. The animals were then checked for internal damage by exposing the thigh muscle (intramuscular administration) or the muscles underlying the skin at the injection site (subcutaneous injection).

***In Vivo* Evaluation of IV as a Prodrug of Phenytoin in Rats**—The availability of phenytoin after intramuscular administration of IV was studied in

Phenytoin Prodrugs VI: *In Vivo* Evaluation of a Phosphate Ester Prodrug of Phenytoin after Parenteral Administration to Rats

S. A. VARIA * and V. J. STELLA ˣ

Received December 22, 1982, from the *Department of Pharmaceutical Chemistry, School of Pharmacy, The University of Kansas, Lawrence, Kansas 66045.* Accepted for publication September 6, 1983. *Present address: Squibb Institute for Medical Research, New Brunswick, NJ 08903.

Abstract □ Tissue damage caused by subcutaneous and intramuscular administration of three phenytoin prodrugs to rats was assessed. Since two of the prodrugs caused significant irritation, only 3-(hydroxymethyl)-5,5-diphenylhydantoin disodium phosphate ester might be useful as a nonirritant phenytoin prodrug suitable for parenteral administration. To confirm the release of phenytoin from this prodrug, phenytoin availability after intramuscular and intravenous administrations of the phosphate prodrug was evaluated in rats and compared with sodium phenytoin. The prodrug quantitatively released phenytoin after intravenous administration, and phenytoin levels from intramuscular administration of the prodrug were far superior to those generated from similarly administered sodium phenytoin. Based on this and earlier studies, it was concluded that this prodrug should be further assessed as a parenteral form of phenytoin.

Keyphrases □ Phenytoin—phosphate prodrug, parenteral administration, rats □ Prodrugs—phenytoin, phosphate ester, parenteral administration, rats □ Anticonvulsants—phenytoin, phosphate prodrug, parenteral administration, rats

The parenteral form of the anticonvulsant drug phenytoin (I), *i.e.*, sodium phenytoin (Ia) dissolved in a vehicle consisting of 40% propylene glycol and 10% alcohol at pH ~12, is hazardous if too rapidly injected intravenously (1, 2); intramuscular injection results in delayed release of phenytoin from the precipitated phenytoin acid at the injection site (3–8). We recently evaluated the potential usefulness of a series of phenytoin prodrugs (9–11). Based on those studies, II–IV were thought to be possible parenteral forms of phenytoin because of their superior solubility properties compared with phenytoin (9). In a dog study, these prodrugs quantitatively released phenytoin after intravenous injection (11), although III was observed to cause significant acute toxicity in the dog and II had only marginal chemical stability (10). It was concluded that IV would be the best candidate among prodrugs II–IV (11) for parenteral administration.

Compound	Observations after Subcutaneous Administration	Observations after Intramuscular Administration
II	Externally, a white patch at the injection site Severe tissue damage and necrosis of the skin	Slight necrosis with inflammation at site of injection
III	Build up of scar tissue and severe skin necrosis	Inflammation at injection site
IV[a]	No visible damage	No visible damage

[a] Doses were 25 mg/kg (phenytoin equivalents). [b] It is realized that more elaborate studies including histopathology would be needed if considerations were given to testing IV clinically. However, these clear-cut findings probably eliminate further evaluation of II and III clinically.

the rat model. Specifically, three different types of crossover studies were carried out on male Sprague–Dawley rats in an effort to evaluate the quantitative nature of the conversion of IV to phenytoin after intravenous and intramuscular dosing. The crossover studies comprised of: (*a*) three rats which received phenytoin-equivalent doses of 7 mg/kg im of IV[2] and 10 mg/kg im of sodium phenytoin; (*b*) three rats which received 7 mg/kg im of IV[2] and 10 mg/kg iv of sodium phenytoin, and a second group of three rats which received 10 mg/kg im of IV and 10 mg/kg iv of sodium phenytoin; and (c) two rats which received 10 mg/kg iv of IV and 10 mg/kg iv of sodium phenytoin. The rats weighed between 250–300 g. Each rat was used for only one crossover study, at the end of which it was sacrificed. The rats were rested for at least 1 week between doses and were fed standard laboratory diet and water *ad libitum*.

Prior to a study, the rats were weighed and anesthetized with 60 mg/kg ip of sodium pentobarbital. The animals were kept on a heated surgical table (38°C) to maintain their normal body temperature. The rats were kept unconscious throughout the experiment by administering smaller doses of sodium pentobarbital (30 mg/kg) whenever the animal showed signs of regaining consciousness.

The jugular vein was exposed by means of a small incision on the ventral side of the neck region. The right jugular vein was used to administer aqueous solutions of IV and also to obtain blood samples at various time intervals. At the end of the experiment the area of incision was cleaned with ethanol, and the incision was closed using a nonabsorbable, sterile, surgical silk suture[3].

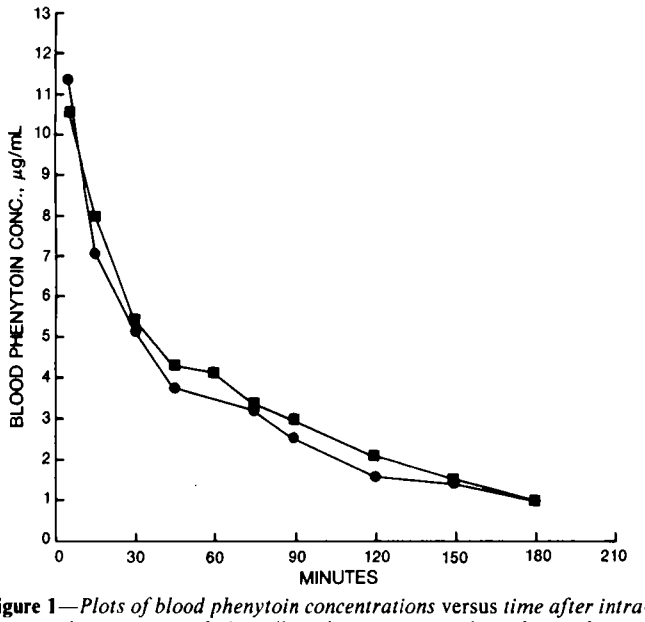

Figure 1—*Plots of blood phenytoin concentrations* versus *time after intravenous administration of 10-mg/kg (phenytoin equivalent) doses of Ia (●) and IV (■) to the same rat.*

[2] After having carried out these two partial studies, it was found that one particular batch of IV (prepared just before this *in vivo* study) was only 70% pure as confirmed by GC and TLC (9). The impurity was determined to be inorganic in nature. Hence, instead of administering 10 mg/kg (phenytoin equivalents) of IV, rats in study a and the first study b received a 7-mg/kg (phenytoin equivalent) dose of IV. This was the only batch of IV that was so contaminated. Earlier batches reported (9–11) were pure.

The rats were then placed in metabolism cages with access to food and water.

Administration of sodium phenytoin intravenously and intramuscularly leads to precipitation of phenytoin at the injection site. If blood samples were obtained after intravenous administration of sodium phenytoin from the same vein where sodium phenytoin had been administered, it may show erroneous blood levels of the drug. To overcome this problem, sodium phenytoin was administered intravenously through the exposed femoral vein and blood samples were obtained from the left jugular vein.

The various routes of administration of sodium phenytoin and IV were as follows.

1. For IV, fresh aqueous solutions were intravenously administered into the right jugular vein, with blood samples from the same vein; intramuscular administration was into the thigh muscle, with blood sampling also from the right jugular vein.

2. For sodium phenytoin, the drug was dissolved in a solvent of propylene glycol–alcohol–water (4:1:5) with the pH adjusted to 11.5–12 with sodium hydroxide. This was administered intravenously into a femoral vein, and blood was sampled from the left jugular vein. Intramuscular administration was into the thigh muscle, with blood sampling also from the left jugular vein. The volume administered did not exceed 250 μL. Intravenous injections of sodium phenytoin and IV were infused slowly over a 1-min period.

Blood samples obtained from the jugular vein were transferred to containers[4] containing 3 mg of EDTA and were immersed in an ice bath. A measured quantity (usually 100–200 μL) of blood was extracted into 2 mL of toluene containing the internal standard. The GC procedure described earlier (12) for the determination of phenytoin was then followed. No effort was made to determine the presence of the prodrug, as earlier studies had indicated rapid conversion of IV to phenytoin in rat tissues (9).

RESULTS AND DISCUSSION

Compound IV has been shown to have physicochemical properties that are ideal for a prodrug of phenytoin for parenteral use (9–11). Although prodrugs II and III had been projected as possible oral delivery forms of phenytoin (9, 10), they may also be potentially useful parenteral prodrugs.

Emergency use of parenteral phenytoin, *e.g.*, in cases of controlling seizures in patients with head injuries, may require the administration of the prodrug intramuscularly. A study was undertaken, therefore, to qualitatively assess the extent of the localized tissue damage caused by prodrugs II–IV after intramuscular and subcutaneous administration to rats.

To be clinically acceptable, intramuscular administration of a drug should cause minimal tissue damage at the injection site. Intramuscular administration of sodium phenytoin has been reported to be painful, probably due to the precipitation of phenytoin (7). It has also been shown to cause hemorrhage, hematoma, and necrosis at the injection site in cats and rabbits (3, 8).

Table I summarizes the extent of tissue damage observed after subcutaneous and intramuscular administration of II–IV to rats. There were only some minor qualitative differences between the 1- and 7-d observations; the results were, therefore, summarized together. Esters II and III cause tissue damage after subcutaneous as well as intramuscular administration. The tissue damage may have been caused by the ester or the products formed on hydrolysis of the ester. Recently, Adachi *et al.* (13) have shown that aged solutions of cephalothin caused pain when administered intraperitoneally to mice, which was attributed to the acetic acid produced on hydrolysis of cephalothin. The possibility of irritation and tissue damage caused by the acids produced on hydrolysis of the esters cannot be ruled out. Another possibility for the cause of the tissue damage was the methanesulfonate anion of II and III. Administration of the hydrochloride salt of 3-(hydroxymethyl)-5,5-diphenylhydantoin *N*,*N*-dimethylglycine ester was found to cause tissue damage comparable to that caused by II[5]. Many parenteral dosage forms of amine drugs for intramuscular use are administered as their hydrochloride salts and have

[4] Vacutainers, No. 6496; Becton, Dickinson and Co., Rutherford, N.J.

[5] The hydrochloride salt was not extensively evaluated with respect to its physicochemical properties because of its hygroscopic properties. It was prepared in a small quantity specifically for this test.

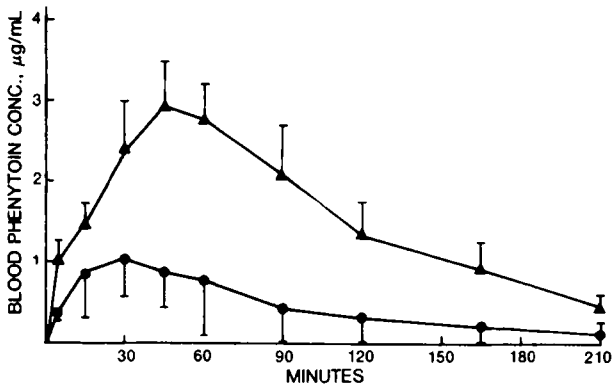

Figure 2—*Blood concentrations of phenytoin in rats* (n = 3) *following intramuscular administration of Ia* (●) *and IV* (▲). *Doses (phenytoin equivalents) were 10 mg/kg of Ia and 7 mg/kg of IV; Bars represent* SD.

not been reported to cause any specific tissue damage due to the choice of the hydrochloride salt. Thus, it seems that the counter anion of II and III does not cause the observed tissue damage.

Ester IV did not exhibit any tissue damage after subcutaneous or intramuscular administration. Thus, IV could be a suitable prodrug candidate for intramuscular delivery of phenytoin, providing that the ester is well absorbed from the site of injection and is quantitatively converted to phenytoin *in vivo*.

The bioavailability of phenytoin after intramuscular and intravenous injections of IV to rats was studied. The specific aims of this study were to (*a*) determine whether IV was quantitatively converted to phenytoin *in vivo* after its intravenous administration, (*b*) compare the levels of phenytoin obtained after intramuscular administration of IV with those obtained after intramuscular administration of sodium phenytoin (Ia), and (*c*) determine the absolute bioavailability of IV after intramuscular administration. All the studies carried out in rats were crossover studies, as described in the *Experimental Section*. Crossover studies were used instead of a single treatment per rat in order to minimize the effects of differences in the elimination half-lives of phenytoin due to variations in the extent of protein binding of phenytoin among rats (14).

Gerber *et al.* (15), Ashley and Levy (16, 17) and Vicuna *et al.* (18) have shown that phenytoin displays dose-dependent or nonlinear kinetics in rats. The apparent half-lives of phenytoin after intravenous administrations of 10-, 25-, and 40-mg/kg doses of phenytoin to rats increased from 0.6 to 1.2 to 2.5 h, respectively (15). There is considerable controversy as to whether the dose dependency exhibited by phenytoin in rats is due to saturation of the enzyme system responsible for metabolism of phenytoin to 5-(*p*-hydroxyphenyl)-5-phenylhydantoin (*p*-HPPH) or to product inhibition in which *p*-HPPH can have an inhibitory effect on the biotransformation of phenytoin. However, it has been reported by a number of workers (15-18) that the pharmacokinetics of phenytoin approaches linear elimination kinetics in rats after a 10-mg/kg iv dose of phenytoin. Thus, for the present study, doses of 10 mg/kg (administration equivalent) of IV and Ia were used, and the data was evaluated assuming linear phenytoin elimination kinetics.

To determine whether IV reverted quantitatively to phenytoin *in vivo*, a crossover study in which each rat received either a 10-mg/kg (phenytoin equivalent) dose of IV or a 10-mg/kg (phenytoin equivalent) dose of Ia intravenously was undertaken. Figure 1 is a linear plot of blood phenytoin concentrations as a function of time in one rat after intravenous administrations of Ia and IV. Semilogarithmic plots of blood phenytoin *versus* time after intravenous administrations of IV and Ia showed that phenytoin exhibited two-compartmental pharmacokinetics in the rat, which is consistent with the results obtained by other workers (14, 16, 17). Compound IV produced plasma phenytoin levels similar to those obtained after the intravenous administration of an equivalent dose of Ia. The percentage ratios of the areas under the plasma concentration *versus* time profiles from 0 to 180 min after intravenous administrations of IV and Ia were 109.7 and 91.2% in the two rats studied. This suggests that IV was completely hydrolyzed to phenytoin in these rats.

The evaluation of IV as an intramuscular form for the delivery of phenytoin required the determination of blood levels of phenytoin after intramuscular administration of the prodrug and Ia. Figure 2 shows a plot of the mean blood concentrations of phenytoin *versus* time obtained after intramuscular administrations of IV and Ia at doses of 7 and 10 mg/kg (phenytoin equivalents), respectively, to three rats. Table II summarizes the area under the blood phenytoin concentration *versus* time curves from 0 to 210 min obtained in each rat after intramuscular administrations of IV and Ia. Statistical analysis of the mean phenytoin blood level data using the paired *t* test showed that the

Table III—Area under the Blood Phenytoin Concentration *versus* Time Curve Obtained in Rats after Administration of IV Intramuscularly and Ia Intravenously [a]

Rat	Intramuscular Administered IV AUC_0^∞, μg·min/mL[b]	Intravenous Administered Ia AUC_0^∞, μg·min/mL[c]	F[d]
4	522	723	1.0
5	527	786	1.0
6	330	578	0.8
7	837	763	1.1
8	2209	2695	0.8
9	552	467	1.2

[a] Rats 4-6 received 7 mg/kg of IV intramuscularly; rats 7-9 received 10 mg/kg of IV intramuscularly. Compound Ia was administered at a dose of 10 mg/kg. All doses were phenytoin equivalents. [b] AUC_0^∞ was calculated using the trapezoidal method. [c] AUC_0^∞ was calculated using $(A/\alpha) + (B/\beta)$. [d] Calculated by AUC_0^∞/Dose (intramuscular) ÷ AUC_0^∞/Dose (intravenous).

blood levels of phenytoin at 5, 30, 45, and 60 min after intramuscular administrations of IV and Ia were significantly different ($p < 0.05$). The one-way ANOVA showed the mean area under the blood phenytoin concentration *versus* time curve from 0 to 210 min was significantly different ($p < 0.01$).

