The sensitivity of the radioligand binding method is only surpassed by the GC–MS technique (3), which has a detection limit of 50 pg/mL. However, this GC–MS assay has several disadvantages compared with the radioligand binding test. First, deuterated scopolamine has to be synthesized as an internal standard. Second, the method includes a complicated and time-consuming extraction procedure. Third, scopolamine is hydrolyzed to scopoline in this method, and the latter substance would be detected under the same peak. Additionally, the authors state that scopine and apo-scopolamine (possible metabolites of scopolamine) would also interfere with their assay.

The radioligand binding assay is easily and quickly performed; 50 samples can be determined in half a day, because no extraction is needed. The assay also shows good reproducibility (Table I). Measurements of the urinary excretion of scopolamine after administration of the transdermal system indicate that only 21% of scopolamine is excreted in free form, while 79% is conjugated to glucuronic and/or sulfuric acid. This confirms similar observations from animal studies (12), where the 9′-glucuronide was found to be the main metabolite of scopolamine in the mouse.

If one assumes that during a 64-h period 0.45 mg of scopolamine is absorbed through the skin, then an average of 7% of the total drug is excreted in the urine. This agrees with the results of Bayne *et al.* (3) and with those of Shaw *et al.* (13), both using a GC–MS method. Bayne *et al.* (3) recovered 4–5% of an oral dose unchanged in the urine, while Shaw *et al.* (13) measured 10% of the drug as free scopolamine given either intravenously or intramuscularly. Comparable results from this study, therefore, show the suitability of the radioligand binding technique.

Up to 48 h after removal of the drug system, scopolamine can still be detected in urine, despite its short elimination half-life of ~1 h (14). Similar results were obtained by Shaw and Urquhart (15), who assumed that an intradermal reservoir continues to deliver scopolamine to the circulation even after termination of the transdermal medication.

Determination of 17β-Hydroxy-1α-methyl-17α-propyl-5-α-androstan-3-one in Plasma by Gas Chromatography–Mass Spectrometry with Single-Ion Detection

WERNER KRAUSE ˣ **and UWE JAKOBS**

Received June 16, 1982, from the *Department of Pharmacokinetics, Schering Berlin/Bergkamen, Müllerstrasse 170-178, 1000 Berlin 65, West Germany.* Accepted for publication March 30, 1983.

Abstract □ The topical anti-androgen 17β-hydroxy-1α-methyl-17α-propyl-5α-androstan-3-one is determined in plasma samples by extracting with ether and subsequent mass fragmentography with single-ion detection at *m/z* 303. 17β-Hydroxy-1α-methyl-17α-pentyl-5α-androstan-3-one, added to the samples before extraction, is used as the internal standard. Reproducibility was calculated to be ±5.9% at the 5-ng/mL level and 0.4% at the 20-ng/mL level. The limit of detection is ~1 ng/mL. Total gas chromatography–mass spectrometry analysis time is ~10 min/sample.

Keyphrases □ 17β- Hydroxy -1α-methyl-17α- propyl -5α- androstan -3-one—determination in plasma, gas chromatography—mass spectrometry, single-ion detection □ Mesterolone—17α-propyl analogue, determination in plasma, gas chromatography–mass spectrometry, single-ion detection

17β-Hydroxy-1α-methyl-17α- propyl -5α-androstan-3-one, the 17α-propyl analogue of mesterolone, is currently under investigation as a topical anti-androgen for the treatment of acne and seborrhea. Pharmacological data of this compound, which may act similarly to the 17α-propyl analogue of testosterone (1), have been reported earlier (2).

Topical anti-androgens act locally in the skin, and the systemic availability of this class of compounds should be as low as possible in order to avoid endocrinological disorders. Therefore, any analytical method applied to the determination of these drugs in plasma must be very sensitive to be able to detect very small portions of absorbed substances. Because the drug molecule may be metabolized during passage through the skin, there are also certain requirements regarding specificity of the assay. In the present report an analytical method for the determination of plasma concentrations of 17β-hydroxy-1α-methyl-17α-propyl-5α-androstan-3-one (I) is described, which is devoid of tedious extraction or derivatization procedures and may, therefore, be useful in clinical tolerance studies of this compound when relatively high doses of drug are administered. Furthermore, it may serve for controlling the specificity of an RIA procedure.

EXPERIMENTAL

Subjects and Medication—Two healthy male volunteers (40 and 31 years of age, and 88 and 70 kg, respectively) were treated topically two times daily with 10 mL of a 3% solution of I in 70% aqueous ethanol. The drug was spread over the total body of the volunteers. During the first week the skin area to which the drug has been applied was kept under occlusion for 22 h/d. Blood was drawn into heparinized syringes before the treatment and in weekly intervals up to 8 weeks after the beginning of the 6-week treatment. The samples were immediately centrifuged, and the plasma stored frozen until analysis.

Chemicals—All solvents (ethanol, *n*-hexane, and ether) were of analytical reagent grade[1] and were used without further purification.

Extraction Procedure—Fifty nanograms of the internal standard (17β-hydroxy-1α-methyl-17α-pentyl-5α-androstan-3-one) dissolved in 50 μL of *n*-hexane was transferred into a 15-mL stoppered test tube and evaporated to dryness under a stream of nitrogen. One milliliter of plasma was added, followed after a short mixing time by 3 mL of ether. After thoroughly mixing on a vortex mixer for 1 min and centrifugation at 1200×*g* for 5 min, the organic phase was transferred to another test tube and evaporated to give a final volume of ~10 μL. One microliter of this solution was analyzed by gas chromatography–mass spectrometry (GC–MS). The recovery of the extraction procedure was determined by spiking 1-mL plasma samples with either 20 or 50 ng of radiolabeled I, with subsequent determination of the radioactivity in the organic phase.

Gas Chromatography–Mass Spectrometry—A GC–MS system[2] with the following components was used: a gas chromatograph[3], a quadrupole mass spectrometer[4], and a data system[5]. The gas chromatograph was equipped with a CP-SiL 5-coated open-tubular glass column (25 m × 0.25 mm) used in the direct-coupling mode or, alternatively, a CP-SiL 5 CB wall-coated open-tubular fused silica column (25 m × 0.23 mm), which was directly introduced into the ion source.

The temperature program applied to the column was 240°C for 1 min, then rising to a final temperature of 260°C at a rate of 10°C/min. Using the fused silica column the program was 200°C for 2 min, then 10°C/min up to 300°C. The injector was kept at 290°C, the direct coupling device at 280°C. Helium was used as carrier gas with a pressure of 14 psi in front of the column. The split ratio was 1:5.

Calibration Curve—The standard curve was constructed with 1-mL blank plasma samples containing 0, 5, 10, 15, 20, and 50 ng of I and 50 ng of the internal standard. These samples were extracted by the method described above. The peak areas of the internal standard and drug were measured, and the calibration curve (peak area ratio of drug/standard *versus* the concentration of I) was constructed. The precision of the assay was calculated from consecutive determinations of the drug within 1 d and by comparison with the results obtained on different days.

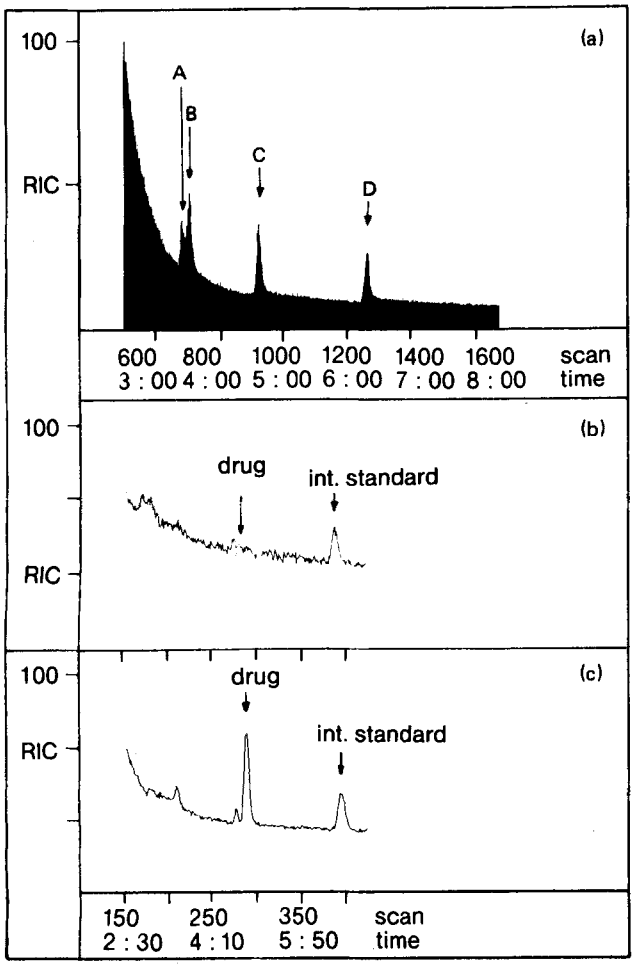

Figure 1—*Mass fragmentograms of (a) a mixture of mesterolone (A) and its 17α-methyl- (B), 17α-propyl- (C), and 17α-pentyl (D) analogues; (b) a plasma extract containing 5 ng of internal standard; and (c) a plasma extract with 7.5 ng of I and 5 ng of internal standard. The chromatograms were obtained with a CP-SiL 5 glass capillary column.*

RESULTS AND DISCUSSION

Assay—This report describes a sensitive and highly selective method for the determination of I in plasma utilizing GC–MS with single-ion detection. Plasma samples are extracted with ether after the addition of the internal standard, and the extract is evaporated to dryness, taken up in *n*-hexane, and injected directly into the GC–MS system.

Detection of the substances eluted from the chromatographic column is performed by means of single-ion measurements at *m/z* 303. This mass constitutes the base peak of the spectrum of both the drug and the internal standard, and it probably results from cleavage at the propyl and pentyl side chains.

The retention times of I and the internal standard using the glass column were 4.8 and 6.7 min, respectively. Figure 1 shows chromatograms of a blank plasma sample, of a sample containing drug and internal standard, and of some reference compounds.

Plasma concentrations of I were determined by comparing the peak areas of the drug and the internal standard added to the plasma before extraction.

Table I—Calibration Curves of the Assay Obtained on Five Different Days

Day	Calibration Curve[a]	Correlation Coefficient (r)
1	$y = -0.020 + 0.022x$	0.9990
2	$y = 0.001 + 0.019x$	0.9995
3	$y = 0.005 + 0.020x$	0.9997
4	$y = -0.007 + 0.021x$	0.9990
5	$y = -0.006 + 0.021x$	0.9997
Mean	$y = -0.005 + 0.021x$	0.9994

[a] Data obtained with the fused silica column; y = peak area of the drug/peak area of the internal standard and x = concentration of the drug (ng/mL).

Table II—Interassay Variation of Different Concentrations of I Using the Fused Silica Column

Amount Added ng/mL	Peak Area Ratio (Drug/Standard)	n	*RSD*, %
5	0.100 ± 0.016	5	16.0
10	0.201 ± 0.012	10	5.7
15	0.300 ± 0.011	5	3.7
20	0.394 ± 0.009	14	2.2

Table III—Plasma Concentrations of I Determined After Repeated Daily Topical Applications of 600 mg of Drug to Two Male Volunteers

Week	Subject 1	Subject 2	Mean ± *SD*
0	0	0	0 ± 0
1	16	14	15 ± 1
2	—	8	—
3	18	12	15 ± 4
4	20	15	18 ± 4
5	12	11	12 ± 1
6	11	11	11 ± 0
7	0	0	0 ± 0
8	0	0	0 ± 0

Typical calibration curves of the assay are described in Table I. The recovery of the extraction process was determined by measuring the radioactivity in the organic phase of samples spiked with ^{3}H-labeled drug. With 20 and 50 ng/mL, 83 ± 4 and 80 ± 1% were recovered in the ether phase (n = 5 each), respectively.

The recovery of the internal standard was identical with that of I, as could be demonstrated by establishing a calibration curve of unextracted drug. The data obtained were identical with that described in Table I.

The overall accuracy of the assay, expressed as the standard deviation of seven consecutive plasma determinations of 5 ng/mL, was 5.9%. With 20 ng/mL, an accuracy of 0.4% was calculated. The interassay variation, determined by comparing peak area ratios on different days, is given in Table II. The limit of detection was found to be ~1 ng/mL.

Plasma Concentrations—After daily repeated topical applications of 600 mg of I to two male volunteers, plasma levels of the drug were <20 ng/mL (Table III). During the first week of treatment the body was kept under occlusion for 22 h/d, while in the following weeks there was no occlusion. However, there were no differences in plasma levels between the two parts of the study. One week after the last treatment, the concentration of I had dropped below the limit of detection of ~1 ng/mL.

The analytical assay described differs from other methods for the detection of steroids by its simple extraction and, more importantly, lack of derivatization for a GC analysis. For similar molecules, such as testosterone and dihydrotestosterone, less simple procedures have been described in the literature (3–6). These compounds are extracted with ether, purified on Sephadex LH 20 and Lipidex 5000, derivatized with silylating agents, and finally detected in a high-resolution mass spectrometer either by single-ion monitoring or by metastable peak determination.

In the present report, on the other hand, ether extracts are taken to dryness, the residue is dissolved in *n*-hexane, centrifuged, and the supernatant injected onto the column; the drug concentration is assayed by single-ion detection in a quadrupole mass spectrometer. Deterioration of the capillary column, either the glass or the fused silica columns used, was not observed as might be expected from the very simple extraction procedure. The column was heated every evening at 300°C for 1 h. Therefore, we were able to analyze >300 plasma samples without any loss of resolution. The method described, therefore, seems to be suitable for routine analysis of I in clinical studies.

Stability of Cefotaxime Sodium as Determined by High-Performance Liquid Chromatography

V. DAS GUPTA

Received December 3, 1982, from the *Department of Pharmaceutics, College of Pharmacy, University of Houston, Houston, TX 77030.* Accepted for publication February 24, 1983.

Abstract □ The stability of cefotaxime sodium in water (with either hydrochloric acid, phosphate buffers, or other ingredients) dextrose, and sodium chloride has been studied using a stability-indicating high-performance liquid chromatographic method with a relative standard deviation of 1.9% based on six injections. The optimum pH range of stability was determined to be ~4.3–6.2. In this pH range, the decomposition process was catalyzed only by the solvent. At pH ≤3.4, the hydrogen ion also catalyzed the reaction while at pH >6.2, the hydroxyl ion hastened the process of decomposition. The solutions in 5% dextrose and 0.9% NaCl injections were stable for at least 1, 22, and 112 d at 24°C, 4°C, and −10°C, respectively. For both solutions, the loss in potency was <5% at −10°C in 224 d, <9% at 4°C in 42 d, and <3.1% at 24°C in 1 d.

Keyphrases □ Cefotaxime sodium—stability as determined by high-performance liquid chromatography □ Stability—cefotaxime sodium, determined by high-performance liquid chromatography

Cefotaxime sodium, a new semisynthetic cephalosporin antibiotic, is effective against a wide variety of microorganisms when administered intravenously. Stability studies (1) indicate that solutions for intravenous use are stable for 24 h at 25°C, 10 d under refrigeration (<5°C) and for at least 13 weeks in the frozen state. It also appears that cefotaxime solutions exhibit maximum stability in the pH range of 5–7 and that it is not advisable to prepare solutions with diluents having a pH >7.5 (1). In general, cephalosporins have been reported to be stable (2).

Elrod *et al.* (3) reported the various methods available for the quantitation of β-lactam antibiotics, including microbiological (4), iodometric (5), colorimetric (6–8), and high-performance liquid chromatographic (HPLC) (9–12) assays. The two official procedures often specified for cephalosporins are the microbiological agar diffusion (13) and hydroxylamine (14) methods. An HPLC procedure for the quantitation of cefotaxime in serum (15) has been reported.

The purpose of this investigation was to study the stability of cefotaxime sodium at various pH values and in intravenous admixtures. A stability-indicating HPLC method is described which is rapid, accurate, and sensitive.

EXPERIMENTAL

Materials—All chemicals and reagents were either USP, NF, or ACS quality and were used without further purification. Cefotaxime sodium[1] powder was used as received. The high-pressure liquid chromatograph[2] was equipped with a multiple-wavelength detector[3], a recorder[4], and an integrator[5]. A semipolar[6] column (30 cm long × 4 mm i.d.) was used.

The mobile phase for method A contained 0.02 M ammonium acetate and 18% v/v of methanol in water. The flow rate was 2.5 mL/min, the sensitivity was 0.1 AUFS (254 nm), and the chart speed 30.5 cm/h. The temperature was ambient. Chromatographic conditions were the same for method B except that the mobile phase contained 9% v/v of acetonitrile instead of methanol and the sensitivity was 0.04 AUFS.

Methods—A stock solution was prepared fresh daily by dissolving 100 mg of cefotaxime sodium in enough water to make 100 mL of the solution. The stock solution was diluted further with water as needed. The standard solution contained 100 μg/mL of cefotaxime sodium. All the antibiotic solutions were prepared using a simple solution method (Table I). After the initial data (physical appearance, pH values[7], and assays) were obtained, the solutions were stored either at room temperature (24 ± 1°C), under refrigeration (4 ± 1°C), in the freezer (−10 ± 1°C), or at all the three temperatures.

At appropriate intervals, solutions of cefotaxime were assayed using the HPLC method. Before analysis, all solutions were diluted with water to an appropriate concentration (identical to the standard solution based on the label claim). Before dilution, the solutions were always brought to room temperature by putting the bags/bottles in tap water.

A 20-μL aliquot of the assay solution was injected into the chromatograph using the described conditions. For comparison, an identical volume of the standard solution was injected after the assay solution eluted. The concentration of cefotaxime sodium in the standard solution was identical to label claim of the assay solution.

Since preliminary investigations indicated that the peak heights were related directly to the concentrations (range tested was 0.3–2.4 μg), the results were calculated using:

$$\frac{(Ph)_a}{(Ph)_s} \times 100 = \text{percent of label claim} \qquad \text{(Eq. 1)}$$

where $(Ph)_a$ is the peak height of the assay solution and $(Ph)_s$ is the peak height of the standard solution of an identical concentration based on the label claim.

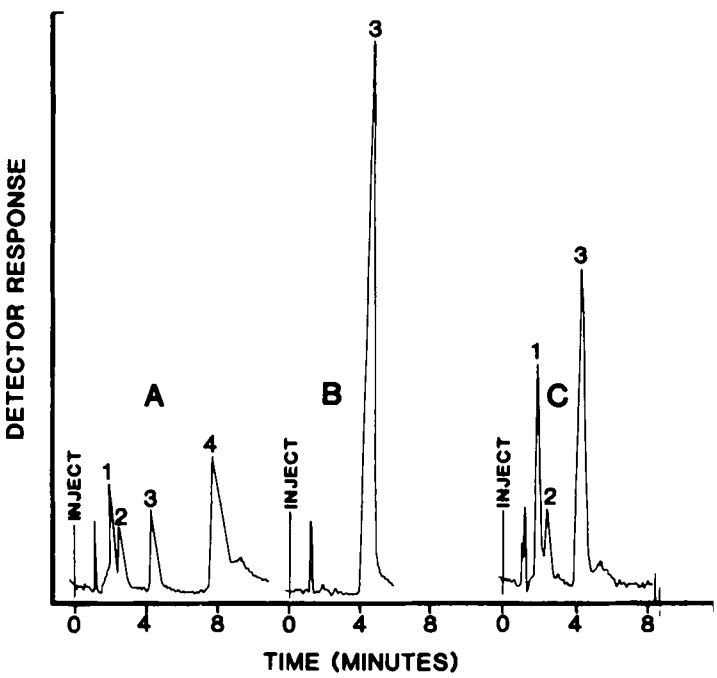

Figure 1—*Typical chromatograms; peak 3 is from cefotaxime and all others are from the decomposition products. Chromatograms A–C are from a 3-d old solution (pH 1.5), a standard solution, and 3-d old solution (pH 8.5), respectively. Chromatographic method A was used (see text).*

12	1.0	8.5	0.1 M Phosphate	0.3	Bottle

[a] Adjusted with KCl. [b] Ionic strength of this solution was not adjusted. [c] The original plastic Viaflex PL 146 bags (Travenol Laboratories), from which either 5% dextrose or 0.9% NaCl injection in water was withdrawn to make the solutions. [d] All bottles are 60-mL amber colored glass; Brockway Glass Co., Brockway, Pa.

RESULTS AND DISCUSSION

Assay Method—The method developed is reproducible with a relative standard deviation of 1.9% based on six injections. The developed procedure separated a number of decomposition products (Fig. 1A–C) from the intact drug (peak 3 in Fig. 1).

The HPLC methods developed are stability indicating (Fig. 1). In a solution of pH 1.5, there was no intact drug present after 7 d of storage. Instead there were four new peaks from the decomposition products. The author feels that the HPLC method may be better, since the results are more accurate and precise compared with the microbiological assay method. Moreover, the decomposition products, especially when only the 3-acetoxy group may have been hydrolyzed, could interfere with the microbiological assay technique, since the intact β-lactam moiety is expected to be active against the bacteria. With the HPLC procedure, this interference is not expected, due to separation of the decomposition products.

Effect of pH and Order of Reaction—The decomposition was first order (Fig. 2). The optimum pH range of stability (Fig. 3) was in the 4.3–6.2 range. At pH values of 3.4 and 7.5, the decomposition was ~10% faster than in the 4.3–6.2 pH range. At pH 1.5, the degradation was the fastest (~11 times faster than in the optimum range), and at pH 8.5 the K_{obs} was ~3 times faster than the K_{obs} between pH 4.3 and pH 6.2. The increase in buffer concentration (phosphate) and the ionic strength (solutions 6–8 in Table I) did not affect the decomposition constant. Since pH had very little effect on K_{obs} the pH range of 4.2–6.2 and reaction was catalyzed only by water, it can be assumed that K_w in Eq. 2 is 0.056 d^{-1} (K_{obs} in the pH range of 4.3–6.2):

$$K_{obs} = K_H(H^+) + K_w + K_{OH}(OH^-) \qquad \text{(Eq. 2)}$$

Neglecting the effect of OH^- at pH 1.5 and that of H^+ at pH 8.5, the K_H and K_{OH} values were estimated to be 18.0 and 3.3×10^4 $M^{-1} \cdot d^{-1}$, respectively.

Decomposition of Cefotaxime—It is well documented (2) that at lower pH, the β-lactam moiety undergoes hydrolysis (K_1 step in Scheme I, *cf.* Ref. 2), and at higher pH (~8), the side chain undergoes hydrolysis (K_2 step). In Fig. 1A (as compared with Fig. 1B) the additional unidentified peaks are from the hydrolysis of side chain (peaks 1–2) and lactonization (peaks 4–5) of the β-lactam ring. In Fig. 1C, the additional peaks (peaks 1 and 2) are from the hydrolysis of the 3-acetoxy group (side chain). The decomposition of cefotaxime in this assay solution of pH 1.5 was fast. It is obvious that decomposition products from the side chain elute immediately after the solvent, while those from the β-lactam lactonization elute after the intact drug (Fig. 1A). This was expected, since the hydrolysis of the 3-acetoxy group produced more polar product(s) while lactonization produced less polar product(s). Lactonization predominates only in the acidic medium (2). In these investigations, peaks 3–4 were small in solutions of pH 2.8 and 3.4 and absent in others (pH 4.3–8.5). The absence of lactonization in neutral and basic solutions was expected. Obviously, lactonization does not proceed even under weakly acidic conditions. Peaks 1–2 were larger in pH 8.5 solution, since hydrolysis of the 3-acetoxy group was fastest at this pH (highest in the series of solutions studied).

Stability of Intravenous Solutions—The testing results of intravenous solutions indicate (Table II) that the manufacturer-recommended (1) expiration date of 24 h at room temperature is reasonable. However, cefotaxime sodium solutions were stable for 22 d at 4°C *versus* the manufacturer-recommended expiration date of 10 d. Even in 35 d, the loss in potency was <5%. The frozen

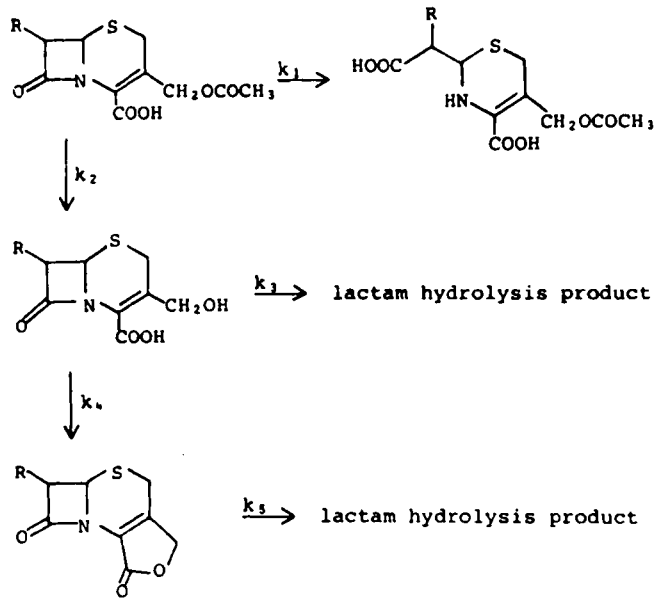
[a] Results (using chromatographic method A) of buffered solutions are presented in Figs. 2 and 3. The increase in buffer concentration and the ionic strength (solutions 6-8, Table I) did not affect the K_{obs} value. All solutions containing 1.0 mg/mL of cefotaxime sodium were clear and pH values were constant to the last day of these investigations. The solutions containing 1% cefotaxime sodium were very slightly yellow in color on day 0. The intensity of color increased after 1, 25, and 112 d of storage at 24°C, 4°C, and −10°C, respectively. [b] These were determined using chromatographic method B. The results obtained on selected samples with chromatographic method A were similar. The pH value is in parentheses.



Scheme I—Decomposition of Cefotaxime. R represents the amide side chain.

solutions were stable for at least 16 weeks. In 32 weeks, the loss in potency was <5%, and the change in pH was negligible. However, an additional important factor must be considered, *e.g.*, a poor mixing technique could contaminate the admixture and make it unsuitable for use.

Serotonergic Receptor Antagonist from *Nandina domestica* Thunberg

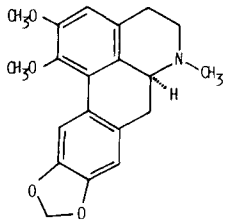
N. SHOJI *, A. UMEYAMA *, T. TAKEMOTO *, and Y. OHIZUMI ‡x

Received May 10, 1982, from the **Faculty of Pharmacy, Tokushima-Bunri University, Tokushima-shi, Tokushima 770*, and the ‡*Mitsubishi-Kasei Institute of Life Sciences, 11 Minamiooya, Machida-shi, Tokyo 194, Japan.* Accepted for publication March 21, 1983.

Abstract □ A crude methanolic extract of the fruit of *Nandina domestica* Thunberg strongly inhibits serotonin-induced contractions of the rabbit aorta. The extract of the fruit has been fractionated to afford nantenine (*O*-methyldomesticine) as the active agent.

Keyphrases □ *Nandina domestica* Thunberg—nantenine, extraction, serotonergic receptor antagonist, isolated rabbit aorta □ Nantenine—serotonergic receptor antagonist extracted from *Nandina domestica* Thunberg, isolated rabbit aorta □ Serotonergic receptor antagonist—nantenine, extracted from *Nandina domestica* Thunberg, isolated rabbit aorta

The fruit of *Nandina domestica* Thunberg (Berberidaceae) has been used to treat asthma, whooping cough, pharynx tumor, and uterine bleeding in Japan for many years (1). Chemical studies on the constituents of the plant have revealed that presence of numerous alkaloids in this species (1–18). Initially, it was found that the crude methanolic extract of the fruit selectively inhibited serotonin-induced contractions of isolated rabbit aorta without producing inhibitory effects on contractions induced by potassium chloride or histamine. In this paper, the isolation and the determination of the chemical structure of the antiserotonergic substance from the fruit are described.



Fruits of *Nandina domestica* Thunberg (4 kg)

EXPERIMENTAL[1]

Isolation—The dried, powdered fruit[2] (4 kg) of *N. domestica* were extracted with methanol (3 × 6 L) at room temperature yielding an extract (729 g), which was fractionated and monitored for inhibitory effects on the serotonin-induced contraction of rabbit aorta, as shown in Scheme I. The pharmacologically active *n*-butyl alcohol fraction was evaporated to dryness *in vacuo*, the residue (158 g) was chromatographed on silica gel[3] eluted with chloroform–methanol mixtures of increasing polarity, and fractionated successively. Each fraction was monitored by TLC[4] with chloroform–methanol–water (65:30:4) as the developing solvent and Dragendorf reagent as the detecting spray. The active second fraction (fraction II) was evaporated to dryness *in vacuo*, and the residue (44 g) was rechromatographed on silica gel using the chloroform–methanol solvent system. The active fraction (12.8 g) from the first eluate (fraction A) was recrystallized from ethyl acetate to give 8.0 g of nantenine as colorless needles ($C_{20}H_{21}NO_3$), mp 140–141°C [lit. (2) mp 139°C], $[\alpha]_D$ + 102.0° (*c* 1.0, $CHCl_3$) [lit. (2) $[\alpha]_D$ + 101.7°]; ^{1}H-NMR (pyridine-d_5): δ 2.43 (s, 3, N—CH_3), 3.72 (s, 3, C(1)—OCH_3), 3.76 (s, 3, C(2)—OCH_3), 6.00 (s, 2, O—CH_2—O), 6.66 (s, 1, C(3)—H), 6.87 (s, 1, C(8)—H), and 8.20 ppm (s, 1, C(11)—H); ^{13}C-NMR (pyridine-d_5): δ 29.66 (t, C-4), 35.52 (t, C-5), 44.03 (q, N—CH_3), 53.47 (t, C-7), 55.86 (d, C-6a), 60.06 (q, C(1)—OCH_3), 63.02 (q, C(2)—OCH_3), 101.47 (t, O CH_2—O), 108.95 (d, C-3), 109.22 (d, C-8), 111.80 (d, C-11), 126.21 (s, C-11b), 127.28

[1] Melting points were obtained on a Yanagimoto micro melting point apparatus and are uncorrected. Optical rotation was recorded on a Jasco DIP-180 digital polarimeter. UV spectra were obtained with a Hitachi 200-20 spectrophotometer. IR spectra were obtained on a Hitachi R-22 spectrometer. ^{1}H- and ^{13}C-NMR spectra were recorded on a Shimadzu LKB-9000B.

(s, C-11c), 128.25 (s, C-7a), 129.44 (s, C-3a), 131.68 (s, C-11a), 145.24 (s, C-2), 147.01 (s, C-9*), 147.13 (s, C-10*), and 152.60 ppm (s, C-1). Assignments are interchangeable between carbons with an asterisk. The MS and UV spectra were identical with published spectra (11, 13).

Bioassay—Male albino rabbits (2–3 kg) were killed by cervical dislocation. The aortae were removed and cut into helical strips. The strips were mounted vertically in a 20-mL organ bath containing Krebs–Ringer bicarbonate solution (pH 7.4) of the following composition (in mmoles): sodium chloride, 120; potassium chloride, 4.8; calcium chloride, 1.2; magnesium sulfate, 1.3; monobasic potassium phosphate, 1.2; sodium bicarbonate, 25.2; and glucose, 5.8. The solution was bubbled with a gas mixture of oxygen–carbon dioxide (95:5, v/v) and maintained at 37°C. A resting tension of 1 g was applied to the strips and isometric contractions were recorded with a force displacement transducer.

Male Wistar rats (300–350 g) were killed by a blow on the neck and the stomach was removed. The fundus was cut longitudinally into strips (20 × 2 mm) as described by Offermeiser and Ariens (19). The strips were suspended in a 20-mL organ bath containing Krebs–Ringer bicarbonate solution. The solution was aerated with oxygen–carbon dioxide (95:5 v/v) and maintained at 37°C. A resting tension of 0.5 g was applied to the strips. Mechanical responses were recorded isotonically on a pen recorder through an isotonic transducer.

RESULTS AND DISCUSSION

A methanolic extract of the fruit of *N. domestica* almost completely inhibited the serotonin-induced contractions of isolated rabbit aorta and had no effect on contractions induced by potassium chloride or histamine. To isolate the active substance, fractionation of the methanolic extract of the fruits were performed (Scheme 1), accompanied by a bioassay using isolated rabbit aorta. Silica gel chromatography of the *n*-butyl alcohol-soluble portion of the methanolic extract afforded the active substance as colorless crystals (8.0 g, 0.2% dry weight of the fruit). The compound showed a positive Dragendorff test and its physicochemical properties (*i.e.*, melting point, specific optical rotation, UV absorption, and mass spectrum) agreed with those of nantenine (1, 5, 6, 11, 13), which was previously isolated as a major alkaloid of the same material. Furthermore, the ^{1}H- and ^{13}C-NMR spectra also supported the identity of the active substance as nantenine (see *Experimental*).

In isolated rabbit aorta, nantenine (3×10^{-6} M) produced a parallel, right shift of the dose–response curve for the contractile effect of serotonin, but had no effect on the dose–response curves for histamine and potassium chloride (Fig. 1), indicating competitive antagonism. Furthermore, in rat stomach strips, nantenine (3×10^{-6} M) shifted the dose–contractile response curve for serotonin to the right in a similar manner, but the dose–response curves for carbachol and potassium chloride were not affected by nantenine (Fig. 2). These results suggest that nantenine selectively inhibits the contractile response of these tissues to serotonin. On the basis of the present results, it is concluded that *N. domestica* Thunberg has a serotonergic receptor blocking action in the isolated rabbit aorta, and that the main active compound is nantenine.

Computation of Model-Independent Pharmacokinetic Parameters During Multiple Dosing

Keyphrases □ Pharmacokinetic parameters—model independent, multiple dosing

To the Editor:

In a recent article, Bauer and Gibaldi (1) reported an alternate, noncompartmental method to calculate pharmacokinetic parameters during multiple dosing. The method was based on reverse superposition from which a single-dose drug concentration–time curve was derived from data obtained at steady state. The following method would be a more general approach for computation of model-independent pharmacokinetic parameters during multiple dosing. The plasma drug concentration–time curve after the Nth dose (C_N) of a fixed dose of a drug at a given dosing interval of τ can be described by Eq. 1, when a drug obeys linear pharmacokinetics:

$$C_N = \sum_{i=1}^{n} A_i \frac{1 - \exp(-Nk_i\tau)}{1 - \exp(-k_i\tau)} \exp(-k_i t) = \sum_{i=1}^{n} I_i \exp(-k_i t) \quad \text{(Eq. 1)}$$

where A_i and I_i are the coefficients of the specific first-order rate constant, k_i, after a single dose and the Nth dose, respectively; t is the time after each drug administration. The total area under the plasma drug concentration–time curve (AUC) from the time after the Nth dose is given to time infinity, $\text{AUC}(\infty)_N$ can be obtained as follows:

Computation of Model-Independent Pharmacokinetic Parameters During Multiple Dosing

Keyphrases □ Pharmacokinetic parameters—model independent, multiple dosing

To the Editor:

In a recent article, Bauer and Gibaldi (1) reported an alternate, noncompartmental method to calculate pharmacokinetic parameters during multiple dosing. The method was based on reverse superposition from which a single-dose drug concentration–time curve was derived from data obtained at steady state. The following method would be a more general approach for computation of model-independent pharmacokinetic parameters during multiple dosing. The plasma drug concentration–time curve after the Nth dose (C_N) of a fixed dose of a drug at a given dosing interval of τ can be described by Eq. 1, when a drug obeys linear pharmacokinetics:

$$C_N = \sum_{i=1}^{n} A_i \frac{1 - \exp(-Nk_i\tau)}{1 - \exp(-k_i\tau)} \exp(-k_i t) = \sum_{i=1}^{n} I_i \exp(-k_i t) \quad \text{(Eq. 1)}$$

where A_i and I_i are the coefficients of the specific first-order rate constant, k_i, after a single dose and the Nth dose, respectively; t is the time after each drug administration. The total area under the plasma drug concentration–time curve (AUC) from the time after the Nth dose is given to time infinity, $\text{AUC}(\infty)_N$ can be obtained as follows:

0022-3549/84/0400-0570$01.00/0

© 1984, American Pharmaceutical Association

$$\mathrm{AUC}(\infty)_N = \int_0^{\infty} C_N dt = \sum_{i=1}^{n} \frac{I_i}{k_i} = \mathrm{AUC}(\infty) + \sum_{i=1}^{n} \frac{A_i[1 - \exp(-(N-1)k_i\tau)\exp(-k_i\tau)]}{k_i[1 - \exp(-k_i\tau)]} = \mathrm{AUC}(\infty)_{ss} - \sum_{i=1}^{n} \frac{A_i \exp(-Nk_i\tau)}{k_i[1 - \exp(k_i\tau)]} \quad \text{(Eq. 2)}$$

When the dosing interval is located in the terminal phase, Eq. 2 can be approximated by Eq. 2a:

$$\mathrm{AUC}(\infty)_N = \mathrm{AUC}(\infty) + C_{\min N-1}/k_n = \mathrm{AUC}(\infty)_{ss} - (C_{\min ss} - C_{\min N-1})/k_n \quad \text{(Eq. 2a)}$$

where $\mathrm{AUC}(\infty)$ and $\mathrm{AUC}(\infty)_{ss}$ are the total areas after a single dose and at steady state, respectively; $C_{\min N-1}$ and $C_{\min ss}$ are the plasma drug concentrations at the dosing interval after the $(N-1)$th dose and at steady state, respectively; k_n is the terminal phase disposition rate constant.

The $\mathrm{AUC}(\infty)_N$ can be obtained by numerical integration using the trapezoidal rule from the time course data of plasma drug concentrations:

$$\mathrm{AUC}(\infty)_n = \int_0^{t^*} C_N dt + \int_{t^*}^{\infty} C_N dt = \sum_{i=1}^{n} \frac{1}{2}(C_{Ni} + C_{Ni-1})(t_i - t_{i-1}) + \sum_{i=1}^{n} \frac{I_i \exp(-k_i t^*)}{k_i} \quad \text{(Eq. 3)}$$

The residual area from t^* (usually the last sampling time point) to infinity is usually approximated by C_N^*/k_n, where C_N^* is the estimated drug concentration at time t^* after the Nth dose.

The total area under the first moment of the plasma drug concentration–time curve after the Nth dose, $\mathrm{AUMC}(\infty)_N$ can be calculated as follows:

$$\mathrm{AUMC}(\infty)_N = \int_0^{\infty} tC_N dt = \sum_{i=1}^{n} \frac{I_i}{k_i^2} = \mathrm{AUMC}(\infty) + \sum_{i=1}^{n} \frac{A_i[1 - \exp(-(N-1)k_i\tau)\exp(-k_i\tau)]}{k_i^2[1 - \exp(-k_i\tau)]} = \mathrm{AUMC}(\infty)_{ss} - \sum_{i=1}^{n} \frac{A_i \exp(-Nk_i\tau)}{k_i^2[1 - \exp(-k_i\tau)]} \quad \text{(Eq. 4)}$$

When the τ is located in the terminal phase, Eq. 4 can be approximated by Eq. 4a:

$$\mathrm{AUMC}(\infty)_N = \mathrm{AUMC}(\infty) + C_{\min N-1}/k_n^2 = \mathrm{AUMC}(\infty)_{ss} - (C_{\min ss} - C_{\min N-1})/k_n^2 \quad \text{(Eq. 4a)}$$

where $\mathrm{AUMC}(\infty)$ and $\mathrm{AUMC}(\infty)_{ss}$ are the total area moments after a single dose and at steady state, respectively. The $\mathrm{AUMC}(\infty)_N$ can also be obtained as follows:

$$\mathrm{AUMC}(\infty)_N = \sum_{i=1}^{n} \frac{1}{2}(t_i C_{Ni} + t_{i-1}C_{Ni-1})(t_i - t_{i-1}) + \sum_{i=1}^{n} \frac{I_i}{k_i^2}(1 + k_i t^*)\exp(-k_i t^*) \quad \text{(Eq. 5)}$$

The residual area moment from t^* to infinity is usually approximated by:

$$\frac{C_N^*}{k_n^2} + \frac{t^* C_N^*}{k_n}$$

According to the statistical concept of moments for pharmacokinetics, the mean residence time of a drug in the body (MRT) after a single dose is defined as follows (2):

$$\mathrm{MRT} = \frac{\mathrm{AUMC}(\infty)}{\mathrm{AUC}(\infty)} = \frac{\sum_{i=1}^{n} A_i/k_i^2}{\sum_{i=1}^{n} A_i/k_i} \quad \text{(Eq. 6)}$$

This concept can be extended to the observed data after the Nth dose and at steady state by applying Eqs. 2a and 4a as follows:

$$\mathrm{MRT} = \frac{k_n^2\,\mathrm{AUMC}(\infty)_N - C_{\min N-1}}{k_n[k_n\mathrm{AUC}(\infty)_N - C_{\min N-1}]} = \frac{k_n^2\mathrm{AUMC}(\infty)_{ss} - C_{\min ss}}{k_n[k_n\mathrm{AUC}(\infty)_{ss} - C_{\min ss}]} \quad \text{(Eq. 7)}$$

For the data obtained during the dosing interval:

$$\mathrm{MRT} = \frac{k_n^2\mathrm{AUMC}(\tau)_N + k_n\tau C_{minN} + C_{minN} - C_{minN-1}}{k_n[k_n\mathrm{AUC}(\tau)_N + C_{minN} - C_{minN-1}]} = \frac{k_n\mathrm{AUMC}(\tau)_{ss} + \tau C_{\min ss}}{k_n\mathrm{AUC}(\tau)_{ss}} = \frac{\mathrm{AUMC}(\tau)_{ss}}{\mathrm{AUC}(\tau)_{ss}} + \frac{\tau C_{\min ss}}{k_n\mathrm{AUC}(\tau)_{ss}} \quad \text{(Eq. 8)}$$

Although Bauer and Gibaldi (1) stated that the apparent volume of distribution at steady state, Vd_{ss}, cannot be calculated directly from steady-state data, Vd_{ss} can be calculated from the MRT (using Eq. 7 or Eq. 8) after multiple intravenous bolus dosing of a drug as (3):

$$Vd_{ss} = \mathrm{TBC}\cdot\mathrm{MRT} \quad \text{(Eq. 9)}$$

where total body clearance (TBC) after the Nth dose and at steady state can be calculated as:

$$\mathrm{TBC} = \frac{k_n\cdot\mathrm{Dose}}{k_n\mathrm{AUC}(\infty)_N - C_{\min N-1}} = \frac{\mathrm{Dose}}{\mathrm{AUC}(\tau)_{ss}} \quad \text{(Eq. 10)}$$

No model has to be assumed to calculate MRT, Vd_{ss}, and TBC after multiple dosing. This method can be applied to data obtained from any number of doses including steady state and does not require the plasma drug concentrations derived by means of reverse superposition. The method describes an exact solution and its approximation. The approximation requires an assumption that doses must be administered during the terminal phase. This assumption is generally valid. When the assumption is not valid, one may use the exponential equations to calculate the residual area and area moment.

Analytical Profiles of Drug Substances, Vol. 12. Edited by KLAUS FLOREY. Academic Press, 111 Fifth Avenue, New York, NY 10003. 1983. 735 pp. 15 × 23 cm. Price $47.00.

Continuing the yearly volumes in the series, analytical profiles of 17 drug substances are given in 713 pages. These are: amantadine, amikacin sulfate, benzocaine, dibucaine and dibucaine hydrochloride, estrone, etomidate, heparin sodium, hydrocortisone, metoprolol tartrate, phenylpropanolamine hydrochloride, pilocarpine, pyrazinamide, pyrimethamine, quinidine sulfate, quinine hydrochloride, rutin, and trimipramine maleate. There are also two profile supplements: dioctyl sodium sulfosuccinate (8 pp.) and isopropamide (12 pp.). The main profiles for each of these are in Volume 2.

This volume follows the pattern set in Volume 11. It has all of the strengths of the extensive data given in an analytical profile (including structures, spectra, tables of properties and chromatographic systems, and extensive references) and the lack of consistency inherent in having different authorships of each profile [see review of Vol. 11, *J. Pharm. Sci.*, **72,** 582 (1983)]. One reference which was looked for was found as reference 69 under pilocarpine; however, the authors listed are not correct. This volume, like the others in the series, is a valuable reference for those engaged in pharmaceutical formulation and quality control and those needing information on drug metabolism, biopharmaceutics, and pharmacokinetics.

Cell Surface Receptors. Edited by P. G. STRANGE. John Wiley and Sons, Inc., One Wiley Drive, Somerset, NJ 08873. 1983. 298 pp. 16 × 24 cm. Price $79.95.

Dr. Strange has assembled a collection of some 15 reviews, average length 20 pages, dealing with a variety of membrane receptors and approaches to the study of receptor structure and function. Included are chapters on α_2-adrenoceptors, opiate, benzodiazepine, dopamine, and calcium receptors, focusing largely on structure–activity relationships seen through pharmacological and radioligand binding studies. Other chapters discuss receptor changes and regulation including neuroleptic–dopamine interactions, biogenic amine changes in schizophrenia, regulation of GnRH receptors, cyclase defects in pseudohypoparathyroidism, and the implications of coexistence of amine and peptide transmitters. Coupling mechanisms are considered in chapters on phospholipids and adenylate cyclase. Final chapters discuss the gene coding of the nicotinic acetylcholine receptor and radioreceptor assays in quantitative drug assay.

Despite the necessary brevity of the chapters, there is material of interest to expert and nonexpert alike. Each chapter is, at least, adequately written with decent illustrations and few misprints. Few will leave the book without both gaining some useful insights and a deepened appreciation for the rapid pace of development of the study of pharmacological receptors. However, it is difficult to determine the primary audience for this book. To the nonexpert, graduate student, or new worker in the field, the volume is simply not systematic enough; however, the volume could certainly be a helpful supplementary volume accompanying a more basic course. For this purpose, the book is highly priced. To the expert, the volume may be useful in providing brief reviews in a number of receptor areas, but probably not to the extent of individual purchase.

In summary, I enjoyed reading this book and obtained some useful insights into a number of receptor areas. I do not recommend it for individual purchase, but an institutional purchase would certainly be appropriate.

Manufacturing Processes for New Pharmaceuticals. By MARSHALL SITTIG. Noyes Publications, Mill Road at Grand Avenue, Park Ridge, NJ 07656. 1983. 612 pp., 15 × 23 cm. Price $84.00.

This is Chemical Technology Review No. 220 from Noyes Publications. The book describes the processes for the manufacture of nearly 500 new-chemical-entity pharmaceuticals. The great majority of the compounds are undergoing some level of FDA review, with approval as new drugs being the ultimate goal. The author states in the foreword to the book that the information used in the reviews was obtained from the patent literature, and that the new drugs described have attained generic name status, but in most cases have not yet received trade names.

The arrangement within the reference is alphabetical by generic name. There is no index or cross-index of the compounds listed in the book by chemical name. The lack of such a chemical name index detracts from the value of the book, since its not possible to conveniently determine whether or not a particular compound is listed in the book, unless the generic name is known.

Under each entry in the book, the generic name is given first, followed by the therapeutic function of the compound, the chemical name, the empirical chemical formula, the structural formula, in some cases a product description (usually limited to the melting point), the code number of the compound, the manufacturer and country, the manufacturing process, and references. The manufacturing processes are described in detail. In some cases, several alternative syntheses are given. Where intermediates are involved, the syntheses of the intermediates are given. In addition to the one or more patent references given with each compound, other references are frequently given, where results of pharmacological studies or other data on therapeutic uses, adverse effects, or precautions may be found.

The book is intended as a guide to future drugs. The book should thus be of interest to scientists engaged in the design and development of new drugs. Furthermore, some of the chemical synthesis manufacturing methods reported for the wide range of compounds in the book will be of interest to medicinal and organic chemists.

Antibiotics: An Introduction. By ROLAND REINER. Thieme-Stratton Inc., 381 Park Avenue South, New York, NY 10016. 1982. 172 pp. 12 × 19 cm. Price $9.95.

This small volume is intended to provide "a condensed introduction to the chemistry, biochemistry, biology, pharmacy, and medical usage of antibiotics." The book begins with a brief historical outline in tabular form of the discovery of important chemotherapeutic agents. This is followed by very brief discussions concerning the detection and determination of antibiotic activity and the production and isolation of antibiotics. The chapter entitled "Chemistry of Antibiotics" includes a limited discussion of the structure proof of penicillin and oxytetracycline, followed by a series of schemes illustrating the partial and total synthesis of several antibiotics. The synthetic pathways are not discussed. The chapter on "Mechanism of Action of Antibiotics" is presented in tabular form listing the antibiotic class and site of action with minimal discussion. A chapter entitled "Chemotherapeutic Properties of Antibiotics" provides a brief overview of the clinical use, antibacterial spectrum, administration and dosage, and bacterial resistance of important antibiotics. The information is presented primarily in tabular form. The final chapter, about one-third of the book, is entitled "Structural Formulas and Main Properties of Individual Antibiotics." This chapter consists primarily of the structural and empirical formulas and molecular weight of over 100 antibiotics. A bibliography containing an extensive listing of mono-

Antibiotics: An Introduction. By ROLAND REINER. Thieme-Stratton Inc., 381 Park Avenue South, New York, NY 10016. 1982. 172 pp. 12 × 19 cm. Price $9.95.

This small volume is intended to provide "a condensed introduction to the chemistry, biochemistry, biology, pharmacy, and medical usage of antibiotics." The book begins with a brief historical outline in tabular form of the discovery of important chemotherapeutic agents. This is followed by very brief discussions concerning the detection and determination of antibiotic activity and the production and isolation of antibiotics. The chapter entitled "Chemistry of Antibiotics" includes a limited discussion of the structure proof of penicillin and oxytetracycline, followed by a series of schemes illustrating the partial and total synthesis of several antibiotics. The synthetic pathways are not discussed. The chapter on "Mechanism of Action of Antibiotics" is presented in tabular form listing the antibiotic class and site of action with minimal discussion. A chapter entitled "Chemotherapeutic Properties of Antibiotics" provides a brief overview of the clinical use, antibacterial spectrum, administration and dosage, and bacterial resistance of important antibiotics. The information is presented primarily in tabular form. The final chapter, about one-third of the book, is entitled "Structural Formulas and Main Properties of Individual Antibiotics." This chapter consists primarily of the structural and empirical formulas and molecular weight of over 100 antibiotics. A bibliography containing an extensive listing of mono-

Analytical Profiles of Drug Substances, Vol. 12. Edited by KLAUS FLOREY. Academic Press, 111 Fifth Avenue, New York, NY 10003. 1983. 735 pp. 15 × 23 cm. Price $47.00.

Continuing the yearly volumes in the series, analytical profiles of 17 drug substances are given in 713 pages. These are: amantadine, amikacin sulfate, benzocaine, dibucaine and dibucaine hydrochloride, estrone, etomidate, heparin sodium, hydrocortisone, metoprolol tartrate, phenylpropanolamine hydrochloride, pilocarpine, pyrazinamide, pyrimethamine, quinidine sulfate, quinine hydrochloride, rutin, and trimipramine maleate. There are also two profile supplements: dioctyl sodium sulfosuccinate (8 pp.) and isopropamide (12 pp.). The main profiles for each of these are in Volume 2.

This volume follows the pattern set in Volume 11. It has all of the strengths of the extensive data given in an analytical profile (including structures, spectra, tables of properties and chromatographic systems, and extensive references) and the lack of consistency inherent in having different authorships of each profile [see review of Vol. 11, *J. Pharm. Sci.*, **72,** 582 (1983)]. One reference which was looked for was found as reference 69 under pilocarpine; however, the authors listed are not correct. This volume, like the others in the series, is a valuable reference for those engaged in pharmaceutical formulation and quality control and those needing information on drug metabolism, biopharmaceutics, and pharmacokinetics.

Cell Surface Receptors. Edited by P. G. STRANGE. John Wiley and Sons, Inc., One Wiley Drive, Somerset, NJ 08873. 1983. 298 pp. 16 × 24 cm. Price $79.95.

Dr. Strange has assembled a collection of some 15 reviews, average length 20 pages, dealing with a variety of membrane receptors and approaches to the study of receptor structure and function. Included are chapters on α_2-adrenoceptors, opiate, benzodiazepine, dopamine, and calcium receptors, focusing largely on structure–activity relationships seen through pharmacological and radioligand binding studies. Other chapters discuss receptor changes and regulation including neuroleptic–dopamine interactions, biogenic amine changes in schizophrenia, regulation of GnRH receptors, cyclase defects in pseudohypoparathyroidism, and the implications of coexistence of amine and peptide transmitters. Coupling mechanisms are considered in chapters on phospholipids and adenylate cyclase. Final chapters discuss the gene coding of the nicotinic acetylcholine receptor and radioreceptor assays in quantitative drug assay.

Despite the necessary brevity of the chapters, there is material of interest to expert and nonexpert alike. Each chapter is, at least, adequately written with decent illustrations and few misprints. Few will leave the book without both gaining some useful insights and a deepened appreciation for the rapid pace of development of the study of pharmacological receptors. However, it is difficult to determine the primary audience for this book. To the nonexpert, graduate student, or new worker in the field, the volume is simply not systematic enough; however, the volume could certainly be a helpful supplementary volume accompanying a more basic course. For this purpose, the book is highly priced. To the expert, the volume may be useful in providing brief reviews in a number of receptor areas, but probably not to the extent of individual purchase.

In summary, I enjoyed reading this book and obtained some useful insights into a number of receptor areas. I do not recommend it for individual purchase, but an institutional purchase would certainly be appropriate.

Manufacturing Processes for New Pharmaceuticals. By MARSHALL SITTIG. Noyes Publications, Mill Road at Grand Avenue, Park Ridge, NJ 07656. 1983. 612 pp., 15 × 23 cm. Price $84.00.

This is Chemical Technology Review No. 220 from Noyes Publications. The book describes the processes for the manufacture of nearly 500 new-chemical-entity pharmaceuticals. The great majority of the compounds are undergoing some level of FDA review, with approval as new drugs being the ultimate goal. The author states in the foreword to the book that the information used in the reviews was obtained from the patent literature, and that the new drugs described have attained generic name status, but in most cases have not yet received trade names.

The arrangement within the reference is alphabetical by generic name. There is no index or cross-index of the compounds listed in the book by chemical name. The lack of such a chemical name index detracts from the value of the book, since its not possible to conveniently determine whether or not a particular compound is listed in the book, unless the generic name is known.

Under each entry in the book, the generic name is given first, followed by the therapeutic function of the compound, the chemical name, the empirical chemical formula, the structural formula, in some cases a product description (usually limited to the melting point), the code number of the compound, the manufacturer and country, the manufacturing process, and references. The manufacturing processes are described in detail. In some cases, several alternative syntheses are given. Where intermediates are involved, the syntheses of the intermediates are given. In addition to the one or more patent references given with each compound, other references are frequently given, where results of pharmacological studies or other data on therapeutic uses, adverse effects, or precautions may be found.

The book is intended as a guide to future drugs. The book should thus be of interest to scientists engaged in the design and development of new drugs. Furthermore, some of the chemical synthesis manufacturing methods reported for the wide range of compounds in the book will be of interest to medicinal and organic chemists.

Solid-State Chemistry of Drugs. By STEPHEN R. BYRN. Academic Press, 111 Fifth Avenue, New York, NY 10003. 1982. 346 pp. 15 × 23 cm. Price $55.00.

The literature on solid-state chemistry is not abundant, and the topic of solid-state chemistry of drugs *per se* has not been treated previously in book form. (Granted, chapters in books and reviews in journals have appeared.) Dr. Byrn's book hence fills a void. It is refreshing to note, at the onset, that it does this very well.

The book is, first of all, self-contained. It commences with morphological descriptions and definitions, followed by a broad overview of what actually happens in a solid when the molecules contained in it (or some of them) undergo chemical change. It then gives examples of the various types of solid-state reactions documented in the literature (and of pharmaceutical interest).

A chapter is devoted to methods of analysis, in a somewhat different way than the casual reader might expect. The tools of trade in this field, if mechanistic understanding is the goal, are X-ray, spectroscopy, and thermal methods. In other words, the analysis section is not cluttered with specific assay methods, but rather with the specific tools. It might have been instructive to have a section dealing with high-vacuum techniques of gas analysis, since these are frequently used in solid-state kinetics in isothermal studies of gas-producing reactions.

The chapter on solid-state kinetics is excellent and covers all essential principles. Particularly useful is Table I, where one particular reaction is treated by a large number of different mechanistic models, leading to the conclusion (not surprisingly) that simply fitting the data to a model will not, in itself, serve as a selection criterion. That philosophy is true in general, but is well stated.

A large chapter is devoted to polymorphism, an important aspect not often thought of as "chemistry" (as implied in the title of the book). But, it certainly belongs in the book and should be of great usefulness to those working in this particular field.

The book contains a wealth of examples. It is written in a very pleasant style. A must for the pharmaceutical scientist involved in solid dosage forms.

Dermatological Formulations: Percutaneous Absorption. By BRIAN W. BARRY. Marcel Dekker, 270 Madison Avenue, New York, NY 10016. 1983. 479 pp. 16 × 23.5 cm. Price $55.00 (20% higher outside the U.S. and Canada).

This is a concise, single-authored overview of percutaneous penetration as it relates to dermatological formulations. Demonstrating the breadth and depth of his personal reading and experience, Dr. Barry singlehandedly tackles many different areas. He starts with a brief overview of the structure, function, diseases, and topical treatment of human skin. The second chapter is a classical review of the principles of diffusion through membranes. He next discusses the facts and theory related to skin transport and properties influencing percutaneous absorption. Following a brief review of methods for quantitating absorption, he ends with two strong chapters on formulation and rheology of dermatological vehicles.

This book is heartily recommended for the novitiate as well as the expert. Being a personal statement, you will enjoy the author's strengths and weaknesses in terms of understanding the field. The index is unique in that it allows you to find the primary places where each author is mentioned throughout the book. In the short time that I have had it, I easily justified the cost of the book by rapidly finding author references.

Alkaloids, Volume 1: Chemical and Biological Perspectives. Edited by S. WILLIAM PELLETIER. Wiley-Interscience, 605 Third Avenue, New York, NY 10158. 1983. 398 pp. 16 × 24 cm. Price $60.00.

Alkaloids never seem to cease attracting the interest of chemists. Since the turn of the century, numerous books and series have been published on the subject. This is another ambitious, comprehensive treatise intending to add new perspectives to the subject. The series takes a new topic-oriented approach, departing from the traditional descriptive system based on the class of compounds.

The first volume begins with the nature and definition of an alkaloid by the editor and includes such mixed topics as "Arthropod Alkaloids: Distribution, Functions, and Chemistry," by T. H. Jones and M. S. Blum; "Biosynthesis and Metabolism of the Tobacco Alkaloids," by E. Leete; "The Toxicology and Pharmacology of Diterpenoid Alkaloids," by M. H. Benn and J. M. Jacyno; and "A Chemotaxonomic Investigation of the Plant Families of Apocynaceae, Loganiaceae, and Rubiaceae by Their Indole Alkaloid Content," by M. V. Kisakurek, A. J. M. Leeuwenberg, and M. Hesse. All were written by unquestionable experts in their particular field and provide not only first-hand information by researchers themselves, but also deep insights into the individual subjects.

Dr. Pelletier's devotion to the chemistry of alkaloids, especially diterpenoid alkaloids, is widely known, and his ability to cover this broad topic is also well-proven by his earlier publication in *The Royal Society of Chemistry—Specialist Periodical Reports* on alkaloids. In the first volume he has certainly exercised his knowledge of the topics and taken advantage of his close acquaintance with top researchers in the individual fields. However, it remains to be seen in future volumes how successful the series will be in raising the interest of interdisciplinary readers in such diversified areas as medicinal chemistry, natural products chemistry, pharmacology, pharmacognosy, biochemistry, phytochemistry, plant taxonomy, oncology, forensic science, and medicine as originally intended. At any rate, in conjunction with recent research interest in natural products chemistry, books taking the multidisciplinary approach as, for example, a series on marine natural products with the same subtitle (*Marine Natural Products: Chemical and Biological Perspectives*, P. J. Scheuer, Ed., Academic Press, Volumes I–V), are seen more and more on the bookshelves.

This is a concise, single-authored overview of percutaneous penetration as it relates to dermatological formulations. Demonstrating the breadth and depth of his personal reading and experience, Dr. Barry singlehandedly tackles many different areas. He starts with a brief overview of the structure, function, diseases, and topical treatment of human skin. The second chapter is a classical review of the principles of diffusion through membranes. He next discusses the facts and theory related to skin transport and properties influencing percutaneous absorption. Following a brief review of methods for quantitating absorption, he ends with two strong chapters on formulation and rheology of dermatological vehicles.

This book is heartily recommended for the novitiate as well as the expert. Being a personal statement, you will enjoy the author's strengths and weaknesses in terms of understanding the field. The index is unique in that it allows you to find the primary places where each author is mentioned throughout the book. In the short time that I have had it, I easily justified the cost of the book by rapidly finding author references.

Alkaloids, Volume 1: Chemical and Biological Perspectives. Edited by S. WILLIAM PELLETIER. Wiley-Interscience, 605 Third Avenue, New York, NY 10158. 1983. 398 pp. 16 × 24 cm. Price $60.00.

Alkaloids never seem to cease attracting the interest of chemists. Since the turn of the century, numerous books and series have been published on the subject. This is another ambitious, comprehensive treatise intending to add new perspectives to the subject. The series takes a new topic-oriented approach, departing from the traditional descriptive system based on the class of compounds.

The first volume begins with the nature and definition of an alkaloid by the editor and includes such mixed topics as "Arthropod Alkaloids: Distribution, Functions, and Chemistry," by T. H. Jones and M. S. Blum; "Biosynthesis and Metabolism of the Tobacco Alkaloids," by E. Leete; "The Toxicology and Pharmacology of Diterpenoid Alkaloids," by M. H. Benn and J. M. Jacyno; and "A Chemotaxonomic Investigation of the Plant Families of Apocynaceae, Loganiaceae, and Rubiaceae by Their Indole Alkaloid Content," by M. V. Kisakurek, A. J. M. Leeuwenberg, and M. Hesse. All were written by unquestionable experts in their particular field and provide not only first-hand information by researchers themselves, but also deep insights into the individual subjects.

Dr. Pelletier's devotion to the chemistry of alkaloids, especially diterpenoid alkaloids, is widely known, and his ability to cover this broad topic is also well-proven by his earlier publication in *The Royal Society of Chemistry—Specialist Periodical Reports* on alkaloids. In the first volume he has certainly exercised his knowledge of the topics and taken advantage of his close acquaintance with top researchers in the individual fields. However, it remains to be seen in future volumes how successful the series will be in raising the interest of interdisciplinary readers in such diversified areas as medicinal chemistry, natural products chemistry, pharmacology, pharmacognosy, biochemistry, phytochemistry, plant taxonomy, oncology, forensic science, and medicine as originally intended. At any rate, in conjunction with recent research interest in natural products chemistry, books taking the multidisciplinary approach as, for example, a series on marine natural products with the same subtitle (*Marine Natural Products: Chemical and Biological Perspectives*, P. J. Scheuer, Ed., Academic Press, Volumes I–V), are seen more and more on the bookshelves.

Annual Review of Pharmacology and Toxicology, Volume 23. Edited by ROBERT GEORGE, RONALD OKUN, and ARTHUR K. CHO. Annual Reviews Inc., 4139 El Camino Way, Palo Alto, CA 94306. 1983. 713 pp. 15 × 22 cm. Price $27.00.

This review of pharmacology and toxicology continues a successful series of monographs in these areas. The book contains 27 different reviews and a review of the reviews. Each of the reviews is written by a person familiar with the area of research. The reviews are normally concise and well referenced; important tables and figures are included in many of the reviews. The initial review by Leslie Iversen on "Nonopioid Neuropeptides in Mammalian CNS" provides some insight into the re-

graphs is provided. However, failure to reference the material in the individual chapters is a serious omission.

This book may serve as a quick reference for chemical structures and chemotherapeutic properties of a large number of antibiotics. However, the handbook approach used to present the material makes this book unsuitable as a text.

Solid-State Chemistry of Drugs. By STEPHEN R. BYRN. Academic Press, 111 Fifth Avenue, New York, NY 10003. 1982. 346 pp. 15 × 23 cm. Price $55.00.

The literature on solid-state chemistry is not abundant, and the topic of solid-state chemistry of drugs *per se* has not been treated previously in book form. (Granted, chapters in books and reviews in journals have appeared.) Dr. Byrn's book hence fills a void. It is refreshing to note, at the onset, that it does this very well.

The book is, first of all, self-contained. It commences with morphological descriptions and definitions, followed by a broad overview of what actually happens in a solid when the molecules contained in it (or some of them) undergo chemical change. It then gives examples of the various types of solid-state reactions documented in the literature (and of pharmaceutical interest).

A chapter is devoted to methods of analysis, in a somewhat different way than the casual reader might expect. The tools of trade in this field, if mechanistic understanding is the goal, are X-ray, spectroscopy, and thermal methods. In other words, the analysis section is not cluttered with specific assay methods, but rather with the specific tools. It might have been instructive to have a section dealing with high-vacuum techniques of gas analysis, since these are frequently used in solid-state kinetics in isothermal studies of gas-producing reactions.

The chapter on solid-state kinetics is excellent and covers all essential principles. Particularly useful is Table I, where one particular reaction is treated by a large number of different mechanistic models, leading to the conclusion (not surprisingly) that simply fitting the data to a model will not, in itself, serve as a selection criterion. That philosophy is true in general, but is well stated.

A large chapter is devoted to polymorphism, an important aspect not often thought of as "chemistry" (as implied in the title of the book). But, it certainly belongs in the book and should be of great usefulness to those working in this particular field.

The book contains a wealth of examples. It is written in a very pleasant style. A must for the pharmaceutical scientist involved in solid dosage forms.

FREE RADICALS AND CANCER. Edited by ROBERT A. FLOYD. Marcel Dekker, Inc., 270 Madison Avenue, New York, NY 10016. 1982. 541 pp. 16 × 23.5 mm. Price $69.75 (20% higher outside the U.S. and Canada).

The role of free radicals in cancer development has been of concern to, and studied by, many investigators in the past three decades. Up to the present, however, there is as yet no clear-cut settlement of this seemingly simple but actually complicated problem and probably there never will be. This is perhaps one of the main reasons that the editor is compiling the thoughts of many investigators from all over the world into one volume.

Thirteen groups of researchers contributed their findings and interpretations. These include (titles abbreviated): C. Nagata *et al.* (Free Radicals from Chemical Carcinogens and Significance in Carcinogenesis) from Japan; [illegible] *et al.* (Nitroxide Metabolism in Liver Microsomes) from the Federal Republic of Germany; H. M. Swartz (ESR Studies of Cancer) of Illinois; E. Cavalieri *et al.* (Multiple Activation Mechanisms in Aromatic Hydrocarbon Carcinogenesis) of Nebraska; A. M. Bobst (Spin Bioassays with Nucleic Acids) of Ohio; J. Cadet and R. Téoule (Binding of Radiosensitizing Drugs to DNA) from France; F. R. DeRubertis and P. A. Craven (Activation of Guanylate Cyclase and Evidence for a Free Radical Mechanism) of Pennsylvania; N. M. Emanuel (Free Radicals and Growth of Tumors) from the U.S.S.R.; R. Sridhar (Radiation Sensitizers in Therapy) of Oklahoma; R. A. Floyd (Free Radicals and Arylamine Carcinogenesis) of Oklahoma; E. G. Janzen and E. R. Davis (Detection of Free Radicals by Spin-Trapping) from Canada; J. A. Hinson *et al.* (Role of Free Radicals in the Mutagenicity of *N*-Hydroxy-2-acetylaminofluorene) of Maryland; and J. E. Biaglow *et al.* (Metabolic Activation of Carcinogenic Nitro Compounds to Oxygen-Reactive Intermediates) from the U.S. and Canada. It is probably unavoidable that writings which came from such a variety of sources would contain material with duplicate or even contradictory information. Actually this is perhaps a clever way to inform the readers of the vastness and the uncertainties of this field of study.

Aside from the key question raised at the beginning of this review, there are other points that deserve to be mentioned. Although free radicals have been detected in many carcinogens with or without enzymatic action, they have also been detected in normal and pathological tissues. Throughout this book it is reported that even some compounds possessing recognized antineoplastic action, such as doxorubicin hydrochloride (Adriamycin), or prophylactic property against cancer information, such as ascorbic acid, produce free radicals in ESR measurements. To make the situation even more complicated, some carcinogens do not produce free radicals. Free radicals generally are defined as species having ESR signals in the g = 2.00 region with line shapes and power-saturation characteristics typical of organic free radicals (the latter exclude paramagnetic metals). However, measurement of free radicals depends on a number of variable experimental conditions, including the preparation of samples, the temperature during measurement, the solvent used, the type of tissue examined, and animal species differences. Therefore, one should be extremely careful and cautious in making empirical and qualitative correlations and straightforward interpretations.

The relationship of free radicals to cancer can perhaps be approached in another aspect. That is, to study the quantitative rather than the qualitative characteristics of free radicals in certain types of cancer detection, diagnosis, and response to treatment. There are already indications in this book that an in-depth study of ESR signals may reveal characteristic information in the development and progression of certain types of tumors and tumor response to therapeutic treatment. Studies along this line should be extremely useful in cancer research.

After reading all of the material presented in this book, one may assume that free radical formation may well be just a phenomenon observed during the cellular proliferation (rather than limited to only during the cancer growth) or a phenomenon observed as formation of intermediates during metabolic activation of many chemical compounds (not necessarily limited to mutagens, carcinogens, or antineoplastic agents). The situation is analogous to that of the numerous studies on drug–DNA intercalation: that the observed phenomenon may not be the real, or the major, or even the minor, mode of biological action.

This book is recommended to those scientists who are interested in these aspects of biology and medicine, as well as to oncologists and physicians who are forever searching for the fundamental knowledge of the secret of life.

Current Trends in Organic Synthesis. Proceedings of the Fourth International Conference on Organic Synthesis. Edited by HITOSI NOZAKI. Pergamon Press, Maxwell House, Fairview Park, Elmsford, NY 10523. 1983. 429 pp. 18.5 × 27.5 cm. Price $90.00 (£45.00).

The 30 lectures compiled from the talks presented at the 1982 IUPAC meeting in Tokyo (August 1982) constitute an impressive review of the current state of the art in the field of organic synthesis. Because the book is a reproduction of the authors' manuscripts, there are a few typographical errors and unclear figures, but these minor shortcomings in no way detract from the overall appeal of this volume. As outlined in the Preface, the book is divided into four areas: synthesis of natural products, methods for achieving stereoselectivity, new synthetic methodology, and new reactions.

The group of lectures on natural product synthesis begins with a presentation by E. J. Corey on his work in the leukotriene field, which includes synthetic methodology developed for use in this area, but with applications throughout organic synthesis, as well as total syntheses of LTB and several rationally designed inhibitors of lipoxygenase enzymes. The next lecture, by W. Bartmann, discusses the synthesis of stable analogues of PGI2, illustrating the intimate connection between chemical synthesis, biological testing, and development of commercially feasible syntheses characteristic of industry. C. Heathcock then describes the efforts of his group in the area of stereoselective aldol condensation reactions and their application to his ongoing total synthesis of erythromycin. B. M. Trost outlines the observations that lead to the development of the total synthesis of verrucarol as well as continuing work on its elaboration to verrucarin A. A review of the numerous examples of the Diels–Alder reaction developed by the group of M. E. Jung and their application to steroid and anthracycline natural products is offered next. Highly selective protecting group chemistry is the focus of a lecture by C. B. Reese on the total synthesis of yeast alanine tRNA, a nonadecaribonucleotide. W. Nagata presents the work that led to the first industrially feasible synthesis of a 1-oxacephem, illustrating the multiplicity of routes attempted and new methodology that had to be developed along

markable changes that have taken place in understanding chemical substances that are important in the central nervous system over the past ten years. Cannon's review on "Structure–Activity Relationships of Dopamine Agonists" is well illustrated with chemical formulas, which is an important aid in following the discussion. Current Trends in Organic Synthesis. Proceedings of the Fourth International Conference on Organic Synthesis. Edited by HITOSI NOZAKI. Pergamon Press, Maxwell House, Fairview Park, Elmsford, NY 10523. 1983. 429 pp. 18.5 × 27.5 cm. Price $90.00 (£45.00).

The 30 lectures compiled from the talks presented at the 1982 IUPAC meeting in Tokyo (August 1982) constitute an impressive review of the current state of the art in the field of organic synthesis. Because the book is a reproduction of the authors' manuscripts, there are a few typographical errors and unclear figures, but these minor shortcomings in no way detract from the overall appeal of this volume. As outlined in the Preface, the book is divided into four areas: synthesis of natural products, methods for achieving stereoselectivity, new synthetic methodology, and new reactions.

The group of lectures on natural product synthesis begins with a presentation by E. J. Corey on his work in the leukotriene field, which includes synthetic methodology developed for use in this area, but with applications throughout organic synthesis, as well as total syntheses of LTB and several rationally designed inhibitors of lipoxygenase enzymes. The next lecture, by W. Bartmann, discusses the synthesis of stable analogues of PGI2, illustrating the intimate connection between chemical synthesis, biological testing, and development of commercially feasible syntheses characteristic of industry. C. Heathcock then describes the efforts of his group in the area of stereoselective aldol condensation reactions and their application to his ongoing total synthesis of erythromycin. B. M. Trost outlines the observations that lead to the development of the total synthesis of verrucarol as well as continuing work on its elaboration to verrucarin A. A review of the numerous examples of the Diels–Alder reaction developed by the group of M. E. Jung and their application to steroid and anthracycline natural products is offered next. Highly selective protecting group chemistry is the focus of a lecture by C. B. Reese on the total synthesis of yeast alanine tRNA, a nonadecaribonucleotide. W. Nagata presents the work that led to the first industrially feasible synthesis of a 1-oxacephem, illustrating the multiplicity of routes attempted and new methodology that had to be developed along

the way. S. Wolfe's lecture shows how an academic laboratory can branch out into exploration of combining chemical with enzymatic reactions to fashion new and important compounds in the β-lactam field, including the commercial product ceftizoxime. Finally, Y. Kishi discusses his group's efforts toward the determination of the stereochemistry of the *entire palytoxin* molecule, mentioning numerous synthetic methods developed in the pursuit of this gargantuan task.

The next group of lectures discusses the development of methodology for achieving stereoselectivity in synthetic reactions. W. Oppolzer begins by describing his work using chiral precursors to direct carbon–carbon bond-forming reactions and his exploitation of the metallo-ene reaction to construct complex carbon skeletons. D. Enders continues with a discussion of his work on the use of metallated chiral hydrazones to form carbon–carbon bonds with high stereoselectivity. Y. Ito next illustrates applications of the intramolecular Diels–Alder reaction of *o*-quinodimethanes to the construction of steroidal and alkaloidal skeletons. G. Posner discusses his results in stereoselective carbon–carbon bond formation *via* conjugate addition of Grignard reagents to chiral 2-sulfinylcycloalkenones. P. Bartlett shows the potential of his iodolactonization chemistry for controlling the stereochemistry along a carbon chain. An elegant stereocontrolled synthesis of the side chains of two vitamin D3 metabolites *via* remote asymmetric induction during a nitrone cycloaddition reaction is presented next by M. Uskokovic. B. Fraser-Reid then discusses his progress toward the ansa chain of rifamycin starting from readily available chiral precursors. S. Hanessian continues this theme of chiral templates with an in-depth look at the strategy and chemistry he is employing in an assault on boromycin. E. Vedejs next discusses the importance of local conformational effects which he has used in conjunction with his sulfur-mediated ring expansion strategy to approach erythronolide. Finally, W. C. Still illustrates his application of molecular mechanics calculations to the determination of macrocycle conformations with the syntheses of eucannibinolide and rosaramicin.

Nine lectures demonstrate the role of organometallic reagents in the development of new synthetic methodology. H. C. Brown provides a thorough review and update on hydroborating reagents which can achieve remarkable chemical selectivity. E. Negishi next discusses the allylation and vinylation of organometallics, especially metal enolates, *via* nickel and palladium catalysis. H. Yamamoto shows how oxime sulfonates can be used with organoaluminum reagents to provide α-alkylated amines or as precursors for intramolecular cyclization to interesting heterocycles. Additions of organometallic reagents to acetylenes and vinyl halides for the preparation of conjugated dienes is the theme of a lecture by J. Normant. M. Semmelhack next illustrates some interesting applications of nickel and chromium chemistry to the synthesis of quinone natural products. I. Kuwajima discusses several features of his trimethylsilyl enol ether chemistry culminating in a synthesis of showdomycin. The preparation and functionalization of various heterocyclic systems by using the trimethylsilyl group for activation is presented by H. Vorbruggen. The array of functionality available from the ring-opening reactions of cyclopropanes generated by the addition of carbenes to silyl enol ethers is outlined by J. Conia. Finally, M. Mikolajczyk demonstrates the utility of sulfur-substituted Wittig reagents for the formation of five-membered ring systems.

The last group of lectures describes much new chemistry which should see widespread application in future synthetic work. G. Stork begins by presenting his recent work on radical cyclization reactions, stressing the power of his methodology for generating pentacyclic systems. H. Musso next discusses rules governing the direction of hydrogenolytic cleavage of cyclopropane bonds. E. Vogel reviews the chemistry developed in the pursuit of various novel annulene structures. M. Makosza demonstrates the versatility of nitroarene substitution reactions by carbanions containing a leaving group at the carbanionic site for the construction of various aromatic and heteroaromatic systems. Finally, D. J. Sam concludes by outlining the potential of dichlorine monoxide as a powerful yet selective chlorinating reagent.

While much of the above material has appeared in print since this meeting was held, readers will still find this book a useful compendium of the work currently being pursued at the frontiers of organic synthesis. It may thus be useful to students as an introduction and overview of the field and to long-time practitioners of the art of synthesis as a review and indication of trends for the future. It is a worthwhile investment for both academic and industrial chemistry libraries.

Putting an End to Secret Formulations

"Secret nostrums" were a scourge of the past that pharmacy, medicine, and the general public had to deal with in their collective efforts to advance rational therapy. From the medical scientist's viewpoint, it is basic, elementary, and essential that, if at all possible, one knows exactly what it is that is being used as an agent of treatment. Without complete composition information, how else is it possible to practice either good medicine or good pharmacy?

We recently attended a scientific conference at which University of California Pharmacy School Dean—and former Food and Drug Commissioner—Jere E. Goyan was a featured speaker. During his presentation, he observed that in the former dark days of science, "magic was medicine"; but in the present, enlightened period of science, "medicine is magic."

It is wonderful if medicine is able to produce results that can be described as "magical." However, it is in no one's best interest—and certainly not in the patient's nor in the practitioners' who are treating that patient—for the product used in treatment to be a secret formula: a sort of "magic potion," if you will.

But yet, that is still what prevails to a large degree even today.

Granted, drug manufacturers are required by law and regulation to make known the identity and quantity of the medicinally active ingredients in their products. However, they are not required to do so with respect to the so-called "inactive" ingredients. This despite the fact that these "inactive" ingredients may pose a serious health hazard to many patients. For reasons of safety, patients either may need to avoid, or may wish to avoid, such ingredients as lactose, tartrazine, cyclamates, saccharin, monosodium glutamate, sulfites, nitrites, as well as miscellaneous other preservatives, colors, or flavoring agents.

Yet, most drug manufacturers not only are unwilling to list such inactive ingredients in the labeling or advertising of their products, but adamantly refuse to divulge the information in response to specific requests.

When queried as to the basis for this policy, the usual response is "trade secrets." To which we can only retort: "Baloney!"

Every manufacturer must surely realize that the sophistication of trained laboratory personnel and the instruments and advanced equipment available today would enable any competition to "crack" a product's formula, both qualitatively and quantitatively with relative ease and speed. Competent pharmaceutical analysts would find such a task to be only a moderate challenge at most. And when we have stated this view to our industrial scientist colleagues, they have generally admitted—although usually "off the record"—that such is indeed the case.

So what is the real reason for this carefully maintained cloak of secrecy?

In our opinion, it has virtually nothing to do directly with competitors—any real trade secrets are much more likely to be involved in how the product is put together, than what is in it. No, we believe that the underlying reason for this policy on the part of so many drug firms is simply due to their desire to maintain an aura of the unknown, of magic, and of mystique surrounding their products. And this is not done out of concern about competing firms, but rather for the effect they believe it has on physicians, pharmacists, and patients.

As early as 1970, the American Pharmaceutical Association, by formal action of its House of Delegates, adopted a policy statement that "the Association seek legislation or regulations to require a full disclosure of therapeutically inactive as well as active ingredients of all drug products."

Subsequently, this official APhA policy position was broadened and strengthened on several occasions: most notably in 1980, when it was explicitly clarified that the policy was intended to cover both prescription and nonprescription drugs, and that disclosure included not only a passive willingness to reveal the information, but also an active listing of the information in product labeling and advertising.

Regrettably, however, the "proponents of magic" prevailed in the policy-making offices of corporate drugdom, and few companies have been willing to break with the operating policy of composition secrecy.

In recent months, however, the issue has heated up considerably. *First*, Ralph Nader's Health Research Group filed a "citizens' petition" with the Food and Drug Administration seeking new regulations to require that inactive ingredient information be listed on labels, in package inserts, and in the *Physician's Desk Reference*. *Second*, Jeffrey L. Brown, chairman of pediatrics at United Hospital in New York, filed suit in Washington, DC, federal court to force FDA to divulge the names of all approved drug products containing lactose as an ingredient. *Third*, Congressman Richard L. Ottinger (D.-NY) introduced legislation (H.R. 4126) to require disclosure of both active and inactive drug ingredients.

FDA initially refused freedom-of-information and similar efforts to get it to reveal the requested composition information. But then the agency notified the industry that, in effect, it would no longer serve as the industry's guardian angel; it would not defend against trade secret lawsuits unless the companies themselves defended against those suits.

How each individual drug company decides to act remains to be seen. But for the prescription drug industry's major trade group, the Pharmaceutical Manufacturers Association, this clearly presented a serious dilemma: is their primary concern to protect patients' lives or company dollars?

In rapid succession, the PMA first jumped in, and then scrambled out. Indeed, PMA's retreat was so hasty that the trade press was still carrying reports about PMA's February 27 decision to intervene in the case even after PMA actually withdrew from the lawsuit on March 14.

But, embodied in PMA's announcement to the press that it decided to withdraw from the case was an explanatory statement that, in our view, was most gratifying: "PMA withdrew . . . because it concluded that, while the identity of inactive ingredients is legally a trade secret, the medical justification for disclosure of the presence of lactose nevertheless warrants release of that information . . . . PMA recognizes the concerns of those who favor disclosure of inactive ingredients generally and intends to work with all interested parties toward a fair and equitable solution to the overall problem."

It appears that a new day has dawned, and that human lives rather than dollars may yet prevail as the subject of principal industry concern. Welcome aboard, PMA!

LITERATURE SURVEY

Novel Anti-Inflammatory Agents

ERNEST CULLEN

Received October 12, 1982 from *Boehringer Ingelheim Ltd., Ridgefield, CT 06877.*

Keyphrases □ Literature survey—anti-inflammatory agents □ Anti-inflammatory agents—literature survey

The nonsteroidal anti-inflammatory (NSAI) drugs currently in use are characterized by their ability to relieve the pain, fever, and inflammation associated with inflammatory disorders; to inhibit the synthesis of endogenous prostaglandins (PG's) by blocking the action of the cyclooxygenase (CO) enzyme; and, in relation with this inhibition, to cause GI irritation. As useful as they are, they do not interfere fundamentally with the progression of the disease. The question of the relevance of PG's on the course and/or the regulation of the disease has not been settled [for review see (1, 2)].

In the past few years, anti-inflammatory (AI) compounds having a profile of action on the arachidonic acid cascade metabolism distinct from that of the classical NSAI drugs have been reported. Some affect both pathways of arachidonic acid metabolism, while others have no effect on these endogenous mediators.

A nonexhaustive survey of these nonclassical NSAI agents along with the recently disclosed AI immunomodulators and of the classical agents currently in clinical trial is presented. Excluded are the steroids, the disease-modifying antirheumatic drugs (DMARD) such as penicillamine and gold salts, and the cytotoxic agents such as cyclophosphamide.

NONCLASSICAL, NONSTEROIDAL ANTI-INFLAMMATORY AGENTS

Inhibitors of Both Pathways of Arachidonic Acid Metabolism—3-Amino-1-[(*m*-trifluoromethyl)phenyl]-2-pyrazoline (I)[1] (3, 4), timegadine (5), and benoxaprofen (6) (Fig. 1) have in common AI activity and the capacity to inhibit both the cyclooxygenase (CO) pathway leading to the PG's and the lipoxygenase (LO) pathway leading *inter alia* to 5,12-dihydroxy-eicosatetraenoic acid (5,12-HETE), a potent chemotactic agent for polymorphonuclear leukocytes (7). The dual inhibition property of compound I, is reported to be of the same order both for CO and LO, while timegadine shows superior inhibitory activity for the CO system (5, 8). In the case of benoxaprofen, published data indicate a lower inhibition for CO and actually the low ulcerogenic activity of this product was related to this finding (9).

The activity profile of substances blocking both pathways of arachidonic acid should in some respects at least parallel that of the steroids. In fact, like dexamethasone, I was found to cause a dose-dependent reduction in leukocyte migration into inflammatory sponge exudate (3, 10). Benoxaprofen also inhibits migration of cells into inflammatory sites (6, 11). Moreover, the latter was found equipotent with hydrocortisone in the granuloma pouch test—in contrast to most NSAI agents (9) which are not active or weakly active in that test.

According to a recent paper (12), the action of I on the CO enzyme is selective: it inhibits PG production in inflammatory exudate but not in the GI tract—thus explaining its nonulcerogenicity as compared with aspirin and indomethacin.

Benoxaprofen, it is claimed, has the convenience of once-a-day dosage. It has been launched in Great Britain, Germany, and France (13), and it was currently being introduced in the United States when it was voluntarily recalled by the manufacturer after reports of deaths associated with the drug (14). The product, it was reported, induced photosensitivity and onycholysis in 10% of the patients (15).

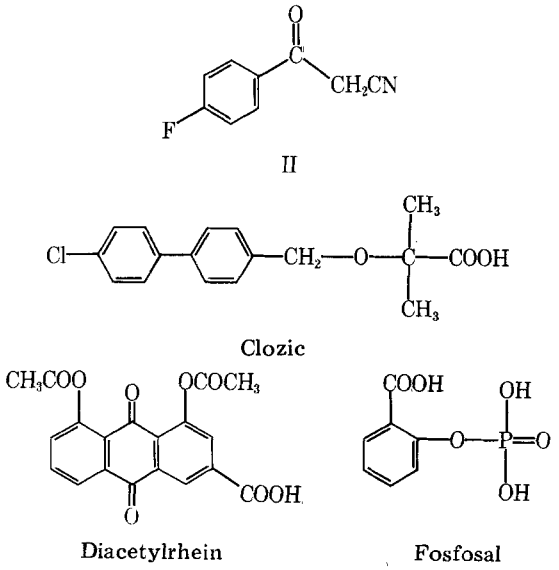

Figure 2.

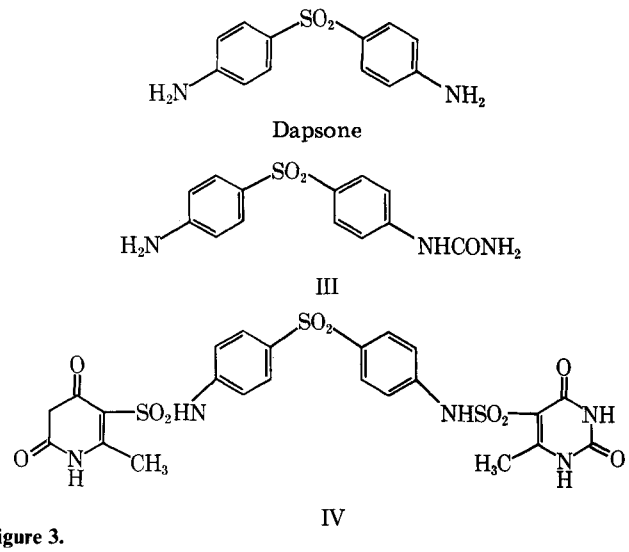

Figure 3.

Timegadine, which had been chosen out of a series of more than 100 guanidine derivatives, has only recently been submitted for clinical evaluation. In animal studies it showed low acute toxicity, low gastroulcerogenic effect, and high AI activity in both acute and chronic assays (16). Noteworthy is the fact that it can suppress the development of secondary lesions in the adjuvant arthritis (AA) screen when given only for a short period after the adjuvant injection (17). The tuberculin hypersensitivity reaction is enhanced by timegadine. Experimental allergic encephalomyelitis (EAE) (a model for cell-mediated immune response) is not inhibited by this product. Because of these results, it was concluded that the effect of timegadine in AA is not due to an immunosuppressive action (17).

Agents Having AI Effects not Mediated through Inhibition of Prostaglandins—*p*-Fluorobenzylacetonitrile (II)[2], (18, 19), clozic (20) and diacetylrhein (21) (Fig. 2) are novel agents which have in common, as opposed to the classical NSAI drugs, a markedly reduced potency in blocking the synthesis of PG's.

The acetonitrile II and clozic possess minimal acute AI or analgesic activity but are reported to be very potent in chronic assays. They produce little or no GI irritation in laboratory animals. For clozic, activity in type II collagen-induced arthritis is also claimed (22).

Clozic has been compared with penicillamine and gold salt clinically in a double-blind study testing 30 and 40 rheumatic patients, respectively, over a 6-month period. Similar activity to gold and penicillamine was found with substantial lowering of the biochemical markers of disease activity and with no serious side effects (23). If this result is confirmed in a long-term, larger clinical trial, then clozic would be the first example of a penicillamine-like drug susceptible to detection by conventional screening in animal models.

Diacetylrhein does not block PG production, on the contrary, it stimulates its synthesis. In *in vivo* experiments with rat inflamed exudate it produced, at 4 mg/kg po, an increase (69%) in total PG-like substances, while indomethacin, at 0.2 mg/kg, under the same conditions, produced a decrease (−72%) of the same substances. A confirmation of this is the ability of diacetylrhein to counteract indomethacin-induced gastric damage in a dose-dependent manner. The product has the same AI potency as aspirin in experimental animal models. In the retinoic acid-induced rabbit ear cartilage degeneration assay, it was shown to have the potency of hydrocortisone (21). In a short-term clinical study it was found to be well tolerated and effective, the therapeutic effect persisting for several weeks after suspension of therapy (24, 25). A controlled double-blind clinical evaluation confirmed the therapeutic value of this drug in the treatment of osteoarthritis of the hip and knee (26). It is assumed that the drug exerts its action through its ability to inhibit the release of proteases (21). It also forms water soluble Cu-complexes, and this may also contribute to its mode of action (25).

Another drug potentially belonging to this group is fosfosal, a compound analogous to aspirin except for the acetyl function, which has been replaced by a phosphono group. This results in substantial modification of the activity profile. Indeed, contrary to aspirin, fosfosal does not inhibit PG synthetase even at very high doses, and probably because of that, produces no significant ulcerogenic effect in rats in spite of its very high acidity. In animal models it was found equipotent to aspirin in analgesic assays and slightly less so in AI tests (27). In a double-blind clinical study with 60 patients, the AI action was confirmed with no sign of serious side effects and good tolerance (28). The compound is reported to produce negligible effect on platelet aggregation induced by ADP (a much smaller effect than aspirin). Another facet of fosfosal is the fact that it is 6 times more potent than aspirin in inhibiting phosphodiesterase activity (27).

Dapsone and Derivatives—It was observed in a clinical study that dapsone (Fig. 3), a well-established antileprotic drug, given at 100 mg/d improved the clinical state of RA patients while reducing some of the biomedical markers of the disease (C-reactive protein and erythrocyte sedimentation rate). Compared with gold, its efficacy was judged slightly less pronounced and its toxic side effects were less severe [for review see (29)]. The fact that dapsone has apparently no effect on the immune system, and that its experimental AI profile is akin to that of the classical NSAI drugs, does not concur with the above findings (30). However, doses at which activity was seen in animals were much higher than the ones used clinically [NB: results of two different assays in AA regarding activity and toxicity are at odds in the literature (30, 31)]. Also,

[2] Code name: CL-224385.

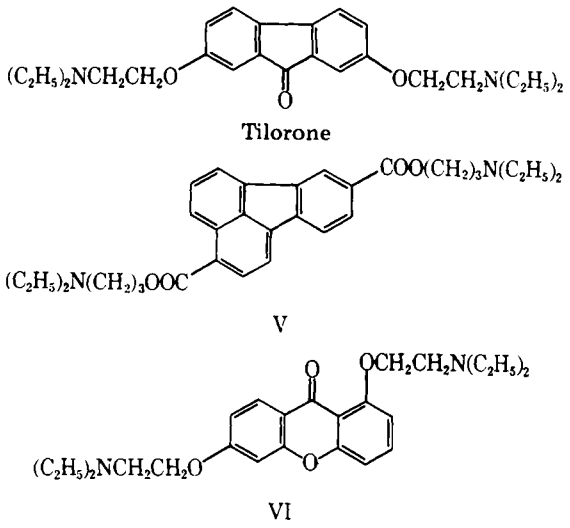

Figure 4.

contrary to the classical drugs, dapsone does not inhibit the PG-dependent ultraviolet-induced erythema, nor does it induce GI irritation in rats. The product has activity in zymosan, anti-IgG, and reversed passive Arthus models of inflammation, and in relation to these effects, it was suggested that dapsone could exert its AI effect by inhibiting complement activation. On the other hand, part of its mode of action must be related to its ability to inactivate the release (and the activity) of lysosomal enzymes from macrophages. It has been reported that dapsone and its urea derivative, (1-[4-(4-sulfanilyl)phenyl]-urea)[3] (III), specifically block *in vitro* incorporation of choline into phosphotidylcholine (lecithin) (32).

In clinical tests with 69 RA patients, 4,4′-bis-[(6-methyluracyl-5-sulfonyl)aminophenyl]sulfone (IV) led to a reduction of morning torpidity, after oral administration of 100–200 mg doses, and to the disappearance of pain syndrome after 10–12 d of treatment, for the majority of the patients (33).

IMMUNOMODULATORS

There seems to be little doubt that RA diseases are directly related to a deficiency in the regulation of the immune system (34). Substances capable of affecting any part of the complicated immunological network may present a potential for more efficacious treatment.

Tilerone-Like Agents—One of the first agents that demonstrated that selective manipulation of the two limbs of the immune system was possible is tilerone (35). A few laboratories have looked upon this interferon inducer as a worthwhile lead. Two examples of this line of research are bis-[3-(diethylamino)propyl] fluoranthene-3,9-dicarboxylate (V)[4] and 1,6-bis[2-(diethylamino)ethoxy]-9H-xanthen-9-one (VI)[5] (Fig. 4).

Like tilerone, these two compounds are able to suppress cell-mediated immune responses and, at the same time, to enhance antibody production (36, 37). Both compounds are effective in several of the cell-mediated immune response assays (EAE, tuberculin skin reaction, developing adjuvant-induced arthritis (D-AA), *etc.*). However, only compound VI is active orally in these tests. Another difference is the fact that VI is devoid of activity in the acute models of inflammation

[3] Code name: MK 241.
[4] Code name: RMI-9563.
[5] Code name: WY-15297.

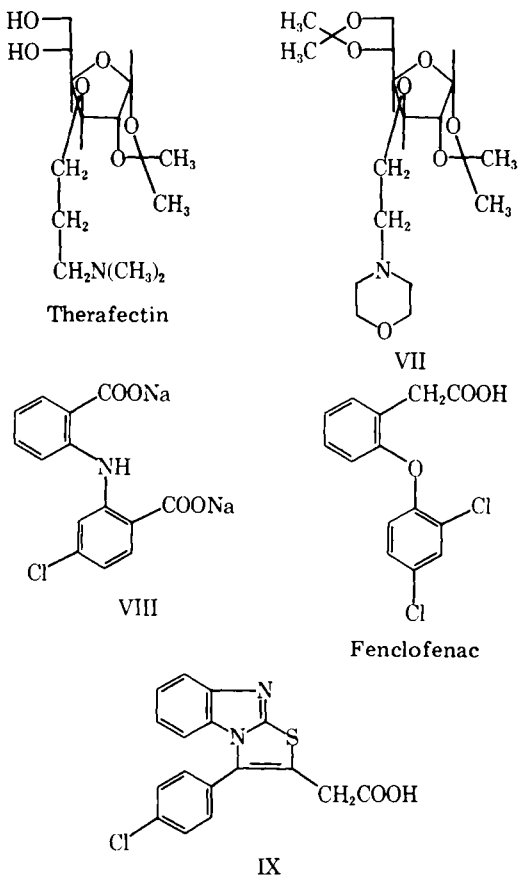

Figure 5.

(carrageenan-induced paw edema (CPE), Na urate, Randall-Sellito yeast tests), while V is active.

Like the steroids and the NSAI drugs, but contrary to immunosuppressive agents, VI is active in established adjuvant arthritis (E-AA) and also in the early phase of D-AA. However in E-AA, unlike the steroids and NSAI drugs, no rebound is observed up to 24 d after the last dosing. The product on the other hand, like the immunosuppressive drugs, is highly active in the EAE (a model in which the NSAI drugs are not active). This agent, it seems, does not fit the standard pattern of either the classical NSAI drugs nor the immunosuppressive agents. This mode of action might reflect selective stimulation of B-cells and suppression of T-cells (37).

Other Compounds—Novel compounds of various chemical classes, unrelated to tilerone, have also been recognized as immunomodulators. Drugs such as the anthelmintic levamisol (38) and more recently the H_2-antagonist cimetidine (39, 40), used in the treatment of peptic ulcers, have been found more or less by serendipity to have an effect on rheumatoid arthritis.

Other agents like therafectin (Fig. 5) first claimed as antiviral, antibacterial, and/or antitumor agents (41) were later discovered to respond positively to AI screening in animal models. Still others, which one would have classified as classical NSAI agents on the basis of their chemical structures, such as Chugai's *N*-(2-carboxyphenyl)-4-chloroanthranilic acid disodium salt (VIII) (42) and fenclofenac (44), were found in fact to have immunomodulating capability.

Therafectin is currently in Phase II of clinical trials in this country. The product is practically devoid of toxicity (in rats $LD_{50} > 10$ g/kg) and active in both the acute and chronic

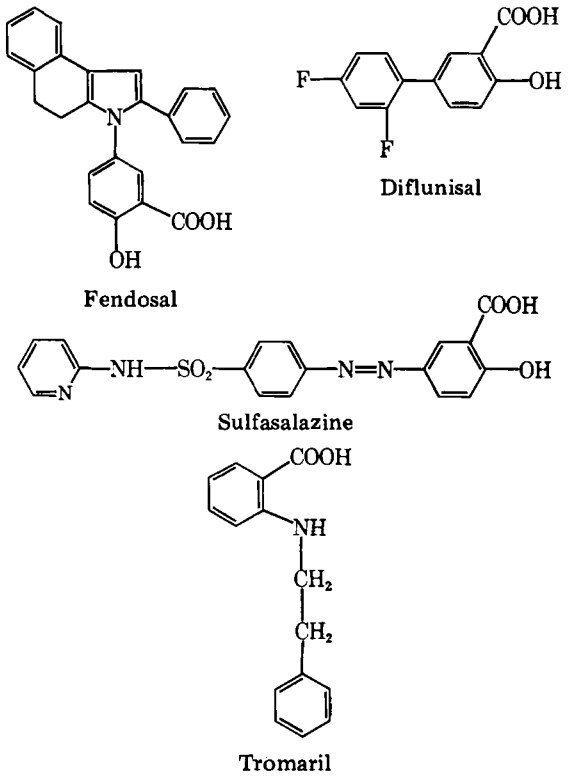

Figure 6.

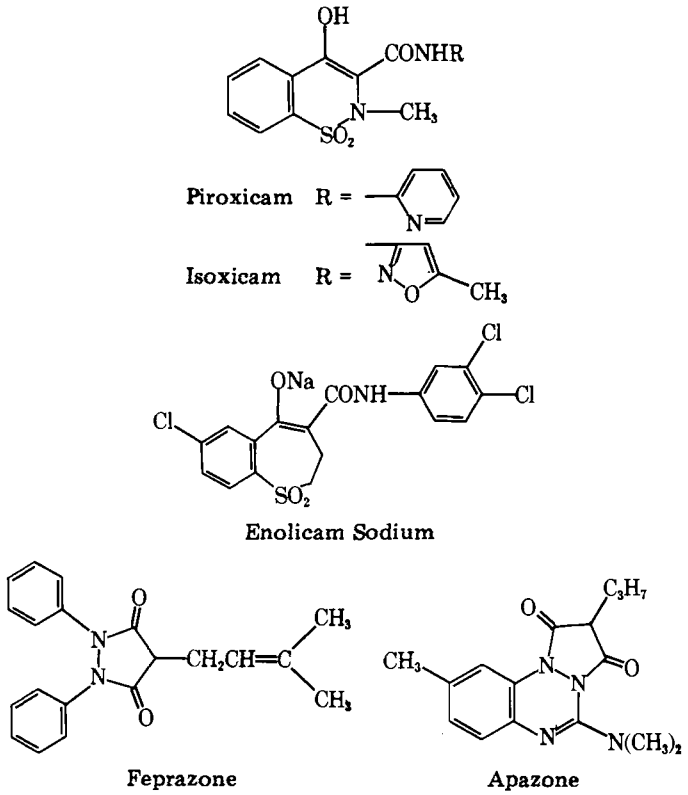

Figure 7.

animal assays of inflammation (CPE, D-AA and E-AA). It is an immunomodulator which primarily stimulates the activity of macrophages (45, 46). Another closely related glucofuranose in which the 5,6-dihydroxy functions are still protected with the isopropylidene group and described as 3-*O*-(2-morpholinoethyl)-1,2,5,6-di-*O*-isopropylidene-α-D-glucofuranose (VII) (47) has been claimed to have immunomodulatory properties.

Contrary to diclofenac sodium (to which it is closely related) the anthranilic acid (VIII) shows no activity in the acute assays, has no effect on tuberculin skin reaction, and no effect on passive cutaneous anaphylaxis in rats. The product is, however, quite active in the D-AA and E-AA assays. It has no immunosuppressive activity, but it enhances antibody levels in immune-deficient animals (42, 48).

As mentioned before, fenclofenac [a close analogue of fenoprofen (Lilly)], first thought to be of the classical type (49) has now been found to modulate the immune system (43). Again in animal studies, this product was found to have minimal activity in the acute but strong activity in the chronic assays. In AA the suppression of edema was seen to persist after treatment was discontinued. The product is 8 times as potent as aspirin in inhibiting PG synthetase. In a 1-year clinical study with 54 rheumatic patients, the effect of fenclofenac was compared with those of penicillamine and placebo (44). It was concluded that fenclofenac can indeed alter the disease profile of rheumatoid arthritis (RA) and, that on the basis of this result, a larger long-term study was warranted. An NDA for this compound has been filed recently in the United States (50).

In the same line, according to recent results of clinical trials, the NSAI agents sulfasalazine (51, 52) (Fig. 6), proquazone (53–55), and diftalone (56) (Fig. 13) would also have some of the characteristics of the disease-modifying agents, since besides improvement in the patient's physical condition, reduction in the RA abnormal parameters was observed. However, these claims have yet to be substantiated. As exemplified in the case of alclofenac (57), preliminary observations are not necessarily confirmed through long-term clinical studies (58–60).

3-(*p*-Chlorophenyl)thiazolo[3,2-*a*]benzimidazole-2-acetic acid (IX)[6] (Fig. 5), contrary to its immediate precursor the 3-hydroxy-2,3-dihydro compound (61), was not transformed *in vivo* to toxic metabolites. Although the product elicited weak inhibition of rat CPE (ED_{50} 200 mg/kg) (inhibition which was not abolished in adrenalectomized animals), it was found to be twice as active as aspirin in inhibiting PGE_2 biosynthesis in sheep seminal vesicles. In the rat AA model, it paralleled levamisole in enhancing the secondary paw edema on days 2–4, but it differs in being quite effective when given therapeutically (on days 16–28) (62).

CLASSICAL NONSTEROIDAL ANTI-INFLAMMATORY AGENTS

Including fenclofenac, sulfasalazine, proquazone, and diftalone [which may be working at a more fundamental level than most of the NSAI drugs in current use (*vide supra*)], there are at present, in clinical trials at one stage or another, more than 40 compounds related to the classical type of AI drugs. The unifying claim here is an improved therapeutic ratio. Several of these new agents are prodrugs of known substances.

Carboxylic Acids—Fendosal (Fig. 6), an indole derivative of salicylic acid, is undergoing Phase III clinical evaluation (63). In animal models this drug was 7–9 times more active than aspirin in the chronic assays (D- and E-AA). It was only slightly more active in the acute tests, but the duration of action was substantially longer than with aspirin (64).

[6] Code name: WY-18251.

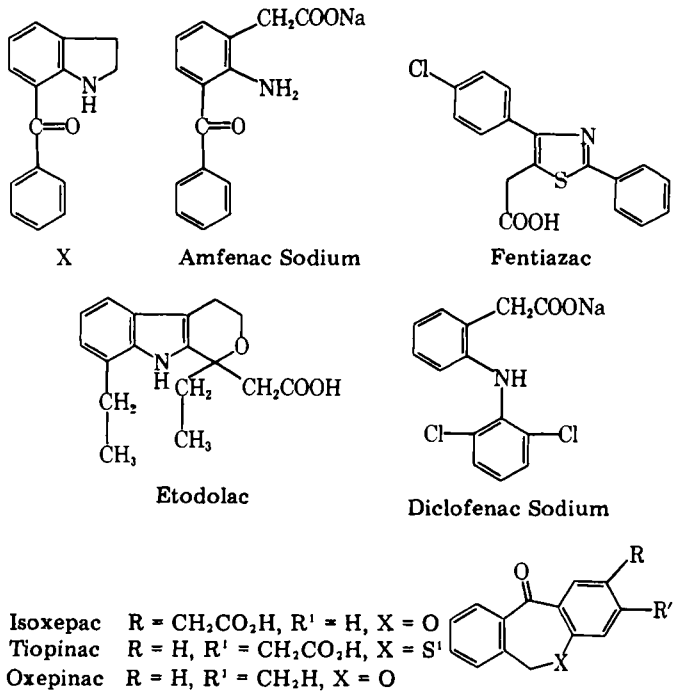

Figure 8.

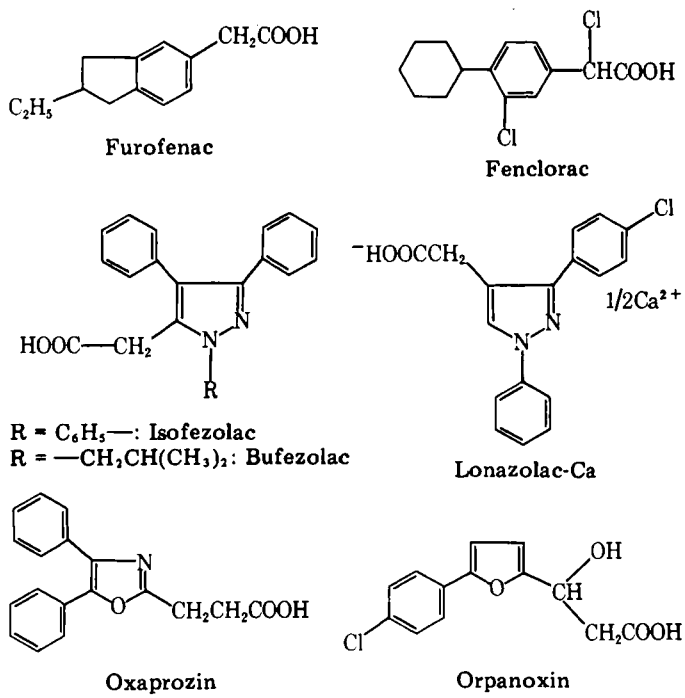

Figure 9.

Diflunisal, a follow-up of flunisal recalled from the clinic (65), was chosen out of more than 500 salicylates. The product is more potent, longer acting, and less toxic than aspirin. Its analgesic potency is about 4 times greater than aspirin. It does not affect platelet aggregation and bleeding time at therapeutic doses in humans. In animal models it was shown to have 7–9 times greater potency than aspirin both in acute and chronic assays (66). Already introduced in 17 countries, diflunisal has recently been approved for marketing in the United States under the analgesic indication (67, 68).

Sulfasalazine was introduced in Great Britain around 1940. Subsequently, on the basis of an unfavorable report, it was abandoned. Later (1965) it was proven effective against ulcerative colitis. Lately this product has been reexamined for the treatment of RA and the results were found particularly encouraging (51, 52). As mentioned earlier, sulfasalazine might have immunological activity.

Tromaril, an anthranilic acid derivative, is reported to be an effective agent in the treatment of rheumatoid disorders. Like the fenamates its side effects were skin rashes, itching, and diarrhea. The product inhibits platelet aggregation without affecting coagulation (69, 70).

Enolic Acids—The enolic acid type of AI drugs, of which butazolidine (PB) is the prototype, has been revived lately by the success story of piroxicam (Pfizer) (Fig. 7). This drug [already approved in 21 countries (71) and recently launched in the United States (68)] has a remarkably long plasma half-life, allowing a once-a-day (20 mg recommended) dose. The compound has high potency and its side effects are confined to the GI tract (72). An analogue, isoxicam, is undergoing Phase III evaluation in the United States (73), while quite a few more are currently in preclinical studies (74).

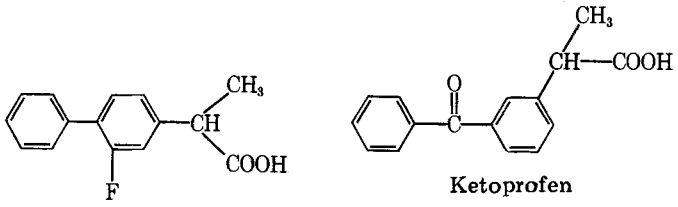
A new group in this class of products comprise the 1-benzothiepin analogues, some of which showed activity in rats at doses as low as 1 mg/kg/d (75). A representative of this group, enolicam sodium, is currently being evaluated in animals (76).

Replacing the *n*-butyl moiety of phenylbutazone (PB) by a prenyl group gave a compound comparable, in animal models, to PB in efficacy, but with fewer side effects on the hematopoietic system and the GI tract. Clinical evaluation, on the whole, indicated the same trend. At present this drug, feprazone, has been introduced in five countries abroad (77). Another congener of PB, apazone, was recalled recently from Phase III clinical trials (78).

Aryl and Heteroaryl Alkanoic Acids—Amphenac sodium (Fig. 8), originally discovered as the metabolite of 7-benzoylindoline (X), has potent AI activity against acute inflammation and comparable or superior activity to PB in suppressing chronic inflammation in rats (79). The product possesses strong analgesic and antipyretic activity. In pyloric-ligated rats or Heidenhain pouch dogs, the compound did not produce gastric mucosal damage; in chronic administration to rats, intestinal lesions were produced at 10 times the rate of PB (80). Relative to aspirin, the inhibition of CO enzymes by this product is about 600 times more efficient (81). Amphenac sodium is currently in Phase II of clinical trials (82).

Contrary to myalex which turned out to be hepatotoxic in humans (83), fentiazac, a close analogue, seems to undergo a metabolic detoxification process (84). In AA tests the product is 5 times more effective than PB (85). It has analgesic and antipyretic activity and the ability to decrease macrophage migration (86). The drug is already marketed in more than 15 countries; in the United States, it is undergoing Phase II evaluation (87).

Isoxepac (Hoechst) which is in late clinical trials (88) was reported to have high levels of gastric intestinal tolerance, its therapeutic index in dogs being 10–12 times that of indomethacin (89). According to the same source, the effective dose in AA rats is 39–78 times lower than the ulcerogenic dose. The Japanese firm Diichi Seiyaku is currently investigating oxepinac, the corresponding analogue with the acetic acid chain at position 3 of the dibenz[*b*,*e*]oxepin system. In animal models this product exhibits potency similar to that of indomethacin both in the acute and chronic assays (90). Syntex has been developing tiopinac, the sulfur analogue of oxepinac, for which



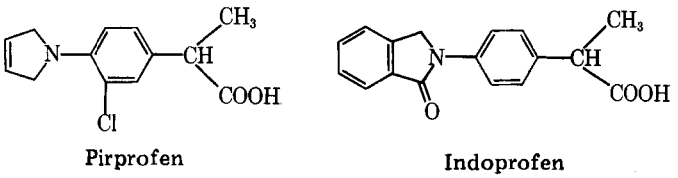


Figure 10.

activity equal to or greater than PB and/or indomethacin was reported. As an analgesic the product is said to be particularly effective against the pain of inflammed joints (91).

Etodolac is structurally related to prodolic acid, and like this compound, which for a while was considered for clinical trials (92), it is more active against the chronic than against the acute model of inflammation (93). The product is a good analgesic and its therapeutic index is 3 and 4 times higher than that of PB and indomethacin (94). It is now in Phase III of clinical assay (95).

Diclofenac sodium[7] is currently undergoing Phase II evaluation in this country (96). Structurally it is close to meclofenamic acid, the first fenamate approved for distribution in the United States. The drug was shown to be equipotent to indomethacin in the CPE, the rat AA, and the mouse writhing phenyl-*p*-benzoquinone assays. Moreover it possesses, as compared with indomethacin, a favorable therapeutic index and the ability to normalize the erythrocyte sedimentation rate (ESR) (97).

Furofenac (Fig. 9) was reported to have marked AI and antiplatelet aggregation activity, low toxicity, and weak ulcerogenicity. It is a PG and thromboxane synthetase inhibitor. In anticipation of clinical trials a metabolic study in animals and in humans has been conducted (98).

Fenclorac presents the singularity of having a chlorine atom α to the carboxy function. The product is in Phase II of clinical evaluation in the United States (99). In animal models its potency lies between aspirin and indomethacin. Its therapeutic ratio, however, is 3–9 times higher than indomethacin. It is also nonulcerogenic in rats at doses less than the LD_{50} (100).

In terms of the AI activity profile, bufezolac is about half as active as indomethacin, while isofezolac is equipotent. The

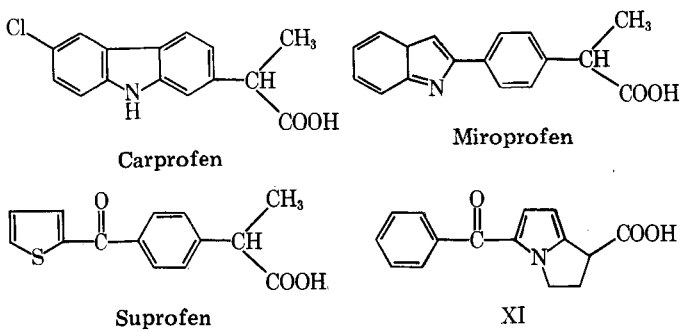

Figure 11.

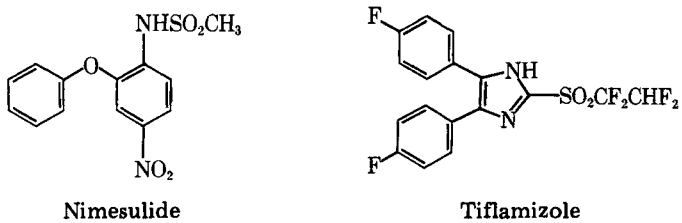

Figure 12.

latter is also more potent in inhibiting the biosynthesis of PG's than indomethacin while the former is much weaker, thus explaining the greater gastric tolerance of bufezolac as compared with isofezolac and/or indomethacin. Results of the analgesic assays as well as the acute toxicity determinations are quite different depending on the animal species tested, thus showing for these two pyrazole derivatives different species sensitivities or a difference in pharmacokinetics between species. These two substances have been considered for clinical trials (101). Structurally they are related to lonazolac calcium[8], which is sold in Germany as an AI drug (102, 103).

Both oxaprozin and orpanoxin have potent analgesic, antipyretic, and AI activity in animal screens (104, 105). The former compared favorably in terms of efficacy with aspirin in clinical studies. It was found to cause significantly less tinnitus and no significant toxic effects (106). The drug is highly protein bound (107) and has a long half-life allowing a once-a-day dosing regimen (108). Regarding orpanoxin, it was speculated that its nonulcerogenicity in rats ($\leq$2 g/kg) was due to its selective lack of effect on stomach PG biosynthesis (105). Clinical work on this substance has recently been deemphasized (109).

Chemically, oxaprozin and orpanoxin are unusual in that they are β-substituted propionic acids. This breaks the unwritten rule that AI activity is restricted to an acetic, α-methylacetic, or again, butyric acid residue which can be transformed to an acetic acid function by β-oxidation.

Flurbiprofen, ketoprofen, pirprofen, and indoprofen (Fig. 10) are either currently in advanced stages of clinical testing or awaiting FDA approval for marketing (110–113). Except for pirprofen, these drugs have already been introduced in several countries abroad for treatment of rheumatoid arthritis and other related diseases. In the classical AI screen, potencies equal to or greater than indomethacin and/or PB have been demonstrated for these compounds (114–117).

Flurbiprofen is well tolerated in humans. In the treatment of RA disease, 100–300 mg was reported to be equivalent to 75–100 mg of indomethacin (110). The product is also being evaluated as an ophthalmic AI agent (118). Ketoprofen was shown in a double-blind crossover study to be equipotent to indomethacin (119). Compared with aspirin, 240 mg of the compound, given daily, had the same effectiveness as 4 g of aspirin, with less side effects (111). Several clinical trials have determined the potency of pirprofen to be the same as aspirin in RA and higher in osteoarthritis (116). It was also found to be a good analgesic agent in the treatment of postoperative pain. Likewise indoprofen (100 and 200 mg) was evaluated in oral and other surgical procedures and found to have superior analgesic activity when compared with aspirin (600 mg) (120). In another clinical study involving RA patients, no difference was seen between indoprofen and indomethacin (121).

[7] Used extensively in Europe, Voltaren.

[8] Active ingredient of Irritren.

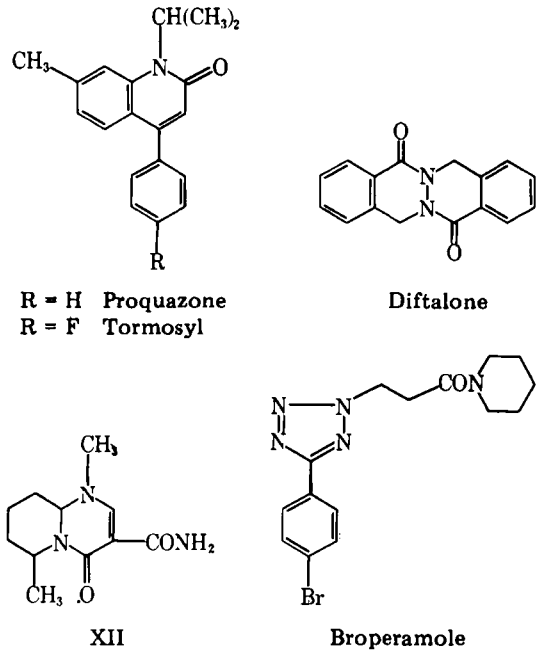

Figure 13.

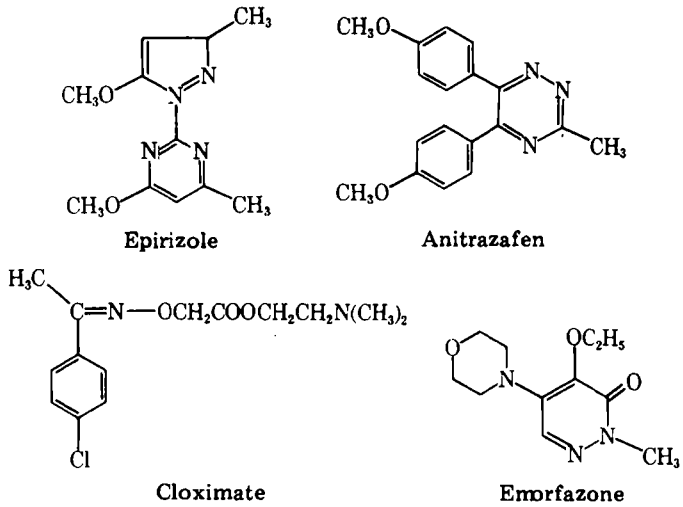

Figure 14.

Double-blind studies comparing carprofen (Fig. 11), indomethacin, ibuprofen, and oxyphenbutazone have been reported. The compound proved highly effective, but it induced GI irritation more often than indomethacin (122). Animal studies, in parallel with indomethacin, had indicated equipotent AI activity, lower potency (10–25 times) in inhibiting PG synthesis, and lower ulcerogenic activity (123, 124).

Miroprofen, a strong analgesic, specifically inhibits pain responses and acute inflammation associated with increased vascular permeability. The substance also has AI activity, being as potent as PB in inhibiting rat AA. Its ulcerogenic potential also compares well with that of PB. Its efficacy in relieving gingivitis was demonstrated in a clinical study (125).

In the rat D-AA screen, suprofen was found to have the highest safety margin when compared with PB, tolmetin, indomethacin, and aspirin: 48:20:16:8:2, respectively. Also observed in the rats undergoing that test was a reduction of bone erosion at 10–40 mg/kg (126). Moreover it was shown that suprofen is a potent antagonist of acetic acid-induced writhing in rats (127) of ultraviolet erythema in guinea pigs (128), and of sodium urate crystal-induced arthritis in dogs (129). In the clinic, drowsiness was observed as one of its side effects (130).

(±)-5-Benzoyl -3*H*- 1,2-dihydropyrrolo[1,2-*a*]pyrrole-1-carboxylic acid (XI) has in lieu of an α-methyl substituent to the carboxylic acid rest, an α-methylene group fixed in a pentacyclic ring (131). This product, which is undergoing phase I clinical trial, is a potent platelet inhibitor with strong analgesic and AI activities (132).

Miscellaneous Acidic Compounds—Nimesulide (Fig. 12), an acidic compound by virtue of its sulfonamide functional group, was reported to respond quite effectively in acute and chronic animal AI assays and to present a marked superiority in the therapeutic index to most reference NSAI drugs (133). Compared with indomethacin, its AI potency was of the same order; however, the product was 10 times less effective in suppressing PG *in vitro* (134). In clinical studies, nimesulide was evaluated in 70 patients with rheumatic disorders for a mean duration of 26 d. A complete cure or significant improvement in 86% of patients was reported. Side effects were mainly GI disturbances (135).