To determine the absolute bioavailability of intramuscularly administered IV, a crossover study was initiated in which the rats received an intramuscular injection of IV followed 1 week later by an intravenous dose of Ia. The same order of administration of IV and Ia was maintained in all the rats (see *Experimental Section* for explanation). The results are reported in two groups of three rats each. The first group of rats received 7 mg/kg (phenytoin equivalents) of IV intramuscularly and the second group of rats received 10 mg/kg (phenytoin equivalents) of IV. The division into two groups occurred as the first group was administered an impure batch of IV[2]; *i.e.*, the ester was only 70% pure, with the other 30% of the dose as inorganic impurities. Thus, instead of administering a 10-mg/kg (phenytoin equivalent) dose of IV, the rats in group 1 were inadvertently administered a 7-mg/kg (phenytoin equivalent) dose of IV. Both the groups received 10-mg/kg (phenytoin equivalent) dose of Ia intravenously. The blood phenytoin concentration *versus* time profiles for a rat in group 2 is shown in Fig. 3. Table III summarizes the areas under the blood phenytoin concentration *versus* time curves (AUC_0^∞) obtained after intramuscular injection of IV, calculated using the trapezoidal method (19). The blood phenytoin concentration (C) *versus* time profile after intravenous administration of Ia was computer-fitted to Eq. 1 using the AUTOAN-NONLIN library program (20, 21):

$$C = Ae^{-\alpha t} + Be^{-\beta} \qquad \text{(Eq. 1)}$$

Equation 1 describes a two-compartment open model. The parameters A, α, B, and β were then used to calculate AUC_0^∞ using:

$$AUC_0^\infty = \frac{A}{\alpha} + \frac{B}{\beta} \qquad \text{(Eq. 2)}$$

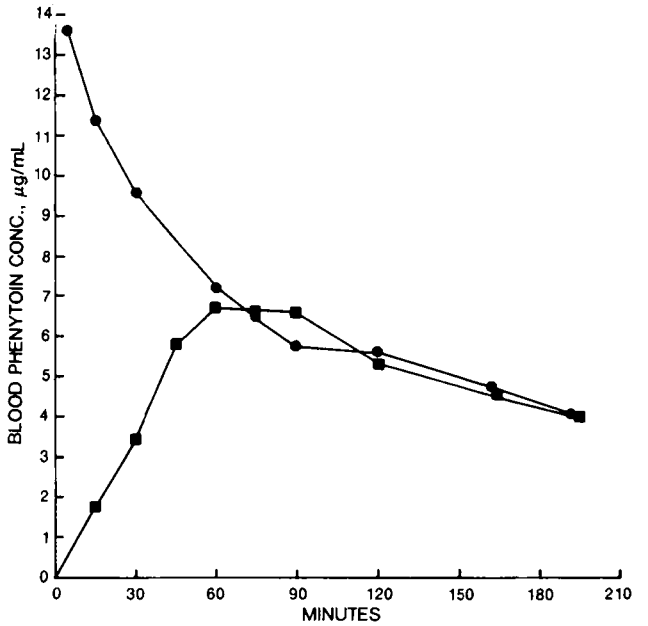

Figure 3—*Plots of the blood phenytoin concentrations* versus *time following administration of 10-mg/kg doses of IV intramuscularly* (■) *and of Ia intravenously* (●) *to rat 8. Doses are in phenytoin equivalents.*

The absolute bioavailability was determined by dividing the AUC_0^∞ values obtained after intramuscular administration of IV by those obtained after intravenous administration of Ia, corrected for dose.

Compound IV was rapidly and quantitatively hydrolyzed following intravenous administration to rats, producing blood levels of phenytoin similar to those obtained after intravenous administration of an equivalent dose of Ia. This is consistent with the rapid and quantitative hydrolysis of IV observed in an *in vitro* rat liver homogenate study (9). Thus, IV must be metabolized catalytically by phosphatase enzymes at a rate faster than the rate at which the ester would be eliminated by other mechanisms. Intramuscular administration of IV showed a higher area under the blood phenytoin concentration *versus* time profile compared with that obtained after intramuscular administration of Ia. The large standard deviation in the AUC_0^{240} value observed after intramuscular administration of Ia reflects the erratic and unpredictable absorption of phenytoin from Ia. This has been attributed to the precipitation of phenytoin at the site of injection. It has been shown that the intramuscular administration of Ia is much less effective, and doses of ~2–3 times higher than the oral dose may be necessary to achieve comparable plasma concentrations on single dose administration (5, 6). Intramuscular administration of IV produced higher blood phenytoin levels, which peaked within 45–60 min; this showed that IV was rapidly cleared from the site of injection. The mean absolute bioavailability of intramuscular administered ester IV was determined, assuming linear pharmacokinetics, to be 98.4%. This suggested that the administered dose of IV was completely absorbed from the site and was quantitatively converted to phenytoin *in vivo*. This is consistent with the quantitative conversion of IV observed after intravenous administration of this prodrug.

Based on rat data presented in this paper, earlier physicochemical studies (9, 10), and an *in vivo* evaluation in dogs (11), it can be concluded that IV would be an ideal prodrug for the parenteral delivery of phenytoin provided it is quantitatively hydrolyzed to phenytoin in humans. Compound IV could be administered intravenously or intramuscularly as an aqueous solution in emergency cases to control seizures. The use of IV as a parenteral delivery form would overcome the problems of precipitation of phenytoin associated with intravenous and intramuscular administration (3, 4, 8) of sodium phenytoin (Ia). It should also be free of the toxic cardiac effects seen after rapid intravenous injections of sodium phenytoin and the tissue damage reported to occur after intramuscular administration of sodium phenytoin.

Labeling Suspended Aerosol Particles with Short-Lived Radionuclides for Determination of Particle Deposition

MARY FAYE SMITH ‡, SHELLEY BRYANT §, SIMON WELCH *§, and GEORGE A. DIGENIS *x

Received February 10, 1983, from the *Division of Medicinal Chemistry and Pharmacognosy, College of Pharmacy, University of Kentucky, Lexington, KY 40536-0053, ‡Pharmaceutical Research and Development Laboratories, Burroughs Wellcome Co., Greenville, NC 27834, and §Lederle Laboratories, Pearl River, NY 10965. Accepted for publication July 29, 1983.

Abstract □ Radiotracer techniques were developed to examine parameters that characterize pressurized aerosols designed to deliver insoluble particles suspended in the aerosol formulation. Microaggregated bovine serum albumin microspheres that were to be suspended were labeled with iodine-131 ($t_{1/2}$ = 8 d). This iodination procedure (>80% effective) is also applicable to iodine-123, which possesses superior characteristics for external imaging and further *in vivo* studies. This report shows that for pressurized aerosols containing suspended particles, each metered dose is approximately equal (not including the priming doses and the emptying doses). Increase in the delivery of the albumin particles out of the canister was best achieved by pretreating the valve assembly with a solution of 2% (w/v) bovine serum albumin in phosphate buffer. Use of a cascade impactor delineated the particle size distribution of the microspheres, with the majority of particles ranging in size from 2 to 8 μm. The data disclosed here indicate that the techniques developed with short-lived radionuclides can be used to (*a*) quantitate each metered dose, (*b*) characterize the particle size distribution profile of the aerosol contents, and (*c*) determine the extent of deposition of the particles in the aerosol canister and all of its components.

Keyphrases □ Radionuclides—short-lived, determination of particle deposition □ Aerosol particles—labeling with short-lived radionuclides, determination of particle deposition □ Particle deposition—determination with short-lived radionuclide labeling, suspended aerosol particles

In recent years, several reports have appeared that deal with the deposition of aerosols in the lungs of rats (1) and humans (2). Previous studies in this area have utilized liquid droplets delivered from nebulizers (3) and liquid droplets or solid particles delivered from pressurized aerosols (2, 4). Various equipment has also been developed for use in the determination of radioactive aerosol retention in the lungs of rabbits (5), as well as in studies designed to observe increased whole lung deposition of particles (6). Studies have also been performed to improve the deposition of aerosols in the lungs by controlling the breathing pattern of the patient (6). Oral adaptor extension devices have been shown to decrease the delivery of an aerosol to the oropharyngeal area (7). These devices are important not only because aerosols are used for site-specific drug delivery (2, 4), but also because the sizes of the aerosolized particles determine their distribution in the respiratory tract (2, 3).

Consequently, some studies have been performed to ascertain the amount of a compound, whether it is a solid or a liquid, that has actually been released in any individual metered dose. Several experimental techniques have been used for these determinations. In one study, weighing of a pressurized aerosol container before and after a designated number of actuations to measure the reproducibility of metered doses from a random sampling of the manufactured canisters has been reported (8). Davies *et al.* (9) have reported that there is great reproducibility and uniformity of delivery in random samples of manufactured pressurized aerosols. Those studies were performed on aerosols in a particle-size analyzer which is dependent on light-scattering techniques. In another study, the measured volume of propellant containing a known amount of particulate matter per dose has been reported (2). In yet another report, the size distribution of particles in commercially available cosmetic aerosols were delineated by microscopy, cascade impaction, and single-particle aerodynamic relaxation time analysis (10). Each of these are reliable accounts, but better quantitation can be achieved with short-lived radionuclides.

The most reliable method for the determination of reproducibility of all delivered doses from any given aerosol at any time, as well as the distribution of the size of particles released and the deposition of the compound in an aerosol canister, is by radioactive tracer methodology. Utilization of short-lived radionuclides in the assessment of quantitation techniques of aerosol particles has been reported in the past. For some time, the incorporation of a radioactive tag has been the major hindrance, due to the techniques needed for tagging the aerosol particle to be studied. Garrard *et al.* (11) have used ^{99m}Tc-labeled Fe_2O_3 colloid in experimentation, whereas Moren (4), Newman *et al.* (2), and Agnew *et al.* (12) have utilized technetium-99m incorporated into synthetic polymer particles. Isawa *et al.* (13) have published results of an aerosol study in which ^{99m}Tc-labeled serum albumin aerosols were scrutinized, although the tagging technique was not disclosed.

In this study, bovine microaggregated serum albumin microspheres labeled with iodine-131 were utilized as the suspended particles of the aerosol formulation. The chemical procedure developed for the labeling of the microspheres with iodine-131 is applicable to iodine-123, which possesses superior characteristics for external imaging (14). Unlike the previously studied synthetic particles (2, 4, 12), the iodinated albumin microspheres, which are currently used in nuclear medicine, can be degraded by the body and, therefore, are available for *in vivo* experimentation.

This report describes techniques which show how short-lived radionuclides can be used in (*a*) quantitation of each metered dose, (*b*) characterization of particle size distribution by the aerosol, and (*c*) determination of the extent of deposition of the particles in the canister and all of its components.

EXPERIMENTAL SECTION

Iodination of Microaggregated Albumin Microspheres—The prepared microaggregated albumin microspheres[1] were first washed with phosphate buffer (pH 8.0) for use in the subsequent experiments. The microspheres were mixed in a mixer[2] and then centrifuged in a tabletop centrifuge[3]. The supernatant was removed, and the microspheres were resuspended in the phosphate buffer. The washing process was repeated a total of five times. To determine the weight of the microspheres, a representative sample was obtained, allowed to dry, and then weighed. The weight of microspheres per volume of solution was then determined and recorded.

The microspheres suspended in the phosphate buffer were then transferred

[a] A canister was filled with propellant and ^{131}I-labeled microaggregated albumin microspheres and crimped. After temperature equilibration, the canister was emptied by releasing the contents, actuation by actuation, into appropriately labeled scintillation vials. [b] Values listed are percentages of each dose to the total activity recovered in all the actuations from each of three aerosol canisters.

to a 1.0-mL glass vial with a magnetic spin-vane stirrer[4] and capped with a plastic cap containing a multiple-delivery rubber septum. The radionuclide was introduced into the closed system, and then *N*-chloro-4-methylbenzenesulfonamide sodium salt[5] (5 mg dissolved in 0.5 mL of buffer solution) was added such that the total concentration was 1–10 μg of microspheres. The reaction was stirred continuously for 5 min on a magnetic stirrer[6], and then sodium metabisulfite[7] in buffer solution (10 mg/0.25 mL) was added, so that the final ratio was 5 μg of sodium metabisulfite[7] to 10 μg of microspheres. The contents of the vial[4] were mixed for an additional 5 min and then transferred quantitatively to a conical centrifuge tube by repeated washings of the vial[4] with the phosphate buffer. The sample was then centrifuged for 8 min, the supernatant was removed, and the labeled microspheres were washed two more times with fresh phosphate buffer.

To determine the efficiency of iodination of the microspheres, two test methods were used. In the first method, the iodinated microspheres were precipitated with 20% trichloroacetic acid[8] and then centrifuged and washed repeatedly with the phosphate buffer. The radioactivity found in the precipitate was considered to be bound to the albumin microspheres. A second test involved the use of a dialysis bag[9] in phosphate buffer. The radioactivity remaining in the dialysis bag and in the total dialysate after 62 h was quantitated.

Preparation of the Aerosol Containers—The iodinated microspheres were suspended in ethanol[10] for use in the modified aerosol canister[11]. The canister was fitted with an insert made of aluminum, stainless steel, or plastic[12] so that when filled it would deliver 20 metered doses of 65 μg/dose (the similar commercially available canister is designed to deliver 200 metered doses).

The freshly prepared albumin microspheres[1] were placed in the plastic[12] insert in a canister and supercooled to −65°C in an acetone–dry ice bath. The propellant, dichlorodifluoromethane[13] (1.3 g), was added, and the valve[14] was put in place and crimped[15]. The closed canister was placed in a warm water bath, *i.e.*, 55°C, to test for crimping leaks. After successfully passing the leak test, the canister was allowed to equilibrate to room temperature for use in the deposition studies.

Determination of the Radioactive Species—By testing the interaction of the canister insert, valves, and contents singly and combined, determination of the radioactive species was attempted. That is, attempts were made to check whether the quantitated activity was due to free iodine, iodinated propellant, or the labeled microspheres. By varying the different parameters, the radioactive deposition was proven.

Experiment 1—Three aluminum canisters were filled with propellant and a known, weighed amount of unlabeled albumin microspheres, crimped closed, and then allowed to equilibrate to room temperature after successfully passing the leak test. The contents of each were then actuated into scintillation vials for later determination by the ninhydrin assay for the amount of protein present.

Experiment 2—Again, three aluminum aerosol containers were used, with the first containing ^{131}I-iodinated microspheres and propellant. After crimping, the canister was warmed to room temperature, cooled to −60°C, and then opened. After evaporation of the propellant, the activity was quantitated. The second canister contained only [^{131}I]NaI and unlabeled microspheres. Propellant was added, the system was crimped hydraulically and allowed to warm to room temperature. After supercooling (−60°C) the aerosol container, the valve assembly was removed, and the contents were permitted to evaporate. The final canister in this portion of the experiment contained only [^{131}I]NaI and propellant that was allowed to evaporate without the crimping, warming, and cooling procedure.

Experiment 3—One of the two canisters containing iodinated microspheres and propellant was crimped closed, heated to 50°C, cooled to −60°C, and opened by removing the valve to allow the contents to evaporate. The other canister was filled with iodinated microspheres and propellant, which were then allowed to evaporate at room temperature.

Metered Dose Determinations—The canister was shaken manually for dispersion, and subsequently, the contents were emptied into plastic scintillation vials[16] lined with gauze. After each actuation, the canister was shaken vigorously for 2–3 s. The end of the valve stem was held with needle-nose pliers, and each metered dose was delivered into a separate appropriate vial. The collection of actuations was continued until the canister was empty. The canister was then dismantled, the inside of the plastic[12] insert was washed exhaustively, and the valve was dismantled to quantitate the deposition of the radioactivity.

Cascade Impaction—Filled and leak-tested aerosol canisters containing the radiolabeled albumin microspheres[1] were also used in the second experiment. An appropriate oral adaptor was fitted onto the canister and the valve stem, and subsequently, the aerosol was actuated in a cascade impactor[17]. A pressure of 18 psi was applied to the cascade impactor with a vacuum pump[18]. The canister was shaken before each actuation into the impactor, and the vacuum was run for an additional 5 min after the last actuation to ensure complete impaction. The glass slides for collecting the sized particles were removed and washed with 3 M NaOH[19]. All washings were collected, and the radioactivity was quantitated.

RESULTS AND DISCUSSION

This study was undertaken to examine several parameters which characterize pressurized aerosols in which the drug used is in the form of an insoluble particle suspended in the aerosol formulation. These parameters include (*a*) accurate quantitation of metered doses, (*b*) characterization of the size distribution of particles ejected from the aerosol, and (*c*) the deposition profile of the aerosol particles in the canister and component parts.

To achieve these goals, microaggregated bovine albumin microspheres (ranging from 3 to 8 μm in diameter) were labeled with iodine-131 by the general methods of McConahey and Dixon (15), Greenwood *et al.* (16), and Hughes and Straessle (17) adapted for use with microspheres in this experiment. The microspheres, which were suspended in phosphate buffer (pH 8.0), were placed in a glass vial[4], and the radioactivity, in this case [^{131}I]NaI, was added. *N*-Chloro-4-methylbenzenesulfonamide sodium salt was added, the mixture was stirred for 5 min, and the reducing agent, sodium metabisulfite, was added to halt the iodination procedure. The radiolabeled microspheres were then washed with phosphate buffer to remove any residual radioactivity.

To ascertain that the iodine was covalently bonded to the protein backbone, the microaggregated albumin microspheres were precipitated with trichloroacetic acid. The total radioactivity found in the supernatant and in the precipitated protein indicated an 80–90% efficiency of iodination. To further determine the covalent linkage of the iodine to the microspheres, an identical sample of the microspheres was dialyzed[9]. The results indicate that 12% of the total radioactivity was found in the dialysate and the dialysis bag, confirming that the majority (>80%) of the radioactivity is associated with the microspheres.

15	Silylated with 100% (v/v) trimethylchlorosilane by immersion		82.9	6.4

[a] Numbers represent percent of total radioactivity delivered from the aerosol. [b] Teflon; DuPont. [c] Bovine serum albumin. [d] Prosil-8; PCR Research Chemicals, Inc.

When the labeled microspheres were photographed[20] under a microscope[21] before and after the labeling process, it was found that their spherical geometry remained unaltered by the iodination procedure.

The labeled microspheres were introduced into an aerosol canister[11] (a plastic insert was used to decrease the fill volume), the propellant[13] was added, and the canister was crimped closed with the valve[14] in place. Leak tests in warm water provided proof of good crimps with no gas leaks, and the filled canisters were subsequently allowed to equilibrate to room temperature for 15 min before use in the experiments.

Experiments were devised to determine the reproducibility of each metered dose from the canister. The aerosol container was shaken; each actuation was collected in individual scintillation vials[16] lined with gauze and quantitated.

The percentage of the total radioactivity collected from each actuation is listed in Table I. In all three experiments, the first three actuations (necessary to prime the valve) had suboptimal amounts of solid particles, as indicated by the smaller amounts of radioactivity delivered. The last three doses also showed lower amounts of radioactivity. The total radioactivity released from the canister represented only 5% of the total quantitated. The majority of the activity was found in the valve. Several attempts were made to improve the delivery of the labeled microspheres from the aerosol canister. These included impregnation of the valve with (*a*) 2, 5, or 10% bovine serum albumin in phosphate buffer, (*b*) 4 or 10% Tween 80 in phosphate buffer, and (*c*) 1% organosilane[22] in dioxane, methanol, or distilled water. The best results (Table II) were obtained when the valve was impregnated with 2% bovine serum albumin in phosphate buffer. A total of 0.4 mL was applied directly into the valve, and it was allowed to air dry at room temperature for 1 h before use. Approximately 50% of the total activity was found in the valve after the albumin pretreatment, indicating an improvement in delivery of the labeled microspheres of ~40%.

The amount of protein present in unlabeled microspheres delivered from the aerosol canister was determined using the ninhydrin assay (4.31 mg), indicating that ~20% had been actuated out of an untreated aerosol container. This value is higher than the reported value of 5% for the radiolabeled microspheres released from the canister by acutating the valve. Further experiments with (a) labeled microspheres and propellant, (*b*) unlabeled microspheres, [^{131}I]NaI, and propellant, and (*c*) [^{131}I]NaI and propellant demonstrated that iodine-131 alone was not responsible for the activity present in the valve assembly, but the iodinated microspheres represented the radioactive species quantitated.

To determine the particle size distribution of the aerosol, a cascade impactor[17] was utilized. Either 2 or all 20 actuations (metered doses) were passed through a cascade impactor[17] subjected to a vacuum of 18 psi[18]. Due to the aerodynamic design of this particle size analyzer, the microspheres exhibited a size distribution profile as shown in Table III. Stage 1, with the largest opening, collected the heaviest or largest particles, whereas stage 6 collected those particles which traveled the fastest, that is, the smallest particles. The size determination provided by the cascade impactor[17] showed that the majority of particles (stages 3-5, Table III), had sizes ranging from 2 to 8 μm.

Dismantling of the emptied canister and quantitation of the residual radioactivity constituted the final aspect of the study. The valve was removed from the canister and separated into six component parts. Approximately 90% of the total radioactivity in the aerosol container was found in the valve[14], with the spring accounting for the highest amount counted (95%). Impregnation of the valve decreased the amount of radioactivity in the spring to 46%. Radioactivity was also present in the plastic[12] insert, and direct counting of the insert with the residue present led to quantitation of the particles that had not been aerosolized (2-10%).

The major drawback in this study was the tendency of the ^{131}I-labeled albumin microspheres to adhere to the various components of the aerosol container. A substantial amount of the total radioactivity was located in the valve apparatus, and therefore, this type of suspended microsphere aerosol system is not practical for drug delivery. However, the data obtained concerning the quantitation of metered doses and the determination of size distribution of particles illustrate the usefulness of tracer methodology in aerosol research.

Table I shows that reasonably equal doses can be delivered in actuations 5-16. The first four primer doses delivered lesser quantities of the formulation. This is probably due to the fact that these primer doses rid the valve of any water in the stem after the leak test and fill the valve chamber with the propellant. The last three doses shown are also smaller. As the pressure decreases, the quantity of particles delivered becomes less because the weight of the microspheres is too great for the amount of propellant remaining.

In the particular valve system utilized, each metered dose delivered is 65 μg. Therefore, determination of a single dose by the conventional weighing-by-difference method would be difficult.

Table III—Determination of Particle Size Distribution Profile of Microspheres Delivered from an Aerosol [a]

Cascade Impactor Stage	Known particle Size Impacted, μm	Particle size, % of total [b] Experiment 1	Particle size, % of total [b] Experiment 2
1	32	15.18	16.59
2	16	9.14	11.30
3	8	23.02	24.06
4	4	24.59	17.42
5	2	14.73	15.80
6	1	9.21	10.59
Filter paper	0.5	4.14	4.24

[a] Data were obtained from ^{131}I-labeled microaggregated albumin microspheres pulled through a cascade impactor with 18 psi pressure applied by two in-line vacuum pumps. [b] Values listed are percentages of total radioactivity recovered on all six glass slides of the impactor plus the filter paper at the bottom of the cascade impactor.

[21] Reichert microscope, Vienna, Austria.
[22] ProSil-8; PCR Research Chemicals, Inc., Gainesville, Fla.

The variability of the amount delivered per actuation could be due to inadequate shaking of the aerosol container. The method of collection of the labeled microspheres could also cause the valve stem to be blocked, thus detrimentally affecting the results.

The cascade impactor, which was used to delineate the particle size distribution profile, showed that the majority of microspheres had sizes ranging from 2 to 8 μm. The size profile seen in Table III lists microspheres with sizes greater than the reported prepared size of 3 to 8 μm, indicating aggregation of the smaller particles into heavier larger clusters. These aggregates were deposited onto the glass slides of the first two stages of the impactor, as dictated by the aerodynamic parameters of this particle-size analyzer. Again, the radiotracer method proved superior to the classical weighing-by-difference procedure for quantitation of the amount of particulate matter present on each slide after only one actuation of the aerosol.

The deposition of the microspheres onto the components of the valve constituted the final portion of this study. Untreated valves permitted the release of ~5–10% of the total radioactivity. By pretreating the valves with albumin solutions, the adherence of the iodinated albumin microspheres to the plastic parts of the valve and the metal spring was significantly decreased. The delivery of the activity from the treated canister, however, was found not to exceed 50% of the total dose. These results indicate that much more work must be done before microspheres utilized as a drug delivery system can be released effectively from present aerosol canisters.

CONCLUSIONS

The advantages of radiotracer methodology described in the study of aerosols are multifold: (*a*) single doses of an aerosol delivered from a canister can be analyzed, rather than multiple doses as required in previous studies, (*b*) short-lived isotopes can be disposed of easily after the passing of an appropriate decay period, and (*c*) by proper choice of the radionuclide label, rapid and accurate data may be obtained both in *in vivo* and *in vitro* studies. Since aerosols are designed to deliver a metered amount of drug to the patient, the elucidation of the size of the dose and its deposition in the patient is an important consideration. The technique outlined here should prove to be useful in answering these problems.

Effects of Solvent Medium on Solubility III: Hydrophilic–Lipophilic Character Exhibited by Some Functional Groups Having Oxygen or Nitrogen in Ethanol–Water

RUBEN H. MANZO ˣ, AMELIA A. AHUMADA, and ERNESTINA LUNA

Received August 12, 1981, from the *Departamento de Farmacia, Facultad de Ciencias Químicas, Universidad Nacional de Córdoba, Sucursal 16, CC 61, 5016 Córdoba, Argentina.* Accepted for publication June 16, 1983.

Abstract □ Solubility data of nine derivatives of the structure p-X_1—C_6H_4—X_2 in ethanol-water at 25°C are reported. The correlation of such sets of data by $\log S_y = P_y \cdot \log S_x + C$ yields the medium effect parameter P_y for a variety of functional groups possessing either oxygen or nitrogen. P_y accounts for the hydrophilic-lipophilic character exhibited by each group.

Keyphrases □ Solubility—effects of solvent medium, hydrophilic-lipophilic character, ethanol-water □ Solvent medium—effects on solubility, hydrophilic-lipophilic character, ethanol-water □ Hydrophilic-lipophilic character—effects of solvent medium, solubility, ethanol-water

The existence of linear relationships between the logarithms of the solubility equilibria of structurally related crystalline compounds, as they vary with changes in solvent or solvent composition has been shown previously (1, 2). Such linear free energy relationships (LFER) are conveniently expressed by:

$$\log S_y = P_y \cdot \log S_x + C \qquad \text{(Eq. 1)}$$

where S_y and S_x are sets of solubility data of compounds A_y and A_x, respectively. By taking a proper solvent condition as reference, Eq. 1 becomes:

$$\log S_y - \log S_y^0 = P_y(\log S_x - \log S_x^0) \qquad \text{(Eq. 2)}$$

or

$$\Delta\log S_y = P_y \cdot \Delta\log S_x \qquad \text{(Eq. 3)}$$

The medium effect parameter P_y depends on the structural difference between A_y and A_x on the one side and on the effects of the solvent change on the solubility of the substrate series (*i.e.*, on the sign of Δlog S) on the other. To illustrate this point, Fig. 1 shows a typical LFER plot of a pair of p-aminobenzoic esters which pass through a solubility maximum when they move from the first to the last solvent condition. There, as the solvent system increases in lipophilicity, the solubility

The variability of the amount delivered per actuation could be due to inadequate shaking of the aerosol container. The method of collection of the labeled microspheres could also cause the valve stem to be blocked, thus detrimentally affecting the results.

The cascade impactor, which was used to delineate the particle size distribution profile, showed that the majority of microspheres had sizes ranging from 2 to 8 μm. The size profile seen in Table III lists microspheres with sizes greater than the reported prepared size of 3 to 8 μm, indicating aggregation of the smaller particles into heavier larger clusters. These aggregates were deposited onto the glass slides of the first two stages of the impactor, as dictated by the aerodynamic parameters of this particle-size analyzer. Again, the radiotracer method proved superior to the classical weighing-by-difference procedure for quantitation of the amount of particulate matter present on each slide after only one actuation of the aerosol.

The deposition of the microspheres onto the components of the valve constituted the final portion of this study. Untreated valves permitted the release of ~5–10% of the total radioactivity. By pretreating the valves with albumin solutions, the adherence of the iodinated albumin microspheres to the plastic parts of the valve and the metal spring was significantly decreased. The delivery of the activity from the treated canister, however, was found not to exceed 50% of the total dose. These results indicate that much more work must be done before microspheres utilized as a drug delivery system can be released effectively from present aerosol canisters.

CONCLUSIONS

The advantages of radiotracer methodology described in the study of aerosols are multifold: (*a*) single doses of an aerosol delivered from a canister can be analyzed, rather than multiple doses as required in previous studies, (*b*) short-lived isotopes can be disposed of easily after the passing of an appropriate decay period, and (*c*) by proper choice of the radionuclide label, rapid and accurate data may be obtained both in *in vivo* and *in vitro* studies. Since aerosols are designed to deliver a metered amount of drug to the patient, the elucidation of the size of the dose and its deposition in the patient is an important consideration. The technique outlined here should prove to be useful in answering these problems.

Effects of Solvent Medium on Solubility III: Hydrophilic–Lipophilic Character Exhibited by Some Functional Groups Having Oxygen or Nitrogen in Ethanol–Water

RUBEN H. MANZO ˣ, AMELIA A. AHUMADA, and ERNESTINA LUNA

Received August 12, 1981, from the *Departamento de Farmacia, Facultad de Ciencias Químicas, Universidad Nacional de Córdoba, Sucursal 16, CC 61, 5016 Córdoba, Argentina.* Accepted for publication June 16, 1983.

Abstract □ Solubility data of nine derivatives of the structure p-X_1—C_6H_4—X_2 in ethanol-water at 25°C are reported. The correlation of such sets of data by $\log S_y = P_y \cdot \log S_x + C$ yields the medium effect parameter P_y for a variety of functional groups possessing either oxygen or nitrogen. P_y accounts for the hydrophilic-lipophilic character exhibited by each group.

Keyphrases □ Solubility—effects of solvent medium, hydrophilic-lipophilic character, ethanol-water □ Solvent medium—effects on solubility, hydrophilic-lipophilic character, ethanol-water □ Hydrophilic-lipophilic character—effects of solvent medium, solubility, ethanol-water

The existence of linear relationships between the logarithms of the solubility equilibria of structurally related crystalline compounds, as they vary with changes in solvent or solvent composition has been shown previously (1, 2). Such linear free energy relationships (LFER) are conveniently expressed by:

$$\log S_y = P_y \cdot \log S_x + C \qquad \text{(Eq. 1)}$$

where S_y and S_x are sets of solubility data of compounds A_y and A_x, respectively. By taking a proper solvent condition as reference, Eq. 1 becomes:

$$\log S_y - \log S_y^0 = P_y(\log S_x - \log S_x^0) \qquad \text{(Eq. 2)}$$

or

$$\Delta\log S_y = P_y \cdot \Delta\log S_x \qquad \text{(Eq. 3)}$$

The medium effect parameter P_y depends on the structural difference between A_y and A_x on the one side and on the effects of the solvent change on the solubility of the substrate series (*i.e.*, on the sign of Δlog S) on the other. To illustrate this point, Fig. 1 shows a typical LFER plot of a pair of p-aminobenzoic esters which pass through a solubility maximum when they move from the first to the last solvent condition. There, as the solvent system increases in lipophilicity, the solubility

of the propyl ester A_y increases at a faster rate (part B, ethanol-water) and decreases more slowly (part A, ethanol-cyclohexane) than that of the methyl ester A_x, as a result of its greater lipophilic portion.