Another nonalkanoic acidic drug is the hexafluoroimidazole derivative tiflamizole. In animal studies, the product was about 10 times as potent as indomethacin in D-AA and E-AA screens (ED_{50} 0.03 mg/kg/d). An unusual feature was the duration of the therapeutic effect following daily oral doses of 0.09 mg/kg for 7 d. The inhibition persisted for more than 70 d when, in the case of indomethacin, there was a flare up after 2–3 days. The drug had a long half-life, was rapidly absorbed, and slowly excreted in various animal species. There was apparently no evidence of metabolites. Tiflamizole strongly suppressed bovine seminal vesicle PG synthetase (IC_{50} $4 \cdot 10^{-7}$ mol/L); nevertheless, its ulcerogenic activity in rats, was found to be weaker than that of the regular AI drugs in use (136–138). This compound is currently in Phase II of clinical evaluation (139).

Nonacidic NSAI Drugs—There are not many nonacidic NSAI drugs available for the treatment of RA. Benzydamine (mostly an analgesic agent) and tiaramide (sold in Japan) are two examples of this class of product. Also, relatively few novel compounds of this type have been developed to the point of clinical trial. Proquazone (Fig. 13), which is sold in Germany and in Switzerland, is actually in Phase II of clinical trials in the United States (140). Like the acidic NSAI drugs, the compound blocks the CO pathway of the arachidonic cascade. It is particularly effective in inhibiting collagen-induced platelet aggregation (141). In clinical tests, proquazone was found to be comparable with indomethacin in terms of efficacy and tolerance (142). Evaluated in postoperative dental pain, it was found to have 5–6 times the potency of aspirin (143). Some lower intestinal intolerance appears to be the main problem. Recent reports would attribute disease-modifying capability to this drug (53–55). Tormosyl, the corresponding fluoro analogue of proquazone, has been evaluated as an analgesic in humans (144).

The phthalazine derivative, diftalone, had AI potency in animal models approximately equal to that of PB, while gastro-ulcerogenic activity (in rats) and manifestations of acute toxic effects were practically absent (145). In the clinic it was found effective for the treatment of RA and comparable with indomethacin. Suppression of the ESR was also reported (56).

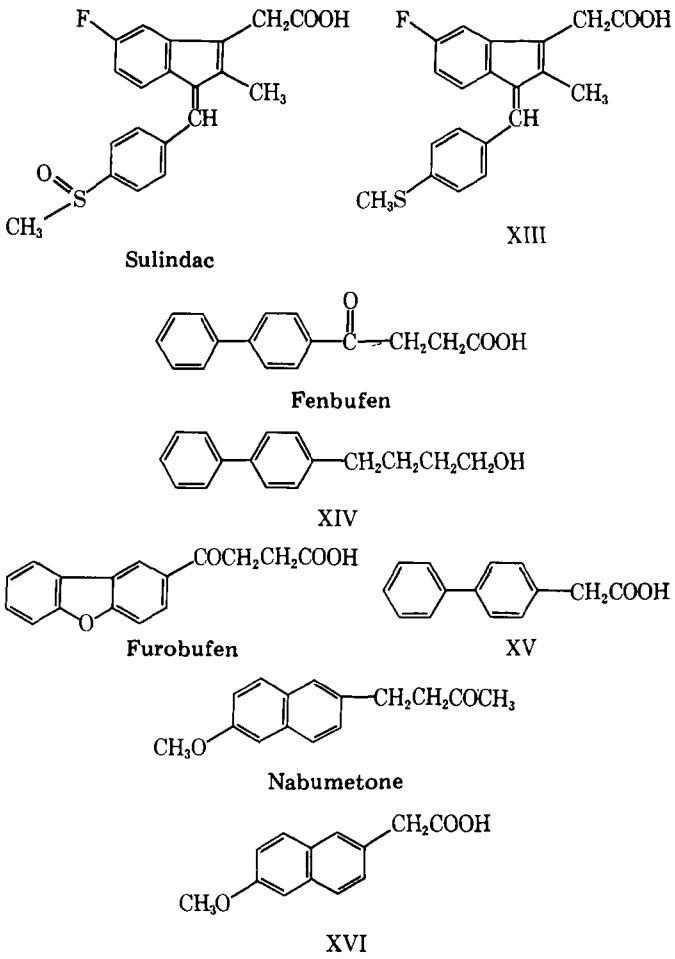

Figure 15.

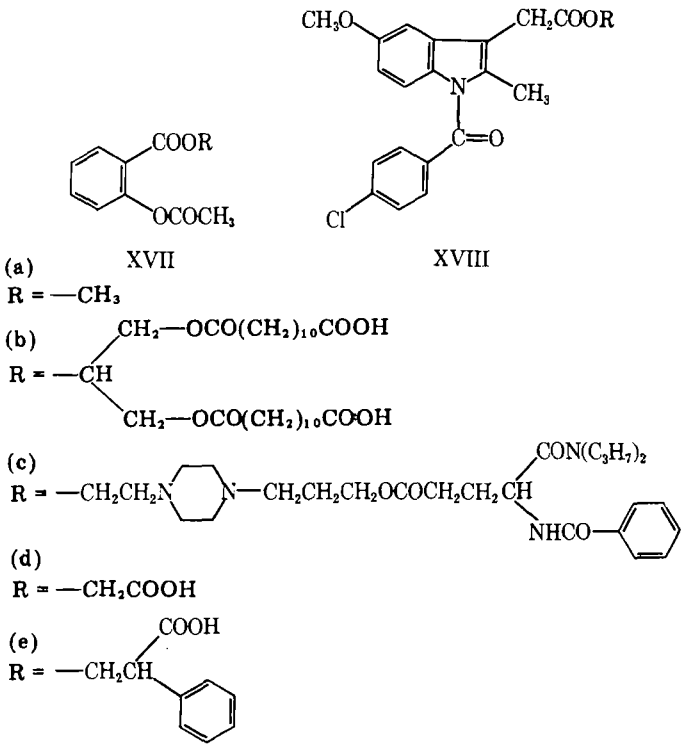

Figure 16.

Antipyretic, analgesic, and AI activity combined with a high therapeutic index as compared with indomethacin have been reported for 1,6-dimethyl-4-oxo-1,6,8,9,9a-hexahydro-4H-pyrido[1,2-*a*]pyrimidine-3-carboxamide (XII)[9]. A marked synergistic effect was observed in the reduction of rat CPE when a low dose of XII was coadministered with indomethacin. It is assumed that the product will be examined clinically and this synergistic effect evaluated (146).

Broperamole showed systemic AI activity 5–6 times that of PB in acute assays, and 10 times in the case of chronic assays. The product caused gastric irritation only at very high doses (147). It had topical AI activity, but less than that of hydrocortisone. The product is undergoing preclinical testings (148).

Epirizole (Fig. 14), a Japanese drug having higher analgesic activity than aminopyrine with less toxicity, is being evaluated for clinical trials in this country (149). Apparently this product can inhibit gastric lesions induced by acidic NSAI drugs (150).

The triazine anitrazafen is 50–100 times more potent than indomethacin in inhibiting fatty acid CO. It was found inactive in rat CPE and AA when given orally, but topically, it inhibited or reversed the formation of erythema induced by ultraviolet light (151). The development of this product, under evaluation for some time, may have been deemphasized (152).

In addition to showing good inhibiting activity in the usual assays of experimental inflammation, cloximate, an oxime ether derivative, showed marked activity in traumatic edema and in the Arthus antigen-antibody assay. Tested in acute and chronic experiments in rats and dogs, it had practically no harmful effect in the gastrointestinal mucosa. It is reported to be as potent as aspirin in blocking the biosynthesis of PGE_2. The product has been submitted to a first clinical trial (153).

Emorfazone, evaluated in acute models of inflammation showed analgesic and AI activity similar to PB (154). It was found to inhibit compound 48/80[10]- induced histamine release from mast cells and from rat skin, to have no effect on the immune system, and not to suppress PG synthesis. The main site of its anti-nociceptive activity was suggested to be in the periphery (155). Treatment of a group of patients with acute cystitis resulted in good to excellent remission of micturition pain in 14 of the 15 cases (156).

Prodrugs—Sulindac (Fig. 15), an indene isostere of indomethacin, was recently introduced in the United States. It is a prodrug for the active corresponding sulfide metabolite XIII. It has longer duration of action, fewer side effects than indomethacin, and it is claimed to be free of GI problems (157).

Fenbufen is characterized by its high analgesic activity, the sustained duration of its analgesic and AI action relative to the other known drugs, and the fact that it does not directly inhibit fatty acid CO. Its activity is due mainly to its main metabolite, biphenylacetic acid (BAA) (XV) which, in this case, must be obtained by quite an unusual transformation. This acid is a potent inhibitor of PG biosynthesis. The low potency of fenbufen to induce gastric irritation can be explained by the fact that BAA is not directly in contact with the GI tract (158, 159). Fenbufen is currently sold in more than 14 countries. Its introduction in the United States is expected in the near future (160).

The fluorene analogue, furobufen, has recently been recalled

[9] Code name: Chinoin-127.

[10] Mixture of polymeric amines; see W. D. M. Paton, *Br. J. Pharmacol.*, **6**, 499 (1951).

from clinical testing (161). In AA assays furobufen elicited similar activity to PB. The product has analgesic but no antipyretic activity (162). Thomae's butyryl alcohol derivative, 4-(4-biphenyl)butanol (XIV)[11], is also metabolized to XV and it presents, not unexpectedly, an activity profile similar to fenbufen[12].

Biotransformation of nabumetone to the active metabolite, 6-methoxynaphthalene acetic acid (XVI), is also responsible for the much reduced ability of this compound to induce gastric lesions as compared with standard drugs such as naproxen and/or indomethacin. The product is now being evaluated clinically (163, 164).

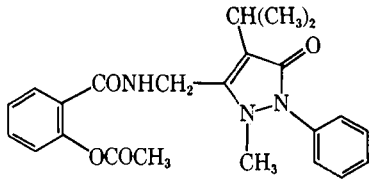
Most attempts to prepare AI prodrugs have revolved around modification of the acidic function, through esterification and/or amide formation, of known inflammation inhibitors. One of the most expedient ways would be esterification with methanol. Indeed, according to a recent report (165), the methyl esters of acidic NSAI drugs were found far less ulcerogenic than the acids, yet their AI activities were not changed appreciably. In the case of the methyl ester of aspirin (XVIIa) (Fig. 16) it was established that the toxicity after long-term oral administration to rats and guinea pigs was less than aspirin. Another study with radiolabeled salicylate derivatives showed that the methyl ester group did not quantitatively change the biodistribution of the active form generated *in vivo* (166).

On the basis that triglycerides are able to pass through the stomach without undergoing hydrolysis and then to be absorbed in the intestines, it was assumed that NSAI drugs incorporated in the triglyceride structure would bypass the stomach and then be metabolized to provide free drug delivery.

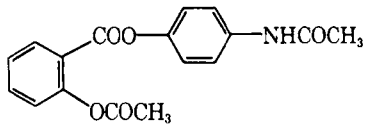
In the case of the triglycerides of aspirin (XVIIIb) it was found that the therapeutic ratio was improved 80-fold over aspirin. However, with indomethacin (XVIIb) only a threefold improvement was experienced. It was concluded that GI damage due to indomethacin is mainly produced systematically by the circulating drug, whereas in the case of aspirin the irritation is primarily the result of local action on the gastric mucosa (167–170). It was shown with the use of radiolabeled compounds that effective therapeutic concentration of the free active salicylate was easily obtained after ingestion of the triglycerides of aspirin (171).

The isoglutaminyl moiety of proglumetacin (XVIIIc) is said to procure protective activity to the gastric mucosa, while the presence of the piperazine nucleus seems important for providing a favorable therapeutic ratio (172). The product caused GI tract damage (in rats) only at dose levels close to the LD_{50} (173).

Acemetacin (XVIIId) was chosen from a series of more than 100 compounds, mostly esters and amides of indomethacin. In animal tests it was found to be more active than indomethacin (in acute and chronic assays), and to be equipotent with corticosteroid in the granuloma pouch test (cotton pellet). It is a weaker inhibitor of PG synthesis than indomethacin and, apparently in connection with that, it causes less damage to the mucous membrane of the gastrointestinal tract (174, 175). In a multicenter long-term study with 200 outpatients, the efficacy of acemetacin was assessed as good to very good in 75% of the cases. Only 3% of the patients gave preference to



XIX



Benorylate

Figure 17.

indomethacin in this study. Damage to the GI tract was observed but in general it was much reduced (176, 177).

Among a large series of esters of indomethacin, tropesin (XVIIIe) had the slowest rate of cleavage by action of serum esterases *in vitro*. Compared with indomethacin, the product exhibited the same AI efficacy, in acute and chronic models of inflammation, and a much lower tendency to induce gastric damage (UD_{50} 50 mg/kg *versus* 1 mg/kg for indomethacin). In a first clinical trial, symptoms of intolerance were not observed with daily doses of tropesin up to 210 mg (178).

The antiarthritic and analgesic activity of the double prodrug of aspirin and isopropylantipyrine (AIA)—*N*-(4-propyphenazon-5-yl)-2-acetoxybenzamide (XIX)—(Fig. 17), was found to have about the same potency as that of each moiety taken separately, but with the difference that the gastric ulcerogenic activity was much less pronounced. This product also showed practically no acute toxicity as shown by the LD_{50} values: 5 g/kg orally and subcutaneously, and 3.68 g/kg intraperitoneally in mice (179).

Benorylate, another example of a double prodrug (aspirin and paracetamol), is now marketed in Europe (180). It is believed that paracetamol, by stimulating stomach PG synthetase, inhibits the erosive action of aspirin (181).

CONCLUSION

Most of the compounds currently under investigation are CO inhibitors and as such are analogues of aspirin and/or indomethacin. Yet these may be justified as useful alternatives in view of individual diversity in response to treatment, if not as offering greater tolerance and, in some cases, the convenience of a once-a-day medication. More importantly, however, is the fact that a few of these may influence some of the more fundamental mechanisms of the disease, overlapping, it would seem, with the newer types of compounds whose mode of action is related either to their capacity to inhibit the chemotaxis of cells perpetuating the disease at the site of inflammation and/or to their selective control of the body's immune system.

Application of Dynamic Mechanical Testing to Characterize the Viscoelastic Properties of Powder-Filled Semisolids

GALEN W. RADEBAUGH * and ANTHONY P. SIMONELLI ˣ

Received January 14, 1983, from the *College of Pharmacy and Institute of Materials Science, University of Connecticut, Storrs, CT 06268.* Accepted for publication May 6, 1983. *Present address: McNeil Consumer Products Co., Exploratory Research and Development, Camp Hill Road, Fort Washington, PA 19034.

Abstract □ A nondestructive technique, dynamic mechanical testing, was used to characterize the viscoelastic properties of dispersions of powdered starch in anhydrous lanolin. The elastic shear modulus (G'), viscous shear modulus (G''), and loss tangent (damping; tan δ) were determined as a function of shear frequency, temperature, and the volume fraction of starch. The results of these studies show that constitutive mathematical models, derived to predict the mechanical behavior of solid-filled polymeric materials, can be applied to solid-filled semisolid pharmaceuticals. In particular, the Kerner equation was useful in describing the influence of starch on the G' of the dispersions. Even though the Kerner equation was unable to predict viscoelastic behavior at all shear frequencies, temperatures, and starch volume fractions, it proved beneficial in postulating mechanisms for starch–starch and starch–anhydrous lanolin interactions within the dispersions. In addition, damping was able to differentiate the influence of temperature. Data obtained from three temperature ranges, where anhydrous lanolin exists in three different structural states, shows that the influence of starch on damping is dictated by the structural state of anhydrous lanolin.

Keyphrases □ Dynamic mechanical testing—viscoelastic properties of powder-filled semisolids, starch–anhydrous lanolin model, Kerner equation □ Viscoelasticity—powder-filled semisolids, starch–anhydrous lanolin model, dynamic mechanical testing, Kerner equation □ Kerner equation—dynamic mechanical testing, application to the viscoelasticity of powder-filled semisolids, starch–anhydrous lanolin model

Pharmaceutical and cosmetic products are commonly heterogeneous dispersions of solid particles in liquid or semisolid vehicles. Usually, their rheology is studied with rotational, continuous shear viscometers (1–4). But unfortunately, continuous shear viscometers destroy the microcrystalline or amorphous three-dimensional networks that determine basic rheological properties and introduce the parameter of variation of structure with time. These viscometers are capable of determining the viscosity of Newtonian systems, but they are unable to determine fundamental viscoelastic parameters such as elastic or viscous moduli (5).

Semisolids in particular have been shown to exhibit complex rheological behavior and are generally classified as viscoelastic (6), *i.e.*, they exhibit spontaneously reversible deformation called elasticity and irreversible deformation called flow. To accurately characterize the viscoelasticity of a semisolid, the method of testing must minimize damage to structure that determines rheological properties. One such nondestructive method, dynamic mechanical testing, has been successfully used to characterize the viscoelastic properties of the heterogeneous semisolid anhydrous lanolin as a function of temperature and shear frequency (7, 8).

Because of the extensive use of solids suspended in ointments in the past and present, it would be invaluable to know the effect of suspended particles on the apparent viscoelastic properties of the ointment and to understand the phenomena associated with any observed changes. Despite the obvious importance of this type of information, there has been, up to now, a lack of information in the literature that examines the effects of powdered fillers on the viscoelastic properties of pharmaceutical semisolids.

This study was therefore initiated and showed that powdered fillers can have a significant influence on the viscoelastic properties of pharmaceutical semisolids. Data that relate temperature, shear frequency, and the volume fraction of starch to changes in viscoelastic moduli are presented for dispersions of starch in anhydrous lanolin. In addition, it is shown that mathematical models, which have been successfully used to predict viscoelastic moduli of powder-filled high polymers, can also be applied to powder-filled pharmaceutical semisolids to interpret changes in viscoelastic moduli in terms of interactions between the powder and the surrounding semisolid phase.

BACKGROUND

Unfortunately, the viscoelastic and mechanical properties of powder-filled pharmaceutical semisolids are not well understood, especially when the particles of powder interact among themselves or with the surrounding semisolid. Therefore, it is pertinent to this report that selected literature dealing with the rheological aspects and mechanical properties of suspensions of solid particles in nonaqueous media be reviewed first. In particular, emphasis will be placed on literature that deals with the mechanical properties of suspensions of solid particles in polymeric materials.

The flow behavior of suspensions of rigid particles in liquids is important because most theories of the moduli of composites have their origin in the theory of the viscosity of suspensions. Einstein's equation for the viscosity of a suspension of spherical particles is fundamental to the theory (9, 10):

$$\eta/\eta_1 = 1 + k_e\phi_2 \qquad \text{(Eq. 1)}$$

The apparent viscosity, η, is related to the viscosity of the suspending media, η_1, the Einstein coefficient, k_e, and the volume fraction of the suspended phase, ϕ_2[1]. When $\phi_2 \ll 1$ and the spheres are noninteractive, $k_e = 2.5$. Equation 1 holds only for very dilute suspensions. Attempts to extend the validity of this equation are numerous (11).

One of the most useful extensions is the Mooney equation (12):

$$\ln(\eta/\eta_1) = k_e\phi_2[1/(1 - \phi_2/\phi_m)] \qquad \text{(Eq. 2)}$$

where ϕ_m is the maximum volume fraction that the particles can attain when packed[2]. Equation 2 is a constitutive equation which adequately describes the viscosity of many kinds of suspensions over a wide range of concentrations.

[1] ϕ_2 is equal to the volume occupied by the particles divided by the total volume of the suspension.

[2] ϕ_m is equal to the true volume of the particles divided by the apparent volume occupied by particles.

Theoretically, ϕ_m is 0.74 for spheres in hexagonal close packing, but generally the value is much less because of irregularities in particle shape and particle-particle interactions. Viscosity generally increases rapidly with concentration and state of aggregation. The Einstein coefficient has been estimated for shapes other than nonagglomerated spheres, including roughly spherically shaped agglomerates of rigid spheres (13). Irregularities in shape generally increase k_e values.

With high concentrations of particles, suspensions become non-Newtonian and viscosity becomes a function of shear rate, $\dot{\gamma}$. For non-Newtonian suspensions that show a decrease in η with an increase in $\dot{\gamma}$, the Cross equation:

$$\eta = \eta_\infty + (\eta_0 - \eta_\infty)[1/(1 + \Omega\dot{\gamma}m)] \qquad \text{(Eq. 3)}$$

often holds (14, 15). The constants Ω and m depend on the system, while η_0 is the viscosity at zero shear rate and η_∞ is the viscosity at high shear rates. It is generally assumed that the shear rate dependence of viscosity seen in these systems is due to structural changes in the suspension, such as the breaking up of agglomerates by shearing forces. Other shear-dependent theories have been proposed by Krieger and Dougherty (16) and Gillespie (17, 18).

For a given instrument, the theoretical equations for shear viscosity and shear modulus should be of the same form for a given instrument geometry (19, 20). Therefore, shear strain in the modulus equation replaces shear rate in the viscosity equation. For a dispersion of a rigid filler in a viscoelastic matrix phase with a Poisson's ratio[3], μ, equal to 0.5, the relationship between relative viscosities and relative shear moduli can be expressed as:

$$\eta/\eta_1 = G/G_1 \qquad \text{(Eq. 4)}$$

where G is the shear modulus of the disperse system and G_1 is the shear modulus of the unfilled matrix phase. Consequently, the same theory that is used to determine the viscosity of a disperse system can be used to estimate its shear modulus. For example, G/G_1 can be substituted for η/η_1 in Eqs. 1 or 2 to yield corresponding equations for the relative shear modulus. It should be noted that the correlation between the relative viscosities and relative shear moduli expressed by Eq. 4 breaks down when μ is <0.5. Fortunately, a theoretical equation has been developed which compensates for this condition (22). In addition, if the rigidity of the dispersed phase is not much greater than that of the matrix, Eq. 4 is not applicable, as the modulus ratio will be substantially less than the viscosity ratio. Actual moduli, lower than predicted, can occur because (*a*) the Poisson's ratio of the matrix is <0.5, (*b*) thermal stresses reduce the apparent modulus, or (*c*) the modulus of the filler is not significantly greater than the modulus of the matrix. On the other hand, when the matrix is a rigid material, the Mooney equation (Eq. 2) predicts shear moduli which are too high (23).

Another constitutive equation that can be used to predict the modulus of a dispersion is the Kerner equation (24). When the dispersed particles are more rigid than the bulk polymer and deformation occurs by shear, the Kerner equation can be written as:

$$\frac{G}{G_1} = 1 + \frac{15(1 - \mu_1)}{8 - 10\mu_1} \cdot \frac{\phi_2}{\phi_1} \qquad \text{(Eq. 5)}$$

where μ_1 is Poisson's ratio of the bulk phase and ϕ_1, the volume fraction of the bulk phase, equals $(1 - \phi_2)$. This equation assumes the particles dispersed in the bulk polymer phase are spherical and that there is good adhesion between the particles and the bulk polymer. Good adhesion between the dispersed phase and the matrix or bulk phase is assumed to exist if the externally applied stress does not exceed the frictional forces between the phases. In many cases where adhesion is poor, Eq. 5 holds because there is little if any relative motion across the dispersed particle-matrix interface. Viscoelastic response can vary dramatically from the case of perfect adhesion to that of no adhesion. Weak agglomerates which break under applied stress show many of the characteristics of poor adhesion.

According to theory, the elastic modulus of a composite system is independent of the size of the filler particles, but experimental data indicates that there is an inverse proportionality between particle size and modulus (23). When the dispersed phase volume fraction is held constant, an increase in the elastic modulus of the dispersion may be attributed to an increase in total particle surface area when particle size is reduced. As particle size decreases, the tendency for particle agglomeration increases, which causes a corresponding decrease in maximum packing volume and a resultant increase in the elastic modulus.

It has also been demonstrated that the distribution of particle sizes has an effect on the moduli and viscosity of suspensions (25–28). Dispersions of

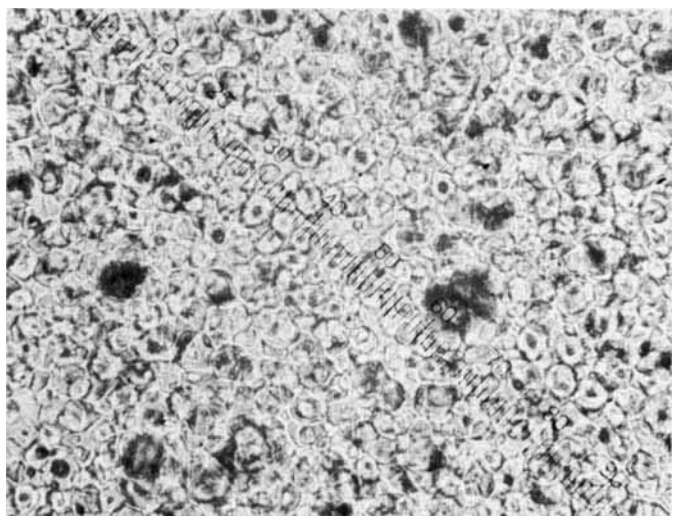

Figure 2—*Photomicrograph of a poured thin film of a starch-filled anhydrous lanolin USP dispersion, $\phi_1 = 0.802$. Original magnification 400×; 1 small division = 3.3 μm.*

[3] Poisson's ratio, μ, is an elastic constant which is defined for small elongations as the decrease in width of the specimen per unit width divided by the increase in length per unit length on the application of a tensile force. It can be shown that the relationship between μ and change in volume of the specimen, ΔV, can be expressed as: $\mu = 0.5 - (\Delta V/2\epsilon V_0)$, where V_0 is the original volume of the specimen and ϵ is the tensile force. When ΔV is sufficiently close to zero, the term $\Delta V/(2\epsilon V_0)$ is insignificant and equals 0.5. This condition holds for materials such as liquids and ideal rubbers. But when ΔV is positive, μ decreases to <0.5; and when ΔV is negative, μ increases to >0.5. Although the equation indicates that μ can be negative when the term $\Delta V/(2\epsilon V_0)$ is >0.5, this does not occur under conditions of small strain testing because ΔV is small compared to V_0 (21).

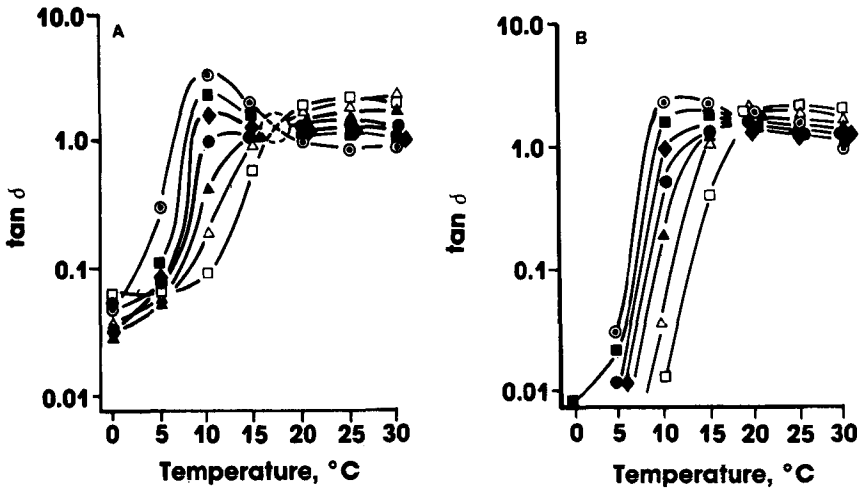

Figure 3—*Effect of temperature on the loss tangent of starch-filled anhydrous lanolin USP, at ϕ_1 equal to 0.802 (A) and 0.586 (B), and 3.54% strain. Key: (⊙) 0.0464 Hz; (■) 0.10 Hz; (◆) 0.215 Hz; (●) 0.464 Hz; (▲) 1.0 Hz, (△) 2.15 Hz; (□) 4.64 Hz.*

various particle sizes can pack more closely than monosized particles. Consequently, there is a larger maximum packing fraction and, hence, a lower modulus at a given concentration of dispersed phase.

In summary, the modulus of the disperse system (or composite) is dependent on the ratio of the moduli of the dispersed phase and matrix phase. The larger the modulus ratio, the greater is the modulus of the disperse system. This is especially true for high concentrations of particles.

EXPERIMENTAL

Materials—Anhydrous lanolin USP from the same production lot was used in all experiments[4]. It is a heterogeneous wax designated by the USP to contain not more than 0.25% water (25), the chemical composition of which has been examined extensively (26, 27). Potato starch[5], USP grade, was used to make the dispersions. When dispersed in anhydrous lanolin, 1 g of starch occupies an ~0.66-mL volume.

Apparatus—The viscoelastic properties of the starch dispersed in anhydrous lanolin were determined with a mechanical spectrometer, equipped with 50-mm cone and plate text fixtures[6]. Samples were oscillated sinusoidally by the output of a digital function generator and phase analyzer[7]. Temperature was controlled by enclosing the mounted sample in an environmental chamber[8]. A functional description of the apparatus, procedures for maintaining sample temperature and calculating the dynamic moduli, and data reproducibility have been previously given (7, 28).

Sample Preparation—Dispersions were prepared in 30-g lots. To prepare the dispersions, the appropriate weighed amounts of anhydrous lanolin and desiccator-dried starch were manually levigated together using a spatula and ointment tile. When the starch particles appeared to be completely coated, the mixture was transferred to a beaker and placed into a water bath at 50°C. After melting, the molten mixtures were gently stirred and placed into a desiccator. The desiccator was then evacuated by a filter pump, which acted to pull entrapped air from the molten mixtures. Deaerated samples were then gently stirred and poured onto the flat test fixture, while preventing air pocket formation. After 30 min at room temperature, the plate was mounted and the cone lowered to the preset gap. The extruded material was removed, and the sample was allowed to equilibrate at the test temperature for 15 min. Dispersions were made that contained the following volume fractions of starch (ϕ_2): 0.0295, 0.0604, 0.126, 0.198, 0.278, 0.366, and 0.414.

Description of Experiments—Samples were tested at 0°C, 5°C, 10°C, 15°C, 20°C, 25°C, and 30°C. At each T, all samples were oscillated over three decades of ν, 0.01–10.0 Hz, at a shear strain (γ) of 3.54%. The γ of 3.54% was the lowest obtainable strain with the equipment used (7). The moduli, G' and G'', and damping, tan δ, are calculated as a function of ν, T, and ϕ_2. In addition, photomicrographs[9] of thin poured films of the dispersions were taken to gain insight into the morphology of the dispersions.

RESULTS AND DISCUSSION

Kerner Equation Predictions—As previously discussed, many empirically derived equations are used to predict the viscoelastic behavior of powder-filled polymeric systems. Most of these equations are similar, but Kerner's equation is most useful (Eq. 5). For dispersions which undergo dynamic mechanical testing, the Kerner equation takes on the form:

$$\frac{G'}{G'_1} = 1 + \frac{15(1-\mu_1)}{8-10\mu_1} \cdot \frac{\phi_2}{\phi_1} \qquad \text{(Eq. 6)}$$

where G' is the elastic modulus of the dispersion, G'_1 is the elastic modulus of the unfilled bulk phase, and ϕ_1 and ϕ_2 are the volume fractions of the bulk phase and filler, respectively. It generally holds when there is adhesion between the phases and the dispersed particles are nearly spherical. If Poisson's ratio, μ_1, equals 0.5, then the slope of the line predicted by a plot of $[(G'/G'_1) - 1]$ *versus* (ϕ_2/ϕ_1) is 2.5.

Deviations from a slope of 2.5 suggest that one or more assumptions on which the equation is based do not hold. For example, slopes of >2.5 could be due to strong interactions between particles, which causes an increase in elastic structure. In contrast, slopes of <2.5 could be caused by slippage at the particle–bulk phase interface, which gives an apparent loss in elastic structure. Other deviations from a slope of 2.5 could be due to irregularities in the shapes of the particles or variations in μ_1.

Experimentally determined elastic moduli, G', of starch-filled anhydrous lanolin dispersions are plotted on Kerner axes for three test frequencies, 0.0464, 0.464, and 4.64 Hz, in Fig. 1. These frequencies are representative of the three decades of shear frequency examined in these experiments. For comparison, a line equal to the "ideal" Kerner equation prediction (slope = 2.5) is presented in each plot.

An examination of the plots shows that at temperatures ≥10°C, an increase in ϕ_2 and ν causes an increase in G', up to a ϕ_2 of ~0.4. The plots also show that the effects of ϕ_2 on G' are enhanced as T and ν increase. An increase in G' occurs with increasing ν because the molecules of anhydrous lanolin do not have time to rearrange themselves within the time frame of straining.

An increase in G' with increasing T can also be explained in terms of particle interaction with anhydrous lanolin. The starch particles tie up anhydrous lanolin molecules by adhesion, thereby providing a more elastic structure. At T = 0°C, G' of the disperse systems do not change with ν and ϕ_2. Each dispersion has the same limiting elastic modulus, G_E, as unfilled anhydrous lanolin. The modulus contribution of the starch to the modulus of the dispersion is apparently shielded by the "frozen" structure of the anhydrous lanolin phase. The shielding action may result from a fluid component of the anhydrous lanolin, or air, adsorbing on the surface of the starch particles.

An increase in G' would also be expected from increasing particle–particle contact. A representative photomicrograph of a starch-filled anhydrous lanolin

dispersion shows a packed network of starch particles (Fig. 2). Two physical mechanisms can be postulated to explain the increase in G' from increasing particle-particle contact. The first is a phenomenon known as bridging. Bridging occurs when the ends of molecules in the disperse phase interact with the surfaces of suspended particles, linking different particles together. As the volume fraction of starch increases, particle density and the probability of particle-particle contact increase. Therefore, it is probable that anhydrous lanolin molecules will bridge more particles, provide more structure, and increase G' because the particles are generally closer to one another. This phenomenon is well illustrated by the interaction of rubber with suspended particles of carbon black (29).

The second mechanism that could cause an increase in G' with increasing particle-particle contact is volumetric dilation. As particle density increases, suspended particles are forced past one another during shear. In the process, there is a dilation in the volume of the dispersion. Resistance to volumetric dilation appears as an increase in G'. The degree of dilation and resultant increase in G' is, therefore, proportional to ϕ_2. This postulate is supported by the Kerner equation (Eq. 6). In this equation, μ_1 compensates for changes in volume of the matrix phase. When there is no change in volume, $\mu_1 = 0.5$, but when volumetric dilation occurs, μ_1 decreases[3]. Therefore, a decrease in μ_1 would be reflected as an increase in G'.

The Kerner equation has proved beneficial for postulating a general mechanism for the influence of starch particles on the elastic modulus of dispersions of starch in anhydrous lanolin, but it must be emphasized that the "ideal" Kerner prediction does not correlate with experimentally determined moduli at all ν and T. As evidenced by Fig. 1, the "ideal" Kerner prediction is approximated only at $\nu \geq 0.464$ Hz and $T = 30$°C. One would intuitively expect ν and T to affect G'/G'_1 because of their demonstrated influence on the viscoelastic properties of anhydrous lanolin. The shapes of the Kerner plots presented in this study may be due to nonlinear viscoelastic behavior. Nonlinear behavior results from testing at strains in excess of that necessary for linear viscoelasticity. The effects of ν and T on G' will subsequently be discussed further in this report. To further study the effects of powdered starch on the viscoelastic properties of anhydrous lanolin, it was decided to examine energy dissipation (7) by measuring damping, tan δ, as a function of volume fraction.

Energy Dissipation Considerations—Like the Kerner equation, the ratio of G'' to G', tan δ, is also an indicator of structural changes. To illustrate, the damping curves for the two volume fractions of starch used in these experiments, 0.198 and 0.414 ($\phi_1 = 0.802$ and 0.586, respectively), are presented in Fig. 3. When the shapes of these curves are compared with those of unfilled anhydrous lanolin in Fig. 4, noticeable differences occur at 0°C, 5°C, 10°C, and 20°C. Essentially, at these temperatures the range of tan δ obtained from 4.64 to 0.464 Hz is narrower for the starch-filled anhydrous lanolin dispersions, which indicates that the internal structure created by the starch tends to dominate the contribution of the anhydrous lanolin.

Changes in the dynamic mechanical properties of polymers as a function of ϕ_2 are often most evident in damping (30). The change in tan δ of solid-filled polymers can be approximated by a volume averaging relation (31, 32):

$$(G''/G') = (G''/G')_1 \cdot \phi_1 + (G''/G')_2 \cdot \phi_2 \qquad \text{(Eq. 7)}$$

where $(G''/G') = \tan \delta$, the damping of the filled polymer; $(G''/G')_1$ and $(G''/G')_2$ are the damping of the pure polymer and pure filler, respectively; and ϕ_1 and ϕ_2 are the volume fractions of the pure polymer and pure filler, respectively. Since the damping of most rigid fillers is very small compared with that of the polymeric bulk phase, the term $(G''/G')_2 \cdot \phi_2$ is almost zero and can be neglected.

Experimentally determined damping values of unfilled anhydrous lanolin, at 0°C, 10°C, and 20°C, are given in Table I. These data represent three temperature ranges where anhydrous lanolin is in three different viscoelastic states (7). The glassy state of anhydrous lanolin is represented by 0°C, while 10°C is within the transition zone from a glassy to a rubbery state, and 20°C is within the region just beyond the transition zone. In Tables II and III, theoretical and experimentally determined damping values of two starch-filled anhydrous lanolin dispersions, $\phi_1 = 0.802$ and 0.586, respectively, are given. The theoretically predicted values were calculated by substituting the values from Table I into Eq. 7.

It is apparent that predicted damping does not equal that determined experimentally. In Table II, where $\phi_1 = 0.802$, it can be seen that the presence of starch increases damping over the temperature range of 0–20°C and over the entire test frequency range. The increases are probably caused by newly introduced damping mechanisms that are not present in anhydrous lanolin alone. The new damping mechanisms may include (*a*) particle-particle friction, where particles touch each other as in weak agglomeration, (*b*) particle-anhydrous lanolin friction, where there is little or no adhesion at the interface, and (*c*) excess damping in anhydrous lanolin near the interface because of induced thermal stresses or changes in anhydrous lanolin molecular conformation. Each of these mechanisms cause the elastic modulus to decrease and the viscous modulus to increase, which both independently give higher damping. An increase in damping indicates that these damping mechanisms cause an increase in energy dissipation during deformation of the dispersion.

In Table III, where $\phi_1 = 0.586$, the presence of starch increases or decreases damping of anhydrous lanolin depending on the temperature. At 0°C, where anhydrous lanolin exists in the glassy state, the experimentally determined damping of this dispersion is lower than that predicted by Eq. 7. At 10°, where anhydrous lanolin is in the transition zone from a glassy to a rubbery state, results are mixed. At low ν, experimental results are higher, while at higher ν experimental results are lower. At 20°C, a temperature just above the transition zone, experimental results are higher at all ν. Damping values lower than those predicted by Eq. 7 can be explained in terms of particle-particle interactions and particle-bulk phase interactions that result in a structure that is not easily deformed or broken by applied stress. These interactions result in increased elasticity and a consequent increase in G'. The viscous modulus, G'', also increases but not as greatly as the rate of increase in G'. Hence, the net result of changes in G' and G'' is a lower tan δ (the ratio of G'' to G').

For dispersions of starch in anhydrous lanolin, it would be appropriate to modify Eq. 7 to the form:

$$(G''/G') = (G''/G')_1 \cdot \phi_1 + (G''/G')_2 \cdot \phi_2 + \text{Interaction Term} \qquad \text{(Eq. 8)}$$

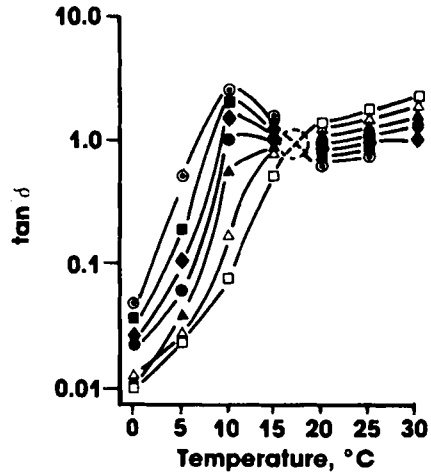

Figure 4—*Effect of temperature on the loss tangent of unfilled anhydrous lanolin USP, at 3.54% strain. Key: (⊙) 0.0464 Hz; (■) 0.10 Hz; (◆) 0.215 Hz; (●) 0.464 Hz; (▲) 1.0 Hz; (△) 2.15 Hz (□) 4.64 Hz.*

[a] ϕ_1 equals 0.586. [b] Calculated using Eq. 7 and data in Table I. [c] Experimentally determined.

where the interaction term accounts for deviations from idealized behavior. The interaction term would be negative when experimentally observed damping is lower than that predicted by Eq. 7. Conversely, the interaction term would be positive when experimentally observed damping is higher than that predicted by Eq. 7.

As previously mentioned, Figs. 3 and 4 illustrate the relationships between tan δ, T, and ϕ_2 for starch-filled and unfilled anhydrous lanolin. A comparison of Fig. 3 to Fig. 4 shows the maxima in the damping curves at the lowest ν all occur at 10°C. Overall, there appears to be no significant difference between Fig. 4 and Fig. 3A. This is a good indication that starch, up to $\phi_2 = 0.198$, does not shift the mechanical transition temperature (analog of T_g) of anhydrous lanolin. There also appears to be no significant shift in the crossover region of the damping curves. But when ϕ_2 reaches 0.414, there is a significant difference in appearance in the damping curves, as evidenced by a comparison of Figs. 4 and 3B. Even though the damping curve generated by a ν of 0.0464 Hz has its maximum at 10°C, its magnitude has been reduced, as is also the case at each ν at ≤10°C. At >10°C, the curves are closer together and most noticeably, the crossover region has shifted from 17°C to ~20°C. These plots suggest that the degree of influence on the transition temperature of anhydrous lanolin is proportional to the volume fraction of starch.

CONCLUSION

Dynamic mechanical testing has been shown to be a sensitive tool to examine the effects of a powdered filler on the viscoelastic properties of a pharmaceutical semisolid. Viscoelastic parameters give insight into fine structural changes of the dispersions that cannot be observed with conventional steady shear rheometers. Even though the widely used Kerner equation was unable to predict the elastic moduli of starch-filled anhydrous lanolin dispersions at all ν, T, and ϕ_2, it did prove useful in postulating mechanisms of interaction between the filler and the bulk phase. One probable reason for the limited applicability of the Kerner equation is the nonlinear viscoelastic effects caused by the introduction of starch into anhydrous lanolin. It must be noted, however, that damping was an effective indicator of the degree of influence starch had on the mechanical transition of anhydrous lanolin from the rubbery state to the glassy state.

APPENDIX: Glossary

G = shear modulus (dyne cm^2 or Pa: N m^2)
G_1 = shear modulus of the unfilled matrix phase
G' = dynamic shear storage modulus (same units as G)
G'' = dynamic shear loss modulus (same units as G)
G_E = limiting value of G'
T = temperature
V_0 = original volume of test specimen
ΔV = change in volume of specimen
T_g = glass transition temperature
k_e = Einstein coefficient
ϵ = tensile force
m = exponent of shear rate in Cross equation
δ = phase angle between stress and strain vectors
γ = strain
$\dot{\gamma}$ = rate of strain
η = shear viscosity (Poise: dyne s cm^{-2} or Pascal seconds: N s m^{-2})
η_0 = shear viscosity at zero shear rate
η_1 = shear viscosity of the suspending media
η_∞ = shear viscosity at very high shear rates
μ = Poisson's ratio (dimensionless)
μ_1 = Poisson's ratio of the bulk phase
ϕ_1 = volume fraction of bulk phase
ϕ_2 = volume fraction of dispersed phase
ϕ_m = volume fraction of maximally packed particles
ν = shear frequency (Hz)
Ω = constant in the Cross equation

Urinary Excretion of Chlorpheniramine and Its Metabolites in Children

KEITH J. SIMONS *x, F. ESTELLE R. SIMONS ‡, GEORGE H. LUCIUK ‡, and EVELYN M. FRITH‡

Received January 27, 1983, from the *Faculty of Pharmacy, and the ‡Department of Pediatrics, Faculty of Medicine, University of Manitoba, Winnipeg, Manitoba R3T 2N2, Canada. Accepted for publication March 27, 1983.

Abstract □ The pharmacokinetics and urinary excretion of chlorpheniramine were studied in 11 patients, aged 6–16 years, with allergic rhinitis. In these children, chlorpheniramine had a mean elimination half-life of 13.1 ± 6.6 h, a mean clearance rate of 7.23 ± 3.16 mL/min/kg, and a mean apparent volume of distribution of 7.0 ± 2.8 L/kg. Over 48 h, the recovery in urine was as follows: chlorpheniramine, 11.3 ± 6.7%; demethylchlorpheniramine, 23.3 ± 11.1%; and didemethylchlorpheniramine, 9.6 ± 9.4%. Urine flow rate and urine pH were uncontrolled and ranged from 2.2 to 113.3 mL/h and 5.1–7.9, respectively, over the 48-h period. In some children urine flow rate and pH were constant, while in others there was great variability. When drug and metabolite excretion rates *versus* both urine flow rates and pH values were analyzed by multiple linear regression, the results were significantly better ($p \leq 0.05$) than when each factor was analyzed independently. The excretion rate of chlorpheniramine and its two demethylated metabolites decreased as urine pH increased and urine flow rate decreased. This information must be considered in future pharmacokinetic studies of this drug.

Keyphrases □ Chlorpheniramine—demethylated metabolites, urinary excretion in children, pharmacokinetics □ Excretion, urinary—chlorpheniramine and its demethylated metabolites, children, pharmacokinetics □ Pharmacokinetics—urinary excretion of chlorpheniramine and its demethylated metabolites, children

Chlorpheniramine, a histamine H_1 receptor antagonist, has been used for over 30 years in the treatment of allergic rhinitis (1). Recently, the development of sensitive, specific HPLC (2) and GLC-MS (3) assays have facilitated bioavailability (4–6) and pharmacokinetic (7–9) studies with chlorpheniramine. The metabolism of chlorpheniramine has been investigated in dogs (10) and humans (11), and the effect of induced, constant urine pH and flow rate on the rate of excretion of the unchanged drug has been evaluated (12). In recent single- and multiple-dose urinary studies (9, 13, 14), no correlation was determined between uncontrolled urine pH and flow rate and chlorpheniramine excretion. We have recently modified an HPLC assay (2) for chlorpheniramine (I), demethylchlorpheniramine (II), and didemethylchlorpheniramine (III) and have studied the pharmacokinetics and efficacy of chlorpheniramine in children with severe perennial allergic rhinitis (15). In this single-dose study (15), timed urine samples were also collected and the effect of uncontrolled urine pH and flow rate on the excretion of chlorpheniramine and two of its metabolites was evaluated.

II: $R_1 = CH_3$, $R_2 = H$
III: $R_1 = R_2 = H$

EXPERIMENTAL

Patients—Chlorpheniramine was given to 11 patients with allergic rhinitis, mean age 11.0 ± 3.0 years and mean weight 39.6 ± 9.2 kg. All patients had received regular chlorpheniramine treatment for at least 6 months during the course of their rhinitis, but no patient had received it within 1 month of study. The protocol for this investigation was approved by the Faculty Committee of the University of Manitoba on the Use of Human Subjects in Research, and signed informed consent was obtained from the parents and the child before the study.

Protocol—Children reported to the Children's Hospital Clinical Investigation Unit at 0800 hours after an overnight fast. They had not received any medications in the preceding 72 h and were examined for nasal symptoms. After placement of an indwelling intravenous needle and withdrawal of 2 mL of blood, each patient received a single 0.12-mg/kg dose of a commercially available chlorpheniramine maleate syrup[1] with 120 mL of water. Uniform meals and snacks were served throughout the study, beginning 2 h after drug ingestion, and standardized activities were provided. Additional blood samples were obtained from the indwelling needle 1, 3, 6, 9, 12, 15, 18, 24, and 30 h after chlorpheniramine ingestion. The serum was separated and frozen at −20°C until the samples were analyzed. Urine samples were collected and pooled every 6 h for up to 48 h. The pooled samples were mixed well and measured; an aliquot was removed and frozen at −20°C until the samples were analyzed. The pH was determined on each aliquot prior to drug analysis.

Liquid Chromatographic Analysis of Chlorpheniramine (I), Demethylchlorpheniramine (II), and Didemethylchlorpheniramine (III)—One milliliter of test serum, urine, or control serum or urine containing standards was transferred into a 16 × 100-mm test tube, and 100 μL of internal standard solution (brompheniramine maleate, 1 μg/mL) was added. To this, 250 μL of 5% KOH and 5 mL of ether were added; the sample was mixed in a vortex mixer for 20 s and centrifuged for 1 min to separate the layers. The ether layer was transferred to a new 16 × 100-mm test tube containing 0.5 mL of 0.5% phosphoric acid, mixed, and centrifuged as before. With the aid of a methanol–dry ice bath, the aqueous layer was frozen and the ether layer discarded. When the aqueous layer was completely thawed the sample was made alkaline with 250 μL of 5% KOH and extracted with 5 mL of ether again as before. The ether layer was transferred to a dry 13 × 100-mm test tube and evaporated at 25°C with the aid of dry nitrogen. The sample was redissolved in 100 μL of mobile phase, and 25–100 μL were injected directly into the HPLC.

[a] — Sample not collected.

A component HPLC system was used, consisting of an injector, a high-pressure pump, an absorbance detector with a fixed wavelength of 254 nm, and a data module[2]. A 30 × 0.39-cm reverse-phase C_{18} stainless steel column[3] was used. The mobile phase was 25% acetonitrile in 0.075 M phosphate buffer (NaH_2PO_4), pH 2.5 (with H_3PO_4). At a flow rate of 2 mL/min, retention times were: didemethylchlorpheniramine, 2.7 min; demethylchlorpheniramine, 3.2 min; chlorpheniramine, 4.3 min; and internal standard, 5.0 min. With this procedure, drug concentrations as low as 1 ng/mL were measured.

Pharmacokinetic Data—After the initial absorption peak there was a second lower peak on all the serum chlorpheniramine concentration *versus* time plots. There were a limited number of data points, so most of the pharmacokinetic values were determined by model-independent methods (16). It was possible to determine a serum half-life by fitting the terminal linear portion of each curve to

$$C_p = C_p^0 e^{-k_e t} \qquad \text{(Eq. 1)}$$

using the BMDP[4] computer program where C_p is the serum concentration at any time t, C_p^0 is the serum concentration extrapolated to time zero (t^0), and k_e is the first-order elimination rate constant. The elimination half-life ($t_{1/2}$) was then calculated from:

$$t_{1/2} = \frac{\ln 2}{k_e} \qquad \text{(Eq. 2)}$$

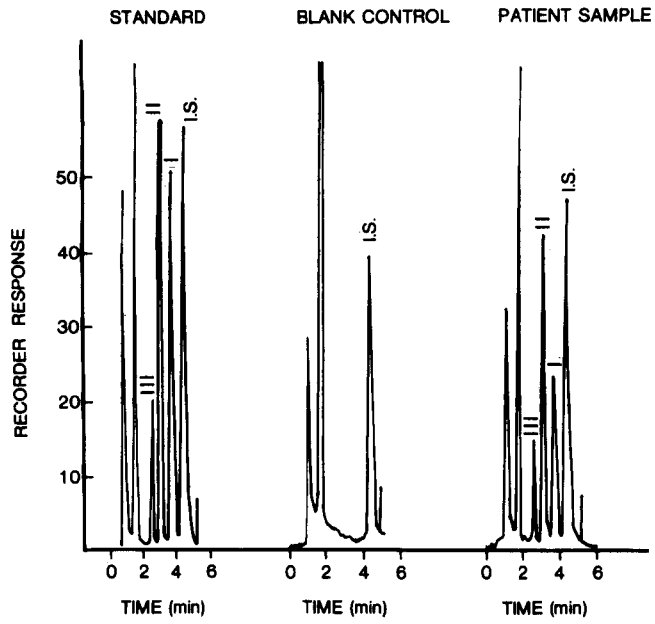

Figure 2—*Chromatograms of chlorpheniramine (I), demethylchlorpheniramine (II), didemethylchlorpheniramine (III), and the internal standard (IS) in urine.*

Total body clearance (CL) was calculated using:

$$CL = \frac{f \cdot \text{Dose}}{\text{AUC}} \qquad \text{(Eq. 3)}$$

where f is the fraction of the dose adsorbed and AUC is the area under the serum chlorpheniramine concentration *versus* time curve, calculated using the trapezoidal rule to time t_n, to which the value C_{p_n}/k was added to extrapolate to infinite time. The apparent volume of distribution (Vd) was calculated using:

$$Vd = \frac{CL}{k_e} \qquad \text{(Eq. 4)}$$

The excretion rate (ER) of chlorpheniramine and its two demethylated metabolites was calculated using:

$$\text{ER} = \frac{dX_u}{dt} \qquad \text{(Eq. 5)}$$

where dX_u was approximated by ΔX_u or the average hourly amount excreted, calculated from each 6-h urine aliquot, and dt or Δt was 1 h. The urine flow rate (UFR) was calculated using:

$$\text{UFR} = \frac{dV_u}{dt} \qquad \text{(Eq. 6)}$$

where V_u was the volume of urine voided in the 6-h period averaged to an hourly rate.

Statistical Analysis—Correlations between urine pH, flow rate, and excretion rate of chlorpheniramine or its two demethylated metabolites were determined using multiple linear regression analyses (17). Results were evaluated using the Student's paired and unpaired t tests (17). All calculations were performed on a programmable calculator[5].

RESULTS AND DISCUSSION

Typical chromatograms of chlorpheniramine (I) in serum are shown in Fig. 1. Chromatograms of I, II, and III in urine are shown in Fig. 2. Calibration curves constructed by plotting the peak height ratio of I from serum to internal standard *versus* I concentration were linear ($r = 1.00$) over the concentration range of 0–30 ng/mL. Compounds I, II, and III extracted from urine also yielded linear calibration curves when the peak height ratio of compound to internal standard was plotted *versus* concentration. The slopes and intercepts of the calibration curves did not vary significantly throughout the period of analysis of all samples from this study. Serum chlorpheniramine concentrations are shown in Table I.

The results of pharmacokinetic studies for each subject are shown in Table II. The mean elimination half-life for I of 13.1 ± 6.6 h obtained in the study (15) was not significantly different ($p = 0.05$) from the mean value of 9.6 ± 3.6 h found in seven children given an intravenous dose of this drug (8). In adults, a wide range of elimination half-life values have been reported following oral (4–6) and intravenous (7, 9) administration. The half-life values in four studies, 20.96 ± 4.94 h (4), 25.1 ± 8.4 h (5), 24.4 ± 6.6 h (7), and 27.9 ± 8.7 h (9), were significantly longer ($p \leq 0.05$) than the values in children. However, half-life values of 17.3 ± 4.4 and 14.6 ± 3.4 h in another study in adults (6) were not significantly different ($p = 0.05$). Since some of the subjects in this latter study were <20 years of age, it is probable that elimination rates for I are age dependent.

±*SD*		3.0	9.2	0.03	6.6	125.42	3.16	2.8	3.5	1.5

Chlorpheniramine was only administered orally to the children in this study, so it was not possible to calculate the absolute bioavailability. The uncorrected values for clearance and volume of distribution were 7.23 ± 3.16 mL/min/kg and 7.0 ± 2.8 L/kg, respectively. When clearance values were calculated using a fraction of the dose absorbed of 0.6 (9), the mean value (4.32 ± 1.92 mL/min/kg) was not significantly different ($p = 0.05$) from the value of 5.39 ± 1.45 mL/min/kg obtained from a previous study in children (8) in which the dose was given intravenously. It was significantly different ($p \leq 0.05$) from the clearance rate of 7.92 ± 1.81 mL/min/kg found in one other study in adults (7), in which there was wide scatter in the serum chlorpheniramine concentrations *versus* time plots.

Using the same 0.6 fraction of dose absorbed (9), the mean apparent volume of distribution was 4.2 ± 1.6 L/kg. This value was not significantly different ($p = 0.05$) from those of 4.30 ± 1.26 (8) and 3.4 ± 0.3 L/kg (9) obtained in children and adults, respectively, given an intravenous dose of I. The uncorrected volume of distribution value of 7.0 ± 2.8 L/kg obtained in these 11 children was also not significantly different ($p = 0.05$) from uncorrected values of 7.6 ± 2.1 L/kg reported previously in adults (4).

The urinary excretion of I and its metabolism to II and III has been reported (13) and confirmed (11). The recovery of unchanged drug and metabolites in 48-h urine samples is shown in Table III. The urine flow rate, pH, and excretion rate values for I, II, and III for each subject are shown in Table IV. Representative plots of urine flow rate, pH, and excretion rates of chlorpheniramine and its two demethylated metabolites *versus* time are shown in Fig. 3. Urine flow rates and pH were not controlled in this study and ranged from 2.2 to 113.3 mL/h and 5.1–7.9, respectively, over the 48-h study period. In some of the children, urine flow rate and pH were constant (Fig. 3a), while in others they were quite variable (Fig. 3b).

Since urine collection intervals varied from study to study (12–14) it was difficult to compare drug recoveries. In adults, recoveries of unchanged drug in 24-h pooled urine samples were 4.5–11% (12), 5.2% (13), and 5.5–15% (14) as compared with 11.29 ± 6.68% (4.13–25.62%) in 48 h in these children. In adults 10.4% (14) and 13.2% (13) was recovered as demethylchlorpheniramine in 24 h compared with 23.30 ± 11.06% (8.40–45.51%) in 48 h in this study. The didemethylchlorpheniramine accounted for only 3.6% (14) and 5.8% (13) of the dose in adults in 24 h, while 9.60 ± 9.44% (1.20–29.20%) of the dose was recovered in the young patients in 48 h. The results were similar despite the differences in the collection intervals. In the present study, 44.19 ± 19.10% (18.60–73.45%) of the dose was recovered in 48 h. However, since only four subjects had half-life values <8 h and some had half-life values as long as 23 h, it is not valid to assume that the 48-h recovery accounts for all drug and metabolites in urine following this single oral dose. In the four subjects with half-life values <8 h, 48-h urinary recovery ranged from 35.18 to 66.29%. The missing 34–65% of the dose was assumed to be eliminated as unextractable metabolites (14). In the dog, oxidative deamination accounted for a fraction of these metabolites, as 11% was identified as 3-(*p*-chlorobenzyl)-3-(2-pyridyl)propanol and 18% as the corresponding propionic acid (10). These metabolites have not been identified in humans (11).

Table III—Percentage of a 0.12-mg/kg Oral Dose of Chlorpheniramine Maleate Recovered in Urine at 48 h

Patient	Dose,[a] mg	III[b], %	II[c], %	I, %	Dose Recovered in 48 h, %

[a] As chlorpheniramine (I) free base. [b] Percent of dose recovered as didemethylchlorpheniramine (III), expressed as chlorpheniramine equivalents. [c] Percent of dose recovered as demethylchlorpheniramine (II), expressed as chlorpheniramine equivalents. [d] Control urine from this patient showed traces of chlorpheniramine and metabolites by HPLC and TLC.

The effect of urine pH and flow rate on the excretion of chlorpheniramine and its metabolites has been reported following single- and multiple-dose studies (12–14). When the urine was acidic, significantly more chlorpheniramine was excreted as unchanged drug than when the urine was alkaline (12–14). In addition, although the demethyl metabolite was similarly affected,

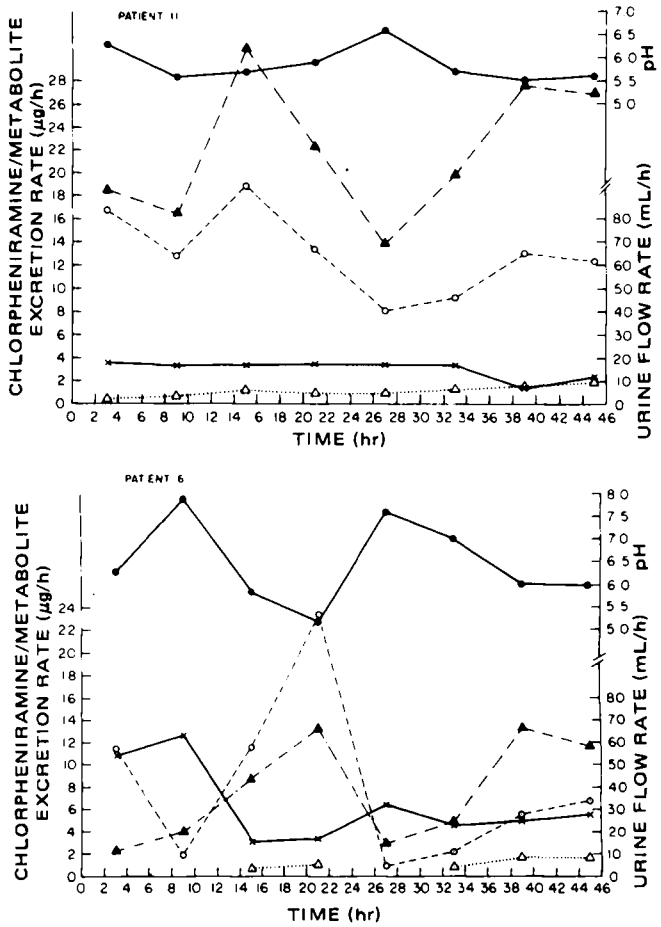

Figure 3—*Urinary excretion rates (μg/h) of chlorpheniramine (⊙), demethylchlorpheniramine (▲), and didemethylchlorpheniramine (△), urine flow rates (mL/h) (×), and urine pH (●) plotted* versus *time in young subjects given 0.12 mg/kg of drug orally.*

Table IV—Urine Flow Rates, pH, and Excretion Rates of Chlorpheniramine (I), Demethylchlorpheniramine (II), and Didemethylchlorpheniramine (III) in 11 Patients Given a 0.12-mg/kg Oral Dose of Chlorpheniramine Maleate

the excretion of the didemethyl metabolite appeared to be minimally affected by pH (14). When urinary pH was maintained in the acidic range, the urinary excretion of unchanged chlorpheniramine was dependent on urine flow rate. This effect can be explained by the theory that the epithelium of the distal convoluted kidney tubules is selectively permeable to the unionized base (12). The effect of urine flow rate on the two demethylated metabolites has not been evaluated to date.

To evaluate the effect of urine flow rate and pH on the excretion rate of I, II, and III, a comparison was made between linear regression analyses of excretion rate *versus* urine flow rate and excretion rate *versus* urine pH and multiple linear regression analysis of excretion rate *versus* both urine flow rate and pH. These calculations were performed on all experimental values and on results obtained after 12 h only. It was assumed that chlorpheniramine absorption would be complete by this time and that a better correlation might be obtained in the postabsorption phase. The correlation coefficients (r) calculated for the single and multiple regression analyses are shown in Table V.

For chlorpheniramine, the mean results obtained from the postabsorption data were virtually identical to the mean results obtained from the total data. The mean correlation coefficient obtained from the multiple linear regression analysis, $r = 0.66 \pm 0.15$, was significantly better ($p \leq 0.05$) than the values obtained from the urine flow rate data, $r = 0.32 \pm 0.21$, and from the urine

[a] Excretion rate to both urine flow rate and pH. [b] Analysis on all data points. [c] Analysis on data points after 12 h only (assuming oral absorption was complete).

pH data, $r = 0.45 \pm 0.27$. The dependence of chlorpheniramine excretion rate on both urine flow rate and urine pH, even in patients where these parameters were not controlled, was clearly demonstrated.

The results obtained from the regression analysis of the demethylchlorpheniramine data were similar. There was no difference between results obtained from the postabsorption data and the total data. The mean correlation coefficient from the multiple linear regression analysis, $r = 0.64 \pm 0.23$, was significantly better ($p \leq 0.05$) than the value from the urine flow rate data, $r = 0.40 \pm 0.19$, but not significantly improved ($p = 0.05$) from the urine pH data, $r = 0.51 \pm 0.26$. Demethylchlorpheniramine appeared to be more dependent on urine pH than on urine flow rate.

For didemethylchlorpheniramine, the mean correlation coefficient for multiple linear regression analysis from the total data, $r = 0.69 \pm 0.24$, was not significantly improved ($p = 0.05$) from the results obtained for urine flow rate, $r = 0.38 \pm 0.28$, or urine pH, $r = 0.51 \pm 0.33$. However, for the postabsorption phase data, the mean multiple linear regression analysis correlation coefficient, $r = 0.77 \pm 0.19$ was significantly better ($p \leq 0.05$) than that obtained from the urine flow rate data, $r = 0.39 \pm 0.29$, or from the urine pH data, $r = 0.51 \pm 0.28$. Didemethylation is probably a sequential metabolic pathway so this metabolite would be formed from demethylchlorpheniramine and would be dependent on the rate of formation of demethylchlorpheniramine from chlorpheniramine. For this reason, the results from the data after 12 h were more consistent ($r = 0.77 \pm 0.19$) than those obtained from the total data ($r = 0.69 \pm 0.24$). From that time, absorption of chlorpheniramine would probably be complete, and the rate of demethylchlorpheniramine formation would be constant or steadily decreasing as the amount of chlorpheniramine decreased.

These results confirm that the chlorpheniramine excretion rate is dependent on urine flow rate and pH (12–14). Demethylchlorpheniramine appears to be more dependent on urine pH than on urine flow rate, and didemethylchlorpheniramine may also be dependent on both urine flow rate and pH. Since urine pH has been reported to have a minimal effect on didemethylchlorpheniramine excretion (14), further studies are required to confirm these findings.

Currently recommended doses for chlorpheniramine are 4–8 mg four times daily. The results of this study, the long chlorpheniramine half-life values (4–9, 15), and the prolonged biological effects (15) of chlorpheniramine suggest that in current dosage regimens chlorpheniramine may be prescribed more frequently than required to produce beneficial effects while minimizing adverse effects. In patients where urine pH may be chronically elevated and urine flow rate reduced, elimination of both the unchanged chlorpheniramine and its metabolites may be further decreased.

Physical Model Approach to Taste Studies of Drugs and Pharmaceutical Formulations

N. F. H. HO

Received January 21, 1982, from the *College of Pharmacy, The University of Michigan, Ann Arbor, MI 48109.* Accepted for publication March 21, 1983. Present address: Pharmacy Research, The Upjohn Co., Kalamazoo, MI 49001.

Abstract □ This paper explores the physical model approach in studying the taste of drugs and assessing physical formulation factors for improving the undesirable taste of drugs. Various aspects of physiology relevant to the taste phenomenon have been reviewed to provide the biophysical basis for mathematical modeling. The model involves non-steady-state mass transport across the aqueous boundary layer and buildup of solute concentration at the essentially impermeable tongue surface. The theoretical predictions are consistent with experimental studies on the lag time to taste perception by the electrophysiological method and also with "instantaneous" psychophysical taste perception when solute concentrations much greater than the taste threshold are applied on the tongue. Within the framework of the non-steady-state model, novel experimental studies involving the use of a porous half-diffusion cell placed on the surface of an extended human tongue and the recording of the times for psychophysical taste response are proposed to quantify and provide mechanistic understanding of the taste of drugs and also physical formulation factors in overcoming undesirable taste properties.

Keyphrases □ Taste perception—drugs and pharmaceutical formulations, physical model approach, non-steady-state mass transport □ Physical model—taste perception, drugs and pharmaceutical formulations, non-steady-state mass transport □ Mass transport—non-steady-state, physical model for taste perception, drugs and pharmaceutical formulations

The taste of drugs and the physical and chemical means to overcome or modify undesirable (usually bitter) taste are continuing and nagging problems for the pharmaceutical scientist. Understanding of structure–taste relationships (*i.e.*, taste quality and intensity) remains qualitative as pointed out by Sinkula (1), who reviewed the state of the science in improving taste properties through structural modification. The physicochemical approaches to masking undesirable taste properties remain largely empirical. The purpose of this paper is (*a*) to review the various aspects of physiology relevant to taste stimulation and (*b*) to explore the physical model approach, both theoretically and experimentally, in studying the taste of drugs and formulation factors affecting taste.

BACKGROUND

A rational approach to the understanding of taste and taste stimulation by drugs, among other important considerations relating to the physicochemical properties of the drug molecule and pharmaceutical formulation, requires some degree of knowledge of the tongue: morphology, ultrastructure, organization and functions of the cells, absorption characteristics, and taste reception.

Loci of Taste Quality—Salty, sour, bitter, and sweet sensations are recognized as the four fundamental qualities of taste. Responses to taste are found everywhere in the mouth, which includes the palate, epiglottis, tongue, and buccal area. It is generally stated in textbooks [*e.g.*, Best and Taylor (2)] that the lowest threshold for bitter is located in the back of the tongue; for salty, at the front; for sweet, on the sides near the front; and for sour, on the sides near the back of the tongue. However, it should not be construed that taste quality is confined to these loci of the tongue. Taste buds are not rigidly specific to any one taste quality, but show multiple sensitivity to taste stimulants. Taste buds appear to be differentially sensitive and may be uniquely distributed (3). A recent systematic study (4) using sodium chloride, sucrose, quinine hydrochloride, urea, and citric acid has improved the understanding of taste recognition and psychophysical intensity responses in humans as a function of locus of stimulation on the tongue and soft palate. Collings (4) found the threshold for bitter to be lower for the front of the tongue and soft palate than for the back of the tongue. The combination of the greater intensity of bitter sensation in the back of the tongue and the low threshold of the soft palate for bitter gave the subjective observation of a strong bitter taste in the back of the mouth. Differential responses to a variety of taste stimulants at specific loci were also reported.

Taste Buds and Cells—Associated with the various loci of taste stimulation on the tongue are four kinds of papillary structures (5): vallate papillae in the back of the tongue; foliate papillae on the sides and near the back; fungiform papillae at the front dorsal surface, tips, and sides; and filiform papillae, which are the prevalent type dispersed throughout the tongue surface. A keratin layer covers the surfaces of the papillae and is interrupted by the pores of the taste buds.

Taste buds are most abundant in the vallate and folliate papillae, served by the IX cranial nerve, and the fungiform papillae, served by the chorda tympani of the VII cranial nerve. The filiform papillae, whose keratinized epithelium ends in tapered points, are devoid of taste buds. With respect to the vallate papillae, which is surrounded by a moat, taste buds are dispersed about the sides of the papillae in the depths of the moat. Taste buds of the foliate (leaf-like) papillae are located on the sides, whereas the buds of the fungiform papillae are found on the flat surface portion.

Taste buds are intermingled with stratified squamous epithelial cells, and both structures rest on a thick layer of connective tissue called the basement membrane (5, 6). The bud reaches from the basement membrane to the epithelial surface and is 70 μm in length and 50 μm in its widest dimension. The pore of the taste bud, from which "taste hairs" of taste cells are extended, is found at the epithelial surface. The pore diameter is ~5 μm and, therefore, would not be a factor in excluding large molecules from penetrating the pore. The bud contains a single pore and a collection of cells. It has been assumed that the bud contains 4–20 taste cells intermingled with the more numerous supporting cells. A study by Murray (7, 8) however, states that the number of cells within a taste bud varies from 30 to 80. The cells are morphologically characterized as types I (60–80%), II (15–30%), III (3–14%), and IV (basal cells, varying from 3 to 5%). With the exception of basal cells, the others (types I, II, and III) are oblong cells which often extend from the basement membrane to the pit of the pore. The so-called "taste hairs" are microvillous structures which are extensions of the plasma membrane of cells. The membrane is thought to be a typical membrane complex, ~80 Å thick in the microvillous region and ~160 Å in the crypts, consisting of proteins, phospholipids, and lipids. The microvilli are 2-μm long and 0.1–0.2-μm wide. All cells in the vicinity of the pore are joined by tight junctions.

The cells in the taste bud are constantly being replaced. The renewal process is modulated by the activity of taste nerves. The interrelationships between cell types are not yet well understood. It is believed that cell types I, II, and III originate from the basal cells and develop into independent cell lines carrying out unique functions in the bud. On the other hand, there is evidence that the different cells may represent various stages in the metamorphosis of a single cell line. The pit of the pore is filled with a dense substance identified as mucopolysaccharides. Histochemical studies have shown the presence of ATPase, nonspecific esterases, and phosphatases in taste buds (7, 9).

Taste Reception—Taste reception appears to be mechanistically a substrate–receptor reaction, nonenzymic in nature, at the microvillous membrane level, whereby local perturbations of the membrane lead to a cascade of electrophysiological and psychophysical events known as taste perception (10–13). It does not depend on the direct interaction of taste stimulants with free nerve endings in the taste bud for the following reasons. First, the numerous nerve fibers in the underlying connective tissue enter the taste bud and continue upward to a level only a few micrometers from, but never in direct contact with, the microvillous membrane and the pit of the pore. Second, nerve fibers are found between cells, but the intercellular spaces are believed to be inaccessible to the molecular diffusion from the outside due to the presence of tight junctions. The nonpenetrability of the epithelium by sodium cyanide and colchicine is claimed to be supportive evidence of the occlusive properties of the tight junctions. Third, many taste stimulants are highly hydrophilic and yet taste is perceived instantaneously.

The sour taste of inorganic and organic acids is due to the dissociated hydrogen ions, the salty taste to the cations and anions of the dissociated salt. Bitter and sweet are found in a variety of chemicals and are not generally at-

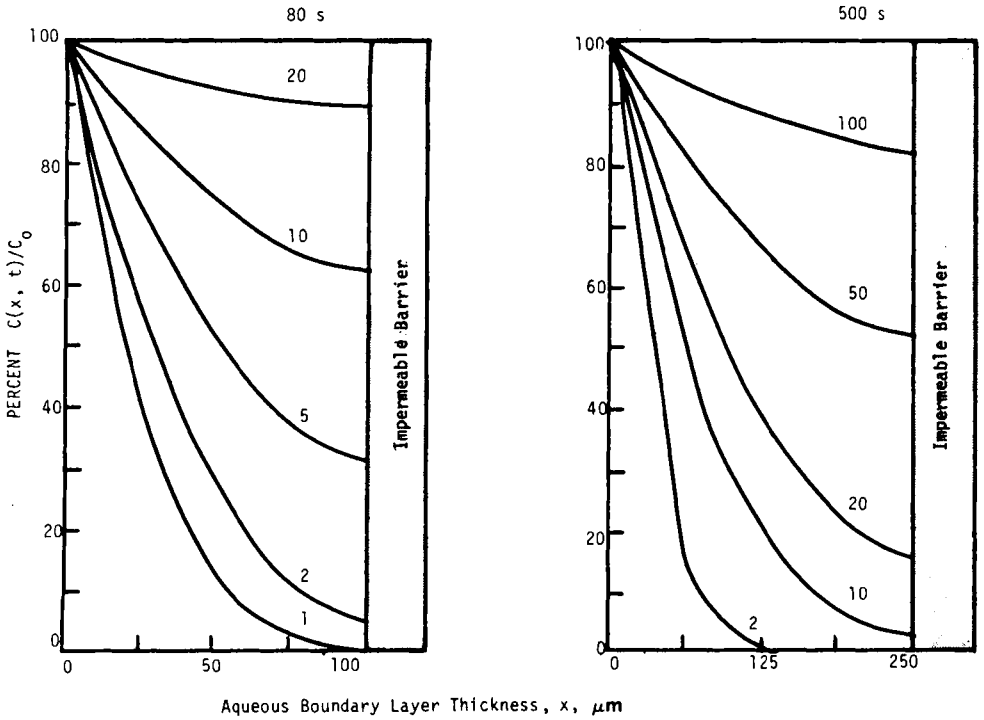

Figure 1—*Percent concentration-distance profile as a function of time for two aqueous boundary thicknesses. Aqueous diffusion coefficient is* 5×10^{-6} *cm²/s.*

tributed to ionic species. Hydrogen bonding is involved at proper geometric sites; often, a small change in configuration will change the sweet taste to bitter and *vice versa*. Beidler and Gross (14) have concluded that each taste cell has many different types of receptor sites and that the number of sites of the same type varies from cell to cell. The Beidler's taste response equation has been applied to all types of taste stimulants with reasonable success:

$$R = \frac{R_m KC}{1 + KC} \qquad \text{(Eq. 1)}$$

where R is the response, R_m is the maximum response, C is the concentration of the stimulus, and K is the binding constant. The binding energy is generally found to be weak, usually a few kilocalories per mole, which supports the reversible nature of taste and the ready removal of stimulants with water and saliva. The taste buds are physiologically rugged to chemical insults, and their sensitivity recovers readily after repeated and long exposures to stimulants.

Permeability of the Tongue—The human tongue appears to be relatively impermeable if the permeability of the rat tongue is a good indicator of the human situation. Mistretta (15) studied the permeability of the rat tongue epithelium in a two-compartment diffusion cell. The surface comprising of fungiform and filiform papillae was highly keratinized. It was estimated that the taste pores (5-μm wide and 1 pore per fungiform papilla) were only 0.0004% of the total surface area. The permeability coefficients of various permeating species are shown in Table I and range from 1.8×10^{-7} to 4.4×10^{-6} cm/s. The progression of the permeability values corresponded roughly with the ether–water partition coefficients. It is conceivable that the tongue, particularly the microvillous membrane of the taste cells, is permeable to more highly lipophilic solutes.

Methods in Studying Taste—Human taste studies are carried out by the psychophysical method. Although the method involves subjective responses on the part of test subjects within well-controlled procedures, it is sensitive and is built around a statistical design to minimize bias and variable responses within and between subjects (3, 16). The electrophysiological method is employed on anesthesized animals, since it involves the surgical implantation of electrodes in the chorda tympani nerve bundle. The response of taste buds is followed by recording neural activity with time (17, 18). The first attempts to record the electrical response in humans undergoing otological surgery under deep anesthesia were made by Diamant *et al.* (19). The electrical taste thresholds of different solutions correlated with subjective values collected from psychophysical experiments.

THEORETICAL

The tongue is a relatively impermeable surface. This important fact provides the rationale for the non-steady-state model for the transport of taste-provoking drugs across the aqueous boundary layer in front of the impermeable tongue surface. In turn, this model lays the foundation for the physical model approach in studying the taste of drugs, and the chemical and physical formulation factors affecting taste, on a quantitative and mechanistically interpretive basis.

Mass transport across the aqueous boundary layer in front of the impermeable tongue surface and the buildup with time of the concentration at the tongue surface are essentially non-steady-state diffusional kinetic situations. The model is consistent with the observation that when taste-provoking molecules in solution are applied to the tongue at concentrations much greater than the taste threshold concentration, taste is detected "instantaneously." Moreover, the model will provide the physicochemical framework in designing novel and remarkably simple experiments in studying (*a*) the taste of drugs and molecular modification effects and (*b*) physical formulation factors on a quantitative mechanistic level.

The non-steady-state change in drug concentration in the aqueous boundary layer with distance x and time t is given by Fick's second law:

$$\frac{\partial C(x,t)}{\partial t} = D\frac{\partial^2 C(x,t)}{\partial x^2} \qquad \text{(Eq. 2)}$$

$$(x > 0 \text{ and } t > 0)$$

The boundary conditions are:

$$C(0,t) = C_0$$

$$C(x,0) = 0$$

$$\left.\frac{\partial C(x,t)}{\partial x}\right|_{x=h} = 0$$

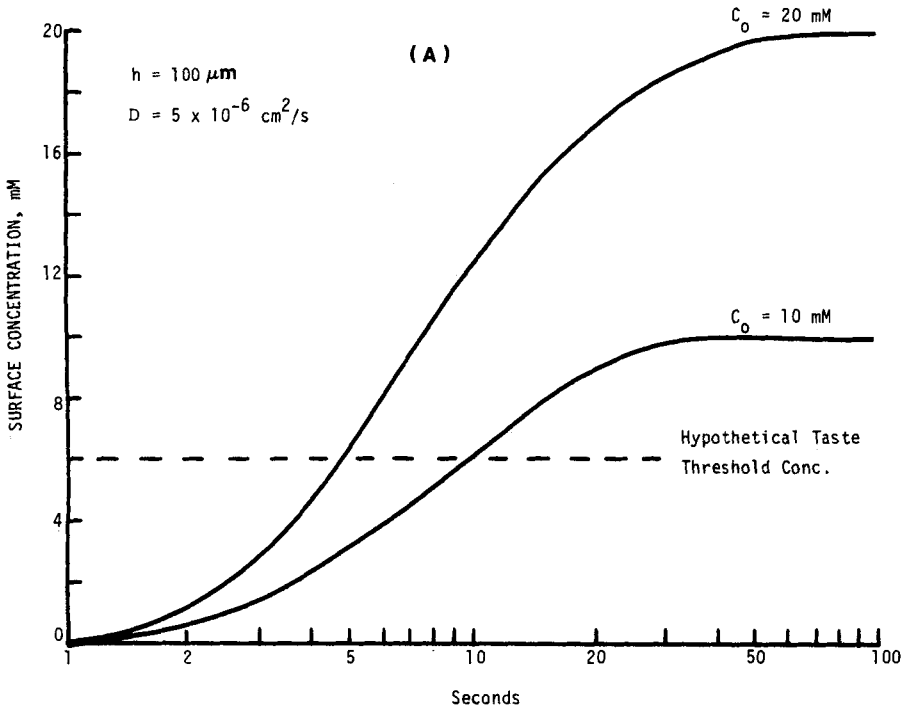
[a] From Ref. 15.



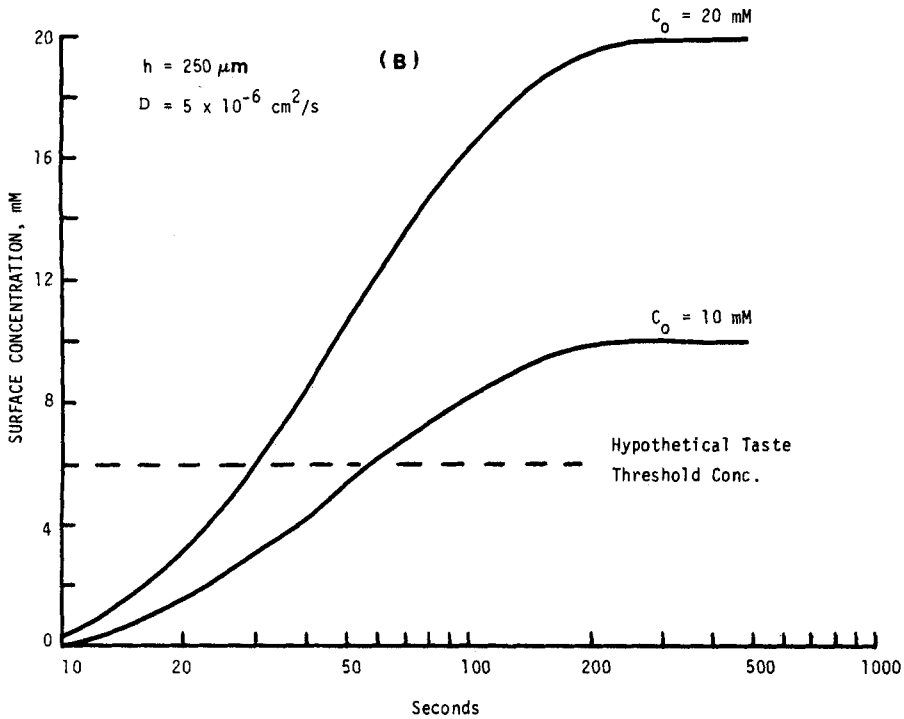


Figure 2—*Surface concentration–distance profiles as a function of time for aqueous boundary layer thicknesses of 100 (A) and 250 μm (B), diffusion coefficient of 5 × 10^{-6} cm^2/s, and bulk aqueous concentrations of 10 and 20 mM.*

The first condition states that the bulk concentration applied on the tongue does not change with time. At time zero, no drug molecules are found within the aqueous layer as described by the second conditions. Because the surface of the tongue is essentially an impermeable barrier, the flux of drug at the membrane surface is effectively zero.

Although the differential equation with its boundary conditions can be readily solved numerically with a computer, one can seek a solution by the Laplace transformation method. It follows that:

$$U(x,s) = C_0 \left[\frac{\cosh (x\sqrt{s/D})}{s} - \frac{\tanh (h\sqrt{s/D}) \cdot \sinh (x\sqrt{s/D})}{s} \right] \quad \text{(Eq. 3)}$$

where $U(x,s)$ is the Laplace transform of $C(x,t)$ and s is a variable of time t. The inverse of the above Laplacian equation is quite complicated. Since one needs only to know the drug concentration at the membrane surface at any time, *i.e.*, $C(h,t)$, with respect to taste response, then Eq. 3 simplifies to:

$$U(h,s) = C_0 \cdot \frac{\operatorname{sech} (h\sqrt{s/D})}{s} \quad \text{(Eq. 4)}$$

In series form:

$$U(h,s) = C_0 \left[2 \sum_{n=0}^{\infty} (-1)^n \cdot \frac{e^{-(2n+1)h\sqrt{s/D}}}{s} \right] \quad \text{(Eq. 5)}$$

whereupon the inverse is:

$$\frac{C(h,t)}{C_0} = 2 \sum_{n=0}^{\infty} (-1)^n \cdot \operatorname{erfc} \left[\frac{(2n+1)h}{2\sqrt{Dt}} \right] \quad \text{(Eq. 6)}$$

As can be seen, the magnitude of the surface concentration at any time t is a fraction of the bulk concentration. After sufficient time, the complementary error function converges to unity so that the surface concentration will finally be equal to the bulk concentration. It is anticipated that whenever

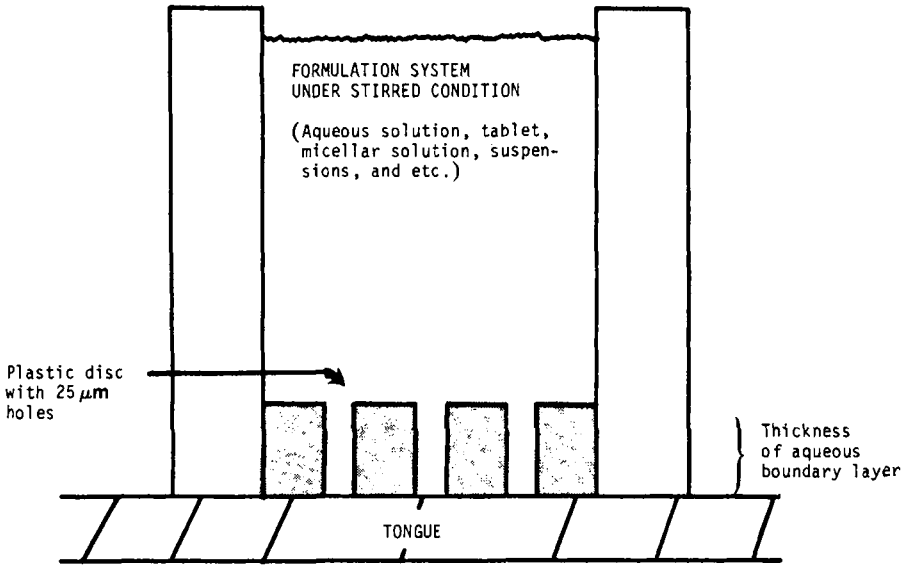

Figure 3—*Schematic diagram of a half-diffusion cell placed over an extended human tongue for psychophysical measurements under non-steady-state transport conditions.*

the concentration buildup at the membrane surface with time equals or exceeds the taste threshold concentration, response to taste occurs. Furthermore, initial taste perception is predicted to occur with high bulk concentrations, C_0, in contrast with lower bulk concentrations, all other factors (diffusion coefficients and aqueous boundary layer thickness) being constant.

DISCUSSION

Figure 1 shows the dimensionless concentration-distance profiles as a function of time for two aqueous boundary layer thicknesses, 100 and 250 μm, as generated from the numerical solution of Eq. 2 and the accompanying boundary conditions. The aqueous diffusion coefficient (D) used was 5×10^{-6} cm^2/s. The influence of the aqueous boundary layer is pronounced. For example, when $h = 100$ μm, the surface concentration is ~0.55% of the bulk concentration within 1 s; in contrast, when $h = 250$ μm, it is only $\sim 4 \times 10^{-6}$% of the bulk concentration. For the 100- and 250-μm boundary layer cases, the surface and bulk concentrations become equal in 80 and 500 s, respectively.

When the non-steady-state surface concentration is plotted against time for various bulk concentrations applied to the tongue, one obtains a family of sigmoidal curves (Fig. 2). Using a hypothetical taste threshold concentration as a point of reference one readily finds interesting relationships between the time at which taste is detected with bulk concentration and aqueous boundary thickness. The higher the bulk concentration, the quicker the detection time for a given diffusion layer thickness. Also, the thinner the diffusion layer, the quicker the detection time for a given bulk concentration. The pattern of the predictions is supportive of the everyday observation that taste is perceived within a fraction of a second after application of taste-provoking solutions at concentrations of at least an order of magnitude larger than the apparent threshold concentration.

In summary, the non-steady-state model provides the basis for the development of a novel experimental design in studying taste problems and for the understanding of the physicochemical factors in overcoming the undesirable taste of drugs *via* pharmaceutical formulations. Figure 3 shows a half-diffusion cell placed over the surface of an extended tongue. The principal feature of the cell is the bottom section which consists of straight cylindrical pores, 50 μm in diameter and of variable length. The pore length fixes the aqueous boundary thickness and may be used to experimentally increase the sensitivity of psychophysical measurements, recorded as the time at which taste is perceived after placing the drug formulation in the previously water-filled pores of the cell. Filling the pores with water before the formulation is placed in the cell fulfills the initial boundary condition for the non-steady-state transport psychophysical taste experiments. It is conceivable that molecular modification and physical formulation factors can be studied within the framework of the proposed experimental design and put on a quantitative and mechanistically interpretive plane. Studies along these lines are being planned.

Carboxyl Group Catalysis of Acyl Transfer Reactions in Corticosteroid 17- and 21-Monoesters

B. D. ANDERSON *[x], R. A. CONRADI, and W. J. LAMBERT *

Received August 6, 1982, from *The Upjohn Company, Kalamazoo, MI 49001.* Accepted for publication March 27, 1983. *Present address: College of Pharmacy, University of Utah, Salt Lake City, UT 84112.

Abstract □ Succinate esters, although frequently employed as water-soluble prodrugs of poorly soluble parent drugs, are not sufficiently stable to allow long-term storage in solution. Intramolecular catalysis of ester hydrolysis by the terminal succinate carboxyl group is a contributing factor to this instability. Methylprednisolone 21-succinate has recently been reported to undergo both hydrolysis and 21 ⇄ 17 acyl migration in aqueous solutions. Intramolecular catalysis by the terminal carboxyl group is seen in both reactions, but the catalytic mechanisms are not well understood. While acyl migration can only be catalyzed *via* the carboxyl group acting as a general acid or general base, hydrolysis may undergo either nucleophilic or general acid–base catalysis. To gain further insight into the catalytic mechanism, hydrolysis of methylprednisolone 21-succinate was carried out in aniline buffers to trap any succinic anhydride (as the anilide) that would form if the catalysis were nucleophilic. The nucleophilic mechanism was shown to account for only 15–20% of the overall catalysis. Comparisons of the rates of the intramolecularly catalyzed reactions of methylprednisolone 21- and 17-succinate were made with the same reactions of methylprednisolone 21- and 17-acetate catalyzed intermolecularly by acetate ion. Interestingly, intramolecular catalysis appears to favor acyl migration over hydrolysis. Hence, the hydrolysis of methylprednisolone 21-succinate is faster in basic solutions (pH > 7.4), while acyl migration becomes the dominant reaction in the catalyzed region of the pH profile between pH 3.6 and 7.4. Arguments are presented to account for these differences in catalytic efficiency in terms of the transition-state structures for the two reactions.

Keyphrases □ Acyl transfer reactions—methylprednisolone 17- and 21-monoesters, carboxyl group catalysis □ Methylprednisolone 17- and 21-monoesters—acyl transfer reactions, carboxyl group catalysis □ Carboxyl group catalysis—methylprednisolone 17- and 21-monoesters, acyl transfer reactions

Carboxyl group catalysis of acyl transfer reactions is an important phenomenon in a host of chemical and biological processes involving esters or amides. Many examples of carboxyl groups acting as nucleophilic, general acid, or general base catalysts either inter- or intramolecularly have been cited (for general reviews on the subject: 1–3). Yet, more work is needed since it is still not possible to predict with certainty the extent to which carboxyl groups in the immediate environment will accelerate a given acyl transfer reaction or *via* what mechanism this will occur.

The role of carboxyl catalysis in the degradation of hemiesters of dicarboxylic acids has been of particular interest from a pharmaceutical perspective because hydroxyl-containing drugs having low water solubility are frequently solubilized for parenteral administration by forming their succinate esters. A classic example of the clinical utility of this approach was the development of soluble 21-succinate esters of corticosteroids for parenteral use. A serious drawback of such derivatives is the limited shelf life of their solutions, which is due in part to intramolecular catalysis by the terminal succinate carboxyl group.

In aqueous solution, 21-esters of corticosteroids undergo ester hydrolysis and 21 ⇆ acyl migration as depicted in Scheme I for esters of methylprednisolone (4–6). Garrett recognized in the early 1960's that the solvolysis of the 21-succinate ester of hydrocortisone is catalyzed by the terminal carboxyl group and suggested that intramolecular nucleophilic catalysis is involved (4, 5). Recently, studies of the degradation of methylprednisolone 21-succinate confirmed that hydrolysis is catalyzed intramolecularly and also revealed that 21 ⇄ 17 acyl migration which was found to occur at an initial rate comparable to the hydrolysis rate is also subject to intramolecular catalysis (6).

Shown in Fig. 1 are the pH–rate profiles for the hydrolysis and 21 → 17 acyl migration of methylprednisolone 21-succinate, reported in an earlier study (6). Intramolecular catalysis of hydrolysis is clearly seen as a deviation of the hydrolysis curve from the simple V-shaped profile (dashed line) typically observed for the hydrolysis of esters. Between pH 4.1 and 6.5, the dominant hydrolytic reaction is hydroxide-ion attack on

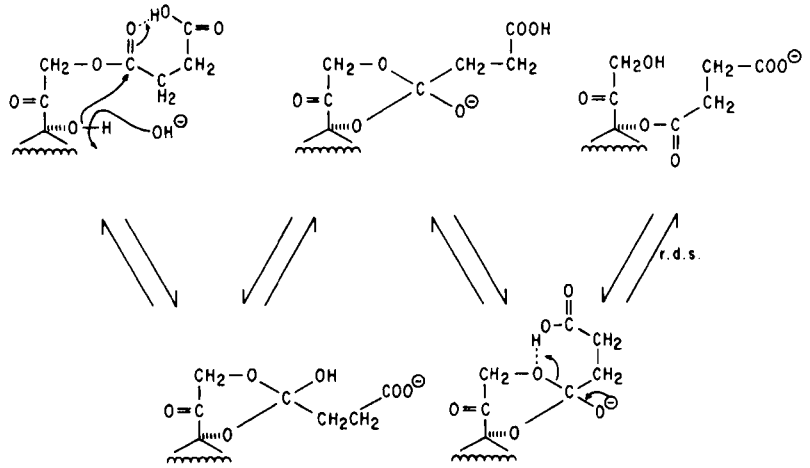
the ionized ester or the kinetically equivalent water attack on the anion. Mechanistically, the increase in rate over that expected from hydrolysis in more basic solutions can be interpreted as being due to one or more of the following kinetically equivalent reactions: (*a*) intramolecular nucleophilic attack by the terminal carboxylate anion; (*b*) intramolecular general base catalysis of attack by water; (*c*) intramolecular general acid catalysis of attack by hydroxide ion, or (*d*) repulsion of hydroxide ion by the negatively charged carboxylate. Mechanisms *a*–*c* are depicted in Schemes II–IV, respectively.

Intramolecular nucleophilic attack by carboxylate anion (Scheme II) results in the formation of succinic anhydride, which in a subsequent step then hydrolyzes in water to give succinic acid. The other possible mechanisms yield succinic acid directly.

Acyl migration is also catalyzed intramolecularly by the terminal succinate carboxyl group of methylprednisolone 21-succinate (or 17-succinate), as evident in Fig. 1, from the acceleration of the migration rate below pH ~ 7.4 compared with that expected based on the rate in more basic solutions. Two possible mechanisms may account for this acceleration: intramolecular general acid-specific base catalysis, or general base catalysis. Two plausible representations of these catalytic mechanisms are shown in Schemes V and VI, respectively, for the 21 → 17 migration. (These diagrams assume that breakdown of the tetrahedral intermediate is rate determining in going from 21 → 17 and, therefore, formation of the tetrahedral intermediate would be rate determining in going from 17 → 21.)

Since catalysis of acyl migration must occur *via* a general acid–base mechanism, it appeared likely that a general catalytic mechanism may also be operative in the hydrolysis. To ascertain the importance of the intramolecular nucleophilic mechanism in hydrolysis, an attempt was made to trap the succinic anhydride (as succinanilic acid) that would form from the intramolecular nucleophilic attack of carboxylate anion on the ester, by carrying out the hydrolysis in aniline buffers.

Of further interest was the observation that intramolecular catalysis brings about a reversal in the relative rates of the 21 → 17 migration and 21-ester hydrolysis. In solutions of pH > 7.4, hydrolysis is slightly faster than 21 → 17 acyl migration, while acyl migration is dominant in the intramolecularly catalyzed region between pH 3.6–7.4. To understand better the



Scheme V—General acid-specific base catalysis of 21 → 17 acyl migration. (Reverse reaction reflects general base catalysis of 17 → 21 acyl migration.)

differences in catalysis of these two similar reactions and to generate additional background information on O → O acyl migration in corticosteroid esters, studies of the degradation of methylprednisolone 21- and 17-acetate in water and in acetate buffers were also conducted.

EXPERIMENTAL

Reagents—Methylprednisolone[1], methylprednisolone 21-hemisuccinate[2], and methylprednisolone 21-acetate[3] were commercially available and used without further purification. Methylprednisolone 17-hemisuccinate was reported previously (6).

Methylprednisolone 17-acetate was prepared as described previously (7); UV: λ_{max} 242 nm (ϵ = 14,900); ^{1}H-NMR ($CDCl_3$-DMSO-d_6, 4:1)[4] δ 7.2-7.35 (d, 1, C_1— H), 6.35-6.5 (d, 1, C_2—H), 5.9 (s, 1, C_4—H), 4.4 (br, 1, C_{11}—H), and 4.15 ppm (s, 2, C_{21}—H_2).

Anal.- Calc. for $C_{24}H_{32}O_6$: C, 69.21; H, 7.75. Found: C, 68.84; H, 7.66.

Succinanilic acid was prepared from succinic anhydride and aniline, mp 145.8-146.8°C [lit. (8) mp 150°C].

Anal.—Calc. for $C_{10}H_{11}NO_3$: C, 62.16; H, 5.74; N, 7.25. Found: C, 62.18; H, 5.82; N, 7.27.

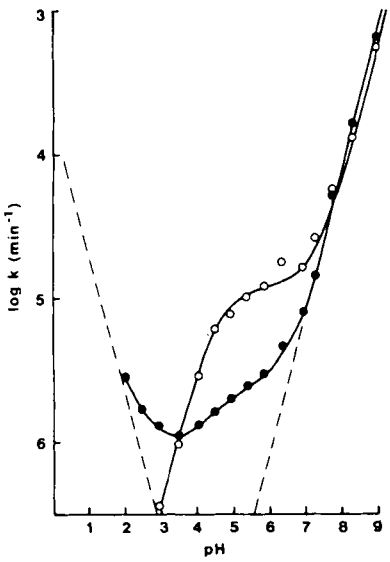

Figure 1—*pH-Log rate profiles for hydrolysis (●) and 21 → 17 acyl migration (○) of the 21-succinate ester of methylprednisolone in aqueous solutions at 25°C.*

All other reagents were of analytical or reagent grade and were used without further purification, except for aniline which was redistilled before use.

Procedure for the Anilide Trapping Experiment—Solutions of methylprednisolone 21-succinate were prepared at a concentration of 5×10^{-4} M in aqueous aniline buffers varying from 4×10^{-4} to 0.04 M aniline with pH values of 5.0, 5.5, and 6.0. At these pH values the intramolecularly catalyzed reaction dominates in the hydrolysis.

The initial rates of formation of methylprednisolone and succinanilic acid were determined at 25°C by measuring the solution concentrations of these reaction products at various times by HPLC. The solutions were monitored until ~1% of the ester had hydrolyzed to methylprednisolone. For the HPLC analysis a 25 cm × 4.6 mm i.d. reverse-phase column[5] packed with 10-μm Lichrosorb RP-8[6] was utilized with a mobile phase consisting of methanol-water-dimethyloctylamine (50:50:0.3) and 0.02 M MES buffer adjusted to pH 5.8. The solvent was pumped[7] at a flow rate of 1.3 mL/min, with sample detection at 254 nm[8].

Methylprednisolone 21- and 17-Acetate Hydrolysis, Acyl Migration Kinetics, and Acetate Buffer Catalysis Studies—Stock solutions of methylprednisolone 17- and 21-acetate in dimethylformamide were diluted 100-fold into aqueous buffers to a concentration of 2.5×10^{-5} M. These solutions were reacted at 25°C during the study. The initial rates of formation of decomposition products were determined by HPLC analysis using one of the following systems.

1. For the degradation of the 21-acetate, a reverse-phase column packed with 5-μm Spheri-5 RP-18[9] was used with a methanol-water (57:43) mobile phase. The flow rate was 1.6 mL/min[10], detection was at 243 nm[11], and the injection size was 500 μL[12].

2. The 17-acetate decomposition kinetics were monitored using conditions similar to those above, but with a mobile phase consisting of methanol-acetonitrile-water (10:32:58).

For comparison with data reported previously for the 21-succinate, the hydrolysis of methylprednisolone 21-acetate was carried out in 0.01 M ionic strength buffers. The studies of catalysis by acetate buffer were carried out

RESULTS

Hydrolysis of Methylprednisolone 21-Succinate in Aniline Buffers— In water, methylprednisolone 21-succinate hydrolyzes *via* several kinetically distinguishable routes (6) as expressed by the following equation for the overall hydrolysis rate constant, k_{hyd}:

$$k_{hyd} = k_{H^+}[H^+]f_u + k_{H_2O} \cdot f_u + k_{cat} \cdot f_i + k_{OH^-}[OH^-]f_i \quad \text{(Eq. 1)}$$

where k_{H^+} and k_{H_2O} represent hydrogen ion and water catalysis of the degradation of the un-ionized fraction, f_u, and k_{cat} and k_{OH^-} represent water- and hydroxide-ion catalyzed breakdown of the ionized fraction, f_i.

The catalyzed region clearly evident in the plot of the logarithm of the hydrolysis rate constant for methylprednisolone 21-succinate *versus* pH in Fig. 1 between pH 4.1–6.5 is the region in which the k_{cat} term in Eq. 1 dominates. This term may represent (*a*) intramolecular nucleophilic attack by the terminal carboxylate anion on the ester linkage, as proposed by Garrett (4) (Scheme II); (*b*) intramolecular general base catalysis of attack by water (Scheme III) or its kinetic equivalent, intramolecular general acid catalysis of hydroxide ion attack (Scheme IV); or (*c*) a composite of all possibilities as expressed by:

$$k_{cat} = k_{nuc} + k_{gen} \quad \text{(Eq. 2)}$$

While they are kinetically indistinguishable, k_{nuc} (representing nucleophilic catalysis) can be differentiated from k_{gen} (representing general acid–base catalysis) since succinic anhydride would be formed as an intermediate in the nucleophilic mechanism and should be detectable by trapping with aniline as demonstrated by Higuchi *et al.* (9). In aniline buffer systems, the reactions shown in Scheme VII are envisioned.

In addition to hydrolysis by water as expressed by k_{hyd} (see Eq. 1), methylprednisolone 21-succinate may also undergo nucleophilic attack by aniline in aniline buffers, so the rate of methylprednisolone (MP) formation is expressed by:

$$\frac{d(MP)}{dt} = k_{hyd}[Ester] + k_{direct}[Free\ Aniline][Ester] \quad \text{(Eq. 3)}$$

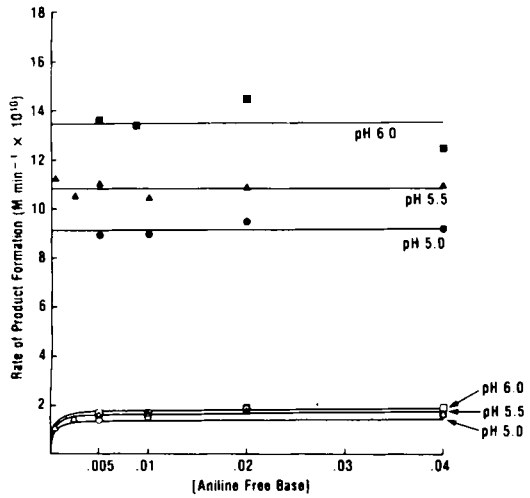

Figure 2—*Plots of the initial rates of methylprednisolone (closed symbols) and succinanilic acid (open symbols) formation* versus *aniline concentration at pH 5.0, 5.5, and 6.0: ester concentration = 5×10^{-4} M; temperature = 25°C.*

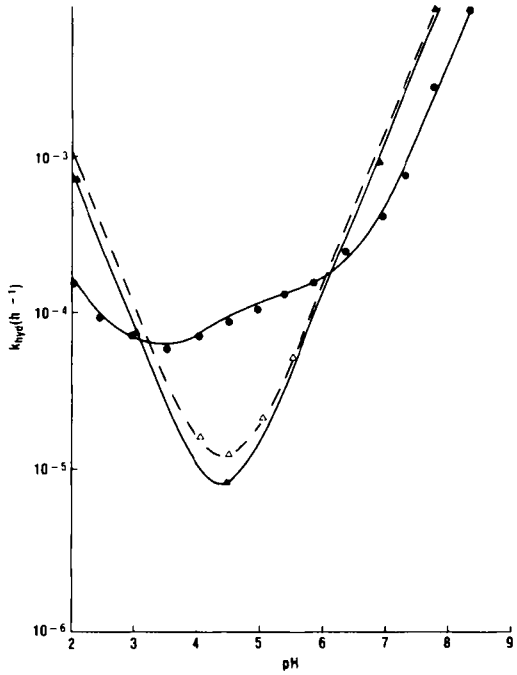

Figure 3—*pH- Hydrolysis rate profiles for methyprednisolone 21-succinate and 21-acetate at 25°C. Key: (●) 21-succinate, μ = 0.01; (▲) 21-acetate, μ = 0.01; (△) 21-acetate, μ = 0.5.*

Succinanilic acid, the product of the reaction of aniline with any succinic anhydride formed as a result of the intramolecular attack by the succinate carboxyl group on the ester linkage, could also be formed from direct attack of aniline on the ester. The rate of formation of succinanilic acid is therefore given by:

$$\frac{d[Anilide]}{dt} = k_{direct}[Free\ Aniline][Ester] + k_6[Free\ Aniline][Anhydride] - k_{-6}[Anhydride] \quad \text{(Eq. 4)}$$

The formation of succinic anhydride, the intermediate of interest, can be expressed by:

$$\frac{d[Anhydride]}{dt} = k_{nuc} \cdot f_i[Ester] - k_6[Free\ Aniline][Anhydride] - k_{-5}[Anhydride] + k_{-6}[Anilide] \quad \text{(Eq. 5)}$$

The rate of direct formation of succinic anhydride from succinic acid was calculated from literature data (9) to be very small relative to the other terms in Eq. 5 and was therefore disregarded. This was also verified experimentally by monitoring anilide formation in a solution containing 5×10^{-6} M succinic acid (equivalent to the amount formed from 1% hydrolysis of a 5×10^{-4} M solution of methylprednisolone 21-succinate) in 0.01 M aniline buffer at pH 5.5. No succinanilic acid could be detected over a 47-h period.

Assuming that the concentration of succinic anhydride would rapidly reach a low steady-state level, i.e., $d[Anhydride]/dt = 0$, this concentration can be expressed as follows:

$$[Anhydride] = \frac{k_{nuc} \cdot f_i \cdot [Ester] + k_{-6}[Anilide]}{k_6[Free\ Aniline] + k_{-5}} \quad \text{(Eq. 6)}$$

Table II—Methylprednisolone 21-Acetate Hydrolysis Rate Constants[a]

Rate Constant	Ionic Strength	Value	95% Confidence Limit
k_{H^+}	0.5 M	0.114 L/mol·h	±38%
k_{H_2O}	0.5 M	4.8×10^{-6} h^{-1}	±66%

[a] See Eq. 8.

Table III—Migration Rate Constants for Methylprednisolone Esters at 25°C [a]

Ester	Reaction	Rate Constant	Value	95% Confidence Limit
Succinate	21 → 17	k_{OH^-}	3.5×10^3 L/mol·h	±27%
		k_{cat}	7.3×10^{-4} h^{-1}	±26%
	17 → 21	k_{OH^-}	1.74×10^4 L/mol·h	±34%
		k_{cat}	3.0×10^{-3} h^{-1}	±17%
Acetate	21 → 17	k_{H^+}	–	–
		k_{H_2O}	3.9×10^{-6} h^{-1}	±22%
		k_{OH^-}	2.5×10^4 L/mol·h	±10%
		k_{ga}	1.1×10^{-5} L/mol·h	±33%
		k_{gb}	1.0×10^{-4} L/mol·h	±10%
	17 → 21	k_{H^+}	5.8×10^{-3} L/mol·h	±19%
		k_{H_2O}	3.1×10^{-5} L/h	±12%
		k_{OH^-}	3.1×10^5 L/mol·h	±13%
		k_{ga}	9.7×10^{-5} L/mol·h	±78%
		k_{gb}	1.4×10^{-3} L/mol·h	±15%

[a] See Eqs. 10 and 11.

Substituting the anhydride concentration from Eq. 6 into Eq. 4 gives, for the rate of anilide formation:

$$\frac{d[\text{Anilide}]}{dt} = k_{\text{direct}}[\text{Free Aniline}][\text{Ester}] + \frac{k_6[\text{Free Aniline}](k_{\text{nuc}}f_i[\text{Ester}] + k_{-6}[\text{Anilide}])}{k_6[\text{Free Aniline}] + k_{-5}} - k_{-6}[\text{Anilide}] \quad \text{(Eq. 7)}$$

Note in Eq. 7 that when k_6 [Free Aniline] is large relative to k_{-5}, the succinic anhydride hydrolysis rate constant, a plot of the initial rate of anilide formation *versus* free aniline concentration at constant ester concentration should be linear, with a slope equal to k_{direct} [Ester] and intercept of $k_{\text{nuc}}f_i$ [Ester]. Higuchi *et al.* (9) give rate constants for k_6 and k_{-5} of 10 L/mol·s and 2.5×10^{-3} s^{-1}, respectively. Therefore, k_6 [Free Aniline] $\gg k_{-5}$ (by 20-fold) when the free aniline concentration is ≥0.005 M. Similarly, plots of the initial rate of methylprednisolone formation *versus* free aniline (Eq. 3) should be linear with the same slope (in the absence of general catalysis by aniline), but with an intercept equal to the total hydrolysis rate in pure water, k_{hyd} [Ester].

Plots of the initial rates of methylprednisolone and succinanilic acid formation *versus* aniline concentration are shown in Fig. 2 at three pH values. The solid lines in Fig. 2 are the theoretical plots representing the rate constants in Eqs. 3 and 7 as reported in Table I.

The data clearly show that nucleophilic catalysis of the hydrolysis does occur as indicated by the level of significance of k_{nuc} in Table I and the positive intercept for the rate of anilide formation in Fig. 2. From the ratio of intercepts (anilide formation/methylprednisolone formation rates) one can obtain the percentage of the overall reaction which is catalyzed *via* the nucleophilic mechanism. These ratios are 0.12, 0.16, and 0.14 at pH 5.0, 5.5, and 6.0, respectively. Since k_{cat} accounts for 85, 88, and 76% of the total hydrolysis at these pH values, based on Eq. 1 and the rate constants in Table I, general catalysis must account for 62–73% of the total. Therefore, both general catalysis and nucleophilic catalysis occur, but the nucleophilic mechanism is a minor component accounting for only 15–20% of the overall catalysis.

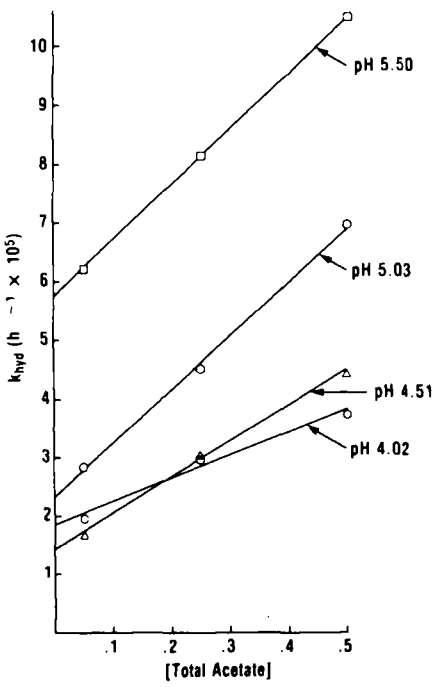

Figure 4—*Hydrolysis rate constant for methylprednisolone 21-acetate* versus *acetate buffer concentration at varying pH.*

Hydrolysis and Acyl Migration of Methylprednisolone 21-Acetate in Water and in Acetate Buffers—*Hydrolysis*—The changeover from nucleophilic to general acid-base catalysis of ester hydrolysis by a catalyst acting intermolecularly occurs when the pK_a of the leaving group is greater than that of the catalyst by ~2.5 units (10). Since the pK_a of the steroid side chain leaving group is ~11 due to possible enolization (11), while that of acetic acid is 4.8, it is assumed that acetate buffer is a general acid-base catalyst in the degradation of methylprednisolone 21-acetate.

The hydrolysis of methylprednisolone 21-acetate can be described by the following rate equation:

$$k_{hyd} = k_{H^+}[H^+] + k_{H_2O} + k_{OH^-}[OH^-] + (f_{A^-}k_{gb} + f_{HA}k_{ga})[Ac_T] \quad \text{(Eq. 8)}$$

where the final term represents the expected influence of the total acetate buffer [Ac_T] acting as either a general base catalyst ($k_{gb} \cdot f_{A^-}$) or general acid catalyst ($k_{ga} \cdot f_{HA}$). The k_{hyd} is plotted *versus* pH in Fig. 3 for systems at ionic strengths of 0.01 and 0.5 and buffer concentrations approaching infinite dilution. Superimposed on these plots is the logarithm of the hydrolysis rate constant *versus* pH for methylprednisolone 21-succinate for comparative purposes.

Figure 4 shows the acetate ester hydrolysis rate constant, k_{hyd}, at various pH values and total acetate buffer concentrations. The rate constants k_{ga} and k_{gb} were determined by rearranging Eq. 8 and plotting the left-hand side of Eq. 9 *versus* the fraction of acetate ion, f_{A^-}:

$$\frac{k_{hyd} - (k_{H^+}[H^+] + k_{H_2O} + k_{OH^-}[OH^-])}{Ac_T} = k_{ga} + (k_{gb} - k_{ga})f_{A^-} \quad \text{(Eq. 9)}$$

This plot is shown in Fig. 5. Values of the rate constants for the hydrolysis of methylprednisolone 21-acetate are shown in Table II. Kinetically, acetate buffer acts primarily as a general base catalyst in this reaction, with $k_{gb} > k_{ga}$ by about fivefold. Whether or not this is true general base catalysis or its kinetic equivalent, general acid-specific base catalysis, cannot be ascertained from the kinetic data.

21 ⇄ 17 Acyl Migration—A previous study of acyl migration in methylprednisolone succinate fit the kinetic data to an equation of the following form (6):

$$k_{mig}^{su} = k_{OH^-}^{mig}[OH^-]f_i + k_{cat}^{mig} \cdot f_i \quad \text{(Eq. 10)}$$

The 21 ⇄ 17 migration of acetate in methylprednisolone acetate esters subjected to acetate buffer can be described by the following rate equation:

$$k_{mig}^{ace} = k_{H^+}^{mig}[H^+] + k_{H_2O}^{mig} + k_{OH^-}^{mig}[OH^-] + (k_{ga}^{mig} \cdot f_u + k_{gb}^{mig} \cdot f_i)[Ac_T] \quad \text{(Eq. 11)}$$

The last term in Eq. 11 again expresses the possible role of acetate [Ac_T] acting as an intermolecular general acid, $k_{ga}^{mig} \cdot f_u$ or general base catalyst, $k_{gb}^{mig} \cdot f_i$. Plots of the logarithm of the forward and reverse migration rate constants *versus*

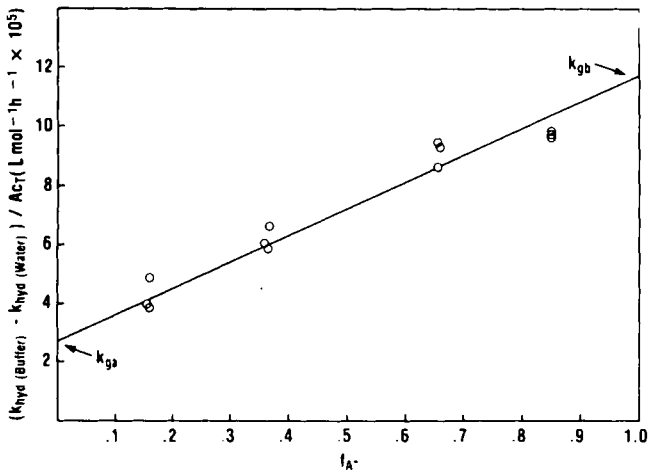

Figure 5—*Plot of* $(k_{hyd\ (buffer)} - k_{hyd\ (water)})/Ac_T$ versus *the fraction of acetate ionized for methylprednisolone 21-acetate (see Eq. 9).*

pH are shown in Fig. 6 for both methylprednisolone succinate and acetate esters in buffers approaching infinite dilution.

The influence of acetate buffer acting intermolecularly as a general acid-base catalyst in the migration (21 ⇄ 17) of acetate in methylprednisolone acetate was assessed by plotting the quantity: $[k_{mig}^{acc}$ (in buffer) − k_{acc} (no buffer)]/Ac_T *versus* the fraction of acetate buffer, Ac_T, in ionized form (f_{A^-}) as done previously for hydrolysis according to Eq. 9. These plots were linear for both the 21 → 17 and 17 → 21 reactions. Values for k_{ga}^{mig} and k_{gb}^{mig} obtained from these plots and all other migration rate constants for both the acetate and succinate esters are listed in Table III.

As observed in the hydrolysis, intermolecular catalysis of migration by acetate buffer appears to involve the acetate acting primarily as a general base in both directions. Mechanistically, however, this is most unlikely.

Calculation of the "Effective Molarity" of the Succinate Carboxyl Group Acting as a General Acid-Base Catalyst— It is a common practice to assess the effect of intramolecularity by comparing the catalytic rate constant in an intramolecular reaction with that of an analogous intermolecular one (12). While the hydrolysis and acyl migration reactions in methylprednisolone acetate are similar to those in the succinate, a correction should be made for the differences in intrinsic reactivity of the two esters. This can be done by dividing the catalytic constants k_{gen} and k_{gb} by k_{OH^-}. (Refer to Tables I and II for the values of these constants.) Thus, for the 21-succinate hydrolysis k_{gen}/k_{OH^-} is 3.0×10^{-8} M and for the 21-acetate hydrolysis k_{gb}/k_{OH^-} is 7.1×10^{-9}M. The ratio of these quantities is the effective concentration of the carboxylate anion in the hydrolysis of the hemisuccinate ester, 4.2 M.

The k_{H_2O} of 6×10^{-5} h^{-1} for the un-ionized succinate ester hydrolysis (Table I) is an order of magnitude greater than that of the acetate ester hydrolysis of 4.8×10^{-6} h^{-1} (Table II). This is evidence for intramolecular catalysis in k_{H_2O} by the terminal carboxyl group, but an effective molarity of the terminal carboxylic acid was not calculated for this reaction.

Following a procedure identical to that described above, the effective molarity of the terminal carboxylate anion of the hemisuccinate ester in catalyzing acyl migration can also be calculated. For the 21 → 17 ester migration (see Table III) k_{gb}/k_{OH^-} for the acetate ester is 4×10^{-9} M and k_{cat}/k_{OH^-} for the succinate ester is 2.1×10^{-7} M, for an effective molarity of ~50 M. In the 17 → 21 ester migration k_{gb}/k_{OH^-} for the acetate ester is 4.7×10^{-9} M and k_{cat}/k_{OH^-} for the succinate ester is 1.7×10^{-7} M, for an effective molarity of ~40 M. These numbers are the same without experimental error, but are significantly greater than the effective concentration of the terminal carboxylate anion of the succinate ester in catalyzing hydrolysis.

DISCUSSION

Comparison of the pH-Rate Profiles of Methylprednisolone Acetate and Succinate Esters—The primary evidence that hydrolysis and acyl migration in methylprednisolone succinate esters are catalyzed intramolecularly by the terminal succinate carboxyl group comes from the observation that the pH rate profiles for these reactions deviate from classical behavior. This is best illustrated by comparisons of the pH-hydrolysis rate and pH-acyl migration profiles of methylprednisolone succinate esters with those of methylprednisolone acetate esters, which exhibit the expected classical behavior (Figs. 3 and 6).

The pH-rate profile obtained for hydrolysis of the acetate ester in Fig. 3 has the typical U-shape generally observed for aliphatic ester hydrolysis in the absence of catalysis (2) and can be described by Eq. 8 (neglecting the acetate buffer term). In basic solution, the hydrolysis rate of methylprednisolone 21-succinate *versus* pH is parallel to that of methylprednisolone 21-acetate. This region represents hydroxide ion attack on the ionized succinate ester or on the neutral acetate ester. In acidic solutions (pH <2) it appears that the two curves again become parallel. This region represents H^+-catalyzed attack of water on the neutral esters. From a comparison of k_{H^+} and k_{OH^-} values in Tables I and II, it is estimated that methylprednisolone 21-succinate is more stable than the 21-acetate in acid by nearly an order of magnitude and in base by roughly fourfold. The lower reactivity of the 21-succinate is assumed to be due largely to a steric effect. Electrostatic repulsion of OH^- attack by the negatively charged succinate carboxylate anion does not appear to be a significant factor in the basic hydrolysis of methylprednisolone 21-succinate, since steric effects alone can account for its decreased reactivity. Steric effects are assumed to be equal in acidic and basic ester hydrolysis, as originally proposed by Ingold (13).