In this study, the purpose has been to use this methodology to get information about the hydrophilic-lipophilic properties of a variety of functional groups possessing either oxygen or nitrogen. These were selected because the information available, mainly obtained from partition coefficient (PC) measurements, regards the high sensitivity of the properties of these atoms to the structural environment (3, 4). Hence, a set of oxygen and nitrogen analogues was obtained by the appropriate variation of the basic structure p-X_1 —C_6H_4—X_2 as indicated in Table I, and their solubility equilibria were measured in hydroxylic mixtures. In such systems, the specific solute-solvent interactions through hydrogen bridges are recognized to play a major role among the factors that determine the solubility behavior of the substrates.

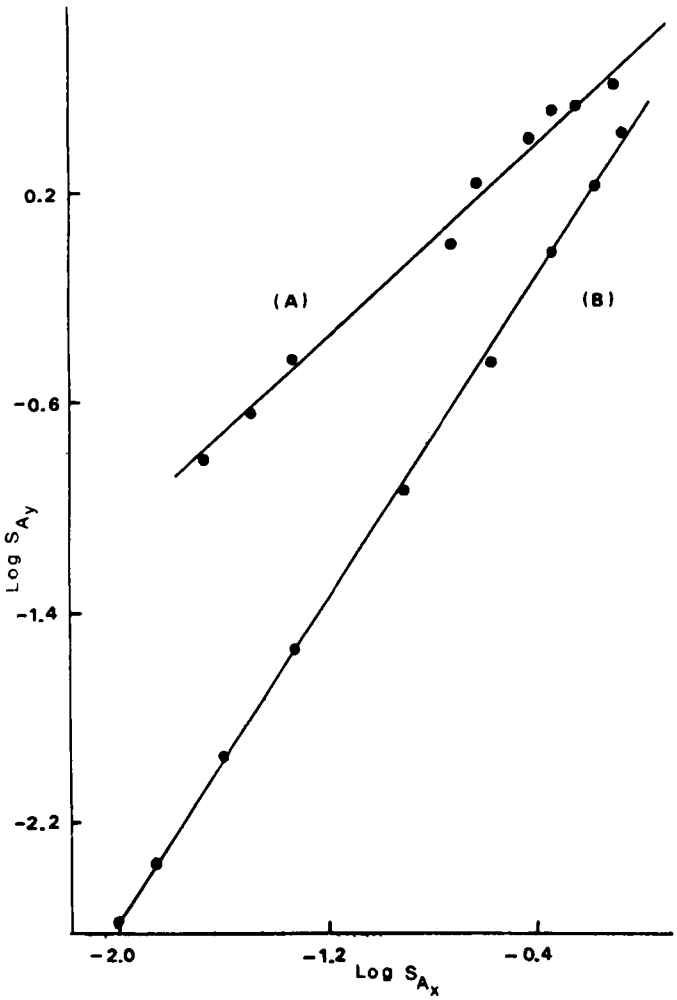

Figure 1—*LFER plot of propyl ester (A_y) and methyl ester (A_x) of* p-*hydroxybenzoic acid in ethanol-water (B) and ethanol-cyclohexane (A); data taken from Ref. 2.*

EXPERIMENTAL SECTION

Substrates—The calculated and literature melting points (mp) of all derivatives are reported in Table I. The following compounds were commercial products, purified by recrystallization: I[1], III[2], IV[2], and VII[2]. Compounds II, V, VI, VIII, and IX were prepared by adequate structural variation of the available derivatives through known techniques (5-7). All products were characterized by their melting points. In addition, for II and VIII, it was considered appropriate to report ^{1}H-NMR[3] and MS[4] data.

Solvents—Mixtures were prepared by mixing exactly measured volumes of absolute ethanol and water, *i.e.*, ethanol-water (40:60).

Solubility Determination and Correlation Procedure—The method employed for the solubility measurements was reported previously (1, 2). For all compounds, a spectrophotometric determination of substrate concentration at λ_{max} was performed. From the values of Table II, the corresponding molalities were calculated, and their logarithms were used in the correlations. The linear regression parameters reported in Table III were calculated by the least-squares method.

RESULTS AND DISCUSSION

Table II reports the solubility of I-IX in ethanol-water mixtures at 25°C. At low solubility conditions, small changes in solvent composition produce significant solubility variations; on the other hand, the lower the substrate

[a] r is the regression coefficient, δ_{sl} is the standard deviation of the slope, and δ_y is the standard deviation of the points from the regression line in the y direction.

concentration, the lower the probability of particular solute–solute interactions. Therefore, to correlate solubility data by Eq. 1, those values corresponding to lower solubilities are preferred to the ones obtained under conditions of higher solubility—near the maximum solubility. A composition variation covering 0–70% of ethanolic content was considered appropriate.

Going from water to ethanol through a series of ethanol-water mixtures, the increase of the ethanolic content increases the lipophilic character of the mixture and raises the solubility of all the substrates studied [(+)$\Delta\log S$]. For a given correlation, a medium effect parameter P_y higher or lower than the unity means that A_y is respectively more lipophilic or hydrophilic than A_x.

Table III reports the results obtained by the correlation according to Eq. 1 when adequately selected pairs of compounds were matched together. As can be seen, good linear correlations were obtained in all cases affording the corresponding P_y parameters.

To get a uniform set of P_y values, the hydrogen atom attached to the aromatic ring was taken as the reference functional group ($P_{yH} = 1$). When direct calculation was not possible, the following procedure was used:

$$P_y = \Delta\log S_{Ar-Y}/\Delta\log S_{Ar-X} \qquad \text{(Eq. 4)}$$

and

$$P_x = \Delta\log S_{Ar-X}/\Delta\log S_{Ar-H} \qquad \text{(Eq. 5)}$$

Table IV—Hydrophilic–Lipophilic Character of Different Functional Groups Attached to the Benzene Ring

Functional Group	$(P_y^H - 1)$	π
$-CONHCH_3$	−0.33	
$-NH_2$	−0.28	−0.49[a]
CH_3COO-	−0.26	−0.58[b]

$-COO(CH_2)_2CH_3$	1.04	1.57[c]

[a] Calculated from log PC (octanol-water) of I (1.63) and VII (1.96), respectively, using as reference log PC of benzoic acid methyl ester (2.12); all data from Ref. 3. [b] Values from Ref. 13. [c] Calculated respectively from log PC of VII or log PC of *p*-hydroxybenzoic acid propyl ester using as reference log PC of phenol; all data from Ref. 3. [d] Concerned with the extension of the alkyl chain. The random value of P_y arises from propyl and methyl esters of both *p*-hydroxy- and *p*-aminobenzoic acids (2), while π is the difference between $\pi_{-COO(CH_2)_2CH_3}$ and π_{-COOCH_3}.

then

$$P_y^H = P_y \cdot P_x = \Delta\log S_{Ar-Y}/\Delta\log S_{Ar-H} \qquad \text{(Eq. 6)}$$

Table IV contains the calculated hydrophilic-lipophilic character of each functional group, which is expressed as $(P_y^H - 1)$. There, a negative value means higher hydrophilic character, while a positive value indicates higher lipophilic character than hydrogen.

Therefore, the inspection of the figures in Table IV reveals the higher hydrophilicity of the aromatic primary amino group with respect to the phenolic hydroxy group, while the respective acetyl derivatives exhibit a reverse order. However, the comparison of the aryl carboxy derivatives (*i.e.*, I and II) again shows a remarkably higher hydrophilic character of the nitrogenated derivative. On the other hand, the methoxy group appears to be more hydrophilic than the fully methylated tertiary amino.

The use of $(P_y^H - 1)$ is a convenient way to express the hydrophilic-lipophilic properties of the functional groups since, as it has been previously stated (1), it is directly related to the expected PC parameter π'_y by:

$$P_y - 1 = \frac{\Delta\log S_y - \Delta\log S_x}{\Delta\log S_x} = \frac{\pi'_y}{\Delta\log S_x} \qquad \text{(Eq. 7)}$$

π'_y has also been regarded as a lipophilic variable (1) whose meaning extends the concept of the lipophilic constant π (3) and hydrophobic constant (14) which arise from partition coefficient measurements.

In addition, Table IV also contains literature values of π for the octanol-water partitioning system, which also consists of two hydroxylic solvents. Because inspection of the columns suggests a parallel variation of both sets of figures, it was considered of interest to match them together in a plot. Therefore, Fig. 2 shows the agreement between the results obtained from medium effects on solubility in ethanol-water mixtures and those obtained from octanol-water partition coefficients.

The results quoted show how LFER applied to solubility equilibria measurements yields reliable information about the hydrophilic-lipophilic properties of different functional groups. It appears that this simple methodology would be a useful and versatile tool to extend our present knowledge of solubility behavior to a wide variety of solvent systems. In addition, the use of Eqs. 2–7 as a means of predicting medium effects on solubility appears to be attractive for the pharmaceutical sciences.

Acute Intravenous Infusion of Disodium Dihydrogen (1-Hydroxyethylidene)diphosphonate: Mechanism of Toxicity

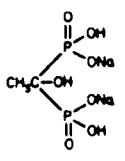
MARION D. FRANCIS ˣ **and CANDICE L. SLOUGH**

Received September 20, 1982, from the *Miami Valley Laboratories, 2N142, Proctor & Gamble Co., Cincinnati, OH 45247.* Accepted for publication July 26, 1983.

Abstract □ The acute intravenous toxicity of disodium dihydrogen (1-hydroxyethylidene)diphosphonate (etidronate disodium; I) and the mechanism of this toxic response have been investigated in 40 beagle dogs. The intravenous toxicity of I is dependent on the total dose administered and the length of the infusion interval. The toxicity of I is directly related to the ability of the drug to bind or complex with the circulating calcium in the blood. Maximum depressions in ionized calcium coincide in time with peak blood levels of I, and at lethal doses electrocardiographic changes indicative of hypocalcemia are observed. For a 2-min infusion of 2 mg of I/kg, no effect is observed on ionized calcium levels, and the electrocardiogram remains normal. At doses of 16 and 32 mg/kg, coincident with an immediate fall in ionized calcium levels, there is a transient rise in total calcium and a fall in phosphorus levels. The ionized calcium level rises, and total calcium level falls and stabilizes at baseline levels within 30 min after the infusion. However, the phosphorus level rises and exceeds the baseline value, reaching 3-4 times normal by 72 h after the infusion. With proven lethal doses of I (60 mg/kg infused over 2 min) and the simultaneous infusion of an ionized calcium salt such as calcium gluconate (20 mg of Ca^{2+}/kg), electrocardiograms remain normal and death is prevented. Thus, an effective antidote in the event of an overdose or too rapid an infusion of I can be employed to prevent acute toxic effects.

Keyphrases □ Etidronate disodium—hypercalcemia, intravenous toxicity, dogs □ Hypercalcemia—treatment with etidronate disodium and calcium gluconate, toxicity, dogs □ Calcium gluconate—hypercalcemia, use with etidronate disodium, dogs

Disodium dihydrogen (1-hydroxyethylidene)diphosphonate (etidronate disodium; I) is a substance which has both therapeutic (1-4) and diagnostic (5, 6) uses in metabolic bone disease. Clinically, the ability of orally administered drug[1] to reduce elevated bone turnover prompted speculation that the drug might be used intravenously to control other disease processes such as hypercalcemia secondary to malignancy or hyperparathyroidism. Studies to examine physiological and pharmacological responses to varying intravenous doses of diphosphonates were therefore undertaken.



I

The mechanism of intravenous toxicity of I might be expected to be similar to that of ethylenediaminetetraacetic acid (II) and polyphosphate compounds (III) because of the chelating properties (7-10) of each of these compounds. However, I differs from II and III in several respects, which could markedly alter its effect on calcium homeostasis.

At physiological pH, I is a less-effective simple chelator of calcium than II and, unlike II, forms polynuclear complexes (11) which can reach molecular weights of ≥20,000. There is some evidence for this formation *in vivo*, but their biological activity is unknown. In addition, I is cleared from the blood both by adsorption on the hydroxyapatite of bone (12) and by renal clearance, whereas II is cleared only by renal excretion. There are also differences in the p*K* values of I, II, and III. Furthermore, although III are adsorbed on hydroxyapatite like I, III are rapidly hydrolyzed *in vivo* to the natural orthophosphate metabolites (HPO_4^{2-}, $H_2PO_4^-$), while I is not metabolized (13). Based on the above differences, the present study was undertaken to establish a broader safety profile for I by clearly defining the acute intravenous toxicity of I and demonstrating the relationship between acute intravenous toxicity, serum ionized and total calcium levels, and diphosphonate blood levels. Subsequent to these studies, intravenously administered I and another diphosphonate (dichloromethylenediphosphonate) have been shown to effectively reduce hypercalcemia associated with malignant disease and hyperparathyroidism in humans (14-18).

EXPERIMENTAL SECTION

Purebred adult male and female beagle dogs weighing 5.7-13.9 kg were used in four experiments. It was necessary to conduct the initial studies in unanesthetized animals to ensure that no signs or symptoms of toxicity were masked by the anesthetic. However, in subsequent experiments, animals receiving toxic doses of I were anesthetized with sodium pentobarbital unless its use was contraindicated.

There is some evidence for this formation *in vivo*, but their biological activity is unknown. In addition, I is cleared from the blood both by adsorption on the hydroxyapatite of bone (12) and by renal clearance, whereas II is cleared only by renal excretion. There are also differences in the p*K* values of I, II, and III. Furthermore, although III are adsorbed on hydroxyapatite like I, III are rapidly hydrolyzed *in vivo* to the natural orthophosphate metabolites (HPO_4^{2-}, $H_2PO_4^-$), while I is not metabolized (13). Based on the above differences, the present study was undertaken to establish a broader safety profile for I by clearly defining the acute intravenous toxicity of I and demonstrating the relationship between acute intravenous toxicity, serum ionized and total calcium levels, and diphosphonate blood levels. Subsequent to these studies, intravenously administered I and another diphosphonate (dichloromethylenediphosphonate) have been shown to effectively reduce hypercalcemia associated with malignant disease and hyperparathyroidism in humans (14-18).

EXPERIMENTAL SECTION

Purebred adult male and female beagle dogs weighing 5.7-13.9 kg were used in four experiments. It was necessary to conduct the initial studies in unanesthetized animals to ensure that no signs or symptoms of toxicity were masked by the anesthetic. However, in subsequent experiments, animals receiving toxic doses of I were anesthetized with sodium pentobarbital unless its use was contraindicated.

Electrocardiography—Electrocardiograms were obtained according to standard procedures (19) on an electrocardiograph unit[2]. Serial six-lead electrocardiograms were obtained immediately prior to dosing and at 5, 10, 15, and 60 min after the start of the infusion. In all experiments, a continuous lead II electrocardiogram was obtained during and for 1–3 min after the start of the infusion.

Infusions—Indwelling catheters[3] were inserted percutaneously into the cephalic vein to facilitate infusions. Dose solutions were delivered manually from a syringe. In the "rescue" study, I was infused into one cephalic vein, and the calcium solution was infused simultaneously into the other cephalic vein.

Dose Solutions—All solutions of I were prepared in sterile distilled water and adjusted to pH 7.4. Solutions were filtered[4] (0.22 μm) into sterile serum bottles. The concentrations of the dose solutions varied with the intended dose level. The diphosphonate concentrations employed were (x to y mg of I/mL, z mg/kg): 1.9 to 4.0, 2; 5.7 to 5.8, 4; 14.5 to 14.7, 8; 27.0 to 32.0, 16; 38.3 to 49.4, 28; 41.1 to 64.0, 32; and 52.8 to 58.4, 37 and 44, and 55.3, 60.

Ten percent calcium gluconate for injection[5] was used as supplied; the concentration of calcium was 9.2 mg/mL. Physiological saline[6] was used as the control infusion solution.

Experiment I—Part 1 of experiment I was designed to determine the acute toxicity of I when doses of 2, 4, 8, 16, and 32 mg of I/kg (two dogs per dose level) were administered intravenously over a 15-s interval. Six males and four females were used. Part 2 of experiment I was a determination of the acute toxicity of I using doses of 2, 4, 8, 16, 28, 37, and 44 mg of I/kg (two dogs per dose level) administered intravenously over a 2-min interval. Nine males and five females were used. These two studies were designed to examine the toxic effects and influence of the duration of the infusion on the toxicity of intravenously administered I.

Experiment II—This experiment was designed to examine the relationship between diphosphonate blood levels and the physiological response to three nonlethal dose levels (2, 16, and 32 mg of I/kg) administered intravenously over a 2-min interval. Six dogs (one male and one female per dose level) were used. In this experiment silicone rubber cannulas were surgically implanted into the jugular vein on the day prior to the infusion to facilitate serial blood sampling. The cannulas were kept patent with heparinized saline (125–250 U/mL).

The diphosphonate dose solution was labeled with carbon-14 in the 1-position, [^{14}C]I, so that the diphosphonate blood level could be monitored by standard radioassay procedures using a scintillation fluid[7]. Total calcium and total orthophosphate were analyzed on an autoanalyzer. Calcium was determined using calcein (20), phosphorus was determined colorimetrically (21), and ionized calcium was determined with a calcium electrode. Serial blood samples were collected immediately prior to the start of the infusion and then at the following intervals: 0.5, 1, 1.5, 2, 3, 5, 10, 15, and 30 min, 1, 2, 4, 24, 48, and 72 h, and 1 week. All analyses were performed on the serum.

Experiment III—A calcium "rescue" experiment was designed to determine if the effects of a lethal intravenous dose of I could be prevented by the simultaneous intravenous infusion of an ionized calcium salt. Preliminary infusions using two dogs (one male and one female) confirmed the lethality of 60 mg of I/kg administered over a 2-min interval. Two other dogs (one male and one female) received only calcium gluconate at 20 mg of Ca^{2+}/kg in order to determine generalized and electrocardiographic responses to 2-min infusions of an ionized calcium salt. Subsequent to the above, two female dogs received infusions of 60 mg of I/kg simultaneously with calcium gluconate (20 mg of Ca^{2+}/kg) over a 2-min interval.

Experiment IV—This experiment served as a control for the preceding series of experiments. Four dogs (two males and two females) received 2-min intravenous infusions of physiological saline.

General Reactions and Anesthesia—The reactions of the dogs to infusions of I were monitored by continuous observation during and immediately after the infusion, and daily for up to 2 weeks. These data were considered important in defining the potential hazards of intravenous administration of I in humans.

Sodium pentobarbital decreases respiration and may affect the cardiovascular system such that the electrocardiogram and distribution of I would be altered (22–24); therefore, anesthesia was not employed in experiments I and II. Having established the relationship between calcium and I in the blood, and the coincident electrocardiographic changes in the conscious dog, dogs receiving lethal doses of I were anesthetized for experiment III.

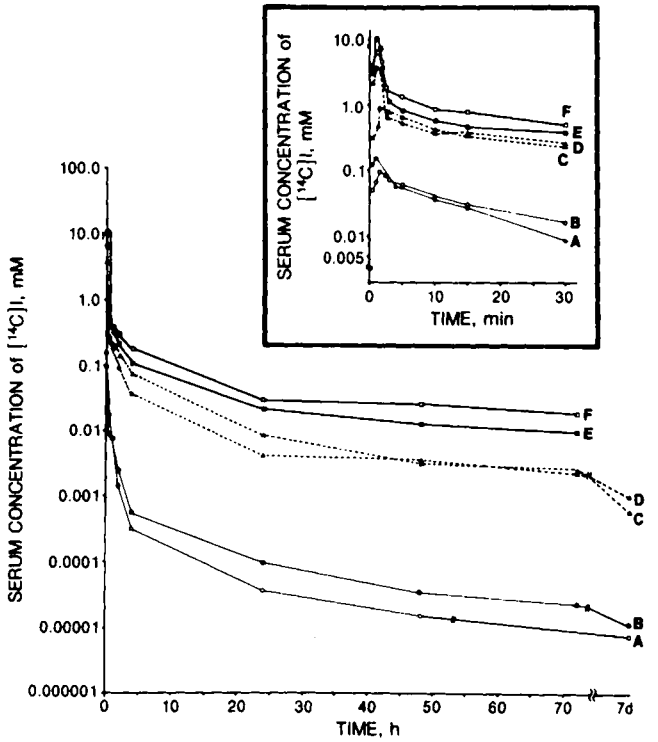

Figure 1—*Concentration of [^{14}C]I in the serum of dogs during and after 2-min intravenous infusions of 2 (A,B), 16 (C,D), and 32 (E,F) mg of [^{14}C]I/kg. Inset shows the first 30 min during and after the infusion.*

RESULTS

Acute Toxicity Studies (Experiment I)—*15-s Infusions*—No drug-related electrocardiographic effects were observed during or after infusions of 2–8 mg of I/kg. At a dose level of 16 mg/kg, an increased respiratory rate and a transient increase in heart rate were observed in both dogs during the infusion. The heart rate returned to normal within 5 min after the start of the infusion. Daily observations, lasting up to 2 weeks, did not reveal adverse effects in dogs receiving up to 16 mg/kg. At a dose level of 32 mg/kg, clonic contractions preceded death, which was observed in both dogs as a cessation of respiration. Electrocardiographically, both animals receiving 32 mg of I/kg developed lethal ventricular arrhythmias within 2–3 min after starting the infusion; tachycardia, QT prolongation, heart block, premature ventricular contractions, and finally, ventricular fibrillation were noted sequentially in both dogs.

2-min Infusions—No significant electrocardiographic effects were observed during or after infusions of 2–8 mg of I/kg. At doses of 16 or 28 mg of I/kg, transient tachycardia was the only consistent electrocardiographic effect and, in all dogs, the heart rate had returned to normal within 5 min after the start of the infusion. As the dose level increased to 37, and finally to 44, mg of I/kg, the dogs resisted restraint and electrocardiographic changes became evident. Electrocardiographically, slight, persistent sinus tachycardia occurred at a dose level of 37 mg of I/kg. Dogs that received 44 mg of I/kg exhibited severe, persistent tachycardia, T waves of increased magnitude, prolonged QRS intervals, ST segment elevation, and premature ventricular contractions. At a dose level of 44 mg of I/kg, one of the two dogs died.

Physiological Response to Nonlethal Doses of I (Experiment II)—*2-min Infusion*—The electrocardiograms of dogs receiving 2 mg of [^{14}C]I/kg appeared essentially normal. At a dose of 16 mg of [^{14}C]I/kg there was a transient increase in heart rate and a prolongation of the QT interval in both dogs. Within 5 min after start of the infusion, these had returned to normal (predose) values. At 32 mg of [^{14}C]I/kg a predominant sinus tachycardia and a prolongation of the QT interval occurred in both dogs. In one dog, these had returned to normal within 5 min, but in the other dog the tachycardia persisted for 30 min. In the latter dog, premature ventricular contractions were observed between 2 and 3 min after the start of the infusion. In dogs receiving 32 mg of I/kg, respiratory rates increased and the dogs resisted restraint. These reactions were absent within 1 min after cessation of the infusion. No toxic symptoms were observed the day after infusion in any dog, and all dogs survived.

Diphosphonate, Total and Ionic Calcium, and Total Phosphorus Levels in Serum—The peak [^{14}C]I serum levels occurred for all dose levels within the 2-min infusion interval and then decreased exponentially (Fig. 1). The

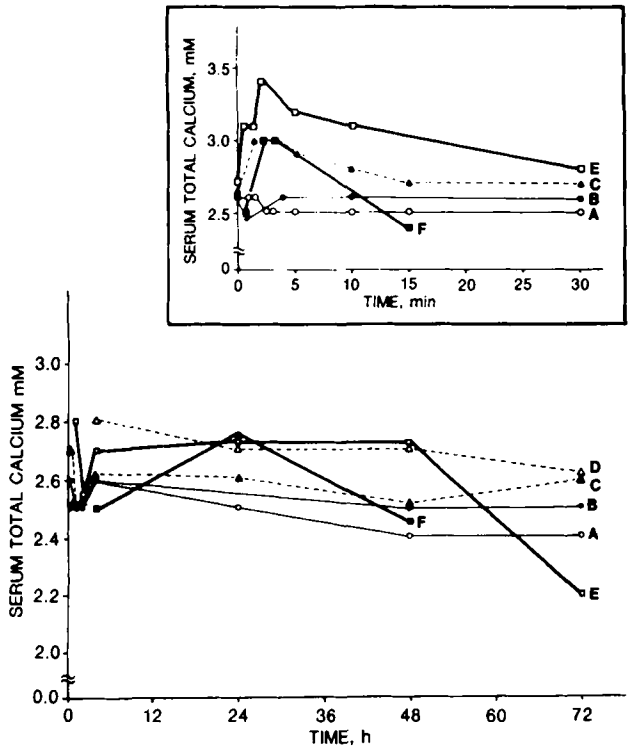

Figure 2—*Concentration of total calcium in serum of dogs during and after 2-min intravenous infusions of 2 (A,B), 16 (C,D), and 32 (E,F) mg of [^{14}C]-I/kg. Inset shows the first 30 min during and after the infusion.*

highest peak serum concentration achieved at each dose level was: 0.15 mM (2 mg of [^{14}C]I/kg), 3.8 mM (16 mg of [^{14}C]I/kg), and 10 mM (32 mg of [^{14}C]I/kg).

At the two highest dose levels (16 and 32 mg of [^{14}C]I/kg) total serum calcium increased 0.4–0.7 mM within 5 min after the start of infusion (Fig. 2), while serum phosphorus for these same animals decreased 0.2–0.5 mM within 15 min (Fig. 3). There was a decrease in ionic calcium within the 2-min infusion interval that was proportional to the serum [^{14}C]I level (Fig. 4). For example, the highest [^{14}C]I serum level (10 mM) corresponded to the lowest

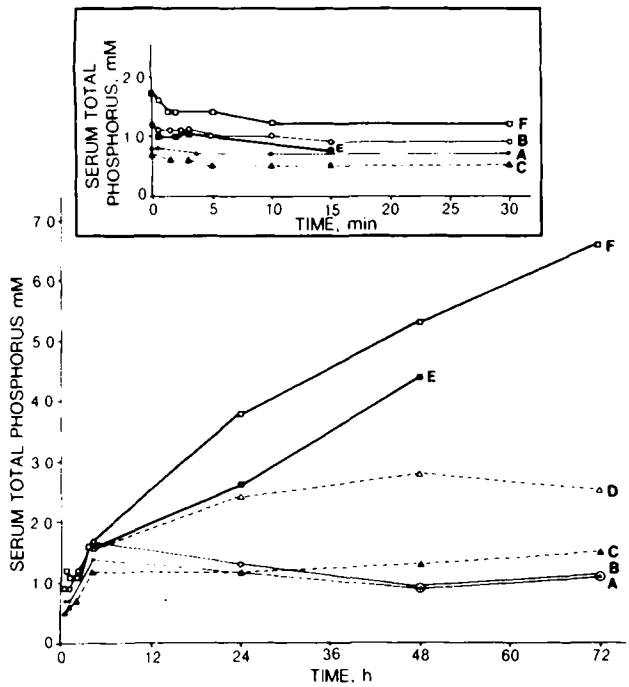

Figure 3—*Concentration of serum orthophosphate in dogs during and after 2-min intravenous infusions of 2 (A,B), 16 (C,D) and 32 (E,F) mg of [^{14}C]I/kg. Inset shows the first 30 min during and after the infusion.*

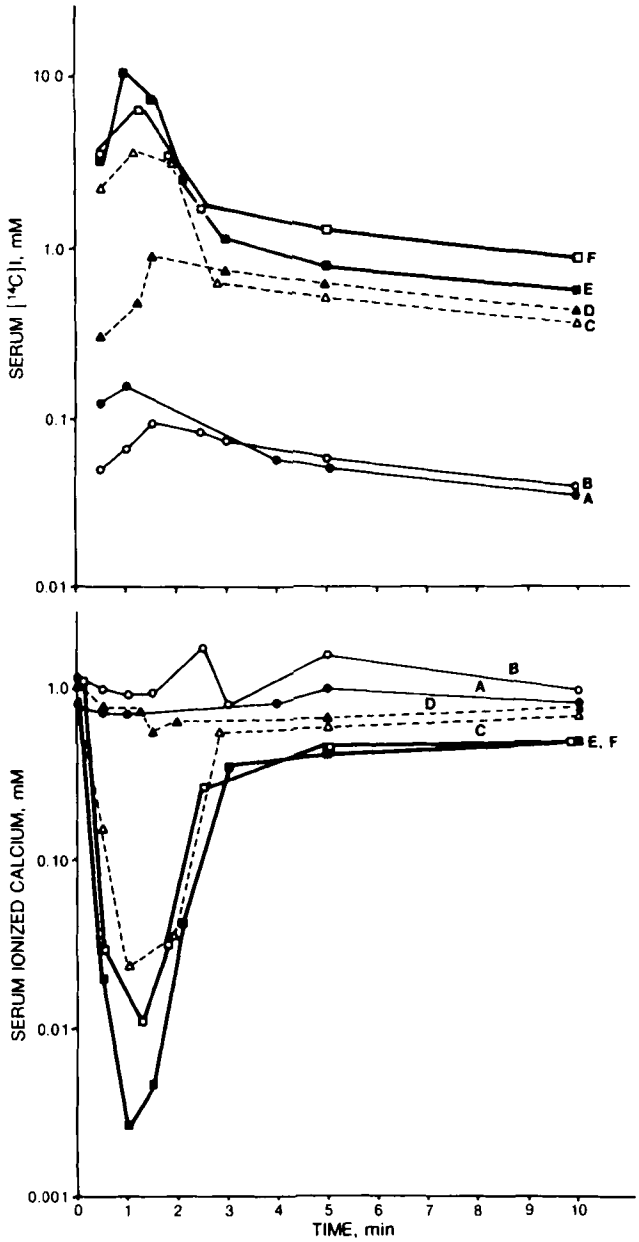

Figure 4—*Concentration of [^{14}C]I and of ionized calcium in the serum of dogs during and after 2-min intravenous infusions of 2 (A,B), 16 (C,D), and 32 (E,F) mg of [^{14}C]I/kg.*

ionized calcium level attained (0.001 mM). The lowest [^{14}C]I blood levels were achieved with a dose of 2 mg of [^{14}C]I/kg and did not alter the baseline ionized calcium (~1 mM). In dogs receiving the two highest levels of bisphosphonate, ionized calcium fell precipitously and then rose rapidly to normal levels within 5 min after the start of the infusion (Fig. 4), while total calcium, after increasing, did not return to normal levels until ~30 min after the start of the infusion (Fig. 2). In these same dogs, serum phosphorus (as orthophosphate) showed a progressive and steady increase (Fig. 3) up to 72 h after the start of infusion (up 5.4 mM). In the dog which exhibited the greatest increase in serum phosphorus, there was a concomitant decrease in both total and ionized calcium at the 72-h evaluation.