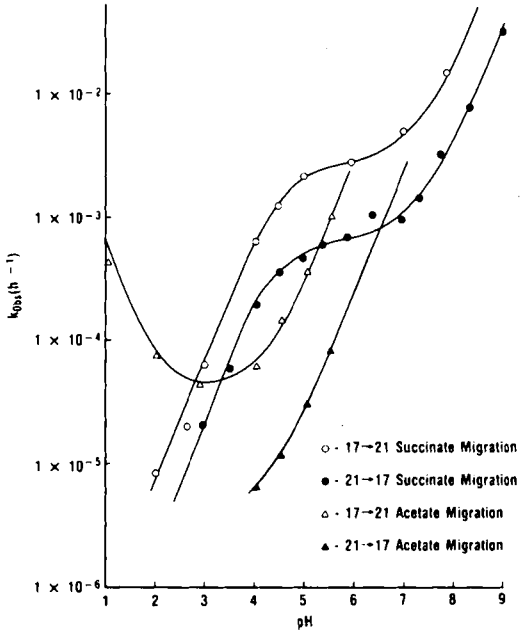

Figure 6—*pH-17 → 21 and pH-21 → 17 migration rate profiles for methyprednisolone acetate and succinate esters at 25°C.*

Between pH ~3-7 the pH-methylprednisolone 21-succinate hydrolysis rate profile deviates from the classical U-shape exhibited by the acetate ester profile. This behavior suggests intramolecular catalysis by the terminal succinate carboxyl group, as discussed previously.

From an examination of the pH-21 ⇄ 17 acyl migration rate profiles in Fig. 6 or from a comparison of k_{OH^-} values in Table III, it is evident that ester migration occurs faster in basic solution in methylprednisolone acetate esters than in the succinate esters. This decreased reactivity at high pH is again attributed to the greater steric bulk of the succinate esters. The pH-rate profiles for acetate ester migration are linear down to a pH of ~4-5, while the succinate ester pH-migration rate profiles deviate from linearity at ~pH 7. Again this behavior is rationalized as intramolecular catalysis of migration by the terminal succinate carboxyl group.

Mechanism of Intramolecular Catalysis of the Hydrolysis of the 21-Succinate— Studies on the solvolysis of 21-hemiesters of hydrocortisone (4, 5) led Garrett to conclude that intramolecular catalysis by the terminal succinate carboxyl group was nucleophilic. This mechanism has been observed in other systems and was further supported by the fact that general acid-base catalysis by acetate buffer was not observed in the reaction. However, in light of the recent observation that 21 ⇄ 17 acyl migration in methylprednisolone 21-succinate is also catalyzed intramolecularly, coupled with the realization that nucleophilic catalysis is not a plausible mechanism for catalysis of acyl migration, it seemed appropriate to reexamine the evidence for the nucleophilic mechanism in the hydrolysis and attempt to establish or refute its existence by trapping any succinic anhydride formed as a result of nucleophilic attack of the terminal carboxylate anion on the ester.

The anilide trapping experiment clearly demonstrates that, while nucleophilic catalysis does occur, the predominant mechanism is general acid-base catalysis. It is reasonable that the mechanism of intramolecular catalysis of methylprednisolone succinate should lie on the borderline between general acid base and nucleophilic but favoring general acid-base catalysis from a

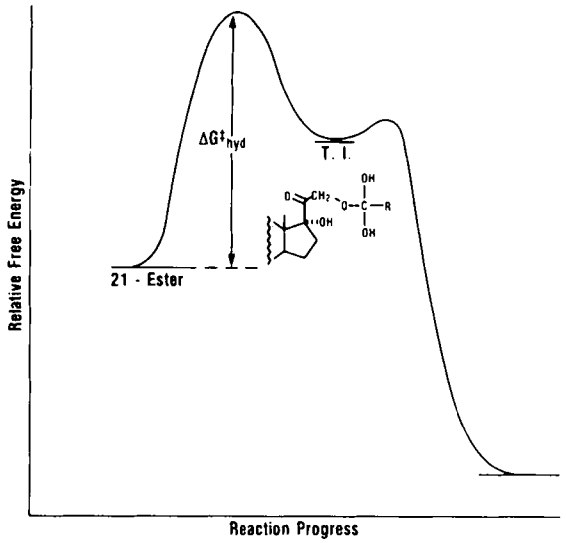

Figure 7—*Relative free energy* versus *reaction progress diagram for methylprednisolone 21-ester hydrolysis.*

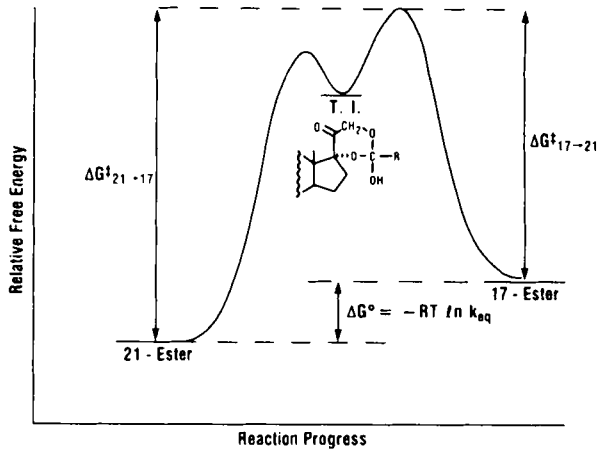

Figure 8—*Relative free energy* versus *reaction progress diagram for 21 → 17 acyl migration in methylprednisolone esters.*

consideration of the catalyst and leaving group pK_a values. Fersht and Kirby (10) have shown that in an exocyclic displacement (that is, when the leaving group does not stay attached to the intermediate anhydride formed on nucleophilic attack by a catalyst), the borderline between intramolecular general base and nucleophilic catalysis lies in the region where the pK_a of the leaving group is 5.5–6.5 units more basic than the attacking nucleophile. Due to possible enolization, the pK_a of the C-17 side chain of methylprednisolone is near 11 (11), while the terminal succinate carboxylic acid is ~4.5, for a pK_a difference of 6.5.

If the *intramolecular* catalytic mechanism is largely general acid-base, then one would expect the reaction to also be catalyzed *intermolecularly* by general acids or bases. Yet, general acid base catalysis by acetate was not seen by Garrett in his studies of the hydrolysis of hydrocortisone succinate (4,5). This is of general importance, since such information is often the primary support for or against the intramolecular nucleophilic mechanism.

General catalysis was not observed in Garrett's studies, since the reaction is already catalyzed intramolecularly. If the magnitude of intramolecular catalysis (as determined by the effective molarity of the carboxylate anion) in hydrocortisone succinate is equivalent to that which would result intermolecularly from a 4 M acetate buffer, then the increase in rate brought about by a 0.3 M solution of acetate (the highest concentration used in Garrett's study) would be only ~7% and may well be overlooked. Thus, the apparent absence of intermolecular general acid-base catalysis in a reaction that is already intramolecularly catalyzed may not be sufficient evidence to rule out a general acid-base mechanism in the intramolecular reaction.

It is more appropriate to test the presence or absence of intermolecular general acid base catalysis in a reaction that is similar to the intramolecularly catalyzed reaction but is not already catalyzed intramolecularly. The results of this study showing that acetate buffer catalyzes the hydrolysis of methylprednisolone 21-acetate make more plausible the conclusion that intramolecular general acid-base catalysis occurs in the hydrolysis of methylprednisolone 21-succinate.

Intramolecular Catalysis Favors Acyl Migration Over Hydrolysis—As shown in Fig. 1 and pointed out earlier, hydrolysis of methylprednisolone 21-succinate is slightly faster than 21 → 17 acyl migration above pH 7.4, while acyl migration dominates between pH 3.6 and 7.4. This dramatic reversal in relative reaction rates is due to the fact that intramolecular catalysis of acyl migration is 4–6 times greater than that of hydrolysis. These differences in catalytic efficiency can be rationalized from a consideration of differences in the transition states of the two reactions.

Referring to the hypothetical diagrams in Figs. 7 and 8 of relative free energy *versus* reaction progress, it is assumed that the transition state for 21-ester hydrolysis (Fig. 7) is a very early transition state, occurring prior to the formation of the tetrahedral intermediate, since OH^- is a much poorer leaving group than the 21-alcoholate. However, the transition state for the 21 → 17 migration (Fig. 8) is quite likely the breakdown of the tetrahedral intermediate. The 17-ester is thermodynamically less favored and, applying Hammond's postulate (14), the transition state should more closely resemble the less stable 17-ester than the 21-ester. In further support of the conclusion that the transition state in the migration occurs between the tetrahedral intermediate and the 17-ester are data showing that the 17,21-hemiorthoester of betamethasone benzoate, which has been isolated, breaks down in acid to the 21-ester (15). Differences in the magnitude of intramolecular catalysis of hydrolysis and 21 → 17 acyl migration are not surprising in view of the fact that the transition states are probably quite different.

Whereas *intramolecular* catalysis by the terminal succinate carboxyl group of 21 → 17 acyl migration is 4–6 times greater than intramolecular catalysis of hydrolysis, this does not appear to be the case in the analogous *intermolecularly* acetate buffer catalyzed reactions occurring in methylprednisolone 21-acetate. Comparing the ratios k_{gb}/k_{OH^-} (see Tables II and III), the magnitude of intermolecular catalysis by acetate buffer of the hydrolysis of methylprednisolone 21-acetate is nearly equal to that of 21 → 17 migration.

It is suggested that intermolecular catalysis of migration by acetate is rendered less effective due to steric (entropic) factors that come into play in the intermolecular reaction but not in the intramolecular mechanism. Using molecular models, it appears that the conformational freedom of the succinate moiety in the transition state is about the same for both hydrolysis and migration. An intermolecular general acid or base appears, however, to be conformationally more restricted in the transition state during migration as compared to hydrolysis.

Ambiguity in the Assignment of the Site of Catalysis—The acetate buffer-catalyzed 21 ⇄ 17 acyl migration reaction in methylprednisolone 21-acetate provides an excellent demonstration of what Jencks refers to as the ambiguity of the assignment of the site of catalysis (16). Applying the principle of microscopic reversibility (17), it is clear that the same transition state is involved in both the 21 → 17 and 17 → 21 migrations. This means mechanistically that if the reaction is general base catalyzed in one direction, it must be general acid-specific base catalyzed in the other. Yet, *kinetically*, both directions appear to be primarily general base catalyzed (Table III). By convention, both reactions are referred to as general base catalyzed even though mechanistically this cannot be. None of the data generated by this study specifically support one general catalytic mechanism over its kinetic equivalent. Indeed, the same ambiguity exists in much of the published literature wherein general base or general acid catalytic mechanisms have been postulated.

Degradation Kinetics in Aqueous Solution of Cefotaxime Sodium, a Third-Generation Cephalosporin

H. FABRE *x, N. HUSSAM EDDINE *, and G. BERGE ‡

Received November 18, 1982, from the * *Laboratoire de Chimie Analytique* and the ‡ *Laboratoire de Pharmacie Chimique, Faculté de Pharmacie, Université de Montpellier, 34060 Montpellier Cedex, France.* Accepted for publication March 27, 1983.

Abstract □ The degradation kinetics of a 3-acetoxymethylcephalosporin, cefotaxime sodium salt, in aqueous solution investigated by HPLC under different conditions (pH, ionic strength, temperature) and using different buffers. The scheme of degradation involves a cleavage of the β-lactam nucleus and the deacetylation of the side chain. In highly acidic medium, the deacetylated derivative is easily converted to the lactone. The degradation rate constants were calculated at three pH values (1.9, 4.0, and 9.0) by measuring the residual cephalosporin and the main decomposition products. The degradation pathway is both supported by the results of a primary salt effect and by the agreement between the theoretical pH-rate profile and the experimental values. In the pH range from 3.0 to 7.0, the main process is a slow water-catalyzed or spontaneous cleavage of the β-lactam nucleus with intramolecular participation of the side chain amido fraction in the 7-position. In alkaline or strongly acidic medium, the hydrolysis is a base- or acid-catalyzed reaction. Of the buffer systems investigated, carbonate buffer (pH 8.5) and borate buffers (pH 9.5 and 10.0) are found to increase the degradation rates, while acetate buffer decreases the degradation rates. The apparent activation energies determined at different pH values are compatible with a solvolysis mechanism and similar to those previously given in the literature for other cephalosporins. Cefotaxime in aqueous solution is slightly less stable than the main cephalosporin derivatives, despite its high resistance to the β-lactamases and its remarkable biological activity.

Keyphrases □ 3-Acetoxymethylcephalosporins—stability in aqueous solutions, HPLC, pH effect, primary salt effect, buffer effect, temperature effect □ Cefotaxime—kinetics and mechanism of degradation, pH-rate profile □ Antibiotics—cefotaxime, stability, degradation profile, kinetics

Systematic studies on the degradation of cephalosporin derivatives are of interest for several reasons: (*a*) a correlation between degradation and antibiotic activity has been shown in first- and second-generation cephalosporins (1), (*b*) some degradation products may be involved in allergic reaction (2), and (*c*) the stability of the compounds has to be known for the synthesis of derivatives (3) and the formulation of drugs. The kinetics of first- and second-generation cephalosporins have been reported in a few instances (1, 3–6). These studies concern a quantitative analysis of the antibiotic itself and sometimes the kinetics of the major degradation product (1, 3). In this report, a systematic kinetic study of a recently commercially available third-generation cephalosporin, cefotaxime sodium salt[1], has been carried out. The quantitation of this cephalosporin and its major decomposition products allowed the proposal of a degradation pathway.

BACKGROUND

Cefotaxime sodium (I) is sodium [6(*R*)-[6α,7β(*Z*)]]-3-[(acetyloxy)-methyl]-7-[[(2-amino-4-thiazolyl)(methoxyimino)acetyl]-8-oxo-5-thia-1-azabicyclo[4.2.0]oct-2-ene-2-carboxylate]. The possible *in vitro* degradation products are deacetylcefotaxime (II), deacetoxycefotaxime (III), deacetylcefotaxime lactone (IV), thiazoximic acid (V), and 7-aminocephalosporanic acid (VI). The *anti* isomer which could be expected as a potential degradation product of I has been shown to be formed only in nonaqueous medium (7) and has not been taken into consideration in this study.

Cefotaxime sodium (I) is an original cephalosporin derivative with a 2-amino-4-thiazolyl side chain and an α-methoximino group in the *syn* position. The former is probably responsible for the very great affinity for transpeptidase, involved in the construction of the bacterial wall, and of the great activity against Gram-negative bacilli. The latter is probably responsible for the stability of the drug against most β-lactamases (8, 9). An exhaustive review of the bacteriological and clinical properties of I has been presented (10).

EXPERIMENTAL

Materials—Compounds I–VI were used as received[2]. UV, IR, and NMR spectra were used to confirm the structure of these compounds. All other chemicals were analytical reagent grade.

Degradation Kinetics in Aqueous Solution of Cefotaxime Sodium, a Third-Generation Cephalosporin

H. FABRE *x, N. HUSSAM EDDINE *, and G. BERGE ‡

Received November 18, 1982, from the * *Laboratoire de Chimie Analytique* and the ‡ *Laboratoire de Pharmacie Chimique, Faculté de Pharmacie, Université de Montpellier, 34060 Montpellier Cedex, France.* Accepted for publication March 27, 1983.

Abstract □ The degradation kinetics of a 3-acetoxymethylcephalosporin, cefotaxime sodium salt, in aqueous solution investigated by HPLC under different conditions (pH, ionic strength, temperature) and using different buffers. The scheme of degradation involves a cleavage of the β-lactam nucleus and the deacetylation of the side chain. In highly acidic medium, the deacetylated derivative is easily converted to the lactone. The degradation rate constants were calculated at three pH values (1.9, 4.0, and 9.0) by measuring the residual cephalosporin and the main decomposition products. The degradation pathway is both supported by the results of a primary salt effect and by the agreement between the theoretical pH-rate profile and the experimental values. In the pH range from 3.0 to 7.0, the main process is a slow water-catalyzed or spontaneous cleavage of the β-lactam nucleus with intramolecular participation of the side chain amido fraction in the 7-position. In alkaline or strongly acidic medium, the hydrolysis is a base- or acid-catalyzed reaction. Of the buffer systems investigated, carbonate buffer (pH 8.5) and borate buffers (pH 9.5 and 10.0) are found to increase the degradation rates, while acetate buffer decreases the degradation rates. The apparent activation energies determined at different pH values are compatible with a solvolysis mechanism and similar to those previously given in the literature for other cephalosporins. Cefotaxime in aqueous solution is slightly less stable than the main cephalosporin derivatives, despite its high resistance to the β-lactamases and its remarkable biological activity.

Buffer Solutions—The buffers used in the kinetic studies were hydrochloric acid–potassium chloride (pH 1.6 and 1.9), citrate (pH 2.2 and 3.0), acetate (pH 4.0 and 5.0), phosphate (pH 6.0 and 7.5), carbonate (pH 8.5), and borate (pH 9.0, 9.5, and 10.0). The buffer concentrations were 0.1, 0.2, and 0.3 M (except at pH 7.5, where concentrations were 0.05, 0.10, and 0.15 M, and at pH 4.0 and 9.0, where buffer concentrations were 0.2 M) and the ionic strength was adjusted to 0.5 with potassium chloride. Primary salt effects were investigated at 0.2 M buffer concentration at pH 2.2, 6.0, and 9.5 with ionic strengths of 0.3, 0.5, and 0.7. The pH of buffer solutions was controlled with a pH meter[3] standardized with pH 2.0, 7.0, and 9.0 solutions.

Kinetic Procedures—Experiments were performed in volumetric flasks. Compound I was dissolved in the buffer solution previously equilibrated at 4°C, 23°C, or 37°C. For the kinetics followed by HPLC, the concentrations used were $\sim 2 \times 10^{-3}$ or $\sim 1 \times 10^{-3}$ M according to the solubility. The samples were assayed immediately after a suitable dilution. For the kinetics followed by UV, the concentrations used were $\sim 2 \times 10^{-5}$ M. All experiments were conducted in the dark in a constant-temperature water bath with a thermoregulator at ±0.2°C or in a refrigerator for the trials at 4°C. pH Values were controlled at the end of each experiment; no significant change was observed.

Analytical Procedures—*Liquid Chromatography*—The liquid chromatograph[4] was equipped with a variable-wavelength UV detector[5] set at 235 nm, an RP 18 column[6], and a 10-μl injection loop. The mobile phase was phosphate buffer (pH 7.6)–methanol (83:17); the flow was 1.5 mL/min.

A mixed stock standard solution was prepared in the mobile phase using I–VI (75 μg of each/mL). This solution was suitably diluted with the mobile phase to give a concentration range from 7.5 to 37.5 μg of each compound/mL.

Ultraviolet—UV spectral changes as a function of time were followed at pH 1.9, 4.0, and 9.0 with a spectrophotometer[7].

pK_a Determinations—The pK_a values of I were determined by the potentiometric titration of a 2.8×10^{-3} M cefotaxime aqueous solution with 0.1 M NaOH, at 20°C, under nitrogen. The two functional groups corresponding to the terminal amino group of the side chain at C-7 and the carboxylic group at C-3 of the cephem ring were acidified with a stoichiometric amount of 0.1 M HCl before titration.

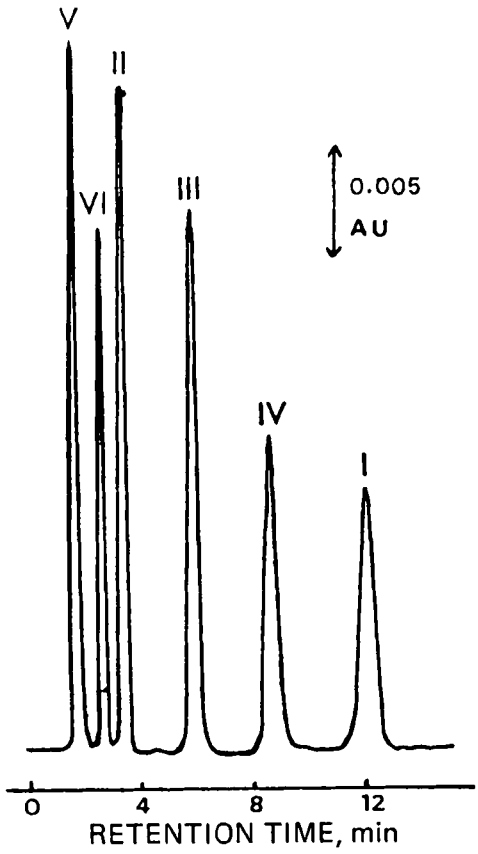

Figure 1—*Chromatogram of a standard solution of I (24.90 μg/mL), II (21.90 μg/mL), III (22.20 μg/mL), IV (23.25 μg/mL), V (14.00 μg/mL), and (26.40 μg/mL). The mobile phase was phosphate buffer (pH 7.6)–methanol (83:17); the flow was 1.5 mL/min and pressure was 175 bars. Detector sensitivity was 0.005 AUFS, chart recorder speed was 0.5 cm/min, and λ = 235 nm.*

[3] Potentiograph Metrohm E 436.

RESULTS AND DISCUSSION

Validity Tests of the Liquid Chromatographic Procedure—A chromatogram of a standard solution recorded at 235 nm (suitable wavelength for a simultaneous determination of I and its degradation products) is shown in Fig. 1. A calibration graph was plotted of the peak areas (or the height measure-

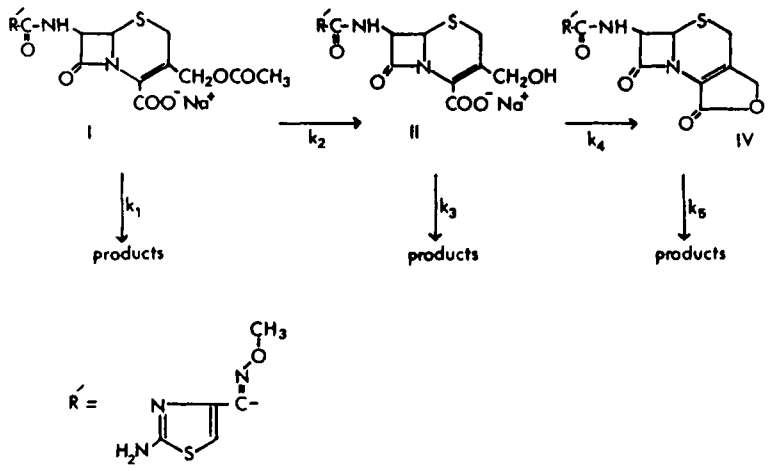


Scheme I

ments) of each solute against solute concentration. The correlation coefficients of the linear regression analysis were always >0.999 by peak areas (as well as height measurements). The repeatability, tested by six replicates and evaluated by the coefficient of variation, was 0.22% (I), 1.15% (II), 0.47% (III), 1.89% (IV), 0.60% (V), and 2.49% (VI). The recovery studies were carried out with a solution of cefotaxime with 1.0% and 3.0% (with respect to I) of II–VI added. The percentage recovered (average of two determinations) was found to be 98.17% for II, 98.64% for III, 107.52% for IV, 99.46% for V, and 98.86% for VI in the former case and 97.10% for II, 98.03% for III, 99.21% for IV, 105.66% for V, and 99.33% for VI in the latter case. Applying the same procedure to the determination of I using a suitable dilution, the recovery was 102.01 and 99.76%, respectively. The minimum amounts detectable were found to be 3.5×10^{-3} μg (I), 1.8×10^{-3} μg (II), 2.0×10^{-3} μg (III), 4.0×10^{-3} μg (IV), 0.8×10^{-3} μg (V), and 2.5×10^{-3} μg (VI). The proposed HPLC procedure therefore allows a satisfactory determination of I–VI. It is a more convenient procedure than TLC (11) for the kinetic studies.

Ionization Constants—The titration curve and the blank determination carried out under the same conditions are shown in Fig. 2. Apparent pK_a values were calculated (12) with a computer. Potentiometric comparative determination with III permitted us to attribute $pK_{a_1} = 2.1$ to the dissociation of the carboxylic group and $pK_{a_2} = 3.4$ to the terminal amino group of the side chain in the 7-position. The pK_{a_3} value of 10.9 may be referred to as the dissociation of the amino group in the α-carbonyl position on the same side chain. It must be noted that the pK_a values in acidic media are approximate values, because these pK_a values are very close to the logarithm of dilution (12).

Kinetic Results—The scheme proposed (Scheme I) for cephalosporin derivatives with an acetoxymethyl group should be valid for I in the entire pH range. The first step in the degradation involves deacetylation. The second step, in acidic medium is the conversion of the deacetylated compound (II) in its lactone form. In addition, I, II, and IV give products resulting from cleavage of the β-lactam ring. To check this postulated pathway, the kinetics of I, II, and IV between pH 1.6 and 10.0 were simultaneously followed by HPLC. Typical chromatograms of acidic, neutral, and basic solutions, withdrawn at ~30–40% cefotaxime degradation (0.2 M buffer concentration, 37°C, and $\mu = 0.5$ ionic strength) are shown in Fig. 3.

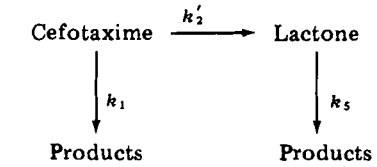
Reaction Order and HPLC Observed Constants—The example of the semilogarithmic plots of the data at various pH values (37°C, $\mu = 0.5$, and 0.2 M buffer concentration) illustrated in Fig. 4 show that the degradation of I follows a pseudo-first-order reaction. The results obtained at all the other pH, temperatures, ionic strengths, and buffer concentrations investigated gave the same order reaction. The observed constants, k_{obs}, for I calculated from the slopes are given in Table I.

According to Scheme I, in the alkaline and neutral pH media where lactone is not formed, the degradation of I may be illustrated by:

$$[I] = C_0 e^{-(k_1+k_2)t} \qquad \text{(Eq. 1)}$$

$$[II] = C_0 \frac{k_2}{(k_1+k_2)-k_3}[e^{-k_3 t} - e^{-(k_1+k_2)t}] \qquad \text{(Eq. 2)}$$

where [I] is the concentration of I at times t, C_0 is the initial concentration of I, and [II] is the concentration of II at time t. In a highly acidic medium, where the deacetylated derivative is very easily converted to lactone, the simplified degradation pathway (Scheme II[8]) was used:



Scheme II

with corresponding equations similar to Eqs. 1 and 2.

In the entire pH range, the kinetics of I, II, and IV were followed for one half-life, but to determine the rate constants k_1–k_5, the kinetics were followed at three different pH values (1.9, 4.0, and 9.0) at 37°C, 0.2 M buffer concentration, and $\mu = 0.5$, for 4–5 half-lives (Fig. 5). The rate constants obtained at these three pH values, analyzed using Eqs. 1 and 2 and B.M.D.P. program P_3R, are listed in Table II.

Reaction Order and UV Observed Constants—Spectral changes for the degradation of I as a function of time at pH 1.9, 4.0, and 9.0 (37°C, 0.2 M buffer concentration, and $\mu = 0.5$) were recorded for 4–5 half-lives (Fig. 6). Absorbance at 260 nm is characteristic of the β-lactam linkage (13). Applying Eq. 3:

$$\ln \frac{A_t - A_\infty}{A_0 - A_\infty} = -k_1' \cdot t \qquad \text{(Eq. 3)}$$

where A_t is the absorbance at time t measured at $\lambda = 260$ nm; A_∞ is the absorbance at infinite time at $\lambda = 260$ nm; A_0 is the absorbance at time zero at $\lambda = 260$ nm; and k_1' is the rate constant determined by UV measurements. Semilogarithmic plots of $(A_t - A_\infty)/(A_0 - A_\infty)$ *versus* time were obtained with a linear correlation of $r > 0.98$. The UV data ascertain for I the first-order reaction determined from HPLC results. The UV values of the pseudo-first-order constants k_1' are listed in Table II.

Table II—Rate Constants Calculated from HPLC Results and UV Measurements [a]

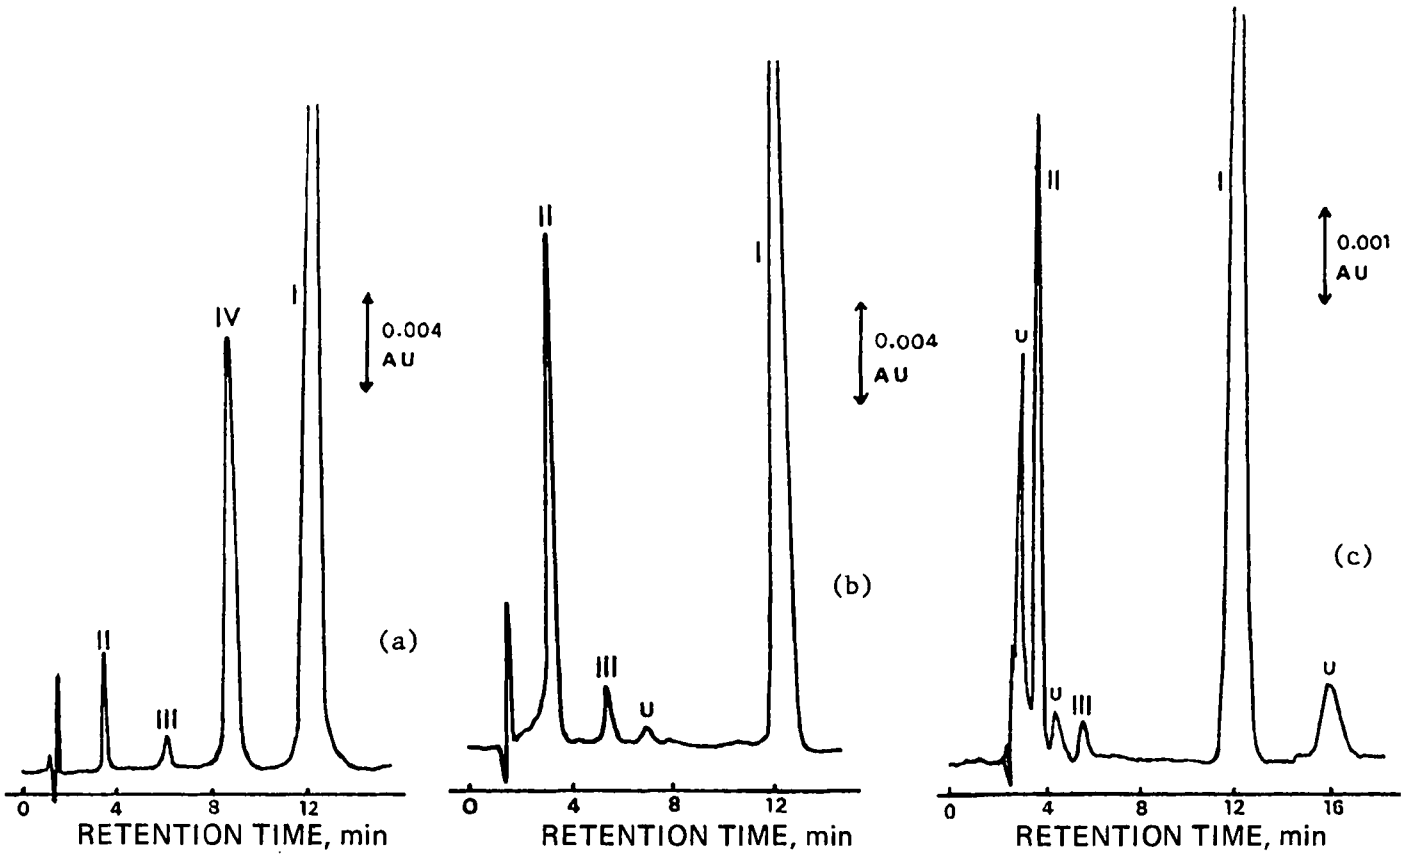

Figure 3—*Chromatogram of a 2 × 10^{-3} M degraded cefotaxime sodium salt solution withdrawn at ~30–40% degradation (0.2 M buffer concentration, 37°C, μ = 0.5) at pH 1.6 (a), pH 6.0 (b), and pH 10.0 (c). Key: (U) unknown peak.*

The UV rate constants may be considered as an estimation of the β-lactam opening rate of the cephalosporins (1, 3, 14) and may be compared with the k_1 values obtained using HPLC. Since the specific extinction coefficients at 260 nm of II ($E^{1\%}_{1cm}$ = 406 at pH 1.9, $E^{1\%}_{1cm}$ = 349 at pH 4.0, and $E^{1\%}_{1cm}$ = 340 at pH 9.0) and IV ($E^{1\%}_{1cm}$ = 418 at pH 1.9, $E^{1\%}_{1cm}$ = 361 at pH 4.0, and $E^{1\%}_{1cm}$ = 353 at pH 9.0) are very similar to those of I ($E^{1\%}_{1cm}$ = 445 at pH 1.9, $E^{1\%}_{1cm}$ = 390 at pH 4.0, and $E^{1\%}_{1cm}$ = 382 at pH 9.0), an approximate estimation of the destruction of the nucleus should be obtained with UV measurements, except if an appreciable production of an absorbing compound is noted. The k'_1 values obtained from UV determination and the k_1 values obtained from HPLC present a rather good concordance, as noted in Table II, in spite of the presence of small amounts of absorbing UV products, probably resulting from the β-lactam cleavage.

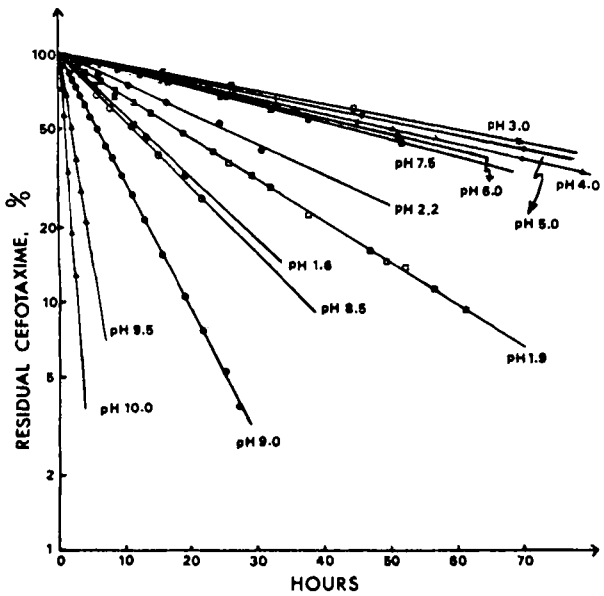

Figure 4—*Apparent first-order reaction of cefotaxime sodium salt solution at various pH values, 37°C, μ = 0.5, and 0.2 M buffer concentration (except at pH 7.5 where the buffer concentration was 0.15 M).*

Buffer Effect and General Acid–Base Catalysis—The values of k_{obs} obtained at constant pH, constant ionic strength (μ = 0.5), constant concentration of I, and constant temperature (37°C), varying only the buffer concentration, are given in Table I. The Student's *t* test was used to determine the significance of differences between the k_{obs} obtained for each buffer concentration. The catalytic effects of the buffers were estimated with a probability p = 95%.

Citrate buffer at pH 2.2 and 3.0 and phosphate buffer at pH 6.0 and 7.5 do not have a catalytic effect. At pH 2.2 and 3.0, the predominant species are H_3A and H_2A^- for citrate buffer (5); at pH 6.0 and 7.5, the predominant species are $H_2PO_4^-$ and HPO_4^{2-}. These species are not general acid–base catalysts.

Carbonate buffer at pH 8.5 and borate buffer at pH 9.5 and 10.0 give a significant catalytic effect on the degradation of cefotaxime. At these pH values, the dominant species, HCO_3^- and $H_2BO_3^-$ are general acid–base catalysts which increase the rate constants. The rate constant k_{obs} is given by:

$$k_{obs} = k_{pH} + k' \cdot [B] \qquad \text{(Eq. 4)}$$

where [B] is the buffer concentration, $k' = k_{HCO_3^-} \cdot f_{HCO_3^-}$ or $k_{H_2BO_3^-} \cdot f_{H_2BO_3^-}$, and $k_{HCO_3^-}$ and $k_{H_2BO_3^-}$ are second-order rate constants of HCO_3^- ions and $H_2BO_3^-$ ions, respectively. $f_{HCO_3^-}$ is the buffer HCO_3^- fraction (#1) at pH

Table IV—Values of Rate Constants at Different Temperatures and the Arrhenius Activation Parameter for I at Different pH [a]

Buffer	pH	Temp., °C	k_{pH}, $h^{-1} \times 10^3$	E_a, kcal·M^{-1}
Citrate	3.0	23	1.938	25.687
		37	13.930	
Acetate	5.0	23	1.607	28.307
		37	14.125	
Phosphate	7.0	4	0.194	
		23	1.679	21.755
		37	13.810	
Borate	10.0	4	3.034	
		23	31.825	28.732
		37	840.720	

[a] At 0.2 M buffer concentration, μ = 0.5.

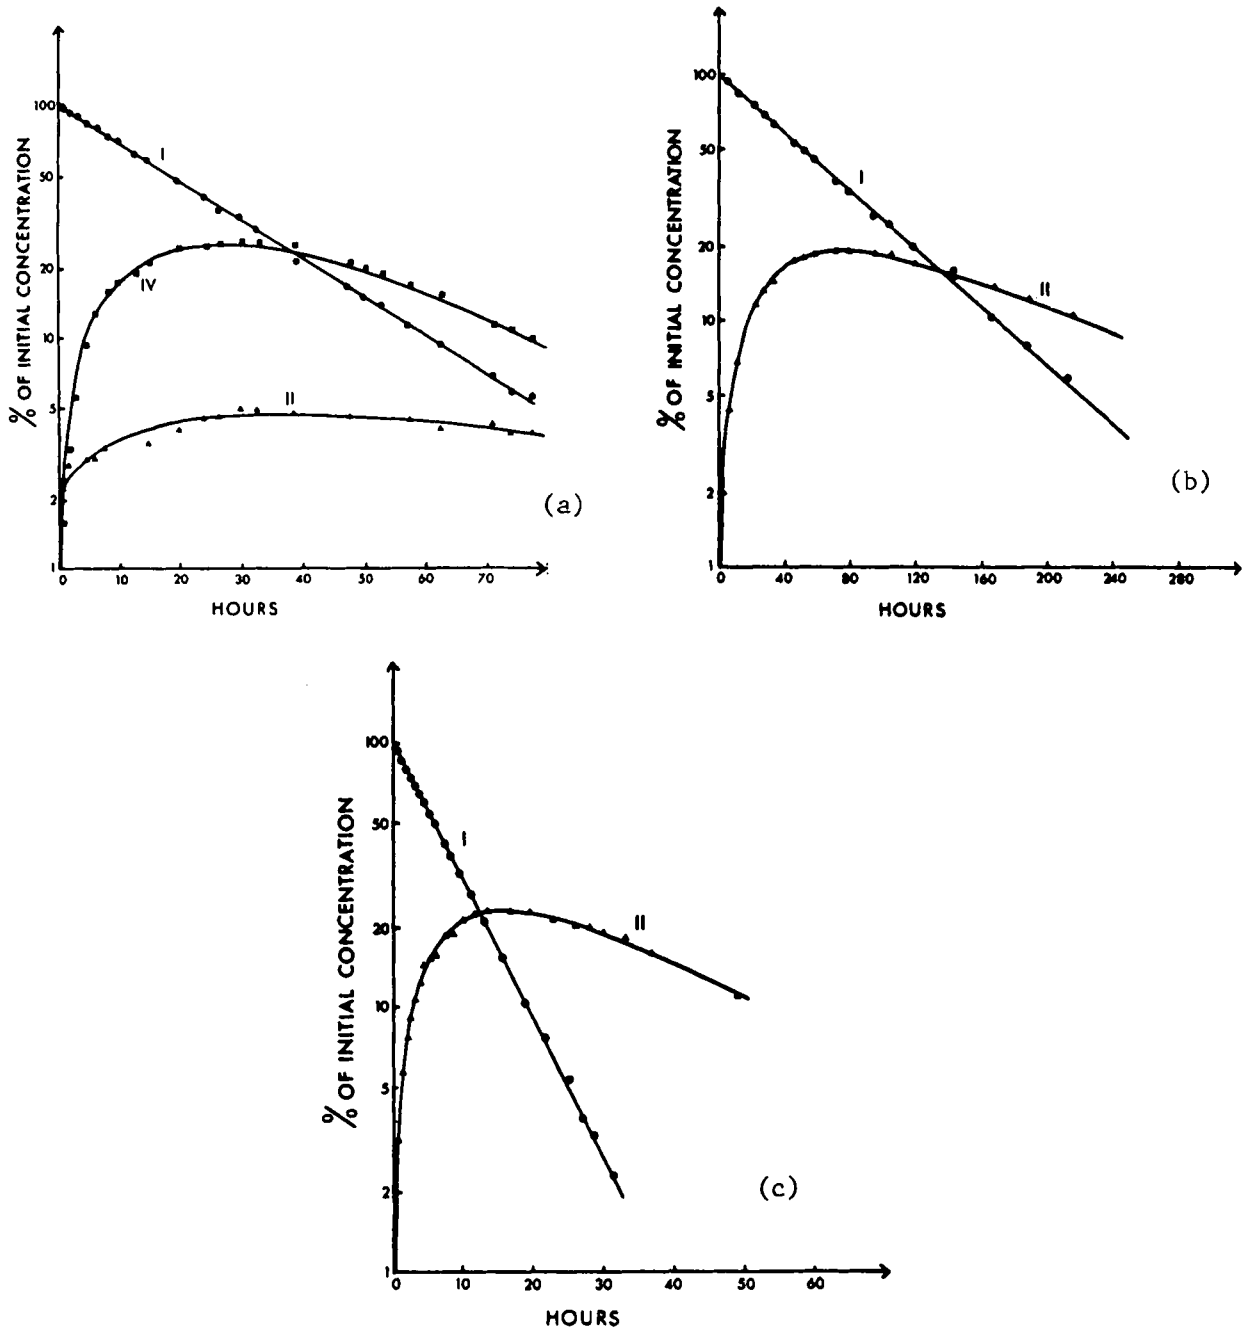

Figure 5—*Kinetics for cefotaxime (●), deacetylcefotaxime (▲), and deacetylcefotaxime lactone (■) during the degradation of a cefotaxime sodium salt solution at 37°C (μ = 0.5 and 0.2 M buffer concentration) at pH 1.9 (a), pH 4.0 (b), and pH 9.0 (c).*

8.5, $f_{H_2BO_3^-}$ is the buffer $H_2BO_3^-$ fraction (# I) at pH 9.5 and 10.0, and k_{pH} is the rate constant at zero buffer concentration.

An estimation of the catalytic effect was made from the plots of k_{obs} against the buffer concentration. The second-order rate constants were determined as $k'_{HCO_3^-} = 77.6 \times 10^{-3}$ $h^{-1}\cdot M^{-1}$ at pH 8.5; $k'_{H_2BO_3^-} = 212.28 \times 10^{-3}$ $h^{-1}\cdot M^{-1}$ at pH 9.5; and $k'_{H_2BO_3^-} = 187.25 \times 10^{-3}$ $h^{-1}\cdot M^{-1}$ at pH 10.0. k' in all cases is increasingly dependent on the buffer concentration. The rate constant, k_{pH} at zero buffer concentration, obtained by the intercept with the y-axis, gives the value of the rate constant independently of the buffer effect (Table I).

With acetate buffer, at pH 5.0 where CH_3COOH and CH_3COO^- species are present, k_{obs} decreases with the buffer concentration. At this pH, the observed rate constant is given by:

$$k_{obs} = k_{pH} + [B]\frac{k_{CH_3COOH}\cdot a_H + k_{CH_3COO^-}K_a}{a_H + K_a} \qquad \text{(Eq. 5)}$$

where K_a is the dissociation constant of acetic acid at 37°C, a_H is the hydrogen ion activity potentiometrically measured, and k_{CH_3COOH} and $k_{CH_3COO^-}$ are the second-order rate constants of CH_3COOH and CH_3COO^- ion, respectively. The catalytic negative effect of acetate buffer at this pH may be estimated by the value of the slope obtained when k_{obs} is plotted against buffer concentration (-10.5×10^{-3} $h^{-1}\cdot M^{-1}$); k_{obs} is decreasingly dependent on the buffer concentration. The protective effect against degradation observed with acetate buffer may be related to the presence of a 3-acetoxymethyl group in the molecular structure of I.

Primary Salt and Ionic Strength Effects—The primary salt effect was investigated at 37°C and pH 2.2, 6.0, and 9.5 for 0.2 M buffer concentration. Ionic strength was varied with potassium chloride solution. The data of k_{obs} for ionic strengths μ = 0.3, 0.5, and 0.7 are given in Table III. The influence of ionic strength on rate constants was demonstrated (15) by Bronsted and Bjerrum. Debye-Hückel theory applied to the kinetics shows that for ionic strengths <0.05, a linear relationship can be obtained between log k_{obs} and $\mu^{1/2}$ according to:

$$\log k_{obs} = \log k_{0,\mu_0} + 2QZ_AZ_B\sqrt{\mu} \qquad \text{(Eq. 6)}$$

where Q is a constant depending on the temperature and the dielectric constant

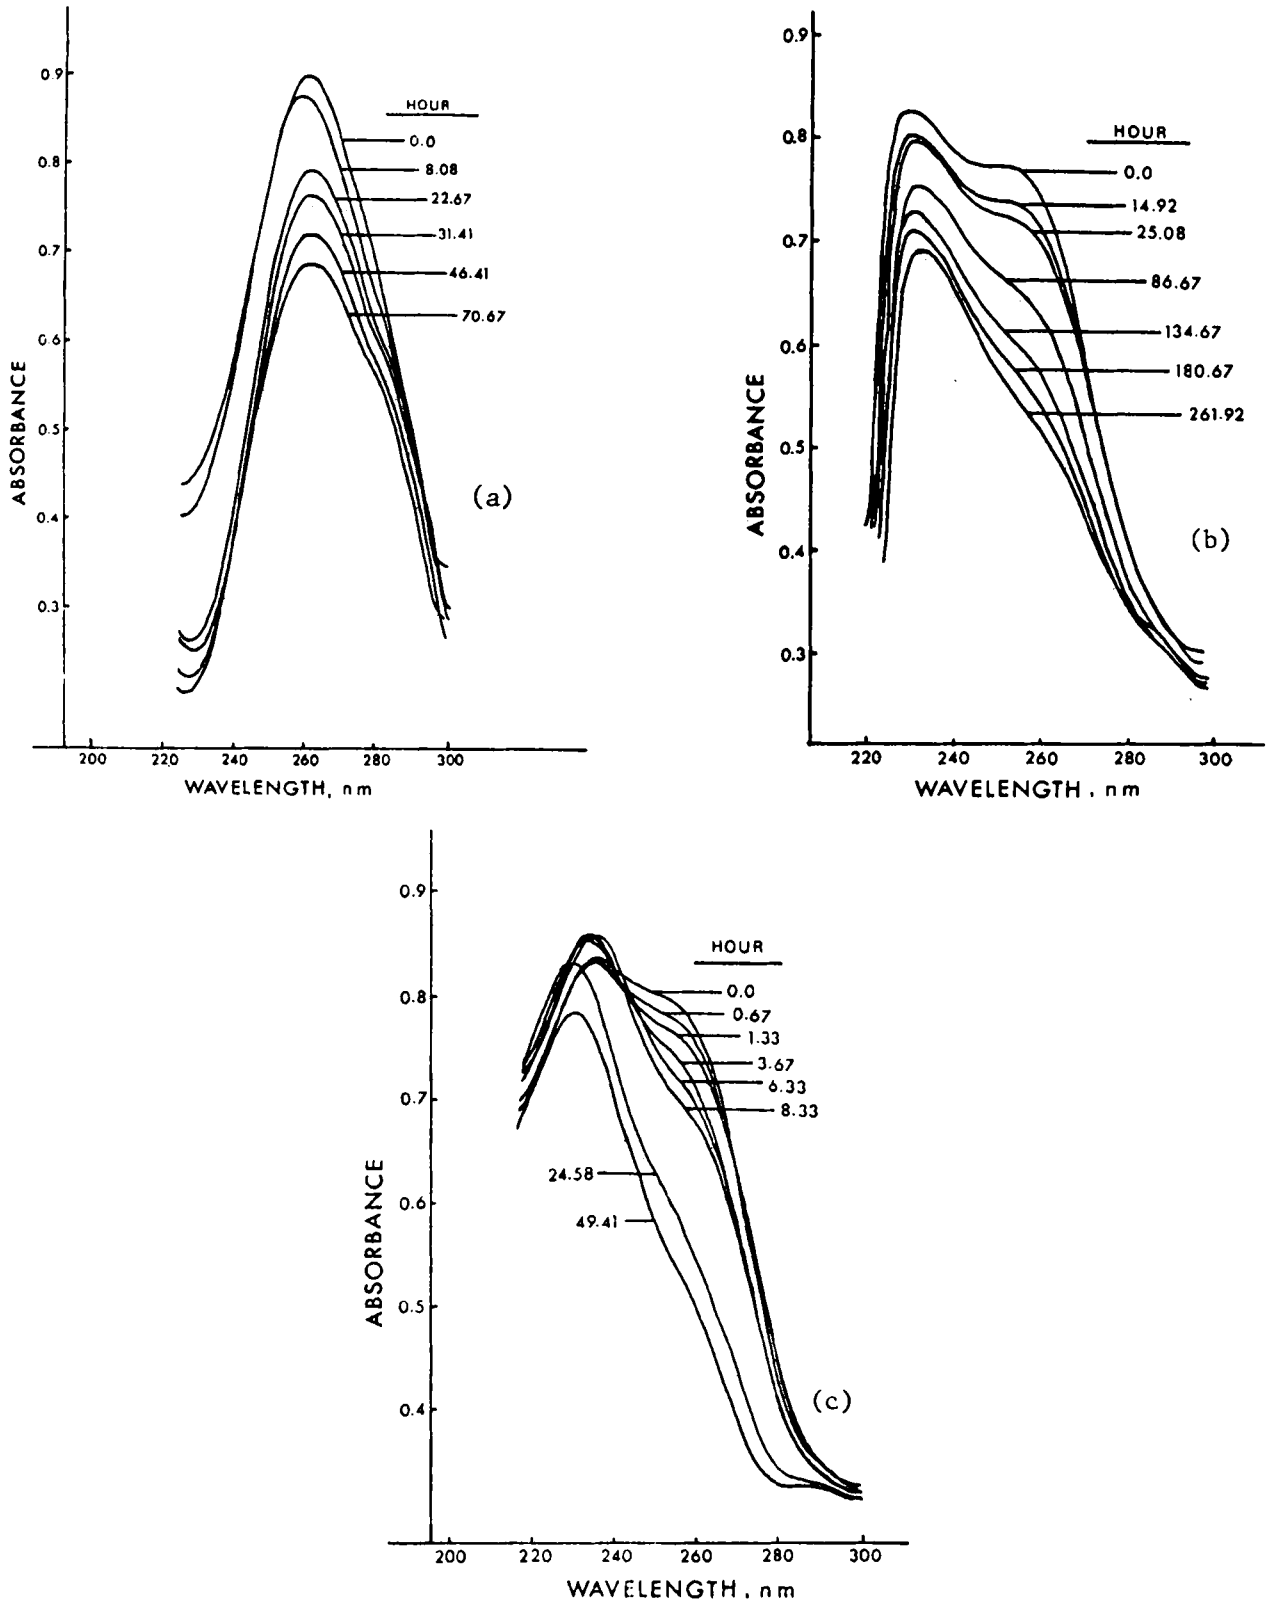

Figure 6—*Spectral changes during the degradation of a 2.0 × 10^{-5} M cefotaxime sodium salt solution (0.2 M buffer concentration, 37°C, μ = 0.5) at pH 1.9 (a), pH 4.0 (b), and pH 9.0 (c).*

of the solvent, Z_A and Z_B are the electric charges of the reactants conducting to the activated complex, and k_{0,μ_0} is the rate constant at zero ionic strength. At higher ionic strength, the second Debye-Hückle (16) relationship gives:

$$\log k_{obs} = \log k_{0,\mu_0} + \frac{2QZ_AZ_B\sqrt{\mu}}{1+\sqrt{\mu}} \qquad \text{(Eq. 7)}$$

The two ways of representation are given in Fig. 7.

A linear representation is obtained when log k_{obs} is plotted against $\mu^{1/2}$ and $\mu^{1/2}/1+\mu^{1/2}$. At pH 2.2 and 6.0 kinetic primary salt effects were negligible, in contrast to pH 9.5 where a kinetic primary salt effect was observed. At pH 2.2 and 6.0, the rate constants are almost independent of the ionic strength because one of the reactants is noncharged. At pH 9.5, the positive slope observed shows that the two reactant species have the same charge.

pH-Rate Profile—The pH-rate profile for the degradation of I was ob-

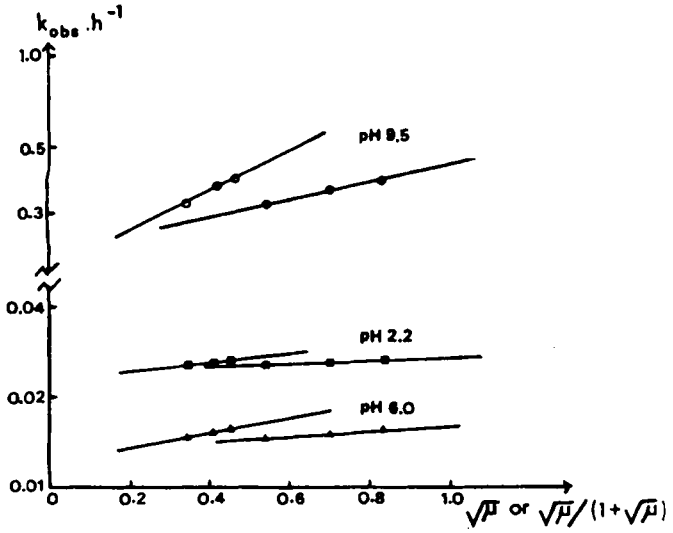

Figure 7—*Plots of log* k_{obs} versus $\sqrt{\mu}$ (●, ■, ▲) *or* $\sqrt{\mu}/1+\sqrt{\mu}$ (○, □, △) *at different pH values (0.2 M buffer concentration, 37°C) for a cefotaxime sodium salt solution.*

tained by plotting the values of log k_{pH} against pH, independently of any buffer effects (except for pH 4.0 and 9.0), at 37°C and $\mu = 0.5$ (Fig. 8). Three distinct regions can be seen: (*a*) a region where the reaction is hydrogen ion catalyzed, between pH 1.6 and 3.0, (*b*) a plateau where the reaction is not pH dependent, between pH 3.0 and 7.0, and (*c*) a region where the reaction is hydroxide ion catalyzed, above pH 7.0. The U-shape of the experimental curve, without inflexion in the pK_a zones (2.1 and 3.4), is characteristic of a reaction both hydrogen ion catalyzed and hydroxide ion catalyzed. The log k_{pH}–pH profile for I was fitted with:

$$k_{pH} = k_H \cdot a_H + k_0 + k_{OH}\frac{K_w}{a_H} \qquad \text{(Eq. 8)}$$

where k_H is the second-order rate constant for the hydrogen ion-catalyzed degradation, identical for the ionized and un-ionized cefotaxime species; a_H is the activity of hydrogen ions potentiometrically determined; k_0 is the first-order rate constant for the spontaneous or water-catalyzed reaction; k_{OH} is the second-order rate constant for the hydroxide ion-catalyzed degradation; and K_w is the autoprotolysis constant of water, $\sim 2.09 \times 10^{-14}$ at 35°C.

From the experimental values at pH 1.60, 6.00, and 9.50, k_H, k_0, and k_{OH} were calculated from Eq. 8 to be $k_H = 1.90\ h^{-1}\cdot M^{-1}$, $k_0 = 0.013\ h^{-1}$, and $k_{OH} = 4626.5\ h^{-1}\cdot M^{-1}$. These constants were used to generate the theoretical pH-rate profile given in Fig. 8, using a computer. A satisfactory fit of the data was obtained.

The good agreement between the experimental data, the theoretical profile, and the results of primary salt effects suggest the following reactions (Scheme III) to occur in the pH region investigated:

$$\text{Cef} + H^+ \xrightarrow{k_H} \text{products}$$

$$\text{Cef} \xrightarrow{k_0} \text{products}$$

$$\text{Cef} + OH^- \xrightarrow{k_{OH}} \text{products}$$

Scheme III

At pH 2.2, due to the overall average charge of the species in solution, the salt effect is not visible. At pH 6.0, I is ionized, the main process is a water attack, and no salt effect is observed. At pH 9.5, where a general base-catalytic effect has been shown with borate ions, a positive salt effect is obtained because I is negatively charged and reacts with hydroxide and borate ions.

Temperature Effect—The effect of temperature was studied with an ionic strength of 0.5 in 0.2 M buffer solutions, at pH 7.0 and 10.0, by measuring the degradation rates at 4°C, 23°C, and 37°C. Other determinations (pH 3.0 and 5.0) were conducted at only two temperatures (23°C and 37°C). The values of rate constants at different temperatures and the Arrhenius activation parameter are given in Table IV. These values are very similar to those obtained for other cephalosporins (1, 5, 6) and correspond to the values generally observed for solvolysis.

Comparative Stability and Reaction Mechanism—In Fig. 8, a stability comparison of I and other cephalosporins is plotted. This graph lists cephalosporins with an acetoxymethyl group in the C-3 position (cephalothin and

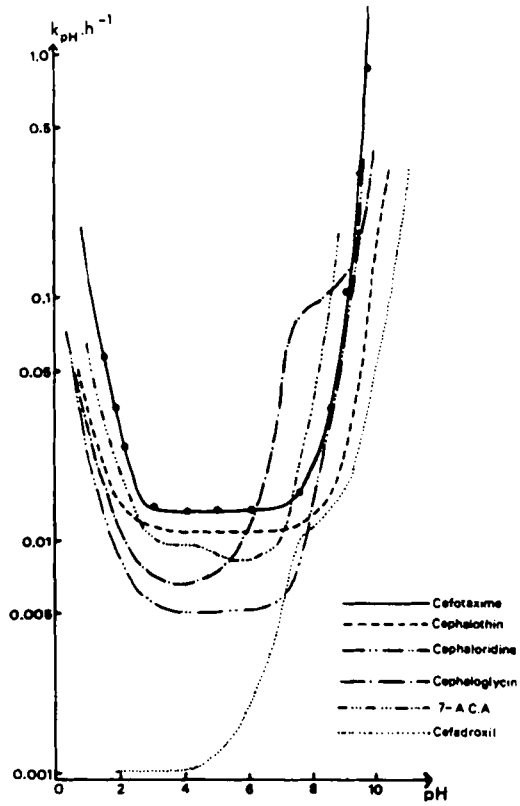

Figure 8—*log* k_{pH}*–pH profile for cefotaxime sodium salt solution at 37°C,* $\mu = 0.5$*. The points are experimental values. The solid lines were generated from Eq. 8 with an analog computer. Comparative stability study with other cephalosporins [cephalothin, cephaloridine, cephaloglycin, and 7-amino-cephalosporanic acid (7-A.C.A). from Ref. 1, cefadroxil from Ref. 6].*

cephaloglycin), cephalosporins without an acetoxymethyl group (cephaloridin and cefadroxil), and 7-aminocephalosporanic acid (7-A.C.A).

In the pH 3.0–7.0 range, where the degradation rates are not pH dependent, the rate constant $k_0 = 13 \times 10^{-3}\ h^{-1}$ calculated for I is similar to the k_0 values obtained from cephalothin and cephaloglycin. As suggested (1) for these two acetoxymethyl cephalosporins, the plateau in this pH range may correspond both to a hydrolytic cleavage of the β-lactam moiety and to an intramolecular attack with a side chain amino group participation. This intramolecular attack should be facilitated by the electron-donating effect of the *O*-methyloxime substituent on the side chain.

In acidic and alkaline media, the rate constants observed are higher than the rate constants given for cephalothin and cephaloglycin. This enhanced reactivity of I should imply a side-chain participation in the degradation, in contrast with cephalothin and cephaloglycin.

From the present results, the scheme of degradation of I in the entire pH range has been found similar to the other acetoxymethyl cephalosporins of the first generation (cephalothin and cephaloglycin). The chemical stability of I under alkaline conditions has not been proven to be reliable for β-lactamase hydrolysis and consequently for the activity against Gram-negative bacteria, as suggested for the cephalosporins of the first and second generations (1). Cefotaxime sodium (I) has a remarkable resistance to hydrolysis of these enzymes (17), in contrast to a fair stability under alkaline conditions. The enhanced resistance to the β-lactamase deactivation has been attributed to the presence of a rigid *syn O*-methyloxime group (17). The biological activity of I has also been related to the original structure of the 7-substituent aminothiazole ring, which plays an important role in the affinity of the molecule against transpeptidase activity in the synthesis of the bacterial wall.

Ocular Delivery of Pilocarpine from Erodible Matrices

GEORGE M. GRASS *ˣ, JOHN COBBY ‡, and MICHAEL C. MAKOID §

Received January 13, 1983, from the *College of Pharmacy, University of Nebraska Medical Center, Omaha, NE 68105.* Accepted for publication March 21, 1983. Present addresses: *School of Pharmacy, University of Wisconsin, Madison, WI 53706; ‡ICI Pharma, 16 Falconer Drive, Mississauga, Ontario, L5N 3M1 Canada; §School of Pharmacy, Creighton University, Omaha, NE 68178.

Abstract □ The present study examined the feasibility of sustaining the release of a water-soluble drug, pilocarpine, to the tear film. Both gels and dried films were utilized as drug delivery systems. *In vitro* studies demonstrated significant prolongation of drug release from these systems as compared with simple aqueous or viscous solutions. The *in vitro* results were supported by *in vivo* miosis studies in albino rabbits.

Keyphrases □ Pilocarpine—sustained release, polymeric delivery systems, *in vitro* release studies, *in vivo* miosis in rabbits □ Drug delivery systems—polymeric gels and films, pilocarpine, sustained release to the cornea, rabbits □ Polymeric matrices—sustained release of pilocarpine to the cornea, *in vivo* miosis in rabbits, *in vitro* release studies

It is well established that ocular drug bioavailability from topical dosing is dependent on several factors, one of the most prominent being the contact time of drug with tissues in the precorneal area of the eye (1). Several investigators (2, 3) have reported that the relatively low-viscosity ophthalmic solutions, while able to somewhat improve the amount of drug that penetrates the cornea to the anterior chamber, generally do not provide a sustaining effect. Conversely, Schoenwald *et al.* (4) and Patton and Robinson (2) have demonstrated that moderately viscous systems, such as gels, can sustain drug delivery to the cornea and anterior segment of the eye. Furthermore, it is known that slowly dissolving lamellae remain in the eye for extended periods of time. Therefore, it is of interest to examine and assess these systems for their potential in ocular drug delivery.

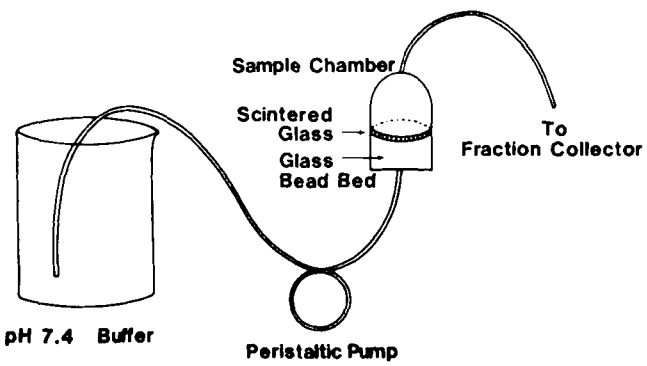

Figure 1—In vitro *dissolution apparatus used to measure appearance of pilocarpine from solutions and lamellae.*

A chronic problem with dissolving hydrogels is their usual high water content, which allows low molecular weight substances to diffuse quickly out of the gel, leaving a "ghost" without active ingredients. Extensive cross-linking of polymers, or dehydration of the gel to a dry film state, could measurably improve the release characteristics of the system.

Due to the need for frequent dosing of pilocarpine from commercial solution preparations, the expense of currently marketed controlled-release devices, and because extensive work has been published regarding ocular absorption of pilocarpine from both solutions and various gel systems, this drug was selected as a model compound for release from several types of ocular polymeric systems.

EXPERIMENTAL

Materials—Reagent-grade polyvinyl alcohol (PVA)[1], with an average mol. wt. of 16,000, and carboxyvinyl copolymer (carbomer 934)[2] were used as received. Tritiated pilocarpine[3], with a specific activity of 20 mCi/mg, was purified by vacuum evaporation immediately prior to use (5). All other chemicals were reagent or analytical grade.

Male albino rabbits[4], weighing 2.5–3.5 kg, were used throughout the study. No special dietary restrictions were used for the animals, and they were maintained in a normal lighting and auditory environment.

Methods—*Preparation of Solutions and Films*—A 4% w/v solution of pilocarpine nitrate, made isotonic with sodium chloride, was prepared in pH 7.4 Sorensen's phosphate buffer. To 10 mL of this solution, tritiated pilocarpine (10 μL) was added to yield a specific activity of ~1.5 μCi/mL. A negligible change in pilocarpine solution concentration occurred through this spiking procedure.

Pilocarpine, 2% in 10% PVA in phosphate buffer, was prepared with a specific activity of ~0.9 μCi/mL. Solutions were refrigerated between uses and were discarded within 7 d.

Erodible polymer films containing drug were prepared in the following manner. The 10% PVA solution in distilled water (40 mL) was poured into

a glass petri dish and allowed to gel for 1 h at 4°C. A 40-mL volume of 2% pilocarpine (specific activity of ~2.75 μCi/mL) in 4% boric acid solution was layered on the PVA gel, covered[5], and allowed to remain at room temperature for 2 h before being refrigerated for an additional 24 h. At this point the excess fluid was drained away, and the dish was covered and stored in the refrigerator (4°C) until use.

Samples were punched from the gel film using a No. 4 cork borer and were weighed on an analytical balance. The gel buttons were employed in dissolution tests within 15 min of punching.

Nonerodible dried films were prepared by adding 1.125 g of glycerol to 40 mL of 0.875% pilocarpine solution (specific activity of ~1.0 μCi/mL) and 40 mL of 20% PVA solution. This solution was poured into a 100 × 50-mm glass petri dish and allowed to air dry for 7 d at ambient conditions. It was assumed that any remaining labile tritium would exchange with water and evaporate with the solvent. Stability of the tritium label was determined after 10 d by dissolving film samples in water and flash evaporating the solvent. Analysis of this solvent by scintillation counting revealed <7% loss of tritium. Samples were punched out as described for the gel matrix.

Carboxyvinyl copolymer (carbomer 934) films were also prepared. Films were prepared as described above (erodible and nonerodible films) with the exception that 100 mg of carbomer 934, neutralized with 2.4 mL of 20% NaOH, was added to the PVA (10% or 20%) solution prior to the addition of other ingredients. Preparation of the sample lamellae and storage was as previously described.

In Vitro *Dissolution*—A pictorial representation of the dissolution apparatus is shown in Fig. 1. The apparatus utilized a peristaltic pump which delivered phosphate buffer (Sorensen's pH 7.4, isotonic) from a reservoir through a flow cell containing the sample lamella and emptied into a fraction collector at a rate of 15 mL/h. The dissolution cell chamber (1 mL) was separated into two compartments by a scintered glass disk. A glass bead bed was placed below the disk to prevent a "tunnel current" through the center of the cell.

The lamella was placed on the scintered glass disk and buffer was pumped through the chamber exiting at a central opening above. Buffer effluent was collected[6] at either 2- or 5-min intervals, depending on the duration of the experiment. The collected samples were assayed by liquid scintillation[7] using liquid scintillation cocktail[8]. Based on standards, counts were converted to concentration of drug. A minimum of six runs was conducted for each experiment.

In Vivo *Studies*—Rabbits, previously acclimated to the testing procedure, were positioned in restraining cages and placed in a room with controlled lighting. A television camera with a macrolens was focused on the rabbit's eye. A television monitor and an observer were physically outside the room containing the rabbit during the experiment to minimize observer interference. To measure pupillary diameter, the observer used a transparent grid placed on the television monitor.

[5] Parafilm M.
[6] Fraction Collector; ISCO, Lincoln, Neb.
[7] Beckman model 230; Fullerton, Calif.
[8] Aquasol II; New England Nuclear, Boston, Mass.

In an attempt to assess the biological performance of these drug delivery systems, the miotic response in albino rabbits was determined. The percent miotic response in the rabbit (%R) was calculated with reference to the diameter of the pupil after prolonged exposure to a high-intensity light source (D_{min}). The appropriate equation is given as:

$$\%R = 100\,[(D_0 - D_t)/(D_0 - D_{min})] \qquad \text{(Eq. 1)}$$

where D_t is the observed pupillary diameter at time t and D_0 is the initial pupillary diameter. D_{min} was measured before dosing, and drug treatment was not initiated until pupil diameter had returned to preexposure values.

Pilocarpine concentration in the solution was selected to be identical to the amount of drug in the gel/film, *i.e.*, 70 μg/25-μL dose as compared with 70 μg/25-mg dose of lamella. In the dried film cases, the dose of drug was 700 μg and, thus, an appropriate level of drug in the solution dosage form was prepared. This method gave reproducible results such that pupillary diameter changes of 0.1 mm (~2%) could be observed easily.

The lamella or solution was then instilled into the eye by pulling the lower eyelid away from the globe and placing the dose in the lower portion of the conjunctival sac. The eyelid was immediately returned to its normal position. During each experimental run, only one eye of each animal was dosed with drug. After instillation of the dose, the observer left the testing room.

Measurements of pupillary diameter were made at 5-min intervals for the first 15 min and every 15 min thereafter. A minimum of three runs was conducted for each experiment. Significance of results was determined by comparison of response values by t test.

RESULTS

***In Vitro* Dissolution**—Pilocarpine solution data fit by nonlinear regression (NONLIN) were found to be cleared by first-order kinetics as given by the following expression:

$$W_r = W_f e^{-k_d t} \qquad \text{(Eq. 2)}$$

where W_r is the weight of drug remaining to be cleared at time t, W_f is the final weight of drug cleared from the chamber, and k_d is the rate constant for clearance. Typical release profiles are shown in Fig. 2. It was found that the half-life ($t_{1/2}$) for clearance of a pilocarpine solution with a viscosity of 1.0 cps was 2.0 min and for a 60-cps PVA solution it was 12.7 min. To account for the delay in appearance of drug from the dissolution chamber to the sample collection (physical distance), a lag time ($t = t_0 - t_{lag}$) was required for all solutions and gel/films.

Pilocarpine release from gel/films is also shown in Fig. 2. Release from these systems, as compared with simple aqueous solutions, is sustained for a significantly longer time.

Release of drug from the gel/films could be either by a dissolution- or diffusion-controlled process or, in some cases, by a combination of both mechanisms. The data were fit by nonlinear regression (NONLIN) to both the Hixon–Crowell dissolution cube root equation (6, 7) and to a diffusion-controlled dissolution equation (8, 9):

$$F_t = 3k_r t^{1/2} - 3(k_r t^{1/2})^2 + (k_r t^{1/2})^3 \qquad \text{(Eq. 3)}$$

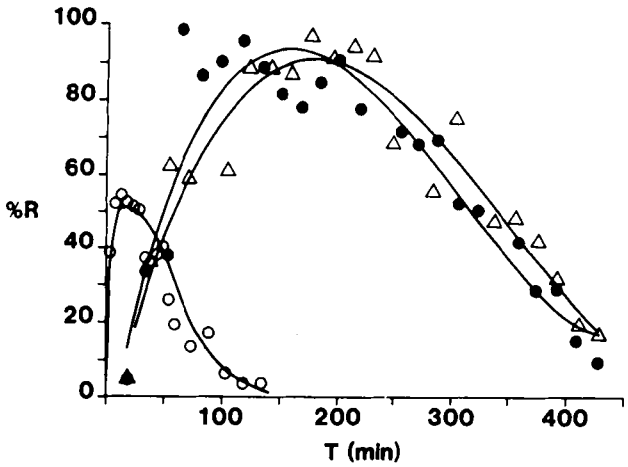

Figure 4—In vivo *comparison of miotic response to a 700-μg dose of pilocarpine nitrate administered as solutions and nonerodible lamellae. Key: (○) 25-μL solution (1.0 cps); (●) nonerodible lamella (no carbomer 934); (△) nonerodible lamella (with carbomer 934).*

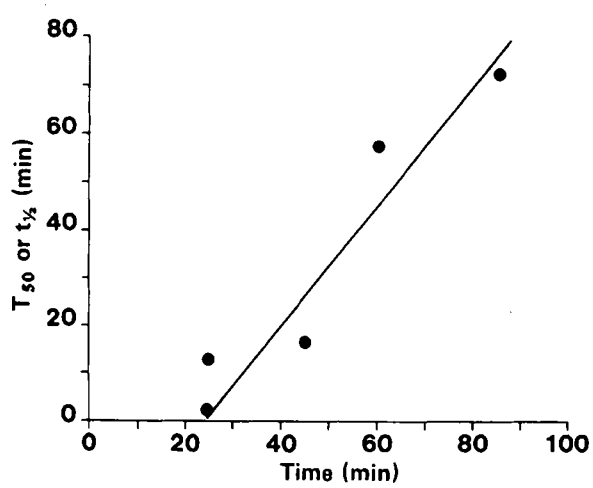

Figure 5—In vivo–in vitro *correlation utilizing* $t_{1/2}$ *for solutions and* T_{50} *for lamellae. Key: (●)* T_{50} *or* $t_{1/2}$. *The time indicated on the* x-*axis is the time at which 90% of the observed maximum response is first obtained.*

where F_t is the fraction of drug released to time t and k_r is the release rate constant.

Both erodible cross-linked lamella types (with and without carbomer 934) displayed identical release characteristics which were best fit by the diffusion equation (Eq. 3). The time to half dissolution (T_{50}) from these cross-linked systems was 16.2 min, calculated from the following equation:

$$T_{50} = (T_0^{1/2} + 0.206/k_r)^2 \qquad \text{(Eq. 4)}$$

where $T_0^{1/2}$ is the root lag time (9).

The cross-linked lamella samples dissolved during the testing procedure, and no visible swelling of the sample was noted during the test period. Although it was anticipated that an ionic-exchange release could retard the release of the cationic pilocarpine, the presence or absence of anionic copolymer in these preparations made no difference in the release rate of pilocarpine from the samples.

Nonerodible dried films were also tested, and the release of drug was best described by the diffusion expression (Eq. 3). Dried films without carbomer 934 did not appear to swell during the time course of testing. These films gave a T_{50} of appearance of 57.5 min. Conversely, the copolymer-containing films swelled to two or three times their original size, but did not undergo appreciable dissolution. These films gave a T_{50} of pilocarpine appearance of 72.4 min.

***In Vivo* Miotic Response**—The low-dose case results are shown in Fig. 3. Note that the peak response times and the 25–30-min postdosing intervals for the 1.0- and 60-cps solutions appear identical. However, the slowly eroding lamellae show a longer time to reach a maximum. The 60-cps solution shows approximately a 1.7 times greater response than the 1.0-cps solution. These results are in agreement with published data on the bioavailability of low- and medium-viscosity ocular pilocarpine solutions (5). The erodible lamellae also show a statistically greater response ($p < 0.001$) as compared with the solution dosage forms. The most significant aspect is the extended duration of effect of the erodible lamellae as compared with the solutions. Bearing in mind that although measurement of miosis allows continuous monitoring of pharmacological response, it is not as sensitive an indicator of drug bioavailability as direct sampling of ocular tissues or aqueous humor for drug concentration (5, 10). Therefore, this extended duration is significant.

The high-dose dried film systems (Fig. 4) show a number of significant differences between the nonerodible systems and the solution dosage form. These lamellae show a greater miotic response ($p < 0.001$) and a longer period of response, as compared with the solutions. There is no statistically significant difference between the lamellae with carbomer 934 as compared with the system without this copolymer.

It has been established previously that there is a linear relationship between dose and bioavailability for pilocarpine over six orders of magnitude of dose (6). The effect of different doses with the solution is clearly different: 20 and 50% of maximum to the 70- and 700-μg doses, respectively. This differential effect is expected on the basis of published drug bioavailability data (11).

***In Vivo–In Vitro* Correlation**—Since a strictly definable peak from miotic response is not discernable, especially for the lamellae formulations, the time at which 90% of the observed maximum response was first obtained was selected. This value correlates reasonably well with the time for 50% release ($t_{1/2}$ or T_{50}) of drug in the *in vitro* studies (Fig. 5). Note that for both drug solutions, the half-life of drug clearance corresponds to the time for removal of drug from the chamber, whereas in the case of lamellae, the dissolution–diffusion process is assumed to be rate limiting. It is recognized that other parameters such as duration of effect or area under the response curve may allow correlation with *in vitro* performance, but these were not examined.

DISCUSSION

To assess the merits of the gel/film pilocarpine systems, it is first necessary to comment on the performance of aqueous and viscous pilocarpine solutions. These systems, therefore, serve as a baseline.

The nonviscous (1.0 cps) solutions provide drug to the absorbing tissue, *i.e.*, the cornea, readily so that the amount of drug absorbed is proportional to the concentration instilled (5). However, the system is not very efficient and ~98% of the applied dose is lost. Significant dilution with tears occurs within 5 min of instillation, thus effectively stopping the flux of drug across the cornea (1). This effect coupled with nonproductive absorption of drug accounts for most of the drug loss.

Conversely, viscous solutions (60 cps) increase the amount of drug absorbed by a factor of 2 or 3 and exhibit a correspondingly greater biological response. This positive influence of viscosity on drug bioavailability can be due to several factors. The better wetting of the cornea by the polymer solution would allow more intimate contact of drug with the absorbing tissue. The increased viscosity of the solution would decrease drainage loss of the drug solution and thereby promote a greater ocular drug bioavailability. Finally, some adsorption of the polymer to the corneal tissue would favor greater absorption of the drug.

The gel/film system would have several of the positive attributes of the viscous solution and should be more dramatic in influence on drug bioavailability. The most obvious expectation is a decreased drainage loss of drug and slow availability of drug from the gel/film to the corneal surface. Both the *in vitro* and *in vivo* results support these postulates.

In an attempt to decrease appearance of drug from the films, the carbomer 934 salt of pilocarpine was prepared and used. No noticeable improvement in the system was evident. This may be explained on the basis that dissolution of the gel itself in the cross-linked systems was prompt and, thus, there was insufficient time for dissolution and subsequent diffusion of the drug from the film. In the dried film case, substantial swelling was noted which would increase both water content and channels for diffusion.

It is evident from this preliminary study that gels/films can sustain the release of water-soluble drugs to the precorneal area. Moreover, it appears that the *in vitro* assessment of drug release provides at least a qualitative yardstick on *in vivo* performance.

Electrochemical Chromatographic Determinations of Morphine Antagonists in Biological Fluids, with Applications

HARTMUT DERENDORF, ALAA EL-DIN A. EL-KOUSSI, and EDWARD R. GARRETT ˣ

Received December 17, 1982, from *The Beehive, College of Pharmacy, J. Hillis Miller Health Center, University of Florida, Gainesville, FL 32610.* Accepted for publication January 27, 1983.

Abstract □ The morphine antagonists naltrexone and naloxone were extracted from plasma and urine, separated on a chromatographic column, and assayed by electrochemical detection. Optimum oxidation potentials were 0.65 V for morphine and 0.75 V for naloxone and naltrexone. Assay sensitivities were 2–5 ng/mL for plasma and 10 ng/mL for urine. The assays were applied to determine red blood cell partition coefficients of 1.83 ± 0.15 (*SD*) for naltrexone and 1.49 ± 0.27 (*SD*) for naloxone in a concentration range of 10–3500 ng/mL. No significant time dependence for the partitioning could be observed. Plasma protein binding in the same concentration range, determined by ultracentrifugation, was 27.7% ± 2.5% (*SD*) for naltrexone and 30.1% ± 5.1% (*SD*) for naloxone. The degree of protein binding did not change in the presence of morphine for morphine–antagonist ratios between 1:10 and 10:1. No concentration dependencies of red blood cell partitioning or protein binding were observed.

Keyphrases □ Naltrexone—HPLC with electrochemical detection, plasma and urine, applications to protein binding and red blood cell partitioning □ Naloxone—HPLC with electrochemical detection, plasma and urine, applications to protein binding and red blood cell partitioning □ Protein binding—naltrexone and naloxone in the presence of morphine, HPLC with electrochemical detection, red blood cell partitioning □ Red blood cell partitioning—naltrexone and naloxone in the presence of morphine, HPLC with electrochemical detection, protein binding

The classical detection methods for high-performance liquid chromatography (HPLC) by spectrophotometric and fluorescence detection are not useful for some drugs with low absorptivities or low fluorescence. Electrochemical detection has been a method of recent choice in selected instances. It combines amperometric titration and liquid chromatography (1) and has been applied to the assays of catecholamines (2), phenolic compounds (3), phenothiazines (4, 5), and morphine (I) (6–8).

The present study describes sensitive and accurate HPLC assays for the antagonists of morphine, naloxone (II) and naltrexone (III) in biological fluids with electrochemical detection. Studies on possible pharmacokinetic interactions between morphine and its antagonists are needed since naltrexone or naloxone are given to morphine-overdosed subjects. Prerequisites for such studies are specific and sensitive assays that allow simultaneous determinations of agonist and antagonist as well as their metabolites.

A facile procedure for the simultaneous determination of I and III or II is described using HPLC with electrochemical detection. The assay was applied to the determination of the protein binding of II and III and the influence of I on their protein binding. The red blood cell partition properties of both antagonists were also investigated.

III

EXPERIMENTAL

Materials—The following analytical-grade materials were used: sodium bicarbonate[1], monobasic potassium phosphate[1], volumetric concentrates of hydrochloric acid and sodium hydroxide[2], 1-butanol[3], and benzene[4]. Acetonitrile[4] was HPLC grade. Morphine (I)[5], naloxone (II)[5], and naltrexone (III)[5] were used as received. Sodium chloride injection USP[6], sodium heparin injection[7], and disposable syringes[8] were used in the preparation of red blood cell suspensions.

Apparatus—For the HPLC assay the following instruments were used: high-pressure pump[9], a six-port injector[10], an electrochemical detector[11] with a working electrode of glassy carbon[12], a strip-chart recorder[13], and an octadecylsilane column[14] with a guard column of the same material.

Plasma protein binding was determined with an ultracentrifuge[15]. A laboratory centrifuge[16] was used in the separation of organic extracts from aqueous phases.

Chromatographic Conditions—The mobile phase was a mixture of 0.04 M monobasic potassium phosphate and acetonitrile (90:10). The flow rate was

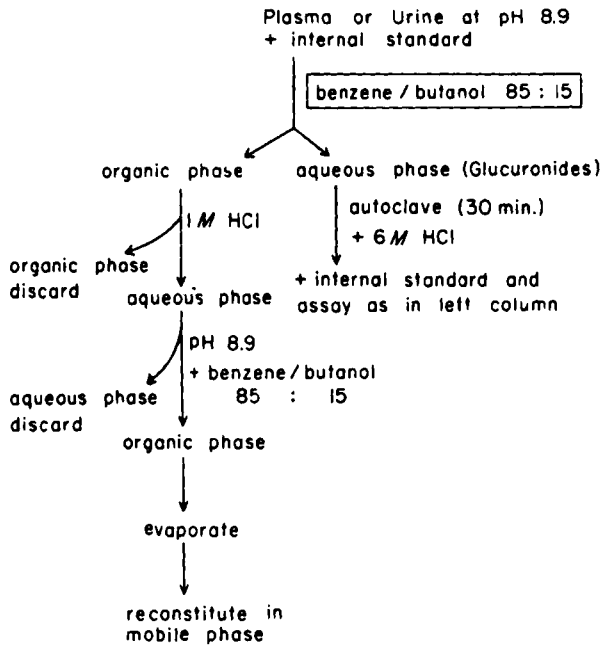

Scheme I—Extraction procedure for plasma and urine.

1.2 mL/min, with a back pressure of 6 MPa. Electrochemical detection was performed with an applied potential of 0.75 V.

Extraction Procedure from Plasma and Urine—Plasma or urine (1.0 mL) was placed in a tube containing 0.25 mL of 1 M sodium bicarbonate adjusted to pH 8.9 with 1 M NaOH. An appropriate amount of internal standard (II, I, or III depending on the compound assayed) was added to give peak height ratios between 0.2 and 4. A 2-mL volume of benzene–1-butanol (85:15) was added, and the mixture was vortexed for 30 s. The phases were separated by centrifugation for 10 min at 3000 rpm, and the organic phase was transferred with a silylated Pasteur pipet into another tube. The extraction was repeated with 2 mL of fresh solvent.

The aqueous phase can be saved for the analysis of the glucuronides. The combined organic phases were extracted with 0.5 mL of 1 M HCl and discarded. The acidic aqueous phase was washed with 2 mL of fresh organic solvent and then neutralized with 0.5 mL of 1 M NaOH. The pH was adjusted to 8.9 with 1 M sodium bicarbonate buffer, and the solution was twice reextracted with 2 mL of benzene–1-butanol (85:15). The organic phases were combined in a vial and evaporated under a nitrogen stream at 55°C. The dried residue was dissolved in 75 μL of mobile phase, and 10–25 μL was injected into the HPLC system. The extraction procedure is given in Scheme I.

The aqueous phase saved after the first extraction can be assayed for glucuronides of the compounds by the method given for morphine after hydrolysis of the conjugate (9).

Determination of Plasma Protein Binding by Ultracentrifugation—Fresh heparinized dog blood was centrifuged for 15 min at 3000 rpm. Plasma aliquots (5 mL) were spiked with different amounts of III or II to give concentrations between 10 and 3500 ng/mL of plasma. Plasma (1 mL) was taken for analysis before ultracentrifugation. After ultracentrifugation at 35,000

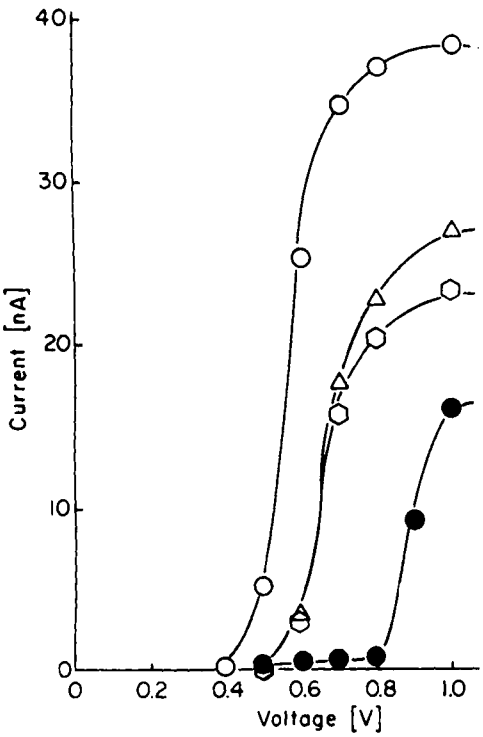

Figure 1—*Chromatographic amperogram for I (○), II (△), III (○), and the background (●) determined by application of different oxidation potentials. The background arises from oxidation of electroactive impurities in the mobile phase.*

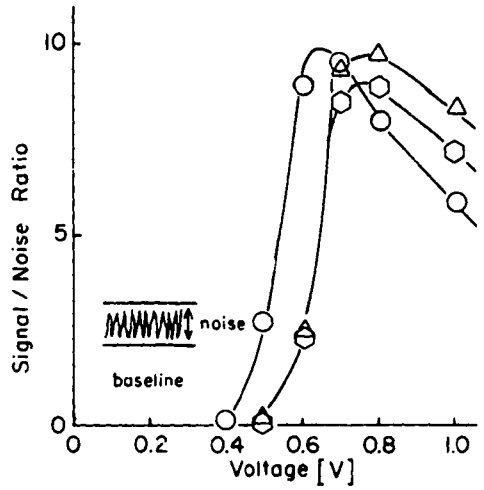

Figure 2—*Determination of optimum oxidation potential by maximization of the signal/noise ratio. Noise was measured as the amplitude of the baseline. The optimum potentials to be applied for detection are 0.65 V for I (○) and 0.75 V for III (○) and II (△).*

rpm for 18 h, 1 mL of the supernatant plasma water was analyzed for III or II. The influence of I on the protein binding of both antagonists was studied in ratios 1:10, 1:2, 2:1, and 10:1.

Red Blood Cell Partition Studies—Fresh heparinized dog blood was centrifuged for 15 min at 2000 rpm. The plasma was removed and isoosmotic phosphate buffer (pH 7.4) was added to the erythrocytes. The red blood cells were gently suspended and centrifuged for 10 min at 2000 rpm; this washing procedure was repeated three times. Red blood cell suspensions in plasma water were spiked with III or II to yield total drug concentrations of 10–3500 ng/mL. The hematocrit was determined routinely using a microcentrifuge with capillary tubes. The spiked suspensions were allowed to equilibrate for 60 min and then centrifuged for 10 min at 2000 rpm. An aliquot of the supernatant solution was analyzed, and the red blood cell partition coefficient was calculated.

For the investigation of a time dependency of the red blood cell partitioning, the procedure was repeated and samples were taken after 4, 6, 8, 10, and 15 min after spiking. A minimum of 4 min of centrifugation is necessary to get a clear supernatant.

To reconfirm the observed red blood cell partition coefficients, the ratio between the drug concentrations in whole blood and plasma were determined. Whole blood (5 mL) was spiked with different amounts of drug to give whole blood concentrations between 10 and 3500 ng/mL. The blood was allowed to equilibrate for 60 min and then centrifuged for 10 min at 3000 rpm. An aliquot of the supernatant plasma was analyzed.

RESULTS AND DISCUSSION

Determination of the Optimum Detection Conditions—Signals for the three compounds were measured after application of voltages between 0.4 and 1.0 V to determine the optimum conditions for the electrochemical detection (Fig. 1). Background is defined as the Faradaic current arising from the oxidation of electroactive impurities in the mobile phase, analogous to the background absorbance in UV detectors. The detection conditions were optimized to find the maximal signal/noise ratio for each of the investigated compounds. Usually measured from peak to peak, the noise is due to pump pulsation, flow hydrodynamics, cell surface reactions, power line noise, and electronic amplification (10). The noise with an electrochemical detector is dependent on the magnitude of the background signal; the greater the background, the greater the noise. The signal/noise ratios for the three compounds are shown in Fig. 2. The maxima of these plots are the optimum potentials to be applied for detection: 0.65 V for I and 0.75 V for II and III.

Chromatographic Separation—With a mobile phase of 0.04 M monobasic potassium phosphate–acetonitrile (90:10) I–III are well separated and can be assayed simultaneously (Fig. 3A). The chromatographic background after extracting blank plasma is clean, so that low concentrations of the compounds can be detected (Fig. 3B, C). Statistics for calibration curves of II and III after extraction from plasma and urine are given in Table I. The limit of assay sensitivity for all compounds was 2–5 ng/mL for plasma and 10 ng/mL for urine. A chromatogram of a plasma sample containing 10 ng/mL of III is shown in Fig. 3D.

Protein Binding of II and III by Ultracentrifugation—The protein binding was determined by the ultracentrifugation method (11) and can be calculated from:

$$f_b = \frac{m(1 - R)}{R + m(1 - R)} \qquad \text{(Eq. 1)}$$

where f_b is the fraction bound to the plasma proteins, R is the ratio of the drug concentration (C_{post}) in plasma water after ultracentrifugation to the concentration (C_{pre}) in plasma before ultracentrifugation, and m is a dilution factor to compensate for the slight dilution of plasma on spiking. A chromatogram of a plasma sample containing 7.6 ng/mL of plasma water after ultracentrifugation is shown in Fig. 3E. The results are summarized in Tables

Table IV—Protein Binding of II and III in the Presence of I at Different Morphine–Morphine Antagonist Ratios

Mean ± *SD*				1.83 ± 0.15

[a] Total amount of drug added to a 5.0-mL red blood cell suspension. [b] PW = plasma water. [c] Red blood cell-plasma water partition coefficient.

II and III. Protein binding of both compounds is low, averaging 30.1 ± 5.1% (*SD*) for II and 27.7 ± 2.5% (*SD*) for III, with no observable concentration dependence. The results are in excellent agreement with a study by Ludden *et al.* (12), who reported a concentration-independent protein binding of tritiated III in dog plasma of 26% over a concentration range of 1–500 ng/mL, determined by equilibrium dialysis. The protein binding of I had been determined to be concentration independent at 36% (13). The presence of I in up to 10-fold higher concentrations than its antagonists does not change the degree of plasma protein binding of II or III (Table IV).

Determination of the Red Blood Cell Partition Coefficient—The red blood cell partition coefficient (D) of a drug can be defined (11) as:

$$D = \frac{C_{RBC}}{C_{PW}} = \frac{A_{tot} - C_{PW}V_{PW}}{C_{PW}(V_B - V_{PW})} \quad \text{(Eq. 2)}$$

where C_{RBC} is the concentration of the drug in the erythrocyte, C_{PW} is the drug concentration in plasma water, A_{tot} is the total amount of drug added to the red blood cell suspension, and V_{PW} is the volume of plasma water (calculated from the hematocrit of the erythrocyte suspension).

The red blood cell partition coefficients of III were determined for six different concentrations (Table V), averaging 1.83 ± 0.15 (*SD*). There was no concentration dependence for the partitioning in the studied concentration range up to 3.5 μg/mL. This relatively high partition coefficient was confirmed by comparing the concentration of III in blood, C_B, and plasma, C_P, after spiking whole blood. The ratio of these two concentrations is related to the degree of protein binding in plasma, expressed as fraction bound (f_b), to the red blood cell partition coefficient D and the hematocrit (H) (14):

$$\frac{C_B}{C_P} = DH(1 - f_b) + 1 - H \quad \text{(Eq. 3)}$$

Substitution of the values previously obtained for D and f_b gives a blood/plasma ratio of 1.16 for blood with a hematocrit of 0.49. This calculated ratio agrees with that obtained experimentally (1.21 ± 0.08) in blood in the investigated concentration range.

The red blood cell partition coefficients of II in the same concentration range are given in Table VI, averaging 1.49 ± 0.25 (*SD*), also with no concentration dependence. Both partition coefficients for III and II were significantly higher than the D = 1.11 previously reported for I (13), in agreement with the hypothesis that erythrocyte partitioning is related to the lipophilicity, which is mirrored by the HPLC retention times on a reverse-phase column. This theory

Table VI—Red Blood Cell Partition Coefficients for II at Different Concentrations

A_{tot}, μg[a]	C_{PW}, ng/mL	D[b]
0.050	9.3	1.30
0.175	28.8	1.79
0.500	87.9	1.47
1.750	278.1	1.83
5.000	955.9	1.16
17.500	3166.7	1.41
Mean ± *SD*		1.49 ± 0.27

[a] Total amount of drug added to a 5.0-mL red blood cell suspension when the volume of plasma water (PW) was 3.45–3.70 mL and the hematocrits were 0.260–0.310. [b] Red blood cell-plasma water partition coefficient.

is further confirmed by the fact that the more lipophilic derivative of I, buprenorphine, has an extremely high red blood cell partition coefficient[17] of ~10.

No time dependence in the red blood cell partitioning could be observed for either compound. Samples assayed 4–5 min after spiking were not significantly different from the samples that were allowed to equilibrate for 60 min, indicating that the partitioning was relatively fast. The lack of correlation between the protein binding and red blood cell partitioning for the investigated compounds suggests that these two properties should be studied separately.

Liquid Chromatographic Determination of Lipophilicity with Application to a Homologous Series of Barbiturates

STEPHEN TOON *, JOACHIM MAYER, and MALCOLM ROWLAND ˣ

Received June 17, 1982, from the *Department of Pharmacy, University of Manchester, Manchester M13 9PL, England.* Accepted for publication May 9, 1983. *Present address: School of Pharmacy, University of Washington, Seattle, WA 98105.

Abstract □ A graphical method for determining the lipophilicity of the members of a homologous series of barbituric acids, from a consideration of their reverse-phase HPLC retention data, is described. The HPLC parameter used as the index of lipophilicity, R_Q, is shown not only to form excellent correlations with the more commonly employed indices of lipophilicity, R_m and log P, but also to have a predictive capability for those log P values that had not previously been determined experimentally.

Keyphrases □ Lipophilicity—homologous series of barbiturates, determination by the HPLC parameter R_Q □ Barbiturates—lipophilicity, determination by the HPLC parameter R_Q □ HPLC—use of the parameter R_Q to determine lipophilicity, homologous series of barbiturates

Since Meyer (1) and Overton (2) first postulated a relationship between the biological response elicited by a drug substance and its lipophilic character, medicinal chemists have sought rapid and reliable methods of determining molecular lipophilicity. The octanol-water partition coefficient (P), classically being determined using the "shake-flask" method (3), has been the index of lipophilicity most commonly employed in correlations between molecular structure and biological response (4, 5). The "shake-flask" approach to the determination of lipophilic character has been shown, however, to have many inherent practical difficulties associated with it (6–8), and as a consequence alternative methods of determining P or other indices of lipophilicity have been sought.

Many of the alternatives have been derived from TLC (9–12) and high-performance liquid chromatography (HPLC) (13–16), but in nearly all instances problems arise when characterizing highly lipophilic or hydrophilic molecules. The potential of the HPLC-based term R_Q (17) as an index of molecular lipophilicity was explored using a homologous series of barbituric acids. Special reference was paid to the correlation of R_Q with the more commonly accepted indices of lipophilicity, log P and R_m, the latter being experimentally determined from reverse-phase TLC studies within the series.

EXPERIMENTAL

The barbituric acids comprising the series (Table I) were obtained either from commercial sources or synthetically by condensing the respective diethyl 2-alkyl-2-ethylmalonate with urea in the presence of sodium ethoxide. The synthetic barbituric acids were characterized by ^{1}H-NMR, elemental analyses, and melting point determinations. All were calculated to be >99% pure.

Liquid Chromatographic Analysis and the Determination of R_Q Values—The analytical system has been previously outlined (17). The basis of the HPLC assay is that the un-ionized barbiturates are separated using a reverse-phase column[1], and then by the postcolumn infusion of pH 10 buffer, the barbiturates are converted to the more strongly UV-absorbing monoanionic species, facilitating detection at 254 nm.

The acetonitrile[2] and acetic acid[3] used in the preparation of the mobile phases were HPLC and analytical grade, respectively. All water used was freshly glass-distilled. The mobile phases were deaerated prior to use by filtration under vacuum through a 0.22-μm microbial filter[4].

The barbiturates were studied individually as solutions in acetonitrile (50 μg/mL), 10 μL of which was used in the analysis, thereby facilitating the measurement of retention times of the various barbiturates (R_T) relative to the unretained solute peak (10 μL of methanol, R_0) at varying concentrations of acetonitrile in the mobile phase. To improve the retention characteristics of 5-ethylbarbituric acid, 0.05% (v/v) acetic acid was added to the mobile phase; the retention of the other members of the series was unaffected by this addition.

R_Q values were calculated at the various acetonitrile concentrations according to:

$$R_Q = \log\left(\frac{R_T - R_0}{R_T}\right) \qquad \text{(Eq. 1)}$$

where R_T is the retention time of the solute and R_0 is the retention time of the unretained solvent. Values of R_Q at 0% v/v acetonitrile (100% v/v water; R_{Q0}) and at 40% v/v acetonitrile (R_{Q40}) were derived for all of the compounds either by direct measurement or by extrapolation/interpolation of the plots of the R_Q *versus* concentration (% v/v) of acetonitrile in the mobile phase.

Thin-Layer Chromatography and Calculation of R_m Values—Silica gel[5] was spread as a water slurry onto 20 × 20-cm glass plates to a thickness of 0.25 mm. After air drying, the plates were activated by heating overnight in an oven at 110°C. The plates were predeveloped in an 1-octanol–acetone (1:9) mixture, after which the acetone was evaporated from the plates by the use of an air blower. The silica gel plates were thus coated with a layer of 1-octanol.

Solutions of the individual barbiturates in acetone (2 mg/mL) were prepared, and 30 μl of each were applied as discrete spots along the baseline, positioned 1 cm from the bottom edge of the TLC plate. The prepared plates were developed in one of seven possible solvent systems composed of differing concentrations of acetone in water (5, 15, 25, 30, 35, 37, and 40% v/v acetone in water).

The ratio of the distance traveled by a given solute (barbiturate), relative to that traveled by the solvent front, was calculated in each instance yielding R_f values, which in turn allowed the calculation of R_m values for the individual barbiturates at varying acetone concentrations according to (18, 19):

$$R_m = \log\left(\frac{1}{R_f} - 1\right) \qquad \text{(Eq. 2)}$$

Assessment of log P—A solution (5×10^{-4} M) of the compound to be investigated (compounds 1, 2, and 3; Table I) was prepared in Sörensen's buffer (pH 5.1, 0.07 M) saturated with 1-octanol. This solution was then shaken gently for 1 h with 1-octanol that had been previously washed successively with 1 M NaOH, 1 M HCl, and the Sörensen's buffer. A period of 1 h to ensure that equilibrium had been achieved is more than adequate; only a few minutes are generally needed (3). The ratio of the volumes of the two phases was chosen so that 20–60% of the solute remains in the aqueous phase after extraction. The concentration of compound in the aqueous phase, adjusted to pH 10 by addition of dilute NaOH, was determined spectrometrically (240 nm) before and after extraction. The partition coefficient (P) of the acid was calculated from the relationship:

$$P = \frac{V_a}{V_o}\left[\frac{Ca(0)}{Ca} - 1\right] \qquad \text{(Eq. 3)}$$

where $Ca(0)$ and Ca are the respective concentrations of the compound in the aqueous phase before and after extraction and V_a and V_o are the volumes of the aqueous and organic phases, respectively.

[a] Leo *et al.* (3) reported $R_{Q40} = 0.121 \cdot \log P - 0.447$ ($n = 10, r^2 = 0.9470$); $R_{Q0} = 0.086 \cdot \log P + 0.021$ ($n = 10, r^2 = 0.9740$); $R_{Q40} = 0.280 \cdot R_m - 0.446$ ($n = 7, r^2 = 0.9470$); and $\log P = 1.465 \cdot R_m + 0.520$ ($n = 6, r^2 = 0.9619$). [b] Taken from Hansch and Leo (30). [c] Taken from Yih (31).

RESULTS AND DISCUSSION

The barbituric acid series under investigation varies widely in lipophilic character (Table I) and problems were encountered in determining TLC R_m values for the more lipophilic members of the series. Although a TLC solvent containing <40% acetone yielded a suitable migration from the baseline of the more hydrophilic homologues, hence facilitating the calculation of R_m values, elution from the baseline of the lipophilic *n*-hexyl through *n*-nonyl homologues was not afforded under such conditions. Furthermore, a solvent containing ≥40% acetone was found to strip the 1-octanol layer from the precoated plates, rendering them useless for the purpose in hand.

For those members of the series that did lend themselves to TLC analysis, a linear relationship was shown to exist between R_m and the acetone concentration (% v/v) in the developing solvent (Fig. 1). Similar relationships have previously been demonstrated for other molecular series, including the benzodiazepines and penicillins (9, 11).

Our results highlight the problem in quantitating lipophilic character of highly nonpolar compounds by TLC. Hulshoff and Perrin (20) have proposed a TLC-based method for the determination of the relative partition coefficients of very lipophilic basic compounds, based on the manipulation of developing solvent pH. While promising, this method has received only limited application (21).

Most HPLC approaches to the determination of lipophilicity are based on attempts made at formulating relationships between the capacity factor k' [$k' = (R_T - R_0)/R_0$; R_T and R_0 as previously defined] and P. The capacity factor (k') of a solute is only constant under any given set of chromatographic conditions. If k' values are to serve as the index of lipophilicity for the members of a homologous series, therefore, they should be obtained, for each homologue, under identical chromatographic conditions, an almost impossible constraint when dealing with a series of widely ranging lipophilicities.

Initial attempts at obtaining k' values for the barbituric acid series using a single isocratic HPLC system proved fruitless. The maximum possible concentration of organic solvent in the mobile phase that allowed a suitable retention time for the most hydrophilic homologue, 5-ethylbarbituric acid, was 10% v/v acetonitrile in 0.05% v/v aqueous acetic acid. Elution of the more hydrophobic homologues was not afforded under these conditions, with predicted retention times for these compounds being in excess of 10 h.

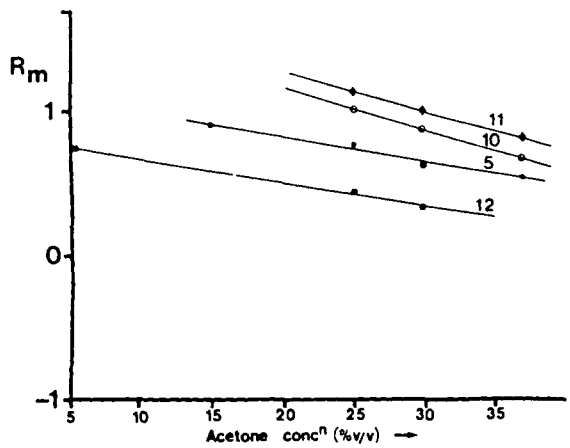

Figure 1—*Plot of* R_m *against acetone concentration in the mobile phase for various barbiturates. See Table I for key to the numbers.*

Yamana *et al.* (22) noted a linear relationship between log k' and the concentration of methanol in the HPLC mobile phase for a series of penicillins and cephalosporins. Such a relationship facilitates the calculation of k' values for the individual homologues at two or more mobile phase compositions, those which yield adequate retention times of the solute in question. These empirically determined k' values may then be extrapolated to give k' values at any desired mobile phase composition. Yamana *et al.* extrapolated their plots of log k' *versus* mobile phase composition to obtain log k' values for all members of their series at 0% v/v methanol (100% v/v water), these values in turn being shown to be highly correlated with the respective log P and R_m values.

The values of k' and log k' do not always vary linearly with mobile phase composition (17); thus, extrapolation of k' *versus* mobile phase plots is not always possible. As seen in Fig. 2, log k' for the barbiturate series is proportional to the concentration of acetonitrile in the mobile phase for many, but not all, of the homologues.

In contrast to k', we have found R_Q to vary linearly with mobile phase composition in all the cases we have examined, even when marked nonlinearity has been shown to exist between log k' and mobile phase composition (17). Plots of R_Q *versus* the concentration of acetonitrile in the mobile phase (Fig. 3) were back-extrapolated to yield R_Q values at 0% v/v acetonitrile (R_{Q0}) for all of the homologues. R_{Q0} values obtained in this manner were found to form good correlations with both TLC R_m values as well as with literature log P values (Fig. 4). The choice of a reference state of 0% v/v acetonitrile in water in relating R_Q values to other measures of lipophilicity is arbitrary. A better reference point would be one at which R_Q could be empirically determined for the maximum number of homologues, thereby reducing the number of R_Q values obtained by extrapolation, giving increased confidence in the R_Q data. A mobile phase of 40% v/v aqueous acetonitrile provides such a reference point.

Using the regression equation of R_{Q0} against log P, octanol–water partition coefficients were predicted for the two lowest homologues as being (log P) −1.52 for 5-ethylbarbituric acid and 0.02 for 5-methylbarbituric acid. As no literature values for log P were available for these two homologues, empirical determination was necessary to check the predicted values. The experimentally determined values for 5-ethylbarbituric acid and 5-ethyl-5-methylbarbituric

acid were −1.26 and 0.2, respectively, illustrating the good predictive capabilities of R_Q.

Pretreatment of column packings prior to the determination of lipophilicity using an HPLC based method has been the cause of considerable debate. Several workers have capped the reverse-phase column prior to use (23), while others have coated the column with 1-octanol (24–26). Baker *et al.* (27), proposed that the ordered side chains and residual silanol groups of untreated octadecylsilane packing material best reflects a biolayer, and partition data obtained from such systems are more suitable for use in biological correlations. A commercially available untreated reverse-phase packing material was used throughout our experimental procedure. In view of the excellent correlations obtained between R_Q values and other indices of molecular lipophilicity, we feel that pretreatment of the column packing prior to use may be unnecessary.

The thermodynamic basis of HPLC-derived lipophilicity data has been the subject of several investigations (28, 29). The thermodynamic basis of R_Q, if there is one, is unclear. From a theoretical standpoint, however, we should point out that the ratio $(R_T - R_0)/R_T$ cannot exceed 1 and R_Q cannot therefore exceed 0. Several of the extrapolated R_{Q0} values (Table I) are numerically greater than zero. Even so, these R_Q values form excellent correlations with the more commonly accepted indices of lipophilicity.

HPLC offers several advantages in the determination of lipophilicity over more conventional approaches, the main ones being speed and analytical sensitivity; these advantages are inherent in the proposed parameter R_Q. Unlike k' (the HPLC term most commonly used to quantiate molecular lipophilicity), R_Q has been found to vary linearly with mobile phase composition

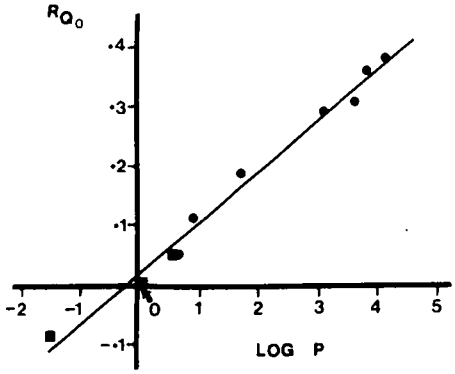

Figure 4—*Plot of* R_{Q0} *against log P for various barbiturates taken from the literature (●) or determined experimentally (■). Straight line is the line of best fit using the 10 literature log P values. See Table I for key to the numbers.*

in all cases examined. This linear correlation allows interpolation and some extrapolation from empirically determined R_Q values to values at any selected mobile phase composition. At a minimum, R_Q values need only be empirically determined at two differing mobile phase compositions to obtain any desired value of R_Q. From a practical viewpoint, we feel that as many empirically determined R_Q values as possible should be used, from solute retention data where R_T falls within the range of $1.5\text{–}15 \times R_0$. R_Q thus provides a rapidly determined index of lipophilicity which can be applied to compounds of widely ranging lipophilic character.

Agglutination Kinetics of Enzymatically Treated Normal and Diabetic Rat Hepatocytes

ANWAR B. BIKHAZI *x and LUTFIYYEH H. TURYAKI

Received April 6, 1982, from the *Department of Physiology, Faculty of Medicine, American University of Beirut, Beirut, Lebanon.* Accepted for publication January 13, 1983. *Present address: Department of Physiology, Faculty of Medicine, c/o Office of the American University of Beirut, 850 Third Ave., New York, NY 10022.

Abstract □ The effect of trypsin and neuraminidase treatments on concanavalin A-induced agglutination of viable hepatocytes from normal and diabetic rats are reported. Trypsin (1.0 μg/mL) treatment resulted in an increased rate of hepatocyte agglutination in both normal and diabetic cells in the presence of 100 μg/mL of concanavalin A. However, neuraminidase treatment resulted in a decrease in the rate of cytoagglutination in the normal cells and an increase in the rate in the diabetic counterpart. The results suggest that trypsin may have caused the removal of a surface protein and/or split a peptide bond on the agglutinin receptors resulting in identical receptor exposure and clustering in normal and diabetic cells. The neuraminidase data suggest that the arrangements of the neuraminic acid moieties on the receptors in normal cell membranes were different from those in the diabetic cells, eliminating the possible effect of changes in the surface charge density. In conclusion, normal cells carry numerous clustered (possibly some in the "cryptic" state) agglutinin receptors in the cell membrane as compared with cells from diabetic rats.

Keyphrases □ Agglutination—kinetics of enzymatically treated normal and diabetic rat hepatocytes, trypsin, neuraminidase □ Trypsin—agglutination kinetics of enzymatically treated normal and diabetic rat hepatocytes, neuraminidase □ Kinetics—agglutination of enzymatically treated normal and diabetic rat hepatocytes, trypsin, neuraminidase □ Neuraminidase—agglutination kinetics of enzymatically treated normal and diabetic rat hepatocytes, trypsin

The cell surface is considered to be an attractive target for the binding of proteins like lectins. The carbohydrate-binding specificity of the lectin concanavalin A has been useful in the detection, characterization, and study of membrane alterations and cytodifferentiations in cell surface membranes (1–5). Studies on the pretreatment of normal and transformed cells with proteolytic enzymes, neuraminidase, β-galactosidase, phospholipases, and other enzymes prior to agglutination have elucidated the mode and extent of cell membrane transformations (6–9).

Recently, it was reported (10) that rat hepatocytes dispersed by collagenase perfusion were highly agglutinable by concanavalin A. Furthermore, agglutination was twice as fast in normal cells as compared with cells obtained from streptozocin-treated diabetic rats. This manuscript reports cytoagglutination studies with concanavalin A after pretreating the normal and diabetic hepatocytes with trypsin and neuraminidase.

EXPERIMENTAL

Preparation of Rat Hepatocytes—Dispersed liver parenchymal cells were isolated and tested for viability by the procedure of Bikhazi *et al.* (10, 11). The trypan blue exclusion test for cellular viability was routinely performed before and after the experiments, and preparations showing ≥90% viable cells were used.

The metabolic state of the hepatocytes during the incubation period was examined by following the respiration rate of cell suspensions in several separate experiments. Oxygen tension was recorded continuously with the aid of a biological oxygen monitor. Rates were determined from the slopes of the oxygen tension curves and were calculated in terms of microliters of O_2 per milligram of cell protein. Protein was determined by the biuret reaction, with bovine serum albumin as a standard, using centrifuged cell pellets dissolved in 1 M NaOH to minimize possible interference from medium components.

Preparation of Diabetic Rats—Rats were rendered diabetic by injection with 65 mg/kg iv of streptozocin[1]. The procedure and blood glucose level tests were reported previously by Bikhazi *et al.* (10, 11).

Agglutination of Hepatocytes from Normal and Diabetic Rats—For the control experiments ~9×10^6 hepatocytes were suspended in 225 mL of Ca^{2+}- and Mg^{2+}-free phophate-buffered saline (pH 7.4). Cell counts were recorded kinetically by an automated counter[2] at 0, 5, 10, 20, and 30 min (10, 11).

Treatment with Concanavalin A—Two milliliters of Ca^{2+}- and Mg^{2+}-free phosphate solution containing concanavalin A was added to 225 mL of buffer to obtain a 100-μg/mL solution of the lectin. The hepatocytes were then dispersed in this solution, and cell counts were obtained as described above.

Treatment with Trypsin and/or Neuraminidase—The experiments included treatment of normal or diabetic cells with trypsin or neuraminidase and measuring agglutination in the absence of the lectin. The cells were dispersed in Ca^{2+}- and Mg^{2+}-free buffer solutions containing 0.22, 0.74, or 1.0 μg/mL of trypsin[3]. Treatment was allowed to proceed for 5 min, then cell counts were recorded at 0, 5, 10, 20, and 30 min. For neuraminidase[3] (88 ng/mL), the hepatocytes were treated with the enzyme for 15 min before cell counts were recorded. In another experiment, concanavalin A (100 μg/mL in the suspension) was added after the above treatments to induce agglutination.

Treatment with Neuraminidase, Trypsin, and Concanavalin A—After treating the hepatocytes for 15 min with 88 ng/mL of neuraminidase, trypsin (1.0 μg/mL) was added and the suspension was allowed to mix for 5 min. Concanavalin A was then added and the cytoagglutination was recorded as above.

Treatment with Trypsin, Trypsin Inhibitor, Neuraminidase, and Concanavalin A—Trypsin (1.0 μg/mL) was added to the cell suspension after cell counts were recorded. After 5 min, trypsin inhibitor (1.3 μg/mL) was added to quench the trypsin activity. Neuraminidase (88 ng/mL) was then added, the suspension was stirred for 15 min, and a second cell count recording was obtained. Afterward, concanavalin A (100 μg/mL) was added, and cell counts were recorded at 5, 10, and 20 min.

Data Analysis—The physical model on irreversible agglutination (10, 12) was used in the data analysis and interpretation. The general second-order rate relationship derived by Higuchi *et al.* (13) and further supported by Bikhazi *et al.* (10, 12) was used to describe the agglutination rate. The following equations were used:

$$\frac{1}{H_S} = \frac{1}{H_S^0} + Kt \qquad \text{(Eq. 1)}$$

where:

$$K = \frac{16\gamma K_0 r_S T}{3\eta} \qquad \text{(Eq. 2)}$$

and H_S is the number of hepatocyte singlets at any time t, H_S^0 is the number of singlets at $t = 0$, γ is the sticking probability constant (which measures the stickiness of the cells), K_0 is the Boltzmann constant, r_S is the hepatocyte radius, T is the temperature in degrees Kelvin, and η is the viscosity of the medium (10, 12).

RESULTS

Average Number, Mean Diameter, and Viability of Rat Hepatocytes—The average number of isolated cells per liver was ~1.2×10^8 hepatocytes. The mean hepatocyte diameter was taken as 20 μm (10), and cellular viability was routinely tested using the trypan blue exclusion test. The rate of oxygen production was estimated to be 1.0 μL/mg dry weight/h, which is within the normal range for mammalian cells (11). The protein content of hepatocytes was ~16% of the wet weight, near the value reported for whole liver (11).

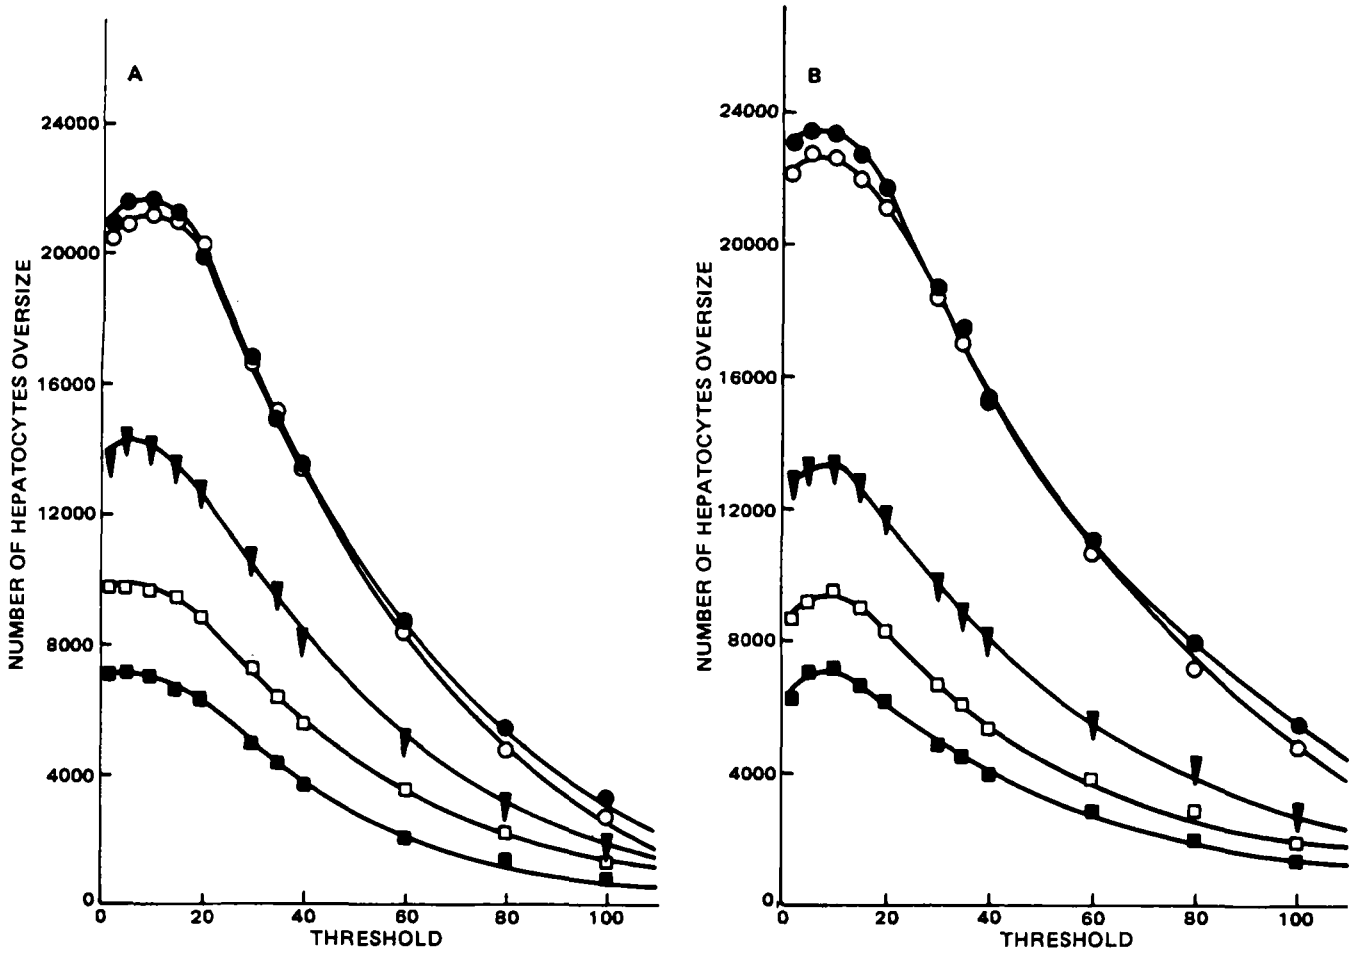

Figure 1—*Representative cumulative size distribution curves for normal (A) and diabetic (B) rat hepatocytes with respect to time in the presence of 1 μg/mL of trypsin and 100 μg/mL of concanavalin A. Key: (●) 0 min, trypsin-treated cells without concanavalin A; (○) 0 min, concanavalin A added after trypsin treatment; (▼) 5 min; (□) 10 min; (■) 20 min.*

Second-Order Rate Plots for Agglutination—The value of H_S (Eq. 1) was estimated from the cumulative size distribution curves as exemplified in Fig. 1. The cell counts (H_S) at threshold 30 (volume 4.2×10^3 μm^3) and at 0, 5, 10, and 20 min were used to draw the linear curves of $1/H_S$ *versus* time (t). All data were treated similarly to Fig. 2, which represents the least-squares line fitted to the experimental data. The slopes of the least-squares lines were estimated, and γ values (Eq. 2) were calculated (10, 12) (Table I).

Hepatocyte Agglutination—Bikhazi *et al.* (10) observed that the agglutination rate of normal cells was double that of diabetic cells in the presence of 100 μg/mL of the lectin. Hepatocytes were not agglutinable after trypsin treatment. Figure 1 represents typical time-dependent cumulative size distribution plots of normal and diabetic cells after treatment with trypsin followed by concanavalin A. The effect of trypsin treatment was obvious when compared with the non-trypsin-treated cells (Table I).

Curves similar to those of Fig. 1 were observed after treatment with trypsin and trypsin inhibitor followed by concanavalin A, except that the rate of agglutination was less than when the inhibitor was absent. These findings suggest that trypsin has no proteolytic action on concanavalin A.

Table I—Sticking Probability Constants for Hepatocyte Agglutination with Concanavalin A after Various Treatments

Treatment[a]	Sticking Probability Constants[b], $\gamma \times 10^7$ cm^{-1}/hepatocyte	
	Normal Cells	Diabetic Cells
Concanavalin A	8.78 ± 0.92 (A)	3.23 ± 0.46 (G)
Trypsin	3.23 ± 0.02 (B)	4.16 ± 0.92 (H)
Neuraminidase	0	0
Trypsin plus concanavalin A	36.05 ± 3.23 (C)	34.20 ± 4.16 (I)
Neuraminidase plus concanavalin A	4.53 ± 0.69 (D)	8.78 ± 0.92 (J)
Trypsin plus trypsin inhibitor plus concanavalin A	13.86 ± 3.70 (E)	9.70 ± 1.84 (K)
Trypsin plus trypsin inhibitor plus neuraminidase plus concanavalin A	7.85 ± 1.85 (F)	13.86 ± 0.46 (L)

[a] Concentrations: concanavalin A, 100 μg/mL; trypsin, 1.0 μg/mL; neuraminidase, 88 ng/mL; trypsin inhibitor, 1.3 μg/mL. [b] Mean ± *SEM*; $n = 6$. Letters in parentheses are codes for statistical analysis. Significant differences: $p < 0.001$ (A,C), (A,G), (B,C), (B,E), (C,E), (G,I), (G,K), (H,I), (K,L), (G,J); $0.001 < p < 0.01$ (E,F), (J,L); $0.01 < p < 0.02$ (F,L), (H,K); $0.02 < p < 0.05$ (A,E), (E,K); $0.05 < p < 0.1$ (B,H); $0.1 < p < 0.2$ (A,D), (D,J). No other combinations showed statistical differences.

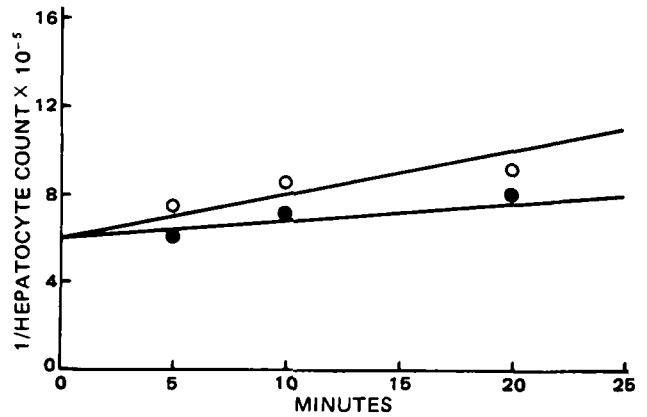

Figure 2—*Representative second-order plot of diabetic rat hepatocyte agglutination, 1/hepatocyte count* versus *time. Straight lines are least-squares fit to the experimental data in the presence of 88 ng/mL of neuraminidase and 100 μg/mL of concanavalin A. Key: (●) 100 μg/mL of concanavalin A; (○) 88 ng/mL of neuraminidase plus 100 μg/mL of concanavalin A.*

No agglutination was seen after neuraminidase treatment. Table I shows that there was no effect of neuraminidase treatment on concanavalin A-induced agglutination in normal cells, but a drastic increase in cytoagglutination was observed in diabetic cells.

Neuraminidase treatment after trypsin treatment caused a marked decrease of γ in normal cells, while the reverse was true for diabetic cells (Table I). After treatment with both enzymes, the agglutination rate of normal cells remained the same as those of the untreated cells. However, diabetic hepatocytes showed an increase in the agglutination rate after trypsin treatment followed by the neuraminidase effect. This was also observed for the neuraminidase *versus* the trypsin-neuraminidase results.

DISCUSSION

A number of postulations have been reported in the literature on the effect of proteolytic enzymes on normal and transformed cell agglutination induced by lectins. These include the exposure of cryptic receptors (14, 15), clustering of receptors (16–18), and changes in surface morphology characterized by a reduction (19) or increase in surface microvilli (20, 21).

In the absence of trypsin inhibitor, the proteolytic effect of trypsin continued throughout the course of the experiments, suggesting that the 5-min enzymatic treatment was not sufficient for complete receptor exposure and/or rearrangement. The agglutination rates of both cell types with concanavalin A after trypsin treatment (with and without inhibitor) were almost the same. Therefore, the proteolytic action of trypsin may have caused the removal of a surface protein and/or split a peptide bond on the agglutinin receptors, which could result in identical exposure and clustering (rearrangements) of the receptors in normal and diabetic cells.

Neuraminidase is an enzyme which normally hydrolyzes peripheral *n*-acetylneuraminic (sialic) acids. After hydrolysis, the removal of the surface sialic acid could cause a reduction in the net negative surface charge of the cells thus reducing the forces of repulsion between adjacent cells, favoring cytoagglutination (22). The results presented in Table I indicated cytodispersion and repulsion rather than agglutination after normal cells were treated with neuraminidase. It is, therefore, possible that the hydrolysis of the neuraminic acid moieties (the target moieties for concanavalin A-induced agglutination) on the glycoprotein receptors actually took place. However, in the case of diabetic cells, the opposite effect was observed. Therefore, in normal hepatocytes, the arrangements of the neuraminic acid moieties on the glycoprotein receptors seemed to be different from those in the diabetic cell membranes. The surface charge density may not be a factor since after neuraminidase treatment and in the absence of concanavalin A, agglutination was not observed (Table I).

The pretreatment of normal cells first with trypsin and then neuraminidase had no effect on the rate of concanavalin A-induced hepatocyte agglutination (Table I). This was contrary to diabetic cells, where the rate of agglutination drastically increased after consecutive treatment with both enzymes. The data suggest that normal cells (as compared with diabetic cells) carry clustered agglutinin receptors, some of which may be in the "cryptic" state. Trypsin normally causes increased receptor mobility and further exposure of the "cryptic" receptors. In the presence of both trypsin and neuraminidase, agglutination of the diabetic cells was maximal.

Effect of Sulfaphenazole on Tolbutamide Distribution in Rabbits: Analysis of Interspecies Differences in Tissue Distribution of Tolbutamide

OSAMU SUGITA, YASUFUMI SAWADA, YUICHI SUGIYAMA, TATSUJI IGA[x], and MANABU HANANO

Received October 4, 1982 from the *University of Tokyo, Faculty of Pharmaceutical Sciences, Department of Pharmaceutics, 3-1, 7-Chome, Hongo, Bunkyo-ku, Tokyo 113, Japan.* Accepted for publication April 5, 1983.

Abstract □ The effect of sulfaphenazole on the distribution of tolbutamide was examined by comparing the change in the steady-state volume of distribution (Vd_{ss}) determined from *in vivo* plasma elimination with the tissue-to-plasma concentration ratio of various tissues (K_p) in rabbits; this effect was compared with that previously reported in rats. In rabbits, the K_p values of six tissues studied (*i.e.*, brain, heart, spleen, small intestine, muscle, and skin) increased in the presence of sulfaphenazole; except for brain, lung, and adipose tissue, the tissue-to-plasma unbound concentration ratio ($K_{p,f}$) of other tissues did show a significant decrease. This suggested that both the tissue and plasma protein binding of tolbutamide were affected by sulfaphenazole and that the increase in K_p was due mainly to the displacement of plasma protein binding of tolbutamide by sulfaphenazole, which was greater than that of tissue binding, while no change in K_p was due to a parallel change in both the plasma protein binding and tissue binding of tolbutamide. In both rabbits and rats, the Vd_{ss} calculated from plasma concentration *versus* time curve was very close to that calculated from the K_p values and volumes of various tissues in the presence and absence of sulfaphenazole, respectively. The interspecies difference of the effect of sulfaphenazole on the tissue distribution of tolbutamide between rabbits and rats was elucidated from both *in vivo* tissue distribution and *in vitro* plasma protein binding studies.

Keyphrases: □ Sulfaphenazole—effect on tissue distribution of tolbutamide, rabbits, interspecies comparison □ Tolbutamide—tissue distribution in rabbits, effect of sulfaphenazole, interspecies comparison □ Tissue distribution—tolbutamide in rabbits, effect of sulfaphenazole, interspecies comparison

In previous papers (1, 2) a blood flow rate-limited pharmacokinetic model was developed to study the effect of sulfonamide on the plasma elimination and tissue distribution of tolbutamide in rats. The tissue-to-plasma concentration ratio (K_p) of all tissues studied increased in the presence of sulfaphenazole, but the tissue-to-plasma unbound concentration ratio ($K_{p,f}$) did not show a significant alteration. This suggested that the tissue binding of tolbutamide is not affected by sulfaphenazole and that the increase of K_p is due mainly to the displacement of plasma protein binding of tolbutamide by sulfaphenazole. The purpose of this study was to investigate an interspecies difference in the effect of sulfaphenazole on the tissue distribution of tolbutamide in rabbits and rats, and to determine whether this finding would encompass other species.

EXPERIMENTAL

Sodium tolbutamide[1] and sulfaphenazole[2] were used. [^{14}C-carbonyl]tolbutamide[3] (48.09 mCi/mmol), which was found to be ≥98–99% pure by TLC, was used as the radioactive compound. All other reagents were commercially available and analytical grade.

Animal Experiments—Adult male albino rabbits[4], weighing 2.6–2.9 kg, were used. Under light ether anesthesia, the femoral vein and artery were cannulated with polyethylene tubing[5]. Cannulated rabbits were kept in a supine position on restraining plates. After a loading dose of 53.6 mg of sulfaphenazole/kg, 57.1 mg/kg/h was infused through the femoral vein cannula for 8 h with a constant-rate infusion pump[6]; with this dosage, steady-state concentrations of sulfaphenazole (153.3 ± 3.5 μg/mL, n = 4) and N^4-acetyl sulfaphenazole (201.7 ± 9.6 μg/mL, n = 3) were obtained at 2 h after the initiation of infusion, as reported previously (3). The rabbits were then given 80 mg/kg of tolbutamide containing 3.33 μCi/kg of [^{14}C]tolbutamide in physiological saline through the other femoral vein cannula. The control rabbits were given physiological saline instead of sulfaphenazole. The body temperature was kept at 37°C by a heat lamp.

After removal of arterial blood samples, the animals were sacrificed 6 h after tolbutamide administration by an injection of saturated potassium chloride solution into the carotid artery. The brain, heart, lung, liver, kidney, spleen, pancreas, small intestine, adipose tissue (around the kidneys and bladder), muscle (abdominal), and skin (dorsal) were quickly excised, rinsed well with cold saline, blotted, and weighed. The wet weights of these tissues were not altered in the presence of sulfaphenazole. All tissues and plasma were stored at −20°C until assayed.

The separation of the metabolites from tolbutamide was carried out according to Shibasaki *et al.* (4) as described in a previous paper (2). With this method, unchanged tolbutamide could be separated from its metabolites, *i.e.*, hydroxy- and carboxytolbutamides (4). Briefly, tissue samples except for skin were homogenized[7] with a threefold excess volume of 0.5 M phosphate buffer (pH 5.0). Four milliliters of each homogenate or 50 μL of the plasma was shaken for 30 min and then extracted twice with 6 mL of *n*-heptane–chloroform (4:1 v/v). The extracts were combined and shaken with 1 mL of 0.5 M NaOH for 15 min, and the aqueous phase was used for the determination of tolbutamide. The concentration of ^{14}C-labeled tolbutamide was determined[8] after addition of a 0.5 mL of 0.5 M HCl and 10 mL of scintillation fluid[9].

The skin was oxidized to $^{14}CO_2$ in a sample oxidizer[10], and then the radioactivity was determined as described before. The value of the plasma free fraction of rats was obtained from a previous paper (2), but that of rabbits was determined by an ultrafiltration method at 37°C as reported previously (1, 3).

Statistical Analysis—All means are presented with their standard error (mean ± SE). Statistical analysis was performed using the Student's t test, with p = 0.05 as the minimal level of significance.

RESULTS

The tissue-to-plasma concentration ratios (K_p) in rabbits 6 h after intravenous bolus administration of tolbutamide in the presence and absence of sulfaphenazole are listed in Table I. In the presence of sulfaphenazole, the K_p values of six tissues, *i.e.*, brain, heart, spleen, small intestine, muscle, and skin, increased significantly. The relationships between the K_p values in the presence and those in the absence of sulfaphenazole are shown in Fig. 1a and are compared with that of rats (Fig. 1b), which were reported previously (2). The plasma free fractions (f_p) of tolbutamide in the absence and presence of sulfaphenazole are listed in Table II. The f_p increased significantly in the presence of sulfaphenazole. The tissue-to-plasma unbound concentration ratios ($K_{p,f}$) were calculated by the following equation and are also listed in Table II:

$$K_{p,f} = \frac{K_p}{f_p} \qquad \text{(Eq. 1)}$$

Significant decreases in $K_{p,f}$ were shown in the heart, liver, kidney, spleen,

pancreas, small intestine, muscle, and skin of the sulfaphenazole-treated rabbits, but there did not appear to be significant changes in the brain, lung, and adipose tissues. The relationships between the $K_{p,f}$ values in the presence and those in the absence of sulfaphenazole are shown in Fig. 2a, and are compared with those of rats (Fig. 2b) as reported previously (2).

The volume of distribution at steady state (Vd_{ss}) calculated by Eq. 5 in the *Appendix* and that based on the unbound drug except for the blood space ($Vd_{T,f}$) calculated by Eq. 7 in the *Appendix I* are listed in Table III along with those for rats, which were calculated from the data reported previously (2). In both the sulfaphenazole-treated rabbits and rats, a significant increase was observed in $\overline{Vd}_{ss}$, whereas in $\overline{Vd}_{T,f}$ a significant decrease was observed only in rabbits. The extent of decrease in $Vd_{T,f}$ for rabbits in the presence of sulfaphenazole was smaller than that of the bound fraction ($1 - f_p$) calculated by f_p in Table II. Using the values of K_p, $K_{p,f}$, and volumes of various tissues listed in Tables I, II, and IV, the Vd_{ss} and $Vd_{T,f}$ were calculated by Eqs. 8 and 10 from the *Appendix I*, respectively, and are listed in Table III with those of rats, which were calculated from the data reported previously (2). The Vd_{ss} significantly increased in the presence of sulfaphenazole in rabbits as well as in rats. A significant decrease in $Vd_{T,f}$ was shown in rabbits in the presence of sulfaphenazole, but in rats no alteration was shown. The extent of changes in $\overline{Vd}_{ss}$ and $\overline{Vd}_{T,f}$ calculated by Eqs. 5 and 7 in the *Appendix I* was comparable with that of those parameters (Vd_{ss} and $Vd_{T,f}$) calculated by Eqs. 8 and 10 in the *Appendix I*, respectively.

DISCUSSION

When metabolism is the rate-determining step of plasma drug elimination (1, 3), the Vd_{ss} can be expressed as follows (10) (see *Appendix I*):

$$Vd_{ss} = \frac{V_B}{s} + \sum_j K_{p_j} \cdot V_j = \frac{V_B}{s} + \sum_j f_p \cdot K_{p,f_j} \cdot V_j \qquad \text{(Eq. 2)}$$

Previously, the effects of sulfaphenazole on the plasma free fraction and intrinsic clearance of tolbutamide in rats (2) and rabbits (3) have been reported. The plasma protein binding showed a nonlinearity and was decreased in the presence of sulfaphenazole in both animals. But little has been reported for the effect of sulfaphenazole on the tissue distribution of tolbutamide (1).

Although the K_p values for many tissues studied in the presence of sulfaphenazole significantly increased in rabbits, the $K_{p,f}$ values calculated by Eq. 1 showed a significant decrease. From these findings, it was suggested that the tissue binding of tolbutamide in rabbits may depend on the plasma tolbutamide concentration or may be decreased in the presence of sulfaphenazole or N^4-acetylsulfaphenazole. The increase in Vd_{ss} (1.2-fold of that for the control rabbits) might be explained by a simultaneous decrease in the plasma protein binding of tolbutamide (0.45-fold of that for the control; Table II) and in the tissue binding (0.53-fold of that for the control; Table III). The decrease in the tissue binding of tolbutamide can be seen in the decrease in $Vd_{T,f}$ (Table III).

In sheep, Thiessen and Rowland (5) reported that although the plasma free fraction of tolbutamide increased, the distribution volume did not show an alteration in the presence of sulfadimethoxine. Accordingly, in sheep a parallel change in both the plasma protein binding and the tissue binding of tolbutamide might minimize any change in Vd as a function of the plasma free fraction. However, in rats, although the K_p values for most of the tissues

Table I—Tissue-to-Plasma Concentration Ratios (K_p) of Tolbutamide in Rabbits [a]

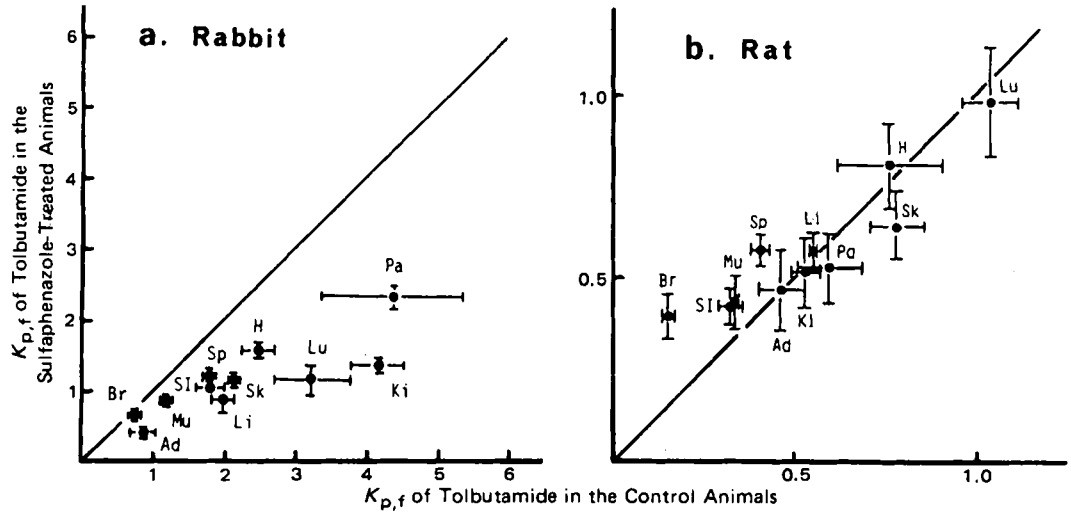

Figure 2—*Relationship between the tissue-to-plasma unbound concentration ratios ($K_{p,f}$) of tolbutamide in the presence and absence of sulfaphenazole in rabbits (a) and rats (b). Abbreviations are the same as those in Fig. 1. The data for rats were obtained from a previous paper (2). The line shows that of unity (slope = 1).*

studied in the presence of sulfaphenazole and at a higher steady-state concentration of tolbutamide than that of the control, significantly increased, the $K_{p,f}$ values calculated by Eq. 1 did not show an alteration (Figs. 1b and 2b). Consequently, the tissue binding of tolbutamide may not depend on the plasma tolbutamide concentration and may not be decreased in the presence of sulfaphenazole, whereas the plasma protein binding of tolbutamide showed a nonlinearity and was decreased in the presence of sulfaphenazole (2). From these findings, it was suggested that in rats the increase in K_p might be explained mainly by an alteration of the plasma protein binding of tolbutamide.

The difference in the effect of sulfaphenazole on the tissue distribution of tolbutamide between rats and rabbits may be due to the presence of a higher concentration of N^4-acetylsulfaphenazole in rabbits than in rats. As previously reported, the displacement of thiopental by sulfadimethoxine was not revealed in the tissue binding using rat muscle, liver, and adipose tissue homogenates (6). Moreover, the tissue binding of tolbutamide was not significantly influenced by phenylbutazone using rabbit muscle homogenates (7). Wardell (8) also reported that phenylbutazone did not affect significantly the tissue binding of sulfadimethoxine using rat muscle, liver, and kidney homogenates. Consequently, the increase in Vd_{ss} of tolbutamide in rats in the presence of sulfaphenazole might be explained by the unchanged tissue binding of tolbutamide and the increase in the plasma free fraction of tolbutamide, caused by the displacement of the plasma tolbutamide binding by sulfaphenazole. As shown in Table IV, the difference between $\overline{Vd}_{ss}$ and Vd_{ss}, calculated by Eqs. 5 and 8, respectively, in both the control rabbits and rats may result from the nonlinearity of the plasma protein binding (2, 3), since the plasma concentration of tolbutamide 6 h after intravenous bolus administration was lower than the *in vivo* mean plasma concentration for 6 h (see footnote in Table III). On the other hand, the close agreement between $\overline{Vd}_{ss}$ and Vd_{ss} in the presence of sulfaphenazole may be due to the linearity of the plasma protein binding of tolbutamide, which was observed only in the presence of sulfaphenazole (2, 3).

In rabbits, the $K_{p,f}$ values were greater than unity in most of the tissues studied (Fig. 2 and Table II) and were different from those of rats, which were not greater than unity in all tissues (1). The comparison of $Vd_{T,f}$ and f_p among rabbits, rats, sheep, and humans is summarized in Table V. It was shown that the distribution of tolbutamide to the tissues was approximately two times higher in rabbits and sheep than that in humans and rats. A remarkable interspecies difference was also shown in f_p between humans and rats, whereas only a small difference was shown in the tissue distribution of tolbutamide between the two species. This suggests the possibility of the animal scale-up from rats to humans for the prediction of Vd of humans using the data of the tissue distribution of tolbutamide obtained in the rat study.

In the present study, the interspecies difference of the tissue distribution of tolbutamide between rabbits and rats was demonstrated from both the *in vivo* tissue distribution and *in vitro* plasma protein binding.

APPENDIX I: Calculation of the Volume of Distribution

The volume of distribution at steady state (Vd_{ss}) is given by:

$$Vd_{ss} = Vd_B + Vd_T \qquad \text{(Eq. 3)}$$

The volume of distribution for the blood space (Vd_B) can be expressed by:

$$Vd_B = \frac{V_B \cdot C_B}{C_p} = \frac{V_B}{s} \qquad \text{(Eq. 4)}$$

The Vd_{ss} is calculated by two methods as follows:

Method 1—The Vd_{ss} calculated by plasma concentration *versus* time curve ($\overline{Vd}_{ss}$) is given by (9):

$$\overline{Vd}_{ss} = \frac{\text{Dose} \cdot \text{AUMC}}{(\text{AUC})^2} \qquad \text{(Eq. 5)}$$

From Eq. 3 (10), the following equation is obtained:

$$\overline{Vd}_T = \overline{Vd}_{ss} - Vd_B = f_p \cdot \overline{Vd}_{T,f} \qquad \text{(Eq. 6)}$$

Table III—Effect of Sulfaphenazole on Volume of Distribution of Tolbutamide [a]

Animal	Volume of Distribution, mL/kg	Control, $n = 4$	Sulfaphenazole, $n = 3$
Rabbit	$\overline{Vd}_{ss}$ [b]	222.84 ± 1.89	268.90 ± 13.97[f]
	$Vd_{T,f}$ [c]	1336.54 ± 14.88	703.42 ± 46.72[f]
	Vd_{ss} [d]	152.19 ± 4.91	237.41 ± 3.82[f]
	$Vd_{T,f}$ [e]	1061.01 ± 74.68	656.00 ± 13.23[f]
Rat	$\overline{Vd}_{ss}$ [b]	216.76 ± 2.13	297.79 ± 6.46[f]
	$\overline{Vd}_{T,f}$ [c]	597.39 ± 7.95	436.73 ± 11.83
	Vd_{ss} [d]	146.79 ± 3.50	273.89 ± 26.82[f]
	$Vd_{T,f}$ [e]	381.90 ± 13.99	405.59 ± 53.82

[a] Results are given as the mean ± *SE*. [b] Calculated by Eq. 5 in *Appendix I*: Dose·AUMC/(AUC)^2 (9). [c] Calculated by Eq. 7 in *Appendix I*: $(\overline{Vd}_{ss} - V_B/s)/f_p$. The f_p values calculated from the C_f of the *in vivo* mean plasma concentration (C_t) for 360 min were used. The C_t was calculated mathematically by: $C_t = \text{AUC}_{0\ 360\ min}/360$ min. In rabbits, the mean f_p values were 0.127 in the absence and 0.299 in the presence of sulfaphenazole, respectively, while in rats the mean f_p values were 0.286 in the absence and 0.546 in the presence of sulfaphenazole, respectively. [d] Calculated by Eq. 8 of *Appendix I*: $Vd_B + \Sigma K_{p,j} \cdot V_j$ (10). [e] Calculated by Eq. 10 of *Appendix I*: $\Sigma_j K_{p,j} \cdot V_j / f_p$. The f_p values at 360 min after intravenous bolus administration of tolbutamide were used (see Table II). [f] Significantly different ($p < 0.05$) from the control.

Table IV—Volumes of Blood and Tissues in Rabbits and Rats [a]

Tissue	Rabbits, mL/kg	Rats, mL/kg
Blood	73.8[b]	75.4[b]
Gastrointestinal tract[c]	51.5	44.3
Lung	7.3	4.6
Brain	2.6	4.6
Heart	2.6	4.3
Liver	42.8	44.3
Kidney	6.4	7.9
Muscle	500.0[d]	500.0[d]
Skin	100.0	175.0
Adipose tissue	51.5	40.0
Pancreas	0.4	3.6
Spleen	0.4	3.6

[a] Determined experimentally from the wet tissue weight by assuming a density of 1.0, except for muscle and blood volume. [b] The blood volume was calculated according to Bischoff *et al.* (11) as: $V_{plasma} = 44 \times (\text{body weight, kg})^{0.99}$ and $V_{blood} = V_{plasma}/(1 - H_t)$, where H_t is the hematocrit value and was determined to be 0.41 in this study. Body weights used were 2.8 kg for rabbits and 280 g for rats. [c] Includes the stomach, small intestine, and large intestine; the K_p of the small intestine was used to calculate the distribution volume (Vd) of tolbutamide for this tissue. [d] The muscle volume was assumed to be half of the body weight (12).

The volume of distribution based on the measurement of the unbound drug in plasma except for the blood space ($\overline{Vd}_{T,f}$) is given by:

$$\overline{Vd}_{T,f} = \frac{\overline{Vd}_{ss} - V_B/s}{f_p} \quad \text{(Eq. 7)}$$

In this paper, the $\overline{Vd}_{T,f}$ of humans and sheep were calculated by using the data reported previously (4, 12), respectively. The mean value of 1.36 (1.33 for rats and 1.39 for rabbits) was used as the value of s. The V_B was calculated by the equation in footnote b of Table IV.

Method 2—The Vd_{ss} calculated by tissue-to-plasma concentration ratios at 6 h after intravenous administration of tolbutamide is given by the following (10):

$$Vd_{ss} \simeq Vd_B + \sum_j K_{pj} \cdot V_j \quad \text{(Eq. 8)}$$

The subscript j represents all tissues studied. From Eqs. 3 and 8, the following equation is obtained:

$$Vd_T = \sum_j K_{pj} \cdot V_j \quad \text{(Eq. 9)}$$

The volume of distribution based on the measurement of the unbound drug in plasma except for the blood space ($Vd_{T,f}$) is given by:

$$Vd_{T,f} = \sum_j K_{p,f_j} \cdot V_j = \sum_j K_{pj} \cdot V_j/f_p \quad \text{(Eq. 10)}$$

Appendix II: Glossary

Vd_{ss} = volume of distribution at steady state (mL)
Vd_B = total amount of the drug in the blood compartment divided by the concentration of the drug in plasma (mL)
Vd_T = total amount of the drug in all tissue compartments divided by the concentration of the drug in plasma (mL)
$Vd_{T,f}$ = total amount of the drug in all tissue compartments divided by the concentration of the unbound drug in plasma (mL)
K_p = tissue-to-plasma concentration ratio
$K_{p,f}$ = tissue-to-plasma unbound concentration ratio
V_B = blood volume (mL)
V = volume of the tissue (mL)
s = plasma-to-blood concentration ratio
C_p = plasma concentration (μg/mL)
C_B = blood concentration (μg/mL)
AUC = area under the plasma concentration *versus* time curve [μg/(ml·min)]
AUMC = area under the moment curve (μg/[mL·(min)^2])
f_p = plasma free fraction

Table V—Interspecies Difference in the Total Amount of Drug in All Tissue Compartments Divided by the Concentration of the Unbound Drug in Plasma ($Vd_{T,f}$) and the Plasma Free Fraction (f_p)

Species	$Vd_{T,f}$, mL/kg	f_p
Rabbit	1336.5	0.127
Rat	597.4	0.286
Sheep	1341.2[a]	0.146
Human	639.2[b]	0.093

[a] Calculated by Eq. 7 of *Appendix I* using the reported value (5). [b] Calculated by Eq. 7 of *Appendix I* using the reported value (13).

Bioanalyses and Pharmacokinetics of Nafronyl in the Dog

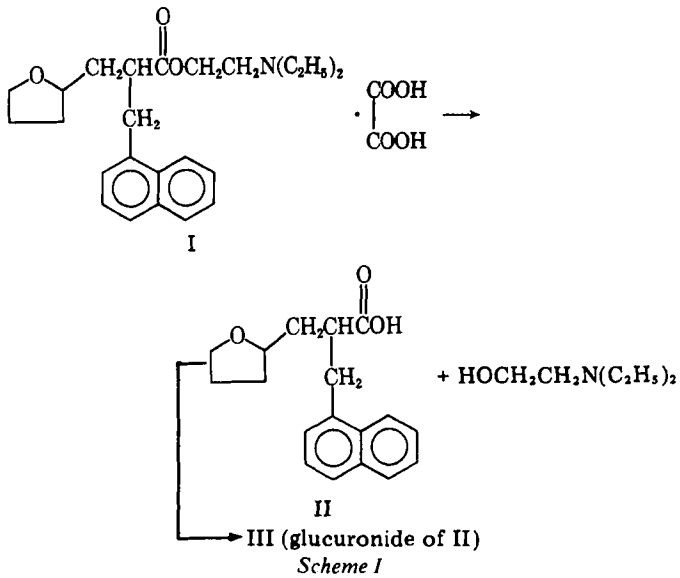
EDWARD R. GARRETT

Received November 24, 1982, from *The Beehive, College of Pharmacy, J. Hillis Miller Health Center, University of Florida, Gainesville, FL 32610.* Accepted for publication January 10, 1983.

Abstract □ Improved specific and sensitive reverse-phase HPLC assays of nafronyl (I) and its acidic metabolite and hydrolysis product (II) in biological fluids were developed with sensitivities of 3–6 ng/mL using fluorometric detection with 225 nm excitation and 330 nm emission wavelengths. There were no significant differences in the stabilities and assays of I and II in plasma obtained using heparin, citrate phosphate dextrose solution, EDTA, citrate, or oxalate as anticoagulant. Inordinately high membrane binding did not permit the quantification of the high plasma protein binding of I by ultrafiltration; its instability precluded the use of equilibrium dialysis. Plasma protein binding of II by ultrafiltration was 76.4% and was not concentration dependent. The apparent red blood cell–plasma partition coefficients for I and II were 2.00 and 0.49, respectively, with almost all anticoagulants; the red blood cell–plasma water partition coefficient for II was 2.08 when corrected for plasma protein binding. Thus, both I and II had erythrocyte binding sites in addition to simple volume partitioning. Only heparin-treated blood gave anomalously low erythrocyte–plasma partition coefficients, indicating that heparin inhibited the partitioning of I and II into red blood cells from plasma water. The total body clearance of nafronyl (I) referenced to total plasma concentration [1295 ± 65(*SEM*) mL/min] was dose independent (35–70-mg range) and showed biphasic plasma half-lives (intravenous) of 12 and 100 min. Only 34% of the nafronyl appears as systemically circulating II in the plasma. Apparent volumes of distribution similarly referenced were 39.8 and 163 L for the central compartment and total body, respectively. Renal clearances referenced to total plasma concentration were 8.3 and 0.18 mL/min for I and II, respectively. The respective total urinary excretions of I, II, and the glucuronide of II (III) were 0.48, 0.021, and 0.32% of the administered intravenous doses. The respective total urinary excretions of I, II, and III for a bile-cannulated dog were 0.005, 0.16, and 0.40%. The total body clearance of intravenously administered II was 225 mL/min, with a renal clearance of 0.057 mL/min referenced to total plasma concentration. The respective total urinary excretions of II and III were 0.027 and 0.44% of the intravenous dose of II. Respective plasma half-lives of II (intravenous) were 2.5, 10.9, and 225 min. The apparent volume of distribution referenced to total plasma concentration was 2.2 L (9.1 L referenced to plasma water concentration). The apparent overall volume of distribution referenced to plasma concentration was 73 L. The bioavailability of nafronyl (I) was 0.3–2.7% of the oral 250-mg dose of I. The bioavailability of II was 10–17% of the oral 250-mg dose of I, indicating high presystemic and/or first-pass metabolism of I and II. Additional metabolites of nafronyl, probably the major ones, could be chromatographically identified and quantified. Their extraction and fluorescent properties indicated that they were hydroxylated naphthalenic compounds containing carboxylic acid groups and their glucuronides. Only one major unconjugated metabolite (IV) was found in significant quantities in plasma. In addition to IV, other organic extractable nonconjugated compounds (V, VI, and VII) appeared in urine and bile. Conjugates of VII were also present in urine and bile.

Keyphrases □ Nafronyl—pharmacokinetics in the dog, HPLC, red blood cell partitioning, plasma protein binding, effect of different anticoagulants, bioavailability □ Pharmacokinetics—nafronyl in the dog, HPLC, red blood cell partitioning, plasma protein binding, effect of different anticoagulants, bioavailability □ Bioavailability—nafronyl in the dog, HPLC, red blood cell partitioning, plasma protein binding, effect of different anticoagulants, pharmacokinetics

The vasodilator and metabolic activator nafronyl [2-diethylamino)ethyl tetrahydro-α-(1-naphthylmethyl)-2-furnpropionate (I) (1, 2) is prepared as the oxalate. Its smooth ıuscle relaxation properties, along with its ability to increase ɔripheral and cerebral blood flow, cerebral ATP concentraɔns, and glucose utilization may have value in the treatment senile brain disease (1–3). Tetrahydro-α-(1-naphthyl-ɔthyl)-2-furanpropionic acid (II), a hydrolysis product of ı (Scheme I), was observed by TLC in the plasma and urine of dogs, humans, and rats (4, 5) administered I, but was not



Scheme I

quantified. The glucuronide of II (III) was also observed in the bile and urine of dogs administered I intramuscularly (4).

Fontaine *et al.* (4) showed prolonged (at least through 5 h, but low, plasma levels of I (3.4–5.1 μg/mL of plasma) after administration of 40 mg/kg im of I to dogs. Detection of I in plasma was 80 ng/mL for three of six dogs at 24 h after intramuscular administration, with maxima of ~5 μg/mL at 1 h by the use of a nonspecific fluorometric assay (6). Minor amounts of the intramuscularly administered dose (0–0.4%) were excreted unchanged into dog urine, half within 6 h. As much as 20% of the dose was still present at the site of intramuscular injection at that time (4).

Bile collected over 12 h from bile-cannulated dogs contained 0.013% of the intramuscular dose of I and contained 0.42% of the injected dose as total I (free and liberated by β-glucuronidase), presumably fluorometrically analyzed; this agreed with the estimates of nafronyl equivalents obtained from measured spectrophotometric absorbance at 224 nm of acid extracts of ether-extracted alkalinized bile (4). The remaining aqueous phase after this extraction was acidified and extracted with ether. These ether extracts, back-extracted into 0.1 M NaOH and assayed spectrophotometrically at 224 nm, accounted for 33% of the dose in nafronyl absorbance equivalents, of which 22% was II, measured by quantifying TLC-separated amounts. After β-glucuronidase hydrolysis, the similarly treated bile accounted for 40% of the dose in nafronyl absorbance equivalents, of which 29% was II (free and liberated by β-glucuronidase). These ether extracts showed at least three identifiable TLC spots in addition to the one assignable to II. The IR chromatograms indicated the presence of both the naphthalenic and carboxyl groups in these metabolites, and two of the three contained phenolic hydroxyls. Since there was an increase in their presence after β-glucuronidase treatment, the glucuronide conjugates of these naphthols must also be metabolites of nafronyl (4).

0022-3549/84/0500-0635$01.00/0
© 1984, American Pharmaceutical Association

After oral administration of 150 mg of nafronyl to a human, plasma levels of I of 720 ng/mL at 1 h and 110 ng/mL at 6 h were claimed (4), and 0.6% of unchanged I was recovered in the urine within 2 d. After administration of 80 mg im of nafronyl to a human, plasma levels of I of 290 ng/mL at 1 h and 550 ng/mL at 3 h were noted, and 1.6% of unchanged I was recovered in the urine within 2 d (4). An apparent terminal plasma half-life of 90 min was observed for I when 100 mg of nafronyl was administered orally to two human subjects (7).

Since the above is the sum total of published studies on nafronyl pharmacokinetics, there is a need for systemically determined pharmacokinetics, disposition, and bioavailabilities. The purpose of this study was to determine the pharmacokinetic parameters of nafronyl after intravenous administration by quantitatively monitoring the time courses of both I and II and their possible conjugates in plasma, urine, and bile as a function of dose in the dog. Selected studies were conducted to estimate the oral bioavailability of nafronyl and to identify possible quantitative methods of monitoring the time courses of as yet unidentified metabolites.

The recent developments of HPLC methods for the bioanalyses of nafronyl (7) and nafronyl plus its derived metabolite, II (8), using UV detection at 224 nm after selective extractions from biological fluids, have provided specific and sensitive assays. These methods have been applied recently to the complete delineation of the solution stability of nafronyl as a function of pH and the optimization of analytical methods (8) in plasma. In this present report, further assay modifications and increased sensitivities with the use of fluorometric detection are given. Since questions had been raised as to the possible effects of different anticoagulants on the stability and assay of nafronyl in plasma, these factors were studied when various anticoagulants were used in blood procurement.

EXPERIMENTAL

Materials—Acetic acid[1], sodium acetate[1], potassium and ammonium oxalate[1], dibasic and monobasic potassium phosphate[1], and volumetric concentrations of sodium hydroxide[2] and hydrochloric acid[2] were all analytical grade. Dichloromethane[3] and acetonitrile[3] were HPLC and UV grade. β-Glucuronidase, purified from *Escherichia coli*[4], (1,344,100 Fishman U/g, 1,816,490 U/g with $CHCl_3$) and beef liver[5] (50 Fishman U/g) were used as received. EDTA was a 2% solution of the disodium salt[6]. Citrate phosphate dextrose solution USP[6] contained 1.61 g of hydrous dextrose USP, 1.66 g of sodium citrate dihydrate USP, 0.19 g of anhydrous citric acid USP, and 0.14 g of sodium biphosphate USP dissolved to 63 mL with water for injection USP. The oxalate anticoagulant solution was 1.2 g of ammonium oxalate and 0.89 g of potassium oxalate in 100 mL of water for injection USP.

The pharmacokinetic studies used sodium chloride injection USP[6], sodium heparin injection USP[7], intravenous delivery system sets[6], evacuated blood collection tubes[8], disposable syringes[9], 5-French urethral catheters[9], three-way stopcocks[10], 16-gauge vein catheters, 14-gauge needles[11], and carbocaine hydrochloride[12]. Pure I and II were used as received[13].

Crystalline butacaine hemisulfate[4] was the internal standard for red blood cell partitioning, protein binding, plasma stability studies, the pharmacokinetic studies of bile-cannulated dog E, and most of the oral studies. Procaine hydrochloride[4] was the internal standard in all other pharmacokinetic studies.

Apparatus—The HPLC system[14] used for plasma stability, red blood cell partitioning, and protein binding studies contained a single pump, an alkyl phenyl column, and a manual injector. The variable-wavelength detector[15] was set at 225 nm, with a strip-chart recorder[16]. The system was modified for analyses in the intravenous pharmacokinetic studies to use a radial-compression module[17], an automatic injector[17], a fluorescence detector[18] with excitation at 225 nm and emission at 330 nm, and an integrator[19]. In the bile-cannulated dog E pharmacokinetic study, a different detector[20] and injector[20] were used.

Liquid Chromatography—*With Haloalkane Extraction (Method A)*—This method was used in the pharmacokinetic studies. Plasma (2 mL) was adjusted to pH 3.5 with 0.35 mL of 0.2 M HCl, vortexed, and extracted with 5.0 mL of dichloromethane with mild shaking. The samples were centrifuged at 3000 rpm for 10 min and 3 mL of the organic phase was evaporated to dryness under a stream of nitrogen. The residue was reconstituted with 0.5 mL of acetonitrile–0.1 M acetate buffer pH 4.0 (80:20) containing 9.8 μg of procaine hydrochloride and 50 μL was injected into the HPLC (for method A1) or the residue was reconstituted with 0.5 mL of acetonitrile–0.1 M acetate buffer, pH 4.2, (10:90) containing 46 μg of butacaine hemisulfate, and 30 μL was injected into the HPLC (for method A2). Undiluted urine (1 mL) was adjusted to pH 3.5 with 0.175 mL of 0.2 M HCl, vortexed, extracted, evaporated, and reconstituted as above.

Method A1—This method was used for all intravenous pharmacokinetic studies except with the bile-cannulated dog study. Assay of I (retention time 5.4 min) used a mobile phase of acetonitrile–0.1 M acetate buffer pH 4.0 (80:20) through a radial cyano cartridge[21], with a flow rate of 3.0 mL/min. The assay of II (retention time 4.8 min) used a mobile phase of acetonitrile–acetate buffer pH 4.5 (50:50) through a radial C_8 cartridge[21], with a flow rate of 2.0 mL/min.

Method A2—In the oral and bile-cannulated dog studies only one system was used for the assay of I and II. A 5-μm C_8 column[22] (12 cm) maintained at 45°C was used, with a mobile phase of acetonitrile–0.05 M acetate buffer pH 4.0, (53:47) with a flow rate of 1.1 mL/min. A 25-μL aliquot of the 0.5-mL reconstituted residue was injected onto the HPLC. Peak area ratios to internal standard were used in all these pharmacokinetic studies for the assays.

Acetonitrile Deproteinization (Method B)—This method was used in the plasma stability, red blood cell partitioning, and protein binding studies. Acetonitrile (1.5 mL) containing 5.0 μg/mL of the internal standard butacaine sulfate was added to a 0.5-mL plasma sample, vortexed at high speed for 20 s, and centrifuged at 3000 rpm for 5 min; 50 μL of the supernatant was injected into the HPLC. The mobile phase of acetonitrile–0.1 M acetate buffer pH 4.5 (50:50) was passed through an alkyl phenyl column at a flow rate of 1.5 mL/min. Peak height ratios to internal standard were used in these *in vitro* studies.

Glucuronide Assay in Urine (Method C)—After extraction of the pH 3.5-adjusted urine with dichloromethane for assay of I and II as in method A1 and checking, in several instances, a second extraction to ascertain complete extraction, the urine samples were hydrolyzed with freshly prepared (100 Sigma or Fishman U/mL) β-glucuronidase (*E. coli*). Phosphate buffer at pH 7.0 (1 mL) and β-glucuronidase solution (0.2 mL) were added to 1 mL of the previously extracted urine. The mixture was incubated at 37.5°C for 30–40 min. An aliquot (1 mL) was adjusted to pH 2.5–3.0 with 0.5 mL of 0.2 M HCl, extracted with dichloromethane, and assayed for the aglycone using method A1. In one study, plasma was treated similarly to determine the presence of a generated aglycone, II. No significant II was found in plasma after β-glucuronidase treatment.

Glucuronide Assay in Urine and Bile in Bile-Cannulated Dog E (Method D)—Plasma and nonhydrolyzed urine and bile were extracted at pH 3.5, and the extracts were assayed by the single-injection HPLC method (method A2) in the bile-cannulated dog E study for the simultaneous determination I and II, using butacaine as the internal standard. The bile and urine were hydrolyzed by β-glucuronidase (*E. coli*) as in method C, except that the samples

were adjusted to pH 2.0 before extraction and the dried extracts were reconstituted in acetonitrile–0.1 M acetate buffer pH 4.2 (10:90) for injection because interfering impurities resulted from the plastic tips of the automatic injector[20] when the acetonitrile concentration was as high as that in the mobile phase (53% acetonitrile). The preextracted bile was also hydrolyzed with 0.2 M NaOH for 30 min at room temperature and adjusted to pH 2 with HCl before extraction and assay by method A2.

Pharmacokinetic Studies in Dogs—The dogs were healthy mongrels weighing 22–26 kg; dog E was female. All were negative for microfilaria. Initial hematocrits ranged between 0.43 and 0.38, with white blood counts of 11,500–15,000 (normal range).

The dogs were fasted for 24 h before each study, and a jugular vein catheter[12] was inserted *via* venipuncture using carbocaine as an anesthetic. The end of the catheter was fitted with the three-way stopcock[10]. The dead volume of the catheter was filled with 0.5 mL of heparinized sodium chloride solution (100 U/mL) to prevent clotting. The dog was placed in a clean metabolism cage overnight. On the day of the study the dog was placed in a dog sling[23] and an intravenous drip of 0.9% NaCl was started to keep the catheter open and to water-load the dog. A 5-French urethral catheter[9] was placed and the dog voided of urine prior to drug administration.

The drug was prepared by dissolving the appropriately weighed amount in 10 mL of isotonic saline. In the metabolite study, the appropriate amount of II was dissolved in 0.1 mL of propylene glycol before adding isotonic sodium bicarbonate to 10 mL. The percentage of propylene glycol was 0.67%.

Blood (60 mL) was drawn before drug injection for use in the plasma calibration curves. The drug solution (10 mL) was injected *via* the jugular catheter, and the stopcock and the catheter were flushed with 10 mL of isotonic saline; the time was measured from the end of the flush. For the oral studies, 250 mg of I was dissolved in 20 mL of deionized water. The solution was injected through a plastic feeding tube[9], which had been inserted orally to reach the stomach. It was followed by a 30-mL rinse of deionized water.

The normal time course for sampling in the intravenous pharmacokinetic studies was 2, 4, 6, 9, 12, 15, 20, 25, 30, 40, 50, 60, 70, 80, 90, 110, 150, 180, 240, and 300 min. The catheter and stopcock were filled with 1.0 mL of fresh blood before sampling, which was then discarded. Blood (5 mL) was taken in a syringe and transferred to a heparinized tube. The sample was centrifuged at 3000 rpm for 5 min, and the plasma was extracted immediately for assay of I and II. The red blood cells were handled under sterile conditions, resuspended in isotonic saline, and infused back into the dog after the last urine sample was obtained. The dog was then treated with antibiotics to lower the risk of infection.

Urine samples were collected through the urethral catheter at the following times: 15, 30, 45, 60, 75, 90, 105, 120, 140, 160, 180, 210, 240, 300, and 360 min. The volume and pH were recorded, and the samples were placed in an ice bath. All samples were extracted after the last plasma sample had been obtained and were assayed for I, II, and glucuronide by the methods described previously.

The sampling times were modified for the oral studies. Blood samples were obtained at 10-min intervals up to 200 min and then at 30-min intervals up to 480 min. Urine was collected at 20-min intervals up to 240 min and thereafter at 30-min intervals up to 540 min. Bile was collected at 20-min intervals up to 220 min in the bile-cannulated dog study.

Evaluation of β-Glucuronidase, Acid, and Alkaline Release of Conjugates of the Derived Acid—Biological fluids to be assayed for conjugates of II (*i.e.*, III) were obtained from the nondosed animal and were used to establish calibration curves, with graded amounts of II added to dichloromethane-preextracted fluids prior to the solvolytic and analytical processes. A 1-mL aliquot of urine, plasma, or bile was extracted at pH 3.5 with 5 mL of dichloromethane for 10 min with shaking, the normal process in the assay of nonconjugated I or II. The aspirated aqueous phase was then hydrolyzed at 37.5°C with *E. coli* β-glucuronidase (40 Fishman U/mL) after adjustment to pH 7.0 with phosphate buffer or with beef liver β-glucuronidase (0.016 Fishman U/mL) after adjustment to pH 4.5 with acetate buffer. Finally, the solutions were adjusted to pH 3.5 and extracted with 10 mL of dichloromethane. The organic extract was evaporated under nitrogen and reconstituted in 500 μL of mobile phase, with 50 μL injected for assay by method A1.

Urine samples, taken at different times from dog A (dosed with 70 mg of *nafronyl*), were assayed several times to determine when complete release of the conjugates of II was obtained. Dichloromethane-preextracted urine (1.0 mL) from dog A was mixed 1:1 with 0.1 M NaOH, 0.2 M NaOH, 1 M HCl, and 6 M HCl. After 15 and 30 min at room temperature, the alkaline samples were adjusted to pH 2. The urine samples were extracted with 10 mL of dichloromethane and assayed by method A1 for II.

Nafronyl Stability in Plasma Containing Various Anticoagulants—The stability of nafronyl (I) was investigated in fresh dog plasma prepared with different anticoagulants. The amounts per milliliter of blood were: heparin, 0.5 U; citrate phosphate dextrose solution USP, 0.14 mL; 0.2% EDTA, 0.125 mL; 3.78% sodium citrate, 0.111 mL; and ammonium–potassium oxalate solution, 0.1 mL. Blood (50–80 mL) was withdrawn from the jugular vein using a 16-gauge needle and syringe containing the necessary amount of anticoagulant. The blood was centrifuged for 15 min at 3000 rpm; no hemolysis was observed. Clear plasma (5–17 mL) was transferred into a clean stoppered tube and equilibrated. Nafronyl (I) (0.075–0.27 mg) was added, and the mixture was vortexed 1 min to give final concentrations between 15 and 19 μg/mL. After the addition of plasma to I, a timer was started. Aliquots (0.5 mL) of the mixture were assayed with time by the acetonitrile deproteinization procedure (method B).

Table I—Nafronyl Stabilities in Fresh Dog Plasma Prepared Using Various Anticoagulants [a]

Anticoagulant	$10^3 k$ [b], min^{-1}	$t_{1/2}$, h	Amount Transformed at t_∞, %
Heparin	1.99	5.77	49.3
Citrate phosphate dextrose solution	4.40	2.63	40.7
EDTA	3.68	3.19	38.5
Sodium citrate	3.49	3.31	36.1
Oxalate	3.41	3.33	40.4

[a] All studies, except for heparin at 22°C, were performed at 37.5°C. The concentration of nafronyl was 16 μg/mL. [b] Obtained from the slopes of data plotted in accordance with Eq. 5.

Calibration curves were prepared (0.4–4 μg/mL of injected solution) from stock solutions of I, II, and butacaine dissolved in acetonitrile. In the EDTA, sodium citrate, and oxalate studies, the calibration curves were prepared from the same blank plasma that was used for the stability study, and the injected solutions had the same composition as those injections made in the studies. The plasma used for the calibration curves in the heparin study had been refrigerated overnight. The calibration curve for the citrate phosphate dextrose solution study was prepared from compounds in the mobile phase.

Protein Binding—The protein binding of I and II in the heparinized dog plasma was investigated using a cone[24] filtration technique (9). Fresh whole dog plasma was filtered to obtain the plasma water. Plasma water (1.5 mL) and plasma (1.5 mL) were spiked with 2–16-μg/mL concentrations of I and II. A 0.5-mL aliquot of each was assayed using acetonitrile deproteinization (method B) to determine the initial concentrations. The plasma water was then filtered at 3000 rpm for 20 min, and 0.5 mL of filtrate was assayed. The spiked plasma was then filtered through the same cone used to filter the plasma water, which contained substances at the same concentration.

Red Blood Cell Partitioning—Calibration curves for the assay of I, II, and mixtures of I and II were prepared at 0.2–16 μg/mL in whole blood and plasma obtained by centrifugation from the same blood. Calibration curves were established for mobile phases at 25% of these concentrations, since they were injected without the dilution by acetonitrile needed for deproteinization. The blood samples were obtained with different anticoagulants: heparin, oxalate, citrate phosphate dextrose solution, and 0.2% EDTA in concentrations given previously. The hematocrits (H) of the blood samples were measured and portions centrifuged to recover the plasma. The spiked blood samples were carefully mixed and centrifuged at 3000 rpm for 5 min, and the separated plasma samples were assayed by method B using acetonitrile denaturation. The final hematocrits of the spiked blood samples were corrected for the dilutions made by the addition of the compounds. The corrected hematocrits (H') were 0.83 of those experimentally determined in the blood samples.

The spiked plasma and mobile phase were also assayed by this method. The concentrations per milliliter (C_p) in the separated plasma of spiked blood were ascertained from the calibration curve established for spiked plasma. The amount of drug in the plasma obtained from 1 mL of spiked blood is $A_{P-B} = (1 - H')C_p$. The amount of drug in the red blood cells obtained from 1 mL of spiked blood is $A_{RBC-B} = C_0 - A_{P-B}$, where C_0 is the concentration of spiked drug per milliliter of blood. The concentration of drug in the red blood cells of spiked blood is $C_{RBC} = A_{RBC-B}/H'$. Thus, the apparent red blood cell–plasma partition coefficient is:

$$D' = C_{RBC}/C_p = A_{RBC-B}/H'C_p = \frac{(C_0 - A_{P-B})/H'}{C_p} = \frac{C_0 - (1 - H')C_p}{H'C_p} = \frac{C_0}{H'C_p} - \frac{1 - H'}{H'} \quad \text{(Eq. 1)}$$

An alternate method to calculate the apparent red blood cell–plasma par-

	Mean ± *SEM*		1.2 ± 0.2		0.0 ± 0.1

[a] $D' = C_{RBC}/C_p = R = m/m'$, where m is $\Delta PHR_p/\Delta C_p$ in the plasma concentration curve, $m' = \Delta PHR/\Delta C_0$ in the blood concentration curve, PHR is the peak height ratio of I and II, and H' is the corrected hematocrit of the spiked blood samples. [b] Effected on mixtures of I and II, each 0.4–4.0 μg/mL of blood. [c] Separate studies for I and II.

tition coefficient, D', is based on the HPLC calibration curves, established in spiked plasma or mobile phase, that pass through the origin and conform to:

$$PHR_p = mC_p \qquad \text{(Eq. 2)}$$

where C_p is the spiked concentration in plasma or mobile phase that gives the peak height ratio, PHR_p. Calibration curves for drugs spiked in plasma and mobile phase were superimposable.

Apparent calibration curves were also prepared for the assay of drug in the plasma samples separated from spiked blood of different concentrations, C_0, obtained with different anticoagulants. This conformed to:

$$PHR_p = m'C_0 = m[(1 - H')C_p + H'C_{RBC}] = mC_p \qquad \text{(Eq. 3)}$$

Since $D' = C_{RBC}/C_p$ and $R = m'/m$, this equation can be rearranged to:

$$D' = \frac{1 - R + RH'}{RH'} \qquad \text{(Eq. 4)}$$

for the estimations of D'.

RESULTS AND DISCUSSION

Unless specified all concentrations of I, II, and III are given as equivalent to nafronyl (as the oxalate).

Improvements in Chromatographic Assays—The HPLC assay methods developed herein substantially improved analytical sensitivity for nafronyl (I) and its derived acid metabolite (II) over those published previously (8) for a haloalkane extraction method using 224-nm spectrometric detection, where the standard errors of regression of concentration on peak area or peak height or their ratios to that of a butacaine internal standard were 100–200 ng/mL of plasma. The columns and conditions for these new studies with fluorometric detection (225-nm excitation, 335-nm emission) using method A1 and dichloromethane extraction gave calibration curves in the 0–300-ng/mL range, which indicated analytical sensitivities of 2–15 ng/mL in urine and plasma.

Some examples of linear regression equations with standard errors of the estimates for nafronyl (I) concentrations in plasma (ng/mL) as the oxalate in plasma are: $C \pm 4.0$ ng/mL = (522.6 ± 10.0)PHR − 11.9 ± 3.3, r = 0.99960; $C \pm 6.2$ = (347.0 ± 2.5)PAR + 10.9 ± 3.1, r = 0.99983; $C \pm 5.1$ = (10.27 ± 0.06) PH + 0.60 ± 2.60, r = 0.9991. Some examples of linear regression equations with standard errors of the estimates of II concentrations in plasma (ng/mL) are: $C \pm 3.6$ = (8.56 ± 0.60)PH − 5.8 ± 5.2, r = 0.9952; $C \pm 2.15$ = (4.744 ± 0.072)PA + 8.3 ± 1.6, r = 0.99965. In urine for I: $C \pm 5.6$ = (3.78 ± 0.17)PH − 7.11 ± 5.10, r = 0.9993; $C \pm 6.1$ = (894.0 ± 5.6) PHR − 6.4 ± 2.8, r = 0.99986; $C \pm 7.1$ = (828.9 ± 20.6)PAR − 5.4 ± 9.8, r = 0.9993. In urine for II: $C \pm 0.59$ = (2.363 ± 0.016)PH − 4.6 ± 0.6, r = 0.9979; $C \pm 5.6$ = (3.78 ± 1.71)PH − 7.1 ± 5.1, r = 0.996. Similar values were obtained for II in urine treated with β-glucuronidase for the assay of III.

The different mobile phases and columns selected for the respective assays of I and II in method A1 permitted the assay of I with a respectable retention time of 5.4 min. The faster moving II in this system eluted with large peaks for urine (0–2 min) and plasma components (0–1.5 min). The system for II increased its retention time to 4.74 min, well separated from interferences from plasma. It was difficult to observe any metabolite that had smaller retention times to I and II and would fall within the retention time intervals of interfering plasma and urine components.

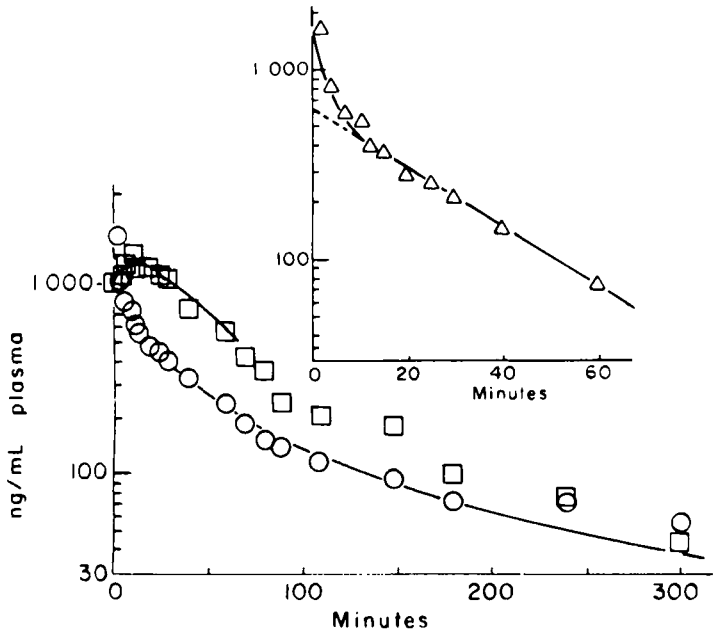

Figure 1—*Plasma concentrations of I (○) and II (□) in equivalents of nafronyl oxalate against time for dog A given a 70-mg iv bolus dose of I. The curve through I was calculated from the sum of exponentials (Eq. 10) using the parameters in Table III. The inset (△) is the feathered data for I with the curve calculated from the first two exponentials. The curve through II was calculated from Eq. 15 using the parameters in Table III.*

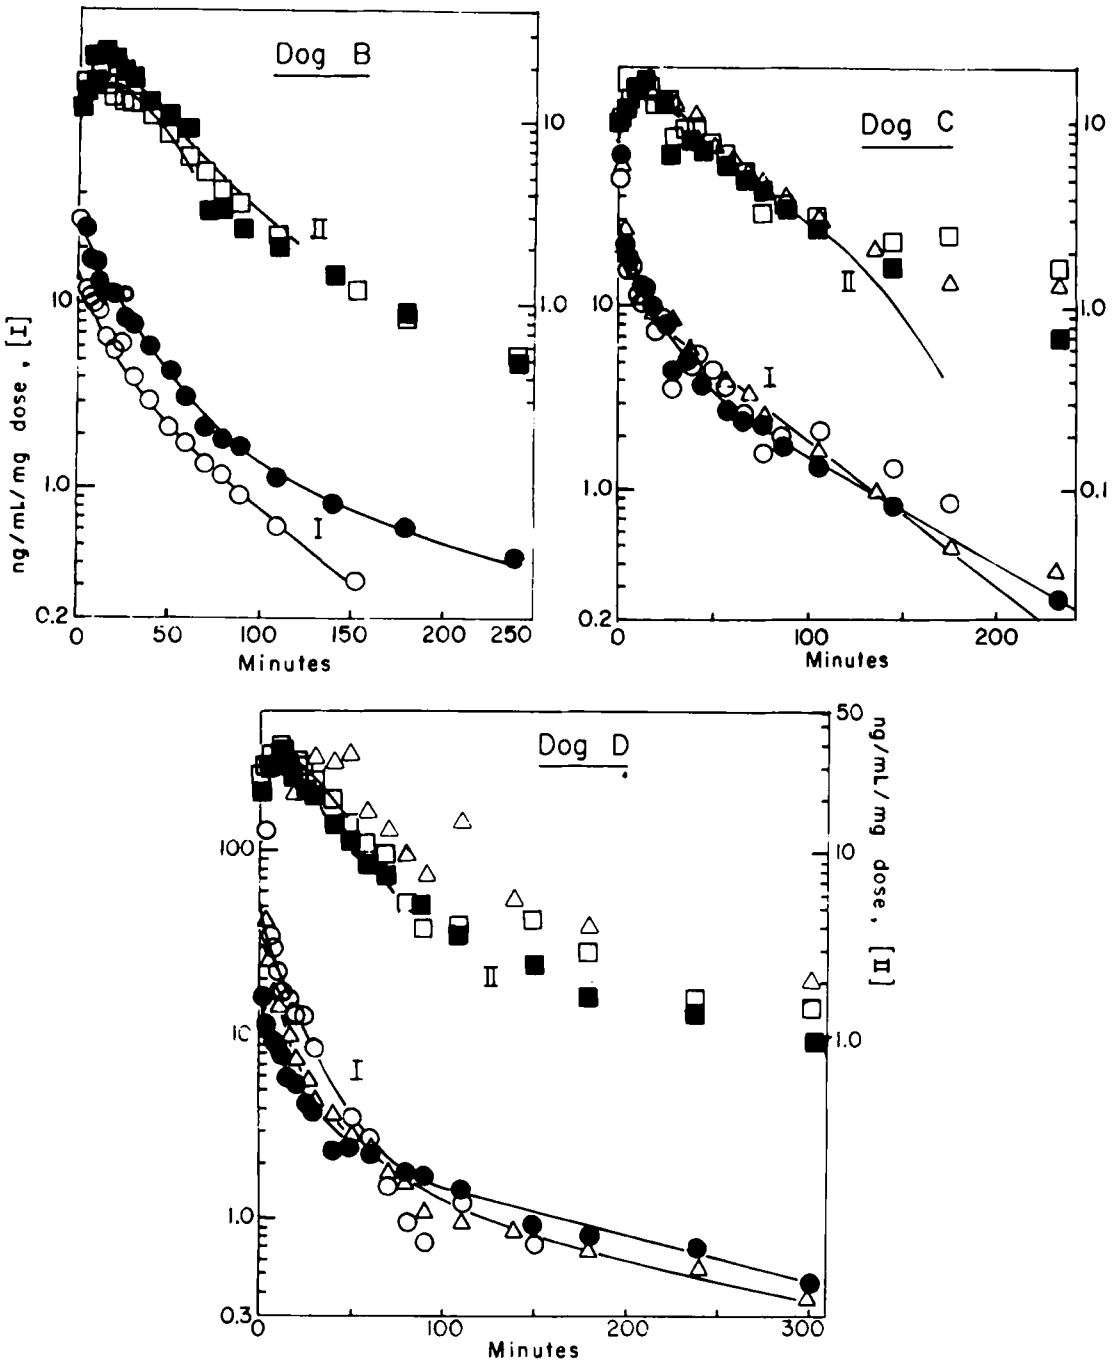

Figure 2 *Plasma concentrations of I and II in equivalents of nafronyl oxalate per milligram of an intravenous dose of I against time for dogs B, C, and D. The curves through I were calculated from the sum of exponentials (Eq. 10) using the parameters in Table III. The curves through II were calculated from Eq. 15 using the parameters in Table III. Key: (○, □) 35 mg; (△) 53 mg; (●, ■) 70 mg.*

Examples of linear regression equations from HPLC method A2 for simultaneous assay of I (10.9 min) and II (3.9 min) with butacaine internal standard (6.1 min) (2.25-nm excitation, 330-nm emission) for plasma are $C_I \pm 21.4$ ng/mL = (51.8 ± 1.4)PA + 4.1 ± 14.7, $r = 0.9940$; $C_I \pm 21.8$ ng/mL = (537.4 ± 14.7)PAR + 4.7 ± 15, $r = 0.9992$; $C_{II} \pm 23$ = (37.6 ± 4.2)PA − 17.9 ± 24, $r = 0.9937$. For urine, they are: $C_{II} \pm 12.5$ ng/mL = (732 ± 40)PAR − 25 ± 10.6; $C_I \pm 8.4$ ng/mL = (70.9 ± 2.6)PA − 23 ± 7. For bile examples are: $C_{II} \pm 18$ ng/mL = (547 ± 44)PAR − 8.5 ± 14.4; $C_{II} \pm 29$ ng/mL = (58.4 ± 7.7)PA − 11.7 ± 23.5. The symbols PH and PA represent peak height and peak area, respectively, whereas PHR and PAR are the respective ratios to the internal standard.

Release of Conjugates of Derived Acid from the Urine of a Nafronyl-Dosed Dog—Preliminary studies of urine samples obtained from dog A treated with *E. coli* β-glucuronidase showed no significant change at 15, 30, and 60 min in the HPLC assay of generated II from dichloromethane-preextracted urine containing III. A similar study with β-glucuronidase (beef liver) showed no significant change in the HPLC assay of generated II at 3, 5.5, and 9 h.

Dichloromethane-preextracted urine (1.0 ml) from a nafronyl-dosed dog was hydrolyzed with 0.1 M NaOH, 0.2 M NaOH, 1 M HCl, and 6 M HCl. Significant peaks for II were observed from the alkaline hydrolyses, but none for the acid hydrolyses. There was a decided NaOH concentration effect. Peak heights of generated II were 19 and 11 mm after 15 and 30 min of hydrolysis, respectively, for 0.1 M NaOH and 40 and 49.5 mm after 15 and 30 min of hydrolysis, respectively, for 0.2 M NaOH. The latter peak height corresponds to 200 ng of II/mL of urine and compared well with the 251 and 192 ng/mL assayed after glucuronidase hydrolyses from bovine and *E. coli* (30 min at 37.5°C) sources, respectively.

Effect of the Use of Different Anticoagulants on the Plasma Stability Studies of Nafronyl—Previous studies of nafronyl stability at 1.25 μg/mL of fresh dog plasma at 24.5°C showed an apparent half-life of 3.2 h for the loss of 50% of nafronyl to II. The remaining 50% of nafronyl appeared to maintain its stability thereafter (see Figs. 10 and 11 in Ref. 8).

[a] As oxalate salt (I). [b] Estimated from best fit of experimental plasma levels, $[I] = A'e^{-\alpha' t} + Ae^{-\alpha t} + Be^{-\beta t}$ in ng/mL *versus* time t. [c] For most studies only the latter two exponentials were needed, *i.e.*, $A' = 0$. However a third exponential was needed in three cases; estimated values of α' in min^{-1} ($t_{1/2}^{\alpha}$ in min) were: dog A 0.371 (1.87); dog D 0.153 (4.52); dog D 0.243 (2.85). [d] Ratio of dose to total area under plasma level of I–time curve, where the calculated $AUC_{\infty}^{I} = A'/\alpha' + A/\alpha + B/\beta$ and that calculated from the trapezoidal rule plus the quotient of the last observed plasma level, p_n, and β were within 2% of each other in all cases. [e] Estimates from slopes of ng excreted renally/min against plasma level in ng/mL at the midtime of the interval of excretion agreed with estimates from the slope of cumulative amounts renally excreted at time t plotted against the area under the plasma level–time curve (AUC_t) at that time in accordance with $\Sigma U = CL_{ren}^{I}$ ($AUC_t - AUC_0$) (see Figs. 3 and 4). [f] Value of AUC at $\Sigma U = 0$ from the best linear plot of prior data in Figs. 3 and 4. [g] Estimated from appropriate plots (Fig. 7) in accordance with $[II]/AUC_I = CL^{I \to II}/V_{II} - (CL^{II \to X}/V_{II})(AUC_{II}/AUC_I)$. [h] Calculated from $\Sigma U_{\infty} = CL_{ren}^{I}$ ($AUC_{\infty} - AUC_0$). [i] Determined by best fit of terminal urine data to $\Sigma U^{III} = \Sigma U_{\infty}^{III} - \Sigma U_{\infty} e^{-kIII t}$. [j] Estimated from the AUC^{II} calculated from the trapezoidal rule plus the quotient of the terminal plasma level of II and the estimated terminal rate constant of 3.08×10^{-3} min^{-1}. $kV_C^I = D/(A' + A + B)$. [k] CL_{tot}^{II}/β. [m] Data were widely scattered at the low level of assay detection; this value is only a crude estimate. [n] Due to equipment failure, urinary amounts could not be assayed. [o] Final urinary amounts excreted were higher than predicted from the best linear fit of $\Sigma U = CL_{ren}^{I}$ ($AUC - AUC_0$). [p] Bile-cannulated female dog. [q] Renal catheter improperly placed in female dog so that urine could not be obtained at timed intervals. [r] Average only for the 70-mg doses of all normal dogs; bile-cannulated dog E excluded. [s] Average excluded 35-mg doses and bile-cannulated dog E. [t] Average excluded outlier value for dog B at 35-mg dose. [u] Average excluded outlier dog C at 53.6-mg dose. [v] Average is 10^{-4} AUC^{II} adjusted for 70-mg dose, *i.e.*, 10^{-4} AUC/70-mg dose; excludes the studies of dog D, which gave values significantly higher with average 10^{-4} AUC adjusted for 70-mg doses at 240 min and at infinity of 16.8 ± 3.0 and 20.4 ± 3.4, respectively. The overall averages, including dog D studies were 10.7 ± 1.5 and 13.0 ± 1.8 at 240 min and at infinity, respectively.

Plots in accordance with:

$$\ln (P_{\infty} - P) = -kt + \ln P_{\infty} \qquad \text{(Eq. 5)}$$

were linear for both I and II and of the same slope, where P_{∞} is the asymptotic peak height or area ratio of nafronyl or II to internal standard with time, P is the peak height or area ratio of I or II at time t, and $t_{1/2} = 0.693/k$. The curves for nafronyl concentration *versus* time in fresh dog plasma were similar in the present studies when different anticoagulants were used. They decreased with decelerating rates to an asymptote, and changes in both I and II concentrations could be characterized by Eq. 5. The data are given in Table I. The use of different anticoagulants has no significant effect on the stability estimates of nafronyl in fresh dog plasma.

There were no interferences in the chromatograms of I and II by any of the anticoagulants used in these studies in the assay range of 0.4–4.0 μg/mL of injected solutions. Calibration curves constructed in plasma obtained from blood samples using the different anticoagulants did not show any significantly different regression statistics. A typical calibration curve by method B in the range of 0.4–4.0 μg/mL using a 50-μl sample of the supernatant from acetonitrile-denatured plasma showed a standard error of estimate for the assay from linear regression of ±43 and ±30 ng/mL for I and II, respectively. Correlation coefficients for six values were >0.9996.

There was no significant difference in the calibration curve statistics of I when materials were injected in the mobile phase or in the supernatant of acetonitrile-denatured plasma. However, II gave a 10% decrease in peak height ratio when injected in the supernatant of acetonitrile-denatured plasma than in mobile phase.

Protein Binding—Filtration (33%) of 2.0–16.0 μg/mL of I in spiked plasma water and plasma subsequently filtered through cones prefiltered with plasma containing the same concentration showed no detectable I in the respective filtrates. This inordinately high cone binding did not permit protein binding estimates of I by this method. Filtration (30%) of 2.0–16.0 μg/mL of II in plasma water gave the same concentrations of II in the filtrate as was in the plasma water, indicating insignificant cone binding of II. When the plasma containing II was filtered through the cone previously used to filter the plasma water, with the same concentration of the fraction bound, f_b, could be calculated from:

$$f_b = \frac{PHR_p - PHR_f}{PHR_p} \qquad \text{(Eq. 6)}$$

where PHR_p and PHR_f were the peak height ratios for the assay of the same volumes of each by method B in the plasma and filtrate, respectively. The respective plasma concentrations (C_p in μg/mL) and fractions bound, f_b, were (C_p, f_b): 16.0, 0.762; 12.0, 0.777; 8.0, 0.751; 4.0, 0.767; and 2.0, and 0.815. If the last datum is excluded, since assay sensitivity was less at this lowest concentration, the average fraction of II bound to plasma protein is 0.764, and no concentration dependence is indicated.

Red Blood Cell–Plasma Partition Coefficients—The red blood cell-plasma partition coefficient D' (Table II) of I was 2.00 when the anticoagulants citrate phosphate dextrose solution, oxalate, and EDTA were used. This indicated a specific binding to erythrocytes in addition to volume partitioning. When the blood samples were heparinized, there was a significant decrease in the partition coefficient to 1.2, indicating a possible competition between I and heparin for these erythrocyte binding sites.

The red blood cell–plasma partition coefficient of II (Table II) averaged 0.49 (excluding one outlier of 1.15) when the anticoagulants citrate phosphate dextrose solution, oxalate, and EDTA were used. If the fraction of II bound to protein, f_b, was taken as 0.764, the true partition coefficient, D, between the concentration in red blood cells, C_{RBC}, and plasma water, C_{PW}, would be 2.08, indicating an erythrocyte binding in addition to volume partitioning. Since:

$$D' = C_{RBC}/C_p = \frac{C_{RBC}}{C_{PB} + C_{PW}} \qquad \text{(Eq. 7)}$$

where C_{PB} is the concentration of II bound to plasma protein, and:

$$1 - f_B = \frac{C_{PW}}{C_{PB} + C_{PW}} \qquad \text{(Eq. 8)}$$

thus:

$$D = \frac{C_{RBC}}{C_{PW}} = D'/(1 - f_b) = 0.49/0.236 = 2.08 \qquad \text{(Eq. 9)}$$

When the blood samples were heparinized, there was an apparent inhibition of the partitioning of II into the red blood cells from plasma.

Plasma Pharmacokinetics and Possible Dose Dependencies— Plasma level–time data for nafronyl (I) were fitted to a sum of exponentials. A typical

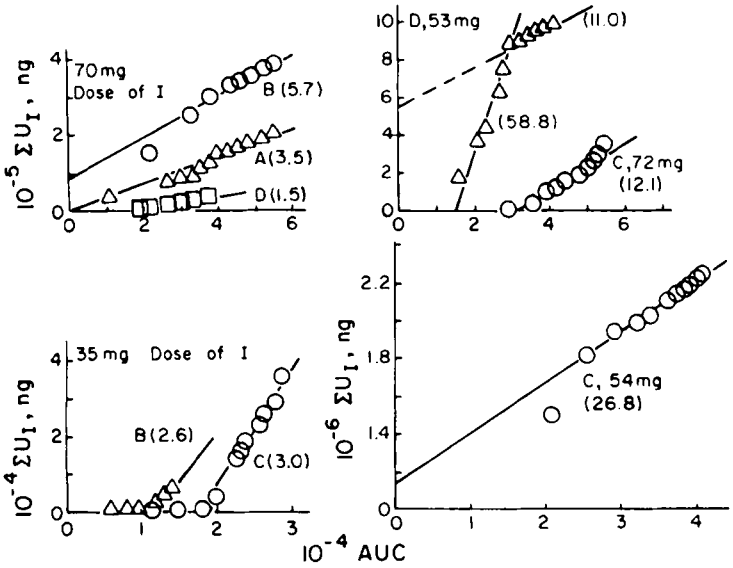

Figure 3—*Renal clearance plots for I in accordance with Eq. 11, where AUC_0^I (ng·min/mL) is the area under the plasma level–time curve from the intercept of the linear plots. The plots are labeled with the dog identification, nafronyl dose, and the estimated CL^I_{ren} values in mL/min (in parentheses).*

example is given in Fig. 1, and the parameters of best fit in accordance with:

$$C(\text{ng/mL}) = A'e^{-\alpha' t} + Ae^{-\alpha t} + Be^{-\beta t} \qquad \text{(Eq. 10)}$$

are listed in Table III for the various studies. In most cases, only two exponentials were needed.

The plasma level–time data for I and its derived acid (II) as ng/mL/mg of the dose of I are plotted semilogarithmically against time for the studies at various doses in dogs B, C, and D (Fig. 2). Such plots of I and II for three different doses were superimposable for dog C, indicating no dose dependency of nafronyl pharmacokinetics. Whereas nafronyl (I) and the acid (II) plasma levels/mg of dose were higher at the 70-mg dose than at the 35-mg dose in dog B, the reverse was observed in dog D. Thus, dose-dependent pharmacokinetics of nafronyl (I) and its derived acid (II) cannot be concluded.

The apparent parallelism, in general, of these semilogarithmic plots of plasma levels against time for the various doses (Fig. 2) indicates that there are insignificant differences in the fitted rate constants (α and β) within a dog, notwithstanding the apparent differences in the best-fit parameters (Table III). The terminal plasma levels at the lower doses have the expected higher errors in their estimation since their levels approach the limits of valid detection. The half-lives of the biphasic curve for nafronyl averaged 12 ± 12 (*SEM*) min for α and 100 ± 18 min for β.

The apparent volumes of distribution references to total plasma concentration of nafronyl averaged 39.8 ± 5.1 (*SEM*) and 163 ± 24 (*SEM*) L for the central compartment and total body, respectively (Table III). These values are in high excess of extracellular and total body water, respectively, indicating a high degree of sequestration in body tissues.

Clearances—Total body clearances of nafronyl (CL^I_{tot} = Dose/AUC_∞) averaged (excluding outlier dog B at the 35-mg dose) 1295 ± 65 (*SEM*) mL/min. The renal clearances of nafronyl (CL^I_{ren}), estimated from both the slopes of plots of the rates of urinary excretion ($\Delta U^I/\Delta t$) against plasma levels at the midpoint of the urinary collection interval ($p_{t\,mid}$) and the slopes of plots of cumulative amounts excreted (ΣU^I) against area under plasma level–time curves (AUC^I), were not significantly different and averaged 8.3 ± 3.0 mL/min, which would indicate a high protein binding if unbound drug was excreted solely by glomerular filtration. These latter plots (Fig. 3) frequently did not go through the origin and could be best characterized by a straight line conforming to the equation:

$$\Sigma U = CL_{ren}(\text{AUC} - \text{AUC}_0) \qquad \text{(Eq. 11)}$$

where AUC_0 is the area under the plasma level–time curve at $\Sigma U = 0$ as estimated from the extrapolation of the best linear plot of ΣU *versus* AUC. The plots for $\Delta U/\Delta t$ *versus* $p_{t\,mid}$ which gave the same estimates of renal clearance, were linear for the lower plasma concentrations and did go through the origin. There were no significant urinary pH changes within a study and no statistical dependence of apparent renal clearance $(\Delta U/\Delta t)/p_{t\,mid}$ on urine flow rate.

A rational explanation for the non-zero intercepts of the linear plots in

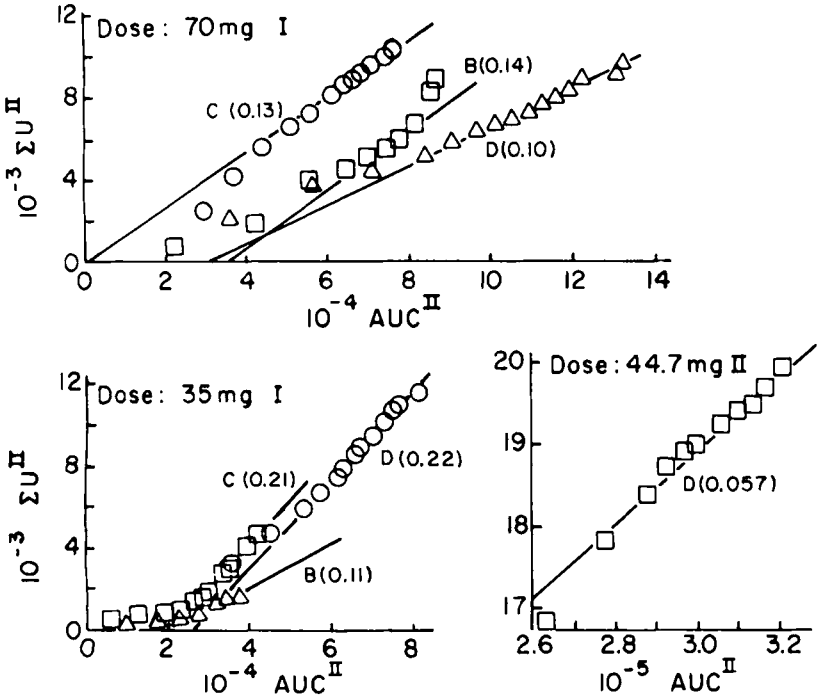

Figure 4—*Renal clearance plots for II (dose equivalent to 74.8 mg of nafronyl oxalate) in accordance with Eq. 11, where AUC_0^{II} is as defined in Fig. 3. The plots are labeled with the dog identification, dose, and the estimated CL^{II}_{ren} values in mL/min (in parentheses).*

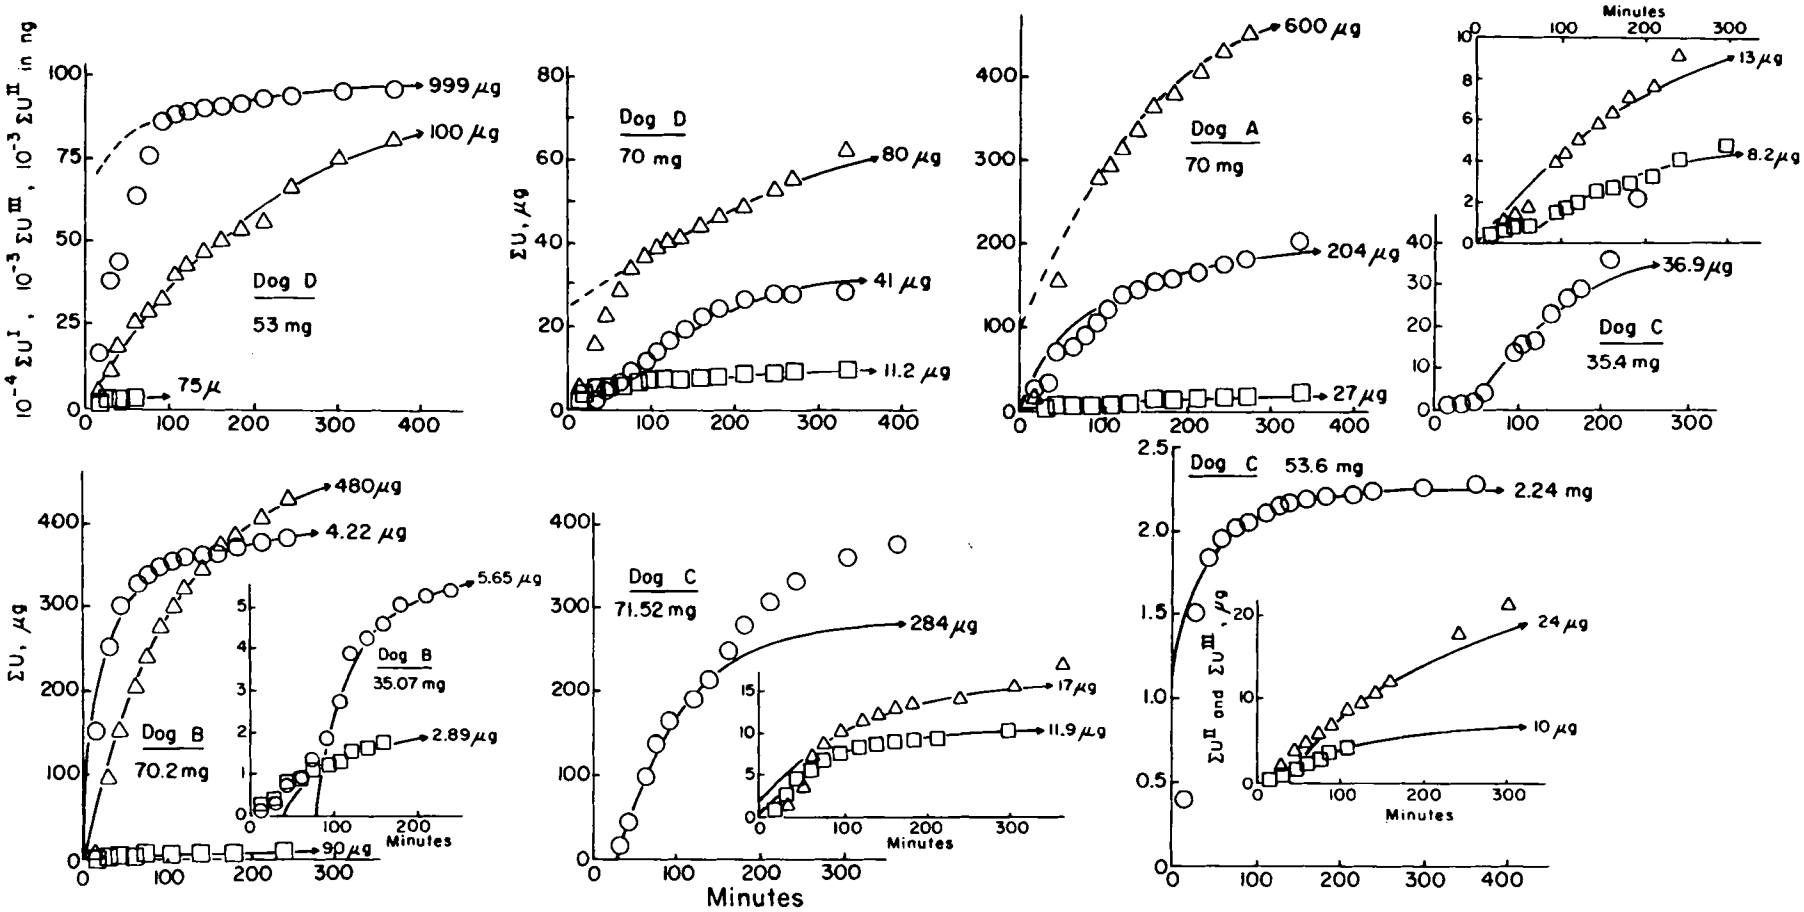

Figure 5—*Cumulative amounts of I (○), II (□) and the glucuronide III (△) excreted into the urine after intravenous administration of a labeled dose of I. The curves through the data for I and II were calculated from* $\Sigma U = CL_{ren}(AUC - AUC_0)$ *for the parameters in Table III. The curves through III were calculated from* $\Sigma U^{III} = \Sigma U_\infty - \Sigma U'^{III}_\infty e^{-k_{III}t}$ *using the parameters in Table III.*

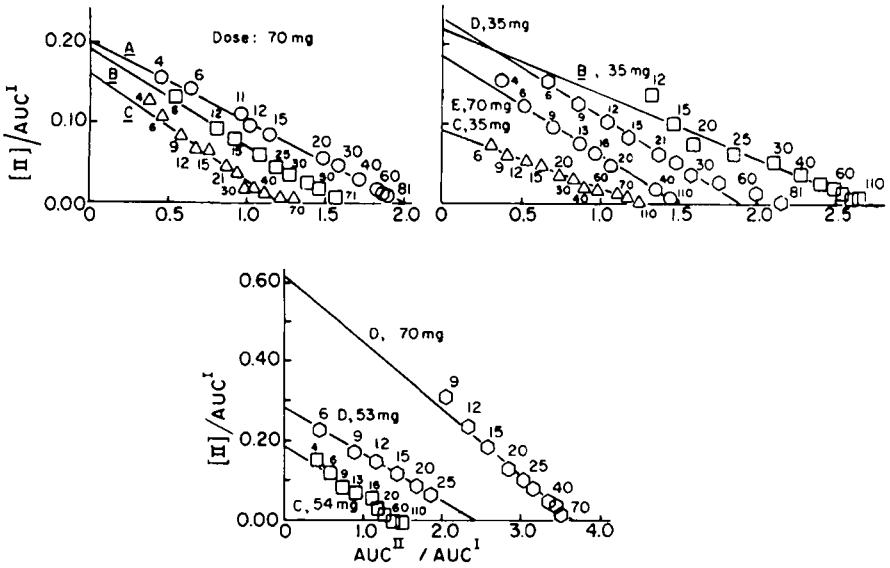

Figure 6—*Plots of the quotients of II plasma levels and the area under the plasma level-time curve of I against the ratios of the areas of II and I until that time in accordance with* $[II]/AUC^{I} = CL^{I\rightarrow II}/V_{II} - (CL^{II\rightarrow X}/V_{II})(AUC^{II}/AUC^{I})$ *where* $CL^{I\rightarrow II}$ *and* $CL^{II\rightarrow X}$ *are the clearances of I to II and of II, respectively, and where* V_{II} *is the apparent volume of distribution of II. The curves are labeled with the intravenous dose of I and the dog identification; each datum point is labeled with the time after administration.*

accordance with Eq. 11 is that monitored plasma levels did not reflect those at the sites of renal clearance at early time periods when pseudo-steady-state conditions had not been achieved for the drug. The hypothesis of decreasing concentration gradient from the plasma monitoring site to the glomerulus is a reasonable explanation for this renal lag. This is also consistent with the possible extrahepatic clearance of nafronyl, supported by its 3.2-h half-life in plasma *in vitro* (1). In one dog study (dog D, 53.0-mg dose) the assays of initial plasma levels of I from the femoral vein were consistently less than those taken simultaneously from the jugular [time(min), femoral, jugular (ng/mL)]: 4, 595, 1318; 6, 477, 950; and 15, 185, 536. This has been observed previously with other highly metabolized and quickly cleared drugs. An example is sulmazole (10) where the initial early plasma levels from the femoral and jugular veins did not agree. Drugs that are not highly metabolized and are more slowly cleared do not show significant differences between levels from jugular and femoral plasma. An example is the immunomodulatory 1,2-*O*-isopropylidene-3-*O*-3′-(*N*′,*N*′-dimethylamino-*n*-propyl)-D-glucofuranose hydrochloride (11).

The hepatic flow in the dog is in the range of 30–45 mL/min/kg [750–1125 mL/min for a 25-kg dog (12)]. If there is no biliary excretion of unchanged nafronyl, its metabolic clearance, $CL^{I}_{tot} - CL^{I}_{ren}$, referenced to total plasma

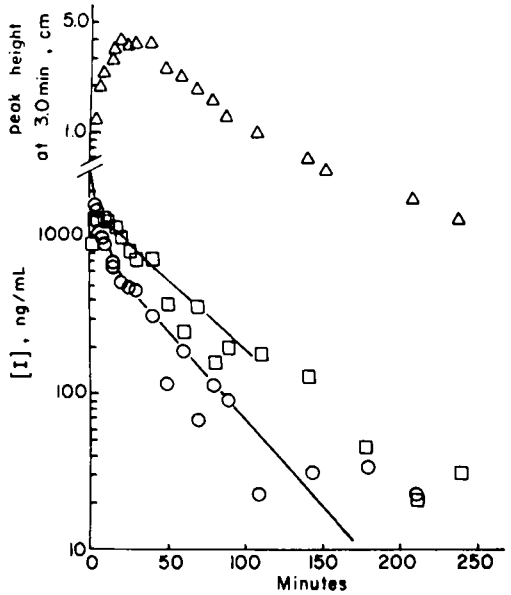

Figure 7—*Plasma concentrations of I (○) and II (□) in equivalents of nafronyl oxalate against time for bile-cannulated dog E after a 70.5-mg iv bolus dose of I. The curve through I was calculated from the sum of exponentials (Eq. 10); the curve through II was calculated from Eq. 15. The peak height at retention time 3.00 min of IV, which differed from I (10.9 min), II (3.90 min), and the internal standard (6.15 min), is also plotted against time (△).*

concentration is 1287 mL/min. Since this value exceeds even the highest expected extreme of maximal hepatic flow rate, which is the maximal hepatic clearnace possible, extrahepatic metabolism of nafronyl is indicated.

The renal clearances of the derived acid (CL^{II}_{ren}) were obtained by the methods described for nafronyl and averaged even lower, 0.18 ± 0.04 mL/min. This would imply a renal clearance of unbound II of 0.8 mL/min (0.18/fraction unbound), indicative of a high excess of tubular reabsorption. Generally, an AUC_0 was observed in accordance with Eq. 11 (Fig. 4). The assay of initial plasma levels of II from the femoral vein were consistently less than those taken simultaneously from the jugular [time(min), femoral, jugular (ng/mL in nafronyl equivalents)]: 4, 807, 1930; 6, 1116, 1930; and 15, 1324, 1789.

Urinary Excretions—The percentage of the dose renally eliminated at 330 min and the estimated total eliminated at infinite time are given in Table III. The latter values for I and II were estimated from Eq. 11 for $AUC = AUC_\infty$ using the estimates of CL_{ren} and AUC_0 given in Table III. Extremely small percentages of the dose are eliminated by this route; averaging 0.48 ± 0.25% for nafronyl (I) and 0.021 ± 0.004% for the derived acid (II). Plots of the cumulative urinary excretion of I and II with time are given in Fig. 5 for the various studies. The curves through the data were drawn in accordance with Eq. 11 for the particular AUC_0 and CL_{ren} values given in Table III.

Semilogarithmic plots of amount not-yet-excreted of the conjugate of II, (*i.e.*, III), assayed as II for solvolysis, against time ($\Sigma U^{III}_\infty - \Sigma U^{III}$) were linear after the first 10–70 min, for a chosen ΣU^{III}_∞ in accordance with:

$$\ln (\Sigma U^{III}_\infty - \Sigma U^{III}) = \ln \Sigma U^{III}_\infty - k_{III}t \qquad \text{(Eq. 12)}$$

where ΣU^{III}_∞ is obtained from the intercept of the extrapolated linear terminal data. The estimated ΣU^{III}_∞, $\Sigma U'^{III}_\infty$, and k_{III} values of urinary excretion of the III are given in Table III. The cumulative amounts of renally excreted conjugates are plotted against time in Fig. 5. The curve through the data is plotted in accordance with the nonlogarithmic transformation of Eq. 12:

$$\Sigma U^{III} = \Sigma U_\infty - \Sigma U'_\infty e^{-k_{III}t} \qquad \text{(Eq. 13)}$$

for the specific parameters listed in Table III and, as expected, gave excellent fits. The terminal half-lives of urinary excretion of III derived from k_{III} averaged 145 ± 18 min. The percentage of the dose renally eliminated as III (the conjugates of II) were the ΣU^{III}_∞ values and averaged 0.32 ± 0.12%.

Since the total amounts of these three compounds (I, II, and III) were only 0.82% of the total administered nafronyl dose, it is apparent that >99% of the administered dose is eliminated by processes other than renal and/or as other metabolites in the dog.

Relationships Between Metabolic Clearances of Nafronyl (I) and the Total Clearance of Its Acid Metabolite (II), and the Fitting of II Plasma Levels with Time—If there are no dose-dependent pharmacokinetics of I and its produced acid metabolite, a relation can be constructed (13, 14) from the constant metabolic clearance of nafronyl to the metabolite, $CL^{I\rightarrow II}$, and for the constant total clearance of the metabolite, $CL^{II\rightarrow X}$, as:

$$II = CL^{I\rightarrow II}AUC^{I} - CL^{II\rightarrow X}AUC^{II} \qquad \text{(Eq. 14)}$$

to calculate the amount of metabolite II in the body at any time, where AUC^{I} and AUC^{II} are the areas under the plasma level-time curves of I and II at that time. The amount of II can be formulated as $V_{II}[II]$ on the presumption that

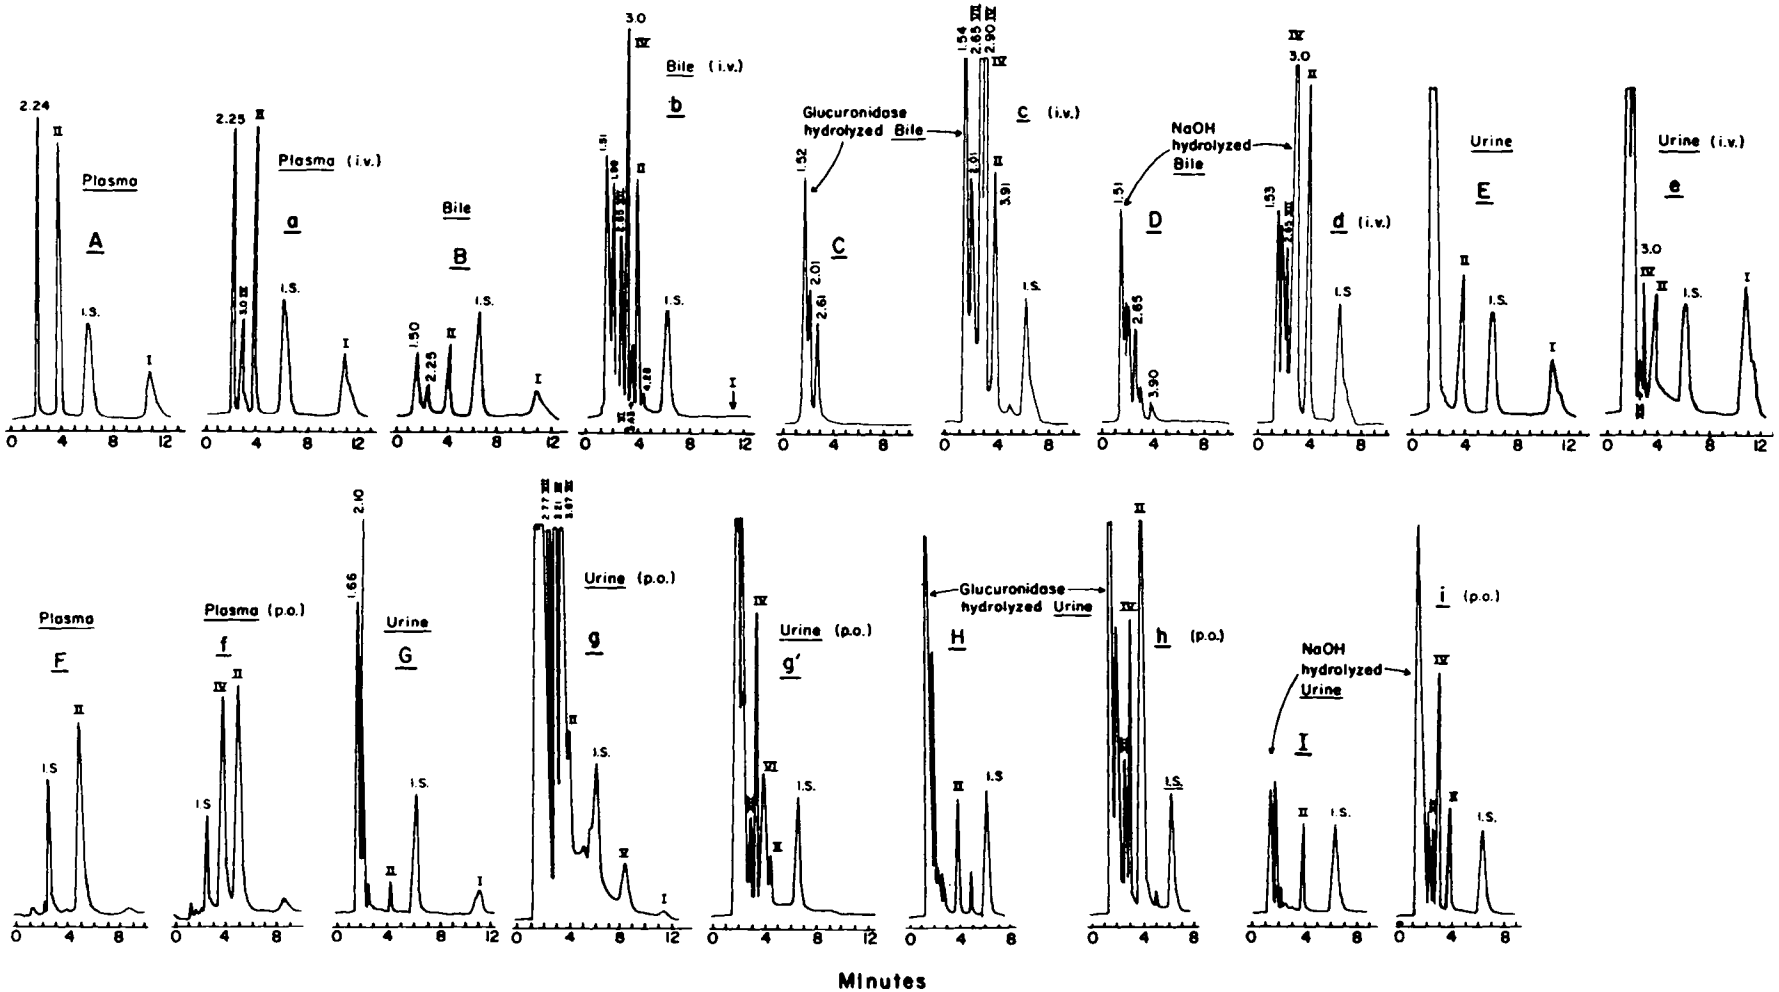

Figure 8—*Chromatograms (method A2) of organic extracts of plasma, urine, and bile, alone or spiked with I and II, from normal dogs (A–E) and from bile-cannulated dog E (a–e) after a 70.46-mg iv bolus dose of I. The internal standard (I.S.) was butacaine. Numbers at peaks represent retention times. Key: (A) plasma spiked with 325 ng/mL of I and 328 ng/mL of II; (a) plasma sample at 40 min; (B) nonhydrolyzed bile spiked with 250 ng/mL of I and 101 ng/mL of II; (b) nonhydrolyzed bile sample at 200 min; (C) blank bile treated with β-glucuronidase; (c) β-glucuronidase-treated bile sample at 214 min; (D) Blank bile treated with 0.2 M NaOH; (d) 0.2 M NaOH-treated bile sample at 214 min; (E) urine spiked with 752 ng/mL of I and 303 ng/mL of II; (e) urine sample at 190 min. Comparisons of chromatograms of organic extracts of plasma and urine spiked with I and II (identified (F–I) with samples taken from a dog orally administered 250 mg of I (f–i) are also presented. Key: (F) plasma spiked with procaine (internal standard) and 530 ng/mL of II using method A1; (f) plasma sample of dog C at 140 min; (G) urine spiked with butacaine (internal standard), 103 ng/mL of I, and 84 ng/mL of II using method A2; (g) urine sample of dog D at 201 min; (g') urine sample at 482 min; (H) urine spiked with butacaine and 303 ng/mL of II, treated with β-glucuronidase using method A2; (h) β-Glucuronidase-treated 160-min urine samples from dog D; (I) urine spiked with butacaine and 788 ng/mL of II, treated with 0.2 M NaOH using method A2; (i) 0.2 M NaOH-treated 270-min urine sample from dog D.*

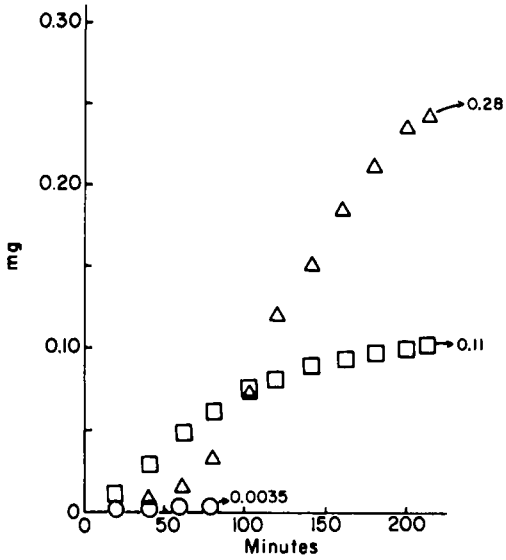

Figure 9—*Plots of cumulative amounts of I (○), II (□), and III (△) excreted into bile with time in the study of bile-cannulated dog E. The curves are labeled with the estimated total amounts eliminated in bile.*

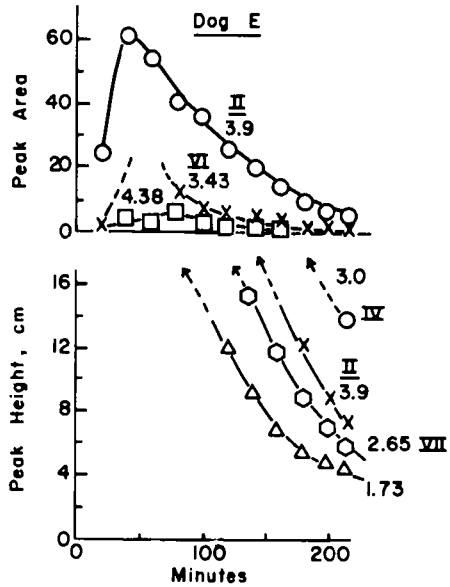

Figure 10—*Time course of peak heights and areas of peaks, labeled with retention times, appearing in chromatograms (method A2) of nonhydrolyzed bile taken from dog E (administered 70.46 mg iv of I) that did not appear in bile from the control dog. The dashed lines indicate higher values that could not be estimated. Values for II (3.9-min retention time) are given for comparison.*

the formed II is rapidly equilibrated in a one-compartment body model of volume V_{II} and plasma concentration [II]. Thus, Eq. 14 can be rearranged to:

$$[II] = \frac{CL^{I\to II}}{V_{II}} \cdot AUC^{I} - \frac{CL^{II\to X}}{V_{II}} \cdot AUC^{II} \qquad \text{(Eq. 15)}$$

or:

$$\frac{[II]}{AUC^{I}} = \frac{CL^{I\to II}}{V_{II}} - \frac{CL^{II\to X}}{V_{II}} \cdot \frac{AUC^{II}}{AUC^{I}} \qquad \text{(Eq. 16)}$$

Thus, if the premises are valid, plots of the quotient of acid metabolite plasma concentrations and the area under the plasma level–time curve of nafronyl ($[II]/AUC^{I}$) against the ratios of the respective areas of II and I (AUC^{II}/AUC^{I}) should give a straight line where $CL^{I\to II}/V_{II}$ and $CL^{II\to X}/V_{II}$ can be obtained from the intercept and slope, respectively.

Such plots for the various studies in the dogs are given in Fig. 6, and their linearities are consistent with the premises. The derived clearance/volume ratios are listed in Table III. The $CL^{II\to X}/V_{II}$ ($= 0.693/t_{1/2}$) ratio also has the significance of an elimination rate constant for II. The average of the half-lives (Table III) for this II elimination was 6.4 ± 0.5 min.

The total areas under the curves for II (obtained by the trapezoidal rule plus terminal plasma divided by terminal rate constant for II) per 70-mg dose were consistent for dogs A, B, and C at all doses and averaged 9.83 ± 0.57 × 10^4 ng·min/mL for a 70-mg dose of I. Dog D showed a significantly higher total area under the curve for II, which averaged 26.4 ± 3.4 × 10^4 ng·min/mL for a 70-mg dose of I. This implies that dog D has a greater metabolic formation of II from I and/or a smaller apparent volume of distribution, V_{II}, for the acid metabolite.

The validity of this development was challenged by calculating plasma levels of II from Eq. 15 using the obtained parameters given in Table III. The curves drawn through the plasma level [II] against time in Figs. 1, 2, and 7 are based on these calculations and are consistent with the actual data for a significant portion of their time course (*i.e.*, up to 110 min), but not for all. This can be reconciled by postulating that V_{II} is the volume of the central compartment for the acid metabolite, II, and V_{II} is not representative of the apparent overall volume of distribution of II when the slow equilibration of II among other tissues becomes significant.

Pharmacokinetic Study in Bile-Cannulated Dog E—In the pharmacokinetic study of bile-cannulated dog E, a single injection method (method A2) was used for the simultaneous assay of both II (retention time, 3.90 min) and I (10.9 min) with butacaine as internal standard (6.15 min). Plasma (Fig. 7) and bile were assayed for both I and II. An additional peak (IV) at 3.00-min retention time was observed in plasma samples (compare Fig. 8 A and a). The maximum concentration of IV (Fig. 7) in the plasma was observed at 25 min, in comparison with the 9-min maximum of II in plasma, with a peak height equivalent to IV to that of 350 ng/mL of II at retention time 3.90 min in the plasma. It is apparent that an unknown metabolite (IV) can be observed in plasma that lags after II. This could be a metabolite derived from II.

The cumulative amount of II excreted in the bile can be estimated as 0.16% of the dose (0.14% at 214 min). The low amount of I was 0.005% (0.0043% at 80 min) (Fig. 9). Additional HPLC peaks were observed on bile assay after drug administration (Fig. 8b). These peaks did not appear in the bile assay when drugs were not administered (Fig. 8B). The chromatograms of the extracts (before hydrolysis) gave peaks at 1.5, 1.73, 1.99, 2.65 (VII), 3.0 (IV), 3.43 (VI), and 4.38 min, as well as the very small amounts of I (10.9 min) and II (3.9 min). The time courses of the concentrations of these compounds of different retention times, in terms of peak height or peak area, are shown in Fig. 10 at the times they could be evaluated. Since bile at each time interval was very constant (3.4 ± 0.2 mL/20 min), these peak heights and areas are good estimates of the relative rates of elimination. The dashed lines in Fig. 10 indicate peak heights or areas that were so out of scale that they could not be estimated. For purposes of comparison, the peak heights and areas of II from the bile samples are also given. It is apparent that there were large amounts of the same 3.0-min retention time material (IV) that could be detected in plasma (Figs. 7 and 8a). It must be concluded that multiple organic-extractable metabolites derived from nafronyl are excreted into the bile in significant quantities and have the potential of being quantified by HPLC.

The extracted bile samples were subjected to alkaline (0.2 M NaOH) and β-glucuronidase (*E. coli*) hydrolysis and again extracted with methylene chloride. These extracts were assayed and showed significant peaks at 3.0 (IV), 3.6 (VI), and 3.9 (II) min for β-glucuronidase hydrolysis (Fig. 8, C and c) and at 3.0 (IV) and 3.9 (II) min for alkaline hydrolysis. There may be others, but the background from similarly treated bile samples from the nondosed animal makes it difficult to determine conclusively if the metabolites were present in the extracts of hydrolyzed bile. The presence of II in these hydrolyzed bile extracts is conclusive proof of conjugates of II, *i.e.*, III, excreted into bile; this can be estimated as 0.40% (0.34% at 214 min) of the administered nafronyl dose (Fig. 9). This estimated yield of III was based on the assay of the extract of alkaline-hydrolyzed bile, preextracted for II since the HPLC base line at 3.90 min (Fig. 8d) was so much better than that of the extract of β-glucuronidase-treated bile (Fig. 8c). The question is yet unanswered as to whether the presence of IV is due to its release from a conjugate or due to its incomplete extraction from the bile prior to the hydrolysis. The total areas under the respective peaks up to 214 min after drug administration were 215 (IV, 3.0 min) as compared with 149 (II, 3.9 min) after β-glucuronidase treatment. The 3.6-min (VI) peak total area was 36.5. The total areas up to 214 min were 248 (IV, 3.0 min) as compared with 278 (II, 3.9 min) after alkaline hydrolysis of the bile. The 2.65-min (VII) peak total area was 118.

In general,the dichloromethane extracts of β-glucuronidase-treated samples showed large backgrounds; the 3.0-, 3.4-, and 3.9-min peaks did not arise from a constant baseline, so peak area quantification of these peaks may not be accurate. This may possibly explain, in part, the difference in the estimates of these peak areas from the two methods of hydrolysis (Fig. 11).

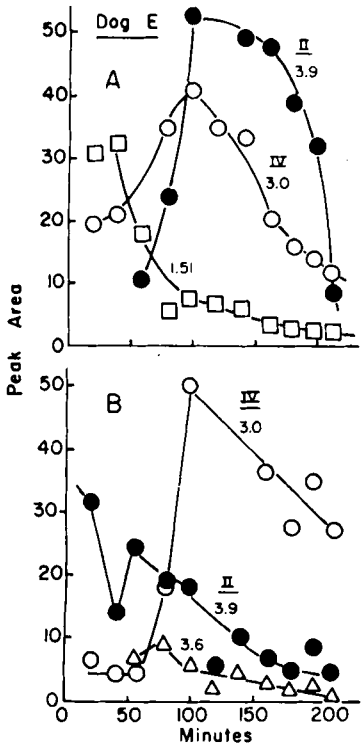

Figure 11—*Time course of peak areas, labeled with retention time, appearing in chromatograms (method A2) of hydrolyzed bile taken from dog E (administered 70.46 mg iv of I) that did not appear in hydrolyzed bile from the control dog. Values for II are given for comparison. Key: (A) β-glucuronidase-treated bile; (B) 0.2 M NaOH-treated bile.*

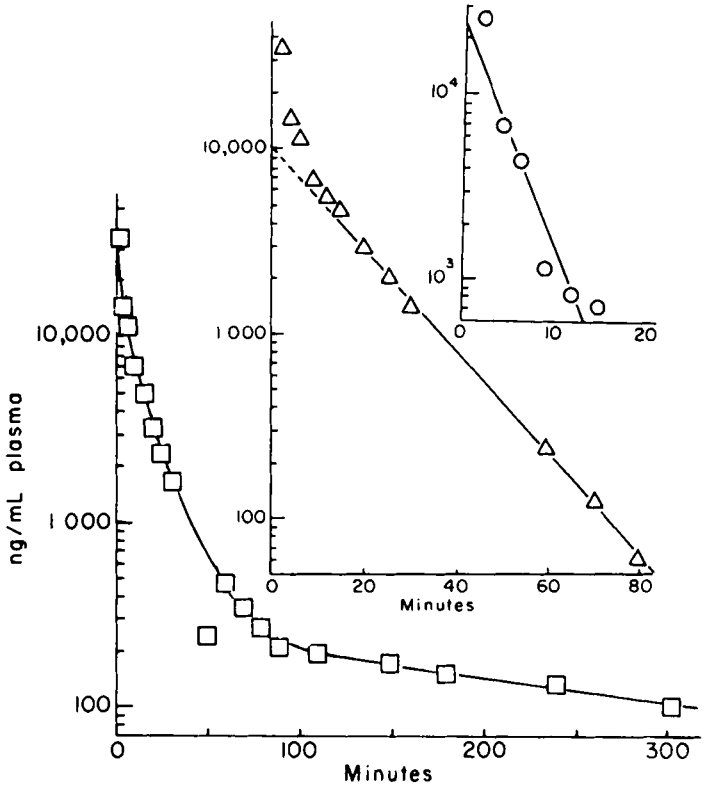

Figure 12—*Plasma levels of II, in equivalents of nafronyl oxalate, against time for a 44.7-mg iv (74.8-mg equivalent) bolus dose of II given to dog D. The curve through the data points was calculated from the sum of exponentials (see text). The insets show the successive feathering necessary to obtain the parameters of the three exponentials.*

Unfortunately the urinary catheterization of female dog E did not permit the collection of urine at different intervals of time. Nevertheless, assay of the organic extracts of the few urine samples obtained show a compound (IV) at a retention time of 3.0 in addition to those peaks assignable to I (10.9 min) and II (3.9 min); this peak did not exist in spiked urine from the same dog (compare E and e, Fig. 8). The 2.66-min peak (VII) observed in extract of nonhydrolyzed and alkaline-hydrolyzed bile was also observed.

Pharmacokinetics of an Intravenously Administered Bolus of II—The plasma levels of II on administration of 44.7 mg iv (74.8 mg as equivalents of nafronyl oxalate, I) of II are plotted against time in Fig. 12. The data were fitted to the sum of three exponentials for time t, in min, to calculate plasma levels in ng/mL as equivalents of nafronyl oxalate by:

$$[\mathrm{II}],\ \mathrm{ng/mL} = 24{,}500e^{-0.280t} + 10{,}000e^{-6.34\times10^{-2}t} + 270e^{-3.08\times10^{-3}t} \qquad \text{(Eq. 17)}$$

to demonstrate half-lives of the three respective phases as 2.47, 10.91, and 225 min. The total clearance of II is 225 mL/min. The area under the curve per milligram of nafronyl equivalent dose is 4451 ng·min/mL per milligram.

The renal clearance of II from a plot (Fig. 4) in accordance with Eq. 11 was 0.057 mL/min, the same value obtained from the slope of the linear plot with zero intercept of the rate of urinary excretion against the plasma level at the midpoint of the urine collection interval. The estimated total urinary excretions were 0.027 and 0.441% of the dose, unchanged and as the glucuronide, respectively. The terminal rate constant of renal elimination of the glucuronide, k_{III}, was 9.59×10^{-3} min^{-1} for a half-life of 72 min. In addition to [II] in the urine (retention time, 4.0 min), extremely large peaks due to other compounds were observed at ~1- and 2-min retention times.

The apparent volumes of distribution of the central and pseudo-steady-state volumes of distribution referenced to total plasma concentration are 2.15 and 73.0 L, respectively. The respective values for a 0.236 fraction unbound to plasma proteins are 9.1 and 310 L, respectively. The former value implies relatively instantaneous distribution in the total body water; the latter implies a high degree of sequestration in the relatively slowly equilibrated total body tissues.

Estimation of the Extent of Nafronyl Metabolic Transformation through Its Acid Metabolite—There are several methods to estimate the fraction of nafronyl generating its acid metabolite (II). The relative area under the plasma level-time curve of II for administered nafronyl (I) to administered acid (II) can estimate the fraction being metabolized by this route:

$$f_{\mathrm{I}\to\mathrm{II}} = \mathrm{AUC}^{\mathrm{II}}_{\mathrm{II\ admin}}/\mathrm{AUC}^{\mathrm{II}}_{\mathrm{I\ admin}} = 1404/4451 = 0.32 \qquad \text{(Eq. 18)}$$

where both the numerator and denominator are given per milligram of the administered dose of I and the latter is based on the $\mathrm{AUC}^{\mathrm{II}}_{\infty}$ average per 70-mg dose given in Table III.

The average of the ratio of total clearance of II to its apparent volume of distribution ($CL^{\mathrm{II}\to\mathrm{X}}/V_{\mathrm{II}}$), as based on application of Eq. 16 to the plasma concentration data obtained from the pharmacokinetic studies of intravenously administered I (Fig. 6), was 0.120 ± 0.009 min^{-1}. This value can also represent the apparent rate constant ($t_{1/2} = 6.4 \pm 0.5$ min) for the elimination of II and is of the same magnitude as the 10.9 min half-life observed for intravenously administered II (Fig. 12) during the significant portion of the time courses of I and II (Figs. 1, 2, 7) on which the estimations of $CL^{\mathrm{II}\to\mathrm{X}}/V_{\mathrm{II}}$ were based (Eq. 16). If $CL^{\mathrm{II}\to\mathrm{X}}$ is equated to the 225 mL/min observed in the pharmacokinetic study of II (Fig. 12), the apparent volume of distribution, V_{II}, is estimated as $(0.120 \pm 0.009) \times 225 = 1875 \pm 245$ mL, which is not significantly different from the estimated apparent volume of distribution of the central compartment of II (Fig. 12) of 2151 mL. These considerations support the premise that the greater time course of II formation from I, with its concomitant elimination, occurs largely in the central compartment before significant equilibration of II among the tissues has been effected. The average of the ratio of the clearance of I *via* II to the apparent volume of distribution, V_{II}, is $CL^{\mathrm{I}\to\mathrm{II}}/V_{\mathrm{II}} = 0.246 \pm 0.044$ min^{-1} (Table III, Eq. 16, Fig. 6). Thus, if V_{II} is 1875 ± 245 mL, the estimated clearance ($CL^{\mathrm{I}\to\mathrm{II}}$) is $0.246 \times 1875 = 461$ mL/min. Since the average total clearance of I less its renal clearance is $CL^{\mathrm{I}}_{\mathrm{met}} = 1287$ mL/min, the fraction of I cleared to II is:

$$f_{\mathrm{I}\to\mathrm{II}} = CL^{\mathrm{I}\to\mathrm{II}}/CL^{\mathrm{I}}_{\mathrm{met}} = 461/1287 = 0.36 \qquad \text{(Eq. 19)}$$

This latter value is in reasonable agreement with the 0.32 value estimated from Eq. 18, implying that not all of the I is metabolized through systemically appearing II, that 60–70% of nafronyl has primary metabolites other than II, and/or that I and its derived metabolites are excreted in bile so as not to appear in the systemic circulation. The high metabolic clearance of I, in excess of the hepatic flow, could permit sequential metabolism within the first pass through the liver.

Pharmacokinetics and Bioavailabilities of Orally Administered Nafronyl—Extremely small concentrations of orally administered nafronyl (I) were observed in the plasma of dogs (Fig. 13). The apparent terminal half-lives

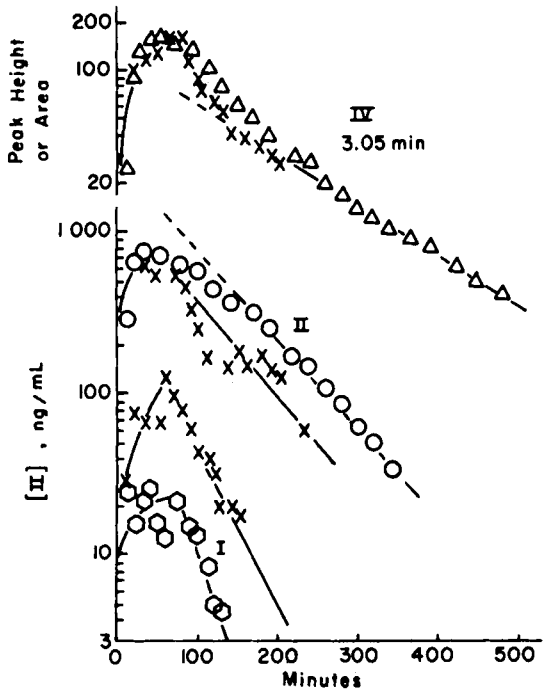

Figure 13—*Time courses of I, II (plotted as I equivalents), and IV in plasma after oral administration of 250 mg of I to dogs D (○, △, ○) and C (×), as assayed by the single-injection method A2 or its modification. The peak heights of IV at 3.05 min are plotted for dog D; the peak areas of IV at 2.48 min are plotted for dog C.*

(20–30 min) of I on oral administration were between those of the α (9 min) and β (100 min) phases obtained on intravenous administration. The estimated bioavailabilities of I, determined from the ratios of the AUC^{I}/mg values (oral to intravenous), were 0.3–2.7% of the 250-mg oral dose in three studies (Table IV). When dog D was administered 502 mg, the dog regurgitated the material 25 min after administration.