Calcium "Rescue" (Experiment III)—Both dogs infused with 60 mg of I/kg died. Within 1 min after initiation of the infusion, tachycardia was evident in both dogs. Electrocardiographic changes were similar to those which occurred with lethal doses in experiment I. Infusions of calcium gluconate, on the other hand, were associated with emesis and transient electrocardiographic changes consistent with hypercalcemia.

Animals that received a combination of I and calcium gluconate did not display any significant electrocardiographic effects during the first 5 min of the experiment. Sinus tachycardia was observed in one dog 1 h postdose. Negative P waves and second degree atrioventricular block were observed in the other dog through the 15-min tracing, but this arrhythmia was absent in

the 1-h tracing. The dogs that received I plus calcium gluconate appeared normal during the 2-week postdose observation period.

Control Infusions (Experiment IV)—No general reactions were observed in response to 2-min intravenous infusions of saline. No significant electrocardiographic changes were observed in these dogs.

DISCUSSION

The intravenous administration of high doses of I can produce rapid death; however, the toxic effect is both time and dose dependent. The lethal toxicity of I relates directly to the concentration of I achieved in the blood. Identical doses administered over a shorter period of time produce a higher blood concentration and result in higher toxicity.

The toxicity of I is directly related to its ability to bind or complex with the circulating calcium of the blood. For a given infusion interval, when the intravenous dose of [^{14}C]I was increased, the concentration in the blood rose proportionally (Fig. 1). At the two highest dose levels (16 and 32 mg of [^{14}C]I/kg), the concentration of ionized calcium in the blood fell, with the maximum depressions of ionized calcium coinciding in time with the peak blood levels of [^{14}C]I (Fig. 4). The ionized calcium returned rapidly to near-normal concentrations within 5 min, despite the significant concentration of I beyond this time. The use of electrocardiography during infusions of increasing diphosphonate doses was found to be a useful diagnostic tool for detecting progressive signs of increasing cardiotoxic effects. The electrocardiographic effects observed at the high dose levels of I are consistent with depressions in ionized calcium and indicate the sensitivity of heart muscle to low ionized calcium levels, in spite of elevations in total calcium (Fig. 2). No effect on ionized calcium levels was seen at the 2-mg/kg dose of I administered over a 2-min interval, and no significant electrocardiographic changes were observed in these dogs.

The rise in total calcium observed with high parenteral doses of I (Fig. 2) has been observed previously (25). For the animals showing the greatest rise in total calcium, serum phosphorus fell (Fig. 3). The rise in total calcium reflects mobilization of calcium to satisfy ionized calcium homeostasis in the blood. The fall in serum phosphorus levels probably does not relate to the rise in total calcium since ionized calcium fell. The fall in phosphorus is probably effected by stimulation of parathyroid hormone release (26) with consequent clearance of phosphorus by the kidneys. After returning rapidly to normal (as did the total calcium and ionized calcium levels), serum phosphorus increased slowly and steadily above normal for up to 72 h after the infusion (Fig. 3), reaching a maximum level that was 3–4 times normal in dogs receiving the highest dose of I. This delayed and elevated serum phosphorus level has been observed on numerous occasions in humans given high daily oral doses of I (20 mg of I/kg), and is attributed to an increased tubular reabsorption of orthophosphate by the kidney (27).

The lethal effects (depression in ionized calcium) of the very high doses of I can be overcome by simultaneous infusion of an ionized calcium salt, such as calcium gluconate. Similar studies with another diphosphonate (disodium dichloromethylenediphosphonate) have confirmed this "rescue" effect[8]. In these studies, calcium gluconate maintained normal serum ionized calcium, while total calcium rose above normal until shortly after the infusion period. In the present study, in the absence of calcium gluconate, maximum depression in ionized calcium would be expected during the first 5 min after the start of infusion (see Fig. 4). During this period, electrocardiographic changes were observed but, with simultaneous infusion of calcium gluconate, normal electrocardiographic patterns were obtained. Calcium chloride can achieve the same effects as calcium gluconate[8], but the gluconate salt is preferred (28), since toxic effects of calcium administration have been reported and the chloride salt seems more toxic than the gluconate salt.

This series of studies describes the lethal and sublethal toxic responses of I administered over two infusion intervals. The studies define the dose levels of I which can be administered safely by intravenous injection. In addition, the studies provide insight into the mechanism of toxicity, and describe a means to prevent death associated with lethal doses of intravenously administered disodium dihydrogen (1-hydroxyethylidene)diphosphonate.

In Vitro Dehalogenation of *para*-Substituted Aromatic Halides in Rat Liver Preparations

M. T. SCOTT * and J. E. SINSHEIMER ˣ

Received December 27, 1982, from the *College of Pharmacy, The University of Michigan, Ann Arbor, MI 48109.* Accepted for publication August 4, 1983. *Present address: Analytical Research and Development, DuPont Pharmaceuticals, Garden City, NY 11530.

Abstract □ The *in vitro* dehalogenation of a series of *para*-substituted halobenzenes was studied using HPLC separation followed by scintillation counting or neutron-activation analysis. Microsomal and cytosolic deiodination were established for iodobenzene substrates whose *para*-substituents were CO_2H, CHO, NO_2, OH, and C_6H_5 but not for *para*-iodobenzonitrile. A nonglutathione cytosolic deiodinase was only indicated with 4-iodobiphenyl as the substrate. *In vitro* dehalogenation could not be established for 4-bromobiphenyl using neutron-activation analysis.

Keyphrases □ Dehalogenation—rat liver *in vitro* studies, microsomal, cytosolic □ Aromatic halides—effect of *para*-substitution on *in vitro* dehalogenation □ Glutathione—role in *in vitro* dehalogenation, *N*-ethylmaleimide inhibition

There has been considerable human exposure to aromatic halides due to their use in medicine as well as their widespread applications in industry and agriculture. In addition to the medicinal use of thyroxine and iodohydroxyquin preparations, acyl iodides have been employed as radiopaque diagnostic agents. Also, ^{131}I- or increasingly, ^{123}I-labeled aromatic iodides have been synthesized as potential tumor-imaging agents (1–4). Polychlorinated and polybrominated biphenyls are ubiquitous environmental pollutants with well-established toxicities (5–10).

The possibility of contact with these compounds is evident and has prompted numerous investigations, especially with the biphenyl compounds. *In vivo* dehalogenation plays a small but significant role in the metabolism of these compounds (11–13). Therefore, it was basic to an understanding of their potential toxicity to study the mechanism and extent of *in vitro* dehalogenation in the rat by direct measurement of liberated halide. *para*-Substituted aromatic halides labeled with iodine-125 or chlorine-36, or containing unlabeled bromine or chlorine, were chosen as the model compounds.

EXPERIMENTAL SECTION

Apparatus—The liquid chromatograph consisted of a microprocessor controller[1], two pumps[2], a dynamic-flow mixer[3], and an injection valve[4]. A reverse-phase C_{18} column[5] was used for radiohalide detection by either a radiochemical detector in a liquid scintillation mode[6] or by liquid scintillation counting[7] of the eluant. A cumene-based cocktail[8], at a flow rate of 3.0 mL/min, was used with the radiochemical detector, while a xylene-based cocktail[9] was used for liquid scintillation counting of the eluant.

Synthesis—^{125}I-labeled compounds, except for [4,4′-^{125}I]diiodobiphenyl, were synthesized by an exchange reaction using a melt procedure (14). Labeled 4,4′-diiodobiphenyl was synthesized as previously described (15). Radiochemical purity was established by reverse isotopic dilution analysis and HPLC.

General Melt Procedure—The unlabeled iodo compound (25 mg) and acetamide (100 mg) were added to a flask followed by sodium[^{125}I]iodide[10] (1–2 mCi) in acetone. Sodium thiosulfate (10^{-7} M, 20 μL) and ammonium chloride (10^{-7} M, 20 μL) were also added to prevent oxidation of the iodide and to prevent degradation of the reactant, respectively. Reaction conditions for specific compounds and their yields are outlined in Table I. Water (4 mL) was added, and the mixture was extracted with chloroform (4 × 4 mL), dried over sodium sulfate, and evaporated to dryness under a stream of nitrogen. The solid was dissolved in a small volume (~1 mL) of chloroform and passed through a small silica gel column[11] to remove inorganic iodide-125. The eluant was evaporated using nitrogen, and the solid was recrystallized in methanol (except for the iodobiphenyl compounds, which were recrystallized in ethanol).

Reverse Isotopic Dilution Analysis—A known amount of radiolabeled material was added to 500–1000 mg of accurately weighed unlabeled material. Mixtures were recrystallized until a constant specific activity of ±5% was achieved. From each recrystallization, three 10-mg aliquots, accurately weighed, were counted (Table I).

Radiochemical Purity by Liquid Chromatography—A reverse-phase C_{18} column[12], with methanol–water (90:10) as the mobile phase, was used to determine the purity of the ^{125}I-labeled substrates. The presence of any inorganic iodide-125 in the ethanolic or buffer solutions is listed in Table I.

Pretreatment of Animals—Male Sprague–Dawley rats[13] (250–300 g) were quarantined for 2 d before a single intraperitoneal injection of a commercial mixture of polychlorinated biphenyls[14] [500 mg/kg (16)] in corn oil. Rats had free access to food and water for 4 d, after which time the food was removed. The rats were killed on day 5 by asphyxiation using carbon dioxide.

Liver Fractions—Preparation of microsomal and cytosolic fractions were carried out as previously described (15). The procedure of Levine and Murphy (17) was used for the preparation of glutathione-depleted cytosol.

Incubation Procedures—The incubation conditions were modifications of those previously described (15), and studies with *N*-ethylmaleimide[15] and glutathione-depleted cytosol were performed. Mixtures of 20 μL of the ethanolic substrate solution (containing at least 40,000 cpm of substrate), 460 μL of homogenate, and 20 μL of buffer (0.01 M Na_2HPO_4–0.25 M sucrose, pH 7.4) or microsomal additive solution were incubated for 2 h at 37°C. Microsomal additive solutions consisted of magnesium chloride (15 μmol), nicotinamide (20 μmol), and NADPH (0.05 μmol) contained in 20 μL of buffer. *N*-Ethylmaleimide was added to selected substrate solutions to inactivate cytosolic glutathione such that the final concentration of imide was 0.0025 M. Five experimental and three control values were run for each experiment. Controls consisted of immersing the homogenate for 5 min in boiling water, cooling, and then following the incubation procedure as above.

Analytical Procedures—*Deiodination Studies*—The enzymatic reaction was stopped by the addition of 150 μL of 20% trichloroacetic acid. Following centrifugation (2000×*g*) and removal of the supernatant, the pellet was washed with 0.5 mL of buffer. After recentrifugation the two supernatants were combined, and the total supernatant was centrifuged and filtered through a 0.45-μm membrane[16] prior to injection into the liquid chromatograph. Samples were stored frozen until HPLC analysis.

To separate inorganic iodide from unreacted substrates and metabolites, 1.0 mL of *in vitro* solution was injected into the liquid chromatograph and eluted with a mobile phase of methanol–water (20:80) using a reverse-phase C_{18} column[5]. With the radiochemical detector, cpm measurements were taken every minute for 5 min after injection. When a scintillation counter was used, the first 4 mL of eluant was collected in a scintillation vial and counted for 5 min following the addition of 1 mL of methanol. The methanol was used to preserve a homogeneous solution with the cocktail (14 mL). Between injections, the chromatograph was flushed with methanol (30 mL) and equilibrated again with the solvent system.

4,4′-Diiodobiphenyl [f]	225 (48)	48.5	17.97 (82.5)	98.6 ± 1.6		

[a] Synthesized by the method of Elias and Lotterhos (14). [b] Radiochemical yield, expressed as percentage, in parentheses. [c] Reverse isotopic dilution. [d] Incubation in pH 7.4 phosphate buffer for 2 h at 37°C. [e] Mean of three experimental values ± SD. [f] Synthesized as previously described (16).

Debromination and Dechlorination Studies of Unlabeled Substrates—The enzymatic reaction was stopped with the addition of 150 μL of 35% H_2SO_4. The aforementioned procedure for iodide was then followed except that Tris-sucrose buffer was used; the HPLC procedure for separation of inorganic bromide and chloride was identical to that for iodide. The eluant (4 mL) was condensed by lyophilization after addition of 160 μL of concentrated ammonium hydroxide to prevent charring.

For bromide analysis, the residue was transferred to quartz tubes[17] with 1.0 mL of deionized water. Following lyophilization overnight, ≤0.5 mL of deionized water was added and the tubes were sealed. They were placed in the reactor at a neutron flux of 1.5×10^{13} neutrons/cm^2/s for 50 h. Bromide was determined by gamma-ray analysis of bromide-82 ($t_{1/2}$ = 35.34 h, 554.3, 619.0, and 776.5 keV) using two Canberra 22% coaxial Ge (Li) detectors and two multichannel analyzers[18].

For chloride analysis, the lyophilized material was transferred to small polyethylene tubes[19] with deionized water (0.25 mL). Tubes were placed in the reactor core at a flux of 1.5×10^{13} neutrons/cm^2/s for 15 min. Chloride was determined as chloride-38 ($t_{1/2}$ = 37.3 min, 1642.0 and 2167.5 keV) with the aforementioned instrumentation.

Glutathione-*S*-Transferase Assay—Glutathione-*S*-transferase was assayed by the method of Habig *et al.* (18). The concentration of *p*-nitrobenzyl chloride in the final solution was 0.00025 M, and the concentration of glutathione, when required, was 0.005 M in 0.5 M Na_2HPO_4 buffer, pH 7.4. The substrate was delivered in 25 μL of acetonitrile. Cytosol (100 μL) was used and UV absorbance measurements were taken at 310 nm every minute for 10 min.

Glutathione Determination—Glutathione was determined by the Ellman thiol assay (19) as modified by Benke *et al.* (20). A glutathione stock solution (0.002 M) was prepared in 0.1 M Na_2HPO_4 buffer (pH 8.0) containing 0.5% trichloroacetic acid and 0.001 M EDTA (tetrasodium salt). Four hundred microliters of stock solution was added to 4.55 mL of buffer, followed by the addition of 50 μL of 0.01 M 5,5′-dithiobis(2-nitrobenzoic acid). The absorbance was measured at 420 nm

RESULTS AND DISCUSSION

Analytical System—A reverse-phase HPLC technique similar to the systems previously reported for iodide (21, 22) was developed for separating inorganic halide from unreacted substrates and metabolites. Liquid scintillation counting of the eluant, following injection of sodium [^{36}Cl]chloride[10] in a simulated incubation mixture, resulted in quantitative recovery of inorganic chloride-36. Recovery of chloride-36 was independent of solvent composition from 10 to 90% methanol.

The analysis of inorganic iodide-125 required that carrier sodium iodide be added to the samples. Quantitative recovery was independent of solvent composition from 10 to 90% methanol. *para*-Iodobenzoic acid was chosen to determine the optimal solvent composition because resolution of this polar substrate and inorganic iodide could pose a difficult problem. Methanol–water (20:80) was suitable for all the substrates since complete resolution of inorganic and organically bound iodide was obtained in a minimal amount of time (~5 min).

Stability of Substrates—*In vitro* dehalogenation was expected to liberate trace quantities of halide; therefore, the purity of the labeled substrates, and the stability of the carbon–iodine-125 bond in ethanolic substrate solution and in buffer under incubation conditions, was of crucial importance if statistically significant levels of deiodination were to be obtained. Table I shows the percent inorganic iodide-125 found for the substrates in ethanol and in buffer under incubation conditions. The percentage of inorganic iodide in ethanol was determined by injection of an aliquot of an ethanolic solution of substrate containing 500 μg of carrier sodium iodide.

All solutions were freshly prepared and injected into the chromatograph within 5 min of preparation. Deiodination in buffer was carried out by incubating an aliquot of ethanolic substrate solutions in pH 7.4 sodium phosphate buffer (0.010 M) under the same conditions used in the *in vitro* experiments. HPLC conditions were also as described for *in vitro* dehalogenation studies.

Deiodination in ethanol was about the same as that in buffer under incubation conditions. Deiodination of [*p*-^{125}I]iodobenzaldehyde was statistically greater (Student's *t* test, $p \leq 0.05$) in buffer than in ethanol; there was no statistical difference in deiodination of the phenol in ethanol or buffer.

Dechlorination and Debromination Studies Using Neutron-Activation Analysis—Neutron-activation analysis was an attractive alternative to using radiolabeled substrates for *in vitro* debromination and dechlorination studies. Therefore, a feasibility study was undertaken using simulated incubation mixtures containing ammonium bromide or ammonium chloride and the reverse-phase HPLC conditions described above. These samples contained bromide and chloride equivalent to 0.5, 1.0, and 2.0% biotransformations, based on the incubation of 100 μg of 4-bromobiphenyl or 4-chlorobiphenyl. Bromide analysis at 554.0 and 776.9 keV was used. Results of analysis at 619.0 keV were not used due to interference from another radioisotope. HPLC analysis at either 554.0 or 776.9 keV of blanks containing no ammonium bromide did not show statistically significant bromide levels; therefore, bromide contamination as a result of the workup and analysis was not a problem. Statistically significant levels of bromide were observed for all three of the simulated biotransformations.

Neutron-activation analyses at 1641.3 and 2165.9 keV of simulated, dechlorinated samples indicated high background levels which were consistent with known interference in this method by other elements, particularly sodium and potassium in the measurement of chloride. It was estimated that there would have to be at least a 3% biotransformation for detection of chloride in this background. Therefore, while neutron-activation analysis of bromide was a viable technique for study of debromination, this technique was not useful under the conditions of our incubations for chloride measurements.

Neutron-activation analysis of the HPLC effluent following injection of the supernatant of the incubation medium of 4-bromobiphenyl with cytosol (for three sets of determinations) gave 0.206 ± 0.032% *versus* 0.169 ± 0.032% for the respective control at 553.8 keV and 0.209 ± 0.032% *versus* 0.156 ± 0.019% at 776.0 keV. Neither measurement, compared to the respective control, was statistically significant at $p \leq 0.05$.

Debromination (~1%) of 4,4′-dibromobiphenyl has been reported in the rabbit (12) and pig (13). However, Safe *et al.* (12) did not detect any debrominated metabolites of 4-bromobiphenyl after administration to pigs or rabbits. Analysis of the *in vitro* incubation of tritiated 4-bromobiphenyl with rabbit liver microsomes also showed no debrominated metabolite (12). Thus, while debromination is known to occur, it has not been detected with 4-bromobiphenyl previously or in this study. Analysis of *in vitro* debromination studies was hampered by low substrate solubility. *In vitro* debromination was expected to be less than deiodination based on aromatic carbon–bromine bond strength compared with that of the carbon–iodine bond.

Microsomal Deiodination—The results of deiodination in microsomes are shown in Table II. Each substrate exhibited statistically significant deiodination above its control value except for [*p*-^{125}I]iodobenzonitrile. The relatively high variance of the control values and the low amount of substrate activity prevented detection of a statistically significant difference in deiodination between microsomal samples and the respective controls. Control values, in general, agreed with those found in Table I for incubation in buffer.

Deiodination of the substrates was ≥ ~2%, and there was no unique specificity of the microsomes for any of the substrates. The results for [*p*-^{125}I]-iodonitrobenzene and [4-^{125}I]iodobiphenyl generally agreed with previous

[d] Adjusted enzyme activity from a different source for this cytosolic fraction, by comparison of cytosolic activities with the nitro compound as the substrate. [e] Not determined. [f] Substrate could not be incorporated into the medium without excessive loss of enzymatic activity.

results determined in this laboratory: 2.5 ± 0.52% for labeled *p*-iodonitrobenzene and 0.6 ± 0.04% for [4-^{125}I]iodobiphenyl (15).

The microsomal deiodination of these compounds can be explained by considering them as substrates for the mixed-function oxygenase system with arene oxide formation at the iodocarbon. The possible loss of iodide during a subsequent "N.I.H. shift" (23) involving this arene oxide would be analogous to the mechanism proposed for the loss of bromide or chloride in polyhalogenated biphenyl compounds (12, 13).

No correlation was found between microsomal deiodination and the electron-withdrawing character of *para*-substituents, as indicated by their Hammett values (24). Furthermore, no correlation was found between microsomal deiodination and the lability of the carbon-iodine bond as evidenced by the radiochemical yield in the exchange reaction used in their preparation.

Cytosolic Deiodination—Results of cytosolic deiodination are also shown in Table II. Six of the seven substrates exhibited deiodinations that were statistically significantly greater than the control values ([4,4′-^{125}I]diiodobiphenyl did not). [*p*-^{125}I]Iodonitrobenzene deiodinated to the greatest extent above the respective control value, indicating a unique specificity of glutathione-*S*-transferase for the nitro compound. The extent of this transformation, although large, was not unexpected. The metabolism of *p*-chloronitrobenzene resulted in ~7% of the dose being excreted as the mercapturic acid (25). The more labile carbon-iodine bond would facilitate increased deiodination. Cytosolic control values generally agreed with those in buffer and ethanol (Table I), although control values for the benzoic acid, nitro, 4-iodobiphenyl, and phenol substrates were significantly higher than their deiodination in buffer. Nonenzymatic glutathione conjugation of the nitro compound was believed to account for the high amount of deiodination found in the respective control. The reduction in deiodination when free glutathione levels were reduced with the addition of *N*-ethylmaleimide would further substantiate this belief. Pabst *et al.* (26) have established that nonenzymatic conjugation of glutathione with *p*-nitrobenzyl chloride and 1,2-dichloro-4-nitrobenzene was significant at or near physiological pH in the rat. Deiodination of the *p*-nitro and 4-iodobiphenyl substrates agreed well with values previously reported from this laboratory (15). No correlation was found between cytosolic deiodination and the electron-withdrawing character of the *para*-substituent for the acid, aldehyde, nitrile, nitro, phenol, or 4-iodobiphenyl substrates as measured by their Hammett values (24). There was also no correlation with the radiochemical yield of the syntheses of these compounds.

Kraus (27) reported the dechlorination of α-hexachlorocyclohexane in rat liver cytosol by a mechanism that was not dependent on glutathione and by a glutathione-*S*-transferase mechanism. Our previous studies also indicated a second cytosolic dehalogenase (16). An efficient means of inhibiting glutathione-*S*-transferase was sought in order to explore the nature of this second cytosolic dehalogenase system.

N-Ethylmaleimide is known to bind to thiols (28). [p-^{125}I]Iodonitrobenzene was incubated as described with 0.1–40.0 mM *N*-ethylmaleimide to determine the optimal concentration for the inhibition of glutathione-*S*-transferase. Deiodination decreased as the concentration of *N*-ethylmaleimide increased up to 2.5 mM. Increasing its concentration >2.5 mM resulted in no statistically significant decrease in deiodination. Thus, 2.5 mM *N*-ethylmaleimide was chosen as the optimal concentration in the final incubation mixture. Confirmation of the inhibition of glutathione-*S*-transferase was also established by measuring the concentration of glutathione in cytosol with and without *N*-ethylmaleimide. The standard Ellman thiol assay (19) as modified by Benke (20) showed that glutathione was below detectable levels with the addition of 2.5 mM *N*-ethylmaleimide.

Results of cytosolic deiodination with *N*-ethylmaleimide present are shown in Table II. [4-^{125}I]Iodobiphenyl and [*p*-^{125}I]iodophenol were the only substrates to exhibit statistically significant deiodination above the respective control values.

These two possible indications of a second nonglutathione cytosolic deiodinase were also studied by the use of an anion-exchange preparation (17) of glutathione-depleted cytosol. Glutathione concentration was again assayed by the Ellman procedure (20) and found to be below detectable limits. Further evidence of the efficiency of glutathione removal was demonstrated by determining the glutathione-*S*-transferase activity of intact and glutathione-depleted cytosol. The procedure of Habig *et al.* (18) with *p*-nitrobenzyl chloride as the substrate was used to follow the UV absorbance of the glutathione conjugate. Formation of the conjugate did not increase with time when glutathione-depleted cytosol was used. When the depleted cytosol was reconstituted with glutathione (5 mM), the rate of formation of the conjugate was not statistically different from that of intact cytosol. Therefore, this depletion procedure inhibited glutathione activity, but did not adversely affect glutathione-*S*-transferase.

The results of deiodination of [*p*-^{125}I]iodophenol and [4-^{125}I]iodobiphenyl using glutathione-depleted cytosol are shown in Table II. The deiodination of the biphenyl was statistically significant above the respective control value, but this was not the case for the phenolic compound. Thus, this confirmation of the presence of a cytosolic nonglutathione dehalogenase could only be established for the iodobiphenyl substrate. The microsomal and cytosolic glutathione systems were the more generally applicable deiodination mechanisms.

Determination of Bupropion and Its Major Basic Metabolites in Plasma by Liquid Chromatography With Dual-Wavelength Ultraviolet Detection

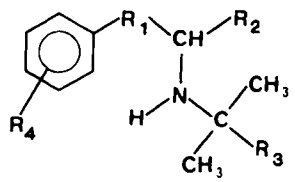
THOMAS B. COOPER ˣ, RAYMOND F. SUCKOW, and ALEXANDER GLASSMAN

Received March 11, 1983, from the *Analytical Psychopharmacology Laboratory, New York State Psychiatric Institute, New York, NY 10032.* Accepted for publication September 14, 1983.

Abstract □ A method for the determination of bupropion and its three major basic metabolites in plasma is described. Following an extraction from alkaline plasma into 1.5% v/v isoamyl alcohol in *n*-heptane, a portion of the acid-backwashed extract was injected onto a column packed with trimethylsilyl reverse-phase material and eluted with a phosphate buffer–acetonitrile (80:20) mobile phase containing an ion-pairing reagent and triethylamine. The compounds were detected with a dual-wavelength UV detector (214 and 254 nm) to optimize sensitivity and facilitate simultaneous detection. The method provides an absolute recovery of ~85% for bupropion and ~98% for the metabolites. Day-to-day reproducibility did not exceed 4.0% for all compounds. The detection limits were ~5 ng/mL for bupropion and 100 ng/mL for the major metabolites. The limit of 100 ng/mL for metabolite quantitation is imposed by the internal standard concentration selected for steady-state studies. In single-dose pharmacokinetic studies, 10% of the steady-state concentration of internal standard was used; this permitted a 10-ng/mL lower limit of detection. Steady-state plasma levels of bupropion and the metabolites from eight different patients are presented.

Keyphrases □ Bupropion—metabolites, HPLC, dual-wavelength UV detection □ Antidepressants—bupropion and its metabolites, HPLC, dual-wavelength UV detection

Bupropion hydrochloride[1] [(±)-2-*tert*-butylamino-3′-chloropropiophenone hydrochloride], a chemically unique antidepressant currently undergoing clinical evaluation, appears to be free of any significant anticholinergic or cardiovascular effects (1–3). The assay of bupropion in biological fluids has been limited to RIA (4) and high-performance liquid chromatography (HPLC) (5). The RIA procedure appears to be sensitive (<1 ng/mL) and specific for bupropion, whereas the HPLC method is less sensitive (50 ng/mL). However, neither method quantitates metabolites.



I: R_1 = C=O, R_2 = R_3 = CH_3, R_4 = 3-Cl
II: R_1 = C=O, R_2 = CH_3, R_3 = CH_2OH, R_4 = 3-Cl
III: R_1 = CHOH, R_2 = R_3 = CH_3, R_4 = 3-Cl (*erythro*)
IV: R_1 = CHOH, R_2 = R_3 = CH_3, R_4 = 3-Cl (*threo*)
V: R_1 = CHOH, R_2 = CH_3, R_3 = CH_2OH, R_4 = 3-Cl (*erythro*)
VI: R_1 = C=O, R_2 = C_2H_5, R_3 = CH_3, R_4 = 4-F
VII: R_1 = C=O, R_2 = C_3H_7, R_3 = CH_3, R_4 = 4-F

Current interest in biologically active metabolites of psychotropic drugs led us to develop an HPLC procedure which separates and quantitates bupropion and its major basic metabolites in plasma with dual-wavelength UV detection.

EXPERIMENTAL SECTION

Apparatus—Chromatography was performed with a dual-piston solvent delivery pump[2] with either a manual injector[3] or an automatic sample processor[4]. The column was 25 cm × 4.6 mm i.d. packed with 5-μm particle size trimethylsilyl material[5]. The effluent was monitored at 254 and 214 nm by

ACKNOWLEDGMENTS

The authors would like to thank William Harrity and Amy Khan, National Science Foundation Undergraduate Research Participants, Grants No. SPI 7826914 and SPI 8026361, respectively, and Randy Olenyk for their laboratory assistance. This study was supported in part by a Training Grant 5-T32-GM07767 from the National Institutes of Health.

The authors are grateful to Mr. John Jones and The University of Michigan's Phoenix Memorial Laboratory for their cooperation in conducting our neutron-activation analyses.

Determination of Bupropion and Its Major Basic Metabolites in Plasma by Liquid Chromatography With Dual-Wavelength Ultraviolet Detection

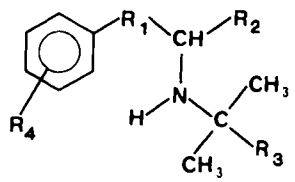
THOMAS B. COOPER ˣ, RAYMOND F. SUCKOW, and ALEXANDER GLASSMAN

Received March 11, 1983, from the *Analytical Psychopharmacology Laboratory, New York State Psychiatric Institute, New York, NY 10032.* Accepted for publication September 14, 1983.

Abstract □ A method for the determination of bupropion and its three major basic metabolites in plasma is described. Following an extraction from alkaline plasma into 1.5% v/v isoamyl alcohol in *n*-heptane, a portion of the acid-backwashed extract was injected onto a column packed with trimethylsilyl reverse-phase material and eluted with a phosphate buffer–acetonitrile (80:20) mobile phase containing an ion-pairing reagent and triethylamine. The compounds were detected with a dual-wavelength UV detector (214 and 254 nm) to optimize sensitivity and facilitate simultaneous detection. The method provides an absolute recovery of ~85% for bupropion and ~98% for the metabolites. Day-to-day reproducibility did not exceed 4.0% for all compounds. The detection limits were ~5 ng/mL for bupropion and 100 ng/mL for the major metabolites. The limit of 100 ng/mL for metabolite quantitation is imposed by the internal standard concentration selected for steady-state studies. In single-dose pharmacokinetic studies, 10% of the steady-state concentration of internal standard was used; this permitted a 10-ng/mL lower limit of detection. Steady-state plasma levels of bupropion and the metabolites from eight different patients are presented.

Keyphrases □ Bupropion—metabolites, HPLC, dual-wavelength UV detection □ Antidepressants—bupropion and its metabolites, HPLC, dual-wavelength UV detection

Bupropion hydrochloride[1] [(±)-2-*tert*-butylamino-3′-chloropropiophenone hydrochloride], a chemically unique antidepressant currently undergoing clinical evaluation, appears to be free of any significant anticholinergic or cardiovascular effects (1–3). The assay of bupropion in biological fluids has been limited to RIA (4) and high-performance liquid chromatography (HPLC) (5). The RIA procedure appears to be sensitive (<1 ng/mL) and specific for bupropion, whereas the HPLC method is less sensitive (50 ng/mL). However, neither method quantitates metabolites.