The apparent terminal plasma half-lives of II after oral administration of 250 mg of I were 55–110 min (Figs. 13 and 14). The estimated bioavailabilities of II, determined from the ratios of the AUC^{II}/mg values obtained after oral administration of I to those obtained after intravenous administration of II, were 9.7–16.7%. It is apparent that there is a definite presystemic and/or first-pass metabolism of both I and II on oral administration. In one of the 250-mg po studies of dog C, a time lag of 100 min was observed before significant appearance of II in the plasma (Fig. 14).

In all dogs, a peak assignable to a compound other than I or II was observed in the plasma, but was not present in control plasma. This peak, IV, was observed with all HPLC methods. The chromatograms of extracted plasma for dog D, 250 mg po, were similar to those given in Fig. 8a. Chromatograms for dog D in the second study are given in Fig. 8F,f. The retention times of I, II, and IV from plasma extracts in other mobile phases and HPLC systems are listed in Table IV. The time course of IV in the plasma generally paralleled that of II (Figs. 13 and 14). Peak heights and areas of IV and II were very similar at a given time (Fig. 14). For purposes of comparison, the maximum peak height of IV for dog D, 250 mg (Fig. 13) at 3.05-min retention time, corresponded to a concentration of II (retention time, 4.03 min) of 678 ng/mL equivalents of I.

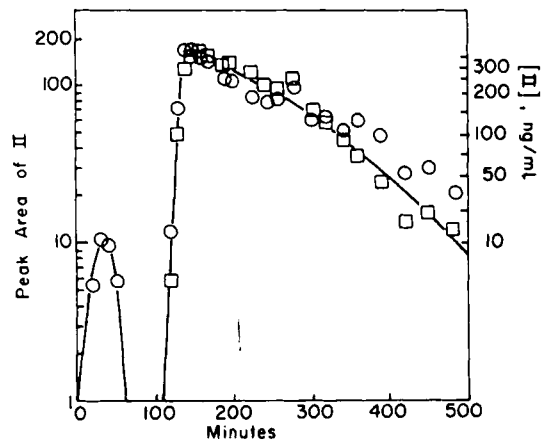

Figure 14—*Time course of peak areas of II (○) and IV (□) in extracts of plasma after oral administration of 250 mg of I to dog C. In this system the retention times of II and IV were 4.97 and 3.74 min, respectively. A 100-min lag period existed before significant absorption of I and II was observed.*

Table IV—Parameters and Bioavailabilities of Orally Administered Nafronyl (I)

Dog (Weight, kg)	D(26.0)	C(23.8)	C(21.8)	D(25.0)
Dose, mg	250	251	251	502
AUC^{I}_{∞}/mg dose[a]	8.39	35.1	3.54	—[f]
AUC^{II}_{∞}/mg dose[a]	744	470	430	440
Bioavailability, %

VII	2.62	2.62	—[j]	—[j]

[a] Estimated total area in nafronyl equivalents under plasma level-time curve per mg of oral dose calculated from trapezoidal rule plus the quotient of terminal plasma level and the rate constant for the terminal loss of plasma concentration. [b] Calculated from 100-AUC^{I}_{∞}/mg dose po ÷ AUC^{I}_{∞}/mg dose iv, where the latter denominator is the total clearance, 1295 mL/min. [c] Bioavailability of II from the administered oral dose of I, calculated from 1.666-AUC^{II}_{∞}/mg dose po ÷ AUC^{II}_{∞}/mg dose iv, where the latter value is 4451/mg dose of II (as I equivalents) taken from the intravenous study. [d] Based on total amounts excreted in urine at 430 min in nafronyl equivalents; III was assayed as organic-extractable II after hydrolysis of previously extracted urine by either β glucuronidase or 0.2 M NaOH. [e] Mobile phase composition and column differed, but single-injection method was used. [f] Peak for I merged with the peak for the internal standard and could not be readily quantified as to peak height or area. Also, dog regurgitated at 23 min after oral administration. [g] Too many interferences with the peaks for I and II to permit their quantification and/or identification in urine. [h] Plasma level data for I were too scattered to estimate. [i] The assay for I used a different mobile phase than the assay for II where IV was observed. Retention times for I were 4.2 min for dog C and 6.62 min for dog D. The urine studies for these dogs showed peaks in addition to those in blank urine for the mobile phase used to assay I, with decreasing peak height magnitudes at 1.85 > 3.86 > 2.63 > 3.55 > 4.20 (I) min for dog C and at 4.15 and 3.00 min for dog D. [j] Not studied.

The cumulative amounts of I and II excreted unchanged in the urine after oral administration of 250 mg of I were in the ranges of 0.003–0.061 and 0.030–0.42%, respectively. In addition to these compounds, extractable from nonhydrolyzed urine, IV, V, VI, and VII were identifiable at separate retention times in the urine extracts (Fig. 8G, g, and g′). Retention times in various mobile phases and systems are given in Table IV. The time courses of peak heights in sampled urine at these various retention times are given in Fig. 15 and can be compared with that for II. Some of these peaks were well out of the recording range for many of the collection intervals. Corresponding peaks for IV and VII had been observed previously in organic extracts of nonhydrolyzed urine samples obtained from a dog administered I intravenously (Fig. 8e). Corresponding peaks for IV, VI, and VII have been observed previously in organic extracts of bile from this dog (Figs. 8b, c, d).

β-Glucuronidase and NaOH treatment, after prior extraction of the urine, gave chromatograms of subsequent organic extracts (compare H and h and I and i in Fig. 8) that indicated significant amounts of II (3.95 min) derived from its glucuronide (*i.e.*, III) and additional higher peaks with retention times

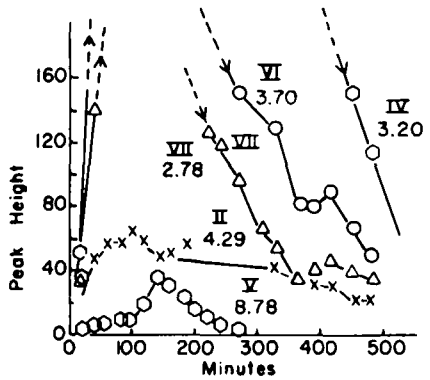

Figure 15—*Plots of peak heights against time of various chromatographic peaks obtained on assay (method A2) of urine extracts of dog D after oral administration of 250 mg of I.*

of 3.00 min (IV) and 2.62 min (VII). It is not possible to state if IV or VII were derived from glucuronides or if they were just not as completely removed as II in the extraction prior to hydrolysis. The cumulative amount of III in the urine (estimated as II after treatment) was 0.07–0.28% of the dose (Table IV).

Summary of Pharmacokinetics of Nafronyl in the Dog—Intravenously administered nafronyl (I) is rapidly cleared, with a total body clearance referenced to total plasma concentration of 1295 mL/min. Dose-dependent plasma pharmacokinetics of I and derived II could not be concluded in the 35–70-mg dose range. The plasma level–time data of I were usually well characterized by a sum of two exponentials with respective half-lives of 12 and 100 min. The latter was similar to the 90 min suggested for humans (7). The initial phase accounted for the major fraction (0.85) of the loss of I in plasma. The time course of derived II from I in the plasma could be quantified by a systemic metabolic clearance of I to II of 461 mL/min in an apparent volume of distribution, V_{II}, of the central compartment of II of 1.88 L, with a simultaneous total body clearance of II of 225 mL/min.

The estimated renal clearance of nafronyl was 8.3 mL/min with a renal elimination of only 0.5% of unchanged drug. This indicated a net metabolic clearance of I in excess of hepatic blood flow, favoring extrahepatic metabolism. Although the derived acid (II) was a major plasma metabolite of nafronyl, it could only account for 30–40% of the intravenously administered drug in the plasma and 0.02% in the urine, with a renal clearance of II of 0.18 mL/min. Thus, other metabolic transformations of nafronyl must exist that do not give direct formation of systemically appearing II.

The glucuronide (III) of II in the urine, liberated by β-glucuronidase or alkali, only accounted for 0.32% of the intravenous dose of I. The bile accounted for 0.005% of the dose as I, 0.16% of the dose as II, and 0.40% of the dose as III. Thus, >98.5% of the intravenously administered nafronyl dose is not eliminated as I, II, or III in bile and urine, and these compounds do not account for the principal fates for nafronyl disposition in the dog.

Considerable amounts of a chromatographically identifiable compound (IV) also extractable into dichloromethane, appeared in plasma after intravenous and oral nafronyl administration. It also appeared in normal and hydrolyzed preextracted bile and urine in considerable quantities and was consistent with the naphthol-containing carboxylic acid suggested previously to be a metabolite (4). Chromatographically identifiable, but as yet uncharacterized, compounds other than IV that were also extractable into dichloromethane appeared in normal (V, VI, and VII) and hydrolyzed preextracted (VII) urine and in normal (VI and VII) and hydrolyzed preextracted (VII) bile in apparently large quantities. Undoubtedly, these compounds can account for the major fates of nafronyl (I) and II in the dog. Other possible unextractable compounds could exist.

A study of the pharmacokinetics of intravenously administered II demonstrated a triphasic plasma level–time curve with respective half-lives of 2.5, 10.9, and 225 min. The initial two phases accounted for 99.2% of the loss of II in plasma. The total body and renal clearances were 225 and 0.057 mL/min, respectively. The percentages of the dose renally excreted and as glucuronide were 0.027 and 0.44%, respectively. Thus, II is also metabolized by routes other than glucuronidation.

The bioavailability of I after oral administration of 250 mg of nafronyl to the dog is only 0.3–2.7%. The percentage of potentially systemically available II was only 10–17%. These facts clearly demonstrate presystemic and/or first-pass metabolisms of both I and II.

Quantitative Microradiography for Studying Dental Enamel Demineralization and Remineralization

DAVID H. BERGSTROM *, JEFFREY L. FOX *, and WILLIAM I. HIGUCHI *x

Received May 17, 1982, from *The Dental Research Institute* and the *College of Pharmacy, The University of Michigan, Ann Arbor, MI 48109.* Accepted for publication March 7, 1983. * Present address: Department of Pharmaceutics, College of Pharmacy, The University of Utah, Salt Lake City, UT 84112.

Abstract □ A method for quantitative determination of mineral density changes in dental enamel has been developed. It utilizes the quantitative microscopy capabilities of image analysis or photometer systems. Characteristic demineralization of bovine enamel in acetate buffers containing calcium and phosphate has been used to demonstrate the results. The method together with chemical kinetic data obtained from spectrophotometric and ion-selective electrode measurements of the bulk solution for calcium, phosphate, and fluoride permit important basic studies to be conducted on demineralization and remineralization of dental enamel.

Keyphrases □ Microradiography—quantitative study of dental enamel demineralization/remineralization □ Dental enamel—demineralization/remineralization, quantitative study using microradiography □ Demineralization—dental enamel, simultaneous remineralization, quantitative study using microradiography

Although the literature contains many references (1-5) utilizing microradiographic techniques to observe mineral changes that occur in enamel, the vast majority of these are largely qualitative in nature and are thereby limited in their usefulness. Until recent years, technology has limited the ability of researchers to obtain quantitative information from microradiographic images. The purpose of this present study was to develop and critically examine such a quantitative method and its limitations. The application of an image analysis system[1] to this quantitative determination of mineral density changes has been successful. Close examination of the density profiles obtained after incorporation of the internal standard data yields information not readily apparent from visual examination. The method is demonstrated here using demineralization of bovine tooth enamel, but it has also found application in synthetic hydroxyapatite compacts as well as examining the mineral density changes occurring in solutions containing fluoride.

EXPERIMENTAL

Dissolution Medium - A buffered solution ~32% saturated (on a molar basis) with respect to the thermodynamic solubility of hydroxyapatite was used for the demineralization procedure. The solution was a 0.1 M acetate buffer containing 7.05 mM each of total calcium and phosphate in the form of calcium chloride and dibasic sodium phosphate. The pH was adjusted to 4.5 with concentrated sodium hydroxide and the ionic strength to 0.5 M by the addition of sodium chloride.

Bovine Teeth Preparation—Incisors from 8-week old strictly Kosher calves were obtained from packing houses in the Chicago area. These are crate-fed calves whose diets are uniformly controlled and thus provide an excellent experimental system. From these, only reasonably flat teeth without any obvious surface defects were used experimentally. The pellicle was removed from the labial surface using 400-, and 600-grit silicon carbide[2] abrasive disks.

Dissolution Procedure—A bovine tooth was selected and covered with nail enamel, except for a 0.25 cm^2 square window on the labial surface. The tooth was then placed in 10 mL of 0.1 M acetate buffer containing 7.05 mM each of calcium and phosphate for varying lengths of time. It has been calculated that the dissolution medium is not saturated with respect to hydroxyapatite after these periods of dissolution. During demeneralization the solution and sample were gently agitated with a wrist-action shaker[3]. The temperature was maintained at 30°C throughout the procedure.

Sample Preparation for X-ray Analysis—The demineralized sample was mounted in a circular saw[4] with a high concentration diamond wafering blade.[5] Sections were cut through the exposed window perpendicular to the enamel surface as thin as possible. Each thin section was then ground with 600-grit silicon carbide paper plane-parallel to a thickness of 100 μm as determined by a micrometer. Final polishing using diamond paste[6] on a rayon cloth was done to remove any small aberrations resulting from the initial grinding procedure.

X-ray Method—The thin section of enamel was placed in direct contact with the emulsion of a 5 × 5 cm high-resolution glass plate[7]. A wedge made of bovine enamel was cut from the block enamel using the circular saw. The wedge was placed on the plate directly opposite the enamel surface to be analyzed. The internal standard is essential because it allows comparison of the negatives of different samples by factoring out any deviations due to variations in the time and temperature during the film development process. The sample was positioned in the center of the X-ray beam[8] for 25 min, with the instrument settings at 40 kVp and 3 mA. The exposed negative was developed in developer solution[9] according to the manufacturer's instructions. Quantitation of the mineral density *versus* position was accomplished using the image analysis system (Fig. 1). Scans were made through the demineralized region as well as the adjacent wedge (Fig. 2). The data were recorded on magnetic tape; a program[10] utilizing the wedge and sample data was employed to calculate the mineral density *versus* position.

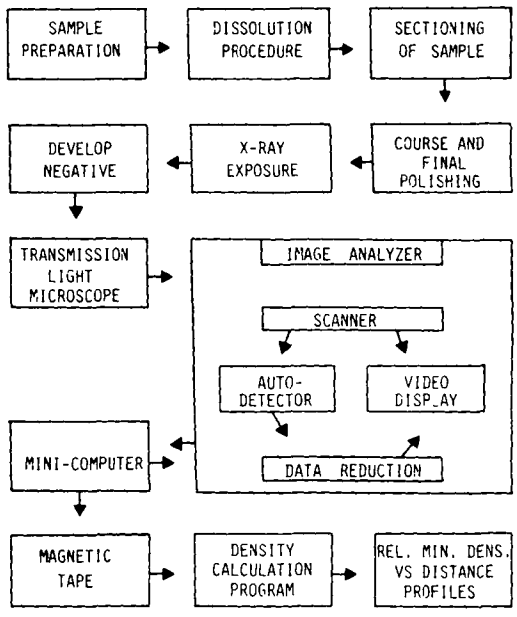

Figure 1—*Schematic representation of the methodology for obtaining relative mineral density* versus *position in enamel.*

RESULTS AND DISCUSSION

Contact Microradiography Technique—Contact microradiography, an extension of the conventional macroradiography, allows a rapid and convenient means of studying the density changes that occur within a block of enamel or a synthetic pellet (1) during the demineralization and/or remineralization process. This method possesses a very great depth of field and has the same resolution limit as transmitted light microscopy (~0.25 μm) (6). Several factors limit the resolution: (*a*) a lack of geometric sharpness results from the finite apparent source of the X-rays in relation to the source film distance; under the experimental procedure followed here this blurring of the image would be insignificant at ~0.02 μm as calculated by a previously described method (7); (*b*) high resolution glass plates have a photographic graininess limit of 0.15 μm; and (*c*) the lack of sharpness in the image at the edge of a sample resulting from the diffraction of the X-ray beam at the edge of a sharp electron-dense boundary. Again this effect was calculated to be ~0.2 μm and comparable to the film graininess (6). Considering all these contributions it can be assumed that structural detail down to ~0.5 μm can be observed. To test the resolution limit of the entire quantitative procedure, a scan was made over the sharp edge of a nondemineralized bovine tooth sample (Fig. 3), and the resolution limit was ~4 μm.

The system used to generate X-rays was operated at an accelerating voltage of 40 kVp and a current of 3 mA. The exposure time was 25 min, and the source-to-sample distance was 25 cm. A continuous spectrum of X-rays was produced, the wavelength of the most energetic being 0.05 nm. In an enamel sample the principal X-ray absorber at this wavelength is the calcium atom. The mass absorption coefficients of the inorganic *versus* organic components of enamel differ by a factor of 20. Absorption of X-rays of this wavelength by the organic material can be considered negligible.

The use of a wedge of bovine enamel exposed and further processed under the exact same conditions as the sample permits comparisons to be made between different negatives. Corrections can be thus made for any differences between negatives which may arise due to variations in time and temperature during the film development process. The angle of the wedge was determined by the trigonometric tangent function examining a negative on which the wedge resting on its side, had been exposed to X-rays.

Data Handling and Generation of Density Profiles—Using a computer program[10] the image data on the magnetic tape was transformed using the bovine wedge data as an internal standard to allow calculation and plotting of relative mineral density *versus* position.

In preparing a scan across the sample, the overall light level of the total image produced must be adjusted to allow maximum sensitivity of all the pixels (picture elements). The level of grayness can vary greatly between samples, so this adjustment must be made before each scan. When adjusting what is called white level sensitivity, the gray level values or scanner reading for the baseline value obtained from the exposed negative was not identical for two scans from the same negative (Fig. 3B *versus* Fig. 4B).

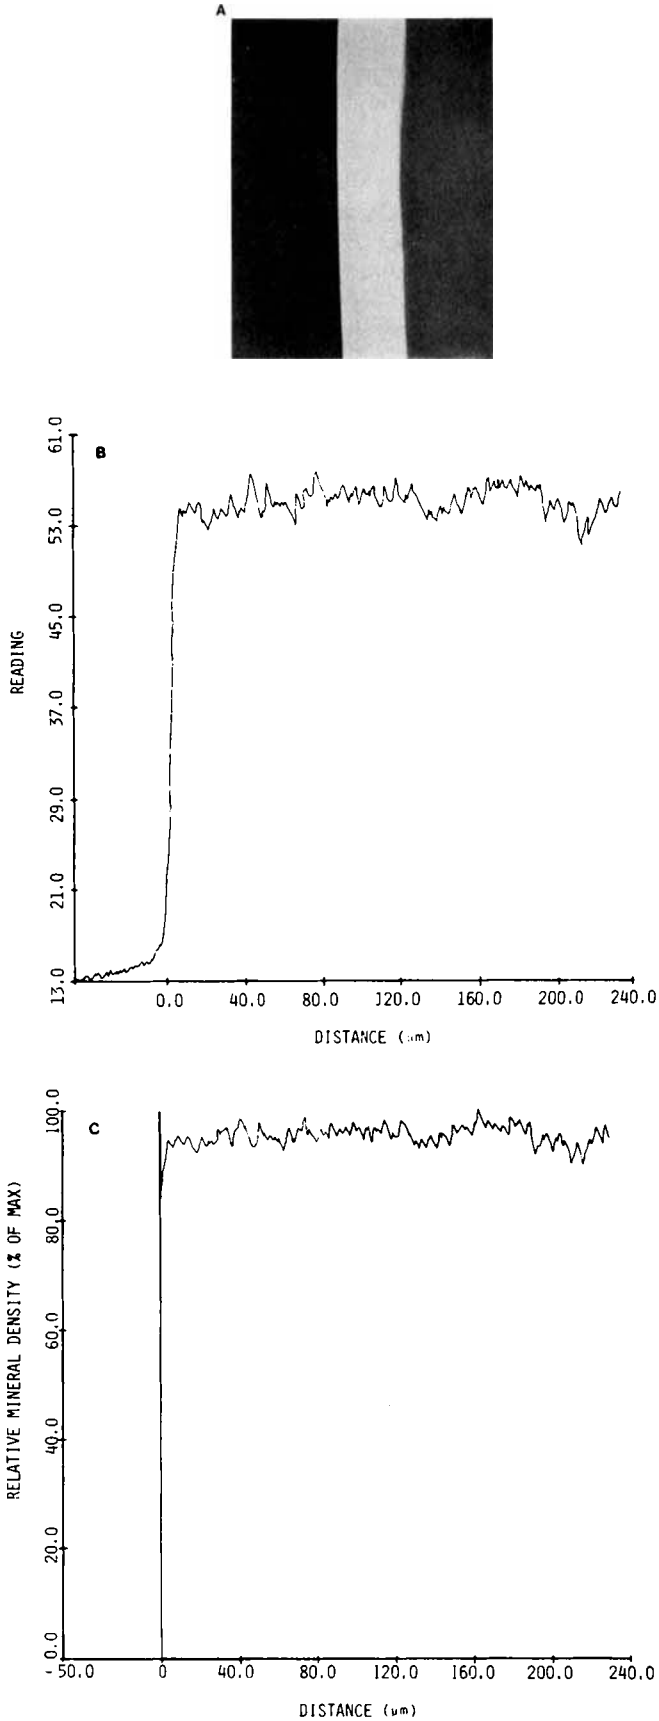

Figure 3—*(A) Photograph of a control sample of bovine enamel. Note the sharp edge between the exposed negative and the enamel. (B) Data obtained directly from the image analyzer after scanning from the negative onto the enamel to a depth of 230 μm. (C) Profile of relative mineral density* versus *position in enamel obtained after including the information obtained from the wedge data.*

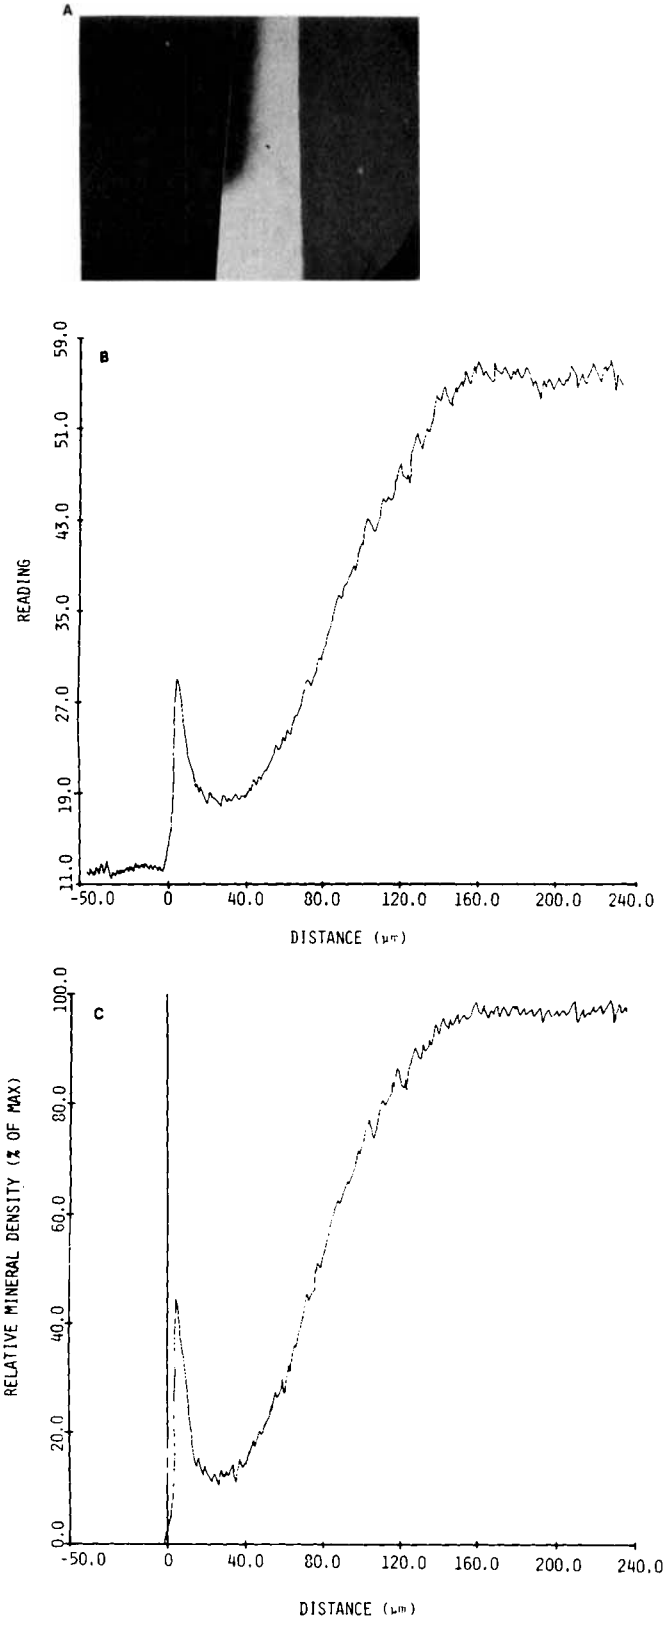

Figure 4—*(A) Photomicrograph of bovine enamel after 24 h demineralization at pH 4.5 in solution containing [calcium] = [phosphate] = 7.05 mM. (B) Image analyzer scanning of the microradiograph indicates mineralization of surface enamel is greater than that at depths further into the enamel. (C) Profile of mineral density* versus *position for (A) relative to the enamel at a depth of 230 μm.*

Initially it was thought that either the X-ray beam intensity or the photographic emulsion was not uniform, but scans made across different regions of blank negatives were essentially flat, indicating uniform exposure. To test

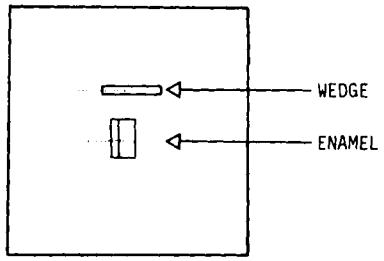

Figure 5—*Pictorial representation of microradiograph depicting relative positions of wedge and sample. The dotted lines show direction of image analysis scan.*

whether this variable baseline reading was due to this need to change the light intensity between samples, several scans across the same wedge in the exact same spot on the same negative were made. Results indicated that although the absolute values were changing they were changing at both ends of the curve so that the shape of the calibration curve remained constant. The placement of the wedge and sample (not to scale for clarification) is depicted in Fig. 5. The dotted line indicates the path each scan followed. These data allow normalizing the raw image analysis data obtained from the sample to that of the wedge and calculating from this the relative mineral density *versus* distance (see Figs. 2, 4B, and 4C).

The relative mineral density is defined as the normalized scanner reading at a point divided by the maximum reading in the sample × 100. The maximum scanner reading in the sample is taken as the average of the last 20 data points. In this it is assumed that there has been no acid demineralization in this deep recess of the enamel.

Application of the Method as Shown by Results of Experiments on Bovine Tooth Dissolution—In the development of this quantitative technique, samples of bovine enamel were exposed to a demineralizing solution for varying lengths of time (0, 1, 2, 3, 4, 5, 6, 12, and 24 h) and the resultant changes in mineral density were observed. For samples in which dissolution occurred for short periods of time, the mineral density was very low at the surface and increased monotonically until it reached the density of sound enamel. With increasing dissolution time, the mineral density at the original surface tended to increase, while the mineral beneath it remained less dense. The density again reached the maximum of sound enamel at sufficient depth (Fig. 4C). The longer dissolution times give rise to what has been termed a "subsurface lesion" or "white spot" phenomenon. This quantitative X-ray microradiographic technique has been shown to be an excellent method to study the demineralization and/or remineralization of enamel as well as synthetic hydroxyapatite compacts.

APPENDIX: Image Analysis

Image Analysis—Quantitative determination of the mineral density *versus* position in the tooth was obtained from the microradiograph using the image analysis system. This system is composed of three major components. The first is a transmission light microscope with high-quality optics, fitted with a 16× objective and 10× eye piece. The image analyzer itself is of modular design capable of a variety of image analysis functions, one of which is the image digitization used here. The third component of the system is a minicomputer system with a peripheral terminal and tape drive. The minicomputer functions here to collect and store the digitized image as it comes from the image analyzer and later to transfer this information to magnetic tape for further processing. A second function of the minicomputer is to instruct the system in its operations according to a user-defined protocol (average gray level determination) to be discussed later.

Image Production—The image analyzer uses a television camera to convert an optical image into an electronic signal. The first step then is to produce a high-quality image of the sample. The image analyzer cannot improve the quality of the projected image; in fact, its usefulness is severely limited by the quality of the image. Inherent in any image of good quality is lack of shading or uneven illumination in the image plane. Although an excellent grade microscope is used to produce the image, the optics are limited and image analysis off the optical axis of the microscope can result in incorrect measurements. In object plane scanning systems, *i.e.*, conventional microdensitometers, this problem is overcome by restricting the measurement area to a very small region in the center of the field on the optical axis of the microscope. In image plane scanners, *i.e.*, the system used herein, the measurement area is over a broad range, not limited to the optical axis of the microscope, so the resultant potential for error in off-axis operation must be corrected for. Fortunately, a unique comprehensive shading device has been developed which automatically corrects for illumination errors.

Glare or stray light arising from multiple reflections within the microscope

is another major source of error in microdensitometry, not unique to the image analysis method used here. Some of this stray light can affect the apparent optical density of the measured object. Glare tends to be specimen dependent, so its effect varies from field to field. In this system a dynamic glare correction is automatically applied. The transmission light microscope is the device utilized to produce an optical image which is then projected onto the photosensitive face of the vidicon tube scanner[11].

Image Scanning—The face of the vidicon tube is made of material that produces a local potential difference proportional to the intensity of light striking it. The sampling method of the scanner then converts the optical image to an electronic signal consisting of continuously varying analog voltage. High voltage corresponds to bright (white) portions of the image, while low voltage corresponds to the darker regions.

Image Digitization—The total image is composed of ~500,000 picture points or pixels, each of which is sensitive to the light intensity incident on it and contributes to the total analog video signal. It is within the auto detector module (see Fig. 1) that the analog video signal of each pixel is assigned a "gray level" value between 0 and 63. The 63 value corresponds to the brightest area over the total image, the 0 value set to some internal standard for black. The result of this digitization procedure is a digital image consisting of a matrix of numbers each with a value between 0 and 63. This is the basic data set produced by the image analysis system.

Data Reduction Module—To allow selectivity as to what portion of the total field is to be scanned, a variable frame size option is employed. This allows restricting the measurement to some quadrilaterally defined portion of the field. A frame size measuring 600 pixels horizontally by 10 pixels vertically is used to scan each sample. The 600 horizontal pixels under the 160× magnification of the microradiograph allows a sufficiently wide scan to be made across the sample and adjacent negative.

The minicomputer interface allows further processing of the 600 × 10 matrix of pixels, each with a value between 0 and 63. In this case, it is the 10 vertical pixels that are acted upon. To minimize any error due to variable sensitivity of a particular pixel, some defect in the microradiograph itself (dust or a scratch), a single value is obtained from the 10 vertical numbers by simply taking the average. This produces what is called an "average gray level" for 600 horizontal sampling points. Using appropriate calibration methods it was determined that under these conditions each pixel has a width of 0.46 μm. The data are then transferred to magnetic tape as a pair of numbers corresponding to position in scan and the average gray level or "reading" at that position.

Quantitative Microradiographic Study of Simultaneous Demineralization/Remineralization of Dental Enamel in Weak Acid Buffers

DAVID H. BERGSTROM *, JEFFREY L. FOX *, and WILLIAM I. HIGUCHI *x

Received May 17, 1982, from *the Dental Research Institute and the College of Pharmacy, The University of Michigan, Ann Arbor, MI 48109.* Accepted for publication March 7, 1983.

*Present address: Department of Pharmaceutics, College of Pharmacy, The University of Utah, Salt Lake City, UT 84112.

Abstract □ The remineralization behavior of weak acid-treated bovine tooth enamel has been investigated using a recently developed quantitative microradiographic method. Acetate buffer solutions at pH 4.5 containing calcium, phosphate, and 10 ppm fluoride were used in this study. When the solution ion activity product ($K_{FAP} = a_{Ca}^{10} a_{PO_4}^{6} a_F^2$) was 1×10^{-108}, the remineralization of the demineralized region was relatively uniform and complete. On the other hand, when the K_{FAP} was $\sim \leq 1 \times 10^{-112}$, remineralization of the outer 10–20 μm was incomplete. In addition, for the smaller K_{FAP} solutions there was significant demineralization in the deeper recesses of the originally demineralized region. These results agree with a recent chemical kinetics study in which it was proposed that $K_{FAP} = 1 \times 10^{-112}$ demarcated the region of solution conditions in which remineralization only occurs from that in which simultaneous demineralization/remineralization takes place. A model consistent with all of the data is proposed.

Keyphrases □ Microradiography—quantitative study of dental enamel demineralization/remineralization, solution ion activity product □ Dental enamel—demineralization/remineralization, solution ion activity product, quantitative microradiography □ Demineralization—dental enamel, simultaneous remineralization, solution ion activity product, quantitative microradiography

Recently, Fox *et al.* (1) investigated the influence of the solution ion activity product ($K_{FAP} = a_{Ca}^{10} a_{PO_4}^{6} a_F^2$) on the remineralization of weak acid-treated bovine tooth enamel and hydroxyapatite pellets. Solutions containing calcium-45, phosphate, and fluoride in acetate buffers were used. The calcium-45/fluoride molar ratios determined for the remineralized enamel by perchloric acid etch biopsy indicated the predominant formation of fluorapatite [$Ca_{10}(PO_4)_6F_2$; FAP] or fluoridated hydroxyapatite [$Ca_{10}(PO_4)_6(OH)_{2-x}F_x$], where $0 \leq x \leq 2$ when $pK_{FAP} \simeq 108$. When the pK_{FAP} of the solutions were ≥112, the calcium-45/fluoride ratios were found to be considerably <5. From these results, the authors proposed that a pK_{FAP} value of ~112 marked the demarcation between remineralization only and simultaneous demineralization/remineralization for these acidic remineralizing solutions.

The purpose of the present investigation was to study the remineralization of bovine tooth enamel under the same conditions as those of Fox *et al.* (1), employing a recently developed (2) quantitative microradiographic technique. A special point of interest was to examine the hypothesis that simultaneous demineralization/remineralization sets in when the pK_{FAP} value is ~ ≥112 for these solutions.

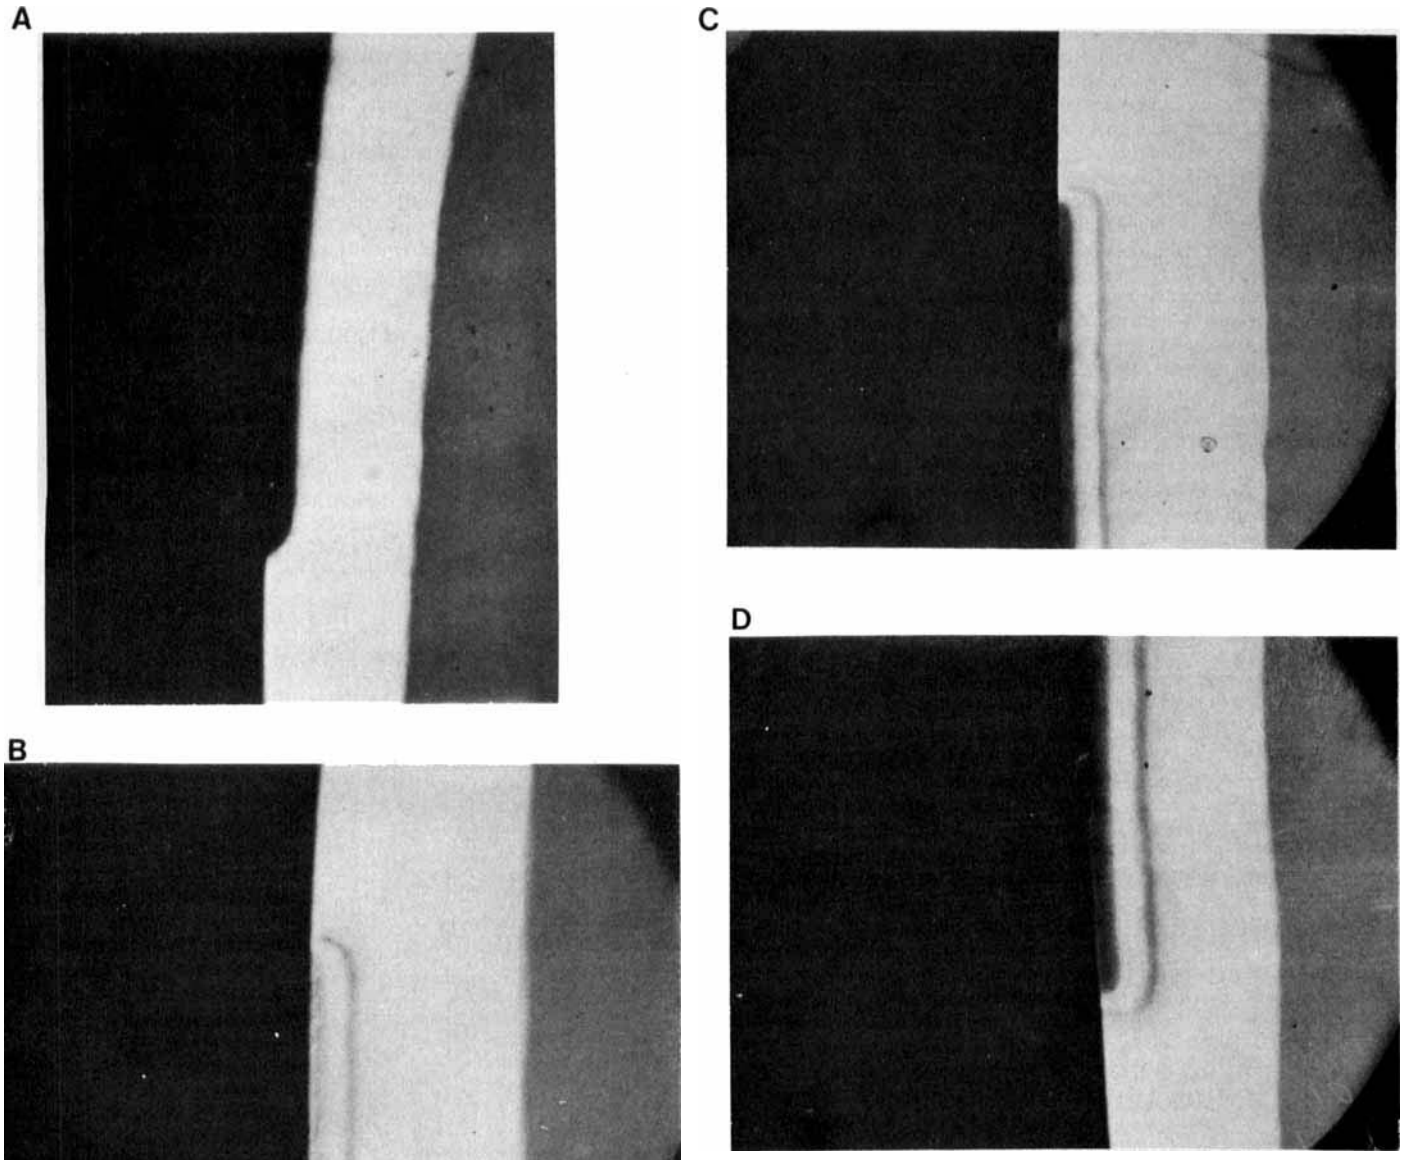

Figure 1—*Bovine tooth enamel demineralized for 6 h in 10 mL of 0.10 M acetate buffer (μ = 0.5, pH 4.5) with calcium = phosphate = 3.5 mM. Remineralization was done in different solutions (see Table I) for 24 h. Key: (A) no remineralization; (B) solution 1, pK_{FAP} = 108; (C) solution 2, pK_{FAP} = 112; (D) solution 3, pK_{FAP} = 118.*

EXPERIMENTAL

Buffer Dissolutions—*Dissolution*—A solution ~16% saturated (on a molar basis) with respect to the thermodynamic solubility of hydroxyapatite was used for demineralization. The solution was 0.1 M acetate buffer containing 3.5 mM each of total calcium and phosphate. The pH was adjusted to 4.5 with sodium hydroxide and the ionic strength to 0.5 M by the addition of sodium chloride.

Remineralization—For remineralization, 0.1 M acetate buffers (pH 4.5) containing different amounts of total calcium and phosphate depending on the desired bulk solution activity product ($K_{FAP} = a_{Ca}^{10} a_{PO_4}^{6} a_F^2$) as shown in Table I were employed. These solutions also contained 10 ppm fluoride (in the form of sodium fluoride) with sodium chloride added to adjust the ionic strength to 0.5 M. All chemicals used were of analytical grade.

Bovine Teeth—Teeth from 8-week old strictly Kosher calves were obtained from packing houses in the Chicago area. From these, only reasonably flat incisors without any visible surface defects were used experimentally. The pellicle was removed from the labial surface using 400- and 600-grit silicon carbide abrasive disks.

Demineralization and Remineralization Procedures—A selected bovine tooth was covered with nail enamel except for a 0.25-cm^2 window on the labial surface. The tooth was then placed in 10 mL of the 16% partially saturated buffer solution for 6 h. From experimental results obtained by Yonese *et al.* (3) the demineralizing solution was not saturated with respect to hydroxyapatite after 6 h of demineralization. During demineralization the solution was gently agitated with a wrist-action shaker. The temperature was maintained at 30°C.

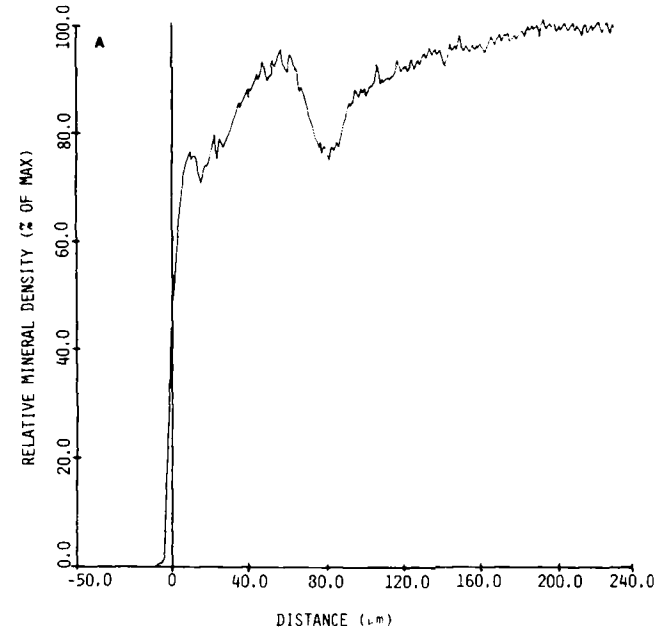
Table I—Ion Activity Products of Solutions [a] Used in this Study

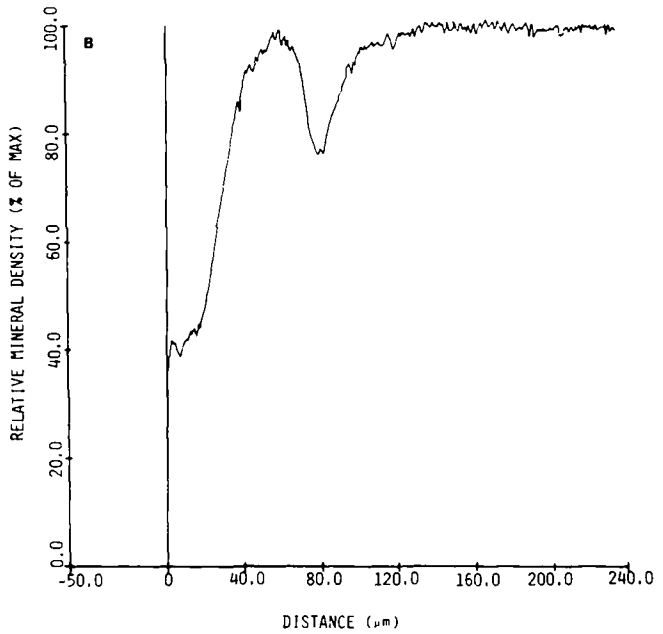
Solution	Calcium, mM	Phosphate, mM	Fluoride, ppm	pK_{FAP}	pK_{HAP}
1	12.00	12.00	10	108	120
2	6.87	6.87	10	112	124
3	2.86	2.86	10	118	130

[a] pH 4.5; μ = 0.5; 0.1 M acetate buffer.

The previously demineralized sample was immediately placed in 50 mL of the desired remineralization solution. During the remineralization the solution was again gently agitated and maintained at 30°C.

Sample Preparation—The demineralized/remineralized tooth was mounted on a circular saw fitted with a high concentration diamond wafering blade. Sections as thin as possible were cut through the exposed window perpendicular to the enamel surface. Each section was then ground plane-parallel to a thickness of exactly 100 μm as determined by a micrometer. Final polishing, using diamond paste on a rayon cloth, was done to remove any small aberra-





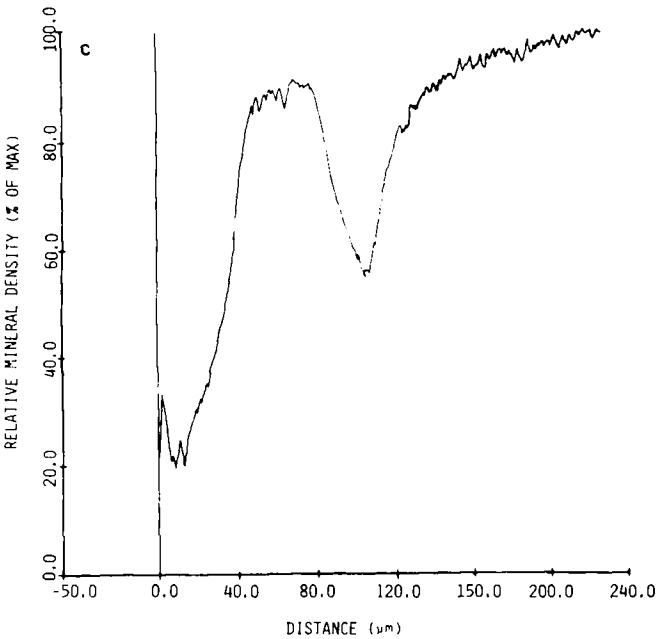


Figure 2—*Relative mineral density* versus *distance for remineralization experiments described in Fig. 1. Key: (A) $pK_{FAP} = 108$; (B) $pK_{FAP} = 112$; (C) $pK_{FAP} = 118$.*

tions resulting from the initial grinding using 600-grit silicon carbide paper.

X-Ray—A section was placed in direct contact with the emulsion on a 5 × 5 cm high-resolution glass plate[1]. Directly opposite the enamel surface to be analyzed, a wedge made of bovine enamel was placed. The wedge allowed comparison of the negatives of different samples by factoring out any deviations in the time- and temperature-dependent film development process.

The sample was placed in the center of the X-ray beam[2] for 25 min. The instrument settings were 40 kVp and 3 mA. The negative was developed in developer solution[3] according to the manufacturer's instructions.

Density Profiles—Quantitation of the demineralization/remineralization process was accomplished using the image analysis system[4]. By the procedure outlined in the previous article (2), scans were made across the sample as well as on the adjacent step wedge. The data recorded on magnetic tape were analyzed by a computer program in which the wedge data and sample data were used to calculate the mineral density *versus* position in the tooth.

RESULTS AND DISCUSSION

As shown by the photomicroradiographs (Fig. 1) and the mineral density *versus* position profiles (Fig. 2), the influence of the solution activity product on the remineralization of bovine tooth enamel is profound. Remineralization under conditions in which the solution activity product equals 10^{-108} gives a relatively uniform and essentially complete recovery of mineral density to the original surface of the previously demineralized sample (Figs. 1B and 2A). Under conditions where the pK_{FAP} of the remineralization solution is high (*i.e.*, 112) the recovery appears less complete, particularly in the outer 20 μm (Figs. 1C and 2B). There is also the appearance of a less dense band at a depth slightly greater than that produced by the demineralization treatment alone. The experimental results for conditions in which the solution activity product was varied from 10^{-114} to 10^{-118} also indicated this less dense outer 20 μm in the enamel sample. The band below the original "lesion" (Fig. 1A) depth was now significantly deeper and more diffuse (Figs. 1D and 2C).

Mineral density profiles of this type indicate that the situation is more complex than that of simple mineral deposition in the form of fluorapatite (1). Indeed, simultaneous dissolution must also be occurring in order to explain the loss of mineral deeper than the original "lesion." The presence of a more highly remineralized region under the less dense outer 20 μm found when remineralization was done in solutions with $pK_{FAP} \geq 110$ indicates that the

bulk solution activity product is not the sole determinant of the remineralization process.

The following discussion attempts to present a mechanism that is consistent with the present observations and with the chemical kinetic data obtained by Ludwig *et al.* (4), Fox *et al.* (1), and Katdare *et al.* (5). Thermodynamic calculations show (Table I) that a bulk solution with $pK_{FAP} = 108$ is supersaturated with respect to fluorapatite and saturated or supersaturated with respect to the ion activity products, K_{HAP} values, governing the relatively rapid rate of hydroxyapatite dissolution [*i.e.*, $pK_{HAP} = 120$ for site 1 and $pK_{HAP} = 128$ for site 2 described by Fox *et al.* (6)]. Ludwig *et al.* (4) have shown, however, that for apatite powder containing ~5% carbonate, the corresponding apparent solubilities may be greater by approximately four orders of magnitude in the K_{HAP} values. The carbonate level in the bovine enamel used in these experiments is ~4%. The modest band of demineralization (at ~80 μm depth) observed with the $pK_{FAP} = 108$ case is consistent with this consideration. With increasing pK_{FAP} the solutions become increasingly unsaturated with respect to hydroxyapatite (and carbonate apatite), and the deeper and wider band of demineralization observed at ~110 μm for $pK_{FAP} = 118$ would be consistent with this thinking.

The remineralization behavior in the region 0–20 μm is in agreement with the results of experiments with hydroxyapatite and carbonate containing apatite crystal suspensions reported by Katdare *et al.* (5). At $pK_{FAP} = 108$, fluorapatite suspension crystal growth rates were found to be relatively rapid but decreased significantly (*i.e.*, by a factor of ~10) at $pK_{FAP} = 112$, and the rates were negligibly slow at $pK_{FAP} = 116$. These findings by Katdare *et al.* (5) may easily explain the rather complete and uniform remineralization observed at $pK_{FAP} = 108$ in the region 0–20 μm and the much poorer extent of remineralization in this region at $pK_{FAP} = 112$ and 118. It may be concluded, therefore, that the remineralization behavior in the outer 10–20 μm may be primarily controlled by the bulk solution activity product.

The most interesting aspect of the results in Figs. 1 and 2 is that related to the highly mineralized region at intermediate depths (*e.g.*, at ~50 μm in the $pK_{FAP} = 112$ experiment). The following process is proposed to explain why remineralization occurs at intermediate depths but not at or near the surface (for the $pK_{FAP} = 112$ and 118 experiments). Ludwig *et al.* (4) have shown that, even for apatites containing ~5% carbonate, dissolution rates should be negligible when $pK_{FAP} \leq 115$. Therefore, for lesions to form at 80–90 μm in the $pK_{FAP} = 108$ and 112 experiments, it is reasonable to postulate that the microenvironment (aqueous pores) pK_{FAP} values in the deep recesses of the lesion must be >115 as a result of aqueous fluoride depletion caused by fluorapatite (or fluorhydroxyapatite) formation or fluoride adsorption in the outer layer and at intermediate depths. Fluorapatite deposition and fluoride depletion at the intermediate depths (40–50 μms) would be enhanced because mineral dissolution at 80–90 μm and the resultant outward flow of calcium and phosphate ions may significantly elevate the K_{FAP} values to far above the bulk K_{FAP} value. This simultaneous dissolution (at 80–90 μm) and remineralization (at 40–80 μm) process continues until sufficient aqueous fluoride concentrations (corresponding to $pK_{FAP} \simeq 115$) can build up in the deeper regions of the lesion.

To test the hypothesis that continued dissolution beneath the level of the original lesion is a transient phenomenon, additional studies have been conducted at different pK_{FAP} values for 3, 6, 12, 24, 48, and 96 h. At $pK_{FAP} = 116$, for example, the simultaneous dissolution and remineralization did not proceed beyond 12 h, and the lesion pattern remained essentially unchanged beyond that time period. Interestingly, Fox *et al.* (1) found that ^{45}Ca-labeled hydroxyapatite pellets dissolved only for 12–16 h in $pK_{FAP} = 116$ solutions. These are bulk-solution conditions for which simultaneous dissolution and remineralization will occur. The simultaneous demineralization/remineralization then appears to be a transient phenomenon indicating that once sufficient remineralization has occurred at the intermediate depths, dissolution no longer continues under the control of the microenvironmental K_{HAP} in the deeper regions of the enamel.

These results support the hypothesis by Fox *et al.* (1) that $pK_{FAP} \simeq 112$ marks the demarcation between mainly remineralization only and simultaneous demineralization/remineralization. For high pK_{FAP} solutions (*e.g.*, 118), fluoride deposition *via* fluorapatite or fluorhydroxyapatite formation occurs mainly at intermediate depths and involves, to a large extent, the reaction between bulk solution fluoride and the calcium and phosphate ions dissolved from the deeper regions of the lesion. For $pK_{FAP} = 108$, the remineralization is mainly controlled by the bulk solution, and the contribution to fluorapatite or fluorhydroxyapatite formation from the mineral dissolved in the lesion is minimal.

Statistical Prediction of Drug Stability Based on Nonlinear Parameter Estimation

SHANG-YING P. KING *, MIN-SHYA KUNG ‡, and HO-LEUNG FUNG *x

Received November 15, 1982, from the *Department of Pharmaceutics and ‡Department of Statistics, State University of New York at Buffalo, Amherst, NY 14260. Accepted for publication April 28, 1983.

Abstract □ The classical approach in Arrhenius prediction of drug stability uses two sequential steps of linear regression involving (*a*) a function of drug content *versus* time to obtain the rate constants (*k*) at several elevated temperatures and (*b*) the relationship of logarithm of mean *k versus* reciprocal temperature to predict the room temperature rate constant and hence the shelf-life of the drug. Uncertainties in drug content determinations are often neglected in the second regression. The classical approach also provides a wide and unsymmetrical 95% confidence interval for the predicted shelf-life. We have developed equations which allow for direct statistical prediction of shelf-life using observed values of drug content, time, and temperature. Nonlinear regression analysis was employed to provide parameter estimates of drug shelf-life and the energy of activation. The developed approach was shown to provide good estimates of shelf-life with meaningful statistics of reactions over a wide range of stability and energetics, with various kinetic orders, with different levels of noise in the data, and with different types of data structure. Comparison between the nonlinear approach and the classical approach showed that the nonlinear approach provided better mean estimates of shelf-life with much smaller and more symmetrical 95% confidence intervals than the classical approach. The method appears sufficiently robust and wide-ranging as to be potentially applicable for the prediction of the drug stability of pharmaceutical products.

Keyphrases □ Drug stability—statistical prediction of shelf-life, nonlinear parameter estimation, comparison with classical Arrhenius prediction □ Nonlinear parameter estimation—drug stability, statistical prediction of shelf-life, comparison with classical Arrhenius prediction □ Shelf-life—statistical prediction of drug stability, nonlinear parameter estimation, comparison with classical Arrhenius prediction

The establishment of the projected expiration date (or shelf-life) of a pharmaceutical product is of importance to the pharmaceutical industry. Accelerated stability testing using the Arrhenius equation is often employed to treat stability data obtained under elevated temperature storage conditions for the prediction of the shelf-life of drug products. The classical approach consists of two sequential steps which include (*a*) the choice of a proper order for the degradation reactions to describe the drug content (amount or concentration) *versus* time relationship for determining rate constants at each elevated temperature and (*b*) the application of the Arrhenius equation to predict (or extrapolate) the room temperature rate constant, and hence the shelf-life of the drug, through the use of the mean rate constants obtained at several elevated temperatures. Linear regression analysis (1) is the statistical method employed in each of these two steps.

Although this classical linear approach has been used quite frequently, the method of data treatment appears to suffer from two statistical problems. First, since Arrhenius treatment often employs only the mean rate constants obtained at elevated temperatures to predict drug shelf-life, errors associated with the determination of drug content are not included (and thus they are often ignored) in the analysis of accelerated stability data. Second, the 95% confidence interval of the predicted room temperature rate constant derived from the confidence band of the best-fitted straight line may be so wide as to make the predicted shelf-life of little value (2). Because of these inherent problems in the classical approach, it seems desirable to develop an alternate approach for the treatment of accelerated stability data so as to provide an improved prediction of drug shelf-life.

This study was initiated to develop and test mathematical relationships among drug content, time, and temperature, which take into account the errors in the drug content data for the prediction of shelf-life of drug products. A one-step nonlinear approach is proposed for the treatment of accelerated stability data. Comparison of this approach with the classical method is reported.

BACKGROUND

The shelf-life or expiration date of a drug product is defined as the time period required for a drug to decompose to a specified fraction of the labeled drug content, usually 90%. This shelf-life may be determined by directly monitoring the drug content in the drug product as a function of time at some ambient storage conditions, *e.g.*, 25°C and certain humidity and light levels. The proper order for the degradation reactions was determined usually by examining the best fit of plots of drug content *versus* time (for a zero-order reaction) or of the logarithm of drug content *versus* time (for a first-order reaction). Linear regression analysis may then be used to estimate the rate constant at the specified storage conditions. The time for the lower 95% confidence limit curve about the fitted straight line to reach 90% of the labeled drug content is assigned as the shelf-life of the pharmaceutical product (3, 4).

Although the shelf-life of the drug product can be accurately determined by the previously described method, it is usually a time-consuming process. To obtain a predicted shelf-life in a shorter period of time, accelerated stability testing is employed. Most frequently, accelerated stability testing is coupled with the use of the Arrhenius equation for the prediction of drug stability (5, 6). This approach involves two steps. First, a correct order of degradation reaction is determined to describe the functional relationship between drug content and time at several elevated temperatures. The equations for zero-, first-, and second-order degradation reactions are respectively:

$$C = C_0 - kt \qquad \text{(Eq. 1)}$$

$$C = C_0 \exp(-kt) \qquad \text{(Eq. 2)}$$

$$\frac{1}{C} - \frac{1}{C_0} = kt \qquad \text{(Eq. 3)}$$

where k is the rate constant. C_0 and C are the drug contents at time zero and time t, respectively. Both reactants are assumed to have the same initial contents for the second-order reaction. The equation for the first-order reaction can also be expressed in a linearized form:

$$\ln C = \ln C_0 - kt \qquad \text{(Eq. 4)}$$

The linear regression method may then be used to obtain the rate constant at each elevated temperature by using Eq. 1, 4, or 3 for each order of reaction.

In the second step, the Arrhenius equation (Eq. 5 or 6) is employed to relate the logarithm of mean k linearly to the reciprocal of the elevated temperature, T.

$$k = A \exp\left(\frac{-E_a}{RT}\right) \qquad \text{(Eq. 5)}$$

$$\ln k = \ln A - \frac{E_a}{RT} \qquad \text{(Eq. 6)}$$

where R is the gas constant.

In employing the Arrhenius approach, several assumptions are implicit:

0022-3549/84/0500-0657$01.00/0
© 1984, American Pharmaceutical Association

(*a*) that the kinetic model is valid, (*b*) that analytical accuracy is not compromised over the time of the stability study, and (*c*) that the Arrhenius equation is valid, *i.e.*, linear extrapolation beyond the observed data is feasible. In practice, after obtaining the estimates of the energy of activation (E_a) and frequency factor (A) through the use of Eq. 6 *via* the least-squares technique, the rate constant at room temperature and, subsequently, the shelf-life can then be predicted. The 95% confidence interval of the predicted room temperature rate constant can be derived from the confidence band of the regressed straight line (2, 7). The linearity of the Arrhenius plot can be checked statistically using the F ratio test (8, 9).

Besides the classical linear approach described, other methods using the Arrhenius relationship were also reported for stability prediction. Lordi and Scott (10) designed stability charts to facilitate the analysis of accelerated stability data. Kirkwood (11) suggested a maximum likelihood nonlinear approach for the prediction of the shelf-life of biological products using all the available drug potency *versus* time data. Nonisothermal kinetic methods (12–18) have also been developed for stability prediction.

Carstensen and Su (7) suggested a nonlinear approach for estimating the parameters of E_a and A in the Arrhenius equation (Eq. 5). The equations were derived by substituting the Arrhenius equation (Eq. 5) into either the equation of a zero-order reaction (Eq. 1) or that of a first-order reaction (Eq. 2). The form of the zero-order equation (Eq. 7) and first-order equation (Eq. 8) were, respectively:

$$C = C_0 - tA \exp\left(\frac{-E_a}{RT}\right) \quad \text{(Eq. 7)}$$

$$C = C_0 \exp\left[-tA \exp\left(\frac{-E_a}{RT}\right)\right] \quad \text{(Eq. 8)}$$

The Gauss-Newton iterative technique was used to obtain the parameter estimates of E_a and A. However, a digital computer was not used and the computational steps associated with the estimation of A and E_a may be too tedious.

Recently, Scher (19) proposed a method of kinetic ratio parameter for product stability calculation. Both Eqs. 7 and 8 were used to derive equations for the calculation of the shelf-life (t_{90}) of the drug. Equations 9 and 10 were employed for the zero-order and first-order reactions, respectively:

$$t_{90} = (C_0 - C) \Big/ \left[A \exp\left(\frac{-E_a}{RT}\right)\right] \quad \text{(Eq. 9)}$$

$$t_{90} = \ln (C_0/C) \Big/ \left[A \exp\left(\frac{-E_a}{RT}\right)\right] \quad \text{(Eq. 10)}$$

Davies et al. (20, 21) suggested the use of the logarithmic forms of Eqs. 8 and 10 to calculate drug shelf-life. The statistical properties of the parameter estimates of E_a and A in the equation for the first-order reaction (Eq. 8) were evaluated through the use of the Monte Carlo method of computer simulations (22). The simulation results showed that estimates of E_a and A were robust, and meaningful statistics of these two parameter estimates could be obtained. The relative standard deviation of the frequency factor (A) was large in comparison with the prescribed standard deviation of normal distribution for generating random errors in the data. After obtaining estimates of A and E_a, the shelf-life (t_{90}) may then be estimated using Eq. 10. The "approximate" standard deviation of the shelf-life (t_{90}) may be calculated by using the standard Taylor expansion (23) expressed as:

$$(SD_{t_{90}})^2 = (t_{90,A} SD_A)^2 + (t_{90,E_a} SD_{E_a})^2 + 2(t_{90,A} t_{90,E_a} \mathrm{COV}_{E_a,A}) \quad \text{(Eq. 11)}$$

where $t_{90,A}$ and t_{90,E_a} are, respectively, the partial derivatives of t_{90} with respect to A and E_a; SD_A and SD_{E_a} are the standard deviations of A and E_a, respectively; and $\mathrm{COV}_{E_a,A}$ is the covariance of E_a and A. No simulation was attempted to evaluate the statistical properties of the predicted shelf-life (t_{90}) as estimated by this nonlinear approach.

In this report, the nonlinear approach was further modified to facilitate a direct prediction of drug stability using observed values of drug content, time, and temperature. Extensive computer simulations were made to evaluate the statistical properties of the parameter estimates of E_a and t_{90}. The applicability and versatility of this nonlinear approach were evaluated as well.

THEORETICAL

The assumptions made in the subsequent mathematical derivations are that (*a*) the energy of activation (E_a) is not a function of temperature and (*b*) normal storage condition at room temperature is set at 25°C. Since a direct prediction of the shelf-life of the drug at 25°C is desired, modification of the Arrhenius equation appears necessary. The degradation rate constant at 25°C (k_{298}) can be obtained from the Arrhenius equation:

$$k_{298} = A \exp\left(-\frac{E_a}{R298}\right) \quad \text{(Eq. 12)}$$

Rearrangement of Eq. 12 yields:

$$A = k_{298} \exp\left(\frac{E_a}{R298}\right) \quad \text{(Eq. 13)}$$

Substituting Eq. 13 for A into the Arrhenius equation (Eq. 5) yields:

$$k = k_{298} \exp\left(\frac{E_a}{R298}\right) \exp\left(-\frac{E_a}{RT}\right) \quad \text{(Eq. 14)}$$

If drug degradation follows a first-order reaction, Eq. 2 can be used to describe the functional relationship between content and time. Substitution of Eq. 14 for k into Eq. 2 and rearrangement yields:

$$C = C_0 \exp\{-k_{298} t \exp[(E_a/R)(1/298 - 1/T)]\} \quad \text{(Eq. 15)}$$

For a first-order reaction, t_{90} can be determined by using the following relationship:

$$t_{90} = 0.1054/k_{298} \quad \text{(Eq. 16)}$$

Substituting Eq. 16 for k_{298} into Eq. 15 yields:

$$C = C_0 \exp\{-t(0.1054/t_{90}) \exp[(E_a/R)(1/298 - 1/T)]\} \quad \text{(Eq. 17)}$$

Equation 17 can be used now to provide direct estimates of t_{90} and E_a *via* nonlinear regression analysis. Time (t) and temperature (T) are the two independent variables. Similarly, equations for either zero- (Eq. 18) or second-order (Eq. 19) degradation can be derived as follows:

$$C = C_0\{1 - t(0.1/t_{90}) \exp[(E_a/R)(1/298 - 1/T)]\} \quad \text{(Eq. 18)}$$

$$C = \frac{C_0}{1 + t(0.11/t_{90}) \exp[(E_a/R)(1/298 - 1/T)]} \quad \text{(Eq. 19)}$$

EXPERIMENTAL

Generation of Data With or Without Error—Data were generated by using Eqs. 17–19 for first-, zero-, and second-order reactions, respectively. Different sets of input theoretical values of E_a and t_{90} were assigned to each case. A single temperature sequence [323 K, 333 K, 343 K, and 353 K (50–80°C)] and a specified time scale for each temperature were employed to generate, at first, errorless drug content data. Drug content data were expressed as percent of content at time zero. Random numbers, which were also expressed as percent, were selected from a normal distribution with a mean of zero and a prescribed standard deviation (24, 25). These selected random numbers (used as noise) were added to the errorless drug content data to obtain simulated experimental "raw data." The normality of the generated error distribution was tested by using the chi-square goodness-of-fit test (26). The mean and standard deviation of the error distribution were also computed to ascertain that the mean was close to zero and that the standard deviation was close to that prescribed.

Calculation of Initial Estimates for Nonlinear Regression Analysis—Since the nonlinear regression method uses the iterative technique, the proper initial estimates of the parameters should be provided to initiate the iteration (27). The initial estimates of E_a and t_{90} were calculated in the following manner: (*a*) the functional relationships between drug content and time (Eqs. 1, 4, and 3) were employed to estimate the rate constants at these temperatures; (*b*) the linearized form of the Arrhenius relationship (Eq. 6) was used to obtain the values of E_a and A; and (*c*) the shelf-lives (t_{90}) can be calculated using Eqs. 20–22 for zero-, first-, and second-order reactions, respectively:

$$t_{90} = (0.1C_0/A) \exp\left(\frac{E_a}{R298}\right) \quad \text{(Eq. 20)}$$

$$t_{90} = (0.1054/A) \exp\left(\frac{E_a}{R298}\right) \quad \text{(Eq. 21)}$$

Statistical Methods—The Monte Carlo method of computer simulations (28) was used to evaluate the reliability of the statistics for the estimates of E_a and t_{90}. The NONLIN computer program (29) was employed to obtain values of final estimates of E_a and t_{90} in the nonlinear approach. After obtaining the final estimates of E_a and t_{90} for each set of data, a certain sampling distribution for either E_a or t_{90} was formed. The mean, standard deviation, and bias of the sampling distribution of the parameter estimates were determined. The bias, in absolute values, is defined as the difference between the parameter estimate and the theoretical value. The statistics of the parameter estimates were evaluated by the closeness of the mean of the sampling distribution of each parameter estimate to its theoretical value, and the relative magnitudes of the standard deviation and the bias.

For comparison, the classical linear approach was also used to obtain the predicted shelf-life of the drug. The shelf-life was estimated through steps involving (*a*) the use of the linearized form of drug content-time relationship to obtain the rate constants at elevated temperatures, (*b*) the application of the Arrhenius equation (Eq. 6) to estimate E_a and A, (*c*) the extrapolation from straight line with the best fit in the Arrhenius plot to obtain the room temperature rate constant and its 95% confidence interval, and (*d*) the transformation of the room temperature rate constant and its 95% confidence interval to the corresponding value of shelf-life and its 95% confidence interval. Three computer programs written in FORTRAN IV were employed to generate the simulated experimental data, to calculate the initial estimates for nonlinear regression analysis, and to obtain values of the shelf-life and its 95% confidence interval through the use of the classical linear approach.

RESULTS

Before performing the computer simulations, Eqs. 17–19 were fitted to errorless data. In every case, NONLIN gave final estimates of E_a and t_{90} exactly identical to the input theoretical values. Standard deviations of these two estimates were close to zero. However, they were found to be highly correlated, with a correlation coefficient of 0.97 in all cases. Estimates of E_a and t_{90} obtained from the simulated "raw data" with prescribed errors also had the same high correlation coefficient. The high dependence between parameter estimates might complicate the separate estimation of each parameter (30). Metzler and Tong (31) indicated that this high correlation between parameters may imply meaningless statistics of the final estimates.

To examine this high correlation problem between the computer estimates of E_a and t_{90} and to evaluate the applicability of this "one-step" nonlinear approach, the Monte Carlo method of computer simulations was employed to probe into the statistical properties of these two final estimates. The simulations were divided into four parts which examined (*a*) the influence of data noise on the final estimates of E_a and t_{90}, (*b*) the influence of different theoretical values on the estimates of E_a and t_{90}, (*c*) the influence of various orders of reaction on the final estimates of E_a and t_{90}, and (*d*) the influence of the "extensiveness" of stability data on the estimates of E_a and t_{90}. It was reasoned that if estimates of these two parameters with meaningful statistical properties could be obtained under a wide range of conditions and different distributions of random errors in the data set, this high correlation between them may be assumed to be attributed to the nature of the mathematical function employed for estimating these parameters.

The simulated experimental "raw data" employed for examining the influence of data noise, different theoretical values, and various orders of reaction on these two final parameter estimates were generated using a single temperature sequence of 50–80°C and a variable time scale for each temperature. The time scales were selected to achieve ≥60% degradation of drug content at the lowest temperature and ≥80% degradation of content for three higher temperatures. The specifications of the computer simulations is shown in Table I. A wide range of stability and energetics values were chosen to test this nonlinear mathematical relationship. Thirty sets of data with 32 data points per set were generated for each case.

Table III—Influence of Initial Estimates on Final Parameter Estimates of a First-Order Reaction [a]

	Initial Estimate		Final Estimate	
SD	E_a	t_{90}	E_a	t_{90}

[a] Theoretical values: E_a = 25.00 kcal/mol; t_{90} = 124 week.

The results for simulations which examined the influence of data noise on final estimates of E_a and t_{90} are shown in Tables II–IV. At all three noise levels, mean estimates for E_a and t_{90}, obtained as the average from 30 individual estimates given by NONLIN, were very close (within 3.3%) to the assigned theoretical values. The standard deviations of the estimates given by NONLIN, on the average, were found to be acceptable estimates of the standard errors of mean estimates for both E_a and t_{90} in all cases. Both standard errors of mean estimates and average biases of the estimates were small and responded well to the change of the noise level in the constructed data. Estimates of E_a and t_{90} also did not vary excessively among these 30 sets of data.

The effect of initial estimates on the computed estimates of E_a and t_{90} was also tested for each set of data. The data, shown in Table III, represented simulation trials from one representative run for each noise level. One of these three sets of initial estimates was calculated using the linear approach, as described in the experimental section. The other two sets of initial estimates were arbitrarily chosen to provide different starting points to initiate the iteration step. The results clearly indicated that the locations of the initial estimates had no apparent effect on final estimates of E_a and t_{90}.

The examination of the residuals in the regression analysis revealed that the standard deviations of residuals obtained were also consistent with the prescribed standard deviations (Table IV). The r^2 values, which can be used as measures of good fit (27), were close to 1.0 in all cases. The randomness of the residuals in a representative set of data is shown in Fig. 1. The composite results showed, therefore, that estimates of E_a and t_{90} with meaningful statistics can be obtained with Eq. 17 using simulated data with different levels of data noise.

Results for studies which examined the influence of different theoretical values and of various orders of reaction on the parameter estimates of E_a and t_{90} are shown in Tables V and VI, respectively. The statistics of the parameter estimates for E_a and t_{90} were shown to be satisfactory for these conditions.

The influence of the "extensiveness" of stability data on the final parameter estimates of E_a and t_{90} was also tested. Specification of different types of data

	353	0.07	0.56	71.0
Type III	323	0.4	3.2	93.1
	333	0.4	3.2	79.5
	343	0.4	3.2	50.1
	353	0.4	3.2	14.1

[a] At the last sampling time, using errorless data for estimation.

structure is shown in Table VII. The same temperature sequence (50-80°C) was used for all three types of data structure. "Raw data" with type I structure, representing an example of extensive data gathering, were generated employing a variable time scale to achieve ≥80% degradation in drug content at each temperature. Simulated "raw data" with type II structure were generated using a variable time scale for each temperature as well. However, these time scales were set to account for degradation of the drug content to only ~30% completion. Data with type III data structure were generated by employing a fixed sampling time and frequency for all four temperatures studied. Thus, data structures shown as type II and III represented situations in which only limited kinetic data were available, as often the case in real accelerated stability trials. Simulations using these types of data structures are shown in Table VIII. Despite considerable differences in the degree of "extensiveness" in the data base, it was shown that good estimates of E_a and t_{90} with satisfactory statistical properties could be obtained for each type of data structure.

Sometimes the initial drug content, C_0, is not known and should be estimated together with the estimation of E_a and t_{90}. Simulations for estimating these three parameters are shown in Table IX. The nonlinear approach is shown to be capable of providing good mean estimates and meaningful statistics for C_0, E_a, and t_{90}. Based on kinetic principles, Eqs. 17-19 can be easily modified to determine the shelf-life at any chosen content, *i.e.*, either as percent of initial or of labeled strength.

Comparison between the classical linear approach and the nonlinear approach for the prediction of drug stability was made by using a first-order degradation reaction as an example. The "raw data" generated for the study that examined the influence of data noise on the final estimates of E_a and t_{90} were employed for this comparison between the two methods. The shelf-lives (t_{90}) and their 95% confidence intervals as estimated by using either the classical linear approach or the present nonlinear approach for three representative sets of data (each at three noise levels) are shown in Fig. 2. The nonlinear approach appeared to provide better mean estimates of drug shelf-life with much smaller and more symmetrical 95% confidence intervals than did the classical approach in all cases examined.

It is desirable to compare the nonlinear approach with the classical linear approach using real stability data. Accelerated stability data of vitamin A in multivitamin tablets (2) and of NAD (32) were employed for this purpose; results of this comparison are shown in Table X. The linear and nonlinear methods provided identical mean estimates of shelf-life in both cases. Moreover, the nonlinear method also provided a more symmetrical and smaller 95% confidence interval in the prediction of vitamin A stability than did the classical linear approach. However, both linear and nonlinear methods predicted somewhat longer shelf-lives of these two compounds than that experimentally determined at room temperature. It is possible that both systems possess some degree of non-Arrhenius behavior, a problem that neither the linear nor the nonlinear approach can correct.

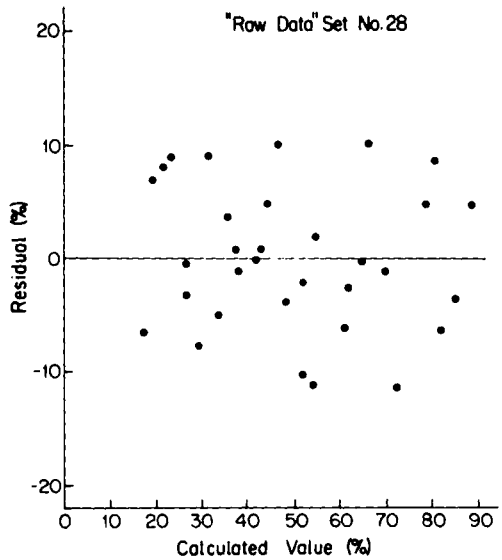

Figure 1—*Representative plot of residuals. Calculated values are expressed as percent of drug content at time zero. Residual is the difference between the observed value and calculated value of drug content for each data point.*

DISCUSSION

The nonlinear approach shown in this report appears to be capable of predicting the shelf-life (t_{90}) directly and reproducibly. The uncertainties in the estimated t_{90} are the reflection of the errors inherent in the observed drug content data. The nonlinear approach can be applied to various orders of degradation reaction and a wide range of different theoretical values of E_a and t_{90}. It was shown that although some experimental "raw data" may not be very extensive, good estimation of shelf-life with meaningful statistical properties can still be obtained. Furthermore, this approach provides better mean estimates of t_{90} with much smaller 95% confidence intervals than the classical approach. Obviously, this method of drug stability prediction will be of little value without the aid of appropriate computer programs to carry out the nonlinear parameter estimation procedure. Fortunately, several computer programs including NONLIN (29), BMDP-P3R (33), SAAM (34), *etc.* are available for nonlinear regression analysis. The 1974 version of the NONLIN program was selected in this study because this particular computer program, which can be used to fit various models (27), is a widely used program in the area of pharmacokinetics and related pharmaceutical sciences.

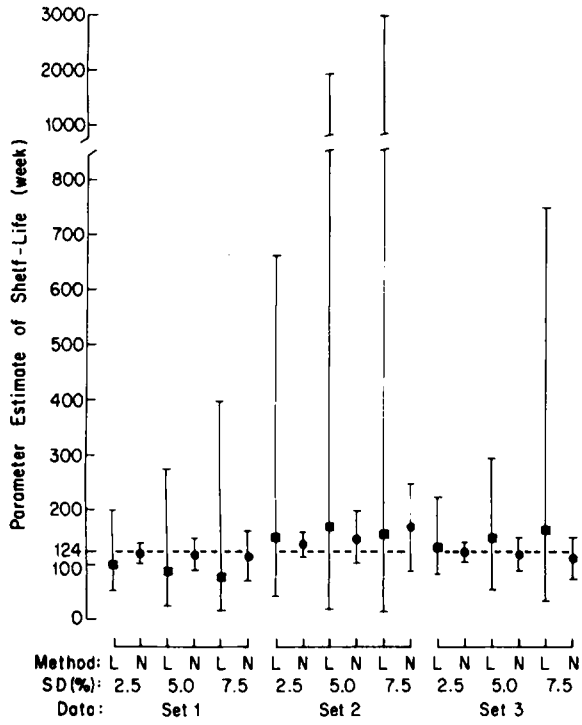

Figure 2—*Plot of the parameter estimate of the shelf-life (t_{90}) for each of the two methods of estimation in three sets of data with three different levels of noise. Data represent mean estimate and its 95% confidence interval after using the nonlinear approach (N, ●) and the classical linear approach (L, ■); (- - - -) represents the theoretical value of shelf-life of 124 weeks.*

A high correlation between E_a and t_{90} was found during the study of computer simulations. This high dependency between the parameter estimates was suggested by Metzler and Tong as a possible indication of meaningless statistics of these estimates (31). The Monte Carlo method of computer simulations was used to examine this high correlation problem and to evaluate the statistical properties of the final estimates of E_a and t_{90} in this report. During the regression analysis for each set of data by NONLIN, the final parameter estimates of E_a and t_{90} converged on the mathematical minimum after only 3-5 iteration steps without any computational difficulty.

The statistics of the parameter estimates can be evaluated by examining the sampling distributions of both E_a and t_{90}. The sampling distributions of both E_a and t_{90} were symmetrical about the mean estimates and had small standard deviations and biases. A large standard deviation is usually reflective of a poor determination of a parameter estimate (35, 36). Examination of the residuals (36) and of the correlation of the observations (r^2 value) can also be used to evaluate the statistics of the parameter estimates in a model. Our results indicated that (*a*) the standard deviations of the residuals were consistent with the prescribed standard deviations and (*b*) the plots of the residuals *versus* the calculated values for each set of data showed the random nature of the residuals. The r^2 values found were close to perfection (*i.e.*, 1.0) in all the data sets examined. Furthermore, it has been stated (37) that if the nonlinear regression method is correct, different sets of initial estimates for each set of data should converge on the same final estimates. Our simulation trials (Table III) showed this to be the case here. Therefore, it appears that good mean estimates of E_a and t_{90} with meaningful statistical properties are obtained using the nonlinear method, even though these two parameters are highly correlated.

Our observation of a correlation between the final estimates of E_a and t_{90} is not unique. Metzler and Tong (31) showed the high correlation between V_{max} and K_m in the parameter estimations of the Michaelis-Menten equation to be accompanied by meaningless statistics. They attributed this result to the peculiar nature of the mathematical function that relates these two variables, in that a change in the estimate of V_{max} may be compensated by a simultaneous change in K_m. However, Bard (22) had shown that meaningful statistical properties of the parameter estimates of A and E_a (Eq. 8) could be obtained despite the high correlation (*i.e.*, r = 0.98) between them. Thus,

Table X—Comparison Between the Classical Linear Approach and Nonlinear Method for the Prediction of Drug Stability using Literature Data

Literature Study	Shelf-Life, week			
	Linear Method		Nonlinear Method	
	Mean	95% CI[a]	Mean	95% CI[a]
I[b]	113.3[d]	49.25-262.2[d]	109.0	61.73-156.2
II[c]	6.49	5.67-7.44	6.63	5.54-7.71

[a] Confidence interval. [b] Prediction of vitamin A stability in multivitamin tablets. The accelerated stability data were obtained from Fig. 1 in the Ref. 2. [c] Prediction of the stability of NAD, taken from Ref. 32. [d] These values were calculated by using the reported rate constants.

it seems that the presence of a high correlation between parameter estimates may not necessarily indicate that the statistical properties of these final estimates are meaningless.

In conclusion, meaningful statistics of the final parameter estimates of E_a and t_{90} can be obtained by the nonlinear approach described in this paper. This approach is applicable over a wide range of different theoretical values of E_a and t_{90}, different orders of reaction, different levels of noise in data, and different types of data structure. The advantage of this nonlinear approach is that it uses data of drug content, time, and temperature to provide a direct estimation of shelf-life with relevant statistics. This method may be potentially useful for the realistic prediction of drug stability of pharmaceutical products.

Behavior of ATP Toward Phenothiazine Drugs

M. R. GASCO ˣ, M. E. CARLOTTI, and M. TROTTA

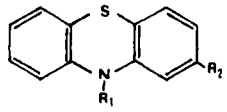
Received January 4, 1982, from the *Istituto di Chimica Farmaceutica e Tossicologica, Università di Torino, Corso Raffaello 31, 10125 Torino, Italy.* Accepted for publication February 21, 1983.

Abstract □ The tricyclic amines promazine, promethazine, chlorpromazine, triflupromazine, and trifluperazine form solid ion pairs with ATP in a 1:2 molar ratio. There is a good correlation between the measured K_{sp} and the apparent diffusion constants of the ion pairs with the critical micelle concentration (CMC) of the corresponding phenothiazines. Solid ion pairs are solubilized by phenothiazine micelles; the binding constants of ATP to drug micelles are calculated from solubility data at 25°C and can be related to the CMC of the phenothiazines.

Keyphrases □ ATP—behavior toward phenothiazine drugs, binding, micellar solubilization □ Binding—behavior of ATP toward phenothiazine drugs, micellar solubilization □ Phenothiazine drugs—behavior of ATP, binding, micellar solubilization □ Micellar solubilization—behavior of ATP toward phenothiazine drugs, binding

The mechanism of action of phenothiazine drugs is difficult to explain because of their great variety of biochemical and physiological effects. Membrane interactions seem to be important particularly in the case of chlorpromazine (1–4). Phenothiazines, like many tricyclic amines, have amphiphatic properties and are surface-active drugs (4–7). Their micelles are able to solubilize *in vitro* various high molecular weight drugs such as pteridine and porphyrin derivatives (8, 9); the binding constants of solubilized compounds with micelles are rather high. Previously, Blei (10) studied the decrease of chlorpromazine surface tension in the presence of ATP, while Moriguchi *et al.* (11) observed the formation of a 1:1 complex between the neuroleptic agent and ATP.

The aim of the present work is to investigate the behavior of five phenothiazines with different pharmacological activity



Promethazine	$R_1 = CH_2CH(CH_3)N(CH_3)_2$	$R_2 = H$
Promazine	$R_1 = CH_2CH_2CH_2N(CH_3)_2$	$R_2 = H$
Chlorpromazine	$R_1 = CH_2CH_2CH_2N(CH_3)_2$	$R_2 = Cl$
Triflupromazine	$R_1 = CH_2CH_2CH_2N(CH_3)_2$	$R_2 = CF_3$
Trifluperazine	$R_1 = CH_2CH_2CH_2$—N N—CH_3	$R_2 = CF_3$

it seems that the presence of a high correlation between parameter estimates may not necessarily indicate that the statistical properties of these final estimates are meaningless.

In conclusion, meaningful statistics of the final parameter estimates of E_a and t_{90} can be obtained by the nonlinear approach described in this paper. This approach is applicable over a wide range of different theoretical values of E_a and t_{90}, different orders of reaction, different levels of noise in data, and different types of data structure. The advantage of this nonlinear approach is that it uses data of drug content, time, and temperature to provide a direct estimation of shelf-life with relevant statistics. This method may be potentially useful for the realistic prediction of drug stability of pharmaceutical products.

Behavior of ATP Toward Phenothiazine Drugs

M. R. GASCO ˣ, M. E. CARLOTTI, and M. TROTTA

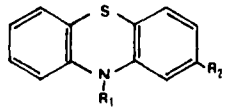
Received January 4, 1982, from the *Istituto di Chimica Farmaceutica e Tossicologica, Università di Torino, Corso Raffaello 31, 10125 Torino, Italy.* Accepted for publication February 21, 1983.

Abstract □ The tricyclic amines promazine, promethazine, chlorpromazine, triflupromazine, and trifluperazine form solid ion pairs with ATP in a 1:2 molar ratio. There is a good correlation between the measured K_{sp} and the apparent diffusion constants of the ion pairs with the critical micelle concentration (CMC) of the corresponding phenothiazines. Solid ion pairs are solubilized by phenothiazine micelles; the binding constants of ATP to drug micelles are calculated from solubility data at 25°C and can be related to the CMC of the phenothiazines.

Keyphrases □ ATP—behavior toward phenothiazine drugs, binding, micellar solubilization □ Binding—behavior of ATP toward phenothiazine drugs, micellar solubilization □ Phenothiazine drugs—behavior of ATP, binding, micellar solubilization □ Micellar solubilization—behavior of ATP toward phenothiazine drugs, binding

The mechanism of action of phenothiazine drugs is difficult to explain because of their great variety of biochemical and physiological effects. Membrane interactions seem to be important particularly in the case of chlorpromazine (1–4). Phenothiazines, like many tricyclic amines, have amphiphatic properties and are surface-active drugs (4–7). Their micelles are able to solubilize *in vitro* various high molecular weight drugs such as pteridine and porphyrin derivatives (8, 9); the binding constants of solubilized compounds with micelles are rather high. Previously, Blei (10) studied the decrease of chlorpromazine surface tension in the presence of ATP, while Moriguchi *et al.* (11) observed the formation of a 1:1 complex between the neuroleptic agent and ATP.

The aim of the present work is to investigate the behavior of five phenothiazines with different pharmacological activity



Promethazine	$R_1 = CH_2CH(CH_3)N(CH_3)_2$	$R_2 = H$
Promazine	$R_1 = CH_2CH_2CH_2N(CH_3)_2$	$R_2 = H$
Chlorpromazine	$R_1 = CH_2CH_2CH_2N(CH_3)_2$	$R_2 = Cl$
Triflupromazine	$R_1 = CH_2CH_2CH_2N(CH_3)_2$	$R_2 = CF_3$
Trifluperazine	$R_1 = CH_2CH_2CH_2$—N N—CH_3	$R_2 = CF_3$

toward ATP, paying attention particularly to variations in the lipophilicity of ATP in the presence of the drugs and to its possible solubilization by phenothiazine micelles.

EXPERIMENTAL

Materials—Promethazine hydrochloride[1], promazine hydrochloride[1], chlorpromazine hydrochloride[1], trifluperazine hydrochloride[1], and triflupromazine hydrochloride[1], ATP[2], non-reinforced dimethylpolysiloxane[3] sheeting in a labeled thickness of 5 mil [12.5×10^{-3} cm, thoroughly rinsed and treated as previously described (12)]; 0.25-μm filter disks[4], Sephadex G-25 medium[5], and glass microfiber papers[6] were commercial samples. A pH meter[7], a spectrophotometer[8], a plate tensiometer[9], a conductimeter[10], and an automatic fraction collector[11] were also used.

Preparation of Solid Complexes—The solid complexes were obtained in aqueous media by mixing 50 mL of ATP (8.0×10^{-3} M) with 50 mL of tricyclic amine ($16.0\text{-}32 \times 10^{-3}$ M). The suspensions were pH 3.5-4.0. All the phenothiazines formed a precipitate, which was separated and analyzed. The same molar ratios of ATP-phenothiazine were employed throughout. The pH was fixed at 5.5 and 6.0 by adding 0.1 M NaOH and 0.1 M 2-morpholineethansulfonate buffer, respectively. This buffer was selected because permeability measurements have shown (12) that it does not form ion pairs with phenothiazines.

Solutions at fixed concentrations of ATP (4.0×10^{-3} M) and chlorpromazine (8.0×10^{-3} M) and increasing concentrations of calcium chloride (2.0×10^{-3}, 4.0×10^{-3}, and 8.0×10^{-3} M) were prepared. No solid complex was obtained from the solution with 8.0×10^{-3} M calcium chloride.

Analysis of Solid Complexes—Solid ion pairs (8-15 mg) were treated with 10 mL of 2 M HCl, and the solution was heated for 15 min in a water bath to promote ATP hydrolysis, then diluted to 25 mL with 2 M HCl. ATP was determined by the malachite green method (13) to evaluate the phosphate obtained by hydrolysis.

The concentration of phenothiazine was determined spectrophotometrically at 310 nm (chlorpromazine, log ϵ = 3.62; promazine, log ϵ = 3.56; promethazine, log ϵ = 3.56; triflupromazine, log ϵ = 3.43; and trifluperazine, log ϵ = 3.60). ATP does not interfere at this wavelength.

The analysis data are reported in Table I. Each molar ratio is the average of three determinations. All the phenothiazines studied form a 1:2 solid complex with ATP. A 1:2 molar ratio was also obtained for the solid ATP-chlorpromazine complex formed at different molar ratios of reactants and in the presence of calcium chloride. In Table II the yields of the solid complex obtained in different media are listed.

Determination of Solubility Products—*Spectrophotometry at 25°C*—Glass-stoppered cylinders containing an excess of solid complex in 6 mL of water were shaken in a water bath kept at 25 ± 0.5°C for 24 h. The samples were then filtered through 0.25-μm filter disks. The ATP and phenothiazine concentrations were determined by the malachite green method and absorbance measurements, respectively, on the filtrate as previously described. The results reported in Table III confirm an ATP-tricyclic amine molar ratio of 1:2.

Conductimetry—Twenty-five milliliters of the drug solution was placed in the titrimeter cell kept at 25 ± 0.5°C. A concentrated solution of ATP was then added; the rate of addition was generally between 0.1 and 1 mL/min, with titration usually complete within 5-10 min. Complexation between the two ions was taken to be the point on the conductimetric titration trace where a marked change in the gradient is observed (Fig. 1a).

Several titration curves were determined using different concentrations of phenothiazines. Double-logarithmic plots were then constructed, reporting ATP concentrations at the break point against drug concentrations. All the studied systems exhibited a straight-line relationship between cation and anion concentration (Fig. 1b), showing that, over the concentration ranges studied, the areas of ion self-association have been avoided (14, 15). Analysis of these double-logarithmic plots gave slopes of ~0.5; the intercept was at log $K_{sp}/2$. By substituting the values:

$$\log [\text{drug}] = \frac{\log K_{sp}}{2} - \frac{\log [\text{ATP}]}{2} \qquad \text{(Eq. 1)}$$

Table I—Experimental Molar Ratios [a] for ATP-Phenothiazine Complexes

Complex	Amount, g	ATP, mol $\times 10^{-5}$ [b]	Phenothiazine, mol $\times 10^{-5}$ [b]
ATP-chlorpromazine	0.0150	1.2	2.5
ATP-promazine	0.0080	0.65	1.4
ATP-promethazine	0.0100	1.0	2.1
ATP-triflupromazine	0.0150	1.0	2.2
ATP-trifluperazine	0.0130	1.0	1.9

[a] Determined spectrophotometrically. [b] Standard deviation of each value is within 5-10%; *e.g.*, for the ATP-chlorpromazine complex, the molar ratio, averaged over three separate measurements, is 2.08 ± 0.11. If the molar ratio is averaged over all the measurements concerning all the complexes (assuming that the ratio is the same for all the phenothiazines) a value of 2.09 ± 0.08 is obtained.

Key: (○) chlorpromazine alone; (●) chlorpromazine in the presence of 0.8 × 10⁻⁴ M ATP; (×) chlorpromazine in the presence of 0.8 × 10⁻⁴ M ATP and 0.6 × 10⁻⁴ M $CaCl_2$; (■) chlorpromazine in the presence of 0.8 × 10⁻⁴ M ATP and 0.8 × 10⁻⁴ M $CaCl_2$.*

a 1:2 interaction between the ATP and the drug was inferred.

Determination of the Critical Micelle Concentration—The critical micelle concentrations (CMC) of phenothiazines were determined by measurements of surface tension using a plate tensiometer at 25 ± 0.5°C in 0.9% NaCl at pH 6.0. The CMC of chlorpromazine was also determined in the presence of ATP and of calcium ions ([ATP] = 0.8 × 10⁻⁴ M; [Ca^{2+}] = 0.6 × 10⁻⁴ M ÷ 0.8 × 10⁻⁴ M) (Fig. 2).

Determination of the Apparent Diffusion Constant—The diffusion cell was of the type used by Nakano and co-workers (16, 17). The glass cell consists of donor and receptor compartments (volume of each, 20 mL) and a membrane (available area, 3.80 cm^2). Twenty milliliters of 0.01 M HCl were added to one arm, and an equal volume of the test solution was placed in the other arm. The concentration of the diffusible phenothiazine drug in the desorbing hydrochloric acid solution was kept at zero, maintaining diffusing phenothiazine in a dissociated form. All solutions were brought to 37°C before being placed in the cell, which was kept at 37°C. The contents of each compartment were stirred by a magnet attached to an electric motor turning at 300 rpm. At scheduled times an aliquot (0.5 mL) of the receptor solution was removed for the absorbance measurements, and the same volume of 0.01 M HCl was added.

The equation derived by Garrett and Chemburkar (18) for steady-state diffusion was used to obtain the apparent diffusion constants, $D = C_1XV/tC_2S$ where C_1 is the concentration of diffusate in the desorbing solution, X is the thickness of the membrane, S is the available area of membrane, V is the volume of the desorbing solution, and C_2 is the concentration of the diffusate. The diffusing solution in 0.9% NaCl at pH 6.0 at 37°C contained 0.8–1.0 × 10⁻³ M tricyclic amine and an ATP concentration eight times the molarity of the drug. D values are reported in Table IV.

Determination of the Binding Constants of ATP to Phenothiazine Micelles by a Solubility Method—Increasing concentrations of tricyclic amines (0.5–40.0 × 10⁻³ M) were added to the solutions of ATP (1.0 × 10⁻³ M) in glass-stoppered cylinders at pH 6.0 in 0.9% NaCl. The cylinders were placed in a water bath and rotated at 25 ± 0.5°C until equilibrium was reached. Agitation for 24 h was sufficient. The ionic strength of the solutions was brought to 0.155 with 0.9% NaCl; therefore, the small amounts of sodium hydroxide used for pH adjustment did not appreciably influence the ionic strength. After 24 h an appropriate volume (4 mL) was filtered through a 0.25-μm filter disk. The concentration of ATP was determined by the malachite green method; each value is an average of three determinations. Comparable results were obtained using glass microfiber papers instead of filter disks. The same procedure was employed to study the solubility of the ATP–chlorpromazine complex at increasing concentrations of chlorpromazine in the presence of a fixed concentration of calcium chloride (7.5 × 10⁻³ M).

The solubility measurements for all the studied phenothiazines were also performed in 0.1 M 2-morpholineethansulfonate buffer (pH 6.0). The results are in agreement with previous data. Variation in the solubility of the ATP–phenothiazine complex was quite similar to the variation of the solubilization of slightly soluble hydrophobic solutes by aggregating micelle-forming surfactants (19, 20). At first, ATP concentration decreases because of solid complex formation; at higher concentrations of the drug, ATP concentration increases since the solid ion pair is solubilized by surfactant micelles. From the solubilization curves the apparent binding constants of ATP with phenothiazine micelles were calculated using (21):

$$\frac{S_{M,W}}{S_W} = 1 + K_bC \qquad \text{(Eq. 2)}$$

where S_W is the concentration of ATP at the CMC, $S_{M,W}$ is the concentration in the presence of micelles of the drug, and C is the surfactant concentration (molarity), which exceeds the CMC value (Table V).

Determination of the Binding Constant of ATP with Chlorpromazine Micelles by Gel Filtration—The binding constant (K_b) of ATP with chlorpromazine micelles was determined by gel filtration according to Herries *et al.* and Yatsimirskii *et al.* (21, 22). The chromatography of Sephadex G-25 was carried out on a 2-cm diameter column with a total volume of 72 mL. Using blue dextran 2000, the void volume V_0 of the packed column was determined to be 29.5 mL. The imbibed volume of the gel V_i, calculated from the water regain and wet density data, was 34.0. Prior to each run the column was first equilibrated with 0.9% NaCl at pH 6.0 and then with the appropriate concentration of chlorpromazine (in 0.9% NaCl at pH 6.0). The run was initiated by addition of 0.5 mL of ATP solution (2 mg/mL) to the column. All runs were done at 25°C. The elution volume V_e was calculated by ATP determined according to the method previously described. The K_b value was determined using (22, 23):

$$\frac{V_i}{V_e - V_0} = \frac{\overline{V}(K_p - 1)}{k'K_d}C + \frac{1}{k'K_d} \qquad \text{(Eq. 3)}$$

where V_i, V_e, and V_0 are the imbibed (stationary), elution, and void volumes, $\overline{V}$ is the molar volume of chlorpromazine in the micelle, K_d is the molecular sieving constant, k' is the proportionality constant between the solute absorbed per unit volume of gel matrix and the equilibrium concentration of monomer solute in liquid, C is the concentration of chlorpromazine, and K_p is the micelle–water partition coefficient of ATP. A plot of the left-hand side of Eq. 3 ($V_i/V_e - V_0$) *versus* chlorpromazine concentration (C) is shown in Fig. 3. At low drug concentrations the values of $V_i/V_e - V_0$ are independent of the concentration of the surfactant. Above the CMC, the values of $V_i/V_e - V_0$ increase linearly with the micelle concentrations.

The product $\overline{V}(K_p - 1)$ can be determined from the slope of the straight line according to Yatsimirskii *et al.* (21). The binding constant is then calculated as $K_b = \overline{V}(K_p - 1)$. Intersection of the lines in Fig. 3 define the CMC of chlorpromazine hydrochloride in the presence of the solute and of Sephadex G-25. The CMC is about twice as great as that determined by the surface tension method. According to other authors (23, 24), such a discrepancy is probably due to strong interaction between the Sephadex dextran and chlorpromazine. In Table V the K_b value obtained by gel filtration is reported.

Table IV—Apparent Constants of Diffusion Through Dimethylpolysiloxane Membrane at 37°C of Phenothiazines[a] Alone and in the Presence of ATP

RESULTS

ATP interacts with phenothiazine drugs to form water-insoluble complexes. A 1:2 ATP–drug complex was obtained (Table I) in the presence and absence

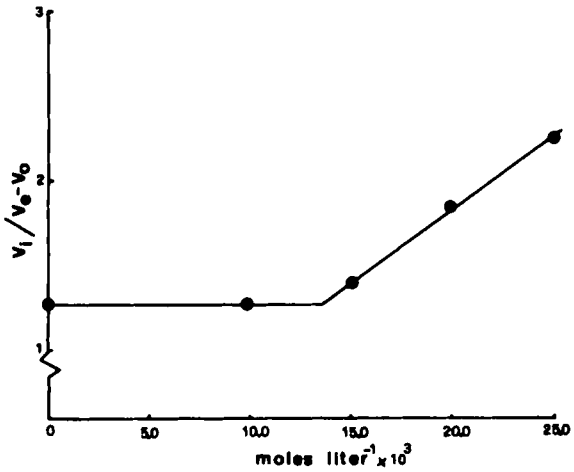

Figure 3—*Plots of* $V_i/V_e - V_0$ versus *chlorpromazine molar concentration.*

of calcium ions. Trifluperazine with two basic sites on the piperazine ring shows a similar behavior. The yields change with the different drugs examined and are pH dependent; all the phenothiazines show a maximum at pH 6.0, where ATP dissociation is highest (Table II). The formation of the ion pairs at pH > 6.0 was not studied because of the partial coprecipitation of some phenothiazine bases.

The CMC of chlorpromazine (Fig. 2) varies in the presence of ATP and calcium ions; by adding only ATP at low concentration, the CMC decreases, probably due to the greater hydrophobicity of the ion pairs. If calcium ions are then also added to the solution, the CMC rises and when the molarity of calcium and ATP are equal, the initial CMC is obtained. This behavior could indicate that a high calcium ion concentration interferes with ion pair formation.

The permeation rate of different phenothiazines through a dimethylpolysiloxane membrane increases in the presence of ATP (Table V). The effect of ATP on the apparent diffusion constant (D) was studied examining solutions containing ATP at concentrations only eight times the molarity of the drug, to avoid the precipitation of the solid complex. Phenothiazine micelles solubilize ATP, giving high apparent binding constants (K_b). The concentration of the drug was indicated in two ways: as molar concentration (C) and as micellar concentration (C_m), where $C_m = (C - \text{CMC})/N$ (N is the aggregation number obtained from the literature (6, 25) assuming that the solubilized compound does not change the size of the micelles). The binding constant of ATP with chlorpromazine micelles decreases in the presence of calcium ions in aqueous solution. The K_b of ATP with chlorpromazine was verified by two methods, obtaining comparable values within the limits of experimental error.

DISCUSSION

The solubility products of the 1:2 solid complexes, obtained by two methods (Table IV), are in good agreement with the yields obtained at pH 6.0. The sequence of solubility products is consistent with that of the surface tensions of the phenothiazine drugs in Ringer's solution at pH 6.0 (26).

A good correlation was also established between the logarithm of the solubility product and the logarithm of the CMC of the phenothiazine involved in the interaction (Fig. 4a, b). A similar dependence was previously observed (15). These results suggest that the increased hydrophobic nature of the interacting amines raises the ion pair stability. Further support to this hypothesis can be noted from Fig. 5, where log D *versus* CMC of phenothiazine is reported. The CMC describes the lipophilicity of the amphiphilic substances; the relation between log D and log CMC shows a linear trend and could be an indirect measure of the lipophilicity of the ion pair. As a consequence, in the presence of phenothiazines at concentrations lower than the CMC, the lipophilicity of ATP greatly increases.

Baur (27) noted that for tricyclic amines the tranquilizing potency rises exponentially with increasing lysis index, a measure of the relative hemolytic potency. Using the lysis index of chlorpromazine (*i.e.*, 1) (27) for comparison, we note a relationship between log (lysis index) and log D of the phenothiazines in the presence of ATP (Fig. 6); permeability data, in this case, can be related to data obtained *in vivo*. On the contrary, no relationship can be found between permeability constants of the ion pairs and partition coefficients (27, 28) or pK_a values (29) of the phenothiazines.

It was shown that certain drugs can be absorbed in their undissociated state,

either directly or by ion pair or complex formation[12]; but ion pairs can also be formed in biological fluids, *e.g.*, between basic drugs and biogenic acids. The role of ATP in the uptake and in the release of biogenic amines is complex and not clearly understood. The behavior of chlorpromazine in the release and uptake of serotonin and biogenic amines from storage sites has not yet been explained (30). In particular, the existence of serotonin–ATP aggregates (up to 12,000–15,000 mol. wt.) was shown by Berneis *et al.* (31) in the storage organelles of blood platelets. Chlorpromazine may interfere with ATP–serotonin aggregates in storage organelles. It is possible that the hydrophobicity of the depressant at first promotes its transport through biological membranes. Subsequently, chlorpromazine might form an ion pair with ATP, partially removing the nucleotide from its aggregates with serotonin. The consequence might be an interference in the uptake mechanism of the monoamine.

Basically, we can regard the micelles as dispersed oil droplets in water (32); the peculiar solvent property of micelle-forming surfactants is closely related to the peculiar nature of the self-association responsible for the formation of the micelles themselves. Micellar solubilization can provide considerable insight into the nature of the interaction of molecules with other lipid assemblies, such as biological membranes, which are responsible for the binding or uptake of molecules and their transport (33).

Figure 7 shows clear trends that suggest a linear correlation, between log CMC and log K_b; probably, lipophilicity of phenothiazines could determine the binding stability between ATP and the micelles. Further support for this

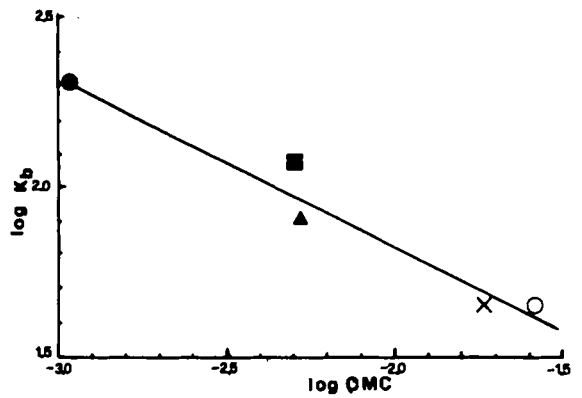

Figure 7—*Relationship between binding constants of ATP to phenothiazine micelles and log CMC of the drugs (0.9% NaCl, pH 6.0, at 25°C). Key: (○) promethazine; (×) promazine; (▲) chlorpromazine; (■) triflupromazine; (●) trifluperazine.*

[12] Unpublished results.

hypothesis arises from the increase of the binding constants (Table V) going from promethazine, an antihistaminic drug, to neuroleptics. The location and distribution of ATP inside micelles could be of interest in elucidating the role of its molecular structure in the solubilization process and in understanding the solubilization capacity of micelles. Phenothiazines are ionic surfactants and their micelles (34) have a core formed from their tricyclic moiety with their cationic head-group outside.

Previously (8, 9), we noted that phenothiazine micelles can solubilize polar molecules; their solubilization occurs, in all cases examined, only when the formation of an ion pair is noted. The solubilization of ATP by phenothiazine micelles can be explained in several ways. Solubilization of ATP might occur as the poorly dissociated ion pair; the lipophilicity of the ion pair is greater than that of ATP, as permeability constants show, for the presence of two phenothiazine hydrophobic molecules. Furthermore, solubilization of the ion pair could be facilitated because the phenothiazine molecules forming the complex are the same as those forming the micelles.

It is possible that *in vivo* bioactive molecules can be solubilized into micelles formed by a drug alone, into mixed micelles of drug and phospholipid, or into membranes, by an ion pair mechanism. Such an interaction might be responsible in part for the activity of drugs and endogenous substances.

High-Performance Liquid Chromatographic Determination of Tracazolate and Its Major Metabolite in Plasma

M. HERMES ˣ and J. O. MALBICA

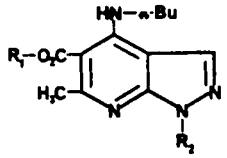
Received December 1, 1982, from the *Biomedical Research Department, Stuart Pharmaceutical Div. of ICI Americas Inc., Wilmington, DE 19897.* Accepted for publication April 12, 1983.

Abstract □ A high-performance liquid chromatographic (HPLC) method is reported that provides for either separate or simultaneous plasma determination of tracazolate and its major metabolite, the free carboxylic acid. Tracazolate is extracted from plasma with hexane and is quantitated by reverse-phase HPLC using an internal standard. The metabolite is extracted in an additional step, methylated, and either quantitated using the same HPLC conditions in a separate determination or combined with the hexane extract for the simultaneous HPLC determination of drug and metabolite. The plasma concentrations of metabolite were as much as 60 times greater than free drug in some animal species, therefore requiring the use of separate determinations for the two compounds. The analyses have limits of reproducible quantitation of 20 ng/mL for tracazolate and 50 ng/mL for the metabolite in plasma. The simultaneous analysis for tracazolate and the metabolite was used to evaluate plasma levels of both compounds *versus* time and dose. Data generated in conjunction with a toxicology study are reported to demonstrate the applicability of the procedure.

Keyphrases □ Tracazolate—free carboxylic acid metabolite, individual and simultaneous assay in plasma, HPLC □ HPLC—tracazolate and its free carboxylic acid metabolite, individual and simultaneous assay in plasma

Tracazolate (I) (ICI 136,753; 4-(butylamino)-1-ethyl-6-methyl-1*H*-pyrazolo[3,4-*b*]pyridine-5-carboxylic acid ethyl ester), a nonbenzodiazepine agent with potential clinical utility as a nonsedative anxiolytic drug (1, 2), is extensively metabolized by a first-pass effect in the rat and dog. The major metabolite (II) is the acid resulting from deesterification of I (3). Although II is inactive in pharmacological screening tests, it is of interest since the circulating levels can be 3- to 60-fold greater than I depending on the species and dosage. Metabolite (II) may be the only drug-related compound in sufficient concentration to measure in plasma, therefore, the quantitation of II may provide an indication of absorption of I at low dosages should plasma levels of I fall below the limits of detection.

The analytical procedures described herein allow for either the separate determination of I and II or for the simultaneous determination of both in plasma. The internal standard used was the 1-butyl analogue of tracazolate (III). Compound IV is the methyl ester of II.



I: $R_1 = R_2 = -CH_2CH_3$ (mol. wt. 304)
II: $R_1 = H$; $R_2 = -CH_2CH_3$ (mol. wt. 276)
III: $R_1 = -CH_2CH_3$; $R_2 = -(CH_2)_3CH_3$ (mol. wt. 332)
IV: $R_1 = -CH_3$; $R_2 = -CH_2CH_3$ (mol. wt. 290)

EXPERIMENTAL

Chemicals and Reagents—All organic solvents used were HPLC grade[1]. The water was purified by ion exchange, activated charcoal filtration, and distillation. Ammonium hydroxide was high purity[2], and 10% aqueous trichloroacetic acid was made from reagent-grade trichloroacetic acid[3]. The methylation of II was carried out with diazomethane[4] (4).

Instrumentation—A liquid chromatograph fitted with an automatic sampler[5] was used with a variable-wavelength UV detector[6] set at 240 nm. The columns used were: a 30 cm × 3.9 mm i.d. stainless steel precolumn (prior to the injector) hand packed with 30–38-μm pellicular packing[7], a 3-cm guard cartridge (between the injector and the analytical column) packed with 5-μm octadecylsilane-bonded packing (ODS)[8], and a 25 cm × 4.6-mm i.d. stainless-steel analytical column packed with 7-μm spherical ODS packing[9]. The mobile phase of methanol–water–20% NH_3OH (90:10:0.05 v/v/v) was pumped at ~2 mL/min and produced ~3000 psi back-pressure. A strip-chart recorder[10] provided a real time record of the chromatography; however, the quantitation was done by computer[11]. The detector signal for the computer was tapped prior to attenuation and had an output of 1 V/AU.

Standard Solutions—Stock solutions of I, II, IV, and the internal standard (III) (1.0 mg/mL) were prepared in methanol. Aliquots of the above stock solutions were further diluted in methanol as spiking solutions. Standard solutions of I, III, and IV were brought to volume with mobile phase solution and were chromatographed directly. Ester IV was previously synthesized in bulk and was used directly to make a stock solution. Matrix standards were prepared with control plasma, 200 μL in a 15-mL centrifuge tube, and spiked with methanol solutions of I and III, for the analysis of I only; II only for the separate analysis of II; or I, II, and III for the dual analysis of I and II. Matrix blanks were not spiked. The internal standard (III) was added to samples obtained from dosed animals for either the single or dual analysis where I was being determined. A 20-μL aliquot of a 1.0-μg/mL internal standard solution in methanol was added to the 200-μL plasma aliquots. The resulting concentration of internal standard was 110 ng/mL.

Sample Preparation—For the extraction of I, 2.5 mL of *n*-hexane was added to each plasma sample in a 15-mL centrifuge tube, vortexed for 30 s, and centrifuged. The hexane layer containing I and III was removed with a Pasteur pipet, and if I was to be measured it was transferred into a labeled test tube. If II was to be extracted, a 10% trichloroacetic acid solution (0.04 mL) and 2.5 mL of methyl *tert*-butyl ether were added to the aqueous residues, which were then vortexed and centrifuged. The methyl *tert*-butyl ether layer containing II was removed with a Pasteur pipet and transferred into a test tube. If both I and II were to be determined simultaneously the methyl *tert*-butyl ether layer was added to the *n*-hexane layer from the previous extraction. The

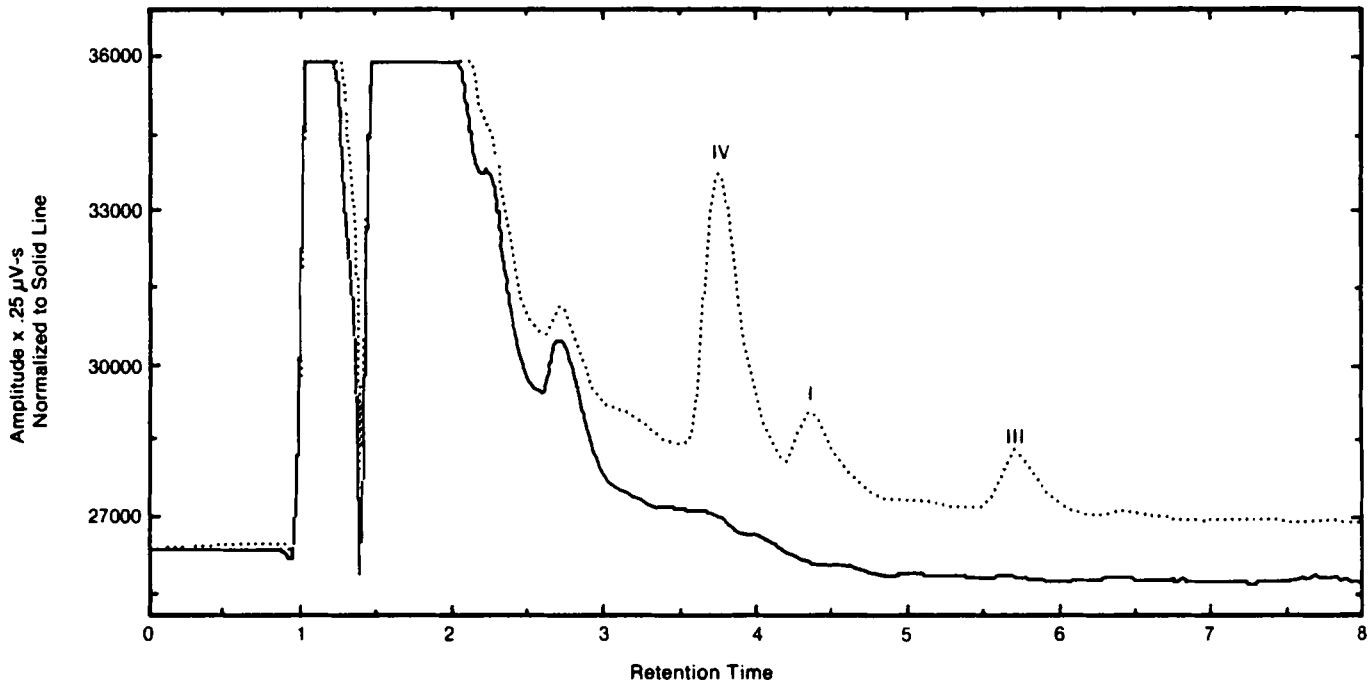

Figure 1—*Tracing of a computer reconstructed chromatogram of a 50-μL injection of a matrix standard (. . .) with 500 ng/mL of IV, 100 ng/mL of I, and 100 ng/mL of III from canine plasma superimposed on the chromatogram of a matrix blank (—). Compound II is not retained on the column, so its methyl ester IV is the species chromatographed and quantitated.*

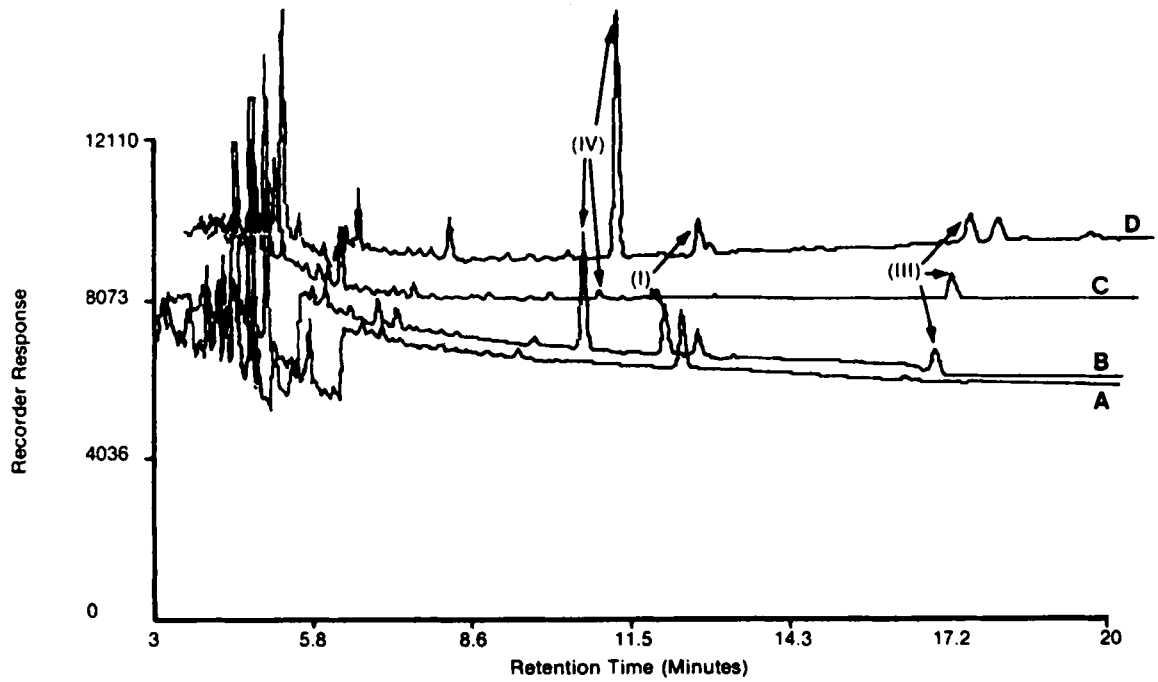

Figure 2—*Tracing of the computer reconstruction of capillary gas chromatograms of a plasma blank (A), a spiked plasma standard (B), and samples at 1 (C) and 6 h (D) postdose from a dog dosed with 80 mg/kg of I.*

organic extracts containing II were evaporated under a gentle stream of dry nitrogen at room temperature to ~0.1 mL. The diazomethane-ether solution (~0.2 mL) was added to each tube, and the tubes were carefully agitated, loosely covered, and let stand for 30 min at room temperature[12]. The extracts were evaporated under an efficient hood with a gentle stream of dry nitrogen at room temperature and removed as soon as they were dry. The dried residues were either tightly capped and stored at −10°C for up to 72 h or diluted with mobile phase solution which remained stable overnight at room temperature.

[12] Mild conditions were required for derivatization because of the potential for the decarboxylation of II at elevated temperatures.

Liquid Chromatographic Procedure—At least four matrix standards were prepared for each sequence of samples. The matrix standard solutions were positioned between the standard solutions and the samples and again after the samples as a reproducibility check. Compound concentration ranges were the same for the standard solutions and matrix standards (see Table I). Peak heights (PH) of I, IV, and III were used as the measure of detector response. Results for the dual determination of I and II or the separate determination of I were calculated by the internal standard method using the average of matrix standard response factors in a multipoint calibration. The concentration of II in the separate determination was calculated using the external standard method, since the internal standard (III) was removed in the initial *n*-hexane extraction.

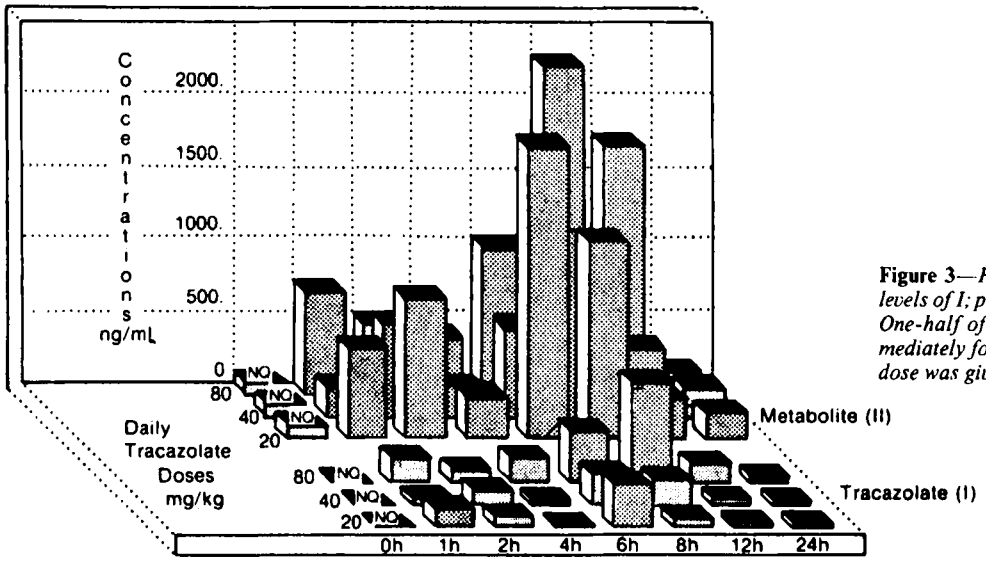

Figure 3—*Pharmacokinetic data from dogs at 3 dosing levels of I; plasma levels of I and II are reported in ng/mL. One-half of the daily dose of I was given by gavage immediately following the predose sample, and the remaining dose was given after the 4-h sample.*

RESULTS

A representative chromatogram, shown in Fig. 1, was from a study for which the dual analysis of I and II was used.

Recovery—Control of plasma pH was found not to be critical for the efficient extraction of I or III. However both pH control and efficient protein precipitation were found to be critical for the extraction of II from plasma. The plasma sample was buffered to pH 1.6 and protein was precipitated (5) when 10% trichloroacetic acid was added at a 1:5 volume ratio to the samples. Methanol spiking solutions were not found to affect the recoveries of I and II when added to plasma at levels of <1% up to 20% (v/v). External standard response factors were calculated and averaged for the matrix standards and the standard solutions. The ratio of the average standard solution response factor and the average matrix standard response factor was used to evaluate the percent recovery of desired compound[13]. Average recoveries of I and II, when extracted from spiked plasma, were 102 and 96%, respectively, during the production of the data listed in Table II. The coefficients of variation for recoveries across the concentration ranges listed in Table II were 4.3% for I and 6.8% for II. The diazomethane methylation of II had an efficiency of 94% *versus* standard solutions of IV. Hexane extracts of plasma resulted in a recovery of 86% of ^{14}C-labeled I added at the 1.0-μg/mL level measured by radiochemical techniques. Methyl *tert*-butyl ether extracts of plasma recovered 85% of ^{14}C-labeled II added at the 2 μg/mL level. Recoveries of [^{14}C]I and [^{14}C]IV were complete when injected directly into the HPLC as solutions in mobile phase.

UV detection was done at the maximum absorbance of I, which occurred at 240 nm with $\epsilon > 30{,}000$ and provided high sensitivity. From Table I, the peak height ratios for the matrix standards were reproducible and linear from 20 to 2000 ng/mL for I and from 100 to 5000 ng/mL for II measured as IV. Correlation coefficients were >0.99 for both curves, and y-intercepts were 0.0478 and 0.5834, respectively. Accuracy and precision were measured from routine calibration data which reflected the accuracy and precision expected in practice. The coefficients of variation were <10% and relatively constant over a wide analytical range for both compounds. The limits of quantification, represented in Table II, were selected to ensure reproducibility of the determination of the low standards on a daily basis.

Specificity—Capillary GC of sample extracts from animals dosed with I was used in the evaluation of specificity. The samples were carried through the sample preparation procedure for the dual determination of I and II described above. The dry residue of the sample extractions containing I, IV, and III was reconstituted in isooctane. This mixture was injected onto a 15-m fused silica capillary column coated with SE52 methyl silicone gum[14]. The column was temperature programmed from 80°C to 230°C in a gas chromatograph equipped with an alkali bead nitrogen detector[15]. As demonstrated in Fig. 2, the elution order of IV, I, and III was the same order as in the HPLC method.

[a] Procedure used for canine plasma samples. [b] Peak height ratios: a sample peak height/III peak height.

No interfering peaks with I or IV were seen under these GC conditions. Specificity was also evaluated by a GC–MS analysis of samples prepared according to the dual procedure from animals dosed with I. Isolated fractions of HPLC eluant of these samples corresponding to the HPLC peaks of I and IV were dried under nitrogen and the residue analyzed by GC–MS[16]. The pure compounds displayed molecular ions of m/z 304 and 290 for I and IV, respectively, a base peak of m/z 215, and several fragments including m/z 99. The mass spectra as well as the GC retention times of the HPLC eluants corresponded to the respective data of the pure compounds.

Stability of Prepared Samples—Plasma samples from animals dosed with I were analyzed several times for both I and II over a period of 5 months and were found to be stable. These plasma samples were stored frozen with intermittant thawing and maintenance at room temperature for several hours during preparation for analysis. Stock and standard solutions of I, II, III, and IV were stable, without measurable alteration, for at least 1 month if refrigerated between uses.

DISCUSSION

The quantitative HPLC procedures for tracazolate and its major metabolite described herein have been used to evaluate circulating levels of these com-

[13] The molecular weight ratio of II and IV was used to properly adjust the percent recovery to a molar basis.

pounds in pharmacological, pharmacokinetic, and toxicological studies in rats, dogs, mice, monkeys, and rabbits. These procedures had reproducible quantifiable limits of 20 ng/mL for I and 50 ng/mL for II. Separate determinations of I and II were required for animal samples in which ratios of the concentration of II to the concentration of I were large enough to significantly degrade the resolution between the HPLC peaks. These high ratios occurred in plasma samples from dosed rats, mice, and rabbits. The separate determinations were used in these cases; otherwise, the selectivity, sensitivity, and other analytical indicators were the same for the plasma of all species tested.

Results from the dual determination of I and II in plasma from dogs are shown in Fig. 3. Part of these results were generated using the standardization curve data reported in Table I. The animals were dosed orally with one-half of the daily dose of I just after the time zero samples were taken and with the remainder of the daily dose after the 4-h samples. The data were evaluated for peak plasma level times (6–8 h) as well as for relationships between dose and plasma levels (no consistent dose response). The low detection limits for both I and II and the low plasma volume requirements for analysis have made this procedure very useful in multisampling and small animal studies. These points and the versatility of this procedure are amply demonstrated in Fig. 3.

Collaborative Study of the USP Dissolution Test for Prednisone Tablets with Apparatus 2

DON C. COX ˣ **and WILLIAM B. FURMAN**

Received April, 19, 1982 from the *National Center for Drug Analysis, Food and Drug Administration, St. Louis, MO 63101.* Accepted for publication April 7, 1983.

Abstract □ Five lots of prednisone tablets that disintegrate within 5 min were collaboratively studied by 11 laboratories using USP Apparatus 2 under carefully controlled conditions. One lot gave complete dissolution. The reproducibility and repeatability of Apparatus 2 for the four lots still dissolving at the end of the test were 2.6 and 1.6% of label claim, respectively, for the 11 laboratories.

Keyphrases □ USP dissolution test—collaborative study of Apparatus 2, five lots of prednisone tablets, 11 laboratories □ USP Apparatus 2—collaborative study of dissolution of five lots of prednisone tablets, 11 laboratories □ Prednisone tablets—dissolution of five lots with USP Apparatus 2, collaborative study by 11 laboratories

The USP dissolution test for prednisone tablets (1) requires that when 12 tablets are tested, an average of ≥80% of the labeled amount of prednisone must dissolve in 30 min. The tablets are individually tested under experimental conditions which must be carefully controlled if reproducible results are to be obtained.

Four common sources of error associated with Apparatus 2 have been identified: misalignment of equipment (2), nonuniformity of the bottom curvature of vessels (3), excess gases in the dissolution medium (4), and the interaction of the test with slowly disintegrating tablets (4). Equipment, tools, and technique were developed and improved between 1978 and 1980 to control the first three sources of error. Certain products consist of slowly disintegrating tablets that do not always settle at the center of the bottom of the vessels; such variability of tablet position before disintegration can give imprecise results (4). However, rapidly disintegrating tablets gave results of sufficient precision to warrant a collaborative study.

The purpose of this collaborative study, conducted by 11 laboratories in the second half of 1980, was to measure the reproducibility and repeatability of Apparatus 2 under state-of-the-art conditions for prednisone tablets that disintegrate within 5 min. The secondary objectives were to determine whether personnel in many laboratories could correctly adjust Apparatus 2 by following a set of detailed instructions and whether the apparatus would hold the adjustment over an ~2-week test period.

Collaborative Study of the USP Dissolution Test for Prednisone Tablets with Apparatus 2

DON C. COX ˣ **and WILLIAM B. FURMAN**

Received April, 19, 1982 from the *National Center for Drug Analysis, Food and Drug Administration, St. Louis, MO 63101.* Accepted for publication April 7, 1983.

Abstract □ Five lots of prednisone tablets that disintegrate within 5 min were collaboratively studied by 11 laboratories using USP Apparatus 2 under carefully controlled conditions. One lot gave complete dissolution. The reproducibility and repeatability of Apparatus 2 for the four lots still dissolving at the end of the test were 2.6 and 1.6% of label claim, respectively, for the 11 laboratories.

Keyphrases □ USP dissolution test—collaborative study of Apparatus 2, five lots of prednisone tablets, 11 laboratories □ USP Apparatus 2—collaborative study of dissolution of five lots of prednisone tablets, 11 laboratories □ Prednisone tablets—dissolution of five lots with USP Apparatus 2, collaborative study by 11 laboratories

The USP dissolution test for prednisone tablets (1) requires that when 12 tablets are tested, an average of ≥80% of the labeled amount of prednisone must dissolve in 30 min. The tablets are individually tested under experimental conditions which must be carefully controlled if reproducible results are to be obtained.

Four common sources of error associated with Apparatus 2 have been identified: misalignment of equipment (2), nonuniformity of the bottom curvature of vessels (3), excess gases in the dissolution medium (4), and the interaction of the test with slowly disintegrating tablets (4). Equipment, tools, and technique were developed and improved between 1978 and 1980 to control the first three sources of error. Certain products consist of slowly disintegrating tablets that do not always settle at the center of the bottom of the vessels; such variability of tablet position before disintegration can give imprecise results (4). However, rapidly disintegrating tablets gave results of sufficient precision to warrant a collaborative study.

The purpose of this collaborative study, conducted by 11 laboratories in the second half of 1980, was to measure the reproducibility and repeatability of Apparatus 2 under state-of-the-art conditions for prednisone tablets that disintegrate within 5 min. The secondary objectives were to determine whether personnel in many laboratories could correctly adjust Apparatus 2 by following a set of detailed instructions and whether the apparatus would hold the adjustment over an ~2-week test period.

[a] Duplicate subsamples of six tablets.

requirement could not be met, the dissolution drive was deemed unsuitable for the study.

All laboratories used similar six-spindle dissolution drives[2], paddles[3], vessels[4], and slotted vessel covers[3] without guide bushings. A transparent water bath was specified. The collaborators were required to use a specially designed centering tool (5), a 2.5-cm depth gauge, and a torpedo level with two bubble indicators at right angles to each other. Step-by-step instructions for the setup of equipment were supplied. The volumes of deaerated dissolution medium were measured[5] in volumetric flasks or calibrated graduated cylinders. The medium was preheated to 37°C before it was added to the vessels[6]. After the medium was placed in the vessels, paddle rotation was started and the system was allowed to equilibrate for 15 min.

Each vessel, vessel position, and corrresponding tablet result were assigned the same number. Thus, for each subsample of six tablets tested simultaneously, every individual tablet result was identified with a particular vessel and position.

The tablets were immersed at 1-min intervals to permit the collaborator to draw and filter an aliquot of dissolution medium after each tablet had been subjected to the test for precisely 30 min. A 50-ml aliquot was taken from the same point in each vessel with a syringe equipped with a glass tube. The aliquot was then forced through a 0.8-μm porosity membrane filter[7], and the first 25 mL was discarded to wash the filter free of material that might interfere with the determinative step and to saturate the filter with drug. The filtered aliquots were diluted, if required, and the absorbances of the solutions were measured manually at 242 nm in a 1-cm cell. Portions of the same batch of dissolution medium used for a subsample were also used as the reference solution in the spectrophotometer and as the diluent for the standard.

Collaborative Study—An intralaboratory study was first conducted in this laboratory. Two analysts, one inexperienced with the dissolution test and the other experienced with the test, were able to follow the instructions and obtain similar results from different equipment. Portions of each lot of tablets, the instructions, and standard prednisone powder were then sent to 10 other FDA laboratories. Seven of the eleven laboratories have been conducting dissolution tests for several years and are considered experienced with the test. The others (laboratories 1, 5, 7 and 10) had received their dissolution equipment within 12 months of participating in the study and were considered relatively inexperienced.

Lots Studied—Four of the lots were commercially manufactured for use as drugs and were received under a certification program conducted in this laboratory. The fifth lot subjected to collaborative study was the USP disintegrating calibrator. All five lots were selected because they disintegrated within 5 min, gave means of six-tablet dissolution results that fell within a range of ~4% of label claim when tested in this laboratory, and responded to minor variations in the test to different extents.

One of the lots subjected to study will be referred to as Tablet 2, the name used to designate this lot in previous papers. Tablet 2, a lot labeled to contain 10 mg of prednisone per tablet, has been extensively studied (3, 4) and was provided for practice and to allow a collaborator to test the apparatus after it had been aligned. The collaborators were required to obtain results from six tablets that fell within 30–50% of label claim and whose mean fell within 35–43%. If the results were outside of these ranges, the collaborator was instructed to discuss the results with this laboratory before continuing the study. The disintegrated tablet particles stay on the bottom of the vessel throughout the test and are somewhat affected by misalignment of equipment and nonuniformity of vessel curvature. If excess gases are present in the dissolution medium, the tablet particles are lifted from the bottom of the vessel during the test, and dissolution results range from 50 to 90% of label claim.

Lot A, tablets labeled to contain 5 mg of prednisone, gives complete dissolution of drug content within 15 min. Lot A was used to assess the technique of each laboratory in the determinative steps: aliquoting, filtering, and measuring absorbance. The dissolution results should agree closely with the content uniformity results. When tested for content uniformity in this laboratory (6), 60 tablets gave a mean of 98.7% of label claim with an *SD* of 1.7%.

Lot B, tablets labeled to contain 5 mg of prednisone, gives dissolution results close to 80% of label claim at 30 min[8]. The disintegrated tablet particles stay on the bottom of the vessel throughout the test; lot B is similar to Tablet 2 in this respect. Lot B, though not extensively studied, is sensitive to misalignment of equipment. When tested for content uniformity (6), 60 tablets gave a mean of 95.1% of label claim with an *SD* of 1.5%.

Lot C, tablets labeled to contain 50 mg of prednisone, was selected because it also gives dissolution results of ~80% of label claim at 30 min[8]. The disintegrated tablet particles rise and circulate in the dissolution medium during the test. The tablets, though not studied extensively, appear insensitive to misalignment of equipment. When tested for content uniformity (6), 60 tablets gave a mean of 105.1% of label claim with an *SD* of 2.3%.

Lot D is the USP disintegrating calibrator[9], labeled to contain 50 mg of prednisone/tablet. This lot has been studied extensively in this laboratory (4) and was included in two collaborative studies (7, 8) conducted by the Pharmaceutical Manufacturers Association. The latter studies revealed large differences in results among laboratories. Although the tablets do not respond to the common systematic errors associated with the test (4), they were included as a blind sample for further study. Lot D is similar to lot C in physical

[2] Nine laboratories used the Model 72RL and two laboratories used the Model 72SI.; Hanson Research Corp., Northridge, Calif.

[3] Hanson Research Corp.

[4] Eli Lilly and Co., Indianapolis, Ind.

[5] Five laboratories used 500- and 900-mL flasks marked T.D./T.C.; Kimble Products, Vineland, N.J. Three laboratories used 500-ml. flasks marked T.C. and 1000-mL graduated cylinders. Three laboratories used 500- and 1000-mL graduated cylinders.

[6] One laboratory deviated from these instructions. Deaerated medium was added to the vessels from graduated cylinders at room temperature. The medium was then brought to 37°C.

[7] No. AAWP, 2.5-cm diameter; Millipore Corp., Bedford, Mass., or equivalent.

[8] This is not a "limiting value." If the paddle speed is increased and the test continued, complete drug dissolution is eventually achieved.

behavior; the tablet particles rise and circulate in the dissolution medium during the test.

Tablet 2 was packaged and labeled in 100-tablet bottles. The tablets from each of lots A, B, and C were tumbled in beakers until each lot was thoroughly mixed. Ten newly purchased bottles of the USP disintegrating calibrator were used as lot D in this study. Lots A, B, C, and D were repackaged in this laboratory by nesting 24 tablets from each lot in cotton in glass bottles possessing metal screw caps. The glass bottles were identified with the appropriate letter designation. Each collaborator was sent one unopened 100-tablet bottle of Tablet 2 and one repacked 24-tablet bottle of each of lots A–D.

Test Sequence—The collaborators were instructed to test a total of 12 tablets from each lot in the following sequence, six tablets being tested at a time: Tablet 2, lots A, B, C, D, A, B, C, and D, and Tablet 2. The study was planned to cover two 5-d work weeks. The first 4 d of the first week were devoted to setting up equipment and testing Tablet 2. The collaborators were then instructed to test six tablets from each of two lots as follows: day 5, lots A and B; day 6, lots C and D; day 7, lots A and B; day 8, lots C and D; and day 9, six tablets of Tablet 2. Laboratories 1, 3, 5, 6, 10, and 11 conformed to this schedule. All laboratories conformed to the sequence in which the tablets were tested. Often, several six-tablet subsamples of Tablet 2 were tested at the beginning of the study; however, only the last six results taken by each laboratory before progressing to lots A–D were used in the statistical analysis.

[a] Duplicate subsamples of six tablets.

Reported Difficulties—When laboratory 3 first tested Tablet 2, high results traced to excess gases in the medium were obtained; subsequent tests of Tablet 2 were satisfactory. At the beginning of the study, laboratory 4 reported that the mean of six tablet results from Tablet 2 fell slightly below the acceptance range. Since the individual tablet results fell within the specified range, laboratory 4 was instructed to continue the study. Midway through the study, laboratory 6 observed background interference in the UV spectra of the tablets and repeated the second six-tablet tests for lots A and B. The background interference was attributed to dirty spectrophotometer cells. Laboratory 9 obtained high results from Tablet 2 at the beginning of the study. A loose drive belt was found on the apparatus. After the belt was adjusted, satisfactory results were obtained.

Laboratory 11 obtained high results from Tablet 2 at the end of the study. Inspection of the dissolution drive revealed that the base of the unit was warped. After the base had been mounted on a plastic plate to provide additional support, laboratory 11 repeated the study and obtained 12-tablet means that were lower by 3.0, 0.8, 7.0, 1.9, and 1.4% of label claim, respectively, for Tablet 2 and lots A, B, C, and D; these means were significantly ($p < 0.001$) lower for lots B and C. The results from the repeated study were used in the statistical analysis.

The results obtained by laboratory 2 for lots C and D were ~20% of label claim below those reported by the other laboratories. Although an adequate explanation could not be found, the cause of the discrepancy was shown to be related to the laboratory and not to the stability of the tablets. Laboratory 2 was asked to repeat the test for lots C and D, and the results of the repeated tests were used in the statistical analysis.

RESULTS AND DISCUSSION

The individual tablet results for each lot and laboratory are given in Tables I–V. The results of the six-tablet subsamples are grouped in rows of six across the tables and correspond to the tablets tested simultaneously. The first subsample tested by each laboratory appears above the second subsample. The results correspond by number to position and vessel number: the results in the "tablet 1" column were obtained from position and vessel 1, *etc.*

To achieve the purpose of the study, it was necessary that the laboratories conduct the dissolution tests under similar conditions and that the laboratories be able to maintain these conditions with respect to time. Because each lot responds differently to changes in the test conditions, such changes within a laboratory could only be monitored by staggering the times at which the lots were tested. Only Tablet 2 and lot B responded to known systematic errors associated with the test. Thus, Tablet 2 was purposely tested at the beginning and end of the sequence, and tests of lot B were spaced within the sequence.

The possibility of a "settling in" effect was noted in a previous collaborative study of Apparatus 2 (9); *i.e.*, differences among dissolution results with re-

spect to time were present in the early days of the study but not later on. In the present study the time between tests and the test sequence were both specified so that all laboratories would be subjected to the same time effects, if present. Several laboratories stated that they could not participate in the study if they were required to observe the exact daily schedule, and these laboratories were instructed to ignore it. However, all laboratories were required to follow the same test sequence.

Reproducibility and Repeatability—The statistical techniques of Steiner, presented in Youden and Steiner (10) were used to assess the reproducibility and repeatability standard deviations of the tablets tested with Apparatus 2. The reproducibility standard deviation measures the agreement of individual results obtained by different laboratories with the same method on identical test material. It may be expressed by:

$$R = (L + I + W)^{1/2} \qquad \text{(Eq. 1)}$$

where L is the error variance among laboratories, I is the error variance of the interaction among laboratories and test material, and W is the error variance within laboratories.

The repeatability standard deviation measures the agreement of successive results obtained by a single laboratory with the same method on identical test materials and conditions. It may be expressed by:

$$S = (W)^{1/2} \qquad \text{(Eq. 2)}$$

The variances necessary to calculate these two standard deviations are obtained from the mean squares derived from an analysis of variance of two crossed classifications, laboratories and test materials, with replication.

The means of the two six-tablet subsamples reported by each laboratory for each lot were treated as duplicate determinations in the step-by-step procedure suggested by Steiner (10) to obtain the reproducibility and repeatability standard deviations. If the subsamples from each lot could be considered identical, the differences among the mean values within and among the laboratories could be attributed to method error. In reality, associated with these subsample means is an inherent variance that is one-sixth the variance of the tablets. The within-laboratory variance contains this source of variance in addition to the within-laboratory error variance. A reduction of this inherent variance would have required a substantial increase in the workload of each collaborator, an impractical approach. Thus, it was important to select lots that gave reasonably uniform dissolution results. The inherent tablet variance is dealt with later in this paper.

Examination of the Reported Means—The six-tablet means reported by each laboratory (Tables I–V) were averaged into 12-tablet means that were then ranked from low to high for each lot. These rank values were summed across the five lots for each laboratory. The rank totals were then tested at the 5% significance level to determine if a laboratory consistently reported high or low results; none did. The ranked 12-tablet means within each lot were then tested at the 5% significance level to determine if any mean within the lot was abnormally high or low [Dixon's test (10)]; none were.

When an analysis of variance is performed on data that can be broken down into classifications of laboratories and lots, the assumption is made that the within-lot variance is constant for the lots. When data are obtained from lots that respond to minor variations in the method to different extents, the within-lot variance can be different from lot to lot. Steiner (10) suggests a statistical test, based on comparison of ranges of laboratory means, to determine groups of lots that have similar variances. The test indicated, at the 5% significance level, that the data from all five lots could not be grouped together. The data from Tablet 2 and lots B, C, and D could be grouped if the data from lot A were removed. Tablet 2 and lots B, C, and D have a common characteristic—they do not give complete dissolution of prednisone at 30 min. Thus, it is logical to treat these lots together in an analysis of variance and to treat lot A separately. When grouped for statistical analysis, Tablet 2 and lots B, C, and D were designated Group 1.

The variances of the six-tablet means reported by each laboratory for each lot in Group 1 were calculated. The ratio of the largest variance to the smallest variance was tested at the 5% significance level and showed that the within-lot variance could be considered constant for the group. An analysis of variance was then performed on this group.

Reproducibility and Repeatability of Group 1—The analysis of variance is shown in Table VI. The *F* ratios indicate that there are no significant differences among the laboratories at the 5% level, but that there is a significant interaction among the laboratories and lots. The significant interaction mean square implies that the lots in this group responded differently to Apparatus 2 from one laboratory to the next. For example, laboratories 2, 3, and 9 reported among the highest results for lot B and the lowest results for lot D; laboratories 6 and 8 reported among the lowest results for lot B and among the highest results for lot D. This interaction was great enough overall to be significant.

The among-laboratory variance, the interaction variance, and the within-laboratory variance were obtained from the mean squares given in Table VI. The reproducibility and repeatability standard deviations were then calculated and are also shown in the table.

Physical Dissolution Characteristics—A tablet whose disintegrated particles stay on the bottom of the dissolution vessel will usually react more to minor differences in Apparatus 2 than tablets whose disintegrated particles are lifted and circulated by the dissolution medium. In this study the former type of product was represented by Tablet 2 and lot B, termed Group 2, and the latter type of product by lots C and D, termed Group 3.

Reproducibility and Repeatability of Groups 2 and 3—Because of their distinctly different physical behavior in the dissolution test, it was of interest to perform an analysis of variance for groups 2 and 3 and to calculate the reproducibility and repeatability standard deviations for each group. Analyses of variance for these groups are shown in Table VII. Group 2 did not show significant differences among laboratories, but did show significant interaction among the laboratories and lots. Group 3 showed significant differences among laboratories, but no significant interaction among laboratories and lots. Thus, lots C and D responded in the same manner to Apparatus 2 in a given laboratory; Tablet 2 and lot B did not. The reproducibility and repeatability standard deviations of each group are given in Table VII. As expected, these terms are somewhat higher for group 2.

Examination of the Individual Tablet Results—A total of 132 results were reported by the 11 laboratories for each lot. Steiner provides a statistical test for rejection of outlying results at the 5% significance level, based on the distance, in standard deviations, that an individual result lies away from the mean Youden and Steiner (10). When one examines a total of 100–200 results, a single result must lie from 3.4 to 3.6 *SD* away from the mean before it can be considered an outlier. The mean and standard deviation for the 132 results for each lot are given in Table VIII. For each of lots A, B, and D, laboratory 9 reported one individual tablet result that was, respectively, 4.4, 4.9, and 3.5 *SD* from the mean of the lot. No cause for these outlying results could be found. The outlier from lot D was borderline and was not far removed from

results reported by other laboratories. Though the outliers from lots A and B are far removed from the rest of the results for these lots, it is doubtful that including them in an analysis of variance would alter conclusions drawn from the analysis.

Analysis of Variance of Each Lot—Usually, the dissolution test is performed on six tablets at one time, each in its own dissolution environment. Differences in the individual tablet results can be attributed to differences in the tablets only if the dissolution environments affect the tablets similarly. Nonuniform environments, such as differences in liquid velocities generated by misaligned paddle shafts or irregular vessels, may cause individual tablets to disintegrate and dissolve at different rates. With the type of six-spindle dissolution apparatus used in this study, each combination of paddle and vessel may produce a different environment; however, each environment can be reproduced. Thus, if the assumptions are made that there is no interaction between subsamples and positions of an apparatus within a laboratory and that the variance obtained from the positions of the apparatus can be pooled, a two-way analysis of variance can be performed on the data reported by each laboratory for each lot. These sources of variances can then be pooled for all the laboratories.

The analyses for all the lots are shown in Table IX. The sources of variance from subsamples, positions, and the interaction between them are vested with the laboratories (11). The F ratios of the laboratories (the laboratories' mean square divided by the between-subsample mean square) indicate differences among laboratories for lots B, C, and D. The between-subsamples' F ratios (the between-subsamples' mean square divided by the interaction mean square) indicate highly significant differences between subsamples within laboratories for all the lots. The among-positions' F ratios (the among-position mean square divided by the interaction mean square) indicate marginal differences among positions for Tablet 2 and lot D, but the F ratio for lot B is highly significant.

Intepretation of the Mean Squares—The interaction mean squares (Table IX) are residual variances that contain the inherent tablet variance and the within-laboratory error variance of the analytical procedure used to determine the quantity of dissolved drug. The design of the study does not permit these variances to be separated. It is reasonable to assume, however, that the variance of the analytical procedure is constant within a laboratory for all the lots. Because lot A dissolves completely, one would expect its dissolution results to be similar to its content uniformity results. If the standard deviation of the content uniformity results for lot A from this laboratory is converted to a variance, a value of 2.89 is obtained. This variance also contains the inherent tablet variance and the within-laboratory error variance (0.77, as percent of label claim) obtained by a different procedure that was used to determine the quantity of the dissolved drug (6). If it is assumed that this laboratory is typical of those in that collaborative study (6), the within-laboratory error variance obtained from that study (0.77) may be subtracted from the variance of the content uniformity results (2.89) to obtain an independent estimate of 2.12 for the tablet variance of lot A. This value for lot A may then be subtracted from the interaction mean square in Table IX (4.79) to obtain an estimate of 2.67 for the within-laboratory error variance of the analytical procedure used in this study. The latter value indicates that the inherent tablet variance is a relatively small part of the interaction mean square of lot C, whereas it contributes a large portion of the interaction variance of lot B.

The among-position mean square contains the interaction mean square and possibly a mean square associated with the influence exerted by different apparatus positions on the tablet results. The magnitude of the latter mean square depends on the dissolution characteristics of the lot under test and on the extent that the positions differ with respect to the alignment of the paddles in the vessels and the uniformity of the vessels. It has been shown that the results obtained for lots A and C are affected very little by the differences in apparatus positions, but that the results for Tablet 2, lot B, and lot D are influenced to various extents by such differences.

The within-subsample mean square is a pooled variance that measures the dispersion of the results of six tablets tested simultaneously. It is obtained by pooling the interaction mean square with the among-position mean square for each lot and is 9.05, 4.58, 22.50, 1.61, and 4.26, respectively, for Tablet 2 and lots A, B, C, and D. It may be expressed by:

$$MS_w = A \qquad \text{(Eq. 3)}$$

The collaborators verified that the apparatuses met or exceeded USP specifications before they started the study. From a practical viewpoint, therefore, the within-subsample mean square represents the residual variance obtainable for each lot at the current state of the art and was taken to represent the tablet variance.

The between-subsample mean square is a pooled variance that measures the dispersion of six-tablet means within a laboratory. It may be expressed by:

$$MS_b = A + 6B \qquad \text{(Eq. 4)}$$

where B is a variance that measures a dispersion that cannot be attributed to A. The B term may be considered as a pooled within-laboratory error variance.

The laboratories mean square is a variance that measures the dispersion of 12-tablet means. It may be expressed by:

$$MS_l = MS_b + 12C \qquad \text{(Eq. 5)}$$

where C is a variance that measures a dispersion that cannot be attributed to A and B. The C term may be considered as a pooled among-laboratory error variance.

If no error existed within or among laboratories, the three mean squares would, in theory, be the same and the corresponding F ratios would be unity. In practice, the mean squares will almost always be different. If they are the same, the F ratios will fluctuate around unity. To measure the probability that the mean squares are the same, the F ratios are compared with tabulated values that would not be exceeded at that probability level. Equations 3–5 can be used to calculate algebraically the within-laboratory error variance (B) and the between-laboratory error variance (C) for each lot. Since the F ratio may fluctuate around unity if two mean squares are equal, the values calculated for B and C may be negative or positive. The significance of B or C should be judged against the probability of the corresponding F ratios.

Acceptance Ranges—If laboratories that exemplified the 11 laboratories in the study obtained mean results from six tablets tested simultaneously, those means would have a dispersion about the overall mean of a lot that can be expressed by:

$$S_m = [(A/6) + B + C]^{1/2} \qquad \text{(Eq. 6)}$$

where S_m is a standard deviation that may be considered as the standard error about the overall mean result. It is the standard deviation for means of six tablets. If B or C is negative, the value may still be summed algebraically as long as the sum of B and C is positive. If the sum of B and C is negative, the sum is assumed to be zero (10) and

$$S_m = (A/6)^{1/2} \qquad \text{(Eq. 7)}$$

The standard deviation of the six tablets in a subsample is expressed as

$$S_t = A^{1/2} \qquad \text{(Eq. 8)}$$

S_m and S_t for each lot are given in Table VIII.

Total	131	17.33	—	7.18	—	30.36	—	8.18	—	6.84	—	—

Acceptance ranges for each of the lots may be established in a manner similar to that used in the PMA studies (7, 8) to establish the acceptance range for the USP calibrators. An acceptance range of six-tablet means could be defined as mean $\pm 2S_m$ for 132 tablets. The standard deviation of six individual tablets should not exceed $1.97S_t$ (12). Thus, from the data in this study, the acceptance range of means of six tablet results for Tablet 2 would be from 32.5 to 45.3% of label claim; the standard deviation of six tablet results should not exceed 5.9%. The acceptance range of means of six tablet results for lot D, the USP disintegrating calibrator, would be from 62.4 to 69.8% of label claim; the standard deviation of six tablet results should not exceed 4.1%.

Reproducibility and Repeatability of Apparatus 2—The repeatability standard deviations of groups 1, 2, and 3 contain two sources of variance: the inherent variance of the tablets and a within-laboratory error variance. The following relationship exists for the mean square of the means of six given in Tables VI and VII and the between-subsample mean squares for the lots reported in Table IX:

$$MS_m = \Sigma(MS_{bj})/mq = \Sigma(A_j)/mq + \Sigma(B_j)/q \qquad \text{(Eq. 9)}$$

where MS_m is the mean square of means of six results for q lots in the group, MS_{bj} is the between-subsample mean square for the jth lot in the group, m is the number of tablets in a subsample, A_j is the within-subsample mean square for the jth lot in the group, and B_j is the within-laboratory error variance attributed to the jth lot. The term $\Sigma(B_j)/q$ can be considered as the within-laboratory mean-square error for the group.

For group 1 (Tablet 2 and lots B, C, and D) this term is 2.52. The repeatability standard deviation of Apparatus 2 for this group is the square root of 2.52, or 1.59% of label claim. The error from the interaction of the laboratories with the samples and the error among the laboratories remain unchanged. The corresponding reproducibility standard deviation of Apparatus 2 for this group is then 2.60% of label claim. The reproducibility and repeatability standard deviations of Apparatus 2 are, respectively, in percent of label claim: for group 2 (Tablet 2 and lot B), 2.86 and 1.71; for group 3 (lots C and D), 2.22 and 1.46.

Effect of Time and Test Sequence—Table IX shows significant differences between subsamples within laboratories. A difference between subsamples within laboratories might indicate an effect that could be associated with time or the sequence in which the lots were tested. Therefore, the data from the six laboratories that followed the daily schedule were tested. For each lot the six-tablet means reported for the first subsample were grouped and compared with a similar group from the second subsample. A one-way analysis of variance showed no significance difference ($p > 0.25$) between the first and second subsample for any of the lots. The test was then repeated for the data from all laboratories. Again, no significant difference was found ($p > 0.1$). Thus, neither the time of testing nor the order of testing contributed significantly to the results.

Effect of Experience—For each lot, the 12-tablet means of the four laboratories that had the least experience were grouped together for comparison to the 12-tablet means of the seven experienced laboratories. A one-way analysis of variance showed no significant difference ($p > 0.05$) between these groups for any of the five lots. Thus, if a laboratory carefully follows the instructions used in this study, the level of previous experience with the test is not significant.

CONCLUSIONS

The laboratories satisfactorily controlled the critical parameters of Apparatus 2. Of a total of 660 tablet results reported by 11 laboratories, only two were considered outliers. The reproducibility standard deviation of Apparatus 2 for means of six tablet results was found to be 2.60% of label claim for a group of four lots of tablets that disintegrate rapidly, are undergoing dissolution at the time the aliquots are taken, and exhibit different dissolution characteristics. The corresponding repeatability standard deviation was 1.59%. Statistical analysis indicated that the lots in this group responded somewhat differently from one laboratory to the next.

Tablet 2 was useful in several laboratories for identification and correction of problems with technique and equipment. The requirement that each laboratory obtain acceptable results from this difficult lot at the beginning of the study was integral to the success of the study. The results indicate that Tablet 2 was marginally affected by the internal paddle-vessel combinations of the dissolution apparatuses used in the laboratories. The mean of 132 tablet results (38.9%) of label claim, and the standard deviation from the within-subsample (38.9% of label claim), results (3.0%) compare favorably with the mean of 72 tablet results (39.7% of label claim) and the standard deviation from the within-position results (2.7%) reported previously by this laboratory (3).

For lot A, the mean (98.9% of label claim) and the within-subsample standard deviation (2.1%) obtained from this dissolution study, compare favorably with the respective values (98.7 and 1.7%) obtained from the content uniformity results in this laboratory. Thus, the laboratories exercised good control over the analytical procedures associated with the measurement of dissolved prednisone. The standard deviation for means of six tablet results (1.8%) is similar to that expected if several laboratories were to test these tablets for content uniformity.

For lot B, the mean of 132 tablets (76.3% of label claim) indicates that this lot comes within 4% of label claim of passing the USP dissolution requirement. This is precisely the type of tablet product that often leads to disagreement in "pass-fail" decisions in different laboratories. The results indicate that lot B was affected by the internal paddle-vessel combinations of the dissolution apparatuses used in the laboratories. Even though lot B possesses this degree of sensitivity to minor variations in the test, 10 of the 11 laboratories obtained results that showed that lot B failed the USP requirement.

Lot C also comes within 4% of label claim of passing the USP requirement. All of the laboratories obtained results that showed that this lot fails the requirement. Since this lot is not affected by the paddle-vessel combinations of the dissolution apparatus, better agreement among laboratories is to be expected.

For lot D, the USP disintegrating calibrator, the mean of 66.1% of label claim obtained in this study compares favorably with the mean of 66.8% obtained in the Pharmaceutical Manufacturers Association study of 1980 (7). The within-subsample standard deviation (2.1%) compares well with that of the PMA study (2.3%). The standard deviation of means of six tablet results found in this study (1.9%) is considerably smaller than that reported previously (7) (5.1%). Both studies indicate significant differences among laboratories. In addition, this study indicates significant differences within laboratories. However, the magnitude of the differences associated with the laboratories is smaller in this study than in the Pharmaceutical Manufacturers Association study. The results indicate that lot D was marginally affected by the internal paddle-vessel combinations of the dissolution apparatuses. This laboratory, however, has not been able to show a correlation between results obtained with this lot and misaligned paddles or irregular vessels (4).

The analysis of variance for group 3 (lots C and D) indicates that the lots respond to Apparatus 2 similarly within a laboratory and that there is a significant bias among laboratories. Thus, a laboratory that obtains a high or low result for lot C is likely to obtain a correspondly high or low result for lot D. The reproducibility and repeatability standard deviations for this group were found to be 2.22 and 1.46% of label claim, respectively, for Apparatus 2.

The analysis of variance for group 2 (Tablet 2 and lot B) indicates that each lot responds differently to perturbations in Apparatus 2 from one laboratory to the next, but that there are no significant differences among laboratories for the group. That the lots respond differently from one laboratory to the next may be explained by the differing degrees of sensitivity these lots show toward dissolved air in the dissolution medium and internal misalignment of the dissolution apparatuses. The reproducibility and repeatability standard deviations for this group were found to be 2.86 and 1.71% of label claim, respectively, for Apparatus 2. These standard deviations indicate that, at present, tablets whose disintegrated particles stay on the bottom of the vessel cannot be tested with the same precision as tablets whose disintegrated particles are lifted and swirled by the dissolution medium. It is encouraging to note that the differences between the precisions are fairly small.

Physicopharmaceutical Characteristics of an Oil-in-Water Emulsion-Type Ointment Containing Diclofenac Sodium

AKIRA TAKAMURA *x, FUMIYOSHI ISHII *, SHUN'ICHI NORO *, and MASUMI KOISHI ‡

Received July 26, 1982, from the **Meiji College of Pharmacy, 1-22-1, Yato-cho, Tanashi-shi, Tokyo, Japan*, and the ‡*Faculty of Pharmaceutical Science, Science University of Tokyo, 12, Ichigaya Funagawara-machi, Shinjuku-ku, Tokyo, Japan.* Accepted for publication April 5, 1983.

Abstract □ The oil-in-water (o/w) emulsion-type ointment was prepared with food additives containing diclofenac sodium. The oil phase and the emulsifier used were 1,2,3-propanetriyl trioctanoate (caprylic acid glyceryl ester) and sugar wax, and sugar ester, respectively. The emulsion stability of the o/w emulsion-type ointment as well as the diclofenac sodium release profile were investigated and compared with those from conventional ointments. The emulsion stability was evaluated in terms of the viscosity of the emulsion product, the particle size distribution of oil droplets, and the zeta potential of the droplets. It was found that sugar esters have excellent properties as emulsifiers, based on the results of viscosity and zeta potential measurements. The *in vitro* release test revealed that the amount of diclofenac sodium released from o/w emulsion-type ointment was greater than from the hydrophilic and absorptive ointments. Accordingly, it was concluded that o/w emulsion-type bases are suitable for pharmaceutical use in ointment products.

Keyphrases □ Diclofenac sodium—release from various topical ointment bases, oil-in-water emulsions, physicopharmaceutical characteristics □ Oil-in-water emulsions—use as a topical ointment base for diclofenac sodium, release rate, physicopharmaceutical characteristics □ Ointment bases—oil-in-water emulsions, topical release of diclofenac sodium, physicopharmaceutical characteristics

In developing procedures for the design of pharmaceutical products, it is necessary to consider the bioavailability and safety of both the drugs and bases. Potent steroidal agents, which have substantial anti-inflammatory properties, have been used for external application for a long time. However, these steroidal agents have side effects (1), which were found to be directly dependent on the amount of drug applied to the skin. Therefore, various nonsteroidal agents (2, 3) have been developed recently to replace the steroidal agents.

Diclofenac sodium is a potent nonsteroidal anti-inflammatory agent, which has been limited to oral (4) and rectal administrations (5). In this investigation, diclofenac sodium was selected for topical application because no toxicity or topical irritation has been reported.

Although reports on ointment application have been published (6–8), few have dealt with the selection of optimum conditions for the preparation of the ointment. Oil-in-water (o/w) emulsion-type ointment bases offer many advantages over other preparations (9): they permit incorporation of aqueous and oleaginous ingredients, they allow a greater release of many incorporated medicaments, and their rheological properties can be controlled easily. Therefore, the selection of oil base and emulsifier is one of the most important factors in the preparation of o/w emulsion-type bases.

1,2,3-Propanetriyl trioctanoate (caprylic acid glyceryl ester, I) a medium-chain triglyceride, and sugar wax were chosen as the oil phase, since the combination is very stable, solubilizes various drugs, is nontoxic, and does not irritate the human skin (10). Sugar ester is a nontoxic, tasteless, odorless, and nonirritative sucrose fatty acid ester (11). Because it is widely and safely used in food (12), cosmetic (13), and pharmaceutical fields (14), it was selected as an emulsifier in this investigation. It is available in a wide range of hydrophilic–lipophilic balances (HLB) from oil to water soluble and has excellent emulsifying and dispersing abilities. Furthermore, Nobile *et al.* conducted standard tests with the sugar ester, and they reported no irritation to the human skin (11).

Various methods have been reported for the examination of drug release from ointment (15–17); however, no unified and simplified method has yet been established. In view of the

Table I—The Constituents of the Hydrophilic and Absorptive Ointments

Hydrophilic Ointment		Absorptive Ointment	
White petrolatum	250.00 g	White petrolatum	400 g
Stearyl alcohol	220.00 g	Cetyl alcohol	180 g
Propylene glycol	120.00 g	Sorbitan sesquioleate	50 g
Sodium lauryl sulfate	15.00 g	Polyoxyethylene lauryl alcohol ether	5 g
Methylparaben	0.25 g	Methylparaben	1 g
Propylparaben	0.15 g	Propylparaben	1 g
Purified water	395.00 g	Purified water	363 g
Volume	1000 g	Volume	1000 g

aforementioned considerations, the o/w-type emulsion, which is a dispersion of microscopic oil droplets in a water phase, seems to be one of the most promising as an ointment base. The purpose of this work was to investigate the effects of surfactant and oil base on the physicochemical properties of ointment bases. In addition, the emulsion stability of the ointment base was evaluated in terms of (*a*) the viscosity of the emulsion product, (*b*) the particle diameter and distribution of oil droplets, and (*c*) the zeta potential of the droplets. The diclofenac sodium release profile from an o/w emulsion-type ointment was investigated and compared with those from conventional ointments.

EXPERIMENTAL

Materials—Diclofenac sodium[1] was recrystallized twice from water, with a melting range of 283–285°C. Sugar wax[2] and 1,2,3-propanetriyl trioctanoate (I, caprylic acid glyceryl ester)[3] were the dispersed phases.

Sugar wax is a sugar ester compound prepared from sucrose and palmitic acid or stearic acid. The average number of fatty acid molecules incorporated is 6.0, and its hydroxyl value and melting point are in the ranges of 80–130 and 60–66°C, respectively. Compound I is the triglyceride of caprylic acid and has the following properties: a saponification value of ~340–360, an acid value of <0.1, an iodine number of <1.0, and a hydroxyl value of <0.5.

The emulsifier used was sugar ester[4] of commercial grade, which is a nonionic surface-active agent synthesized from sucrose and palmitic acid or stearic acid. The average number of fatty acid molecules incorporated is 1.7. The content of dimethylformamide, arsenic, and heavy metals in sugar ester are very low as compared with those allowed by the Japanese Standard of Food Additives. Therefore, sugar ester is absolutely safe as a food, cosmetic, and/or pharmaceutical additive.

Preparation of o/w Emulsion-Type Ointment—The agitator used was a homomixer[5] which has two different blades: a homomixer and a paddle-mixer.

Diclofenac sodium was dissolved in the oil phase, the solution was kept at 80°C in the tank, and water preheated to 80°C was added. The concentration of diclofenac sodium in the ointment was always kept constant at 3.0% in all experiments.

The oil and water were vigorously stirred by both the homomixer and the paddlemixer at 80°C for 10 min. The speed of the homomixer was kept constant throughout the emulsification. The water-in-oil emulsion at 80°C was cooled quickly with ice water and then inverted to an o/w-type emulsion at 55°C. After this temperature was attained, the emulsion was stirred with the paddlemixer alone and gradually cooled to 20°C. The air bubbles trapped in the ointment were removed completely with a vacuum pump during the cooling process.

The conventional ointment bases used were commercial-grade hydrophilic ointment[6] and absorptive ointment[6]. The compositions of these ointments are shown in Table I.

Measurement of the Physicochemical Properties of Ointment Bases—The stability of an emulsion as an ointment base was evaluated by measuring such physicochemical properties as viscosity, particle size, and zeta potential (18). The rheological properties were measured with a rheometer[7] under a shear rate of 7.5–75 s^{-1} at 20 ± 0.1°C. The particle size distribution and the mean diameter of oil droplets were measured with a particle counter[8]. The zeta potential of oil droplets was obtained with the laser system[9]. A 0.1-g volume of o/w emulsion-type ointment was diluted with 50 mL of distilled water, and the zeta potential was measured at 20.0°C.

In addition, the o/w emulsion-type ointment was sealed in a calibrated glass tube and stored in a constant-temperature water bath at 40 ± 0.1°C. The flocculate depth and viscosity of the ointment were measured periodically to evaluate its emulsion stability. A short description of these procedures for evaluation of emulsion stability were given in a previous paper (19).

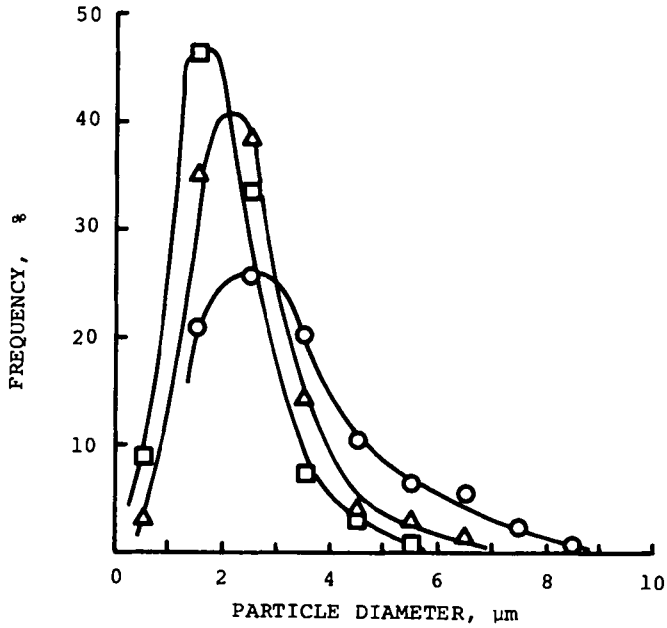

Figure 2—*Effect of rpm of the homomixer on particle diameter distribution of the o/w emulsion-type ointment. Key: (○) 3000 rpm; (△) 6000 rpm; (□) 10,000 rpm.*

Release of Diclofenac Sodium from the Ointment—The apparatus used for studying the drug released from the ointment is a modification of a common dissolution test instrument[10] (20) and is shown in Fig. 1. It consists of a metal dish (25 mm o.d., depth 6 mm), which floats on the surface of distilled water in an inner cylindrical cell. The bottom end of the inner cylindrical cell is covered with a membrane[11]. The distilled water (300 mL) was stirred at 100 rpm with a polytef-coated magnetic stirring bar placed at the bottom of the sink. The external chamber was immersed in a constant-temperature water bath maintained at 37 ± 0.1°C.

The release of the drug from various o/w emulsion-type ointment bases was examined. After reaching the required equilibrium temperature, 2.5 g of the ointment was placed on the bottom surface of the metal dish. This allowed direct contact of the donor ointment with the releasing liquid. Three-milliliter samples were withdrawn from the sink nine times over a 120-min period. The receptor phase volume was kept constant through the release run by replacing the removed sample with an equal volume of distilled water. The drug concentration was determined with a UV spectrometer[12] at a wavelength of 267 nm (21).

In the cases of the hydrophilic and absorptive ointments, diclofenac sodium powder that had been sieved through 150–200-mesh screens was mixed with molten base. The whole base was agitated at 50°C for 10 min until the solid diclofenac sodium melted completely in the base, then the ointment was cooled to 20°C. The drug release from the bases was examined in the same manner as in the case of the o/w emulsion-type ointment. The measurements were repeated five times, and the mean value of drug release concentration was calculated in all experiments.

RESULTS AND DISCUSSION

Selection of Optimum Conditions for Preparation of the o/w Emulsion-Type Ointment—The effect of impeller speed of the homomixer on the particle size distribution of the o/w emulsion-type ointment is shown in Fig. 2. In this case,

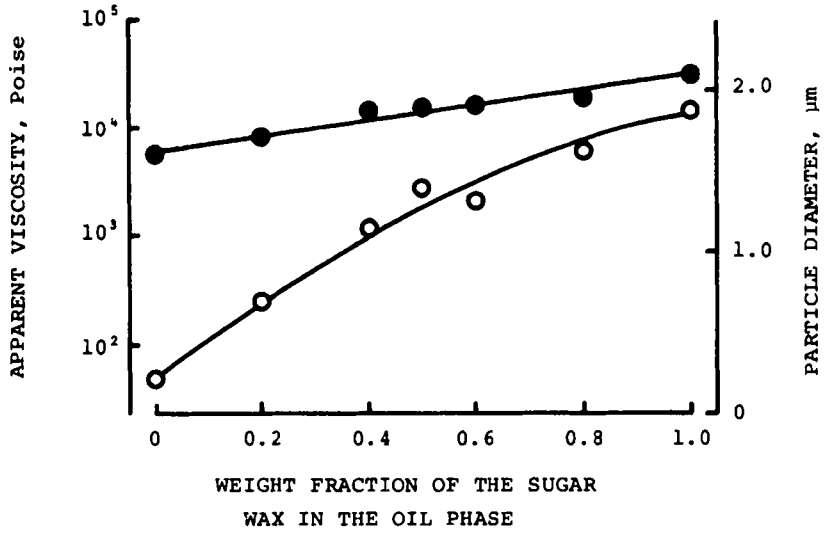

Figure 3—*Plot of viscosity and particle diameter* versus *weight fraction of sugar wax in the oil phase. Key: (○) viscosity; (●) particle diameter. Concentration of oil phase, 42%; concentration of emulsifier, 15%; revolution rate of homomixer, 10,000 rpm. The rate of shear and temperature in the measurement of viscosity were 7.5 s^{-1} and 20.0°C; the time of shear application was 30 s.*

the revolution rate of the paddlemixer was kept constant at 70 rpm. A significant effect of the difference in impeller speed was found on the size distribution curve. A narrower size distribution and a smaller standard deviation were observed with increase of the revolution rate of the homomixer. The mean diameters were 3.51 ± 1.91, 2.31 ± 1.18, and 1.93 ± 0.89 μm at 3000, 6000, and 10,000 rpm, respectively. As is evident in Fig. 2, the revolution rate of the homomixer is a very important dynamic factor in the preparation of a stable emulsion. Hence, it was kept constant at 10,000 rpm in all subsequent experiments.

Figure 3 shows the effect of the weight fraction of sugar wax in the oil phase on the viscosity and the particle size of the o/w emulsion-type ointment. The shear rate in the measurement of viscosity was 7.5 s^{-1}. It is obvious in this curve that the viscosity is remarkably increased with the increase of the weight fraction of sugar wax. This is also associated with a slight increase in the mean diameter of the droplet. This phenomenon would probably be due to complex formation between the crystallized sugar wax molecule and the emulsifier molecule on the surface of droplets during the cooling process of emulsification. Therefore, the o/w emulsion-type ointment would be sufficiently stable due to its high viscosity, which prevents flocculation and coalescence.

The zeta potential is a controlling parameter in the emulsion stability. Changes in the zeta potential with the weight fraction of sugar wax in the oil phase of the emulsion are shown in Fig. 4. The zeta potential of emulsion droplets was −38 mV when the oil phase of emulsion consisted of I alone. The value of the zeta potential gradually decreased with increase of the weight fraction of sugar wax in the oil phase of the emulsion. The minimum in this curve appears at a weight fraction of ~0.5. After the minimum, the curve increases rather rapidly with the increase in the sugar wax concentration. If the oil phase consists of equal parts of sugar wax and I, there probably exists a stable electric double layer on the surface of each droplet in the emulsion. These emulsions are semisolid at room temperature, however, and it seems that the high viscosity is a more important factor in preventing coalescence than the high zeta potential. Based on the results shown in Figs. 3 and 4, a weight fraction of 0.5 of sugar wax in the oil phase was used in all subsequent experiments.

Figure 5 shows the effect of emulsifier concentration on the viscosity of the o/w emulsion-type ointment. The shear rate in the measurement of viscosity was 7.5 s^{-1}. As the emulsifier concentration increased, the viscosity of the ointment increased linearly on a semilogarithmic plot at all concentrations of the oil phase studied. The viscosity of the ointment base was strongly affected by the concentration of sugar ester as an emulsifier. The emulsion prepared with sugar ester presumably has a stable gel structure around each droplet surface, because the globule surfaces of the oil may adsorb and consequently be stabilized by many sugar ester molecules. The viscosity of the emulsion increased remarkably with the increase of the oil concentration at all emulsifier concentrations. The reason for this result could be that as the concentration of the dispersed phase increases, the interaction between oil droplets also increases due to their closer approach in the continuous phase. This will lead to the eventual overlapping of the stream lines surrounding the individual droplets. At this stage, the overall viscosity is no longer the sum of the effects of the individual droplets. In highly concentrated emulsions, small increments in oil concentration produce large increases in relative viscosity.

When comparing the flow behavior of emulsions prepared using two or more different concentrations of emulsifier and/or oil phase, their viscosity should be measured over a wide range of shear rates. Rheograms of the ointment base prepared with four different concentrations of the emulsifier are shown in Fig.

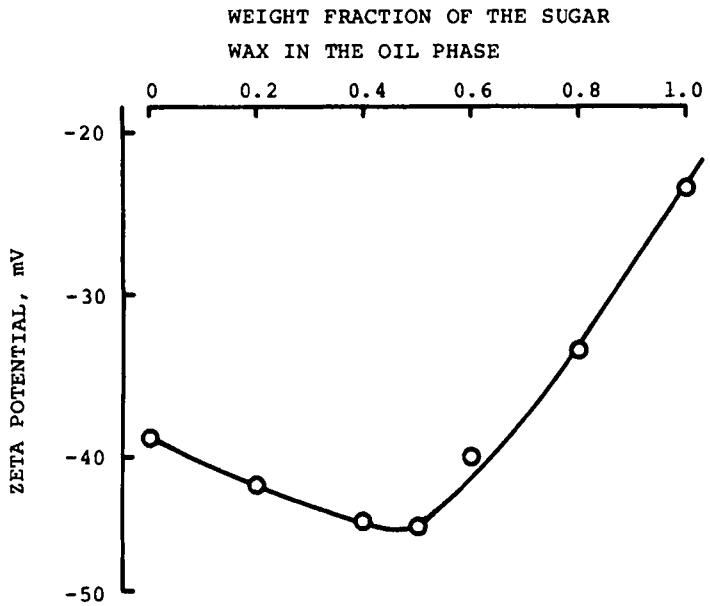

Figure 4—*Plot of zeta potential* versus *weight fraction of sugar wax in the oil phase. The temperature in the measurement of zeta potential was 20.0°C.*

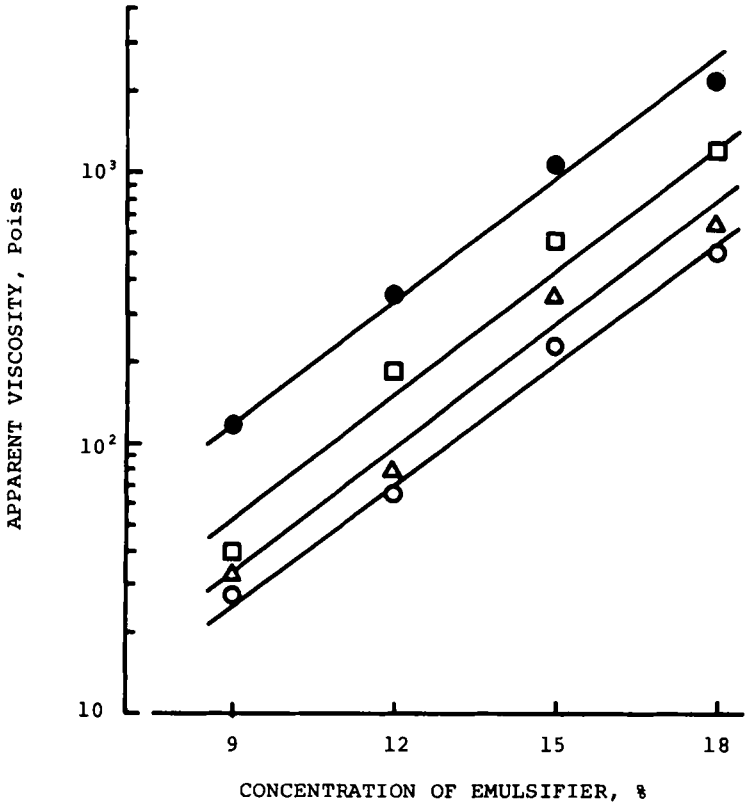

Figure 5—*Semilogarithmic plot of viscosity* versus *concentration of emulsifier. Key: concentration of oil phase (○) 30%; (△) 34%; (□) 38%; and (●) 42%. The rate of shear and temperature in the measurement of viscosity were 7.5 s^{-1} and 20.0°C; the time of shear application was 30 s.*

6. The curves show the relationship between viscosity and shear rate. As is evident in Fig. 6, it is not a horizontal relationship: the viscosity decreased markedly at first and then monotonically with an increase in shear rate. When a low steady shear was applied to the concentrated emulsion, it was often found that a steady stress did not develop instantly. This phenomenon is known as trixotropy. A hysteresis effect appears in all thixotropic ointment bases, as shown in Fig. 6.

The thixotropic behavior of an emulsion-type ointment base is of primary importance in pharmaceutical systems. Thus, it plays an important role in the mixing and flow of materials, their packaging into containers, physical stability, and even patient acceptability. Furthermore, the thixotropic property of a semisolid ointment base may affect the absorption rate of drugs through the skin as well as their biological availability. On the basis of the results shown in Figs. 5 and 6, it is possible to prepare ointments which have desirable rheological properties by controlling the amount of additives such as sugar wax, I, and sugar ester.

***In Vitro* Drug Release Profiles from the Emulsion-Type Ointment**—The equation for the release rate of drugs from an ointment base was derived by T. Higuchi (22), and subsequently, W. Higuchi (23) simplified the equation to:

$$Q = 2C_0(Dt/\pi)^{1/2} \qquad \text{(Eq. 1)}$$

where Q is the amount of drug released to the skin at time t per unit area of contact (mg/m^2), C_0 is the initial concentration of drug in the vehicle (mg/m^3), and D is the diffusion coefficient of drug in the vehicle (m^2/s), respectively. The release characteristic of diclofenac sodium from various o/w emulsion-type ointment bases over a 120-min period is illustrated in Fig. 7. The curve does not start at the origin, but has a short lag time. The experimental data were fairly well approximated by a straight line within 120 min when the amount of diclofenac sodium released was plotted against the square root of time. As shown in Fig. 7, the amount of drug released is indirectly related to the amount of oil phase in the ointment.

In general, the drug release from an emulsion base occurs in two steps: (*a*) transport of the drug dissolved in droplets of oil to the aqueous medium and (*b*) transport of the drug in the continuous aqueous phase across the membrane. In this o/w emulsion-type ointment, the amount of drug released could be controlled and the release prolonged by increasing the concentration of dispersed phase which, in turn, may affect the rate of transfer of the drug molecule from the oil droplets to the aqueous medium, the rate-limiting step for the release.

Figure 8 shows the release profiles of diclofenac sodium from o/w emulsion-type, hydrophilic, and absorptive ointments. The release rate was found to decrease in the order o/w emulsion-type ointment > absorptive ointment > hydrophilic ointment. Comparison of Fig. 7 with Fig. 8 reveals that the amounts of drug released from all o/w emulsion-type ointments are larger than from the hydrophilic ointment. This indicates that the o/w emulsion-type base prepared in this experiment has excellent properties as compared with the commercial grade hydrophilic ointment, and it appears to be very suitable

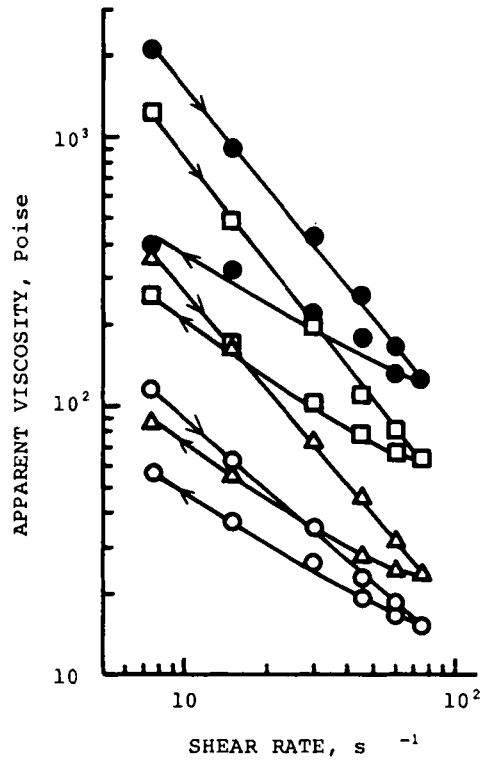

Figure 6—*Plot of viscosity against rate of shear. Key: concentration of emulsifier (○) 9%; (△) 12%; (□) 15%; and (●) 18%. Concentration of oil phase was 42%. The temperature in the measurement of viscosity was 20.0°C; the total time of shear application was 330 s.*

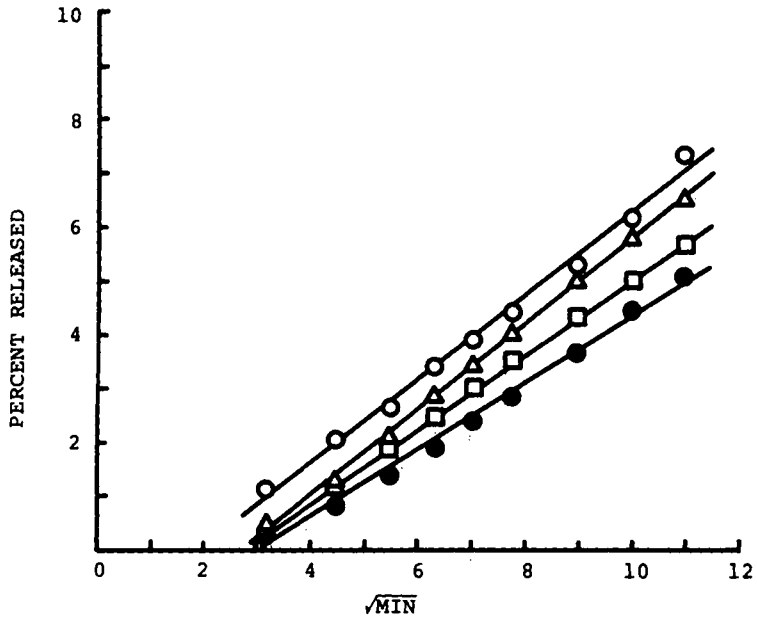

Figure 7—*Diclofenac sodium release from various o/w emulsion-type ointments. Key: concentration of oil phase (○) 30%; (△) 34%; (□) 38%; and (●) 42%.*

for use as an ointment base. In this release exeriment, dissolution of the base itself into the aqueous phase is not a serious problem within 120 min from initiation.

Evaluation of Emulsion Stability in Three Different Ointment Bases—The emulsion stability of the ointment base was evaluated in terms of visual observation and the rheology of the emulsion product. Here, 3% diclofenac sodium was admixed with each of the three different bases: hydrophilic, absorptive, and o/w emulsion-type ointments. Gross visual analysis was used to observe flocculation and creaming of the emulsions stored at a constant temperature of 40 ± 0.1°C after preparation. This analysis utilized three 15-mL calibrated glass tubes to observe each of the emulsions over a 30-d period.

In the hydrophilic ointment, a separated water phase was observed after 10 d. A flocculated oil layer appeared on the top of emulsion of absorptive ointment after 3 d only. However, no significant change was detected at all in the o/w emulsion-type ointment over a 50-d period. Accordingly, the o/w emulsion-type ointment including 3% diclofenac sodium is considered to be more stable than the other ointments, even if it is stored at room temperature for a long period.

The viscosity of each ointment stored at 40 ± 0.1°C was measured periodically with a rheometer over a 14-d period. Figure 9 illustrates the change in relative viscosity of ointment with storage time. Here, the relative viscosity, η_{rel}, was determined according to the equation:

$$\eta_{rel} = \eta/\eta_0 \qquad \text{(Eq. 2)}$$

where η is the viscosity at each storage time and η_0 at the initiation, respectively.

In the cases of the hydrophilic and absorptive ointments, the relative viscosity decreased markedly with the increase in time. The viscosity of the absorptive ointment could not be determined by this rheological method after 7 d because of the appearance of separated oil phase on the surface of the emulsion. On the other hand, no significant change was found in the viscosity of o/w emulsion-type ointment over a 50-d period. Furthermore, it was confirmed that the other physicochemical properties such as melting range, blooming, and deposition of drug crystals were almost unchanged with this base after 50 d at 40°C.

CONCLUSIONS

On the basis of physicochemical tests, it seems that the oil phase in the emulsion base consisting of 50 parts each of sugar wax and I shows excellent stability. From the results of viscosity and zeta potential measurements, sugar ester in the region of 9–18% was found to have excellent properties as an emulsifier, and it appears to be very suitable for use as an ingredient in emulsion-type ointment bases. The *in vitro* release test reveals that the amount of diclofenac sodium released from the o/w emulsion-type ointment was greater than that from the hydrophilic and absorptive ointments. The o/w emulsion-type ointment containing 3% diclofenac sodium appears to be better than conventional ointments, as indicated by visual observations and viscosity

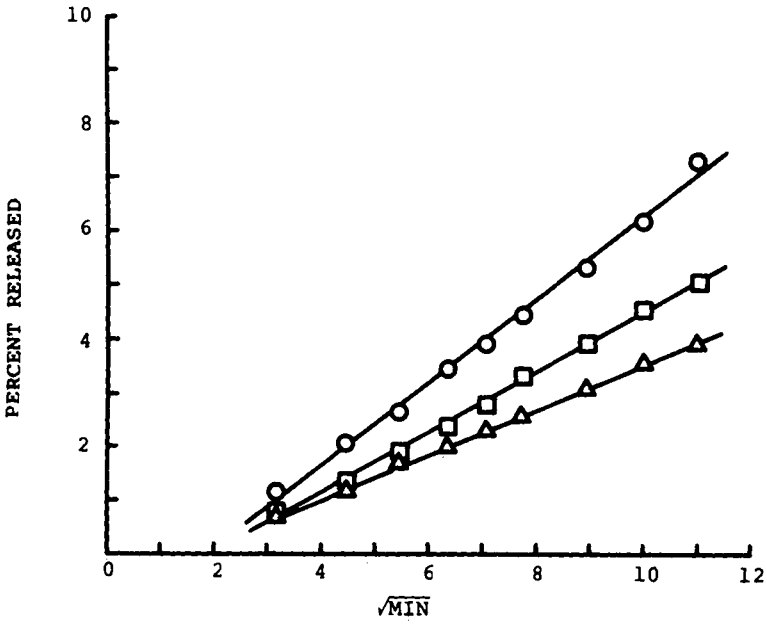

Figure 8—*Plot of diclofenac sodium released* versus *the square root of time. Key: (○) o/w emulsion-type ointment (concentration of oil phase was 30%); (△) hydrophilic ointment; (□) absorptive ointment.*

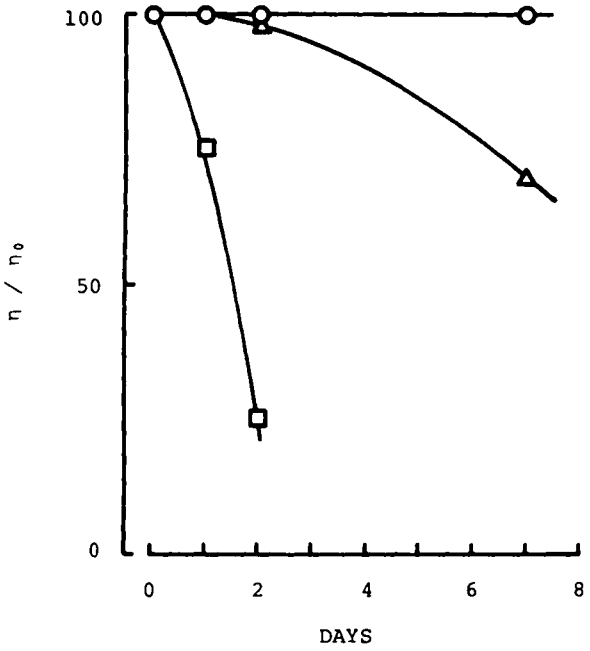

Figure 9—*Change of the viscosity of the ointment with storage time. Key: (○) o/w emulsion-type ointment; (△) hydrophilic ointment; (□) absorptive ointment. The ointments were stored at 40°C. The temperature in the measurement of viscosity was 20.0°C; the time of shear application was 30 s.*

measurements of the base over a 50-d experimental period at 40°C. Finally, the aforementioned properties suggest that these o/w-type emulsions prepared with sugar ester, I, sugar wax, and distilled water are suitable for the pharmaceutical preparation of ointments for clinical use. Future investigations will evaluate the effect of physicochemical properties of the o/w emulsion-type ointment on the indices of bioavailability through *in vivo* percutaneous absorption.

NOTES

Determination of Calcium Gluconate by Selective Oxidation with Periodate

CHEN KUANG-PAIO

Received July 19, 1982, from the *Second Pharmaceutical Factory of Wenchow, Chekiang, People's Republic of China.* Accepted for publication March 7, 1983.

Abstract □ A modified analytical method was developed which can accurately quantitate calcium gluconate and its pharmaceutical preparations in the presence of other calcium compounds or other cations able to complex with EDTA. The proposed method was based on the principle of the Malaprade reaction, according to which gluconic acid is selectively and quantitatively oxidized by sodium periodate. The content of calcium gluconate was calculated from the amount of gluconic acid found. The selective oxidation proceeded at 50°C for 10 min, yielding ~100% recovery of calcium gluconate. The proposed method was accurate, precise, and superior to the compendia EDTA-complexometric method in terms of specificity.

Keyphrases □ Calcium gluconate—determination by selective oxidation with periodate, quantitation, Malaprade reaction □ Periodate—selective oxidation, determination of calcium gluconate, quantitation, Malaprade reaction □ Malaprade reaction—determination of calcium gluconate with selective oxidation by periodate, quantitation

The EDTA-complexometric titration for the determination of calcium gluconate (I) and its pharmaceutical formulations is most commonly adopted by many current national pharmacopoeias (1–6). However, it is known that the official compendia method is only suitable for determining a sample of I which does not contain other calcium compounds or other

cations capable of complexing with EDTA. However, I as prepared by some domestic manufacturers usually contains a certain amount of calcium oxalate, which is a byproduct produced in the fermentation of glucose with *Aspergillus niger*. Commercially available injections of I usually contain a small amount of solubilizing agent, such as calcium lactate (7). Therefore, it is impossible to accurately estimate I with the compendia methods. Because gluconic acid is considered to be a vicinal polyhydroxy alcohol and since some earlier investigators have applied the Malaprade reaction to determine vicinal polyhydroxy alcohols and aldoses (8–11), we were interested in studying the reaction of I with periodate to develop an assay method for I. The proposed method is based on the selective oxidation of gluconic acid with periodate, calculating the amount of I from the amount of gluconic acid found.

EXPERIMENTAL

Drugs and Chemicals—ChP-grade powder[1], tablets[1], and injections[1] of I, starch, talc, magnesium stearate, lactic acid, and analytical- or base-reagent-grade iodine, potassium iodide, arsenic(III) oxide, sodium oxalate, magnesium chloride, sodium bicarbonate, disodium EDTA, and sodium periodate were used.

Volumetric Solutions—Solutions of 0.05 M iodine, 0.025 M sodium arsenite, 0.05 M disodium EDTA, and 0.05 M sodium periodate were prepared and standardized by compendia methods.

Preparation of I Reference Standard—Parenteral grade I (1) was dissolved, recrystallized from redistilled water three times, and dried at 70°C. The content of I was determined by the ChP method (1), containing 100 ± 0.01% of $C_{12}H_{22}O_{14}Ca{\cdot}H_2O$. The oxalate content was <15 ppm, determined by the ferric perchlorate method (12, 13).

Stoichiometric Relation in the Selective Oxidation of I with Sodium Periodate—About 50 mg of I reference standard, accurately weighed, was placed in a glass-stoppered 500-mL flask, 20 mL of water was added, and the mixture was stirred until the sample was completely dissolved. Forty milliliters of 0.05 M sodium periodate was added and mixed. The solution was heated on a 50°C water bath for 10 min. After cooling, 1 g of potassium iodide, 1.5 g of sodium bicarbonate, and 50 mL of 0.025 M sodium arsenite were added. The flask was stoppered, thoroughly mixed, and allowed to stand in the dark for 5 min. The inner walls of the flask and the stopper were rinsed, and the residual sodium arsenite was titrated with 0.05 M I_2, using the starch test system as the indicator. A blank determination was performed simultaneously. The titration reading of 0.05 M I_2 for I reference standard, corrected for the blank, was equivalent to the amount of 0.05 M sodium periodate that reacted with I.

Selection of Optimum Condition for the Selective Oxidation of I with Sodium Periodate—To 5 mL of I reference standard solution (1.00%), were added 20 mL of water and 40 mL of 0.05 M sodium periodate. The solution was mixed as described above, except when the selective oxidation was carried out at different temperatures and time periods.

Recovery of I in the Presence of Other Substances in Accordance with the Sodium Periodate Method—Twenty milliliters of water was added to three 5-mL portions of I reference standard solution (1.00%), respectively. To the first portion, 20 mg of starch, 12.5 mg of talc, and 2.5 mg of magnesium stearate were added. To the second portion, 25 mg of sodium oxalate and 2 mg of magnesium chloride were added. Then, to each portion, 40 mL of 0.05 M sodium periodate was added, and the solution was mixed and heated on a 50°C water bath for 10 min. The procedure was continued as described above.

Comparison of the Sodium Periodate Method with the ChP Method (1) in the Determination of I and its Pharmaceutical Preparations—An aliquot of the sample, equivalent to ~50 or 500 mg of I, was accurately weighed or transferred and analyzed as described above or under the ChP method, respectively.

RESULTS AND DISCUSSION

In 1928, Malaprade (14) described that vicinal hydroxy groups in a C—C bond might be selectively oxidized by a reagent such as periodic acid to produce two aldehyde fragments. Kolthoff and Belcher (15) have reviewed this oxidation, known as the Malaprade reaction, at length and assured that all of the polyatomic alcohols, including vicinal hydroxyl groups, could be oxidized by periodate according to the following general formula (Scheme I):

$$HOCH_2(CHOH)_nCH_2OH + (n+1)IO_4^- \rightarrow 2CH_2O + nHCOOH + (n+1)IO_3^- + H_2O$$

Scheme I

The hydroxyl group at the terminal carbon atom was oxidized to yield formaldehyde, but the hydroxyl group at the intermediate carbon atom was alternatively oxidized to yield formic acid. If a carbonyl and a hydroxyl group were vicinal, the periodate oxidation would yield a carboxyl and a carbonyl function, respectively. Because gluconic acid belongs to a vicinal polyhydroxy alcohol having a terminal carboxyl group, it is possible that gluconic acid may be oxidized by periodate as in Scheme II:

$$HOCH_2(CHOH)_4COOH + 5IO_4^- \rightarrow CH_2O + 3HCOOH + (CO_2H)_2 + 5IO_3^- + H_2O$$

Scheme II

In the bicarbonate alkaline condition, the excess periodate can oxidize the added iodide to iodine quantitatively, but the iodate does not. The liberated iodine subsequently oxidizes the added arsenite and the residual arsenite is then back-titrated by 0.05 M I_2 (Scheme III):

$$IO_4^- + 2I^- + H_2O \rightarrow IO_3^- + I_2 + 2OH^-$$

$$I_2 + AsO_3^{3-} + 2OH^- \rightarrow 2I^- + AsO_4^{3-} + H_2O$$

Scheme III

As a consequence, it is obvious that 1 mol of gluconic acid is equivalent to

Table III—Recovery of I as a Function of Time and Temperature During Selective Oxidation

Temperatures, °C	Recovery of I, %[a]		
	5 min	10 min	30 min
15	89.2	90.9	91.3
40	99.2	99.9	100.2
50	100.0	100.0	100.3
60	100.0	100.2	100.6
80	100.2	100.9	102.1
100	100.9	102.6	104.2

[a] Average of triplicate analyses.

[1] Prepared by the Second Pharmaceutical Factory of Wenchow, China.

Table IV—Recovery of I in the Presence of Other Substances

I Added, mg	Other Substances Added, mg	I Found, mg[a]	Recovery of I, %[a]
50.00	Starch, 20; talc, 12.5 Magnesium stearate, 2.5	50.45	100.9 (*SD* 0.02)
50.00	Lactic acid, 25; calcium hydroxide, 2.5	50.37	100.7 (*SD* 0.08)
50.00	Magnesium chloride, 2; sodium oxalate, 0.5	49.98	99.96 (*SD* 0.05)

[a] Average of triplicate analyses.

5 mol of periodate or to 10 g equivalents of iodine. Hence, 1 mol of I is equivalent to 10 mol of sodium periodate or 20 g equivalents of iodine, *i.e.*, the molar ratio of I to periodate in the selective oxidation is 1:10, and each milliliter of 0.05 M I_2 is equivalent to 0.002242 g of I ($C_{12}H_{22}O_{14}Ca{\cdot}H_2O$, Table I). The average recovery of I is 99.99% (*SD* 0.0161, Table II).

When I reacts with periodate at 100°C over 10 min or at 80°C over 30 min, the formaldehyde would be oxidized successively so that the recovery of I may exceed 100%. On the other hand, if the reaction temperature is low and the period of reaction is short, the selective oxidation of I may be incomplete, resulting in a lowering of recovery. As a rule, it is favorable to keep the selective oxidation at 50°C for as long as 10 min, resulting ~100% recovery (Table III).

Table IV gives the results of recovery of I by the sodium periodate method in the presence of other substances. Some excipients such as starch, talc, magnesium stearate, lactic acid, calcium hydroxide, magnesium ions, and oxalate, *etc.*, occurring in amounts as much as 10-fold of formulation weight in tablets or injections of I, or far more than the compendia prescribed limits, do not interfere with the determination of I using the periodate method. Although lactic acid is an α-hydroxycarboxylic acid, it is not oxidized by periodate under the conditions described previously (16).

[a] From Refs. 12 and 13. [b] Average of triplicate analyses. [c] Percent of labeled amount.

Because the amounts of oxalate present in oral grade I (1) commonly reach 500 ppm (sometimes >1000 ppm) and additive amounts of calcium lactate in I injections are approximated to 1.5% (7), results of analysis in oral grade I or its preparations with the EDTA-complexometric method are usually higher than with the sodium periodate method. Alternatively, owing to the low oxalate content in parenteral grade I (in general, the amounts of oxalate are controlled to <150 ppm in parenteral grade I; if the injections are prepared by I containing oxalate >150 ppm, microcrystalline calcium oxalate would precipitate after standing for several weeks), results of determination obtained by the two methods are almost identical (Table V).

In conclusion, it is apparent that the sodium periodate method is superior to the official EDTA-complexometric method with high specificity, no interference by any excipients or oxalate, *etc.* The proposed method is accurate and precise, not requiring any special apparatus or costly reagents.

Nasal Absorption of Nafarelin Acetate, the Decapeptide [D-Nal(2)^6]LHRH, in Rhesus Monkeys I

SHABBIR T. ANIK ˣ, GEORGIA McRAE, CLINTON NERENBERG, ANN WORDEN, JOANN FOREMAN, JIIN-YU HWANG, STANLEY KUSHINSKY, RICHARD E. JONES, and BRIAN VICKERY

Received January 11, 1983, from the *Institutes of Pharmaceutical Sciences, Biological Sciences, and Pharmacology and Metabolism, Syntex Research, Palo Alto, CA 94304.* Accepted for publication March 1, 1983.

Abstract □ Nafarelin acetate, [D-Nal(2)^6]LHRH, a highly potent superagonist of luteinizing hormone-releasing hormone, was given intranasally to six female rhesus monkeys. Absorption was rapid and very reproducible, with peak levels occurring at 15–30 min and a bioavailability of ~2% relative to a subcutaneous dose. The nasal dose response was highly nonlinear. The nonlinearity was apparently associated with the absorption phase, since elimination profiles at all doses were similar.

Keyphrases □ Nafarelin acetate—nasal absorption, [D-Nal(2)^6]LHRH, rhesus monkeys □ Absorption, nasal—nafarelin acetate, [D-Nal(2)^6]LHRH, rhesus monkeys □ Luteinizing hormone-releasing hormone—analogue, nafarelin acetate, nasal absorption, rhesus monkeys

The delivery of drugs by the nasal route is receiving increased attention as a convenient and efficient method of drug delivery (1–7). In addition to offering advantages such as rapid absorption and avoiding the first-pass effect, it provides for delivery of drugs such as peptides and proteins which are degraded in the GI tract and cannot be given orally. The efficiency of absorption, however, varies considerably between drugs. Whereas a bioavailability of 100% (relative to intravenous) has been reported for nasally administered propranolol in humans (3), the bioavailability was only 1–1.5% for luteinizing hormone-releasing hormone (LHRH) (8). Nevertheless, the high potency of LHRH and its analogues, their large therapeutic ratio, and the need for daily administration in both men and women makes the nasal route extremely attractive for systemic delivery of these compounds.

Nafarelin acetate, a highly potent agonist of LHRH activity, has recently been described (9). In this compound, [D-Nal(2)^6]LHRH, the sixth amino acid in the LHRH decapeptide has been replaced by 3-(2-naphthyl)-D-alanine. This analogue has ~200 times the potency of the native hormone.

The objective of this work was to study the nasal absorption of nafarelin acetate in monkeys, with the purpose of studying the effects of dose and concentration on the systemic availability of this compound *via* nasal administration and establishing a nasal dose equivalent to a therapeutic subcutaneous dose.

EXPERIMENTAL

Study Design—Six adult female rhesus monkeys were used for each dose. The monkeys were sedated before dosing with a 5-mg/kg im injection of ketamine hydrochloride[1]. Approximately 100 μL of a buffered aqueous drug solution was sprayed into each nostril while the animal was held with the head in a vertical position. Immediately after dosing, the animals were placed in a supine position for 5 min.

A heparinized blood sample of ~3 mL was collected from the saphenous vein of each animal at 0 (predose), 5, 15, and 30 min, and 1, 2, 4, and 8 h after administration of the drug. Additional injections of lower doses of ketamine hydrochloride were administered at ~30 min after dosing and immediately prior to the 2-, 4-, and 8-h blood sampling. Blood samples were cooled on ice, and the plasma was separated within 2 h by centrifugation, after which it was stored at −20°C until analyzed by RIA. The monkeys were rested for a minimum of 1 week between doses. In the case of the subcutaneous injection, 0.5 mL of a 10-μg/mL solution of the drug in aqueous buffer was injected in the interscapular area of the monkey, and blood sampling was done as described above.

Radioimmunoassay (10)—A slightly modified nafarelin acetate was conjugated to keyhole limpet hemocyanin (*Megathura crenulta*, mol. wt. 3–7.5 million) using a water-soluble carbodiimide. To provide a suitable functional group for conjugation to the protein, the pyroglutamyl residue in nafarelin acetate was replaced by glutaric acid. Immunization with the protein conjugate was carried out in New Zealand White rabbits using Freund's complete and incomplete adjuvant. The resulting antiserum at a dilution of 1:30,000 yielded a total binding of 45–55%. The radioactive isotope used for labeling was iodine-125. Separation of bound from free radioactivity was carried out with charcoal. The RIA buffer was 0.1 M Tris-HCl, pH 7.2, with 0.5% bovine serum albumin.

Table I—Plasma Level Parameters of Nafarelin Acetate Following Nasal and Subcutaneous Administration in Rhesus Monkeys [a]

Conc. of Solution, mg/mL	Average Volume Administered, μL	Average Dose, μg	Peak Height, ng/mL	AUC, ng·h/mL
Nasal				
0.625	213	133(1.8)	0.23(0.07)	0.63(0.3)
1.25[b]	217	272(4.1)	1.84(0.35)	4.56(1.1)
2.5[b]	173	431(15.7)	8.24(0.7)	15.9(2.1)
1.2	121	140(10.3)	0.82(0.28)	2.31(0.76)
Subcutaneous				
0.01	500	5	1.93(0.35)	5.57(0.97)

[a] Six animals per group except where noted; numbers in parentheses are standard errors. [b] Four animals per group due to inadequate dosing of two animals.

The method was validated by adding known quantities of nafarelin acetate to blank plasma and determining the ratios of measured to added compound. Linear regression analysis for the concentration range of 50–500 pg/mL yielded a slope of 0.96 with a correlation coefficient of 0.999. At 50 pg/mL, the *CV* was 11.3%. Additional validation was obtained from an *in vivo* study in which [^{3}H]nafarelin acetate was administered to monkeys, and plasma profiles were determined by RIA and an HPLC–radiochemical method. Excellent agreement was obtained between the two sets of results.

RESULTS AND DISCUSSION

The plasma level profiles of nafarelin acetate for the three nasal doses and the subcutaneous injection are shown in Fig. 1. As with other drugs, nasal absorption is quite rapid, with peak levels being achieved within 15 min. Reproducibility between animals is excellent, particularly at the higher doses, and suggests that at least in a controlled situation, the nasal route has considerable potential for delivery of this LHRH analogue.

The peak heights and areas under the curve (AUC)[2] are listed in Table I. It is immediately evident that there is a pronounced nonlinearity between the dose administered and the resulting levels of drug in the plasma. For example, a roughly twofold increase in dose from 125 to 270 μg results in an approximate 8-fold increase in peak height and a 6.5-fold increase in AUC. Increasing the dose to 430 μg results in a further fourfold increase in peak height and AUC. Since the elimination profiles are similar for all three doses, this suggests that the nonlinearity is associated with changes in the absorption phase. To determine whether the nonlinearity is a function of the concentration of drug in the solution, or of the total dose administered, an additional experiment was conducted where the drug concentration was 1.2 mg/mL (similar to the previous experiment), but the dose was halved by reducing the volume administered. The results shown in Table I suggest that the nonlinearity in peak levels and AUC observed with the increase in dose appears to be associated with the concomitant increase in the concentration of drug in solution. At a concentration of 1.25 mg/mL, a twofold increase in dose results in a slightly greater than twofold increase in peak height. On the other hand, a twofold increase in concentration (from 0.625 to 1.2 mg/mL) results in a 3.5-fold increase in peak height, even though the dose administered is the same (130–140 μg). An increase in flux across the nasal membrane due to the higher concentration or saturable binding and/or metabolism with membrane or enzyme systems are plausible explanations for these observations. Enzymes such as leucine amino peptidase are known to be present in the nasal membrane (11).

In comparing the plasma level profiles for nasal delivery with that found for subcutaneous injection, it is apparent that the plasma levels for the 270-μg nasal dose are almost superimposable on those for the 5-μg sc dose. This gives a bioavailability of ~2% relative to the subcutaneous dose. These data also agree well with bioassay results, where the minimum effective dose for inhibition of ovulation in female rhesus monkeys was 250 and 5 μg administered daily *via* nasal spray and subcutaneous injection, respectively (12). The reason for the relatively low bioavailability of this compound is presently unknown. Enzymatic degradation in the nasal membrane could be a factor, and there may have been some loss of solution *via* postnasal drip. In any case, these studies show that the monkey can serve as a useful animal for studying nasal delivery of drugs.

[2] AUC values were determined for the 0–8-h time period, since plasma blood levels were below detectable limits at 24 h.

Analysis of Captopril and Hydrochlorothiazide Combination Tablet Formulations by Liquid Chromatography

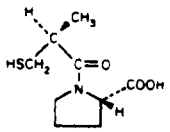
JOEL KIRSCHBAUM ˣ **and SOLOMON PERLMAN**

Received January 10, 1983, from *The Squibb Institute for Medical Research, New Brunswick, NJ 08903.* Accepted for publication March 17, 1983.

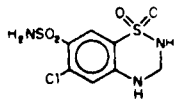
Abstract □ A reverse-phase, high-performance liquid chromatographic (HPLC) procedure was developed for the simultaneous assay of captopril and hydrochlorothiazide in a combination tablet formulation. Gradient elution was used to quantify these two drugs, as well as the oxidized form of captopril, the disulfide. Tablets were extracted with methanol and, after centrifugation, were chromatographed. Initially, a methanol–0.05% aqueous phosphoric acid (25:75, v/v) solution was pumped at 2 mL/min into a phenyl column. After 8 min, the flow rate was increased to 4.5 mL/min and the methanol content of the mobile phase was increased to 45% to elute the disulfide. Detection was at 210 nm. Linearity and repeatability of all constituents were satisfactory. The hydrolytic degradation product of hydrochlorothiazide, 4-amino-6-chloro-1,3-benzene disulfonamide (also called the disulfonamide), could be resolved in test solutions but was not visible in chromatograms of tablets carried through the gradient procedure even after storage at elevated temperatures for prolonged time periods prior to assay. The method can be automated.

Keyphrases □ Captopril—analysis by HPLC, combination with hydrochlorothiazide, tablet formulations □ Hydrochlorothiazide—analysis by HPLC, combination with captopril, tablet formulations

Captopril (I), an antihypertensive agent (1), has been formulated with the diuretic hydrochlorothiazide (II). An assay was needed to quantify these two drugs in a combination tablet formulation (2) together with two degradation products, the disulfide (IV) of captopril and the disulfonamide of hydrochlorothiazide [4-amino-6-chloro-1,3-benzene disulfonamide (III)]. High-performance liquid chromatography (HPLC) has the potential for assaying all four compounds simultaneously. Such an assay should elute the isomeric forms of captopril (3) as one peak, as described in a previously developed assay for captopril bulk material (4). HPLC assays were previously developed for hydrochlorothiazide in tablets (5, 6) and in body tissues (7, 8). The method described below is stability indicating and amenable to automation.



I



II

EXPERIMENTAL

Materials—Captopril[1], the disulfide[1] of captopril, and hydrochlorothiazide[1] were used as received. Water was double-distilled and stored in glass. The disulfonamide[2], HPLC-grade methanol[3], and ACS reagent-grade phosphoric acid[4] were obtained commercially.

Apparatus—A gradient system[5] capable of both flow-rate and mobile-phase composition adjustments was connected to a 50 × 0.2-cm saturator column packed with 37-μm silica. Next in sequence were an inlet filter[6] (2-μm pore size) and a precision loop injector[7] (nominal volume 20 μL), attached to a reverse-phase (medium polarity) phenyl column[8], 5 or 10 μm, 250–300 mm × 4.6 mm i.d., with >7000 theoretical plates per column. The column temperature was maintained slightly above ambient (30°C) by a thermostatically controlled heater[9], to avoid variation in retention time. A variable-wavelength detector[10] set to 210 nm was used. The 20- or 25-cm two-channel strip-chart recorder[11] had input compatible with the detector output. One recorder channel was adjusted to trace the captopril and hydrochlorothiazide peaks on scale. The other channel was set to be ~40 times more sensitive to detect possible impurities. For automated unattended analysis, an autosampler[12] was used in conjunction with a laboratory computer system[13]. Calculations are based on peak area or peak height, which appear to be interchangeable.

Mobile Phase and Gradient Program—At time zero, a mobile phase consisting of methanol–0.05% phosphoric acid in water (25:75, v/v) was pumped at 2 mL/min. After 8 min, the flow rate was increased to 4.5 mL/min and the methanol content to 45%. After 15 min, the methanol content was returned to 25%, and after 20 min, the flow rate was also returned to the original 2 mL/min.

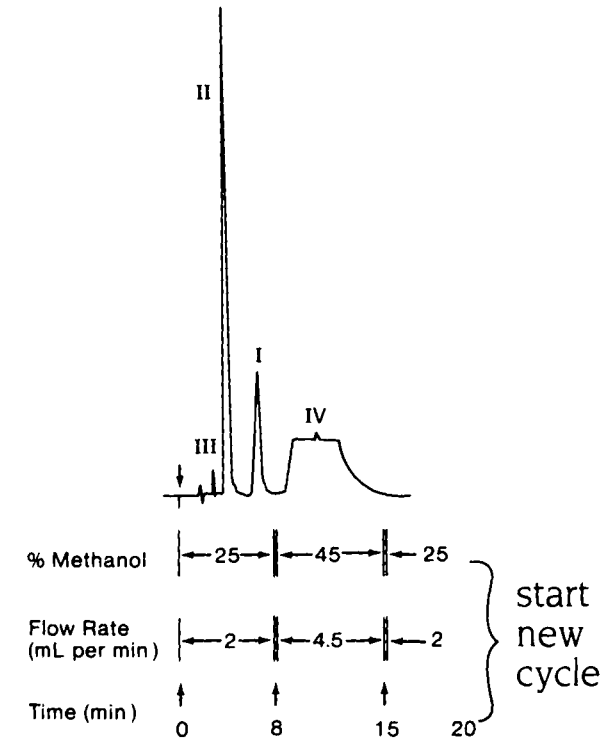


Figure 1—*HPLC of mixed standards for analyzing captopril (I) and hydrochlorothiazide (II) combination tablets, also including the disulfonamide (III) and disulfide (IV). Gradient conditions are appropriately noted, using methanol and 0.05% aqueous phosphoric acid. Detection was at 210 nm (0.16 AUFS) using a phenyl column. For captopril, typical asymmetry factor is 1.25, and number of theoretical plates is 470 (manufacturers' specifications are for >7000 theoretical plates/column using their test systems). Tailing of both standards and samples gradually appears with prolonged use of the column.*

52.0	51.9	+0.1	24.3	24.5	−0.2
50.0	50.3	−0.3	24.4	24.6	−0.2
Mean 50.6	50.7	−0.7	24.5	24.5	+0.4
RSD 2.2%	1.6%		1.5%	1.6%	

Tablet Analyses—Ten formulations were assayed: 12.5, 25, 37.5, 50, and 100 mg of captopril with either 15 or 25 mg of hydrochlorothiazide. For content uniformity, the intact, weighed tablet was extracted with methanol; Twenty-five milliliters of methanol was added to a 12.5-mg captopril/15-mg hydrochlorothiazide combination tablet, and 40 mL of methanol was used to extract all other potencies. For the assay of the drug content of a tablet, 10–20 tablets were ground and the weight of powder equivalent to one tablet was extracted with methanol. After 20 min of ultrasonication, the suspensions were shaken vigorously and then centrifuged at 1500 rpm (1200×*g*).

A mixed standard was prepared consisting of captopril and hydrochlorothiazide equivalent in concentration to the potency of the tablets being analyzed and 0.1% disulfonamide. A second standard containing 0.6% disulfide is necessary since captopril normally contains traces of this reversible oxidation product.

Assay—The column was initially equilibrated by passing 100 mL of methanol 0.5% aqueous phosphoric acid (1:3) through it. Prior to the first injection, the gradient program was activated. After the first cycle, the mixed captopril—hydrochlorothiazide disulfonamide standard was injected twice. All subsequent samples and standards (including the disulfide) were then injected into the column. No daily column cleaning was necessary.

System Suitability Test—The resolution of the mixed standard constituents was as follows: disulfonamide from void volume, ≫1.4; disulfonamide from hydrochlorothiazide, ≫1.4; hydrochlorothiazide from captopril, >2; and captopril from disulfide, >2. Resolution was calculated using $R_S = 2(t_2 - t_1)/(W_1 + W_2)$, where R_S is resolution, t_1 and t_2 are the retention times or distances, and W_1 and W_2 are the respective peak widths of tangents drawn to the baseline. Responses from the initial injections of standard are usually within 1.5% of each other, indicating continuation of the assay.

RESULTS AND DISCUSSION

The gradient HPLC system was developed to quantify captopril, its reversible oxidized form, hydrochlorothiazide, and its possible hydrolytic product, the disulfonamide. Figure 1 illustrates the separation of all four constituents. The baseline aberration occurring after the captopril peak is due to a change in the refractive index of the mobile phase as its composition varies. The disulfide peak is clearly visible above the plateau. (Detectors are available with autozero capability which can electronically correct for such shifts. Alternatively, we successfully used a laboratory data acquisition system[13] to make such a baseline correction.) Separation of all four constituents indicates selectivity of the HPLC system and is the basis of a system suitability test.

Precision of the system (9) was determined by means of six injections of mixed standards to give the following relative standard deviations: disulfonamide, 1.2%; hydrochlorothiazide, 0.5%; captopril, 1.9%; and disulfide, 3.5%. The disulfide value is high due to a combination of long retention time and low (0.6%) concentration. The precision of the method was determined by pooling 10 tablets and then analyzing six tablet weights carried through the recommended procedure. The relative standard deviations are as follows: hydrochlorothiazide, 0.86%; captopril, 1.1%; and disulfide, 4.8%.

The response *versus* concentration curves from 10 to 200% of the concentrations of the standards were found to be linear for all four substances, with calculated correlation coefficients of ≥0.99 for all substances except the disulfide, which was 0.98. Recoveries of captopril and hydrochlorothiazide added to placebo formulation were 100.5% ($n = 5$, $RSD = 0.8$) and 98.7% ($n = 5$, $RSD = 0.8\%$) respectively. No interfering peaks were noted after extracting and injecting placebo tablets. At least six phenyl columns from two vendors[8] have been used, indicating ruggedness.

The gradient assay was verified by using an isocratic HPLC system which could quantitate captopril, hydrochlorothiazide, and the disulfide. This assay used methanol–0.05% aqueous phosphoric acid (55:45, v/v) and a 15%-loaded octadecylsilane column. This system failed to resolve the disulfonamide from the void volume; however, since no disulfonamide appears to be present in any sample studied, it is suitable for verifying the gradient system. Individual tablets of 50 mg of captopril and 25 mg of hydrochlorothiazide were extracted with methanol and simultaneously injected onto the recommended gradient and alternative isocratic systems. The results (Table I) show that the gradient and isocratic systems give similar results for captopril and hydrochlorothiazide, indicating the statistical reliability of the gradient system. The disulfide contents of 0.3% are identical using both systems. No change in strength was observed after storage for 52 weeks at temperatures between ambient and 40°C for these or any other formulations. No other extraneous peaks were detected.

Verification of the absence of disulfonamide was by TLC[14]. The disulfonamide limit of detection by TLC is ~0.01%. However, the compendial (10) colorimetric assay gave values of 0.2–0.4%. Kinetic studies (11) showed these values to be an artifact of the colorimetric method and indicate that this HPLC method has additional utility by replacing an erroneous assay.

For routine assays of the disulfonamide, hydrochlorothiazide, and captopril (but omitting the disulfide), the mobile phase used in the first 8 min of the gradient assay can be used. In this second isocratic system, the disulfide slowly elutes from the column as a broad peak that is unnoticeable because disulfide contents are very low. The first and last chromatograms from a series of repetitive injections are superimposable, indicating that the slow elution of disulfide does not affect the system. The remainder of the chromatogram is similar to Fig. 1, except for the lack of the disulfide plateau region.

In summary, an assay using gradient HPLC has been developed for the active constituents and possible impurities in captopril–hydrochlorothiazide combination tablets. This multiconstituent assay is selective, amenable to automation, and stability indicating.

Quantitation of Diltiazem and Desacetyldiltiazem in Dog Plasma by High-Performance Liquid Chromatography

ROBERT E. WIENS *, DENNIS J. RUNSER ‡, JOSEPH P. LACZ ‡, and DAN C. DIMMITT‡x

Received May 17, 1982, from **Harris Laboratories, Inc., P.O. Box 80837, Lincoln, NE 68501* and ‡*Marion Laboratories, Inc., Kansas City, MO 64137.* Accepted for publication March 24, 1983.

Abstract □ A high-performance liquid chromatographic procedure was developed for the determination of diltiazem and desacetyldiltiazem in dog plasma. Two milliliters of plasma is extracted with a hexane–2-propanol mixture. The assay uses a reverse-phase column maintained at 55°C with a silica saturation column and a pellicular precolumn. The mobile phase is acetonitrile–water (50:50) at pH 6.6 with 1.5-g/L heptanesulfonic acid added as the ion-pair reagent. The procedure is sensitive to 5 ng/mL for both compounds in dog plasma and is linear up to 2000 ng/mL for diltiazem and 1000 ng/mL for desacetyldiltiazem. Preliminary dog mean plasma profiles of diltiazem and desacetyldiltiazem are presented.

Keyphrases □ Diltiazem—quantitation with desacetyldiltiazem, dog plasma, HPLC □ Desacetyldiltiazem—quantitation with diltiazem, dog plasma, HPLC □ HPLC—quantitation of diltiazem and desacetyldiltiazem, dog plasma

Diltiazem hydrochloride, a new antianginal drug being used in Japan for the treatment of angina pectoris, is classified as a calcium antagonist. It affects vascular smooth muscle and dilates coronary vessels, making the drug clinically useful in the treatment of ischemic heart disease (1, 2).

Methods have been published for the determination of diltiazem and/or desacetyldiltiazem, the principal blood metabolite of diltiazem in plasma. A GC method of Rovei *et al* (3), which uses a hexane plasma extract at pH 7 with a nitrogen–phosphorus detector after a complex derivatization procedure, and a TLC–spectrophotometric procedure (4) have been presented. These methods either lack sensitivity (TLC) or are time consuming (GC).

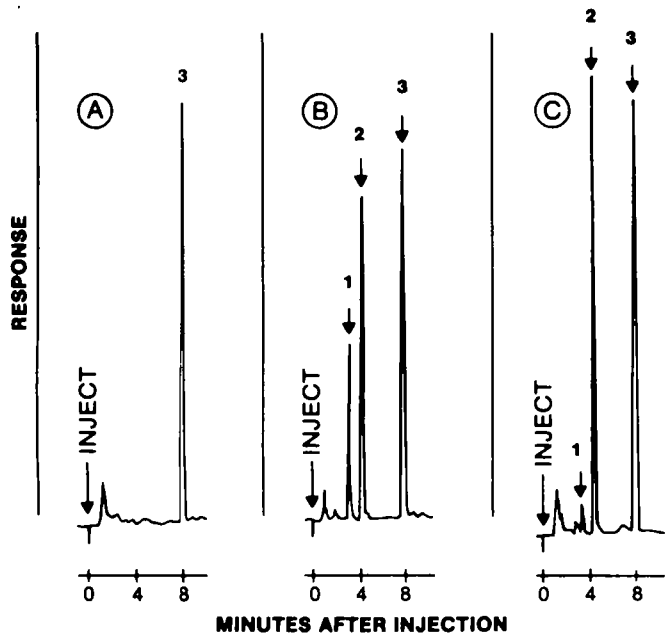

Figure 1—*Chromatograms from (A) blank dog plasma containing 400 ng of prazepam (3), (B) plasma spiked with 100 ng/mL of desacetyldiltiazem (1) and 200 ng/mL of diltiazem (2), and (C) dog plasma following the intravenous administration of diltiazem (2 mg/kg, 1-h postdose).*

Many clinical trials and pharmacology studies have been conducted with this compound; however, few studies have reported the pharmacokinetic parameters in humans or other animal species. The objective of this study was to develop a rapid and sensitive diltiazem and desacetyldiltiazem plasma assay to assess the pharmacokinetics of diltiazem and to present preliminary plasma level data for the beagle dog.

EXPERIMENTAL

Protocol—Six beagle dogs were administered diltiazem hydrochloride in solution at an oral dose of 5 mg/kg and as a bolus dose of 2 mg/kg iv in a crossover design. The dogs were fasted overnight before drug administration and until the 6-h blood collection. Blood samples were collected immediately before dosing and up to 10 h postdose, using sodium heparin as the anticoagulant. The plasma was immediately frozen at −20°C until analysis.

Reagents—Chromatography-grade acetonitrile[1], 2-propanol[1], methanol[1], and hexane[1] were used. Sodium acetate[1] and sodium borate[1] were ACS analytical reagents. Heptanesulfonic acid sodium salt[2] was used as received.

Apparatus—A high-performance liquid chromatograph[3] with an automatic sampler[4] and a reverse-phase C_{18} column[5] was used. A silica saturation column[6] was installed in the oven in front of the injector and a precolumn of pellicular C_{18} packing[7] was inserted after the injector. The column effluent was monitored with a variable-wavelength UV absorbance detector[8] using a dual-pen recorder[9].

Standards—Primary standard solutions of diltiazem hydrochloride [10] (500 μg of free base/mL) and desacetyldiltiazem[10] (500 μg of free base/mL) were prepared in distilled water. A secondary standard solution containing both diltiazem (100 μg/mL) and desacetyldiltiazem (50 μg/mL) was prepared in water. Eight dilutions were made such that 0.1 mL of each dilution would be used to spike 2 mL of blank dog plasma to the concentrations used for the standard curve. The resulting plasma standard curve concentrations were 50, 100, 200, 400, 800, 1600, and 2000 ng/mL of diltiazem and 25, 50, 100, 200, 400, 800, and 1000 ng/mL for desacetyldiltiazem. The internal standard, prazepam[11] (200 μg/mL), was prepared in methanol and then diluted 1:500 in 0.1 M sodium borate buffer (pH 9).

Extraction—A 2.0-mL plasma aliquot from a control dog (standard curve) or unknown sample was placed in a 16 × 150-mm glass culture tube and 1.0 mL of internal standard buffer and 7 mL of hexane–2-propanol (98:2) was added. The tube was closed with a polyef-lined screw-cap and shaken 30 min on a horizonal shaker[12].

Each sample was centrifuged 10 min at room temperature, and 6 mL of the upper hexane layer was transferred to a clean 13 × 100-mm culture tube. The tube was placed in a 40–50°C water bath and evaporated to dryness under a nitrogen stream. The residue was reconstituted by adding 200 μL of mobile phase. The tube was vortexed[13] 30 s to ensure dissolution and centrifuged 2 min to collect the solution. The resulting concentrate was transferred to a microcentrifuge tube[14] and injected onto the HPLC column by the automatic sampler.

Chromatographic Conditions—The mobile phase consisted of acetoni-

trile–water (50:50) containing 1.5 g of heptanesulfonic acid sodium salt/L and 8 g of sodium acetate/L. The final solution was adjusted to pH 6.6 with glacial acetic acid and filtered[15]. The flow rate was 1.5 mL/min, the column temperature 55°C, the detector wavelength 240 nm, and the injection volume 100 μL.

Quantitation—All determinations were performed by hand measuring the peak heights and computing the peak height ratios of each compound as compared with the internal standard. This ratio was calculated and compared with the slope of the standard curve. Replicate and quality control samples (Table II) were processed from blank dog plasma with each set of samples, and a computer program was developed to calculate the ratios, slopes, and intercepts of the standard curves. The quality control samples were spiked and frozen before study initiation, and the replicate samples were spiked at the time of extraction.

RESULTS AND DISCUSSION

A method has been developed to determine diltiazem and desacetyldiltiazem plasma levels utilizing a 10-min HPLC separation. Typical chromatograms obtained from blank plasma spiked with the internal standard, a standard curve sample, and an actual dog plasma sample are presented in Fig. 1. Blank dog plasma without internal standard indicated no interfering peaks.

Sample extraction is pH, solvent, and time dependent. A pH value of 7 has been shown to be successful for the extraction of diltiazem into hexane (3). However, adjustment to pH 9 and the addition of 2% 2-propanol to the hexane increased recovery from 55 to 77% for desacetyldiltiazem and from 70 to 85% for diltiazem, as compared with the pH 7 extraction. Recovery of diltiazem decreased when the two phases were mixed <30 min on the shaker. No diltiazem degradation has been observed under the pH 9 extraction conditions.

Several drugs were tested for use as internal standards and for possible interference with diltiazem and desacetyldiltiazem. Prazepam, diazepam, oxazepam, clonazepam, chlordiazepoxide, medazepam, and propranolol did not interfere with the HPLC separation. Prazepam was chosen as the internal

standard because of its symmetrical peak shape, extraction recovery properties (90%), and appropriate retention time.

Three standard curves were run on successive days (Table I). The accuracy and precision of the method are shown in Table II by the coefficient of variation and mean values for the two quality control samples and two replicate samples. The lower limit of quantitation was calculated after completion of the study by the method of Gabriels (5). The method uses the mean baseline value of the blank plasma samples, a corresponding F value, and the standard deviation. The lower limit of quantitation was 5 ng/mL for diltiazem and desacetydiltiazem.

Stability test samples of diltiazem and desacetyldiltiazem in plasma stored for up to 13 weeks at −20°C indicated no significant breakdown. The tests concentrations of diltiazem ranged from 50 to 500 ng/mL and those of desacetyldiltiazem from 25 to 250 ng/mL.

The mean of the individual plasma diltiazem and desacetyldiltiazem profiles of the six beagle dogs are presented in Fig. 2 for the 2-mg/kg iv and 5-mg/kg oral doses. Both the intravenous and oral data indicate a terminal diltiazem half-life of ~2.2 h and an absolute bioavailability of 55% when the mean of the individual diltiazem areas under the curve from zero to infinity ($AUC_{0\to\infty}$) of the intravenous and oral results are normalized and compared (6). The half-lives were calculated from the elimination rate constant (k) by the equation $t_{1/2} = 0.693/k$. The elimination rate constant (k) was obtained by an intravenous two-compartment model with bolus administration and an oral two-compartment model with first-order absorption and elimination from the central compartment. The data were fitted by the NONLIN (7) regression analysis using subroutines for both sets of data. The $AUC_{0\to\infty}$ values were calculated by the trapezoidal method and normalized for dose assuming linear kinetics.

Analysis of 4-Methylpyrazole in Plasma and Urine by Gas Chromatography with Nitrogen-Selective Detection

RAMANUJ ACHARI* and MICHAEL MAYERSOHN ˣ

Received January 25, 1983, from the *Department of Pharmaceutical Sciences, College of Pharmacy, The University of Arizona, Tucson, AZ 85721.* Accepted for publication March 31, 1983. * Present address: American Critical Care, McGaw Park, IL 60085.

Abstract □ A simple, sensitive, and specific gas chromatographic method for the quantitation of 4-methylpyrazole in plasma and urine is described. Samples containing 4-methylpyrazole, with 3-methylpyrazole as the internal standard, are extracted into ether and the concentrated ethereal extracts are chromatographed on a Carbowax 20M column using nitrogen-selective detection. Standard curves are linear and reproducible over the range of 25–1000 ng/mL for plasma and 0.5–5 μg/mL for urine. Recovery of 4-methylpyrazole is complete from plasma and urine, and the overall between-day coefficient of variation is within 6.0%. No interference is observed from the extractive constituents of plasma and urine. The assay method is suitable for an examination of 4-methylpyrazole disposition in animals and humans.

Keyphrases □ 4-Methylpyrazole—analysis in urine and plasma, gas chromatography with nitrogen-selective detection □ Gas chromatography—analysis of 4-methylpyrazole in plasma and urine, nitrogen-selective detection.

Pyrazole and several of its derivatives have been shown to be inhibitors of the alcohol dehydrogenase enzyme system (1). Because of its apparent low systemic toxicity, 4-methylpyrazole (I) is of particular interest. This compound inhibits the *in vitro* metabolism of alcohols in various animal species (1–3), and it reduces the rate of ethanol elimination in animals (4, 5) and humans (6–8). Several studies have also indicated its effectiveness in reducing the rate of metabolism of methanol (9, 10) and ethylene glycol (11, 12). As a result, 4-methylpyrazole may be a promising alternative to ethanol in treatment of poisoning with alcohols whose toxicity is associated with metabolites formed *via* alcohol dehydrogenase. There have been relatively few studies, however, where plasma concentrations of the compound have been determined (9, 10, 13, 14).

The methods currently available for the determination of I in biological fluids are quite limited. Rydberg and Buijten (15) described potential gas chromatographic (GC) conditions for I which simply involved injecting aqueous solutions of the compound into the column and identifying the chromatographic peak by mass spectrometry. Furthermore, a flame-ionization detector (FID) was employed. With FID, we found that the broad solvent front severely limits the lower measurable concentrations. The GC–MS method (16) of determining I in plasma, although specific, is time consuming and lacking in sensitivity. To examine the disposition of I in animals there is need for a simple, sensitive, and reproducible analytical method for plasma and urine. The present report describes such an assay method, utilizing GC and nitrogen-selective detection, for 4-methylpyrazole (I) using 3-methylpyrazole (II) as an internal standard.

EXPERIMENTAL

Chemicals—4-Methylpyrazole[1] and 3-methylpyrazole[1], the internal standard, were used as supplied. All organic solvents were HPLC grade[2]. Sodium carbonate, sodium chloride, and hydrochloric acid were reagent grade[3].

I II

Gas Chromatography—Samples were analyzed using a gas chromatograph[4] equipped with a nitrogen–phosphorus detector. A 122.0 cm × 2 mm i.d. glass column packed with 5% Carbowax 20M + 2% KOH on 80–100 mesh Chromosorb G (HP)[5] was used. Hydrogen and air flow rates were 3 and 50 mL/min, respectively. Helium was used as a carrier gas at a flow rate of 30 mL/min. The collector voltage was adjusted for adequate sensitivity. The column oven was operated isothermally at 135°C, injection port and detector temperatures were 250°C and 300°C, respectively.

Stock Solutions—A stock solution of I was prepared by dissolving 20 mg in 100 mL of methanol. Working standards were prepared by serial dilution of the stock solution with methanol to encompass the appropriate concentration ranges for plasma and urine. Concentrations of the standards were such that 50 μL added to 1 mL of biological fluid would produce the desired concentration. Solutions of the internal standard were prepared in methanol at a concentration of 4 μg/mL for plasma and 20 μg/mL for urine. All solutions were stored in the refrigerator (0–4°C).

Extraction of Plasma—One milliliter of plasma (containing I) was transferred into a glass culture tube with a polytef-lined screw cap. Fifty microliters (200 ng) of the internal standard solution, 1 g of NaCl, and 0.5 mL of 2 M HCl were added. After addition of 6 mL of ether, the tube was shaken gently for 5 min in a mechanical shaker, centrifuged at 3000 rpm (1000×*g*) for 5 min, and the upper organic layer was withdrawn and discarded. Five hundred microliters of 1 M sodium carbonate was added to the aqueous phase, mixed, and extracted as above with 6 mL of ether. After centrifugation, the clear ether layer was transferred into a 13 × 100-mm disposable glass culture tube containing 30 μL of *n*-butyl alcohol. A boiling chip was added to the tube which was placed in a water bath (45°C). The tube was removed from the water bath after most of the ether had evaporated. If necessary, the extract can be concentrated further by leaving the tube in the water bath for a few minutes after the boiling has ceased. Three microliters of the concentrated ethereal extract was injected into the column. The peak height ratio of I to the internal standard was calculated and the concentration of I was determined with reference to a standard curve.

Extraction of Urine—To 1.0 mL of urine in a glass culture tube (with a screw cap) were added 50 μL (1 μg) of internal standard solution, 1 g of NaCl, and 6 mL of ether. The tube was shaken gently for 5 min in a mechanical shaker and centrifuged for 5 min. The clear organic layer was transferred into a 13 × 100-mm glass culture tube containing 30 μL of *n*-butyl alcohol and treated as described above for the extraction of plasma.

Hydrolytic Treatment of Urine—A 1.0-mL sample of urine was placed into a glass culture tube, 0.5 mL of 2 M HCl was added, and the contents were mixed. The tube was capped tightly and placed in an oven at 115°C. After 1 h the tube was removed from the oven and cooled. One gram of sodium chloride, 50 μL (1 μg) of internal standard solution, and 0.5 mL of 1 M sodium carbonate were added. After addition of 6 mL of ether, the sample was carried through the procedure outlined above.

Standard Curves—Duplicate standards were prepared by transferring 50 μL of the working standards of I and 1.0 mL of blank plasma or urine to glass culture tubes to give final concentrations in the ranges of 25–1000 ng/mL and 0.5–5 μg/mL for plasma and urine, respectively. After addition of 50 μL of internal standard solution, the samples were treated as described above. Standard curves were prepared by plotting peak height ratios of I to the internal standard *versus* concentrations of I.

Extraction Efficiency (Analytical Recovery)—Analytical recoveries of I

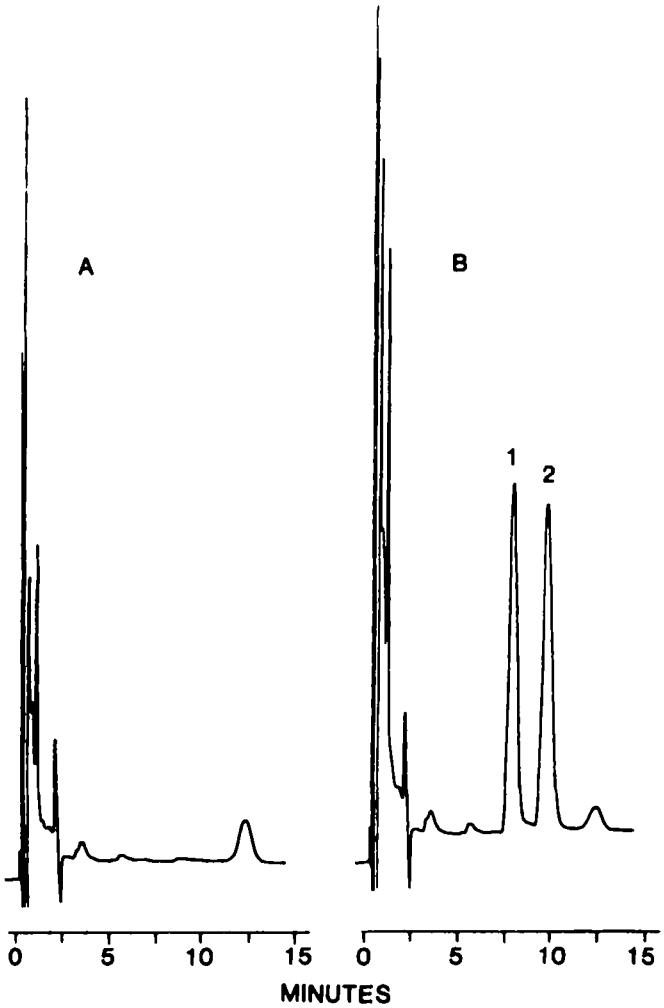

Figure 1—*Chromatograms of ethereal extracts of human plasma. Key: (A) plasma blank; (B) plasma spiked with 200 ng each of 3-methylpyrazole (1) and 4-methylpyrazole (2) (attenuation: 1 × 32).*

and the internal standard from plasma and urine were determined by comparing, respectively, the peak heights of I and internal standard obtained from the extracted spiked plasma and urine samples to those obtained from direct injection of methanolic standards containing equivalent amounts of the compounds. Recoveries of I were also calculated by comparing the peak height ratios of I to the internal standard in the extracted standards to those in the methanolic standards. Three different concentrations of I were used.

RESULTS AND DISCUSSION

A number of different solvents were used for the extraction of I and II from plasma and urine. Hexane and *n*-pentane did not extract either compound. Chlorinated solvents were not suitable for the nitrogen–phosphorus detector. Ethyl acetate gave good extraction of I, but the plasma extracts were not clean and, furthermore, ethyl acetate has a high boiling point. Ether gave the best extraction of I and II; both compounds were completely recovered with a single ether extraction. However, to obtain cleaner extracts an acid-wash step was used for the plasma samples.

Bjorkhem *et al.* (16) also used ether for extraction of I from plasma. However, recovery and reproducibility data were not presented. The ethereal extract was concentrated to ~50-μL under nitrogen. This method of concentrating the ethereal extract would require constant attention since, if the solvent was allowed to evaporate to dryness, almost complete (>90%) loss of I would occur. In our procedure we added 30 μL of *n*-butyl alcohol to the ethereal extract, and the ether was allowed to boil-off in a water bath (45°C). The main advantage of this technique is that the tubes can be left unattended in the water bath without the risk of losing the compound. When ether is evaporated, the compound is retained in *n*-butyl alcohol. However, nitrogen cannot be used to aid solvent evaporation as this will cause the tube to dry and result in almost complete loss of both I and the internal standard (II).

Although I extracts well in the pH range of 4.5–11.5, at higher pH values a small interfering peak was present in the extracts of dog plasma but not in the extracts of human plasma. In the present procedure, plasma was extracted at pH 6–7, which was achieved by adding 1 M sodium carbonate to the acidified plasma.

Table I—Within-Day and Between-Day Reproducibility of the Plasma Assay [a]

Amount Added, ng/mL	Within-Day Found, ng/mL	Within-Day *CV*, %	Between-Day Found, ng/mL	Between-Day *CV*, %
40	41.1 ± 0.45	1.1	40.8 ±0.77	1.9
160	158.5 ± 2.6	1.6	158.7 ± 4.8	3.0
800	805.1 ± 14.4	1.8	790.5 ± 24.3	3.0

[a] Mean ± *SD*; $n = 5$.