I: R_1 = C=O, R_2 = R_3 = CH_3, R_4 = 3-Cl
II: R_1 = C=O, R_2 = CH_3, R_3 = CH_2OH, R_4 = 3-Cl
III: R_1 = CHOH, R_2 = R_3 = CH_3, R_4 = 3-Cl (*erythro*)
IV: R_1 = CHOH, R_2 = R_3 = CH_3, R_4 = 3-Cl (*threo*)
V: R_1 = CHOH, R_2 = CH_3, R_3 = CH_2OH, R_4 = 3-Cl (*erythro*)
VI: R_1 = C=O, R_2 = C_2H_5, R_3 = CH_3, R_4 = 4-F
VII: R_1 = C=O, R_2 = C_3H_7, R_3 = CH_3, R_4 = 4-F

Current interest in biologically active metabolites of psychotropic drugs led us to develop an HPLC procedure which separates and quantitates bupropion and its major basic metabolites in plasma with dual-wavelength UV detection.

EXPERIMENTAL SECTION

Apparatus—Chromatography was performed with a dual-piston solvent delivery pump[2] with either a manual injector[3] or an automatic sample processor[4]. The column was 25 cm × 4.6 mm i.d. packed with 5-μm particle size trimethylsilyl material[5]. The effluent was monitored at 254 and 214 nm by

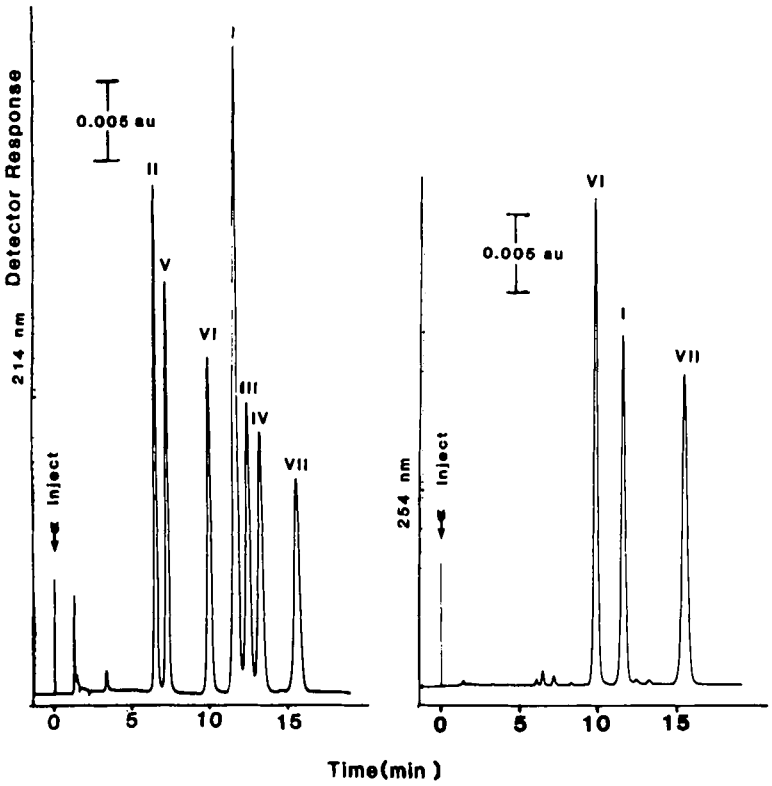

Figure 1—*Dual chromatogram of a standard aqueous solution containing 400 ng each of I, its major metabolites (II, III, and IV), a possible urinary metabolite (V), and internal standards (VI and VII). The compounds were detected at 214 and 254 nm simultaneously.*

a dual (in series) UV detector system[6], a signal recorder[7], and a laboratory data acquisition system[8]. The column temperature was controlled with an aluminum block devised to fit this column and with a circulating water pump[9].

Reagents—Phosphoric acid[10], monobasic potassium phosphate[10], sodium carbonate[10], and sodium bicarbonate[10] were all analytical reagent grade. Sodium heptanesulfonate[11] and triethylamine[12] were used as received. UV-grade acetonitrile[13] and *n*-heptane[10] were used without further purification. Isoamyl alcohol[14] was distilled before use. Distilled water was passed through a water purification system[15] before use.

Standards—Bupropion hydrochloride (I), 3'-chloro-2-(2-hydroxy-1,1-dimethylethylamino)propiophenone hydrochloride (II), (+)(*R**,*S**)-2-(*tert*-butylamino)-1-(3-chlorophenyl)propanol (III), (*R**,*R**)-2-(*tert*-butylamino)-1-(3-chlorophenyl)propanol (IV), (±)(*R**,*S**)-1-(3-chlorophenyl)-2-(2-hydroxy-1,1-dimethylethylamino)propanol (V), 2-(*tert*-butylamino)-4'-fluorobutyrophenone hydrochloride (VI), and 2-(*tert*-butylamino)-4'-fluorovalerophenone hydrochloride (VII) stock solutions (1 mg/mL) were prepared in 0.01 M HCl. Working solutions were further diluted to 1 ng/μL in 0.01 M HCl for I and V, and to 10 ng/μL in 0.01 M HCl for II, III, IV, VI, and VII. The structures and activities of these metabolites have been described elsewhere (3).

Extraction—To 1.0 mL of plasma, 800 ng of internal standard VI and 150 ng of internal standard VII were added to 1.0 mL of 0.6 M carbonate buffer (pH 9.5) and 10 mL of 1.5% v/v isoamyl alcohol in *n*-heptane. The mixture was shaken for 15 min and centrifuged at 1500×*g* for 10 min. The organic layer was then transferred to a 15-mL tube containing 250 μL of 0.1 M HCl. After mixing for 10 min and centrifuging at 1500×*g* for 10 min, the organic layer was removed by aspiration. Suitable aliquots of the aqueous phase were injected for chromatographic separation.

Chromatographic Conditions—The mobile phase consisted of 0.05 M monobasic potassium phosphate–acetonitrile (80:20), with 0.007 M sodium heptanesulfonate and 0.01 M triethylamine added. The final pH of the aqueous portion was brought to 3.0 by the addition of phosphoric acid. The mixture was filtered and deaerated prior to use. The flow rate was 2.3 mL/min, and the column temperature was set at 30°C. The effluent was monitored with a dual UV detector system at 254 and 214 nm in series.

Quantitation—All determinations were performed by calculating the peak height and/or area ratios of each compound to the internal standard. A linear regression analysis for each of the standard curves was performed with an on-line data acquisition system resulting in the computation of the slope, *x*-intercept, correlation coefficient, and standard error. Compound I was quantitated at 254 nm with internal standard VII. Metabolites II, III, and IV were quantitated at 214 nm with internal standard VI.

RESULTS AND DISCUSSION

Bupropion (I) and its major metabolites in plasma were separated and quantitated by HPLC with a dual-wavelength UV detector system. Although all compounds absorb at 214 nm, only I and the two internal standards (VI and VII) absorb at 254 nm (Fig. 1). Since it was found that the steady-state plasma concentration of I was low in comparison to its metabolites, simultaneous quantitation was not possible for all compounds at 214 nm. The major metabolite of I (*i.e.*, II) is usually found at concentrations 10–100 times that of bupropion. Thus, I was quantitated at 254 nm with internal standard VII.

All compounds were adequately resolved and eluted within a 20-min period (Fig. 1). An actual spiked plasma sample is shown in Fig. 2. A drug-free patient plasma sample did not show any interfering endogenous peaks at either wavelength (Fig. 3). Although V is reported to be a urinary metabolite (6), no detectable levels were found in steady-state plasma samples obtained from patients (Fig. 4). Therefore, this metabolite was not included in the precision and accuracy tests in plasma. Figure 2 illustrates that V could be coextracted, separated, and quantitated, thus making this method possibly useful in metabolite studies in urine.

In general, it was found that the addition of triethylamine enhanced peak symmetry. Other amine modifiers such as *n*-butylamine or nonylamine did not afford the resolution needed. Other columns such as an octyldecylsilyl and an octylsilyl-bonded column resulted in longer retention times and inadequate resolution between III and IV.

The detection limit for I is ~5 ng/mL of plasma, and the detector response remained linear at least up to 400 ng. The detection limit for II, III, and IV in this assay was 100 ng/mL, and the detector response showed linearity from 100 to at least 3000 ng.

The limit of 100 ng/mL for metabolite quantitation is imposed by the internal standard concentration selected for steady-state studies. In single-dose pharmacokinetic studies, 10% of the concentration of internal standard used for steady state was utilized; this permitted a 10-ng/mL lower limit of detection.

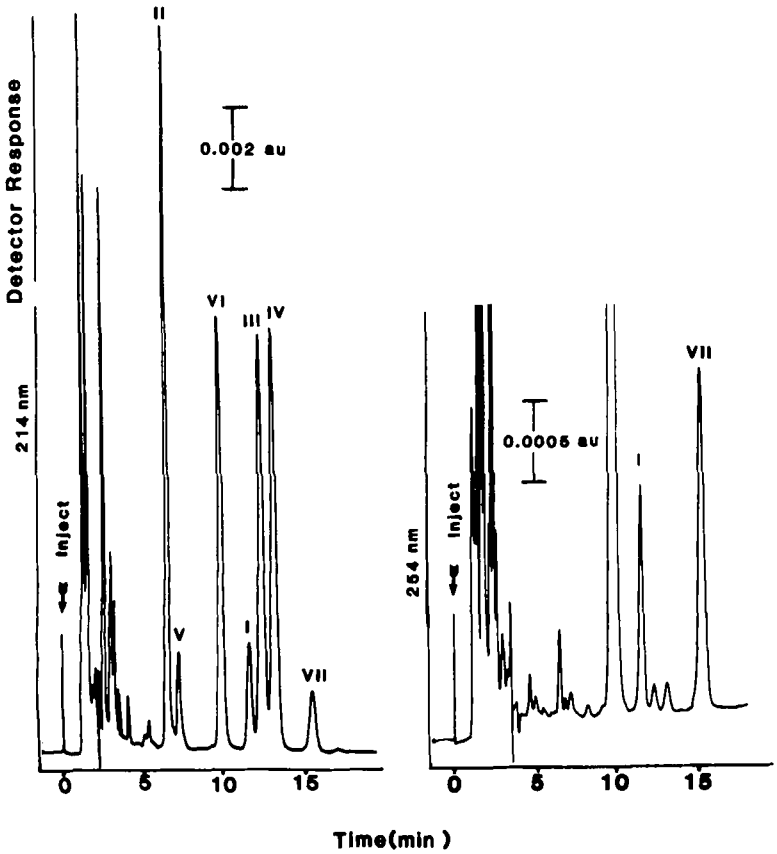

Figure 2—*Dual chromatogram of a 1-mL spiked plasma extract containing 100 ng of I and metabolite V and 1000 ng of II, III, and IV. Fifty microliters of the acid extract was injected. Compounds VI and VII are the internal standards.*

In preliminary single-dose studies, the major metabolites (II and IV) were present at 30 min postdose, reaching a maximum of 2–3 times that of bupropion. Furthermore, inspection of these data clearly indicates that the metabolites have markedly different (longer) half-lives of elimination[16].

The absolute recovery was determined by preparing a solution of known

[a] Data computed from five consecutive standard curves.

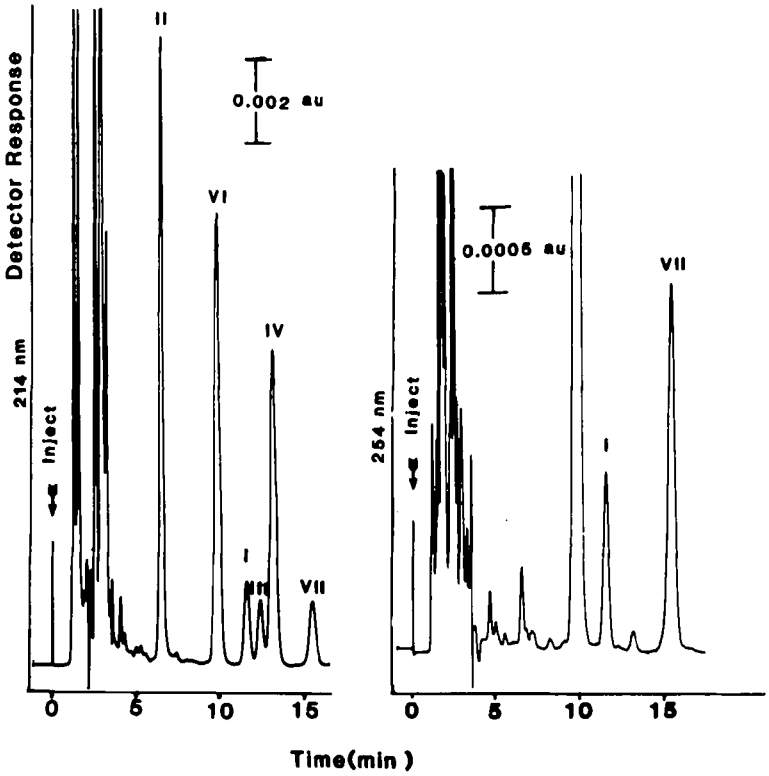

Figure 4—*Dual chromatogram of a 1-mL plasma extract from a patient receiving bupropion. Fifty microliters of the acid extract was injected. The plasma levels were calculated to be 72 ng of bupropion, 831 ng of II, 151 ng of III, and 743 ng of IV. Compounds VI and VII are the internal standards.*

concentration of all compounds. The internal standards were added to each solution, and the sample was injected into the chromatograph. The same standards were added to 1 mL of plasma and processed routinely, except for the internal standards. To 100 μL of the final acid extract, 100 μL of internal standard solution containing twice the usual concentration was added. The tube was capped, thoroughly mixed, and then injected. The difference between the ratios of the standards to internal standards in the processed samples *versus* direct injection samples gave a measure of overall recovery (Table I).

The precision of the method was determined by spiking eight standards; the sample was processed as described above. The percent relative standard deviations for various concentrations are reported in Table II.

A measure of the stability of the assay was demonstrated by the variability in the slope of the linear regression curves on 5 consecutive days (Table III). Accuracy was further assessed by comparing plasma concentrations of bupropion from two single-dose pharmacokinetic studies determined by this method and an RIA procedure (4). Twenty-eight samples (range, 5–130 ng/mL) were analyzed. Least-squares linear regression analysis resulted in the following: slope, 0.93; x-intercept, 2.2 ng/mL; and correlation coefficient, 0.987, where y and x were the bupropion concentrations by HPLC and RIA, respectively. Metabolite concentrations could not be compared since no other method has, as of now, been established.

Several psychotropic drugs and their metabolites were tested to determine potential interference in the assay. All commonly used tricyclic antidepressant compounds (imipramine, desipramine, amitriptyline, nortriptyline, doxepin, and desmethyldoxepin) and the new antidepressant drugs maprotiline, trazodone, mianserin, amoxapine, and chlorimipramine have much longer retention times than VII. Similarly, the major neuroleptic compounds such as chlorpromazine, thioridazine, loxapine, fluphenazine, perphenazine, and haloperidol do not interfere.

Compounds that may interfere are the hydroxy metabolites of amitriptyline, chlordiazepoxide and its *N*-demethyl metabolite, and nordiazepam.

Until now, there has been no reported human steady-state plasma level data for bupropion or its metabolites. The pharmacokinetics of bupropion has been reported (7), but metabolite determinations were not performed. Table IV is a summary of plasma concentration of bupropion and its major metabolites in eight different patients being treated for depression. The dose varied from patient to patient (100–450 mg/d). Although bupropion plasma concentrations averaged 50 ng/mL, the major metabolite (II) was found to be ~50 times higher (2500 ng/mL). The two diastereoisomers (III and IV) were also found in considerably higher concentrations (the *threo* isomer was always present in amounts 3–5 times greater than the *erythro* isomer).

Table IV—Typical Steady-State Plasma Concentrations of I and Metabolites in Eight Depressed Patients [a]

Patient	Dose, mg/24 h	Concentration, ng/mL I	II	III	IV
1	450	68	2784	103	453
2	350	43	3111	542	2226