Typical chromatograms obtained from the ethereal extracts of human blank plasma and plasma spiked with 200 ng each of I and II are shown in Fig. 1. The column used gave sharp and symmetrical peaks for both compounds. The internal standard (II) eluted close to I, but was well resolved. Under the conditions employed, the retention times for I and II were 10 and 8 min, respectively. Extracts of both dog and human blank plasma showed a small and broad peak at 24 min at high sensitivity (attenuation <1 × 64). By carefully spacing the sample injections this peak can be eluted in the region between the solvent front and sample peaks.

Analytical recoveries (mean ± *SD*) of I and internal standard using peak height comparison were 102.6 ± 2.6, and 101.6 ± 1.9%, respectively. Peak heights from the extracted standards were consistently greater than those from the methanolic standards. This would result from the smaller volume of the concentrated extracts in the extracted standards compared with the volume (0.1 mL) of the methanolic standards. This discrepancy could be obviated if the sample extracts could be evaporated to dryness and reconstituted to the

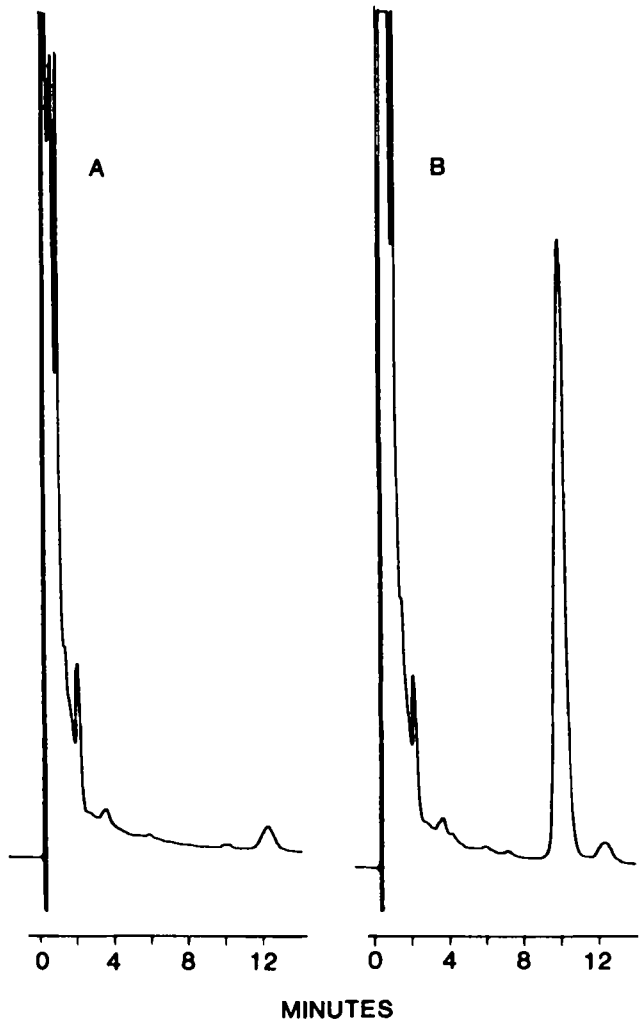

Figure 2—*Chromatograms of ethereal extracts of dog plasma before (A) and 16 h after (B) a 10-mg/kg iv dose of 4-methylpyrazole. The peak corresponds to a concentration of 640 ng/mL (attenuation: 1 × 64).*

Table II—Within-Day and Between-Day Reproducibility of the Urine Assay [a]

Added, μg/mL	Within-Day Found, μg/mL	Within-Day CV, %	Between-Day Found, μg/mL	Between-Day CV, %
1.6	1.62 ± 0.03	1.8	1.62 ± 0.066	4.0
2.7	2.75 ± 0.04	1.5	2.78 ± 0.114	4.1
3.9	4.15 ± 0.14	3.4	4.18 ± 0.194	4.6

[a] Mean ± *SD*; $n = 4$.

same volume as the methanolic standards. Peak height ratio, however, would not be affected by volume difference. Since the extraction efficiencies of I and of the internal standard were independent of each other and the internal standard was completely recovered, recovery of I calculated from peak height ratio measurement would provide a more meaningful value. Using peak height ratio measurement, mean (±*SD*) recoveries of I (six samples) at 100, 500, and 1000 ng/mL were 99.0 ± 1.0, 98.5 ± 1.8, and 99.0 ± 1.5%, respectively.

Standard curves were linear and reproducible over the concentration range of 25–1000 ng/mL. Linear regression statistics for five standard curves prepared on different days over a period of 2 weeks produced a slope of 0.0044 (±0.0001), an intercept of −0.024 (±0.032), and a mean coefficient of determination (r^2) of 0.999.

Assay reproducibility was determined by repeated analysis of plasma samples containing I. Three different concentrations other than those used in the preparation of the standard curves were used. The mean concentrations, standard deviations, and coefficients of variation for within-day and between-day analysis are presented in Table I. These data indicate excellent assay reproducibility, which is further supported by the reproducible nature of the standard curves as shown above.

Plasma spiked with I (1 μg/mL) was stored in the refrigerator (0–4°C), and 1-mL aliquots were analyzed once a week for 6 weeks. Recoveries of I were similar over the 6-week period indicating good stability of I in plasma.

Recovery of I from urine was similar to that from plasma. Standard curves were linear and reproducible over the concentration range of 0.5 to 5 μg/mL with $r^2 > 0.999$. No interference was observed from the extractive constituents of blank urine. Both within-day and between-day assay reproducibility was excellent (Table II). The procedure can be used for concentrations down to 0.1 μg/mL with good reproducibility (coefficient of variation, 4.5%).

The lower sensitivity limit of the GC–MS method (16) was only ~100 ng/mL when 2 mL of plasma was used. Our GC method is simple, rapid, able to quantitate I down to 25 ng/mL with good precision (coefficient of variation, 6.0%), and requires only 1 mL of plasma. This is advantageous, since with greater assay sensitivity plasma concentrations can be monitored for a longer period of time and a smaller dose can be used. The versatile nature of the present method makes it particularly suitable for pharmacokinetic studies of I.

To further evaluate the usefulness of the assay procedure, a 14.5-kg dog was given a 10-mg/kg iv dose of I, and blood and urine samples were obtained. Figure 2 shows the chromatograms of ethereal extracts of dog plasma before and after the administration of I. After hydrolytic treatment of urine samples, the total recovery of I was 2.3% over a period of 96 h. Disposition studies in the dog are currently in progress.

[^{14}C]Normacromerine Fate in the Rat

P. W. FERGUSON ˣ, W. J. KELLER, and F. O. RISINGER

Received August 19, 1982, from the *School of Pharmacy, Northeast Louisiana University, Monroe, LA 71209.* Accepted for publication March 17, 1983.

Abstract □ The biological fate of [^{14}C]normacromerine, a dimethoxylated phenethylamine derivative with putative hallucinogenic properties, was evaluated in male Sprague–Dawley rats at 100 mg/kg po. Urine was the primary elimination route accounting for 50% of administered carbon-14 after 24 h. Of this urine radioactivity, normacromerine comprised 30% at 8 h decreasing to nondetectable levels at 24 h. Carbon-14 in feces represented <10% of the administered dose at 24 h, and $^{14}CO_2$ expiration was not detected. Studies of normacromerine fate in comparison with previously studied phenethylamines may enhance evaluation of hallucinogenic potential of normacromerine.

Keyphrases □ Normacromerine—biological fate in the rat, hallucinogenic potential □ Biological fate—[^{14}C]normacromerine, rat, hallucinogenic potential □ Hallucinogens—normacromerine, biological fate in the rat

Normacromerine (*N*-methyl-3,4-dimethoxy-β-hydroxyphenethylamine), the major alkaloid in extracts of the Dona Ana cactus [*Coryphantha macromeris* (Engelm.) Br. and R.], has been implicated as the chemical responsible for hallucinogenic effects experienced by humans ingesting the cactus (1, 2). The potency of the Dona Ana cactus has been estimated to be one-fifth that of the peyote cactus [*Lophophora williamsii* (Lem.) Coult.] which contains mescaline, another natural hallucinogen (2, 3).

Laboratory studies of the behavioral effects of normacromerine in rats have provided both positive (4) and negative (5) results in support of the hallucinogenic properties of the drug. Absent from these studies has been a thorough evaluation of the mammalian disposition of normacromerine after ingestion. Studies of biological fate of the compound are unavailable in the literature.

Patterns of absorption, distribution, metabolism, and excretion of chemicals determine their extent and duration of action within biological systems (6). Such studies of norma-

Table II—Within-Day and Between-Day Reproducibility of the Urine Assay [a]

Added, μg/mL	Within-Day Found, μg/mL	Within-Day CV, %	Between-Day Found, μg/mL	Between-Day CV, %
1.6	1.62 ± 0.03	1.8	1.62 ± 0.066	4.0
2.7	2.75 ± 0.04	1.5	2.78 ± 0.114	4.1
3.9	4.15 ± 0.14	3.4	4.18 ± 0.194	4.6

[a] Mean ± *SD*; $n = 4$.

same volume as the methanolic standards. Peak height ratio, however, would not be affected by volume difference. Since the extraction efficiencies of I and of the internal standard were independent of each other and the internal standard was completely recovered, recovery of I calculated from peak height ratio measurement would provide a more meaningful value. Using peak height ratio measurement, mean (±*SD*) recoveries of I (six samples) at 100, 500, and 1000 ng/mL were 99.0 ± 1.0, 98.5 ± 1.8, and 99.0 ± 1.5%, respectively.

Standard curves were linear and reproducible over the concentration range of 25–1000 ng/mL. Linear regression statistics for five standard curves prepared on different days over a period of 2 weeks produced a slope of 0.0044 (±0.0001), an intercept of −0.024 (±0.032), and a mean coefficient of determination (r^2) of 0.999.

Assay reproducibility was determined by repeated analysis of plasma samples containing I. Three different concentrations other than those used in the preparation of the standard curves were used. The mean concentrations, standard deviations, and coefficients of variation for within-day and between-day analysis are presented in Table I. These data indicate excellent assay reproducibility, which is further supported by the reproducible nature of the standard curves as shown above.

Plasma spiked with I (1 μg/mL) was stored in the refrigerator (0–4°C), and 1-mL aliquots were analyzed once a week for 6 weeks. Recoveries of I were similar over the 6-week period indicating good stability of I in plasma.

Recovery of I from urine was similar to that from plasma. Standard curves were linear and reproducible over the concentration range of 0.5 to 5 μg/mL with $r^2 > 0.999$. No interference was observed from the extractive constituents of blank urine. Both within-day and between-day assay reproducibility was excellent (Table II). The procedure can be used for concentrations down to 0.1 μg/mL with good reproducibility (coefficient of variation, 4.5%).

The lower sensitivity limit of the GC–MS method (16) was only ~100 ng/mL when 2 mL of plasma was used. Our GC method is simple, rapid, able to quantitate I down to 25 ng/mL with good precision (coefficient of variation, 6.0%), and requires only 1 mL of plasma. This is advantageous, since with greater assay sensitivity plasma concentrations can be monitored for a longer period of time and a smaller dose can be used. The versatile nature of the present method makes it particularly suitable for pharmacokinetic studies of I.

To further evaluate the usefulness of the assay procedure, a 14.5-kg dog was given a 10-mg/kg iv dose of I, and blood and urine samples were obtained. Figure 2 shows the chromatograms of ethereal extracts of dog plasma before and after the administration of I. After hydrolytic treatment of urine samples, the total recovery of I was 2.3% over a period of 96 h. Disposition studies in the dog are currently in progress.

	Urine	Feces
8 (n = 6)	41.0 ± 2.6	0
16 (n = 4)	8.3 ± 1.85	8.0 ± 3
24 (n = 4)	1.4 ± 0.23	1.8 ± 0.32

[a] Total carbon-14 recovered (urine + feces + carcass + carbon dioxide) was 80 ± 3% of the administered dose. Each sample analysis was performed in duplicate. Values are the mean of the sample average ±SE; n is the number of animals evaluated.

cromerine may therefore provide a foundation for more enlightened evaluation of its hallucinogenic activity. Our initial objective in the evaluation of normacromerine was to characterize its previously unknown fate in a mammalian system, thereby establishing a framework for future metabolite studies.

EXPERIMENTAL

[^{14}C]Normacromerine—[^{14}C]Normacromerine (1 μCi/mmol, labeled in the β position) and nonlabeled normacromerine were synthesized *in vivo* from *Coryphantha macromeris* var. *runyonii*, as described by Keller (7, 8). Radiopurity (>99%) was evaluated using silica gel GF 254 TLC plates[1] developed in benzene–chloroform–methanol–58% ammonium hydroxide (8:6:5:1). All normacromerine analyses were performed using this chromatographic system.

Animal Exposures—Male Sprague-Dawley rats (300–400 g) were fasted 16–18 h prior to exposure; however, water was provided *ad libitum*. Each animal received 100 mg/kg of [^{14}C]normacromerine hydrochloride (in water) by oral gavage. This replicated dosage levels used in previous behavioral studies (5). After dosing, the animals were placed into metabolism chambers[2] for collection of expired CO_2, urine, and feces. Chamber air was drawn by vacuum (1 L/min) through 1 N KOH to collect the $^{14}CO_2$. One milliliter of KOH was sampled periodically throughout the initial 8-h postexposure. Each sample was placed into 15 ml of scintillation cocktail[3] for ^{14}C-radioassay using a liquid scintillation counter[4]. Urine and feces were collected and analyzed at 8, 16, and 24 h postexposure. At each time period collected urine was sampled into scintillation cocktail for total ^{14}C-radioassay and the remainder frozen until normacromerine analysis. Feces were collected, freeze-dried, ground to a fine powder, and combusted in a sample oxidizer[5] for total ^{14}C-radioassay. At 8 and 24 h, carcasses were also analyzed for total carbon-14. Following homogenization (1:1 with H_2O), samples of the carcass were combusted and radioassayed to provide a complete carbon-14 animal mass balance (carbon dioxide + urine + feces + carcass).

Urine Analysis—[^{14}C]Normacromerine was extracted (75% efficiency) from alkalinized urine with toluene. The toluene extract was then concentrated under nitrogen in a 40°C water bath[6]. [^{14}C]Normacromerine concentrates were spotted on TLC plates and developed by the standard solvent system. Co-chromatography with nonradioactive normacromerine standards allowed identification and isolation of [^{14}C]normacromerine. Silica gel spots containing [^{14}C]normacromerine were transferred (>90% recovery) into 15 mL of scintillation cocktail for subsequent radioassay.

RESULTS AND DISCUSSION

The 24-h carbon-14 elimination pattern is given in Table I. Urine was the major elimination route; feces accounted for minor excretion of the radiolabel. Elimination as $^{14}CO_2$ was not detected. Total carbon-14 recovery (urine + feces + carbon dioxide + carcass) was 80 ± 3% of the administered dose. This less than optimum recovery reflects an inability to accurately assay the total carbon-14 remaining in the animal at 8 and 24 h postexposure. Levels (<100 cpm/g of tissue) at two to three times the background radioactivity were measured in triplicate 500-mg tissue samples for each of 10 animals. The significant dilution of carbon-14 remaining in the animal (354 ± 72 dpm/g of tissue) was an unavoidable limitation due to the low normacromerine specific activity available from the *in vivo* synthesis.

Table II—Percentage of Urinary Carbon-14 Analyzed as Normacromerine 8, 16, and 24 h after Exposure to [^{14}C]Normacromerine, 100 mg/kg po

Time, h	Percent Normacromerine[a]
8 (n = 4)	30.0 ± 3.8
16 (n = 4)	2.8 ± 1.5
24 (n = 4)	not detected

[a] Values are the mean of sample average ±SE; n is the number of animals evaluated. Each sample was analyzed in duplicate.

Since urine served as the primary elimination route, urine samples were further characterized to quantify [^{14}C]normacromerine. Table II indicates significant *in vivo* mammalian biotransformation of normacromerine. Thirty percent of urine radioactivity at 8 h was normacromerine, decreasing to 0% by 24 h. The remainder was accountable as water-soluble ^{14}C-labeled metabolites.

Our study in rats described normacromerine elimination primarily in urine, minimally in feces, and none as CO_2. Urine and feces analyses indicated normacromerine was significantly absorbed and metabolized to water-soluble metabolites.

Normacromerine is an *O*-methylated analogue of the endogenous neurotransmitter epinephrine and its singly *O*-methylated derivative, metanephrine. In fact, the biosynthesis of normacromerine in *Coryphantha macromeris* involves these catecholamines as precursors (7, 8). Consequently, the mammalian fate of normacromerine could be similar to the mammalian biotransformation of epinephrine and metanephrine. Previous studies of intravenously administered [^{3}H]epinephrine and [^{14}C]metanephrine in rats (9) demonstrated a similar biological fate as observed in these normacromerine studies. Urine was the significant elimination route (65–70% of administered dose after 48 h) and feces a secondary route (15 and 0.3% for epinephrine and metanephrine, respectively). Carbon dioxide was not analyzed. Since [^{14}C]-normacromerine was radiolabeled at the side-chain β position, loss of this carbon as $^{14}CO_2$ was not expected (10) and was not observed in our study. Cumulative carbon-14 recovery in urine and feces at 48 and 24 h postexposure was similar for metanephrine (65–68%) and normacromerine (61%), respectively. Free epinephrine and metanephrine accounted for <10% of urine radioactivity at 48 h. In comparison, no normacromerine was detected at 24 h postexposure. This may reflect enhanced oxidation of normacromerine by liver monoamine oxidases following the oral route of exposure (10). Metabolites of epinephrine and metanephrine in urine were products of monoamine oxidase reactions (3-methoxy-4-hydroxymandelic acid and 3-methoxy-4-hydroxyphenylglycol).

In vitro studies of methoxylated β-hydroxyphenethylamines, such as normacromerine, indicate significant interactions with mammalian monoamine oxidases (11–13). Therefore, the structural similarities between normacromerine, epinephrine, and metanephrine, as well as similar elimination patterns in the rat, suggest that normacromerine elimination products may be similar to monoamine oxidase products of its catecholamine analogues. The synthesis of these novel normacromerine metabolites and their *in vivo* identification, underway in our laboratory, are necessary for complete evaluation of normacromerine fate in the rat.

Understanding of normacromerine disposition will not only enhance evaluation of its hallucinogenic potential, but will provide further insight into comparative metabolism of xenobiotics by plant and animal systems.

Investigation of the Antitumor Activity of Podocarpic Acid Derivatives

EDWARD J. PARISH *x **and D. HOWARD MILES** ‡

Received August 16, 1982 from the *Department of Chemistry, Auburn University, Auburn University, AL 36849 and the ‡Department of Chemistry, Mississippi State University, Mississippi State, MS 37962. Accepted for publication March 23, 1983.

Abstract □ As a class, octahydrophenanthrene lactones, podolactones, and related podocarpic acid derivatives have been reported to possess a wide variety of biological activities, including antileukemic activity, inhibition of plant cell growth, and hormonal and anti-inflammatory properties. In the present study, a series of synthetic intermediates derived from podocarpic acid have been prepared and evaluated with respect to their ability to inhibit human epidermoid carcinoma of the nasopharynx *in vitro*. The significant cytotoxicity demonstrated by methyl 6α-bromo-7-oxo-*O*-methylpodocarpate (50% inhibition of cells at 8.85×10^{-9} M) was markedly higher than that of the other derivatives examined. Further evaluation against L1210 and P388 lymphoid leukemias in mice failed to demonstrate significant antitumor activity.

Keyphrases □ Podocarpic acid derivatives—synthesis, antitumor activity, *in vitro* human epidermoid carcinoma (nasopharynx) screen, L1210 and P388 screens in mice □ Antineoplastic agents—potential, podocarpic acid derivatives, synthesis, *in vitro* human epidermoid carcinoma (nasopharynx) screen, L1210 and P388 screens in mice

Octahydrophenanthrene lactones (I) and related podocarpic acid derivatives (II) have been reported to possess hormonal and anti-inflammatory properties (1). Other similar podolactones have been shown to inhibit the expansion and division of plant cells (III) (2–4) and to have antileukemic activity (IV) (5). In view of their documented biological properties it appeared worthwhile to test a series of synthetic intermediates derived from podocarpic acid for antitumor activity. This report describes the preparation of these derivatives and the results obtained in biological tests against tumors.

RESULTS AND DISCUSSION

Preparation of all derivatives shown in Scheme I proceeded *via* methyl *O*-methyl-7-ketopodocarpate (VI), which was synthesized from podocarpic acid by methylation with dimethyl sulfate and subsequent oxidation using the approach described by Bible and Grove (1) in the synthesis of bromoketone (IIb).

Compound VII was prepared from VI by reduction of the 7-keto group to the corresponding alcohol with sodium borohydride. The resulting epimeric alcohol mixture (the 7α-hydroxyl derivative would be expected to be present in greater abundance) was efficiently dehydrated by *p*-toluenesulfonic acid in refluxing dihydropyran. The synthesis of epoxide VIII was completed by treatment of VII with *m*-chloroperbenzoic acid in ether. The α-configuration of the epoxide in VIII is inferred from X-ray crystallographic studies (6) of IIb and related 6α-bromo-7-oxo-diterpenoids (7). These studies indicate significant intramolecular steric hindrance in that region of the molecule resulting from 1,3-diaxial interactions of the angular methyl group at C-10 and the axial carbomethoxy group at C-4. Both of these groups reside on the β face of the molecule and would mediate an α-approach of the peracid.

Bromoketone IIb was prepared by an adapted procedure derived from the work of Bible and Grove (1). Compounds IX and X were prepared from bromoketone IIb by treatment with *N*-phenylbenzamidine and 1,5-diazabicyclo[5.4.0]undec-5-ene (DBU), respectively, utilizing procedures reported previously (8, 9).

The activity of the freshly prepared synthetic intermediates (Scheme I) against human epidermoid carcinoma of the nasopharynx is shown in Table I. The *in vitro* activity of bromoketone IIb in the 9KB test system was markedly higher than that of VII–X. Since the cytotoxicity demonstrated by IIb was sufficient for confirmation as an active compound at the National Cancer Institute, these compounds were tested in the LE and PS tumor systems (Table II). All derivatives were inactive in both the L1210 and PS tumor systems.

EXPERIMENTAL[1]

Methyl *O*-Methyl-7-ketopodocarpate (VI)—To crude podocarpic acid (V, 500 g) was added ice (500 g), methanol (500 mL), and sodium hydroxide (240 g). This mixture was stirred for 2 h until a dark-brown color persisted, indicative of the formation of the phenoxy anion. The solution was cooled to 15°C and dimethyl sulfate (425 mL, 566.5 g, 4.5 mol) was added dropwise, with stirring, over a period of 1.5 h. The reaction was completed, as evidenced by solidification of the solution. A light-brown solid was obtained by filtration after the addition of 1 L of water. This solid was stirred with 1 L of water and removed by filtration. Recrystallization from acetone yielded 460.1 g of methyl *O*-methylpodocarpate as white crystals, mp 127.0–128.5°C [lit. (10) mp 128°C]. IR(KBr): 1725, 1500, and 1450 cm^{-1}; ^{1}H-NMR ($CDCl_3$): δ 1.10 (s, 3, C—CH_3), 1.32 (s, 3, C—CH_3), 3.70 (s, 3, O—CH_3), 3.80 (s, 3, O—CH_3), 6.71 (m, 2, ArH), and 7.72 ppm (d, 1, J = 7.5 Hz, ArH).

Methyl *O*-methylpodocarpate (100 g, 0.331 mol) was dissolved in 1 L of acetic acid. Chromium trioxide (94 g, 0.93 mol) was dissolved in an 800-mL acetic acid–200-mL water solution, which was then added to the ester solution at room temperature with stirring. After allowing the mixture to stand overnight at room temperature, it was poured into 6 L of saturated aqueous sodium chloride solution. After allowing this solution to stand overnight, the precipitate was removed by filtration and washed with water to yield 74 g (71%) of ketone VI as yellow crystals, mp 121–123°C [lit. mp 121–123°C (11) and 122–124°C (1)]. IR (KBr): 1725 and 1600 cm^{-1}; ^{1}H-NMR ($CDCl_3$): δ 0.98 (s, 3, C—CH_3), 1.20 (s, 3, C—CH_3), 3.68 (s, 3, O—CH_3), 3.86 (s, 3, O—CH_3), 6.66 (m, 2, ArH), and 7.83 ppm (d, 1, J = 8 Hz, ArH).

Compound VII—Methyl *O*-methyl-7-ketopodocarpate (VI, 10 g, 31.6 mmol) was dissolved in tetrahydrofuran (14 mL) and 95% ethanol (20 mL). After dissolving sodium borohydride (2 g) in water (8 mL) and 95% ethanol (3 mL), this solution was added slowly to the ketoester solution. The resulting solution was stirred for 24 h at room temperature, after which the precipitate

[1] IR spectra were obtained using a Perkin-Elmer Model 137 G or a Perkin-Elmer Model 580 spectrophotometer. NMR were obtained on a Jeolco Minimar or a Varian EM-390 spectrometer using $CDCl_3$ as the solvent; tetramethylsilane was used as an internal standard. Mass spectra were obtained using a Perkin-Elmer model 270 mass spectrometer. GC was performed using a Hewlett-Packard Model 402 gas chromatograph with a hydrogen flame detector. A glass column packed with 3% SE-30 on 100–120 mesh GCQ at a column temperature at 270°C with a nitrogen flow rate of 35 mL/min was used for all GC analyses unless otherwise stated. Melting points were obtained on a Fisher-Jones apparatus and are uncorrected. Elemental analyses were performed by Galbraith Laboratories, Inc., Knoxville, Tenn.

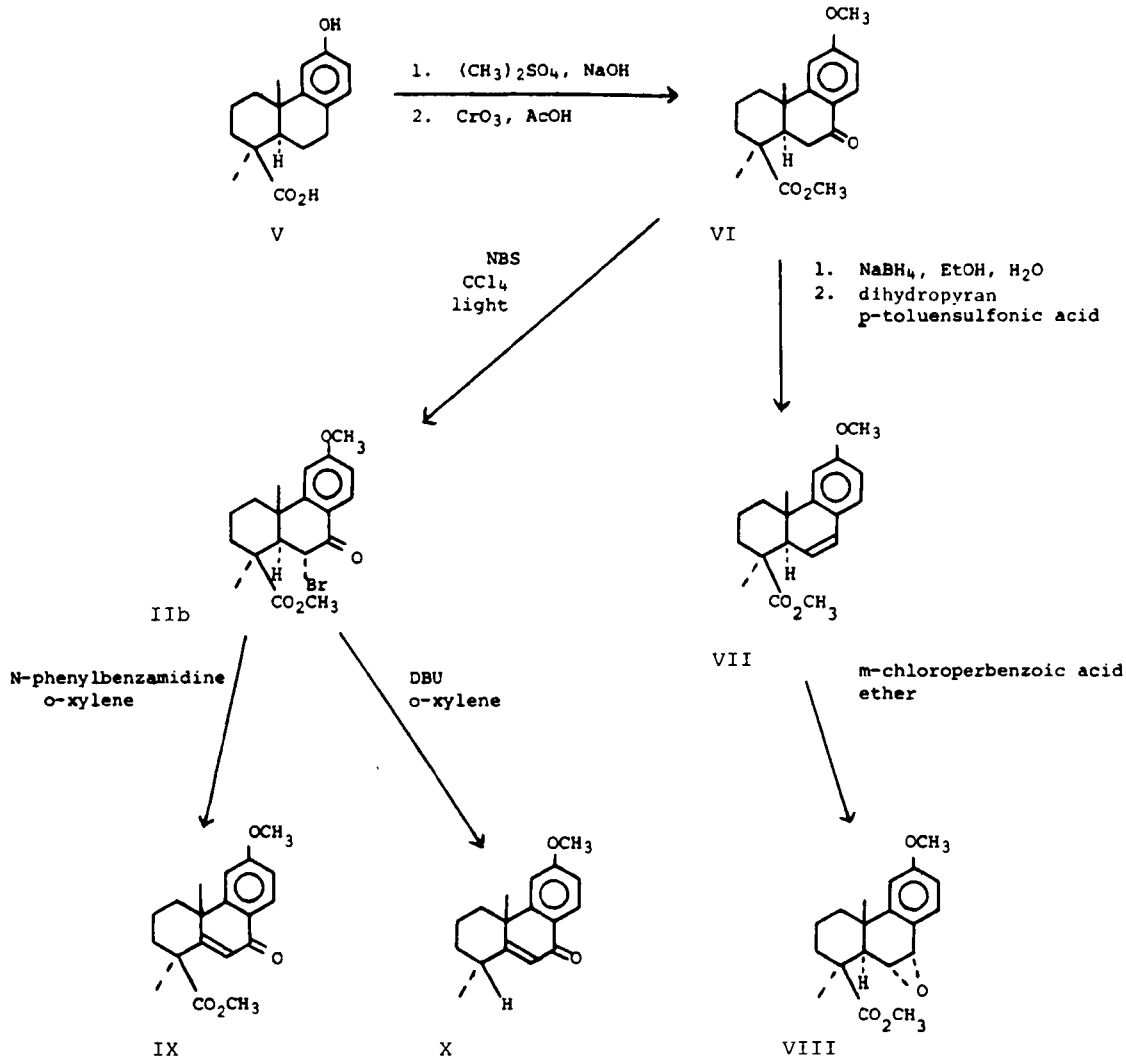

Scheme I

was removed by filtration. Evaporation of the solution *in vacuo* gave a pink syrup. The syrup was dissolved in ether (25 mL), followed by addition of 5% aqueous sodium chloride solution (10 mL). The aqueous layer was extracted several times with 50-mL portions of ether. The ether extracts were combined, washed twice with 5% aqueous sodium chloride (20 mL), dried over anhydrous magnesium sulfate, and evaporated *in vacuo*. Crystallization from ether solution gave 8.8 g (88%) of the alcohol methyl *O*-methyl-7-hydroxypodocarpate as white crystals, mp 100–106°C. IR (KBr): 3500, 1715, 1610, and 1575 cm^{-1}; ^{1}H-NMR ($CDCl_3$): δ 0.88 (s, 3, C—CH_3), 1.32 (s, 3, C—CH_3), 3.70 (s, 3, O—CH_3), 3.82 (s, 3, O—CH_3), 4.51 (m, 1, C*H*OH), and 6.83 ppm (m, 3, ArH). MS: *m/z* 318 (M^+); Calcd. for $C_{19}H_{26}O_4$: *m/z* 318 (M^+).

Anal.—Calc. for $C_{19}H_{26}O_4$: C, 71.76; H, 8.24. Found: C, 71.88; H, 8.35.

The aforementioned alcohol (8 g, 25.2 mmol), dihydropyran (5 mL), and 0.5 g of *p*-toluenesulfonic acid were heated at reflux for 8 h. The mixture was extracted with 200 mL of ether. The organic phase was washed with water, 5% aqueous sodium carbonate, and then water, and dried over anhydrous magnesium sulfate. Evaporation *in vacuo* yielded a yellow syrup, which was chromatographed (dry silica gel, 50:1). Elution with petroleum ether–methylene chloride gave excess dihydropyran in the early fractions and the unsaturated ester VII as a solid in the later fractions (monitored by GC). Compound VII was recrystallized from CCl_4–hexane (slow evaporation) to give light-brown crystals (6.4 g, 85%), mp 84–85°C. IR(KBr): 2950, 1720, and 1600 cm^{-1}; ^{1}H-NMR ($CDCl_3$): δ 0.86 (s, 3, C—CH_3), 1.35 (s, 3, C—CH_3), 3.75 (s, 3, O—CH_3), 3.88 (s, 3, O—CH_3), 6.51 (s, 2, vinylic), and 6.90 ppm (m, 3, ArH).

Anal.—Calc. for $C_{19}H_{24}O_3$: C. 75.96; H, 8.07. Found: C, 75.82; H, 8.14.

Epoxide VIII—To a solution of the unsaturated ester VII (5 g, 16.6 mmol) in 100 mL of dry ether was added slowly a solution of 3 g of *m*-chloroperbenzoic acid in 15 mL of dry ether with stirring. The solution was stirred for 6 h and then was allowed to stand overnight. After the addition of 10% $NaHCO_3$ (15 mL), the mixture was extracted with ether. The organic phase was washed (H_2O), dried ($MgSO_4$), and the solvent was removed to give a light-yellow syrup, which solidified on standing. Recrystallization from chloroform yielded 4.6 g (87%) of white crystals of VIII, mp 158–159°C. IR(KBr): 2950, 1725, and 1500 cm^{-1}; ^{1}H-NMR ($CDCl_3$): δ 1.12 (s, 3, C—CH_3), 1.28 (s, 3, C—CH_3), 3.69 (s, 3, O—CH_3), 3.78 (s, 3, O—CH_3), and 6.88 ppm (m, 3, ArH).

Anal.—Calc. for $C_{19}H_{24}O_4$: C, 72.13; H, 7.65. Found: C, 72.16; H. 7.72.

Methyl *O*-Methyl-6-α-bromo-7-ketopodocarpate (IIb)—To ester VI (46 g, 0.2226 mol) was added 550 mL of carbon tetrachloride. After heating to dissolve the ketone, 28 g (0.157 mol) of *N*-bromosuccinimide was added, and the solution was allowed to stand (catalyzed by sunlight) for 96 h with occasional stirring. The solution was filtered and evaporated *in vacuo*. The residue (mp 123–124°C) was recrystallized five times from aqueous methanol to give

Isocratic Liquid Chromatographic Method for the Determination of Amoxapine and its Metabolites

SCOTT M. JOHNSON, GLORIA NYGARD, and S. K. WAHBA KHALIL ˣ

Received October 1, 1982; from *The Pharmacokinetic Drug Analysis Laboratory, Pharmaceutical Science Dept., College of Pharmacy, North Dakota State University*, and *Veterans Administration Medical Center, Fargo, ND 58105.* Accepted for publication March 23, 1983.

Abstract □ An isocratic reverse-phase liquid chromatographic method for the determination of amoxapine and its major metabolites in human plasma utilizing UV detection is described. Plasma samples were extracted with ethyl acetate after pH adjustement. The reconstituted extracts were injected onto a cyanopropylsilane column and eluted with a mobile phase consisting of 65% acetonitrile and 35% sodium acetate buffer 0.03 M and pH 6. The minimum detectable limit was <10 ng/mL of plasma. Possible interferences from other drugs which might be administered concurrently were studied. The reproducibility and precision of the method are demonstrated by the analysis of samples containing 25–600 ng/mL of plasma. The method is being applied successfully in our laboratory for the analysis of plasma from patients receiving amoxapine.

Keyphrases □ Amoxapine—isocratic HPLC method, determination of metabolites □ Metabolites—isocratic HPLC method, determination of amoxapine

Amoxapine[1], 2-chloro-11-(1-piperazinyl)dibenz[*b,f*]-[1,4]oxazepine, a relatively new antidepressant of the dibenzoxazepine class, has been shown to be a potent antidepressant (1–3). The relationship between tricyclic antidepressant plasma concentrations and therapeutic response has been studied extensively, with inconclusive results (4, 5). The side effects of tricyclic antidepressants have also been correlated to plasma concentrations with mixed results (6). Since the major metabolic pathway of amoxapine is hydroxylation (7), monitoring therapeutic levels of the parent drug and its active

hydroxylated metabolites is important for studying the kinetics and correlating the plasma concentrations with therapeutic response and side effects.

Methodology to determine amoxapine and its metabolites in serum has been limited to GC using derivatization and electron-capture detection (8, 9). However, recently a high-performance liquid chromatographic (HPLC) method (10) was developed using an ODS reverse-phase column and an elaborate three-step extraction procedure. The structurally related compound loxapine (*N*-methylamoxapine) has been analyzed by GC using derivatization and electron-capture detection (8, 9), nitrogen–phosphorus detection (11), or MS (9, 11).

This paper describes the separation and quantitation of amoxapine and its 7- and 8-hydroxylated metabolites from human plasma using HPLC with a reverse-phase cyanopropylsilane column and UV detection. The method has the advantages of involving only one extraction step and no derivatization. The method is sensitive and applicable to the direct determination of plasma levels in the presence of one or more

of several drugs which might be prescribed concurrently. The applicability of the method has been demonstrated by the analysis of plasma from patients receiving amoxapine.

EXPERIMENTAL

Instrumentation—A high-performance liquid chromatograph[2] was equipped with a cyanopropylsilane column[3], 250 mm × 4.6 mm i.d. The deaerated mobile phase was pumped through the column at 3.0 mL/min (13–15 mPa). The column compartment was maintained at 45°C, with UV monitoring at 250 nm.

Chemicals and Reagents—Sodium hydroxide, acetic acid, and sodium acetate were reagent grade. HPLC-grade ethyl acetate, acetonitrile, and methanol were used. Amoxapine (I)[1], 7-hydroxyamoxapine (II)[1], 8-hydroxyamoxapine (III)[1], and trimipramine hydrochloride (IV)[4] were supplied by the manufacturers.

Solutions—Sodium acetate solution, 0.03 M, was prepared in deionized distilled water, and the pH was adjusted to 6 by the gradual addition of acetic acid. The mobile phase consisted of 65% acetonitrile and 35% buffer.

Separate solutions of the drug, each metabolite, and the internal standard were made containing 5 mg/10 mL of methanol. A dilution to a working concentration (5 ng/μL for each) was made in methanol for the drug-metabolite group (I, II, and III). The internal standard stock solution (IV) was diluted with ethyl acetate to a concentration of 20 ng/mL.

Sample Preparation—To 1.0 mL of heparinized plasma in a 15-mL screw-capped centrifuge tube was added an aliquot (5–120 μL) of the drug and metabolite working solution containing 25–600 ng, 0.5 mL of 0.1 M NaOH, and 10 mL of extraction solution. The tubes were vortexed for 10 s and centrifuged for 5 min at 900×*g*. A 9-mL volume of the organic phase was transferred to special concentration tubes[5] and evaporated to dryness at 50°C under a gentle stream of nitrogen.

Separation and Quantitation—The residue was dissolved in 100 μL of methanol and transferred to a polypropylene microvial[6] before injection of 30 μL into the chromatograph. A standard curve was constructed utilizing a minimum of four replicate plasma extractions simulating concentrations of drug and metabolites from 25 to 600 ng/mL. The chromatograms were recorded at a chart speed of 5 mm/min. The peak heights were measured, and the ratios (drug/internal standard and metabolite/internal standard) were calculated and plotted *versus* concentration expressed as nanograms per milliliter of plasma.

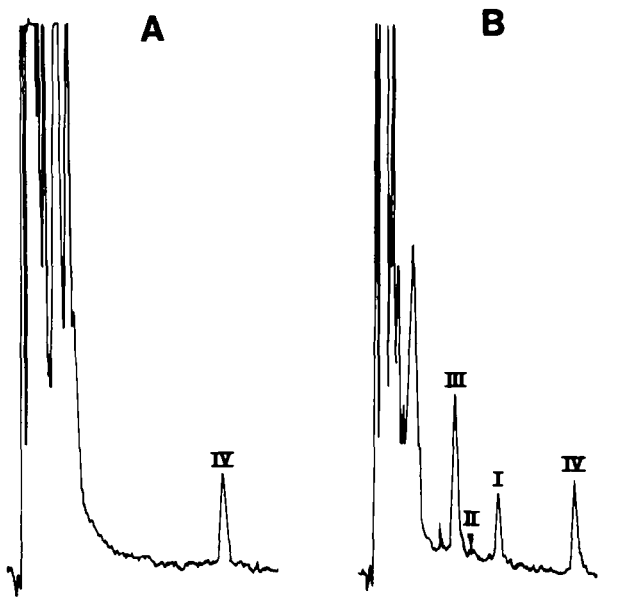

Figure 2—*Typical chromatograms of ethyl acetate extracts of 1.0 mL of plasma. The extracts were reconstituted with 100 μL of methanol, injection volume 30 μL, absorbance at 250 nm. Key: (A) drug free; (B) patient receiving I orally, concentrations of compounds expressed as ng/mL of plasma are I = 72, II = <10, and III = 227.*

Patient Samples—Heparinized plasma samples from patients receiving oral amoxapine were extracted in duplicate using the same procedure. The amounts of drug and metabolites in patient samples were calculated by comparison with a standard curve prepared daily. Possible interferences from normal plasma constituents, as well as other drugs and metabolites, were also studied.

RESULTS AND DISCUSSION

Amoxapine can be extracted readily from basified plasma using a solvent mixture (hexane containing 0.5% diethylamine) reported for the extraction of several tricyclic antidepressants and their metabolites (12). The active hydroxylated metabolites of amoxapine cannot, however, be extracted with that system and, therefore, the polar solvent ethyl acetate was selected.

The use of a cyanopropylsilane column in a reverse-phase mode with a mobile phase of acetonitrile–0.03 M acetate buffer at pH 6 (65:35, v/v) produced excellent separation of the drug from its metabolites and the internal standard. The separation depends on the pH and molarity of the buffer as well as the percentage of acetonitrile in the mobile phase. The mobile phase composition selected for this assay was based on the capacity factor (K) data plotted in Fig. 1. Detection at 250 nm was optimum for the drug, its metabolites, and the internal standard. Monitoring at 254 nm resulted in only a slight loss of sensitivity.

The ratios of peak heights of the drug and metabolites to the peak height of the internal standard were calculated. Linear regression analysis of the data on two separate days (Table I) indicated linearity and reproducibility in the range of 25–600 ng/mL of plasma. Extension of the standard curve beyond 600 ng/mL exhibited nonlinearity. A normal therapeutic range has not been established for amoxapine or its metabolites, but the linear portion of the standard curve encompasses the plasma concentrations which are expected based on normal dosages of amoxapine. Absolute recovery of the drug and its 7- and 8-hydroxy metabolites from plasma were 63, 69, and 68%, respectively, of the theoretical amounts. These values correlate well with data published recently (10). This low recovery may be responsible for the variation in the amount found at low concentrations (Table I). The minimum detectable limits of the assay are 6.5, 9.4, and 8.5 ng/mL of plasma for I, II, and III.

[5] Concentratubes; Laboratory Research Co., Los Angeles, Calif.
[6] Micro-volume sample flask; P. Weidmann & Co., Romanshorn, Switzerland.

No interference with the drug or its metabolites from normal plasma constitutes was observed (Fig. 2A). The retention times of several drugs that might be prescribed simultaneously with amoxapine were determined (Table II). Little interference would be expected under the experimental conditions.

The method has been applied to the analysis of many samples obtained from patients receiving amoxapine orally. The drug and its 8-hydroxy metabolite are present in relatively high concentrations (Fig. 2B). However, the 7-hydroxy metabolite is found in low concentration. This may be due to its short half-life (8).

Major advantages of the method are the small sample volume required, the simplicity and high recovery using a single extraction step with no derivatization, and the use of an isocratic mobile phase. The sensitivity is sufficient for routine analysis of patient samples and for pharmacokinetic studies.

Isosorbide Dinitrate Plasma Concentrations and Bioavailability in Human Subjects after Administration of Standard Oral and Sublingual Formulations

L. F. CHASSEAUD ˣ, A. DARRAGH, E. DOYLE, R. F. LAMBE, and T. TAYLOR

Received September 13, 1982, from the *Department of Metabolism and Pharmacokinetics, Huntingdon Research Centre, Huntingdon, PE18 6ES England and the Institute of Clinical Pharmacology, Dublin, Ireland.* Accepted for publication December 23, 1982.

Abstract □ The bioavailability of isosorbide dinitrate from formulations containing 5, 10, and 20 mg in tablets and 10 mg in solution for oral use and 5 mg in tablets for sublingual use, has been compared. When adjusted for dose, the peak mean plasma drug concentrations after oral administration were similar (*e.g.*, 9.2 ng/mL after a 10-mg tablet) and about one-half that obtained after sublingual administration. Drug concentrations declined monoexponentially with mean half-lives ranging from 25–36 min. The relative bioavailability of isosorbide dinitrate from the oral formulations was not significantly different ($p > 0.05$) over the dose range studied, whereas the relative bioavailability after sublingual administration was about twice as great ($p < 0.01$) as that after oral administration. The plasma drug concentration–time profile after administering the 5-mg sublingual tablet was similar to that obtained after administering orally a solution containing 10 mg, indicating that the latter should be as clinically effective as the former.

Keyphrases □ Isosorbide dinitrate—rate and extent of bioavailability from various oral formulations compared, oral and sublingual formulations compared, humans □ Bioavailability—isosorbide dinitrate, oral and sublingual formulations compared, human □ Vasodilators—isosorbide dinitrate, oral and sublingual formulations compared, humans

Isosorbide dinitrate is an anti-anginal organic nitrate vasodilator that is in extensive clinical use. Following the development of suitably sensitive GC assays (1–3) for the measurement of isosorbide dinitrate in plasma, there have been several reports of the plasma levels of isosorbide dinitrate after the administration of different formulations of the drug (4–9). Sustained-release formulations have proven to be of particular interest. However, none of these reports have compared the relative bioavailability of isosorbide dinitrate from increasing doses of standard oral formulations. Such studies are described in this paper.

EXPERIMENTAL

Drug Administration—Two studies were conducted: the first compared a 5-mg sublingual tablet formulation with a 10-mg oral solution and 10- and 20-mg standard oral tablet formulations of isosorbide dinitrate[1]. The second study compared a 5-mg standard oral tablet formulation[1] with its 10-mg counterpart investigated in the first study. In each study, separate groups of 12 male volunteers each were involved, and the experimental conditions were the same. All subjects (18–40 years old and 58–85 kg) gave their written consent. Within 7 d before and after either study, each subject was given a complete physical examination including routine laboratory screening tests. During the study, the subjects remained under medical supervision. No adverse reactions, apart from headache (4 subjects), were reported by any subject. The studies were approved by the Institutional Review Board. Each of the oral dosage formulations was administered with 100 mL of water according to a complete crossover repeated Latin-square design with an interval of 1 week between doses. The sublingual formulation was retained under the tongue until it completely disintegrated; the subjects were instructed to avoid swallowing during this period. For at least 12 h predosing and for 4 h postdose the subjects fasted, and activity and subsequent diet were standardized.

At predose and after dosing, blood samples were collected into heparinized tubes by venipuncture, immediately cooled, and centrifuged. The resultant plasma was removed and stored at −20°C under conditions in which the drug was stable throughout the assay period.

Drug Assay—Isosorbide dinitrate in plasma was measured by an electron

[1] Formulations (Risordan) were provided by Theraplix, Paris, France. The respective batch numbers were 416, 430, 6659, 6665, 6747 for Risordan 5 mg (sublingual), 5 mg (oral), 10 mg (tablet), 20 mg and 10 mg (solution), respectively.

[a] Nanograms per milliliter ± *SD*. [b] Two tablets (10 mg) administered. [c] ND = not detected (<0.5 ng/mL).

capture GC assay (3) with glyceryl trinitrate as the internal standard. Plasma isosorbide dinitrate levels were calculated by reference to standard curves constructed by adding known amounts of the drug to control human plasma. During this procedure and the subsequent assay, isosorbide dinitrate was completely stable at 4° or 20°C. The recovery of isosorbide dinitrate from plasma over the concentration range 1–15 ng/mL was 91 ± 10% *SD*. The precision of the method for the measurement of isosorbide dinitrate in plasma (n = 5) was 18, 9, and 11% at 1, 5, and 10 ng/mL, respectively.

Data Processing—Apparent half-lives for the decline of plasma drug concentrations were calculated by least-squares regression analysis of log concentration against time from measurements during the terminal linear phase of the plasma drug concentration–time curves. As isosorbide dinitrate kinetics appear to follow a "flip-flop" model (10), these half-lives relate to drug absorption, not to elimination. Areas under the plasma concentration–time curves, scaled to equal doses, were calculated by the trapezoidal rule or by using spline functions, and adjusted to infinite time. Whether the infinite time adjustment was carried out at a concentration of ~2 ng/mL (where assay precision was ~≤10%) or at a lower concentration (where assay precision was poorer), the difference in the resultant calculated mean areas was <~3% (mean 1.4% range 0.3–3.3%).

Areas, peak plasma concentrations and their times of occurrence, and apparent "absorption" half-lives were subjected to an ANOVA for crossover designs (11). Formulation means were compared with the reference mean by Dunnett's test (12, 13) and compared pairwise by the Newman-Keuls procedure (14, 15). The total variance was separated into that due to subjects, day of administration, formulations, and residual.

RESULTS AND DISCUSSION

Plasma Drug Concentrations—Mean concentrations of isosorbide dinitrate in plasma after administration of the various formulations are shown in Tables I and II. Drug levels were detected in the plasma of at least eight subjects at the first sampling time after administration of the tablet formulations and in all subjects after administration of the solution. Drug was not detected (<0.5 ng/mL) in at least five subjects at 150 min after administration of all formulations except the 20-mg dose. Drug was even undetected in the plasma of some subjects at 120 min after administration. Mean plasma drug levels obtained after equivalent oral doses as a solution and as a tablet were generally similar, but as expected, peak mean levels were reached sooner after administration of the solution.

Inspection of the data shows that the peak mean plasma drug levels obtained after administration of 5-, 10-, and 20-mg tablet formulations were linearly related to dose.

The mean plasma drug levels obtained after administration of the 10-mg tablet to two separate groups of subjects in different studies were remarkably similar (*cf.* Tables I and II).

Mean plasma drug levels obtained after the 5-mg sublingual dose were similar to those after a 10-mg oral dose and in the same range as previously reported (4, 9, 16).

With respect to the type of isosorbide dinitrate formulation administered, the plasma drug levels shown in Tables I and II are similar to those reported in the literature (4–7).

Bioavailability Parameters—Peak plasma levels of isosorbide dinitrate and the times of occurrence are shown in Table III. Although the peak levels of the 10-mg tablet and 10-mg solution were similar, the times at which they were reached were significantly different. With due allowance for dose, mean peak levels from the 20-, 10-, and 5-mg tablets (the latter given as 2 × 5 mg) were similar as were their times of occurrence. The former result suggests that over this dose range, at least, a similar proportion of isosorbide dinitrate was probably absorbed unchanged into the peripheral circulation. It should be noted that an oral dose of [^{14}C]isosorbide dinitrate was almost completely absorbed with respect to radioactivity (17), whereas the systemic availability of isosorbide dinitrate orally is ~25% (18) due to considerable first-pass metabolism in the liver and perhaps even during absorption from the GI tract. It has also been reported that a similar proportion of isosorbide dinitrate was absorbed from a 20-mg sustained-release formulation over the 20–100-mg dose range in healthy subjects (19), and from an apparently standard formulation over the 15–120-mg dose range in patients (20).

Although relatively greater with respect to the administered dose, the mean peak level of isosorbide dinitrate following a sublingual dose was reached hardly any sooner than from a 10-mg solution. This result, and the similarity between the respective plasma drug concentration–time curves, implies that a dose of 10 mg of isosorbide dinitrate as an oral solution should produce about the same onset and duration of clinical effect as a 5-mg sublingual dose.

Measured areas under the plasma drug concentration–time curves are shown in Table III. The mean AUC ratios, when adjusted for dose/body weight, after administration of 5-, 10-, and 20-mg tablet formulations were

Table III—Mean (± *SD*) Bioavailability Parameters of Isosorbide Dinitrate for the Various Formulations [a]

Parameter	Oral 5-mg Tablet[b]	Oral 10-mg Tablet	Oral 20-mg Tablet	Oral 10-mg Solution	Sublingual 5-mg Tablet
Peak concentration in individuals (ng/mL)	(14.0 ± 6.1)	10.6 ± 2.3 (14.0 ± 2.8)	22.4 ± 9.9[c,f,g]	11.7 ± 6.2[d]	10.9 ± 5.3

[a] Data in parentheses have been obtained from a different group of subjects. [b] This formulation (given as 2 × 5 mg) was compared statistically ($p > 0.05$) with the 10-mg tablet only. [c] Significantly different ($p < 0.01$) from 10-mg solution (Dunnett's test). [d] Significantly different ($p < 0.01$) from 20-mg tablet (Newman-Keuls pairwise comparison). [e] Significantly different ($p < 0.05$) from 10-mg solution (Dunnett's test). [f] Significantly different ($p < 0.01$) from 10-mg tablet (Newman-Keuls pairwise comparison). [g] Significantly different ($p < 0.01$ or <0.05) from 5-mg sublingual tablet (Newman-Keuls pairwise comparison). [h] Significant differences occur (*c,d,f*) with this parameter when data were adjusted for dose/body weight.

similar to that after a 10-mg solution indicating that there were no dosage form or dose level effects on the extent of bioavailability of isosorbide dinitrate over the 5–20 mg dose range (*i.e.*, a similar relative fraction of the dose of isosorbide dinitrate reached the peripheral circulation unchanged after administration of each formulation). The mean adjusted AUC after administration of the sublingual 5-mg dose was significantly different from those after the oral tablet formulations, as might be expected. Indeed, previous studies have shown that the extent of bioavailability of isosorbide dinitrate from a sublingual formulation was at least twice that from the same formulation given orally (4), since some but not all of a sublingual dose avoids first-pass elimination. A large proportion of a sublingual dose is usually swallowed (18).

The conventional 95% confidence limits (21, 22) of mean areas expressed as a percent of the mean from the 10-mg solution formulation taken as a reference were −19 to +29%, −6 to +50%, and +32 to +109% from the 10-mg oral tablet, 20-mg oral tablet, and 5-mg sublingual tablet, respectively. These limits were −11 to +24% for the 5-mg oral tablet when the 10-mg oral tablet was taken as the reference (Table III). These confidence limits are fairly narrow even though plasma concentrations of isosorbide dinitrate can vary by several-fold between subjects, and the group of subjects studied was not particularly large.

Drug Half-Life—Isosorbide dinitrate kinetics appear to follow a "flip-flop" model (10, 18) and, therefore, the monoexponential decline of the concentrations in plasma can be regarded as reflecting the rate of drug absorption.

Among the orally administered formulations, the drug absorption half-life was shortest after the 10-mg solution dose, but only the drug half-life observed after the 20-mg tablet was significantly longer ($p < 0.01$) than that after the 10-mg solution. A shorter half-life after the sublingual dose would not be expected because the 5-mg tablet was retained in the mouth during disintegration before a notable proportion was swallowed. The half-lives measured in these studies are in close agreement with those reported in the literature (4, 9, 10, 18).

Disintegrating Force as a New Formulation Parameter

PAOLO COLOMBO *, UBALDO CONTE *, CARLA CARAMELLA *, MARIO GEDDO ‡, and ALDO LA MANNA *x

Received November 17, 1982, from the **Dipartimento di Chimica Farmaceutica* and ‡*Istituto di Fisica Generale, Unità G.N.S.M., Università di Pavia, Viale Taramelli 12, 27100, Pavia, Italy.* Accepted for publication March 24, 1983.

Abstract □ Some coated aspirin tablet formulations were evaluated by relating their properties to disintegrating force development patterns. The treatment of disintegrating force–time curves was effected using the Weibull distribution as proposed for dissolution. Such parameters as the maximum disintegrating force developed, the time needed to reach 63.2% maximum disintegrating force (τ_d) the shape parameter, the lag time, and the input value were used for evaluating the formulas examined. It was concluded that the input values, the integrating force development rate at time τ_d, can be employed as a new formulation parameter since, when correlated with the crushing strength, it allows an overall evaluation of the formula examined.

Keyphrases □ Disintegrating force—new formulation parameter, Weibull distribution, coated aspirin tablets □ Formulations—disintegrating force as a new parameter, Weibull distribution, coated aspirin tablets □ Weibull distribution—disintegrating force as a new formulation parameter, coated aspirin tablets

In a previous paper (1), the disintegrating force of tablets was defined as the force developed inside a tablet depending on the liquid–solid contact. It was shown that curves obtained by plotting disintegrating force *versus* liquid contact time had patterns following saturation kinetics dependent on the liquid penetration into voids. Since compact structure (defined by voids distribution and interparticle bonding) and disintegration–dissolution performance are strictly related, the investigations of the disintegration behavior of a tablet should provide a means for the evaluation of the structure obtained.

It is well known that disintegration time as measured by official apparatuses does not satisfactorily describe the disintegration properties of tablets, as demonstrated by the methods proposed to evaluate disintegration (2–5). Because disintegrating force–time curves could be related to the structure of tablets (6), these deserved a deeper investigation in view of their employment not only for studying the bioavailability-related properties of tablets, but also to assess the structure–technological parameter relationships.

The aim of the present work was to employ the disintegrating force parameters for studying coated aspirin tablet

pressed at five different force levels and checked 24 h after compression for porosity, crushing strength, disintegration time (USP XX), and disintegrating force development using the apparatus previously described (1). The results are the mean of at least six determinations.

RESULTS AND DISCUSSION

The disintegrating force–time curves obtained for different formulations are given in Fig. 1. Some show a sigmoidal pattern (*e.g.*, mixture B), some are simple first-order exponential (*e.g.*, mixture E), and some present a steeper initial slope followed by a flattened "tail" in the final part (*e.g.*, mixture G). The analogy existing between these curves and dissolution curves from tablets suggested linearizing them in the way proposed (8) for dissolution, using the Weibull distribution rearranged into the form:

$$\log [-\ln (1 - F/F_\infty)] = b \log (t - t_0) - \log a \qquad \text{(Eq. 1)}$$

where F is the disintegrating force developed at time t and F_∞ is the maximum disintegrating force.

A plot of $[-\ln (1 - F/F_\infty)]$ *versus* t on log–log paper will give a straight line defined by the slope b, the ordinate intercept a, and the lag time t_0. The slope b characterizes the shape of the curve and is dependent on whether a sigmoidal, a simple first-order exponential, or an initially steeper exponential curve is considered. The parameter a can be replaced by the more informative disintegrating force time τ_d defined by:

$$a = (\tau_d)^b \qquad \text{(Eq. 2)}$$

where τ_d represents the time needed to obtain 63.2% of maximum disintegrating force, taken from the end of lag time t_0.

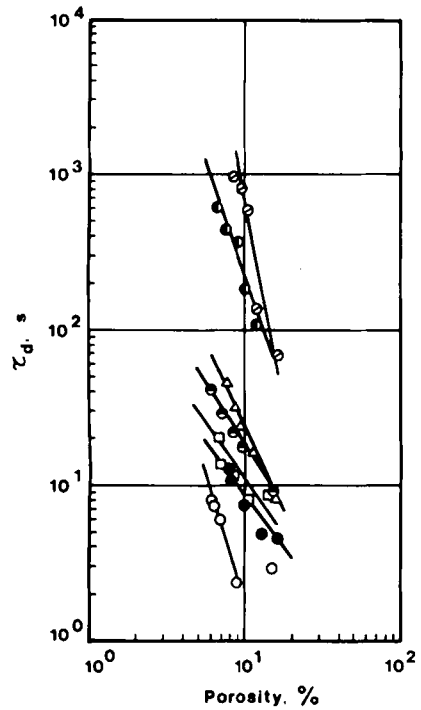

Figure 2—*Log–log plot of τ_d values* versus *porosity. Key: (○) A; (□) B; (⊘) C; (⊖) D; (●) E; (△) F; (◐) G.*

The evaluation of Weibull distribution parameters was performed by means of a program run on a computer[2]. Linear regression analysis, performed on the Weibull distribution rearranged into the form of Eq. 1, allowed the evaluation of b and a parameters. Experimental data were then fitted with a least-squares technique on the original $F(t)$ form of Weibull distribution. Numerical values of t_0, b, and a were estimated from the best fit of the experimental data. Uncertainty of a and b values was <1% ($p = 0.95$).

The results obtained for various mixtures examined are given in Table II. The maximum disintegrating force expresses the ability of the disintegrator, when contacting water, to push apart the bound particles. For the mixtures examined, the higher values of disintegrating force were obtained for E, F, and D, whereas smaller values were measured for C. The maximum disintegrating force increases as compression force increases, until an almost constant value is reached. This confirms that the swelling or repulsion energy of disintegrators can best work when particles are closer to one another (9). For mixture G, the disintegrating force-increasing pattern is not so evident. The disintegrating force development time (expressed by τ_d) always increases as compression force increases, and porosity decreases as shown in Fig. 2. Mixtures G and C have τ_d values markedly higher than the remaining mixtures at the same levels of compression force or porosity.

The comparison between maximum disintegrating force (F_∞) and disintegration time shows that a high value of maximum disintegrating force does not always correspond to a fast disintegration. For example, although mixtures G and A show comparable maximum disintegrating force values (at the highest compression force levels), their disintegration times are markedly different. In this case, τ_d seems to be the decisive factor. In other cases, the opposite situation is seen. The comparison between A (third compression force level) and G (fifth compression force level) mixtures shows that comparable

	170	16	53	11	1.1
	242	24	50	13	1.1
F	44	12	34	9	1.0
	92	21	44	16	1.0
	144	34	53	24	1.0
	188	49	50	33	0.9
	252	66	48	48	1.1
G	62	72	28	110	0.5
	104	143	32	185	0.7
	127	237	32	380	0.6
	177	359	32	450	0.7
	223	505	27	630	0.8

τ_d values correspond to disintegration time values 50% of the other due to differences in disintegrating force values. The above examples clearly indicate that disintegration time depends on both parameters. As previously indicated (6), the joint consideration of F_∞ and τ_d allows an evaluation of the kinetic aspect of the disintegrating force development, which, as recently outlined (10), seems to be the factor governing the disintegration process. The derivative of the Weibull equation at time $t = t_0 + \tau_d$, termed "input," was calculated and employed for the quantitative evaluation of disintegration kinetics.

The good correlation found between input and disintegration time, as expressed in Fig. 3, indicates that it is the disintegrating force development rate that determines the disintegration of the compact. Input depends on compression force (Fig. 4), and a complete characterization of the compact can

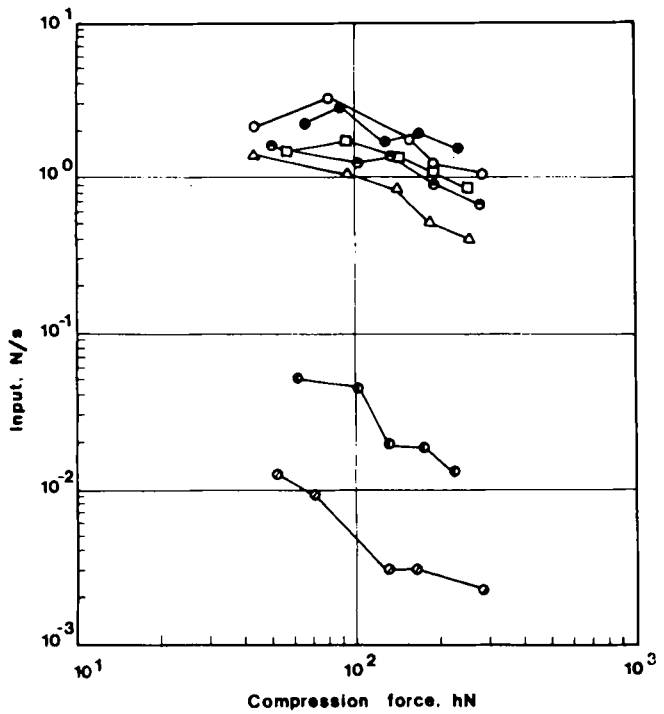

Figure 4—*Log-log plot of input values* versus *compression force. Key: (○) A; (□) B; (⊘) C; (⊖) D; (●) E; (△) F; (◐) G.*

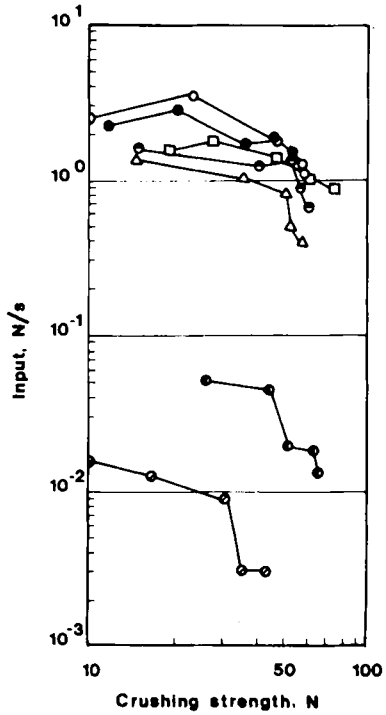

Figure 5—*Log-log plot of input* versus *crushing strength. Key: (○) A; (□) B; (⊘) C; (⊖) D; (●) E; (△) F; (◐) G.*

be obtained by plotting crushing strength *versus* input values (Fig. 5). The graphs allow a visual determination of mixtures for which the crushing strength can be increased without significantly reducing the input value. Mixtures A, E, and B, for which an increase in crushing strength does not correspond to a marked decrease in input values, are easy to handle. For mixtures C and G, the increase of crushing strength corresponds to a concomitant marked reduction of input values, as evidenced by curve slopes. Mixtures F and D show a limiting value of crushing strength above which a little increase causes a large decrease of the input value.

The shape parameter b (Eq. 1) seems to be linked to the disintegration process in the following way:

1. An S-shaped disintegrating force development curve ($b > 1$) indicates the presence of an initial obstacle to water penetration linked to the surface conditions of the tablet.
2. A steeper initial slope in the disintegrating force development curve ($b < 1$) can indicate the presence of an obstacle to water penetration arising inside the tablet.
3. An exponential disintegrating force development curve ($b = 1$) indicates a regular fluid penetration.

The situation relative to $b < 1$ is more critical, since resistence to fluid penetration arising inside the tablet may lead to considerable delay in disintegration, whereas for $b > 1$, the small values of time lag found in the cases examined indicate that the tablet surface conditions do not influence disintegration time too much.

For the mixtures examined, b values depend on compression force and reflect the changes in compact structure. Mixture G shows b values constantly <1, thus enabling the presumption that disintegrator gelatinization enhances the resistance to fluid penetration. Mixtures D, F, B, and E show b values of ~ 1, thus indicating a regular disintegrating force development. Mixtures A and C show the opposite behavior. For the former, b values decrease as compression force increases. This is consistent with the product compression behavior, *i.e.*, starch granules deformed by compression readily absorb water forming a viscosity-increasing gel[3]. For the latter, the poor absorption is likely to be influenced by porosity conditions, thus enhancing the initial hindrance to water penetration. The results obtained indicate that, of the various mixtures examined, A, B, and E show the best overall performances.

CONCLUSIONS

The measurement of disintegrating force provides a deeper insight into the tablet structure obtained by processing a given formula. Whereas a "static" structure evaluation can be obtained through porosity, pore size distribution, *etc.*, disintegrating force measurements allow a "dynamic" evaluation of the structure itself, linked to the disintegration process and consequent active ingredient liberation. The input value, *i.e.*, the disintegrating force development rate at time $t = t_0 + \tau_d$, can be employed as a new parameter for tablet formulation. It is very sensitive to formulation and tablet structure changes and, if correlated with the crushing strength, allows an overall evaluation of the formula examined. The measure of the shape parameter b is a good reflection of the conditions of the compact and completes the structural information on tablet structure. On the basis of the results obtained, it seems justified to propose the measure of the disintegrating force as a very useful and decisive means for formulation evaluation.

Disposition of Ibuprofen in Nephrectomized Dogs

D. S.-L. AU *x, T. H. KUO *, B. MEDERSKI-SAMORAJ ‡, and C. S. LEE *

Received August 26, 1982, from the **Department of Pharmaceutics, College of Pharmacy, University of Houston*, and ‡*Infectious Disease and Clinical Microbiology Program, University of Texas Medical School, Houston, TX 77030.* Accepted for publication March 17, 1983.

Abstract □ The pharmacokinetics of ibuprofen were studied in four nephrectomized and three normal dogs after administration of 214.3–227.6 mg iv of ibuprofen. Blood samples were collected at various time intervals for up to 10 h and serum concentrations of ibuprofen were assayed by an HPLC method. The elimination of serum ibuprofen followed first-order kinetics, with mean half-lives of 2.51 ± 1.10 and 2.81 ± 0.72 h in normal and nephrectomized dogs, respectively. Mean serum clearance of ibuprofen in nephrectomized dogs, 31.0 ± 5.2 mL/h/kg, was higher than that in normal dogs, 12.2 ± 8.6 mL/h/kg, ($p < 0.02$). The difference may be attributed to the greater volume of distribution for ibuprofen in nephrectomized dogs, 125.2 ± 39.0 (88.8–160.4) mL/kg as compared with 53.4 ± 57.8 (26.0–119.9) mL/kg in the normal group ($p < 0.2$).

Keyphrases □ Ibuprofen—disposition in nephrectomized dogs, pharmacokinetics □ Disposition—ibuprofen, nephrectomized dogs, pharmacokinetics □ Pharmacokinetics—disposition of ibuprofen in nephrectomized dogs

Ibuprofen, (±)-2-(*p*-isobutylphenyl)propionic acid (I), is a nonsteroidal anti-inflammatory agent indicated primarily for rheumatic diseases (1). The pharmacokinetics of I have been studied in normal volunteers. The drug is readily absorbed orally, and plasma peak levels are reached within 2 h of administration. The elimination of I from plasma is first order with apparent half-lives of 1.4–2.5 h (2–6). Similar half-lives are observed in arthritic patients, suggestive of no tissue accumulation of I in rheumatic patients (2). Patients with chronic circulatory insufficiency exhibit pharmacokinetic parameter values comparable with those of healthy subjects (7).

The metabolism of I has been studied in humans and several

be obtained by plotting crushing strength *versus* input values (Fig. 5). The graphs allow a visual determination of mixtures for which the crushing strength can be increased without significantly reducing the input value. Mixtures A, E, and B, for which an increase in crushing strength does not correspond to a marked decrease in input values, are easy to handle. For mixtures C and G, the increase of crushing strength corresponds to a concomitant marked reduction of input values, as evidenced by curve slopes. Mixtures F and D show a limiting value of crushing strength above which a little increase causes a large decrease of the input value.

The shape parameter b (Eq. 1) seems to be linked to the disintegration process in the following way:

1. An S-shaped disintegrating force development curve ($b > 1$) indicates the presence of an initial obstacle to water penetration linked to the surface conditions of the tablet.
2. A steeper initial slope in the disintegrating force development curve ($b < 1$) can indicate the presence of an obstacle to water penetration arising inside the tablet.
3. An exponential disintegrating force development curve ($b = 1$) indicates a regular fluid penetration.

The situation relative to $b < 1$ is more critical, since resistence to fluid penetration arising inside the tablet may lead to considerable delay in disintegration, whereas for $b > 1$, the small values of time lag found in the cases examined indicate that the tablet surface conditions do not influence disintegration time too much.

For the mixtures examined, b values depend on compression force and reflect the changes in compact structure. Mixture G shows b values constantly <1, thus enabling the presumption that disintegrator gelatinization enhances the resistance to fluid penetration. Mixtures D, F, B, and E show b values of ~ 1, thus indicating a regular disintegrating force development. Mixtures A and C show the opposite behavior. For the former, b values decrease as compression force increases. This is consistent with the product compression behavior, *i.e.*, starch granules deformed by compression readily absorb water forming a viscosity-increasing gel[3]. For the latter, the poor absorption is likely to be influenced by porosity conditions, thus enhancing the initial hindrance to water penetration. The results obtained indicate that, of the various mixtures examined, A, B, and E show the best overall performances.

CONCLUSIONS

The measurement of disintegrating force provides a deeper insight into the tablet structure obtained by processing a given formula. Whereas a "static" structure evaluation can be obtained through porosity, pore size distribution, *etc.*, disintegrating force measurements allow a "dynamic" evaluation of the structure itself, linked to the disintegration process and consequent active ingredient liberation. The input value, *i.e.*, the disintegrating force development rate at time $t = t_0 + \tau_d$, can be employed as a new parameter for tablet formulation. It is very sensitive to formulation and tablet structure changes and, if correlated with the crushing strength, allows an overall evaluation of the formula examined. The measure of the shape parameter b is a good reflection of the conditions of the compact and completes the structural information on tablet structure. On the basis of the results obtained, it seems justified to propose the measure of the disintegrating force as a very useful and decisive means for formulation evaluation.

Table I—Description of Normal and Nephrectomized Dogs

Dog	Sex	Weight, kg	Physiological Status[a]	Dose, mg iv
1	M	20.0	N	223.5
2	M	18.6	N	227.6
3	F	20.5	N	223.0
4	M	16.0	SN	214.3
5	M	16.8	SN	216.0
6	M	20.6	SN	216.0
7	M	17.4	SN	214.3

[a] Key: (N) normal; (SN) surgically nephrectomized.

animal species, including rats, baboons, and dogs (8, 9). Two major metabolites, the hydroxylated and the carboxylated derivatives of I, were identified in the plasma of the rat, baboon, and human, but not in dog plasma (9, 10). Both metabolites were found in the urine of all four species (9). All species, except the baboon, excreted >50% of the single oral dose in the urine. Of particular interest is the observation in dogs that 46% of the ibuprofen dose appeared in the urine as conjugated and unconjugated metabolites, while no metabolites were detected in plasma, indicating a slow formation but rapid excretion of the metabolites (9). In humans, urinary excretion of I was complete within 24 h following a single oral 200-mg dose (11). In dogs, measurements of total radioactivity in urine and feces accounted for 60% of dose eliminated in 24 h, 80–100% in 3–5 d. The ratio of excreted ibuprofen in urine and feces was on the order of 2:1 (10, 11). In addition, biliary excretion in dogs within 3 h of administration accounted for 25% of a single intravenous dose (9, 10). Ibuprofen (I) is highly bound (~99%) to serum albumin in humans and experimental animals (9). Because of the extensive protein binding, I is characterized by a small volume of distribution, 0.12–0.13 L/kg and 0.18 L/kg in humans (12, 13) and in normal dogs (14), respectively. Half-lives of I ranged from 3 to 3.81 h (14, 15), serum clearance was ~0.5 mL/kg/min (14) in normal dogs.

The pharmacokinetics of I in subjects with renal insufficiency has not yet been reported. Brogard *et al.* (16) recently investigated the pharmacokinetics of benoxaprofen, an analogue of I with a normal half-life of 28 h, and reported a prolonged half-life of up to 69 h in patients with end-stage renal failure. Dosage reduction of benoxaprofen in patients with renal impairment was thus recommended. It is not clear whether I is similarly affected in the renal disease state.

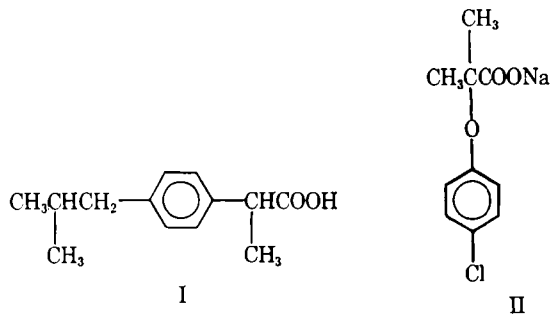
Pharmacokinetic information of I in renal failure is of clinical importance, since a majority of patients with rheumatic arthritis are often the elderly who may be renally insufficient. This study was undertaken to investigate the effect of renal failure in pharmacokinetics of I using a nephrectomized dog model.



EXPERIMENTAL

Materials—Ibuprofen(I) was supplied as free acid[1]. Sodium clofibrate[2] (II) was used as an internal standard for the assay of I. HPLC-grade methanol[3] and acetonitrile[3] were glass-distilled and filtered before use.

Seven beagle dogs, 6 male and 1 female (weighing 16.0–20.6 kg), were used in the study. Specific dog data are shown in Table I. Four dogs were bilaterally nephrectomized, while three normal dogs served as the control. All dogs were catheterized at the radial and jugular veins to facilitate drug administration and blood collection, respectively.

Drug Administration and Sampling Schedule—Doses of I were administered as 5-mL aliquots of a 50% ethanolic solution in normal saline *via* the catheterized radial vein of the forearm. Blood samples, 3–5 mL each, were drawn from a cannula in the jugular vein at 0 (blank), 30, 45, 60, 90, 120, 180, 240, 300, 360, 420, 480, 540, and 600 min following the intravenous administration. Samples were allowed to clot in the evacuated tubes, and sera were collected and stored at −20°C until assayed.

Assay—Serum samples of appropriate size, to which 2 μg of II was added, were acidified with 400 μL of 1 M HCl followed by extraction with 8 mL of ether. The ether extract was separated after centrifugation and evaporated to dryness under a nitrogen stream. The residue was reconstituted in 200 μL of methanol and subjected to HPLC analysis.

A chromatograph[4] equipped with a 100-μL sample loop[5], a variable-wavelength UV detector[6], and a microparticulate reverse-phase octyl column[7] (250 mm × 4.6 mm i.d.) was used for the HPLC analysis. The system was operated at ambient temperature with acetonitrile–water as the mobile phase (50:50, v/v, pH 2.5 as adjusted with phosphoric acid[8]). The flow rate was

SD	0.075	0.72	5.2	39.0

maintained at 2.0 mL/min, and the effluent was measured at 225 nm for absorbance.

Protein Binding Study—Protein binding of I was determined by the equilibrium dialysis method. Serum samples were spiked with known amounts of I to yield concentrations of 5, 10, and 20 μg/mL and incubated at 37°C for 16 h. The spiked samples were dialyzed against isotonic phosphate-saline buffer, consisting of 154 mM NaCl, 0.44 mM KH_2PO_4, and 2.20 mM K_2HPO_4 (pH 7.4) at 37°C for 6 h. After the equilibrium dialysis, the concentrations of I in the serum and the dialysate were measured by the HPLC assay. Dialysate samples were concentrated by lyophilization to raise the concentrations above the detection limit of the assay procedure.

Data Treatment—Serum concentration–time data were fitted to a two-compartment model using the NONLIN program (17). A series of pharmacokinetic parameters were obtained, of which β, the overall elimination rate constant, was further used for area calculation. The area under the concentration–time curve (AUC) was calculated by $AUC_{0\to\infty} = AUC_{0\to t} + C_t/\beta$, where C_t is the last measured serum concentration and $AUC_{0\to t}$ is the area covering the time interval 0 to t, which was calculated by the trapezoidal method. Half-life ($t_{1/2,\beta}$), total clearance (CL_T), and volume of distribution (Vd_β) were subsequently calculated as: $t_{1/2,\beta} = 0.693/\beta$, CL_T = Dose/$AUC_{0\to\infty}$, and $Vd_\beta = CL_T/\beta$. The significance of difference in mean parameter values between normal and nephrectomized groups, including $t_{1/2,\beta}$, CL_T, and Vd_β, were tested by a nonpaired Student's t test.

RESULTS AND DISCUSSION

The HPLC procedures described herein provided adequate sensitivity and good reproducibility for the analysis of I. Figure 1 depicts typical chromatograms, in which I and II exhibited retention times of 7.0 and 4.0 min, respectively. Baseline resolution was achieved without interference of endogenous substances from the blank dog serum. The typical calibration curve, constructed at a concentration range of 0.5–10 μg/mL, yielded a linearity of $y = 0.311x - 0.045$, $r^2 = 0.999$. The mean coefficient of variation was 3.7 ± 1.4% (n = 5), indicating a satisfactory reproducibility of the assay procedure.

[a] Dog 7. [b] Dog 3. [c] n = 3.

Serum concentration profiles for I are shown in Figs. 2 and 3 for normal and nephrectomized dogs, respectively. First-order elimination of I was apparent in all dogs following the single-dose intravenous drug administration. The pharmacokinetic parameters of I in normal and nephrectomized dogs are reported in Tables II and III, respectively. The mean half-life was 2.51 ± 1.10 h for the normal group and 2.81 ± 0.72 h for the nephrectomized group; the difference was not significant ($p > 0.6$). The total clearance of I in nephrectomized dogs ranged from 23.6 to 34.5 mL/h/kg (mean, 31.0 ± 5.2 mL/h/kg), and that in normal dogs averaged 12.2 ± 8.6 mL/h/kg (range, 5.9–22.1 mL/h/kg). Nephrectomized dogs exhibited significantly higher total clearance than normal dogs ($p < 0.02$). The volume of distribution in nephrectomized dogs, 125.2 ± 39.0 mL/kg, was slightly greater than that in normal dogs, 53.4 ± 57.8 mL/kg; the difference was marginally significant ($p < 0.2$). Wide within-group variations were observed for total clearance and volume of distribution in dogs, indicating intersubject variability in the disposition of I.

Half-lives of I in normal dogs, 2.51 ± 1.10 h, as obtained in this study, were comparable with those reported by Kearns and Wilson, 3.81 h (14), and by Fujise, 3 h (15). The total clearance (12.2 ± 8.6 mL/h/kg) and the volume of distribution (53.4 ± 57.8 mL/kg), however, were smaller than the corresponding literature values, 30.1 mL/h/kg and 180 mL/kg (14). It should be

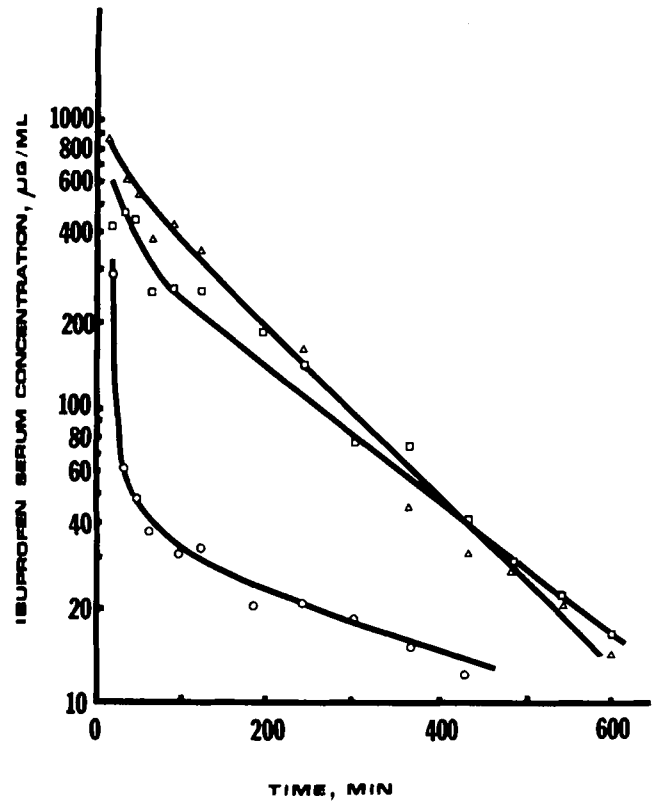

Figure 2—*Time profile of serum concentrations of I in normal dogs. Key: (○) dog 1; (□) dog 2; (△) dog 3.*

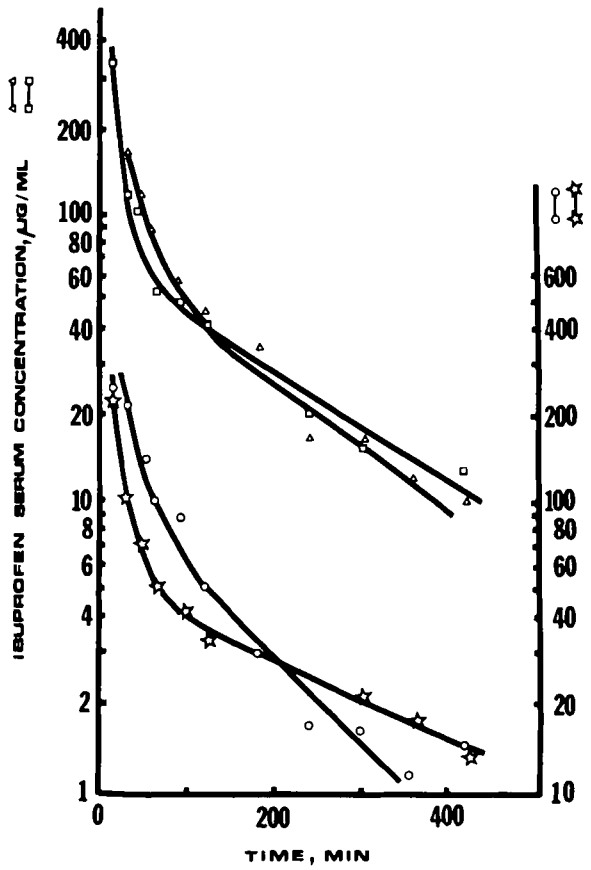

Figure 3—*Time profile of serum concentrations of I in nephrectomized dogs. Key: (○) dog 4; (△) dog 5; (□) dog 6; (☆) dog 7.*

noted that the parameter values reported by Kearns and Wilson were derived from a one-dog study.

No literature information regarding the pharmacokinetics of I in nephrectomized dogs is available. In this study, serum concentrations of I in nephrectomized dogs were lower than the corresponding concentrations in the normal ones. This observation suggests a greater volume of distribution for the nephrectomized dogs, which could be attributable to a reduced protein binding of I in the nephrectomized state. Reduced binding of highly bound organic acid to uremic plasma protein has been demonstrated for phenytoin, resulting in an increased volume of distribution (18). A similar mechanism may be suggested for I, which is also an organic acid with extensive protein binding (9). The reduction in binding of I to serum protein on nephrectomy is shown in Table IV for two dogs, one normal and the other nephrectomized. The protein binding was independent of concentration in the range of 5–20 μg/mL. The percentage of I unbound to serum protein in the nephrectomized dog, 6.8 ± 1.0%, was significantly greater than that in the normal dog, 1.3 ± 0.3% ($p < 0.001$). In a separate binding study of I in uremic patients (19), the fraction of free I in uremic plasma was also found to be higher than that in normal plasma (Table IV). The dogs used for this investigation were nephrectomized 3 d prior to the study and presumably were approaching the chronic uremic state.

Nephrectomy did not significantly alter the half-life of I in dogs; however, increases in both the volume of distribution and total clearance were apparent. Since <8% of the dose is excreted intact in the urine (9, 20), the lack of effect of nephrectomy on the half-life of I was anticipated. Nephrectomy induced increases in the total clearance and volume of distribution. The increased volume of distribution could result from a decreased protein binding of I in the nephrectomized state (Table IV), leaving more free drug available for distribution into the body tissue. The increase in total clearance is secondary to the increase in volume of distribution.

The effects of renal failure on the disposition of I in dogs and those of benoxaprofen in humans (16) are disparate. In dogs, the half-life of I remained unchanged, whereas the volume of distribution and total clearance increased. In humans the half-life of benoxaprofen was significantly prolonged with no distinct changes in other pharmacokinetic parameters. The disparity cautions against the extrapolation of conclusions from one drug analogue to another and from animal model to human subject.

Dynamic Method for Estimating the Extent of Plasma Protein Binding in a Dialysis Experiment

Keyphrases □ Plasma protein binding—dialysis, experimental time □ Dialysis—plasma protein binding, experimental time

To the Editor:

In a protein binding experiment one has a choice between two initial conditions: to place the drug in the plasma or in the buffer. Recent analyses (1, 2) of a linear system with a constant extent of plasma protein have revealed that it takes less time for the buffer drug concentration to reach a given limit of the equilibrium value when the drug is initially placed in the plasma rather than the buffer. This conclusion is also valid for a nonlinear system in which the number of binding sites is finite (3).

Despite the advantage of placing the drug initially in the plasma, a long experimental time may still be needed if permeation of the drug through the dialysis membrane is slow. This may cause some difficulties particularly in maintaining a constant volume in both compartments. In this report, a simple strategy is proposed to shorten the experimental time. The strategy requires two experiments: one with the drug initially placed in the buffer and the other with the drug initially placed in the plasma. The equilibrium value is derived from buffer drug concentrations measured at any given time during these two experiments. Experimental error notwithstanding, the estimate is exact provided the extent of protein binding is constant over the concentration range studied. The errors in applying the proposed method to a nonlinear situation are also considered. This is demonstrated by applying the method to a set of data simulated according to a model with saturable protein binding.

In the following discussion, we consider a dialysis experiment using a membrane with a mass transfer coefficient, M. The mass transfer coefficient is the product of the membrane permeability and the surface area. It has a dimension of volume per unit time. The volumes of the buffer in compartment 1 and the plasma in compartment 2 are V_1 and V_2, respectively. It is assumed that there is no material loss from the solution system and that there are no volume changes in either com-

noted that the parameter values reported by Kearns and Wilson were derived from a one-dog study.

No literature information regarding the pharmacokinetics of I in nephrectomized dogs is available. In this study, serum concentrations of I in nephrectomized dogs were lower than the corresponding concentrations in the normal ones. This observation suggests a greater volume of distribution for the nephrectomized dogs, which could be attributable to a reduced protein binding of I in the nephrectomized state. Reduced binding of highly bound organic acid to uremic plasma protein has been demonstrated for phenytoin, resulting in an increased volume of distribution (18). A similar mechanism may be suggested for I, which is also an organic acid with extensive protein binding (9). The reduction in binding of I to serum protein on nephrectomy is shown in Table IV for two dogs, one normal and the other nephrectomized. The protein binding was independent of concentration in the range of 5–20 μg/mL. The percentage of I unbound to serum protein in the nephrectomized dog, 6.8 ± 1.0%, was significantly greater than that in the normal dog, 1.3 ± 0.3% ($p < 0.001$). In a separate binding study of I in uremic patients (19), the fraction of free I in uremic plasma was also found to be higher than that in normal plasma (Table IV). The dogs used for this investigation were nephrectomized 3 d prior to the study and presumably were approaching the chronic uremic state.

Nephrectomy did not significantly alter the half-life of I in dogs; however, increases in both the volume of distribution and total clearance were apparent. Since <8% of the dose is excreted intact in the urine (9, 20), the lack of effect of nephrectomy on the half-life of I was anticipated. Nephrectomy induced increases in the total clearance and volume of distribution. The increased volume of distribution could result from a decreased protein binding of I in the nephrectomized state (Table IV), leaving more free drug available for distribution into the body tissue. The increase in total clearance is secondary to the increase in volume of distribution.

The effects of renal failure on the disposition of I in dogs and those of benoxaprofen in humans (16) are disparate. In dogs, the half-life of I remained unchanged, whereas the volume of distribution and total clearance increased. In humans the half-life of benoxaprofen was significantly prolonged with no distinct changes in other pharmacokinetic parameters. The disparity cautions against the extrapolation of conclusions from one drug analogue to another and from animal model to human subject.

Dynamic Method for Estimating the Extent of Plasma Protein Binding in a Dialysis Experiment

Keyphrases □ Plasma protein binding—dialysis, experimental time □ Dialysis—plasma protein binding, experimental time

To the Editor:

In a protein binding experiment one has a choice between two initial conditions: to place the drug in the plasma or in the buffer. Recent analyses (1, 2) of a linear system with a constant extent of plasma protein have revealed that it takes less time for the buffer drug concentration to reach a given limit of the equilibrium value when the drug is initially placed in the plasma rather than the buffer. This conclusion is also valid for a nonlinear system in which the number of binding sites is finite (3).

Despite the advantage of placing the drug initially in the plasma, a long experimental time may still be needed if permeation of the drug through the dialysis membrane is slow. This may cause some difficulties particularly in maintaining a constant volume in both compartments. In this report, a simple strategy is proposed to shorten the experimental time. The strategy requires two experiments: one with the drug initially placed in the buffer and the other with the drug initially placed in the plasma. The equilibrium value is derived from buffer drug concentrations measured at any given time during these two experiments. Experimental error notwithstanding, the estimate is exact provided the extent of protein binding is constant over the concentration range studied. The errors in applying the proposed method to a nonlinear situation are also considered. This is demonstrated by applying the method to a set of data simulated according to a model with saturable protein binding.

In the following discussion, we consider a dialysis experiment using a membrane with a mass transfer coefficient, M. The mass transfer coefficient is the product of the membrane permeability and the surface area. It has a dimension of volume per unit time. The volumes of the buffer in compartment 1 and the plasma in compartment 2 are V_1 and V_2, respectively. It is assumed that there is no material loss from the solution system and that there are no volume changes in either com-

0022-3549/84/0500-0708$01.00/0

partment. Furthermore, it is assumed that the free and bound drug are in equilibrium at all times and the binding is linear such that the free fraction of the drug in the plasma is a constant, α.

The proposed approach consists of two experiments: (*a*) a given amount of drug, A_0, is initially added to the plasma compartment; (*b*) the same amount is added to the buffer compartment. When the drug is initially added to the plasma, the total plasma drug concentration is A_0/V_2, and the buffer drug concentration is zero at time zero. The buffer drug concentration at any time, t, is given as:

$$C_P(t) = C_E[1 - e^{-(1/V_1+\alpha/V_2)Mt}] \qquad \text{(Eq. 1)}$$

where subscript P is used to indicate that drug is initially added to the plasma. C_E is the buffer concentration at equilibrium and is given as:

$$C_E = \frac{A_0}{V_1 + V_2/\alpha} \qquad \text{(Eq. 2)}$$

When drug is initially added to the buffer, its concentration is $C_0 = A_0/V_1$ and the plasma concentration is zero at $t = 0$. The drug concentration in the buffer at any time t is given as:

$$C_B(t) = C_E + (C_0 - C_E)e^{-(1/V_1+\alpha/V_2)Mt} \qquad \text{(Eq. 3)}$$

where subscript B is used to indicate that all the drug is initially placed in the buffer and C_E is defined by Eq. 2.

If both C_B and C_P are measured at time t (>0), one can calculate the expected equilibrium concentration by the following expression:

$$C_E = \frac{C_0 \cdot C_P(t)}{C_0 + C_P(t) - C_B(t)} \qquad \text{(Eq. 4)}$$

Equation 4 is derived by simply combining Eqs. 1 and 3.

When the amounts of drug used for these two experiments are not identical, Eq. 4 can still be used with proper correction, because of the linearity of the system. For example, if the initial amount placed in the plasma is A'_0 instead of A_0, and the measured buffer concentration at time t is $C'_P(t)$, the corresponding buffer concentration $C_P(t)$ for an initial amount A_0 in the plasma is:

$$C_P(t) = C'_P(t) \cdot A_0/A'_0 \qquad \text{(Eq. 5)}$$

The adjusted concentration $C_P(t)$ can then be used in Eq. 4 to obtain the equilibrium concentration. Thus, Eq. 4 is a useful expression for calculating the equilibrium concentration in protein binding experiments when the free fraction remains constant over the drug concentration range studied. The basic assumptions of mass conservation and no volume shift within the time frame of the experiment should be independently verified before the application of this expression.

In the following discussion, we will consider the application of this method to situations of nonlinear binding. As an example, we consider a dialysis experiment with unit volume of plasma and buffer. The mass transfer coefficient of the dialysis membrane is 1 volume unit/unit time. There is protein in compartment 2 only. The amount of binding sites, B, in compartment 2 is 100. The dissociation constant, K, is 0.01. The differential equations governing this system are given below:

$$V_1 \frac{dC_1}{dt} = -M(C_1 - C_2) \qquad \text{(Eq. 6)}$$

$$V_2\left[1 + \frac{B \cdot K/V_2}{(K + C_2)^2}\right]\frac{dC_2}{dt} = M(C_1 - C_2) \qquad \text{(Eq. 7)}$$

where C_1 and C_2 are free drug concentrations in compartments 1 and 2, respectively. These equations are numerically solved (4) to generate C_P and C_B at $t = 0.693$ and 1.386 for different initial concentrations. The equilibrium value is then estimated from C_P and C_B using Eq. 4. The percent error of this estimate is defined as the absolute value of the difference between the estimation by Eq. 4 and the theoretical value divided by the theoretical value and multiplied by 100. The theoretical equilibrium concentration for a given initial amount of drug A_0 is:

$$C_E = \frac{-[(V_1 + V_2)K + B - A_0] + \{[(V_1 + V_2)K + B - A_0]^2 + 4A_0K(V_1 + V_2)\}^{1/2}}{2(V_1 + V_2)} \qquad \text{(Eq. 8)}$$

The error is graphically presented as a function of initial amount in Fig. 1. The errors are very small when the initial amount is small. The error starts to increase precipitously when the initial amount exceeds 90. The error peaks between 100 and 110 and eventually drops back to zero when the initial amount becomes very large. The data also indicate a significant decrease in error as the experiment is prolonged.

In addition to the errors in the equilibrium concentrations obtained using Eq. 4, the errors obtained by assuming that the buffer concentrations $C_P(t)$ (drug initially added to plasma) are estimates of the equilibrium concentrations are also presented in Fig. 1. It can be seen that a better estimate of C_E is obtained by $C_P(t)$ alone rather than by application of Eq. 4 in a region (initial amount 100–140) where nonlinear kinetics is expected to prevail. The example serves to point the dangers of the indiscriminate use of Eq. 4 in the nonlinear region.

The errors which result at both low and high initial amounts (relative to $B = 100$) can be appreciated by reference to Eq. 1. Since α, the free fraction in plasma, will vary from $\sim K/B$

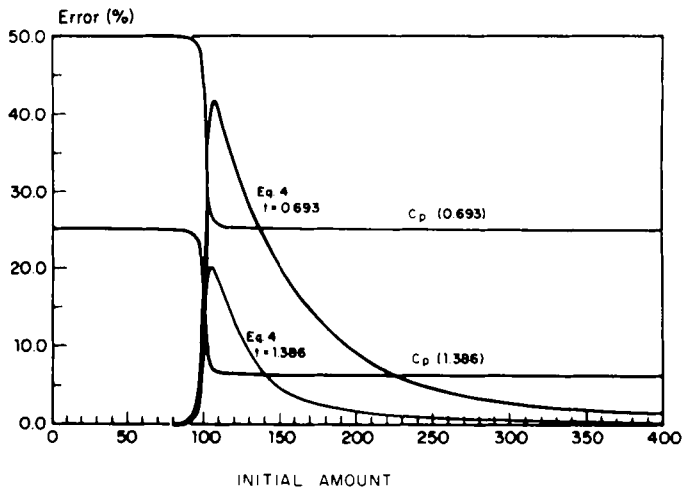

Figure 1—*Errors of estimating the equilibrium value by C_P and Eq. 4 at indicated sampling time plotted as a function of the initial amounts.*

($K \ll B$) at low initial amounts to 1 at high initial amounts, the exponent in Eq. 1 (the reciprocal of the time constant) will vary from M/V to $M/2V$ in those cases where $V_1 = V_2$. For the example considered, where the volumes are unity, the respective time constants are 1 and 0.05, and the respective half-lives are 0.693 and 0.693/2. At low initial amounts, C_P is ~0.5 C_E and 0.75 C_E at the times 0.693 and 0.693 × 2, respectively. The corresponding errors as previously defined would be 50 and 25%. At high initial amounts, C_P is ~0.75 C_E and 0.9375 C_E ($1 - 0.5^4$) C_E at the times 0.693 and 0.693 × 2, respectively. The corresponding errors are 25 and 6.25%.

A criterion for deciding whether Eq. 4 is applicable is easily established by using the equation with a few concentrations paired in time from the two experiments. Since the equilibrium concentration is time independent, the values calculated by concentrations obtained at different times should be in agreement within experimental error. Having established linearity, the free fraction α can be evaluated using Eq. 2.

Nonlinear kinetics should be suspected when a lack of consistency in the estimated equilibrium concentrations is manifested. In principle, the estimated equilibrium values calculated using Eq. 4 converge to the true equilibrium value when evaluated with concentrations obtained at later times (note how relative error changes as function of time in the nonlinear region in Fig. 1). Under such circumstances, Eq. 4 should not be employed.

Influence of Protein Binding on the Accumulation and Depletion of Drug from the Skin

Keyphrases □ Protein binding--accumulation and depletion of drug from skin

To the Editor:

Recently the drug scopolamine has been shown to exhibit a nonlinear sorption isotherm with skin (1). The binding was deduced to be associated with the proteinaceous phase since the sorption isotherm was not significantly changed by removal of lipids (1). For drugs that bind in a saturable fashion to skin, the binding can have dramatic effects on the transport process as manifested by an increase in the diffusional lag time with a decrease in the upstream concentration (2). To elucidate the effect of reversible binding, describable by the law of mass action, on the accumulation and depletion of drug from the skin, a simple model will be considered. A fixed volume of skin will be considered to be well-stirred such that within the skin there are no gradients of free drug normal to the surface. The clearance per unit surface area of free drug from this volume is equivalent to the permeability of the drug through the skin. Sink conditions are assumed to exist, and the product of the free concentration and clearance represents the mass rate input into the body. Analysis of the simple model rather than the transport model characterized by a nonlinear diffusion equation suffices to bring forth the influence of the saturable, reversible binding on the accumulation and depletion of drug in the skin.

The dynamics of the accumulation and depletion of drug will individually be investigated as a function of the steady-state concentration in the skin. The dynamics will then be compared between the two modes at given steady-state concentrations. During the accumulation mode, steady-state concentrations will be envisioned to be established by constant fluxes applied to the skin. Upon removal of the input, the steady-state concentrations become the initial concentrations for the depletion mode. The use of the nonlinear binding to achieved prolonged delivery to the body in the depletion mode and methods to shorten accumulation rates relative to depletion rates are then discussed.

The nonlinear system will exhibit linear behavior when the binding isotherm is in the linear region or the fraction of bound drug becomes very small. Thus, a linear system serves as an extrapolative extreme for the nonlinear system. In the linear system the accumulation of drug within the skin is given by the following equation:

$$C = C_{ss}(1 - e^{-k_{el}t}) \qquad \text{(Eq. 1)}$$

$$C_{ss} = \frac{J \cdot A}{CL}$$

where C is the concentration in the skin during accumulation, C_{ss} is the steady-state concentration, J is the flux applied to the skin, A is the area to which the flux is applied, k_{el} is the elimination rate constant from the skin, CL is the clearance from the skin, and t is time. The depletion of drug from the skin once steady state has been achieved and the input removed is given by:

$$C = C_{ss}e^{-k_{el}t} \qquad \text{(Eq. 2)}$$

where C is the concentration during depletion. In Eq. 2 t is relative to the time depletion commences. The accumulation and depletion curves are symmetrical around $C = 0.5\ C_{ss}$. The symmetry of the curves is maintained regardless of the magnitude of the elimination rate constant. The time to reach 50% of the steady-state concentration in the accumulation mode and the time to fall to 50% of the steady-state concentration in the depletion mode are equal. The equality becomes apparent when the equations are rearranged to express time explicitly as a function of the ratio of the concentration at time t to the steady-state concentration. Equations 3 and 4 correspond to Eqs. 1 and 2, respectively.

$$t = (1/k_{el}) \ln \frac{1}{1 - C/C_{ss}} \qquad \text{(Eq. 3)}$$

and

$$t = (1/k_{el}) \ln \frac{C_{ss}}{C} \qquad \text{(Eq. 4)}$$

Thus, from either Eq. 3 or 4, the time at which $C/C_{ss} = 0.5$ (hereafter called t_{50}), is $(1/k_{el}) \ln 2$.

($K \ll B$) at low initial amounts to 1 at high initial amounts, the exponent in Eq. 1 (the reciprocal of the time constant) will vary from M/V to $M/2V$ in those cases where $V_1 = V_2$. For the example considered, where the volumes are unity, the respective time constants are 1 and 0.05, and the respective half-lives are 0.693 and 0.693/2. At low initial amounts, C_P is ~0.5 C_E and 0.75 C_E at the times 0.693 and 0.693 × 2, respectively. The corresponding errors as previously defined would be 50 and 25%. At high initial amounts, C_P is ~0.75 C_E and 0.9375 C_E ($1 - 0.5^4$) C_E at the times 0.693 and 0.693 × 2, respectively. The corresponding errors are 25 and 6.25%.

A criterion for deciding whether Eq. 4 is applicable is easily established by using the equation with a few concentrations paired in time from the two experiments. Since the equilibrium concentration is time independent, the values calculated by concentrations obtained at different times should be in agreement within experimental error. Having established linearity, the free fraction α can be evaluated using Eq. 2.

Nonlinear kinetics should be suspected when a lack of consistency in the estimated equilibrium concentrations is manifested. In principle, the estimated equilibrium values calculated using Eq. 4 converge to the true equilibrium value when evaluated with concentrations obtained at later times (note how relative error changes as function of time in the nonlinear region in Fig. 1). Under such circumstances, Eq. 4 should not be employed.

Influence of Protein Binding on the Accumulation and Depletion of Drug from the Skin

Keyphrases □ Protein binding--accumulation and depletion of drug from skin

To the Editor:

Recently the drug scopolamine has been shown to exhibit a nonlinear sorption isotherm with skin (1). The binding was deduced to be associated with the proteinaceous phase since the sorption isotherm was not significantly changed by removal of lipids (1). For drugs that bind in a saturable fashion to skin, the binding can have dramatic effects on the transport process as manifested by an increase in the diffusional lag time with a decrease in the upstream concentration (2). To elucidate the effect of reversible binding, describable by the law of mass action, on the accumulation and depletion of drug from the skin, a simple model will be considered. A fixed volume of skin will be considered to be well-stirred such that within the skin there are no gradients of free drug normal to the surface. The clearance per unit surface area of free drug from this volume is equivalent to the permeability of the drug through the skin. Sink conditions are assumed to exist, and the product of the free concentration and clearance represents the mass rate input into the body. Analysis of the simple model rather than the transport model characterized by a nonlinear diffusion equation suffices to bring forth the influence of the saturable, reversible binding on the accumulation and depletion of drug in the skin.

The dynamics of the accumulation and depletion of drug will individually be investigated as a function of the steady-state concentration in the skin. The dynamics will then be compared between the two modes at given steady-state concentrations. During the accumulation mode, steady-state concentrations will be envisioned to be established by constant fluxes applied to the skin. Upon removal of the input, the steady-state concentrations become the initial concentrations for the depletion mode. The use of the nonlinear binding to achieved prolonged delivery to the body in the depletion mode and methods to shorten accumulation rates relative to depletion rates are then discussed.

The nonlinear system will exhibit linear behavior when the binding isotherm is in the linear region or the fraction of bound drug becomes very small. Thus, a linear system serves as an extrapolative extreme for the nonlinear system. In the linear system the accumulation of drug within the skin is given by the following equation:

$$C = C_{ss}(1 - e^{-k_{el}t}) \qquad \text{(Eq. 1)}$$

$$C_{ss} = \frac{J \cdot A}{CL}$$

where C is the concentration in the skin during accumulation, C_{ss} is the steady-state concentration, J is the flux applied to the skin, A is the area to which the flux is applied, k_{el} is the elimination rate constant from the skin, CL is the clearance from the skin, and t is time. The depletion of drug from the skin once steady state has been achieved and the input removed is given by:

$$C = C_{ss}e^{-k_{el}t} \qquad \text{(Eq. 2)}$$

where C is the concentration during depletion. In Eq. 2 t is relative to the time depletion commences. The accumulation and depletion curves are symmetrical around $C = 0.5\ C_{ss}$. The symmetry of the curves is maintained regardless of the magnitude of the elimination rate constant. The time to reach 50% of the steady-state concentration in the accumulation mode and the time to fall to 50% of the steady-state concentration in the depletion mode are equal. The equality becomes apparent when the equations are rearranged to express time explicitly as a function of the ratio of the concentration at time t to the steady-state concentration. Equations 3 and 4 correspond to Eqs. 1 and 2, respectively.

$$t = (1/k_{el}) \ln \frac{1}{1 - C/C_{ss}} \qquad \text{(Eq. 3)}$$

and

$$t = (1/k_{el}) \ln \frac{C_{ss}}{C} \qquad \text{(Eq. 4)}$$

Thus, from either Eq. 3 or 4, the time at which $C/C_{ss} = 0.5$ (hereafter called t_{50}), is $(1/k_{el}) \ln 2$.

© 1984, American Pharmaceutical Association

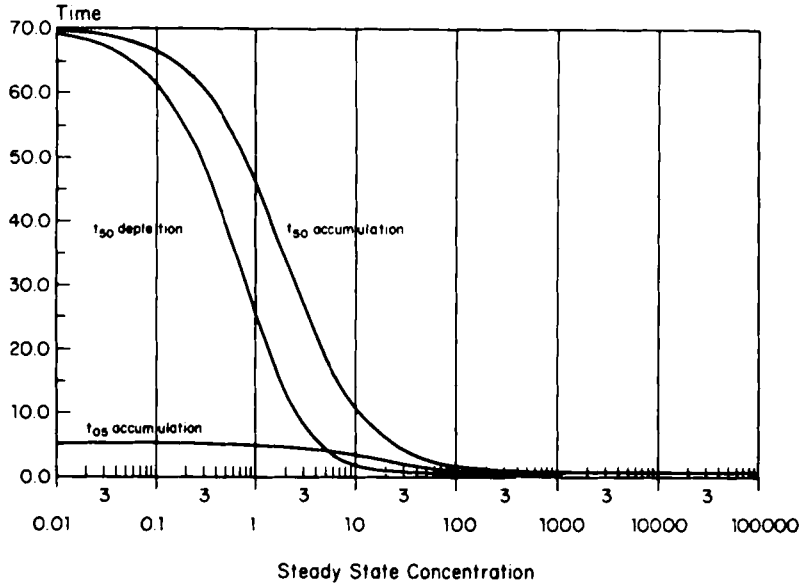

Figure 1—t_{50} *for accumulation and depletion, and* t_{05} *for accumulation,* versus, *the steady-state concentration or normalized flux* (k_{el} = *1*, B = *100*, K = *1*).

The equations representing the accumulation and depletion in the nonlinear system have been solved in closed form (3). The nonlinear differential equations for both modes are integrable and yield implicit solutions of the concentration as a function of time. The equation for the accumulation mode is:

$$\left[\frac{BK}{(K+C_{ss})^2}+1\right]\ln\frac{1}{1-C/C_{ss}} + \frac{BK}{(K+C_{ss})^2}\ln\frac{K+C}{K}+\frac{B}{K+C_{ss}}\cdot\frac{C}{K+C}=k_{el}t \quad \text{(Eq. 5)}$$

where C is the concentration of free drug in the skin at time t, C_{ss} is the steady-state concentration, K is the dissociation constant of the drug protein complex, B is the equivalent concentration of binding sites, and k_{el} is the elimination rate constant.

The equation for the depletion mode is:

$$\left(\frac{B}{K}+1\right)\ln\frac{C_{ss}}{C}+\frac{B}{K}\ln\frac{K+C}{K+C_{ss}}+\frac{B(C-C_{ss})}{(K+C_{ss})(K+C)}=k_{el}t \quad \text{(Eq. 6)}$$

The t_{50} of the steady-state concentration in both the accumulation and depletion modes was evaluated as a function of the steady-state concentration for a nonlinear system where $B = 100$, $K = 1$, and $k_{el} = 1$. The steady-state concentration can be achieved through a constant mass delivery to a defined area of skin. The results of the analysis are presented in Fig. 1. Since the elimination rate constant from the skin is unity, the abscissa for Fig. 1 can be viewed as the flux per unit thickness of skin. Considering the abscissa to represent a flux-like term will be particularly useful when discussing the accumulation mode.

Examination of Fig. 1 reveals that t_{50} for the accumulation mode is always greater than that for the depletion mode except at the extremes in steady-state concentration. At either extreme (high- or low-steady-state concentration) t_{50} for both the accumulation and depletion modes converge, and the common values become independent of the steady-state concentration. At low-steady-state concentrations the binding remains in the linear region throughout the accumulation to and depletion from these upper bounds (steady-state concentrations). At high steady-state concentrations the bound fraction becomes small relative to these steady-state concentrations and the system assumes a linear character. When the free concentrations are in the nonlinear region of protein binding for a significant period of time in either mode relative to the time used to characterize the system, *e.g.*, t_{50}, an asymmetry will be manifested in these times.

The independence of t_{50} from the steady-state concentration, exhibited at the extremes in Fig. 1, is a manifestation of linearity. Note that the time in either Eq. 3 or 4 is a function of C/C_{ss}. In contrast the nonlinear equations (Eqs. 5 and 6) cannot be rearranged to eliminate an explicit dependence of t_{50} on C_{ss}.

The larger value of t_{50} at the low concentration, linear limit compared with the high concentration, linear limit is a manifestation of an apparent volume increase due to the protein binding. Since the clearance from a fixed area of skin is constant, t_{50} will increase as the volume increases. The apparent volume of distribution at the low concentration linear limit relative to the volume at the high concentration linear limit is $(1 + B/K)$. Thus, the apparent 100-fold expansion in volume at the low concentration, linear limit becomes reflected in a corresponding increase in t_{50} at this limit relative to the high concentration, linear limit.

In the nonlinear region between the linear extremes, t_{50} increases monotonically as the steady-state concentration decreases for both the accumulation and depletion modes. The lower the initial concentration, the longer the free concentrations will remain above 50% of the initial concentration (steady-state concentration) in the depletion mode. The depletion of the drug in the skin as measured by the decline in the free concentrations is buffered by the drug–protein interaction. The buffering effect is greater with low concentrations, since under these conditions a larger fraction of the drug will be bound.

Since the steady-state free concentration is proportional to the flux, low initial concentrations can be achieved with low fluxes. To achieve the same mass rate input into the body at steady state, and the same amount of free drug in the skin at the initiation of the depletion mode, a reduction in the flux must be compensated for by an increase in the area. Thus, after removal of the input to the skin, the mass rate input to the body declines from a common value but more slowly with the lower

initial concentration. The extra mass required to prolong delivery to the body is provided for by the larger amount of bound drug in the skin in cases where low initial concentrations and appropriately adjusted areas are used to obtain the same initial amount of free drug.

On the other hand, t_{50} for the accumulation mode is always greater than or equal to that for the depletion mode. Thus, in achieving prolongation to the body by reducing the steady-state concentration a price is paid in terms of an increase in t_{50} for accumulation. The protraction in time required to reach steady state with the reduced flux can be circumvented by first delivering drug to the skin at a high flux for a short duration. After application of the pulse to promote the rapid attainment of the desired free concentration, the mass delivery rate to the body can easily be maintained. For the simple model, the system will be in steady-state instantly if the second flux (maintenance flux) is initiated at a concentration that is its steady-state concentration.

The effect of a pulse, which has a flux 10-fold higher than the maintenance flux, can be elucidated by comparing t_{05}, the time to reach 5% of the steady-state value for the pulse, with t_{50} for the maintenance flux. Since the higher flux establishes a proportionally higher steady state concentration, 50% of the steady-state concentration generated with a given flux and 5% of the steady-state concentration generated with a flux 10-fold higher are the same concentration. The curve representing the relationship between the t_{05} values and the steady-state concentration is presented in Fig. 1. In comparing the difference between t_{50} and t_{05} in Fig. 1, the comparison should be made with t_{05} values at steady-state concentrations 10-fold higher than those for corresponding t_{50} values. The difference increases as the steady-state concentration decreases, reaching the maximum value at the low flux, linear limit. Both t_{05} and t_{50} will become independent of the flux at the limit. The large apparent volume of distribution at this limit causes a magnification of the time constant, t_{50}, t_{05}, and the time differences.

A comparison of the t_{05} values for accumulation with the t_{50} values for depletion, where the flux is 10-fold higher for the former compared with the latter values, indicates the effect of the pulse on the dynamics of accumulation relative to depletion. The t_{05} values are generally less than the t_{50} values for depletion. The pulse reduces the accumulation time such that it is now less than the depletion time; without the pulse the accumulation time is always greater than or equal to the depletion time. Thus, with the use of a pulse followed by a reduced flux, the rapid attainment of steady state, low free concentrations, and prolonged delivery to the body after removal of the input are all achievable.

In principle there is maximum flux on the upper limit of the flux which the skin can accept, hereafter called the maximum flux. The maximum flux is achieved when the penetrant is at unit thermodynamic activity on the skin surface. Conceivably there are circumstances under which the maximum flux should be employed; for instance, if the minimum area of coverage and/or the most rapid termination is desired. The bend (region of nonlinearity) in the free concentration *versus* time curve for the simple nonlinear model occurs at concentrations in the vicinity of dissociation constant and is independent of the initial concentration (4). Therefore, a larger fraction of the drug can be removed from the skin in a given period of time the larger the initial concentration. In a linear system, the same fraction would be removed in a given period of time regardless of the initial concentration.

Using the maximum flux to achieve the highest steady-state concentration in the skin fixes the accumulation time t_{50}. The use of a two-pulse sequence where the flux of the first pulse exceeds the maximum flux is not possible. Although the accumulation time could be shortened by applying the maximum flux to a larger area of skin for a defined period and then reducing the flux, considerations of minimum coverage and/or rapid termination would be compromised.

In conclusion, transdermal input should be designed with a consideration of the influence of protein binding on the transport process. Because of the protein binding, the accumulation and depletion times, defined on the basis of the times to reach or decline to a given fraction of the steady-state concentration, respectively, are not independent of the steady-state concentration. Thus, the dynamics will vary for cases where different fluxes and corresponding changes in area are used to obtain the same total mass input rate. In addition, protein binding creates an inherent assymmetry in the dynamics of the accumulation and depletion modes.

"Coming of Age" for Device Technology

Medically related hoaxes and quackery have been with us for many, many years. The American Medical Association's principal activity during the late 19th century and early 20th century was to expose and debunk such phoney remedies and their fraudulent promoters. Subsequently, after the predecessor to the present-day U.S. Food and Drug Administration was established in 1906, that federal agency assumed national leadership for monitoring the promotion of devices and gadgets claimed to have therapeutic properties or diagnostic value. Other groups—including the American Pharmaceutical Association in particular—provided strong support to these efforts, as well as conducting their own educational programs and professional projects.

Copper bracelets for arthritis sufferers probably have been the most common and well-known hoax, but there have been hundreds and perhaps even thousands of others. The FDA had a museum—a so-called "Chamber of Horrors"—in which its collection of the more unusual and ingenious such items had been exhibited. The agency made wide use of that exhibit in conjunction with its educational campaigns to warn the general public about the uselessness—and, in some cases, even the potential hazard—of such devices.

Those of us educated in the sciences, and especially in the medical and pharmaceutical sciences, recognize the lack of any plausible scientific basis for expecting these devices to have any curative value. But to the average lay person, who is at best only casually schooled in the sciences, the claims appear to be within the realm of possibility. And when one is desperate for a cure—due to the absence of other proven remedies, coupled with pain or a fatal prognosis—that person is quite receptive to the pitch of a medical charlatan.

For years, the FDA has so relentlessly pursued this activity, so dramatically exposed the devices as fraudulent, so widely publicized their worthlessness, and so vigorously prosecuted those people who promoted them, that one might reasonably question whether the agency has been able to adequately retain its objectivity in the matter. In other words, if some seemingly exotic device or treatment came along that did indeed do what was claimed for it, would the FDA be able to recognize its worth, and publicly acknowledge its usefulness? The krebiozen and laetrile episodes were fueled by just such doubts on the part of the public and some of the medical community.

Well, in our view, any such question can now be put to rest.

We recently saw the April issue of the *FDA Consumer*—which is the Agency's magazine for lay readers.

The lead article was entitled "Sealing Teeth to Prevent Cavities." And rather than expose the procedure as a hoax, or even as a well-intended but worthless effort by dentists to protect against the ravages of caries, the article gave a ringing endorsement to the procedure! The FDA staff writer explained in easy-to-understand language the susceptibility of tooth fissures to dental decay, the theory behind the sealants, how they are applied, their relative safety, and the clinical test results recorded for them. The general message of the article can best be conveyed by the writer's own abstract-summary: "*A group of experts recently agreed that sealants can be effective in protecting teeth of youngsters, particularly those teeth that are pitted and have fissures.*" The article itself stated that "*the occurrence of pit and fissure cavities was reduced by approximately 95 percent at the end of one year and at least 50 percent at the end of five years.*"

Then, later on in that same April issue of *FDA Consumer*, was an article discussing a heat-generating device that has been promoted as a treatment of cancer. Our initial reaction was: "*Old hat! FDA has been debunking such devices, and hounding their promoters for as long as we can remember!*"

But, again, this was another case of "man bites dog!"

The FDA staff author described how a new medical device that uses controlled microwave energy to treat certain kinds of cancer has won FDA approval for marketing. The microwave energy produces hyperthermia and is now approved specifically for treatment of four types of malignant tumors: melanoma, squamous carcinoma, adenocarcinoma, and sarcoma.

The article points out that hyperthermia has certain limitations and is a palliative treatment rather than a true cure. But just to suppress and halt the growth of a malignant cancer is a great achievement with respect to this terrible disease. Also described are the clinical test results (with full to partial regression of 83 percent of tumors in one major study), the theoretical basis of the device's principle of activity, the technique employed in utilizing the device, the specialists who will initially employ the device and where it will be available, and the technique that manufacturers will use in testing and standardizing the machines they produce without needing to use human subjects in the testing process.

This FDA author's own abstract-summary also conveys very well the general message of the article: "*A recently approved device offers a new way to treat four types of cancer. In a process called hyperthermia, cancer cells are destroyed by microwave-type heat.*"

And less than a week earlier, we had read that, effective March 30, FDA had granted approval for the general marketing of nuclear magnetic resonance (NMR) imaging equipment for medical diagnostic purposes. NMR is expected to be very useful for *in vivo* pathological analyses as well as more effective three-dimensional visualization than can be achieved by currently available CAT scanning. Other exotic diagnostic applications are anticipated in the near future, and there is a good possibility that certain therapeutic or treatment applications will be approved eventually.

All of this is welcome news in the overall health care picture. New drug discoveries will continue to be important, but there is a growing recognition that pharmaceuticals alone are not sufficient to provide the most efficient and effective treatment for many diseases.

What we are seeing is the emerging era of applied technology. Although, as in the case of drugs, we have long enjoyed some benefits of device technology, they have been very limited and elementary when compared to the new gadgetry, electronics, and computer systems now becoming available.

And even in the pharmaceutical field, the present research and development emphasis is shifting more and more toward sophisticated drug delivery systems and away from exclusive interest in new drug entities. Again, this is applied technology.

In conclusion, what we are witnessing is truly a medical revolution. A field that just a few years ago had been full of phoniness and quackery has now been transformed by modern technology into one of hope and promise. For all of us who are involved, or even just witnessing these events, these indeed are exciting times!

New Insights in the Clastic Binding Hypothesis for Opiate–Receptor Interactions I: Electron-Transfer Mechanism

VERA M. KOLB

Received August 9, 1982, from the *Department of Chemistry and Biochemistry, Southern Illinois University, Carbondale, IL 62901.* Accepted for publication January 19, 1983.

Abstract □ A clastic binding hypothesis for opiate–receptor interactions, in which the key step in eliciting the opiate response is an electron transfer from the opiate nitrogen to the receptor, is analyzed from a chemical point of view and is found to be chemically feasible. An extended form of this hypothesis is proposed in order to accommodate recent observations about the N-demethylation of morphines in the brain. An *in vitro* model system for studying the electron-transfer reactions of morphines is proposed, and the initial experiments in this system are reported.

Keyphrases □ Clastic binding hypothesis—electron-transfer mechanism, opiate receptor interactions, *in vitro* model system □ Opiate-receptor interactions—electron-transfer mechanism, extended clastic binding hypothesis, *in vitro* model system □ Electron transfer—mechanism, extended clastic binding hypothesis, opiate-receptor interactions, *in vitro* model system

Belleau *et al.* (1, 2) presented experimental evidence that the directionality of the lone electron pair on nitrogen (N lone pair) of morphine-type opiates is directly related to their opiate activity. On this basis Belleau and Morgan (3) proposed the clastic binding hypothesis for opiate–receptor interactions. According to this hypothesis, morphine-type opiates achieve productive binding with the opiate receptor *via* a clastic binding process that includes a stereospecific electron transfer from the lone electron pair of opiates to some electrophilic site at the receptor. Such clastic binding is tantamount to injecting electrons at the receptor level. The electron transfer from nitrogen to the receptor was proposed to lead to the oxidation of the *N*-methyl substituent. Such oxidation may lead to a subsequent *N*-demethylation. Contrary to the *N*-demethylation hypothesis of Beckett *et al.* (4) in which the *N*-demethylation is an extrinsic preliminary step in the mechanism of opiate action, in the clastic binding the *N*-demethylation process participates *in conjunction with the opiate receptor* in eliciting the opiate response. According to Belleau and Morgan "the opiate receptor complex would possess an intrinsic and specific oxidative *N*-demethylase activity."

The aforementioned concept obviously requires that the location of the sites of *N*-demethylation within the CNS is proximal to or coincident with that of the opiate receptors. This was indeed found to be the case by Fishman *et al.* (5–7). They have demonstrated that the *N*-demethylation of morphine in rat brain is localized in sites with high opiate-receptor content. Moreover, the *N*-demethylation in the brain was found to proceed only when pharmacological concentrations of the substrate were present: the fact which indicated the biological significance of the reaction. This brain dealkylase was found to be different from that responsible for the same transformation in the liver (6). The brain demethylation of morphine was decreased by tolerance and by opiate antagonists such as naloxone, which itself was not dealkylated in the brain (7). These results provided strong support for the concept that *N*-dealkylation of narcotics in their CNS target sites is intimately involved in the expression of their action.

The *N*-dealkylation reaction occurring in the enzymatic process described above may follow the same mechanistic path as the same reaction occurring in the "test-tube" with the "regular" chemical reagents, or it may follow a different path. We were interested in exploring the former possibility. Specifically, we wanted to find out if the currently available chemical data on electron transfers from the N lone pair of morphines or model compounds, such as tertiary aliphatic amines, to electron acceptors are compatible with the hypothesis of Belleau and Morgan (3) and the findings of Fishman *et al.* (5–7).

THEORETICAL

Electron-Transfer Reactions and *N*-Dealkylations of Morphines—A possible mechanism by which the electron transfer from the N lone pair of the tertiary aliphatic amines to various electron acceptors leads to the *N*-dealkylation is presented in Scheme I. This mechanism has been found to be valid

0022-3549/84/0600-0715$01.00/0

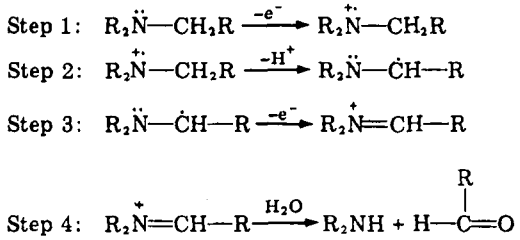


Scheme I—Possible mechanism of the oxidative N*-dealkylation of tertiary aliphatic amines.*

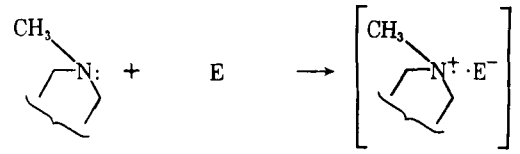
for the electrochemical (anodic) oxidations and dealkylations of tertiary aliphatic amines (8, 9) as well as for their reactions with various chemical agents, such as chlorine dioxide, *N*-bromosuccinimide, manganese dioxide, and ozone (10). Such a mechanism has been recently proposed also for the mitochondrial monoamine oxidase-catalyzed amine oxidation (11).

The first step of the mechanism shown in Scheme I is a one-electron transfer from the nitrogen of a tertiary amine to a suitable (redox-matched) electron acceptor (not shown). This slow step was found to be rate determining in the chemical and electrochemical reactions (8–10). The radical cation produced in the first step undergoes a loss of proton from an α-position yielding, after the rearrangement of electrons, an α-amino radical; this is shown in the second step. The α-amino radical species undergoes a one-electron transfer from nitrogen to give an immonium species, as shown in the third step. The immonium ion is readily hydrolyzed into a secondary (*N*-dealkylated) amine and an aldehyde, as shown in the fourth step.

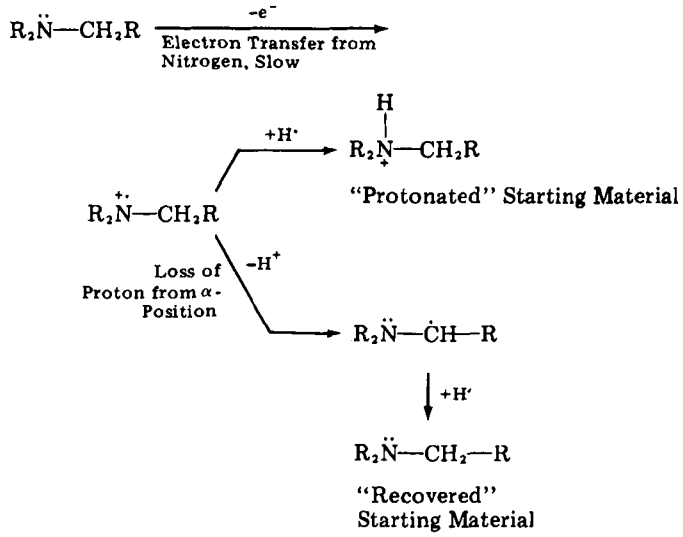
The mechanism presented in Scheme I may be proposed to operate in the cases when the *N*-demethylation of morphine occurs in the brain, namely when the concentration of morphine is at its pharmacological level (5). From this mechanism, however, it is not obvious why the *N*-demethylation does not occur at concentrations of morphine lower than the pharmacological concentration (5). The latter observation may be accommodated, however, by the following hypothesis. The electron transfer from the N lone pair of the morphine nitrogen to the electron acceptor (E) at the receptor may result in the formation of a stable caged radical-anion–radical-cation (RARC[1]) pair (Scheme II) between morphine and a hypothetical electron acceptor at the receptor. No bonds are made or broken in this process[2].

The formation of a RARC (charge-transfer) complex may be the most frequently occurring mode by which the morphine nitrogen interacts with the electron acceptor at the receptor. This mode of interaction, however, would not elicit the biological response according to the clastic binding hypothesis, since the electron transferred from the N lone pair is *not free* to be injected into the receptor, but is confined within the RARC cage. The formation of the RARC complex may be responsible for the affinity of nitrogen to the "amine-binding site" of the receptor (14), which would contribute to the overall affinity of morphine to the receptor, while the injection of the electron from the morphine nitrogen to the receptor would be responsible for the intrinsic activity (efficacy) (15) of morphine.

Only as a rare event would the electron from the N lone pair be injected to the receptor and, thus, be lost from nitrogen. The latter species would become a *free* radical cation which then could further react, as shown in Scheme I, to ultimately lead to *N*-dealkylation. Thus, according to this concept, the pharmacological concentration of morphine would be some critical concentration at which these rare events of the injecting the N lone pair electrons to the receptor cumulate and become "visible." A necessary condition for



Scheme II



Scheme III

inducing analgesia would be the injection of the N lone pair electrons to the receptor, and the *N*-dealkylation would normally accompany this reaction.

From the chemical point of view, however, one would predict that the injection of the N lone pair electron to the receptor does not necessarily have to be accompanied by *N*-dealkylation, since the nitrogen radical cation may react by a pathway different than that shown in Scheme I. Two such possible pathways are shown in Scheme III. According to this Scheme the nitrogen radical cation, formed by the loss of one electron from the N lone pair, may give either "protonated" or "recovered" starting material. The upper arrow in Scheme III shows that the nitrogen radical cation may pick up a hydrogen atom from the receptor (probably in a random fashion), giving material that is the same as the protonated starting material, but is obviously not obtained by protonation of the starting material. (Hence the word protonated in Scheme III is in quotations.) The lower arrow in Scheme III shows a pathway where the nitrogen radical cation loses an α-proton (the same as the step 2 in Scheme I) and the resulting α-amino radical picks up a hydrogen atom from the receptor, giving material that is the same as the starting material, but is not the recovered starting material since the α-hydrogen was exchanged. (Hence the word recovered in Scheme III is in quotations.) This pathway has been observed to occur during photooxidations of tertiary amines[3].

If the morphine radical cation at the receptor follows the pathway(s) shown in Scheme III, even as a rare event, it is conceivable that the abstraction of H· from the receptor would be random and, thus, may cause damage of the receptor site normally involved in the *N*-demethylation, as well as to the electron acceptor at the receptor. The damage of the receptor may become permanent and irreversible in the cases of prolonged use or abuse of morphines. The extent of the damage to the electron-acceptor site does not have to be the same as that to the *N*-dealkylation site. The opiate response still may be achieved if the latter site is damaged. The observed decrease of the brain *N*-demethylation of morphine by tolerance (7) may be caused by the damage of the *N*-dealkylation sites.

In summary, our view of the clastic binding process is the following. The attraction of morphine to its amine-binding site at the receptor is proposed to be achieved *via* formation of a RARC (charge-transfer) complex (Scheme II), an event which is *not* accompanied by the opiate response. Only occasionally a true electron transfer, *i.e.*, the electron injection, to the receptor occurs, leading to the opiate response. Normally, this electron injection is accompanied by *N*-demethylation (Scheme I), but it does not have to be, since other chemically feasible pathways are available, leading to "recovered" or "protonated" morphine, for example (Scheme III). These pathways may normally operate for various *N*-alkyl opiates which may not be dealkylated in the brain and, in the case of tolerance, when the *N*-demethylation is decreased.

Chemical considerations presented above in conjunction with the pharmacological observations on the *N*-demethylation of morphine in the brain suggest that the extended version of the clastic binding hypothesis is feasible both chemically and pharmacologically. Therefore, a detailed study of the electron-transfer reactions of morphines seems worthwhile.

Study of Electron-Transfer Reactions of Morphines in an *In Vitro* Model System—Despite a very extensive research in the field of opiate receptors, relatively little is known about these receptors because they are quite labile

[1] We are suggesting the term RARC pair for the caged radical-anion–radical-cation pair in accordance with the nomenclature introduced by Meyers *et al.* (12) who named the caged radical-anion–radical pair RARP.

[2] The RARC pair is an outer-sphere electron-transfer complex (13). In the latter complexes no bonds are made or broken during the course of the reaction (13). The immediate effect of the outer-sphere electron transfer is the change in the charge on the reactants (13). In the example shown in Scheme II the electron donor (nitrogen) which was neutral became positive, and the electron acceptor (E) which was neutral became negative. These complexes are also called charge-transfer complexes.

[3] Private communication by Prof. Fred D. Lewis, to whom thanks are expressed.

and easily denatured (16). The true nature of these receptors has not as yet being elucidated; after years of careful research by independent investigators, there still exists appreciable controversy over whether the receptor is a protein, a lipid, or both (16, 17).

The question if the protein or the protein part of the opiate receptor can function as an electron-transfer protein, as required by the clastic binding hypothesis, cannot be answered at this time since so little is known about the opiate receptor. If the opiate receptor protein can indeed function as an electron-transfer protein, one may visualize it, in general terms, as shown in Scheme IV (18):

Source of Electron ⟶

Way In ⟶ Trap ⟶ Way Out ⟶ Sink

Scheme IV

Scheme IV represents a directed electron transfer from a source of electron, morphine in this case, to the electron-transfer protein, in this case the opiate receptor (the enclosed block). In this model, the electron-transfer protein has the capability of controlling the electron transfer by a mechanism which "gates" either the "entering" or "leaving" channel. The movement of an electron through the protein may be realized, as suggested previously (18), *via* a localized hop mechanism and electron tunnelling.

We shall concentration only on the "way in" channel of the opiate receptor protein (Scheme IV), since the clastic binding hypothesis deals thus far only with this part of the opiate receptor. It is our desire to model this "way in" channel in such a way as to fulfill the chemical requirements of the proposed extended form of the clastic binding hypothesis, and then to study the chemistry of the electron transfer from morphines in such a model.

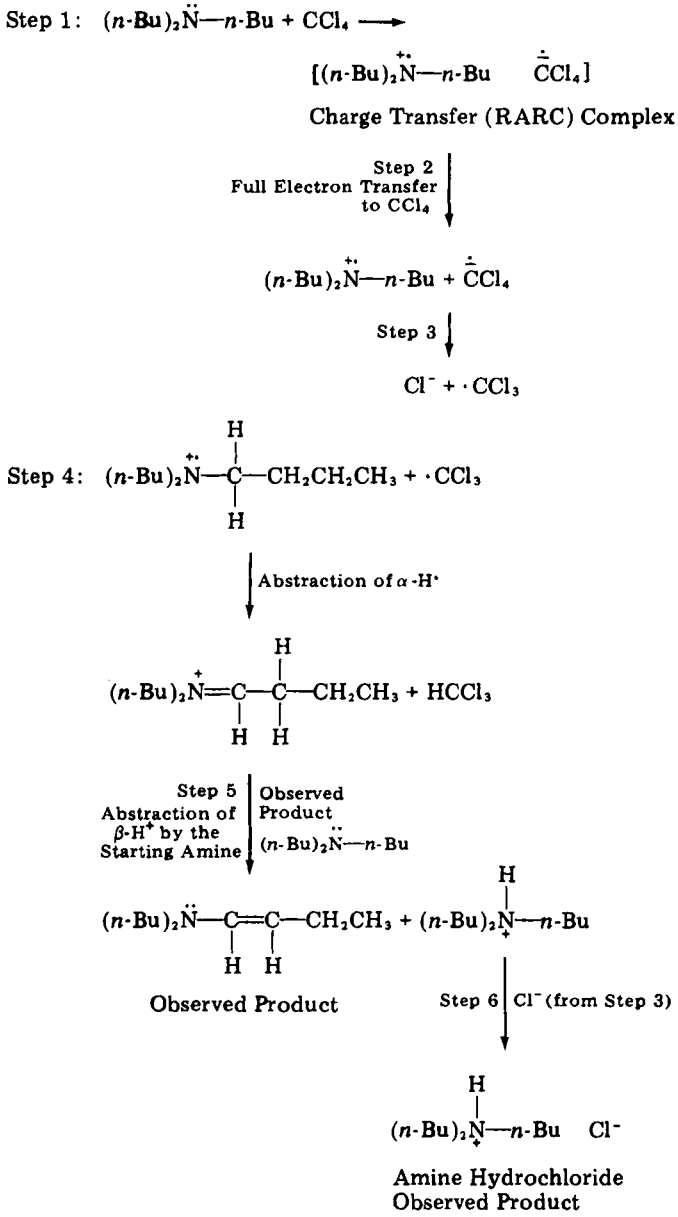
The "way in" channel in Scheme IV is actually the point of injection of the morphine N lone pair to the receptor, and it already has been discussed as "the electron acceptor at the receptor" (E) (Scheme II; see previous section). The chemical requirement for E was that morphine nitrogen can form a persistent RARC or charge-transfer complex with E (Scheme II), which only rarely leads to the actual loss of the N lone pair electron to the electron acceptor, *i.e.*, to the full electron transfer (Schemes I and III).

We decided to explore a possibility that perhalomethanes (CX_4, X = Cl or Br) may represent such models, since we were familiar with their exceptionally good electron-accepting ability (12, 19). In this paper we explore the behavior of carbon tetrachloride (CCl_4) in its reactions with amines in general and with a series of morphines. Work with CCl_3Br, which is a better electron acceptor than CCl_4, is in progress.

The reaction of amines with CCl_4 has been studied extensively (20-30). It is a well-established fact that amines—primary, secondary, and tertiary aliphatic, as well as aromatic—form charge-transfer complexes with CCl_4 (20, 25-27, 30). For example, amines such as triethylamine, di-*n*-propylamine, and tri-*n*-propylamine have been found spectrometrically to form 1:1 charge-transfer complexes with halomethanes (25). The K_f value for the *n*-butylamine-CCl_4 complex of 0.032 M^{-1} indicates a weak bond between the two species, as expected in a charge-transfer complex (27). Since these charge-transfer complexes are outer-sphere electron-transfer complexes in which no bonds are made or broken, their persistency shows as a lack of the actual chemical reaction.

When the N lone pair electron is fully transferred to CCl_4, a series of chemical reactions are initiated which ultimately lead to amine hydrochloride and other products (Scheme V). Such reactions in the case of morphines must be very slow if CCl_4 is to be used as a model for the electron acceptor at the opiate receptor, since the actual loss (injection) of the N lone pair electron to the receptor is proposed to be a rare event. Since the ultimate product of the reaction of an amine with CCl_4 is the amine hydrochloride, as shown in Scheme V and amply demonstrated in other examples (20-29), the speed and the extent of this reaction can be determined by measuring, respectively, the rate of appearance and the amount of amine hydrochloride, or just the halide ion.

The literature data on the rates of the reactions of amines with CCl_4 could not be extrapolated with confidence to the case of morphines, since they are somewhat contradictory. Thus, reports exist stating that amine hydrochloride precipitates were formed rather rapidly after dissolving the amines in CCl_4 (25, 27) and also that the formation of such precipitates is extremely slow (21). These discrepancies may be due to the uncontrolled presence of catalysts, such as UV light, oxygen, Cu^+, Cu^{2+}, Fe^{2+}, brass, and even traces of metal impurities from a stirring bar, all of which have been found to influence the reaction rate. However, the influence of these catalysts is not clear in all the cases. Thus, one report states that the reaction is prevented if light or other catalysts are excluded (26), but another report describes that the reaction proceeds in dark without a catalyst (28).



Scheme V—Chemical reactions leading to the amine hydrochloride (based on Ref. 28).

Therefore, since there were no satisfactory literature data that we could extrapolate to the case of morphines, we undertook the study of the reactions of morphine, oxymorphone, and naloxone with CCl_4.

EXPERIMENTAL

Melting points were determined on a capillary melting-point apparatus[4] and were not corrected. The NMR spectra were taken on a 90-MHz spectrometer[5], and the IR spectra were recorded on a spectrophotometer[6]. TLC was done on aluminum sheets precoated with 0.2 mm of silica gel[7]; the eluant was chloroform–methanol–concentrated ammonium hydroxide (132:12:0.9 by volume). The spots were observed in a UV chamber at the wavelength of 254 nm. The carbon tetrachloride used was an ACS-analyzed reagent[8], containing only 0.5 ppm of chloride ion and 0.02 ppm of heavy metals. Oxymorphone hydrochloride[9], naloxone hydrochloride[9], and morphine[10] were from outside sources.

Conversion of Naloxone Hydrochloride to Naloxone—A solution of nal-

Table I—Reaction of Selected Morphines and Other Amines with Carbon Tetrachloride

Amine	Reaction Time, h	Isolated Product(s)	Yield, %	Reference
Naloxone	3	Trace of amine hydrochloride was presumably formed[a]	trace of Cl^- was observed	this work
Morphine	20	—	—	this work
Oxymorphone	30	Trace of amine hydrochloride was presumably formed[a]	trace of Cl^- was observed	this work
Triethylamine	72	Amine hydrochloride	2.2	21
2-Diethylaminoethanol	72	Amine hydrochloride	24.4	21
Piperidine	24	—	—	22
	72	Amine hydrochloride	2.6	22

[a] See *Experimental*.

oxone hydrochloride (0.70 g, 0.0019 mol) in ethanol and water was poured into an aqueous solution of borax[11] (sodium tetraborate, $Na_2B_4O_7 \cdot 10H_2O$; certified ACS). The resulting solution was extracted three times with chloroform (ACS quality, distilled). The combined chloroform extracts were washed with borax and water, dried (anhydrous magnesium sulfate), and evaporated leaving naloxone as 0.56 g of a white solid (90% yield), mp (chloroform–petroleum ether) 177–178.5°C, (ethyl acetate) 177–178.5°C [lit. (31) mp (ethyl acetate) 177–178°C, 184°C]. The crude as well as the recrystallized material was TLC pure, R_f 0.65.

Treatment of Naloxone with Carbon Tetrachloride—Naloxone (0.35 g, 1.1×10^{-3} mol) was mixed with carbon tetrachloride (30 mL, ~300 times molar excess over naloxone) and the mixture was refluxed to achieve dissolution. After the dissolution was complete, the reflux was continued for 1.5 h under the laboratory fluorescent lights. Air was not excluded, as the reflux was performed in a reflux apparatus equipped with a $CaCl_2$ drying tube on top of the reflux condenser. The solution was then stirred at room temperature for the 1.5-h period. After that time, the solvent was evaporated on a rotary evaporator, and the white solid residue was dried in a vacuum oven, giving 0.34 g of the material (97% recovery).

The IR spectrum of this material was essentially identical with that of the starting material. The C=O stretch was at 1728 cm^{-1} (nujol) as in the starting material, and no peak was observed at 1713 cm^{-1}, which corresponds to the C=O stretch of naloxone hydrochloride (nujol). The NMR spectrum ($CDCl_3$) of the recovered material was essentially identical with that of the starting material. TLC showed only one spot at R_f 0.65, corresponding to naloxone (the eluant would convert any naloxone hydrochloride to naloxone), indicating that no oxidative-degradation products were present.

A test for the presence of trace amounts of naloxone hydrochloride was performed as follows. The recovered material was dissolved in ether (ACS quality, distilled). The ethereal solution was washed three times with distilled water, the combined aqueous layers were acidified with 6 M HNO_3, and an aqueous solution of $AgNO_3$ was added. At first no cloudiness appeared, and only after ~5 min of standing a barely visible cloudiness developed, but no visible precipitate was formed. The theoretical yield of AgCl is 0.154 g. We have found that the AgCl test described above gave an immediate precipitate when applied to only a few milligrams of oxymorphone hydrochloride. This AgCl test gave us >99% accuracy when applied to the determination of chloride ion in a small (0.4×10^{-3} mol) sample of pure thymoxyethyl diethylamine hydrochloride (theoretical yield of AgCl, 0.058 g).

The ether which was used for the extraction, when treated as above (washed with water, the aqueous layer acidified with 6 M HNO_3, and aqueous $AgNO_3$ added), gave a completely clear solution which remained clear even after prolonged standing, thus indicating the absence of chloride ion as determined by the AgCl test. An experiment (blank) was also performed, in which 50 mL of CCl_4 was refluxed under laboratory lights for 13 h and stirred at room temperature in the dark for 17 h, and then worked up in the identical manner as the sample containing naloxone. No trace of chloride ion was observed in the AgCl test.

Conversion of Oxymorphone Hydrochloride to Oxymorphone—Oxymorphone hydrochloride (0.86 g, 0.025 mol) dissolved in water was converted into oxymorphone in the same fashion as the naloxone hydrochloride conversion into naloxone, yielding 0.48 g of oxymorphone (62%), mp (chloroform–petroleum ether) 249–250°C (dec.) [lit. (31) mp. (boiling ethanol, ethyl acetate, or benzene) 248–249°C (dec.)]. The crude as well as the recrystallized material were TLC pure, R_f 0.55.

Treatment of Oxymorphone with Carbon Tetrachloride—Oxymorphone (0.14 g, 0.47×10^{-3} mol) was treated with carbon tetrachloride (50 mL; ~1100 molar excess over oxymorphone) in the same manner as naloxone (*vide supra*), except that the reaction time was 10 times longer in the oxymorphone case. Thus, oxymorphone and CCl_4 were refluxed for 15 h under the laboratory fluorescent lights and stirred at room temperature for 15 h in the dark. The same work-up as for naloxone provided a white fine solid, which represented essentially quantitatively recovered starting material. The IR and NMR spectra of this material did not reveal the presence of oxymorphone hydrochloride and were identical to the corresponding spectra of the starting material. The AgCl test did not provide a visible precipitate, but the cloudiness observed was much more pronounced than in the case of the naloxone reaction; the theoretical yield of AgCl is 0.068 g. TLC showed the presence of only one spot, R_f 0.55, corresponding to oxymorphone, which indicated that no other compounds, such as degradation or oxidation products, were present.

Treatment of Morphine with Carbon Tetrachloride—Morphine (0.0965 g, 0.318×10^{-3} mol), mp 248–250°C (dec.) [lit. (31) mp for the monohydrate 254–256°C (dec.)], was treated with carbon tetrachloride (55 mL; ~1800 molar excess over morphine) under reflux and laboratory fluorescent lights for 5 h and at room temperature in the dark for 15 h. Again, as in the previous experiments, air was not excluded. After the above period, the solvent was removed by evaporation and the residual white solid was dried in a vacuum oven. The IR of this solid was identical, peak by peak, to the IR of the starting material.

This solid was suspended in water in a separatory funnel and shaken with ether, and the precipitate was removed by filtration. The white solid thus obtained showed only one spot on TLC (R_f 0.16) at the same place as morphine, thus indicating that no oxidative-degradation products were present. The aqueous and ether layers were separated. No material was recovered from the ether layer. The aqueous layer was acidified with 6 M HNO_3, and an aqueous solution of $AgNO_3$ was added. No precipitate or cloudiness was observed even after several hours. Only when the solution was looked at against a black background was a slight bluish-gray opaqueness, characteristic of AgCl, observed. After 10 d, a trace of precipitate (AgCl) was observed on the bottom of the flask.

RESULTS AND DISCUSSION

Morphine, oxymorphone, and naloxone, as freshly prepared free bases, were treated with CCl_4 open to air, under the laboratory fluorescent lights, and under reflux. A new polytef-coated stirring bar was used each time to avoid metal contamination, which is possible with used stirring bars. The carbon tetrachloride used was of analyzed-reagent quality and contained only 0.02 ppm of heavy metals. We used the above morphines, with an unprotected phenol moiety, so that the free phenol group could act as a built-in inhibitor (19) for free radicals: this narrowed the number of possible products. The extent of the reaction was followed by measuring the amount of chloride ion, which is formed by the decomposition of $CCl_4^{\cdot-}$ (step 3 in Scheme V). The recovered morphines were inspected by NMR and IR to see if there were any CCl_3-adducts in the phenol ring, since the latter ring would act as scavenger for the CCl_3 radicals formed simultaneously with the chloride ion (step 3).

We have found that the morphines studied react extremely slowly with CCl_4 (Table I and *Experimental Section*). For example, oxymorphone after 30 h of treatment with CCl_4 was completely recovered, with no spectrometric evidence of CCl_3- or other adducts, and only traces of chloride ion were detected.

Table I illustrates, for comparison, the literature results for some other amines of interest: triethylamine, as an example of tertiary amine; 2-diethylaminoethanol, as an example of a hydroxy amine in which, like in oxymorphone and naloxone, the hydroxyl group is in a close proximity to the amino group; and piperidine, a cyclic amine which is found as part of all the morphines. While the results for triethylamine and piperidine show slow reactions similar to our results for the morphines, the reaction of 2-diethylaminoethanol seems to be much faster. This point deserves further investigation. Further studies and evaluations of CCl_4 as an *in vitro* model for an electron acceptor at the receptor are in progress.

New Insights in the Clastic Binding Hypothesis for Opiate–Receptor Interactions II: Proton-Transfer Mechanism

VERA M. KOLB ˣ and STEVE SCHEINER

Received June 22, 1983, from the *Department of Chemistry and Biochemistry, Southern Illinois University, Carbondale, IL 62901.* Accepted for publication August 12, 1983.

Abstract □ *Ab initio* (4-31G) molecular orbital calculations were performed on model systems to investigate the proton-transfer version of the clastic binding hypothesis for opiate-receptor interactions. Ammonia was chosen as the model for the nitrogen-containing portion of the opiate molecule, while ammonia and water were chosen as models for the proton acceptor at the receptor. The equilibrium position of a proton situated between the two molecules is found to be determined primarily by the orientation of the proton-donor molecule with some influence also from the other molecule. Misalignments of the lone pairs can significantly alter equilibrium populations when the proton affinities of the two molecules are similar.

Keyphrases □ Clastic binding hypothesis—proton-transfer mechanism, opiate-receptor interactions, *ab initio* molecular orbital calculations □ Opiate-receptor interactions—proton-transfer mechanism, clastic binding hypothesis, *ab initio* molecular orbital calculations □ Proton transfer—mechanism, clastic binding hypothesis, opiate-receptor interactions, *ab initio* molecular orbital calculations

Belleau *et al.* (1, 2) have presented concrete evidence that the relative spatial orientation of the lone electron pair on nitrogen (N lone pair) or morphine-type opiates is crucial for their opiate activity. On this basis they proposed the clastic binding hypothesis for opiate-receptor interactions (3). According to this hypothesis, morphine-type opiates achieve productive binding with the opiate receptor through a clastic binding process involving a stereospecific electron transfer from the nitrogen lone electron pair of the opiate to some electrophilic site at the opiate receptor. This hypothesis was recently analyzed from a chemical point of view and was found to be chemically feasible (4). An extended form of this hypothesis was proposed (4) to accommodate recent observations by Fishman *et al.* concerning the *N*-demethylation of morphines in the brain (5-7).

Belleau and co-worker (2) later proposed another version of the clastic binding hypothesis according to which the N lone pair of opiates is involved in a stereospecific proton transfer to the receptor leading to strong analgesia. For optimal analgesia, a morphine should have the N lone pair oriented properly for a facile proton transfer. This version of the clastic binding

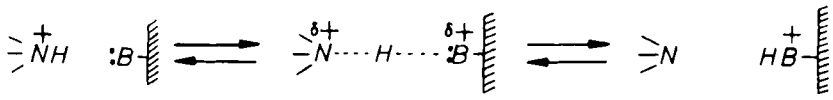

Figure 1—*Schematic representation of the proton transfer between a protonated morphine-type opiate (only nitrogen is shown) and an acceptor base (B) of the opiate receptor (shaded area) (adapted from Ref. 2).*

hypothesis shall be referred to as the proton-transfer version, as opposed to the electron-transfer version which was discussed in the previous paper (4).

We believe that the clastic binding hypothesis shows promise of explaining the mechanism of opiate-receptor interactions and, therefore, deserves further examination. The objective of this paper is to provide new insights into this hypothesis. This paper deals with the proton-transfer version of this hypothesis, while the previous paper (4) concerns the electron-transfer version. (An extensive discussion of the proton-transfer version of the clastic binding hypothesis can be found in Ref. 2.) We summarize here some crucial points with emphasis on those which we are going to investigate (*vide infra*).

BACKGROUND

Belleau and coworkers (2) visualized the proton transfer between a morphine-type opiate and the opiate receptor as shown in Fig. 1. The potency of an analgesic, according to these authors, depends on the position of the equilibrium of the proton, which is affected by the basicity of nitrogen of morphines. To account for the observed influence of the directionality of the N lone pair of morphine-type compounds on their opiate activity, it was proposed that:

1. Only the orientation of the N lone pair which allows a facile, *i.e.*, energetically favorable, proton transfer is favorable for induction of analgesia. There are other orientations of the N lone pair from which the proton transfer is energetically unfavorable.

2. The position of equilibrium of the proton will depend on the N lone pair orientation (in addition to basicity of nitrogen).

We decided to investigate the above two statements in a quantitative manner using *ab initio* quantum chemical methods. These methods are suitable for this type of study since the relative orientations of species to be studied (amine, proton, and the base at the receptor) may be precisely specified and easily varied. SCF calculations were carried out with the 4-31G basis set since this procedure furnishes proton-transfer energy barriers in excellent agreement with much more sophisticated theoretical treatments using large basis sets and configuration interactions (8–11).

To perform *ab initio* calculations it was necessary to model the large morphine molecules by smaller representative systems. Ammonia was chosen as the simplest model of the amine-type nitrogen-containing portion of a biologically active morphine-type opiate. Two different models were chosen to represent the base at the opiate receptor, the nature of which has not as yet been elucidated. We examine the possibility that such a base contains nitrogen or oxygen, as is frequently the case for bases encountered in biological systems (12). The first model is the nitrogen base ammonia which contains a single lone electron pair (Fig. 2). Water was used as the simplest model of an oxygen base and contains two lone pairs (Fig. 3). These two models for the base provide a wide range of basicity, which is expected to include the pK of the receptor within it.

EXPERIMENTAL

All molecular orbital calculations were performed using the *ab initio* Gaussian-70 system of programs (13). The 4-31G basis set (14) was used within the restricted Hartree-Fock formalism.

Before we present our calculations on the simple model systems (Figs. 2 and 3) it is important to define clearly all the parameters of these models in conjunction with the actual case of a morphine undergoing a proton transfer at the opiate receptor (Fig. 4). Both the morphine molecule and the hypothetical base at the receptor have been shown to be sterically fixed at the receptor: morphine by virtue of the noncovalent "lock-and-key" fit (15) and the base at the receptor by virtue of a covalent bond (Fig. 4). The example of a morphine shown in Fig. 4 is oxymorphone, a potent opiate agonist. The example of a base B at the receptor shown in Fig. 4 is a neutral base having one lone electron pair. The N lone pairs of oxymorphone and the base B are shown to be in a less than perfect alignment along the N···B internuclear axis, which is a more likely case than perfect alignment, since morphines may not be the ideal substrates for the opiate-receptor cavity [etorphine, for example, may be a better candidate (16)].

The N···B distance R is unknown. In our calculations on the model systems this distance varied from 2.75 to 3.15 Å, which is a typical range between proton donors and acceptors encountered in biologically important hydrogen-bonded systems (12). The N···B distance R shown in Fig. 4 is likely to be longer than the equilibrium N···B distance (in the absence of steric constraints), due to the postulated less-than-perfect fit between morphine and the receptor. In Figs. 2–4, r refers to the distance between the proton-donating nitrogen atom and the central proton in its equilibrium position. This parameter, r, will depend to some extent on the internitrogen distance R, as will be demonstrated below.

To study the dependence of the properties of the proton transfer on the directionality of the lone pairs, the NH_3 and base molecules (NH_3 or OH_2) were twisted, as illustrated in Figs. 2 and 3. α_1 and α_2 are angles describing the rotation of the nitrogen proton donor and the proton-acceptor B, respectively, from their optimal orientation. Both conrotatory and disrotatory misalignments were studied. For each configuration (defined by R, α_1, and α_2), the equilibrium position of the central proton was located. Scheme I conveniently summarizes the relevant features of the energetics of the proton-transfer process. The left well corresponds to the NH···B state and the right well to N···HB. Between the two is an energy barrier $E^\dagger$ over which the proton must pass. A high value of $E^\dagger$ may prevent proton transfer. ΔE refers to the energy difference between the states ($N^+H\cdots B$) and ($N\cdots H^+B$), and its value will determine the equilibrium population of the proton between the two states (assuming equilibrium is achieved).

RESULTS

$(H_3N\cdots H\cdots NH_3)^+$ System—We begin our discussion with the system in which a proton may be transferred between two ammonia molecules, one of which models the morphine base and the other represents the base at the opiate receptor (Fig. 2). We shall refer to this model as the $(H_3N\cdots H\cdots NH_3)^+$ system.

A study of the energetics of proton transfer in the $(H_3N\cdots H\cdots NH_3)^+$ system has recently been published by Scheiner (17). We summarize briefly here some conclusions of the latter work which are relevant to the objectives of this study. Calculated potential energy curves of the type shown in Scheme I are illustrated in Fig. 5. For internitrogen distances R <2.5 Å, the potential may be seen to contain a single centrally located minimum. At this distance, the preferred position of the proton is midway between the two nitrogens. However, for larger values of R, the potential acquires a symmetric double-well character. The two equivalent energy minima each correspond to a configuration in which the central proton is associated with one ammonia molecule or the other. The magnitudes of the energy barriers to proton transfer increase rather quickly as R is increased. In all configurations, for values of R ranging from 2.45 to 3.15 Å, the hydrogen bond is linear.

If one assumes that there is a meaningful parallel between the model system $(H_3N\cdots H\cdots NH_3)^+$ and the morphine-receptor complex shown in Fig. 4, an important feature emerges: there may be a significant energy barrier for the proton transfer between the morphine and the receptor which may be enlarged or reduced by increasing or decreasing, respectively, the distance R. This feature could provide a simple regulatory mechanism in case the re-

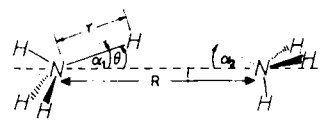

Figure 2—*Model representing a proton transfer from the protonated nitrogen of a morphine-type opiate (NH_3 on the left) and a base B at the receptor (NH_3 on the right). Both NH_3 units belong to the C_{3v} point group with r(NH) = 1.008 Å, θ(HNH) = 109.3°. The equilibrium position of the central proton is defined by the N—H distance r and the angle θ between the N—H and N···N axes. Angles α_1 and α_2 describe the rotations of the proton-donating amine and proton-accepting base, respectively, from their optimal orientations, $\alpha_1 = \alpha_2 = 0°$. Dotted lines represent the C-3 rotation axis of each molecule.*

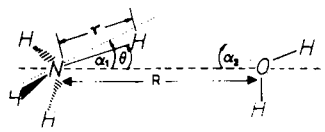

Figure 3—*Analogous to Fig. 2, except that the proton-accepting base at the receptor is modeled by OH_2 with r(OH) = 0.95 Å, θ(HOH) = 111.3°. The corresponding dotted line indicates the C-2 symmetry axis of OH_2.*

ceptor has a point of flexibility (dashed line on the boundary of the receptor in Fig. 4).

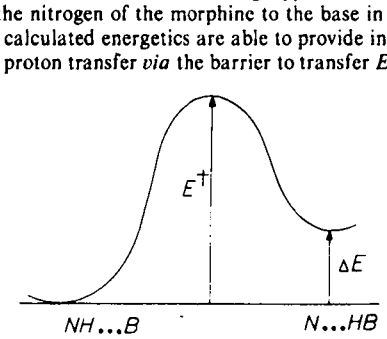
Belleau's claim that only certain orientations of the N lone pair in the system shown in Fig. 1 allow a facile (*i.e.*, energetically favorable) proton transfer is supported to some extent by the study of the energetics in the $(H_3N\cdots H\cdots NH_3)^+$ system in terms of α_1 and α_2 for a range of R values (17). Thus, Scheiner has found that for each R studied (2.73, 2.95, and 3.15 Å) the activation barriers of the systems having $\alpha \neq 0$, *i.e.*, the N lone pair(s) misaligned relative to their optimal orientation, are larger than those of the systems in which the N lone pair(s) are optimally oriented, *i.e.*, $\alpha = 0$. The magnitude of the energy barrier depends on the type of misalignment between the two N lone pairs, and is largest for disrotatory misalignments (*e.g.*, 42.0 kcal/mol for $\alpha_1 = -40°$, $\alpha_2 = 40°$, and $R = 3.15$ Å). Misalignments of 20° produce barrier increases in the range of 1–2 kcal/mol, while much more drastic increases are observed for greater misalignments of the N lone pairs.

In this paper we focus on the influence of the relative spatial orientation of the N lone pairs on the equilibrium position of the central proton and the relative equilibrium populations of the $(H_3NH\cdots NH_3)^+$ and $(H_3N\cdots HNH_3)^+$ states.

Table I contains a summary of the equilibrium position of the central proton in the $(H_3NH\cdots NH_3)^+$ state for a range of intermolecular configurations specified by R, α_1, and α_2. We note that the equilibrium NH distance r remains virtually the same, ~1 Å (1.002–1.087), for all α values and R values studied. As R increases the proton is slightly closer to the NH_3, the proton donor, which is expected since the influence of the other NH_3, the proton acceptor (ammonia on right in Fig. 2), becomes weaker as the distance R increases. The only exception to this trend is found in the last entry of Table I, namely for the largest misalignment studied ($\alpha_1 = 40°$ and $\alpha_2 = -40°$), in which the distance r actually increases very slightly with the increased R. With changing α values the proton is rotated at approximately constant r so that it partially follows the N lone pair of the NH_3, the proton donor. This is seen, for example, in entries 4 and 5 of Table I, which show that when the NH_3 proton donor is rotated by 20° and 40°, the proton is rotated off the N···N axis by 11.9° and 30.3°, respectively, for $R = 2.75$ Å. If we consider the N lone pair as lying along the C-3 symmetry axis of NH_3, α may be thought of as a measure of the "directionality" of the lone pair. [However, this correspondence is only true near the nucleus, as the N lone pair may undergo "bending" toward the proton as illustrated in similar examples (18, 19).]

The calculated values of Θ are a compromise between the left NH_3 which attempts to pull the proton along the lone pair direction (α_1) and the right NH_3 which pulls the proton toward the N···N axis (0°). The difference between α_1 and θ, listed in Table I, provides a measure of the strength of the latter attraction. As the distance R increases, θ becomes closer to α_1, *i.e.*, the proton follows the N lone pair of the proton-donating NH_3 more closely, since the influence of the proton-accepting ammonia diminishes for greater R. The only exception, again, is the case of the largest misalignment, presented in entry 9. In conclusion, the equilibrium position of the proton depends primarily on the direction of the donor lone pair and to a lesser extent on the relative position of the acceptor lone pair. The equilibrium N···H distance, r, generally remains within a narrow range, ~1.05 Å.

As mentioned above, the clastic binding hypothesis requires a proton transfer from the nitrogen of the morphine to the base in order to initiate analgesia. The calculated energetics are able to provide information about the rate of this proton transfer *via* the barrier to transfer $E^\dagger$. In addition, it



Scheme I

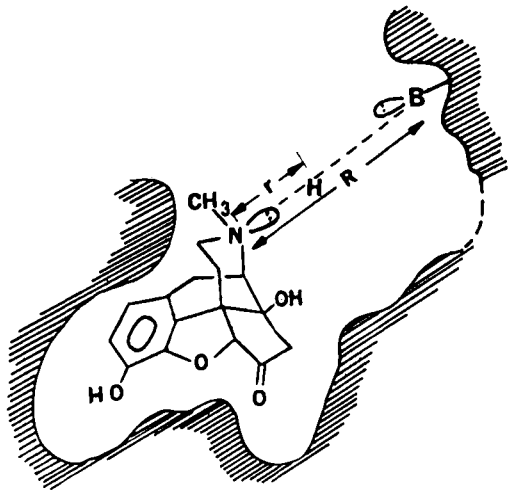


Figure 4—*Schematic representation of a proton transfer from the nitrogen of a morphine-type opiate (oxymorphone) to a hypothetical base B at the opiate receptor. The latter is shown as a shaded area whose shape should not be taken literally. The broken boundary of the receptor indicates a point of possible receptor flexibility and leads to uncertainty in distance R. The lone pairs of oxymorphone and the base B are shown to be in a less-than-perfect alignment along the N···B internuclear axis for reasons discussed in the text.*

would be useful to know something about the relative populations of the NH···B and N···HB states as it is only the latter that leads to analgesia. Information of this type is available from the difference in energy between these two states, corresponding to ΔE in Scheme I. At thermodynamic equilibrium the ratio of relative populations is given by:

$$K = \frac{n(\text{N}\cdots\text{HB})}{n(\text{NH}\cdots\text{B})} = \exp(-\Delta G°/RT)$$

where $\Delta G°$ refers to the difference in Gibbs free energy between the two states. By equating our calculated values of ΔE to $\Delta G°$ we make the following assumptions: (*a*) the difference in entropy between the two states is negligible and (*b*) the zero-point vibrational energies of the two states are about the same. The lack of any major changes in bonding structure, with the exception of the proton motion, would lead one to expect these assumptions to be reasonable.

For the angularly undistorted system ($\alpha_1 = \alpha_2 = 0°$), the symmetry of the potential energy curve leads to a value of $\Delta E = 0$ and therefore to $K = 1$. The same is true for both conrotatory and disrotatory distortions where $\alpha_1 = \pm\alpha_2$. In all of these cases, we would expect equal populations of NH···B and N···HB. However, when one molecule is rotated and the other is not, the symmetry is destroyed and $\Delta E \neq 0$. The calculated values of ΔE in cases where the proton-donor molecule is rotated by α and the acceptor molecule is left undistorted are provided in Table II. Along with these calculated energy differences are included the associated equilibrium constants K. For distortions of only 20°, the ΔE values are quite small and K is thus nearly equal to 1. However, for greater distortions of 40°, the energy differences are greater than 1 kcal/mol and K is of the order of 0.1. We thus see that for such distortions, the population of state NH···B is an order of magnitude greater than that of N···HB. In other words, the equilibrium of the two states is shifted toward that configuration in which the proton is associated with the lone pair with the misalignment.

$(H_3N\cdots H\cdots OH_2)^+$ System—The second system we studied is $(H_3N\cdots H\cdots OH_2)^+$ in which the morphine base is represented by H_3N and the proton acceptor at the receptor is modeled by H_2O (Fig. 3). The latter base has two lone electron pairs, thus providing an electronically different environment than that of the aforementioned NH_3 system. In addition, H_2O has a different basicity than NH_3.

A study of the energetics of proton transfer in the $(H_3N\cdots H\cdots OH_2)^+$ system as a function of R, α_1, and α_2 has recently been published (10, 20). The results of these studies are qualitatively parallel to that of the $(H_3N\cdots H\cdots NH_3)^+$ system, except that the asymmetry of the former system leads to two activation barriers. one for the proton transfer from NH_4^+ to H_2O ($E^\dagger_{NH\to O}$) and one for the proton transfer from H_3O^+ to NH_3 ($E^\dagger_{OH\to N}$). The latter barrier is smaller than the former. The values of activation barriers for proton transfers from NH_4^+ to H_2O vary from 29.1 kcal/mol for the optimally aligned system ($\alpha_1 = \alpha_2 = 0°$) to 52.2 kcal/mol for the system with the greatest misalignment studied ($\alpha_1 = 40°$ and $\alpha_2 = -40°$). The corre-

sponding values for the barriers for proton transfer from H_3O^+ to NH_3 are much smaller: 2.7 and 16.9 kcal/mol.

The comparison between the values for the energy barriers for the proton transfer from NH_4^+ to H_2O and to NH_3 reveals that the latter are much smaller than the former. This difference is undoubtedly due chiefly to the difference in the electronegativities of nitrogen and oxygen atoms (10, 20). The activation barriers for the proton transfer in the $(H_3N\cdots H\cdots OH_2)^+$ system depend on the misalignments between the proton donor and acceptor in a manner very similar to that observed for the $(H_3N\cdots H\cdots NH_3)^+$ system (10, 20).

We report here the effect of the relative spatial orientation of the lone electron pairs in the $(H_3N\cdots H\cdots OH_2)^+$ system on the equilibrium position of the proton (Table III). The analysis of data presented in Table III reveals a picture analogous to that of the $(H_3N\cdots H\cdots NH_3)^+$ system. The r distance, again, is essentially constant and is ~1 Å (1.000–1.046 Å). This distance again decreases slightly with increased R, except for the case of the largest misalignment (entry 9 of Table III), in which r increases slightly. θ Follows α_1 again (*cf.* entries 4 and 5) and to a smaller extent α_2 (*cf.* entries 2 and 3). The $\alpha_1 - \theta$ difference here is as large as 7.3°.

DISCUSSION

While it would be presumptuous to generalize our data on the $(H_3N\cdots H\cdots NH_3)^+$ and $(H_3N\cdots H\cdots OH_2)^+$ systems and claim that they are directly applicable to the situations where the proton is being transferred between the morphine-type opiates and the opiate receptor, we believe that our findings should be considered qualitatively when picturing morphine–receptor interactions in conjunction with the clastic binding hypothesis of Belleau. The previously published calculations of the energetics of proton transfer in the $(H_3N\cdots H\cdots NH_3)^+$ and $(H_3N\cdots H\cdots OH_2)^+$ systems as a function of the distance and the relative spatial orientation of the species between which the proton is being transferred (10, 17, 20) support the claim by Belleau and co-workers (2) that the ease of proton transfer depends on the directionality of the N lone pair (2).

We have presented calculations which show that the equilibrium position of the proton depends on both the N lone pair direction and the orientation of the proton-acceptor molecule. We have shown in both model systems—$(H_3N\cdots H\cdots NH_3)^+$ and $(H_3N\cdots H\cdots OH_2)^+$—that the proton "follows" the N lone pair of the proton donor, and to a lesser extent that of the acceptor. The result is that if the "directionality" of the N lone pair is changed by a certain angle α_1, the proton will change its position by an angle θ, which may differ from α_1 by up to 10° in our model systems. The distance r between the proton and the proton-donating NH_3 stays pretty much constant at ~1 Å. However, the equilibrium populations of the proton on the two molecules may depend significantly on the N lone pair directions. This dependence is maximized in a system such as $(H_3N\cdots H\cdots NH_3)^+$ where the proton-donor and -acceptor molecules have identical proton affinities. When the proton affinities are significantly different there is little dependence on angular characteristics for the following reasons. Even in the angularly undistorted case, ΔE is quite different from 0. In the case of $(H_3N\cdots H\cdots OH_2)^+$, this quantity is about 38 kcal/mol. The equilibrium population of $N\cdots HO$ relative to $NH\cdots O$ is negligible (10^{-28}). Angular distortions of the two groups may increase or decrease ΔE by only a small amount relative to the original 38 kcal/mol. For example, a reduction of ΔE by 2 kcal/mol would only change K from 10^{-28} to 10^{-26}, an increase of 100-fold, but still a negligible amount of $N\cdots HO$. Therefore, for the angular orientations of the lone pairs to have a major effect on the relative populations of the two states, it would be necessary for the morphine and receptor base to have very similar proton affinities.

With regard to the accuracy of the particular quantum chemical method used here, we do not expect our results to be changed in any major way by use of larger basis sets or inclusion of electron correlation. While the specific r(NH) distances in Tables I and III may be somewhat altered, our finding of very small changes in this distance with variations of the hydrogen-bond configuration is expected to be verified. The energetics calculated with the 4-31G basis set at the Hartree–Fock level are also expected to be little changed with more sophisticated procedures, as has been demonstrated previously (8–11, 17, 20).

We may use our results to draw some inferences about the effects of modifications of the relative orientation of the morphine and receptor in Fig. 4. A rotation of the morphine molecule as a whole, with the nitrogen atom as a stationary "pivot" would correspond to twisting of the proton-donor molecule (α_1) in Figs. 2 and 3. α_2,Rotation of the proton acceptor, would be effected by a translatory motion of the entire morphine molecule to bring the nitrogen atom more out of line with the base lone pair. Our results provide evidence that small rotations of these types, *i.e.*, $\leq$20°, would not significantly alter the populations of the "untransferred" state $NH\cdots B$ and the "transferred" state $N\cdots HB$. On the other hand, a large rotation was shown above to lead to a preferential population of the proton on the group with the misaligned lone pair. We therefore infer that a rotation of the morphine about its nitrogen atom (α_1) will inhibit transfer of its proton to the base. This transfer would, however, be enhanced by a translation of the morphine off the base lone pair direction (α_2).

The reader is cautioned that these conclusions are based only on equilibrium populations. Equilibrium might not be achieved in these systems. Secondly, while the equilibrium population of the $N\cdots HB$ state might be increased by the second motion described above, the angular distortion also produces an enlargement of the energy barrier to proton transfer which would act to inhibit

this transfer. Finally, the changes in relative populations would be greatly reduced if the basicities of the morphine and receptor are different. It remains, of course, to elucidate the biological details, such as how the opiate response is elicited by the proton transfer and how the equilibrium population of the proton mediates the opiate activity.

Abstract □ The detection of general-base catalysis in the presence of predominating specific-base catalysis in aqueous buffer solutions is examined for various relationships between k^0_{cat} and k^0_{OH}, the bimolecular rate constants for general-base and hydroxide-ion attack. The three experimental variables that affect the detection of buffer-base catalysis are the type of buffer, conjugate-acid concentration, and ionic strength. Various buffers used in pharmaceutical kinetic studies are considered, and it is concluded that buffers with high K_a values favor detection. Additionally, high conjugate-acid concentrations and ionic strengths appear to optimize the detection of general-base catalysis.

Keyphrases □ Catalysis, general base—detection in the presence of specific-base catalysis, theoretical basis, effect of buffer composition, acid concentration, and ionic strength □ Hydroxide catalysis—detection of coexisting general-base catalysis, theoretical basis, effect of buffer composition, acid concentration, and ionic strength

Aqueous stability studies often attempt to quantitate the dependence of an observed first-order rate constant on the concentrations of potential reactants such as hydroxide ions, hydronium ions, and buffer components (1). Failure to accurately define the rate expression or the reaction pathway can preclude the establishment of a reaction mechanism and limit the accuracy of stability predictions.

The quantitative assessment of buffer catalysis in the presence of predominating hydroxide- or hydronium-ion attack is difficult. The reasons are twofold. First, the pH region of greatest instability is also the region where the efficiency of specific catalysts (*i.e.*, hydroxide or hydronium ions) overshadows that of the buffer catalysts. If one attempts to make use of these faster rates to establish the reaction pathways, then buffer catalysis would probably be overlooked. Subsequent stability predictions would then underestimate the long-term rate of drug loss in buffer solutions in the pH region where buffer catalysis can compete with specific catalysis. The second reason is that in the presence of relatively high ionic strength and buffer concentrations, which are needed to quantitatively determine buffer catalysis in the presence of predominating specific-ion catalysis, secondary-type ionic atmosphere effects can occur even at constant ionic strength. These effects cause small pH changes, which tend to obscure buffer catalysis.

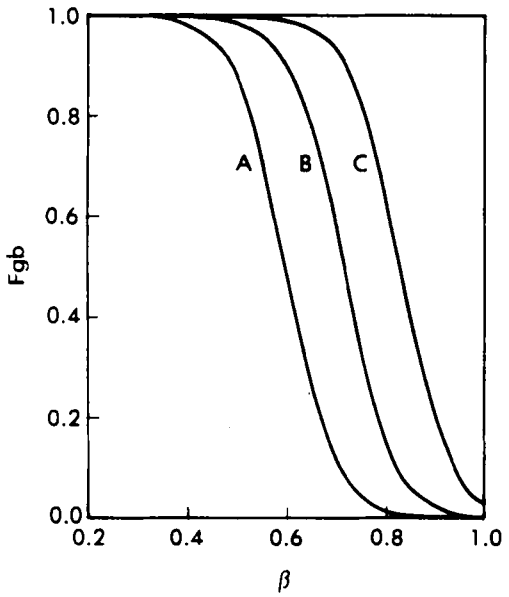

Figure 1—*Fraction of observed general-base catalysis, F_{gb}, as a function of the Brönsted coefficient for a typical buffer (phosphate, pK_a (25°C) = 7.21, p = q = 2). Curves A, B, and C were generated using Eq. 6 and [HB] = 0.01, 0.1, and 1.0, respectively. Ionic atmosphere effects were not included.*

The purpose of this study is to examine the effect of the design of stability studies on the detection of catalysis. A simple rate law was used involving general-base and a related specific-hydroxide degradation pathway. Equations were derived which quantitate the effect of the experimental design on the ability to measure buffer catalysis. Recommendations for detecting buffer-base catalysis in the presence of predominating hydroxide-ion attack are made, and potential problems are examined.

THEORETICAL

Rate Law—When drug degradation is accelerated by general- and specific-base catalysis, the observed first-order rate constant for drug loss, k_{obs}, may be defined:

$$k_{obs} = k^0_{OH}[OH]\frac{\gamma_d\gamma_{OH}}{\gamma_\ddagger} + k^0_{cat}[B]\frac{\gamma_d\gamma_B}{\gamma_{\ddagger'}} \qquad \text{(Eq. 1)}$$

where k^0_{OH} is the bimolecular rate constant for specific-base attack at ionic strength zero, k^0_{cat} is the bimolecular rate constant for general-base attack, [OH] and [B] are specific- and general-base concentrations, γ_d is the activity coefficient of the drug, γ_{OH} and γ_B are the specific- and general-base activity coefficients, and $\gamma_\ddagger$ and $\gamma_{\ddagger'}$ are the transition-state activity coefficients for the specific- and general-base pathways (2). Specific-base attack can involve either nucleophilic hydroxide addition or rate-limiting hydroxide-ion proton abstraction.

General-base catalysis is kinetically indistinguishable from specific-hydroxide and general-acid catalyses (3, 4), which may be defined as:

$$k_{obs(gb)} = \frac{k^0_{cat}K_a}{K_w}[HB][OH^-]\frac{\gamma_{HB}\gamma_{OH}\gamma_d}{\gamma_{\ddagger'}} \qquad \text{(Eq. 2)}$$

where K_a and K_w are the dissociation constants of the buffer and water, and [HB] and γ_{HB} represent the concentration and activity coefficient of the conjugate acid of the base. Division of $k_{obs(gb)}$ by k_{obs} (Eq. 1) yields the fraction due to the general-base pathway, F_{gb}:

$$F_{gb} = \frac{k^0_{cat}[HB]}{\left(\frac{K_w k^0_{OH}\gamma_\ddagger'}{K_a\gamma_{HB}\gamma_\ddagger}\right) + k^0_{cat}[HB]} \qquad \text{(Eq. 3)}$$

The Brönsted relationship may be given by:

$$\log(k/q) = \log GB + \beta(pK_a + \log p/q) \qquad \text{(Eq. 4)}$$

where k is the bimolecular rate constant for the reaction pathway (k^0_{OH} or k^0_{cat}), GB is a constant, β is the Brönsted coefficient, pK_a is the negative logarithm of the dissociation constant for the conjugate acid (and is equal to $pK_w + \log a_{H_2O}$ for hydroxide attack), p is the number of nonequivalent dissociable protons on the conjugate acid base, and q is the number of sites on

0022-3549/84/0600-0724$01.00/0

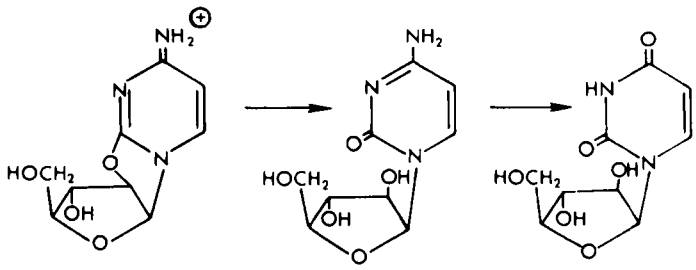

Scheme I

the general base able to accept a proton (3). In practice the Brönsted correlation line may or may not include k^0_{OH}; frequently, specific hydroxide-ion catalysis exhibits negative deviation (3, 4). Assuming that k^0_{OH} is on the Brönsted line made up of k^0_{cat} values allows Eq. 4 to be used to define k^0_{cat} as:

$$k^0_{cat} = k^0_{OH} q \left\{\frac{(p)K_w}{K_a(q)a_{H_2O}}\right\}^{\beta} \qquad \text{(Eq. 5)}$$

and substitution of Eq. 5 into Eq. 3 yields:

$$F_{gb} = \frac{\left\{\frac{(p)K_w}{K_a(q)a_{H_2O}}\right\}^{\beta} K_a[HB]_q}{K_w\left(\frac{\gamma_{t'}}{\gamma_t\gamma_{HB}}\right) + q\left\{\frac{K_w(p)}{K_a(q)a_{H_2O}}\right\}^{\beta} K_a[HB]} \qquad \text{(Eq. 6)}$$

This approach was used to develop the present theory. Where k^0_{OH} values show negative deviation, general-base catalysis will be more readily observed than indicated by this treatment.

DISCUSSION

In Eq. 6, the fraction of general-base attack, F_{gb}, is dependent on the Brönsted coefficient, the activity coefficients for conjugate acid and transition states, the conjugate acid concentration, and the identity of the buffer (*i.e.*, its K_a, q, and p). Initially, for simplicity, it will be assumed that $(\gamma_{t'}/\gamma_t\gamma_{HB}) \cong 1$.

Specific-base attack predominates as the Brönsted coefficient approaches 1. In Fig. 1, F_{gb} is shown as a function of the Brönsted coefficient for a typical general base, dibasic phosphate [$p = q = 2$, pK_a (25°C) = 7.21 (5)], and conjugate acid concentrations equal to 0.01, 0.1, and 1.0 M. The value of F_{gb} decreases sharply when the Brönsted coefficient is between 0.6 and 0.8. A β value of 1.0 is the limiting case, which implies that proton transfer is complete in the transition state (3). Equation 6 then becomes:

$$F_{gb} = \frac{p[HB]}{a_{H_2O} + p[HB]} \qquad \text{(Eq. 7)}$$

Here, except for different p values, all general bases are capable of the same F_{gb} at equal conjugate acid concentrations. Additionally, Eq. 7 shows that for a buffer with $p = 2$, a conjugate acid concentration greater than 9 M is required for 25% buffer-base attack. Clearly this is not experimentally realistic. In contrast, if k^0_{OH} exhibits negative deviation from the Brönsted plot, buffer catalysis may be observed in this limiting case ($\beta = 1.0$). For instance, the log k^0_{OH} value for the conversion of ancitabine to the antileukemic drug cytarabine (Scheme I) was observed to deviate from the Brönsted plot ($\beta \cong 1.0$) by −log 55.

In this case Eq. 6 simplifies to:

$$F_{gb} \cong \frac{p[HB]}{1 + p[HB]} \qquad \text{(Eq. 8)}$$

The prodrug conversion constant in a buffer containing 0.250 M sodium bicarbonate and 0.025 M disodium carbonate ($p = 1$) was observed to be ~24% general-base catalysis (Table I), whereas Eq. 8 predicts 20%.

The value of the Brönsted coefficient will determine whether experimental design is critical in detecting buffer-base attack. The two most important design features are the choice of buffer and concentration of the conjugate acid.

The ability of a buffer to act as a general base is related to the pK_a of its conjugate acid. The larger the pK_a, the better the general base. Therefore, one might expect that general-base attack would be most apparent with an efficient general base such as dibasic carbonate or tribasic phosphate. However, the presence of predominating hydroxide attack, *i.e.*, a Brönsted coefficient of 0.8–1.0, in the high pH range required for the existence of these bases negates the possibility of observing general-base attack. In Fig. 2 the relative amount of general-base attack is shown as a function of the pK_a of the buffer system at three conjugate acid concentrations. Figure 2, generated from Eq. 6 by assuming $p = q = 1$ and $\beta = 0.8$, shows that at a conjugate acid concentration of 0.1 M, general-base catalysis by buffers of p$K_a \geq 7$ cannot be detected. If the conjugate acid concentration is below 0.01 M, it is likely that general-base catalysis will not be detected at $\beta = 0.8$ regardless of the buffer used. In general the lower the pK_a, the more useful the buffer in observing general-base catalysis. By viewing the x-axis in Fig. 2 as a pH scale, the pH region of competitive general-base catalysis can be seen. At lower pH, hydroxide catalysis becomes less effective and, thus, general-base catalysis can become significant.

Figure 3 shows the relationship between F_{gb} and the conjugate acid concentrations for a series of common buffers at $\beta = 0.8$. As the conjugate-acid concentration increases, F_{gb} increases. Thus, doubling the concentration of the general base while maintaining constant conjugate acid concentration will not increase the relative amount of general-base attack. This is due to the fact that such an increase in general-base concentration will also increase the hydroxide-ion concentration.

The kinetics of ancitabine conversion to cytarabine provide an example of the effect of changing conjugate-acid concentrations on F_{gb}. The Brönsted slope for this reaction is approximately one; however, the hydroxide rate constant deviated negatively from the Brönsted plot, allowing general-base catalysis to be observed. The value of k_{obs} is described by Eq. 1 where $k_{OH} = k^0_{OH}\gamma_{OH}\gamma_d/\gamma_t$. The fraction of general-base catalysis, F_{gb}, was determined by estimating k_{OH} from high pH studies and using the following relationship:

$$F_{gb} = (k_{obs} - k_{OH}[OH])/k_{obs} \qquad \text{(Eq. 9)}$$

where [OH] was calculated from measured pH. These values were also approximated using Eq. 8, which allows negative hydroxide rate constant deviation from the Brönsted plot. The agreement between the results (Table I) tends to support the experimental approximations ($\beta \cong 1.0$ and deviation ≅ −log 55) and theoretical considerations (Eq. 6) that were used to derive Eq.

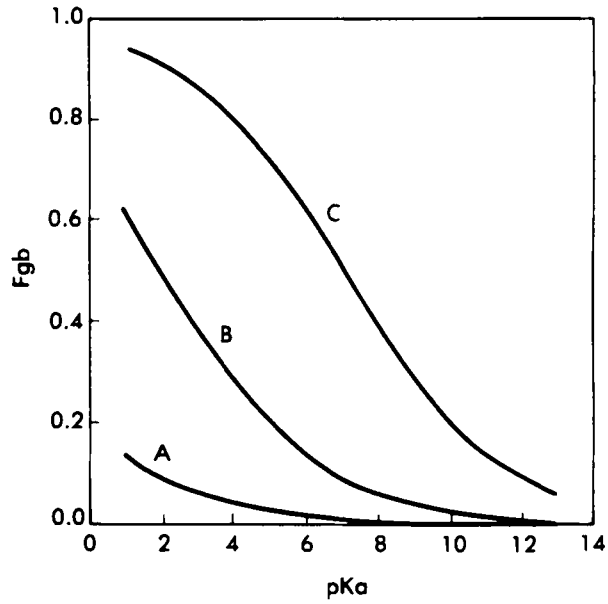

Figure 2—*Fraction of observed general-base catalysis, F_{gb}, as a function of the pK_a of a series of buffer systems. Curves were generated using Eq. 6; p and q were assigned unity and curves A, B, and C correspond to [HB] = 0.01, 0.1, and 1.0, respectively. Ionic atmosphere effects were ignored.*

Table I—Observed First-Order Rate Constants and Fraction of General-Base Catalysis For Ancitabine Prodrug Conversion in Carbonate Buffers at 60°C and μ = 1.0 [a]

[a] Ionic strength adjusted with sodium chloride. [b] Calculated from $k_{OH}(60°C, \mu = 1) = 2.0 \times 10^5\ h^{-1}\ M^{-1}$ and the k_{obs} values using Eq. 9. [c] Calculated from Eq. 8.

8. It is interesting to note that in all of the carbonate buffers used, the concentration of the catalytic buffer base (CO_3^{2-}) was kept constant while the conjugate acid and pH changed (see Table I).

The popular technique of increasing the total buffer concentration while maintaining a constant pH and base-to-acid ratio may or may not allow detection of general-base catalysis. Suppose the Brönsted coefficient is 0.8, and one is attempting to detect base attack using Tris buffers. If constant pH is maintained while the total buffer concentration is increased 10-fold, the conjugate-acid concentration might increase from 0.01 to 0.1 M. The percentage increase in the relative amount of observed general-base catalysis will be only 6% (Fig. 3). Therefore, general-base catalysis would be overlooked. The same technique applied to the monobasic/dibasic phosphate system would result in a 15% increase in k_{obs}, while the formate/formic acid buffer would result in an ~30% increase in k_{obs}.

If one objective in a series of stability studies is to determine buffer-base catalysis, then the approach should be to employ buffers with pK_a values as low as possible using conjugate-acid concentrations as high as is experimentally feasible. Experimental designs which seek to otherwise optimize either the general-base or total buffer concentrations are misdirected.

Activity coefficients are used in Eq. 1 to describe ionic atmosphere effects. Direct extrakinetic measurements of activity coefficients are rare in the pharmaceutical literature. Instead, approximations based on the empirical effect of ionic strength on the logarithm of the activity coefficient of an ion are commonly used (6). Although there are problems associated with these approximations, particularly (as will be discussed later) in solutions of moderately high ionic strength, they conveniently allow the charge of the ion to affect the reaction rate but not its specific chemical identity. By employing ionic strength approximations, salt effects on the two reaction pathways can be evaluated for various combinations of charged and uncharged substrates and buffer components.

As can be seen in Eq. 6, ionic atmosphere effects will influence the relative amount of general-base attack (F_{gb}) to the extent that $\gamma_{\dagger'}/\gamma_{\dagger}\gamma_{HB}$ is affected. Under the ionic strength assumption, ionic atmosphere effects will depend on the charges of the various ions. Since the transition-state charges are equal to the sum of the charges on the reactants (7), the charges on the specific-base ($Z_{\dagger}$) and general-base ($Z_{\dagger'}$) transition states are given by:

$$Z_{\dagger'} = Z_d - 1 \qquad \text{(Eq. 10)}$$

$$Z_{\dagger'} = Z_d + Z_B \qquad \text{(Eq. 11)}$$

where Z_d and Z_B are the charges on the drug and general base and $Z_{OH} = -1$. For a buffer system in which the general base is a monovalent anion and the conjugate acid is neutral (*e.g.*, acetate–acetic acid), $\gamma_{\dagger'}/\gamma_{\dagger}\gamma_{HB} \cong 1$ because $Z_{\dagger'} = Z_{\dagger}$ and $\gamma_{HB} \cong 1$. The value of $\gamma_{\dagger'}/\gamma_{\dagger}\gamma_{HB}$ is also ~1 if the substrate is a monovalent cation, regardless of the charge type of the buffer system. This is because $\gamma_{\dagger'} \cong \gamma_{HB}$ and $\gamma_{\dagger} \cong 1$. In these two situations F_{gb} is unaffected by ionic strength. However, for other combinations of neutral and charged substrates and buffers, the effect of ionic strength can be approximated by using the Güntelberg equation:

$$\log \gamma_i = -Z_i^2 A\sqrt{\mu}/(1 + \sqrt{\mu}) \qquad \text{(Eq. 12)}$$

in which i denotes a central ion, Z_i is the charge on i, A is a function of temperature and solution dielectric constant, and μ is the ionic strength (6).

Table II summarizes the approximated values of $\gamma_{\dagger'}/\gamma_{HB}\gamma_{\dagger}$ for monovalent or neutral substrates and various buffer systems. For neutral or anionic drugs, the effect of increasing ionic strength is to increase F_{gb} if the conjugate buffer acid is anionic and to decrease F_{gb} if the conjugate acid is a cation.

Ionic strength is often maintained constant in pharmaceutical kinetic studies (6). Charged drugs are subject to significant primary and secondary kinetic salt effects which should be quantitated at various fixed ionic strengths or should be normalized by conducting all studies at a constant ionic strength. Uncharged drugs can also be subject to secondary-type salt effects in buffered solutions, and the logarithm of their activity coefficients may display a linear dependence on ionic strength (8).

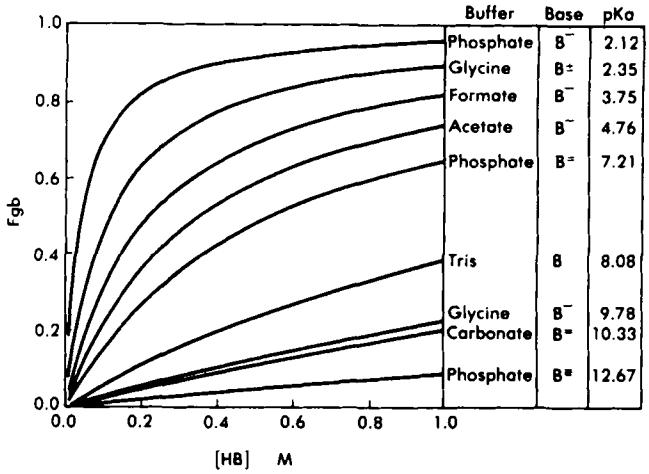

Figure 3—*Fraction of observed general-base catalysis, F_{gb}, as a function of the conjugate-buffer acid concentration for a series of buffers used in pharmaceutical stability studies. Curves were generated using Eq. 6; pK_a (25°C) values were taken from the literature (5). Ionic atmosphere effects were ignored.*

The condition of constant ionic strength sets mathematical limits on the maximum concentration of any given buffer and, thus, sets limits on the maximum F_{gb} value. The maximum concentrations occur in solutions with no added neutral salts. For instance, for a buffer with dibasic and monobasic components such as carbonate or phosphate, the maximum conjugate acid concentration, $[HB]_{max}$, for a fixed ionic strength of μ is given by:

$$[HB]_{max} = \mu - 3[B]_{min} \qquad \text{(Eq. 13)}$$

where $[B]_{min}$ is the minimum concentration of the general base and Eq. 13 was derived using the definition of ionic strength.

To maintain first-order conditions, the attacking species concentrations must be sufficiently higher than the initial substrate concentration to prevent significant loss of buffer catalysts or hydroxide ions. A 5% loss of the attacking species is well within first-order conditions (9). Thus, the minimum general-base concentration should be 20 times that of the initial substrate concentration. Equation 13 can then be written:

$$[HB]_{max} = \mu - 60[D_0] \qquad \text{(Eq. 14)}$$

where $[D_0]$ is the initial drug concentration and is usually selected on the basis of stability-indicating assay detection limits. Since $[HB]_{max}$ can be used in Eq. 6 to calculate the maximum F_{gb} for any given buffer system, a high constant ionic strength chosen by the experimenter will allow for a high maximum F_{gb} value.

CONCLUSIONS

The detection of buffer-base catalysis in the presence of predominating specific-base catalysis is directly influenced by the choice of buffer, conjugate acid concentration, and ionic strength. Two characteristics favor one buffer over another: lower pK_a and, to a lesser extent, the charge types of the buffer base and acid. Despite the fact that buffers with high pK_a values are more efficient general bases, they are unable to compete with hydroxide ions in the pH range where they exist. As can be seen in Fig. 2, it is possible to observe significant buffer-base catalysis in relatively low pK_a buffers.

The ionic charges of the buffer components affect F_{gb} in two ways. First, the maximum conjugate-acid concentration is dependent on the buffer charges, as can be seen in the following equation:

$$[HB]_{max} = \frac{2\mu - \{20(Z_B^2 + |Z_B|)[D_0]\}}{Z_{HB}^2 + |Z_{HB}|} \qquad \text{(Eq. 15)}$$

which is a generalized form of Eq. 14 and was derived from the definitions of ionic strength and first-order conditions. Second, the buffer component charges affect the activity coefficient ratio $\gamma_{\dagger'}/\gamma_{\dagger}\gamma_{HB}$.

The maximum conjugate-acid concentration allows observation of the maximum F_{gb} for any given buffer, and kinetic studies should be conducted near this maximum in order to obtain accurate estimates of k^0_{cat}. Maximum conjugate-acid concentrations are generally ionic strength limited. The higher the ionic strength, the larger the allowable maximum conjugate-acid concentration and, thus, the larger the relative amount of buffer-base catalysis.

Table II—Values for x in the Approximate Equation, $(\gamma_{t^+}/\gamma_t\gamma_{HB}) \cong 10^{x[A\sqrt{\mu}/(1+\sqrt{\mu})]}$, for Monovalent and Neutral Drug in Buffers

Buffer Charges			Values for x Drug Charges		
Base	Acid	Examples (pK_a)	Neutral	Anion	Cation
Monovalent anion	Neutral	Acetate (4.76)	0	0	0
Divalent anion	Monovalent anion	Carbonate (10.33)	−2	−4	0
Trivalent anion	Divalent anion	Phosphate (12.67)	−4	−8	0
Monovalent anion	Zwitterion	Glycine (9.78)	0	0	0
Neutral	Monovalent cation	Tris (8.08)	2	4	0

But, choosing relatively high ionic strength has drawbacks. In particular the ionic atmosphere assumptions used in deriving Eq. 6 tend to fail. In solutions of high ionic strength, the logarithm of an activity coefficient of an ion is not only affected by the ionic strength of the solution, but also by the chemical identities and concentrations of all ions of charges opposite to that of the central ion. This relationship has been empirically described by:

$$\log \gamma_i = \frac{-AZ_i^2\sqrt{\mu}}{1+\sqrt{\mu}} + \sum_j \beta_{ij}C_j \qquad \text{(Eq. 16)}$$

where γ_i is the activity coefficient of an ion i, Z_i is the charge on i, A is a function of the temperature and solution dielectric constant, C_j is the concentration of the jth ion of charge opposite to that of ion i, and β_{ij} is the specific ionic interaction coefficient for ions i and j (7, 10).

The magnitude of the extra-ionic strength salt effects depends on the concentrations of ions and the values of the specific ionic interaction coefficients. One of the major effects of specific ionic interactions in buffer solutions is to cause pH changes at constant ionic strengths. The pH of a buffer solution, such as sodium hydrogen phosphate, sodium dihydrogen phosphate, and sodium chloride, is given by the following equation:

$$pH = pK_a + \log [B]/[HB] + \log (\gamma_B/\gamma_{HB}) \qquad \text{(Eq. 17)}$$

and substitution of Eq. 16 for $\log (\gamma_B/\gamma_{HB})$ yields:

$$pH = pK_a + \log \frac{[B]}{[HB]} - \frac{3A\sqrt{\mu}}{1+\sqrt{\mu}} + \Delta\beta_{Na}[Na^+] \qquad \text{(Eq. 18)}$$

where $[Na^+]$ is the molar concentration of sodium ion and $\Delta\beta_{Na}$ is the difference between the specific interaction coefficient for sodium ion and dibasic and monobasic phosphate ions. For example, the percent change in the hydroxide-ion activity based on measured pH in phosphate buffers at 60°C, wherein the base-acid concentration ratio was kept constant and the ionic strength was kept constant at 1.0, was as much as 80%. The problem of quantitating buffer-base attack in the presence of predominating hydroxide attack is compounded if the hydroxide-ion activity is changing due to specific ionic interactions.

One method of correcting the observed first-order rate constant for the type of secondary ionic atmosphere effect described above has been used in ancitabine hydrolysis studies. It is a general method for cationic substrates that only partly eliminates ionic atmosphere effects at constant ionic strength. It does not correct k_{obs} for specific ionic interactions between the substrate and anions. The approach is to calculate the activity coefficient ratio of the buffer base-acid from experimentally measured pH using:

$$(\gamma_B/\gamma_{HB}) = K_a[HB]/[B]10^{-pH} \qquad \text{(Eq. 19)}$$

Division of k_{obs} as defined in Eq. 1 by Eq. 19 eliminates all activity coefficients except that of the substrate. In the case of ancitabine, it was shown by kinetic measurements in buffers of various ionic strengths that the activity coefficient of the substrate could be approximated by Eq. 12. Similar experimental approaches to the problem of ionic atmosphere effects in solutions of high ionic strength may be necessary to detect buffer catalysis in the presence of predominant specific-acid attack.

Pharmacokinetic Prodrug Modeling: *In Vitro* and *In Vivo* Kinetics and Mechanisms of Ancitabine Bioconversion to Cytarabine

LEE E. KIRSCH * **and ROBERT E. NOTARI** ˣ

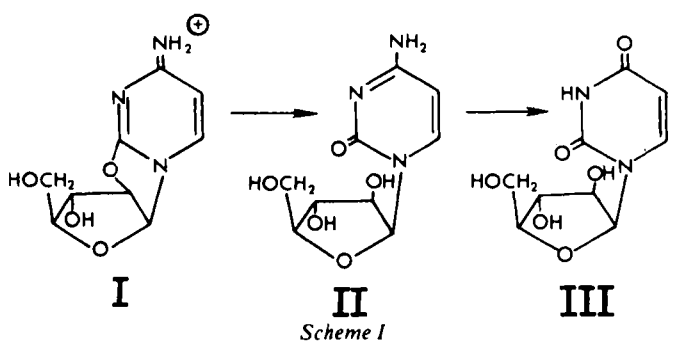
Received November 22, 1982, from the *Lloyd M. Parks Hall, College of Pharmacy, The Ohio State University, Columbus, OH 43210.* Accepted for publication April 18, 1983. *Present address: Product Development Division, Eli Lilly and Company, Indianapolis, IN 46206.

Abstract □ Conversion rates of the prodrug ancitabine to the antileukemic cytarabine have been measured *in vivo* (rabbits) and *in vitro* (in the presence of rabbit blood and human red blood cells, blood, and plasma) using HPLC analyses for the prodrug, drug, and its inactive metabolite, 1-β-D-arabinosyluracil. These observed pH-dependent *in vitro* rate constants were consistent with those for chemical hydrolysis determined from controls using Tris buffers. Hydrolysis of ancitabine to cytarabine is chemically, not enzymatically, mediated. The blood concentration–time course for administered compound was described by a two-compartment open model following a rapid intravenous injection of prodrug, drug, or metabolite in each of three rabbits. The *in vivo* conversion rate constant (k_c) following a rapid intravenous prodrug injection was estimated by simultaneous nonlinear regression of ancitabine and cytarabine blood concentration–time courses using equations for two-compartment prodrug and drug with all possible models describing potential conversion sites. The best fit was obtained for the case allowing simultaneous conversion of the prodrug in both central and peripheral compartments to the drug in the central compartment with a common value for k_c. The resulting k_c value (0.09 h^{-1}, three rabbits) is similar to that for chemical hydrolysis (0.07 h^{-1}) at 38.8°C. Reasons why this agreement is regarded as fortuitous are discussed.

Keyphrases □ Ancitabine—bioconversion to cytarabine, mechanism, *in vivo* and *in vitro* pharmacokinetics □ Prodrug modeling—pharmacokinetics of ancitabine bioconversion to cytarabine *in vivo* and *in vitro*, mechanism □ Pharmacokinetics—prodrug modeling, ancitabine bioconversion to cytarabine *in vivo* and *in vitro*, mechanism

Ancitabine (I) has shown promise as a prodrug of the antileukemic agent, cytarabine (II) in Phase 1 (1, 2) and limited Phase 2 (2) clinical trials in the treatment of human neoplasms which respond to treatment with II. It is resistant to cytidine deaminase which rapidly inactivates II (3–5) to 1-β-D-arabinosyluracil (III) (Scheme I). In theory, the advantage of this prodrug would be to extend the biological duration of cytarabine through rate-limiting conversion (6). However, the acceptability of I is limited by acute vascular instability and parotid pain which have occurred at therapeutic doses (2).

The bioconversion mechanism of I was reported to be chemically rather than enzymatically mediated (7, 8). However, these studies report some striking dissimilarities in observed reversal rates. Wang *et al.* (7) reported 50% conversion of I to II within 6 h in mouse plasma while Ho (8) reported 45–93%, 40–55%, and 43% conversion within 1 h in human, dog, and mouse plasma. Thus, the first-order rates for hydrolysis of I based on the data reported by Ho were ~5–20 times faster than that based on data of Wang *et al.* (7). Despite this, both reports concluded that prodrug reversal was chemically mediated based on the observation that preboiling the plasma resulted in little or no decrease in hydrolysis rates.



Scheme I

An *in vitro* first-order hydrolysis rate constant derived from the data of Ho was employed in a physiological pharmacokinetic model (9). The first-order hydrolysis rate constant value of 0.3 h^{-1}, which may be calculated from data presented by Ho in Fig. 6 (8) for *in vitro* hydrolysis in human plasma, did not describe the human blood concentration–time course for I and II as well as did the value 0.6 h^{-1}. This was taken as evidence that *in vivo* hydrolysis is somewhat faster than that seen *in vitro* (9).

The goals of the present study were: (*a*) to compare the conversion rates of I in blood and plasma with those predicted from aqueous hydrolysis kinetics, (*b*) to estimate the value of the *in vivo* conversion constant using classical pharmacokinetic modeling, and (*c*) to compare the observed and predicted conversion rates with those previously reported.

EXPERIMENTAL

Analytical Methods -A previously reported UV differential assay was used to measure the conversion of I to II in aqueous Tris buffers (10). Biological samples were assayed using reverse-phase HPLC. A fixed-wavelength UV detector and 20-μL sample injector loop were used in conjunction with a 3-cm precolumn and 15-cm analytical column[1]. Sodium heptanesulfonate was used as an ion-pairing agent, and *p*-hydroxybenzoic acid was the internal standard.

Cells were separated from plasma by centrifugation[2]. Plasma proteins were precipitated with 40 μL of 20% trichloroacetic acid/0.25 mL of plasma. The precipitate was removed by centrifugation, and the supernatant was filtered using a microfilter with a 0.2-μm cellulose filter membrane[3]. The filtered samples were assayed using one of three mobile phases at a flow rate of 1.2 mL/min. System A was 0.01 M acetic acid, 0.001 M sodium acetate, 0.005 M sodium heptanesulfonate, and 6% v/v methanol; the detection wavelength was 254 nm. System B was the same except that sodium acetate was 0.01 M. System C was identical to B except that 1% v/v methanol was used, and the detection wavelength was 280 nm.

The HPLC columns were preequilibrated with mobile phase for 12–24 h. Calibration curves were prepared daily from biological fluids spiked with known concentrations of I, II, III, and the internal standard. Two linear plots of peak height ratios *versus* the known concentrations were prepared for each compound in the ranges of 10^{-6}–10^{-4} and 10^{-4}–5×10^{-3} M.

***In Vitro* Kinetic Studies**—Tris buffers were prepared by weighing the free base and hydrochloride salt into double-distilled deionized water to give solutions of the following molar concentrations (base/acid): 0.016/0.084, 0.061/0.0388, and 0.085/0.0156. Sodium chloride was added to adjust the ionic strength to 0.15, which is the approximate value for plasma (11). Reaction solutions were maintained in closed water-jacketed beakers at 38°C, which is between the normal body temperature of humans (37°C) and rabbits (38.8°C) (12). Reactions were initiated by introducing an aliquot of a stock

[a] Concentrations are in M and dose is mol/kg because these units, unlike mass per volume or body weight, are meaningful in considering prodrug → drug stoichiometry. [b] Data points were not used in estimating k_c as explained in the *Results*.

solution of I to give a reaction concentration of 8×10^{-4} M. Samples were removed as a function of time and quenched with 0.1 M HCl. The reaction pH was measured before and after each kinetic run.

Blood was obtained from heparinized rabbits[4] *via* venipuncture of the marginal ear vein. Human venous blood was obtained from healthy volunteers and was heparinized. Heparin solutions were freshly prepared from the sodium salt because commercially available heparin injection USP contains methyl- and ethylparabens as preservatives; the parabens were observed to degrade to the internal standard, *p*-hydroxybenzoic acid. Blood which was not immediately used was refrigerated.

Biological fluids were prepared from heparinized whole human blood which was diluted to 10, 20, and 37% v/v in isotonic phosphate buffer. Human plasma and red blood cells were obtained from heparinized blood by centrifugation. Plasma was similarly diluted in isotonic phosphate buffer to 10, 20, or 37% v/v, while cells were diluted in isotonic saline to 5, 10, and 18% v/v. Although deamination of II has not been reported in human plasma, all dilutions of biological fluids were spiked with the deaminase inhibitor tetrahydrouridine to a final concentration of 1×10^{-4} M as a precaution. Rabbit plasma and heparinized whole blood were diluted to 67% v/v with isotonic saline. One reaction rate, measured in tetrahydrouridine-spiked rabbit blood and in unspiked diluted rabbit blood, showed no apparent change.

These dilutions were maintained at 38°C in water-jacketed beakers, which were stirred and closed. Reactions were initiated by addition of a solution of I to a final concentration of $\sim 1 \times 10^{-3}$ M. Aliquots were withdrawn at appropriate time intervals. Samples of whole blood and resuspended cells were immediately chilled on ice to quench the reaction, whereas plasma was quenched with trichloroacetic acid. Samples were prepared and assayed using the aforementioned HPLC procedures. The pH values of the solutions were determined at frequent intervals.

***In Vivo* Kinetic Studies**—Rabbits[4] were weighed and placed in a restraining cage[5]. Animals were heparinized (1000 U/kg of body weight) with freshly prepared heparin in sterile normal saline. A catheter attached to a sampling port[6] filled with 0.3 mL of 0.1% (w/v) heparin in normal saline was inserted into a peripheral ear artery. A sample of blood (3–5 mL) was withdrawn *via* the catheter after first removing and discarding the heparin solution and five volumes of blood totalling 1.5 mL. This preinjection blood sample was assayed as a blank and also used to prepare the standard curves with known amounts of internal standard and I, II, and/or III. After the blank was withdrawn, 0.5 mL of 0.1% heparin was placed into the port.

For each experiment, solutions of I, II, or III in sterile normal saline were injected *via* the peripheral vein in the ear opposite to that of the arterial catheter. Samples of 0.5 mL were taken at appropriate intervals *via* the arterial catheter using the procedure outlined above for the preinjection blood samples. The samples were placed in microcentrifuge tubes[7] containing 20 μL of the internal standard solution (0.25 mg/mL) and 5 μL of 0.2 M tetrahydrouridine and kept on ice until sample preparation was initiated.

Three animals were used, each of which was given an intravenous bolus dose of I, II, and III (Tables I, II, and III) with sufficient time between experiments to prevent residual blood levels from the previous study. Samples were assayed as described above for I, II, and III.

ference, and two wavelengths (254 and 280 nm) were used to increase sensitivity. The detection ranges are given in Table IV. The lower limit of III was somewhat higher than for I or II because of background interference near the solvent front where III eluted (see capacity factors, Table IV).

During sample preparation, the treatment of plasma with trichloroacetic acid, in addition to precipitating plasma proteins, effectively quenched the conversion of I to II because I is relatively acid stable (10). This was confirmed by quantitative recovery of I from spiked plasma. Trichloroacetic acid was not added directly to blood samples because the resultant cell lysis caused unacceptable background. Instead, blood samples were kept on ice until plasma was separated by centrifugation. To test the effectiveness of the ice-bath quench, synthetic mixtures of I and II were spiked into fresh rabbit blood in concentrations similar to those observed for the first three samples of the intravenous prodrug studies (Table I) and were maintained in an ice bath for periods of time which simulated actual experimental conditions. Controls containing equivalent concentrations of I in blood and in Tris buffer (pH 7.4 at 38°C) were similarly stored. All samples were then prepared and assayed as described under *Experimental*. The mixture (1.1×10^{-3} M I, 2.5×10^{-5} M II) representing the first time point, which was stored for the longest period of 1 h, allowed <2% conversion of I to II. However, this produced a peak height for II which was 70% of those observed for the controls. Therefore, the initial assays for II (labeled as footnote b in Table I) were not used. For the remaining mixtures and storage periods, the peak heights for II in the controls were <15% of that observed in the samples. The rest of the data for II in Table I were therefore used without correction.

***In Vitro* Conversion Kinetics**—Mass balance was confirmed by the sum of the time-dependent concentrations of I and II; III was not detected in any of the reactions. Good first-order plots were obtained for reactions in Tris buffers and diluted whole blood according to:

$$\ln [I] = \ln [I_0] - k_{obs}t \qquad \text{(Eq. 1)}$$

where [I] and $[I_0]$ are the concentrations of I at time t and zero and k_{obs} is the apparent first-order conversion rate constant (Fig. 1).

First-order plots using plasma data showed significant negative deviation (Fig. 1). This was due to an increase in pH with time, thus increasing the hydroxide-ion activity (a_{OH}) which is the dominant catalytic species in aqueous solutions (10). To show that the rate in plasma was consistent with that for chemical hydrolysis, a_{OH} was calculated from measured pH and incorporated into:

$$\frac{-d[I]}{dt} = k_{OH}a_{OH}[I] \qquad \text{(Eq. 2)}$$

The resulting value for the bimolecular rate constant, k_{OH}, agreed with that observed in aqueous solutions (10).

Pharmacokinetics of II and III—The blood concentrations of II (Table II) and III (Table III) arising from rapid intravenous doses (D) of II and III were fitted using NONLIN (13) and Eq. 3:

$$C_1 = \frac{D}{V_1}\left\{\frac{(k_{21}-\alpha)}{(\beta-\alpha)}e^{-\alpha t} + \frac{(k_{21}-\beta)}{(\alpha-\beta)}e^{-\beta t}\right\} \qquad \text{(Eq. 3)}$$

which describes the time-dependent central compartment concentration (C_1) according to a two-compartment open model (Scheme II) where A1 and A2 are the amounts of drug in the central and peripheral compartments and:

$$\alpha,\beta = 0.5\{(k_{12}+k_{10}+k_{21}) \pm \sqrt{(k_{12}+k_{10}+k_{21})^2 - 4k_{21}k_{10}}\} \qquad \text{(Eq. 4)}$$

The estimated parameters are given in Table V.

Table IV—HPLC Analyses for I, II, and III in Biological Fluids

Compound	λ_{max}[a], nm	HPLC System	Capacity Factors	Detection Ranges, 10^4 M	*CV*, %[b]
I	264	A	6.8	1.0-30.0	4.0

II	280	A	9.7	1.0-30.0	6.4
		C	13.7	0.010-4.0	3.9
III	260	C	4.3	0.050-4.0	6.1

[a] UV wavelength of maximum absorptivity in 0.1 M HCl. [b] Coefficient of variation is based on peak height ratios from five analyses of rabbit blood samples containing 10 μg/mL of the compound.

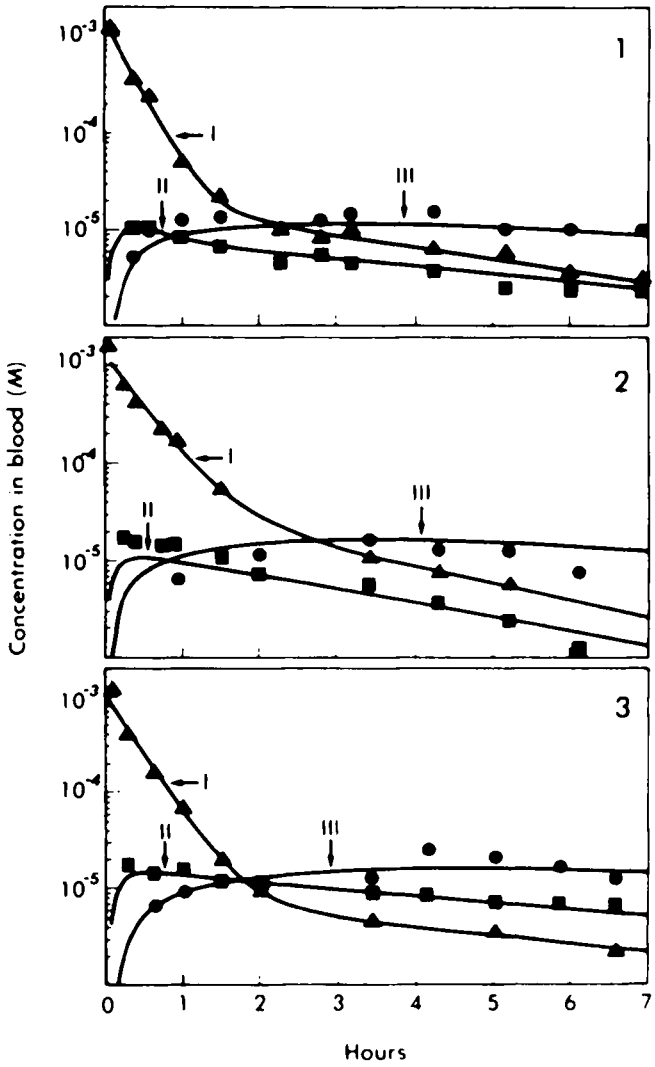

Figure 2—*Time courses for concentrations of I (▲), II (■), and III (●) following administration of 3.8 × 10^{-4}-mol/kg iv doses of I to rabbits 1, 2, and 3. Curves are based on NONLIN (13) fits using Eqs. 5, 6, and 7 for I, II, and III, as described in Scheme III.*

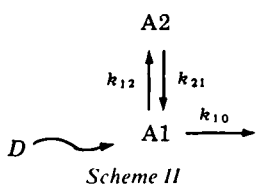
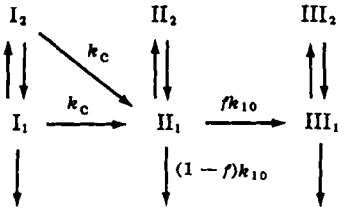
Prodrug Pharmacokinetics—Attempts were made to describe the blood concentrations of I and II arising from doses of I (Table I) using four different models. The elimination (k_{10}) and distribution (k_{12} and k_{21}) parameters of II were fixed at the values obtained from the NONLIN estimates using Eq. 3 following an intravenous dose of II. The elimination and distribution parameters of I (k_c, k'_{10}, k'_{12}, k'_{21}, and V'_1) were adjusted by NONLIN. The four models differed in their routes for prodrug conversion. The simplest model



Scheme II



Scheme III

allowed conversion from I_1 to II_1 only. In the other models conversion was set at $I_1 \rightarrow II_1$ and $II_2 \rightarrow II_1$ (see Scheme III); $I_1 \rightarrow II_1$, $I_2 \rightarrow II_1$, and $I_2 \rightarrow II_2$; or $I_1 \rightarrow II_1$ and $I_2 \rightarrow II_2$. NONLIN fits limiting conversion to $I_1 \rightarrow II_1$ with or without $I_2 \rightarrow II_2$ consistently underestimated the concentration of II, while those using all three routes ($I_1 \rightarrow II_1$, $I_2 \rightarrow II_1$, and $I_2 \rightarrow II_2$) significantly underestimated data for the terminal phase of I_1. However, Eqs. 5–7, based on Scheme III, yielded excellent fits to the blood concentration data for I and good fits for II (Fig. 2):

$$[I] = \frac{D}{V'_1}\left\{\left[\frac{(k_c + k'_{21} - \alpha')}{(\beta' - \alpha')}\right] e^{-\alpha' t} + \left[\frac{(k_c + k'_{21} - \beta')}{(\alpha' - \beta')}\right] e^{-\beta' t}\right\} \quad \text{(Eq. 5)}$$

$$[II] = \frac{Dk_c}{V_1}\left\{\left[\frac{(k_{21} - \alpha)(k_c + k'_{21} + k'_{12} - \alpha)}{(\beta' - \alpha)(\alpha' - \alpha)(\beta - \alpha)}\right] e^{-\alpha t} + \left[\frac{(k_{21} - \beta)(k_c + k'_{21} + k'_{12} - \beta)}{(\beta' - \beta)(\alpha' - \beta)(\alpha - \beta)}\right] e^{-\beta t} + \left[\frac{(k_{21} - \beta')(k_c + k'_{21} + k'_{12} - \beta')}{(\alpha' - \beta')(\alpha - \beta')(\beta - \beta')}\right] e^{-\beta' t} + \left[\frac{(k_{21} - \alpha')(k_c + k'_{21} + k'_{12} - \alpha')}{(\beta' - \alpha')(\alpha - \alpha')(\beta - \alpha')}\right] e^{-\alpha' t}\right\} \quad \text{(Eq. 6)}$$

where α' and β' refer to I and are defined as:

$$\alpha', \beta' = 0.5\{(k'_{21} + k'_{12} + k'_{10} + 2k_c) \pm \sqrt{(k'_{21} + k'_{12} + k'_{10} + 2k_c)^2 - 4[k_c^2 + k_c(k'_{10} + k'_{12} + k'_{21}) + k'_{21}k'_{10}]}\} \quad \text{(Eq. 7)}$$

and α and β are defined in Eq. 4. Allowing unequal k_c values for conversion of $I_2 \rightarrow II_1$ and $I_1 \rightarrow II_1$ did not improve these fits.

The common method for calculating f, the fraction of II that is metabolized to III, is to determine the area under the concentration–time curve for III following an intravenous dose of II (14). Since the duration of III was long relative to I and II and the research goals did not require an accurate assessment of f, the terminal data for III were obtained only after intravenous doses of III. The observed concentration–time course for III, following an intravenous dose of I, was then described by reiterating f values in:

$$[III] = \frac{Dk'_c f k_{10}}{V_1^*}\left\{\left[\frac{(k_{21} - \alpha')(k^*_{21} - \alpha')(k_c + k'_{21} + k'_{12} - \alpha')}{(\beta' - \alpha')(\alpha - \alpha')(\beta - \alpha')(\alpha'' - \alpha')(\beta'' - \alpha')}\right] e^{-\alpha' t} + \left[\frac{(k_{21} - \alpha)(k^*_{21} - \alpha)(k_c + k'_{21} + k'_{12} - \alpha)}{(\alpha' - \alpha)(\beta' - \alpha)(\beta - \alpha)(\alpha'' - \alpha)(\beta'' - \alpha)}\right] e^{-\alpha t} + \left[\frac{(k_{21} - \alpha'')(k^*_{21} - \alpha'')(k_c + k'_{21} + k'_{12} - \alpha'')}{(\alpha' - \alpha'')(\beta' - \alpha'')(\alpha - \alpha'')(\beta - \alpha'')(\beta'' - \alpha'')}\right] e^{-\alpha'' t} + \left[\frac{(k_{21} - \beta')(k^*_{21} - \beta')(k_c + k'_{21} + k'_{12} - \beta')}{(\alpha' - \beta')(\alpha - \beta')(\beta - \beta')(\alpha'' - \beta')(\beta'' - \beta')}\right] e^{-\beta' t} + \left[\frac{(k_{21} - \beta)(k^*_{21} - \beta)(k_c + k'_{21} + k'_{12} - \beta)}{(\alpha' - \beta)(\beta' - \beta)(\alpha - \beta)(\alpha'' - \beta)(\beta'' - \beta)}\right] e^{-\beta t} + \left[\frac{(k_{21} - \beta'')(k^*_{21} - \beta'')(k_c + k'_{21} + k'_{12} - \beta'')}{(\alpha' - \beta'')(\beta' - \beta'')(\alpha - \beta'')(\beta - \beta'')(\alpha'' - \beta'')}\right] e^{-\beta'' t}\right\} \quad \text{(Eq. 8)}$$

which is based on Scheme III wherein α'' and β'' refer to III as evaluated in Eq. 3. All pharmacokinetic values were those previously obtained, while the value for f was manually adjusted between its limits, $0 \le f \le 1$. The best fits (Fig. 2), assessed by visual inspection, were obtained as f approached 1 (Table V).

DISCUSSION

***In Vitro* Conversion**—The pH–rate profile for the hydrolytic conversion of I in the temperature range of 19–80°C, at ionic strengths (μ) of 0.01–1.5 and pH values from 1 to 12 can be constructed by plotting the logarithm of the apparent first-order rate constant (k_{app}) calculated from Eq. 9 *versus* pH:

$$k_{app}\,(\text{in h}^{-1}) = 1.74 \times 10^{17}\, a_{OH} \times \exp\left\{\frac{-1.15\sqrt{\mu}}{1 + \sqrt{\mu}} - \frac{8662}{T}\right\} + 1.12 \times 10^{11} \exp\{-10121/T\} \quad \text{(Eq. 9)}$$

where T is absolute temperature. The accuracy of Eq. 9 is generally good (10). The average deviation between calculated and observed rate constants in aqueous solutions is <20%. The line in Fig. 3 represents the calculated pH–rate profile for chemical conversion at 38°C, $\mu = 0.15$, using Eq. 9. Agreement with the observed constants from studies in Tris buffers (Fig. 3) substantiates the accuracy of the predictive equation.

Each bimolecular rate constant from the three human plasma dilutions was multiplied by a_{OH} for the median pH value of the run. The logarithm of these pseudo first-order constants, together with the k_{obs} values obtained in diluted human blood, red blood cells, and rabbit blood are shown in Fig. 3 as a function of pH. These data agree with those for chemical conversion. The slight positive deviations were independent of the concentration of biological fluid and solids in the dilutions. Therefore, it is concluded that the mechanism of prodrug conversion in human and rabbit blood is chemical hydrolysis.

The results of this study were compared with those in the literature by approximating first-order conversion rate constants from reported data using:

$$k_{app} = \ln(F_r)/t_i \quad \text{(Eq. 10)}$$

where F_r is the reported fraction of $[I_0]$ remaining at the end of the incubation period, t_i. This assumes first-order kinetics and constant pH and mass balance based on [I] and [II]. Based on this study, the first and last assumptions are probably valid. The logarithms of the calculated k_{app} values are plotted in Fig. 3 at the reported pH. The data of Wang *et al.* (7) agree with the results obtained in this study, as do the Tris buffer studies of Ho (8). However the k_{app} values calculated from the biological fluid data of Ho show a large positive deviation.

An unequivocal explanation of the large positive deviation is not possible. However it is likely that chemical conversion continued after the incubation period, which would result in erroneously high rate constants. Ho employed ethanol to quench the reactions. The rate constants for conversion at room temperature in cleaned plasma (the supernatant of plasma treated with ethanol) were determined for comparison. These rate constants, shown in Fig. 3, are similar to those based on data reported by Ho, but much larger than those predicted for hydrolysis at 38°C. The methods of quenching used in this paper (acidification or chilling) were shown to be 100 and 98% effective, respectively.

***In Vivo* Conversion**—The kinetics of simultaneous hydrolysis and distribution in an isobutyl alcohol–aqueous acid two-phase transfer cell behave like the two-compartment open model shown in Scheme II (15). The time-de-

[c] Based on dose-adjusted (3.8×10^{-4} mol/kg) AUC values for drug after intravenous administration of prodrug (AUC_{pd}) and drug (AUC_d) where f_c, the fraction of prodrug converted to drug, is $(AUC_{pd})/(AUC_d)$ and values (in 10^5 mol·h/kg) are: (4.1/64), (4.2/55), and (9.0/74). [d] From NONLIN fit of [III] time course arising from an intravenous bolus dose of III (Table III) except for f, which was estimated as described in the *Results*. [e] Value of NONLIN estimate after adjustment to accommodate [III] time course arising from an intravenous bolus dose of I. Reported value is within the 95% confidence interval of the original NONLIN estimate.

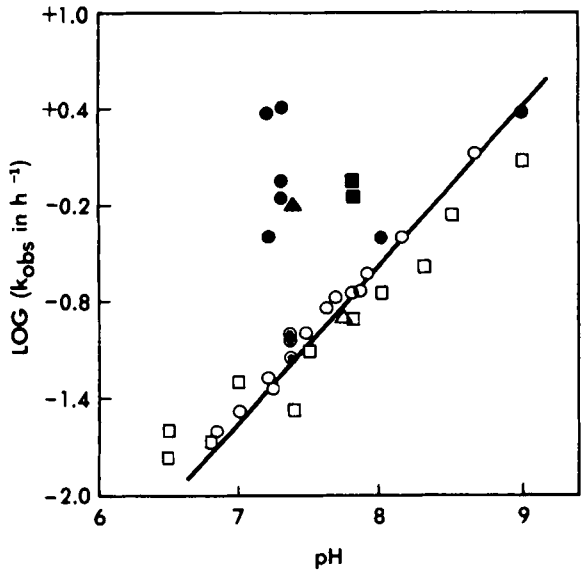

Figure 3—*The pH-rate profile for the conversion of I in rabbits (◎) and* in vitro. *The line represents chemical conversion in aqueous solution at 38°C, μ = 0.15, calculated by Eq. 9. The* in vitro *rate constants are: (○) Tris buffers, diluted human red blood cells, blood, and plasma; (△) diluted rabbit blood; (■) human plasma treated with ethanol; calculated by applying Eq. 10 to the data of (□) Wang* et al. *(7) and (●) Ho (8); (▲) applied to a physiological pharmacokinetic model by Himmelstein and Gross (9).*

pendent concentrations in the aqueous phase were described by Eq. 3, which employed the first-order rate constants for distribution (k_{12} and k_{21}) and hydrolysis (k_{10}). Hydrolysis rate constants (k_h) measured independently in aqueous acid controls agreed with the k_{10} values, which were dependent on acid concentration but independent of stirring rate, which increased k_{12} and k_{21}. Thus, the hydrolysis rate constant can be calculated from the biexponential aqueous phase data using Eq. 3 without any knowledge of the volumes in the transfer cell. The application of an *in vitro* hydrolysis rate constant to an *in vivo* classical pharmacokinetic model would require the achievement of a constant homogeneous apparent volume of distribution in a manner kinetically analogous to the transfer-cell experiments. Thus, if a chemically reversing prodrug were uniformly distributed in a fixed aqueous volume (such as extracellular fluid) with little tissue or plasma protein binding, one would expect its *in vitro* conversion constant to agree with the mechanistically related *in vivo* pharmacokinetic microconstant. *A priori*, ancitabine (I) appeared to possess the pharmacodynamic properties required to demonstrate such a correlation. It does not readily enter cells or deposit into fat (16–18) and its *in vivo* conversion is chemical hydrolysis.

It was not possible to achieve this result with data from rabbits. Although the *in vivo* conversion constants (k_c) agree with those for chemical hydrolysis (Fig. 3), the model of best fit required conversion of both I_1 and I_2 to II_1. A physiological interpretation of the resulting model (Scheme III) is not possible. The average model-independent *Vd* value for I (calculated from CL/β) is 2.9 L/kg, which is larger than that for II (1.4 L/kg) and much greater than the total body water (0.7 L/kg) for rabbits (19). Thus, one (or more) of the requirements for a meaningful correlation is absent, and the observed agreement between the *in vivo* and *in vitro* hydrolysis rate constants must be regarded as fortuitous.

In Fig. 3, the rate constant successfully used by Himmelstein and Gross (9) shows a large positive deviation from the rate constants for chemical, *in vitro* (blood), and *in vivo* (rabbit) conversion. An increased value for the *in vivo* rate constant over the initial *in vitro* estimate based on the results of Ho caused the authors to conclude that hydrolysis occurs somewhat faster *in vivo*. Another explanation for the successful prediction of concentration–time profiles of I and II in humans using high k_c estimates in the physiologically based model might be that the distribution volume for I was underestimated. Since the apparent first-order rate constant is always multiplied by the volume of the specific tissue to obtain a corresponding clearance value, an underestimate in the total volume of distribution would require an overestimate in the conversion constant in order to describe the data. The volume of distribution for I, which was unknown in humans, was assigned a value equal to that for II. The average *Vd* for I in rabbits is twice the value for II. This could explain the successful fit obtained with the high hydrolysis rate constant if the same trend holds in humans. Thus, the conclusion that *in vivo* hydrolysis is somewhat faster than hydrolysis *in vitro* was speculative. No conformatory evidence of facilitated *in vivo* conversion was found in the present study. While both the physiologically based model and the classical model described the *in vivo* data, neither was based on physiological actuality.

The hypothesis that prolonged duration of I is due to the slow hydrolytic conversion of I to II, as proposed by Ho (8) and supported by Himmelstein and Gross (9), is corroborated by the present study. The terminal half-life of II from an intravenous dose of I (Fig. 2, average $t_{0.5} \cong 5$ h) is three times that observed following an intravenous dose of II.

Evaluation of the Bioavailability of a Solid Dispersion of Phenytoin in Polyethylene Glycol 6000 and a Commercial Phenytoin Sodium Capsule in the Dog

S. STAVCHANSKY ˣ and WALTER G. GOWAN

Received November 29, 1982, from the *College of Pharmacy, Drug Dynamics Institute, The University of Texas, Austin, TX 78712.* Accepted for publication April 6, 1983.

Abstract □ In this study a solid dispersion of phenytoin in polyethylene glycol 6000 was prepared by the melt method. The content uniformity of the dispersion indicated a range of 98.7–102.0%. X-ray crystallographic data showed no changes in the crystalline structure of the phenytoin in the dispersion when compared with that in the bulk reagent. Scanning electron micrographs of the dispersion show a reduction in the size of the crystals when compared with the bulk reagent. The commercial product and the dispersion were compared using the USP criteria for the prompt phenytoin sodium dissolution test. The salt dissolved at a rate four times greater than the dispersion. Bioequivalency comparisons between the dispersion containing phenytoin and the commercial prompt phenytoin sodium were studied in six mixed-breed dogs. All samples were analyzed using a commercial enzyme immunoassay system. Statistical analysis of the plasma levels obtained from the animal studies indicate no significant differences ($p > 0.05$) between area under the curve, maximum plasma concentration, and time to peak for the commercial salt and the acid formulation.

Keyphrases □ Phenytoin—bioavailability of the acid and sodium salt in dogs, comparison with *in vitro* dissolution data □ Dissolution—phenytoin and phenytoin sodium *in vitro*, comparison to the *in vivo* bioavailability in dogs

The use of finely subdivided or micronized particles as a means of increasing the rate of dissolution has been considered (1–4). Theoretically, if the dissolution rate is enhanced, the oral absorption rate should be increased if the absorption process is dissolution rate limited. Sekiguchi *et al.* proposed using an inert water-soluble material as a vehicle for a poorly water-soluble drug to enhance the rate and extent of the absorption of the drug (5, 6). Several carriers have been employed to prepare solid dispersions. The most successful include polyethylene glycols (7–11), urea (12), dextrose (12), citric acid (12), succinic acid (13), and polyvinylpyrrolidone (14, 15). Polyethylene glycols have been used to increase the dissolution rate of griseofulvin (7), coumarin (8), dicumarol (9), indomethacin (10), and glyburide (11).

Phenytoin is practically insoluble in water (≅14 μg/mL) at room temperature (16), whereas the solubility of phenytoin sodium is ~66 g/dL in water (17). This difference in solubility results in higher bioavailability for the salt (18–20). If the poor solubility of phenytoin in GI fluids is partially responsible for the great variability observed in phenytoin dosing, then enhancing the dissolution step may result in a more uniform absorption and improved bioavailability.

The purpose of this study is to evaluate the bioavailability in dogs of a phenytoin solid dispersion in polyethylene glycol 6000 using a commercial prompt phenytoin sodium capsule as the reference formulation. Data are presented which indicate that the phenytoin dispersion is bioequivalent to the commercial prompt phenytoin sodium, which is contrary to what one would expect based on the *in vitro* data obtained from the USP dissolution test for phenytoin sodium. The designation "prompt" refers to the fast dissolution category of phenytoin sodium set forth in the USP XX.

EXPERIMENTAL

Preparation of Formulation—A 40% (w/w) solid dispersion of phenytoin[1] in polyethylene glycol 6000[2] was prepared using a melt method. The polymer was melted in a beaker on a thermostatically controlled hot plate at ~65–70°C. The reagent phenytoin was added with constant stirring until a clear liquid was observed. This liquid was poured into a glass mortar which was encased in ice. Solidification of the melt occurred on contact. The mass was dried in an oven at ~40°C for at least 1 h to remove excess moisture. The melt was triturated and then dried for at least 6 h. The powder was sieved through a 60-mesh sieve, and the batch was divided into 750-mg units.

Content Uniformity—Five of the 750-mg units of the phenytoin–polyethylene glycol 6000 dispersion were each dissolved in 1000 mL of 0.1 M NaOH, pH 12.5, in volumetric flasks. Duplicate samples were assayed using a commercial enzyme immunoassay[3]. The five determinations resulted in 98.7–102.0% of the theoretical amount.

Key: (●) 100 mg of prompt phenytoin sodium; (▲) 230 mg of 40% solid dispersion of phenytoin in polyethylene glycol 6000; (◆) 92 mg of the reagent phenytoin. Bars represent 1 SD.*

Assay Procedure—A commercial enzyme immunoassay technique was utilized to assay all samples. This technique has been shown to be comparable in specificity and reproducibility (21, 22) to RIA (21, 23) and GC (21–24), and superior to spectrophotometry (21, 23). The range recommended was expanded by adding or deleting one dilution. Calibrated solutions provided by the manufacturers were used to check the effect of dilutions of samples on accuracy. A coefficient of variation of <10% was observed in each procedure.

Electron Microscopy—The sizes of the various particles were estimated by observation under a scanning electron microscope. Figure 1 shows a sample from the reagent phenytoin. A great variability in dimensions is observed. Figure 2 is a micrograph of the dispersion particles. The large particles are ~10 × 40 μm with several smaller fragments.

Dissolution Studies—Six 100-mg capsules of the commercial prompt phenytoin sodium were compared with six 92-mg samples of the reagent phenytoin and six 230-mg samples of the 40% (w/w) solid dispersion. All

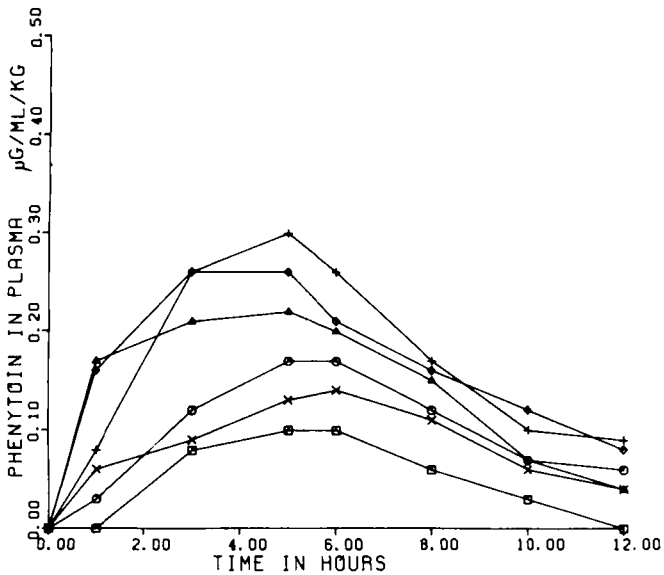

Figure 4—*Observed plasma concentrations of phenytoin obtained from six dogs (13–24 kg). Each animal received 300 mg of the prompt phenytoin sodium.*

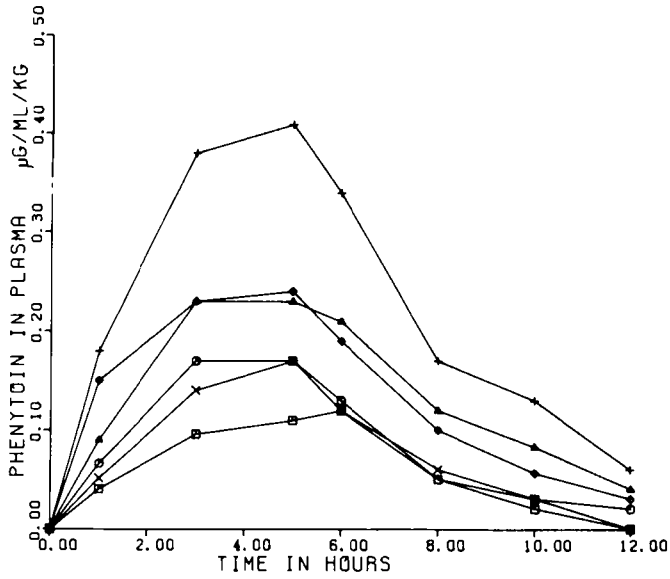

Figure 5—*Observed plasma concentrations of phenytoin obtained from six dogs (13–24 kg). Each animal received 750 mg of the 40% phenytoin solid dispersion.*

samples, equivalent to 92 mg of the phenytoin, were placed in size 1 gelatin capsules. The dissolution criteria were those stipulated for the oral phenytoin sodium in the USP XX. Duplicate samples were drawn and filtered through 0.45-μm filters[4], and were assayed at least twice. An additional study of six intact commercial prompt phenytoin sodium capsules using the same criteria was also performed.

X-ray Diffraction—Spectra were obtained from the reagent phenytoin, polyethylene glycol 6000, and the dispersion. A scanning rate of 3°/min was made from 6° to 70°. The minimum peak height was 2% of the reference peak. Spectra indicate that the phenytoin in the dispersion is the same crystalline form as that in the reagent. Also, no change was noted in the polyethylene glycol 6000 spectra.

Bioequivalence Studies—Six mixed-breed dogs (three of each sex), ~13–24 kg in weight, were used in this study. The animals were housed at the Animal Resources Center, The University of Texas. The dogs were fasted overnight prior to drug administration; water was allowed *ad libitum*. Each animal received 30 mL of water prior to and immediately after oral administration. The dogs were observed for 30 min and then returned to their cages for blood sampling.

The experimental design in the study is a balance of preparations over weeks and each animal received each preparation. The design was repeated twice for a total of two Latin squares. Two dogs received either 300 mg of the commercial prompt phenytoin sodium, 300 mg of phenytoin in the 40% dispersion, or 300 mg of a commercial intravenous phenytoin sodium on each study day. Studies were separated by 1-week wash-out periods to allow for drug elimination as well as to allow for stabilization of the animals' blood volume.

Blood samples were drawn by serial venipuncture. Sampling times after oral administration were at 0, 1, 3, 5, 6, 8, 10, 12, 24, 72, and 96 h. Samples were drawn at 0, 10, 20, 30, 45, and 60 min, and 2, 4, 12, 24, 48, 72, and 96 h after intravenous infusion at 50 mg/min. All blood samples were collected in heparinized evacuated tubes[5] which were gently inverted to allow for complete mixing. The samples were centrifuged at 2500 rpm for 15 min. The plasma was transferred into polyethylene tubes and frozen until assayed.

Statistical Analysis—A three-way ANOVA was performed on the *in vivo* data. The F ratio, as expected, was significant ($\alpha = 0.05$) for the intravenous data for $AUC_{0\rightarrow12}$ when compared with either of the oral preparations. The F ratio was not significant ($\alpha = 0.05$) when the two oral formulations were compared. Paired t tests compared the 40% phenytoin solid dispersion and the commercial prompt phenytoin sodium; this resulted in $p > 0.2$ for C_{max}, t_{peak}, and $AUC_{0\rightarrow12}$.

RESULTS AND DISCUSSION

***In Vitro* Studies**—Figure 1 is the electron micrograph of the reagent phenytoin. It shows a great variation in crystal size; many of the crystals exceed 40 μm in length and 10 μm in width. The micrograph of the dispersion par-

ticles (Fig. 2) shows no large, discrete crystals in the formulation. The majority of the dispersion particles were ≤30 μm. A very small percentage exceeded 50 μm. An accurate estimate of the size of the phenytoin crystals in the dispersion could not be made, although some crystalline shapes could be discerned in the particles. Since none of the large rectangular crystals (>40 μm) observed in the reagent were noted in the dispersion or the residue, the formulation method used in this study must have reduced the particle size of the crystals. This probably occurred during the rapid solidification of the melt and during the trituration steps.

There is no compendial dissolution medium recommended for the comparison of the phenytoin and its sodium salt. Dissolution criteria do exist for the prompt and extended phenytoin sodium. These criteria were utilized to compare the dissolution rates of the phenytoin solid dispersion and the commercial prompt phenytoin sodium. Use of this dissolution test would indicate whether the commercial prompt phenytoin sodium samples would meet compendial standards. It would also serve to indicate whether one could use these dissolution criteria to compare two chemically different commercially available phenytoin products: the salt and the acid. The USP dissolution test for phenytoin sodium stipulates the use of 900 mL of water at 37 ± 0.5°C in Apparatus 1[6] (basket assembly) rotating at 50 rpm.

Prior to the dissolution test, all samples were placed in size 1 gelatin capsule. This was done to compare the rates of dissolution from a uniform capsule size. The percent dissolved of the commercial prompt phenytoin sodium at 30 min was 75.9%, which is much greater than the value obtained at 30 min for the solid dispersion (14.1%), or the reagent phenytoin (7.3%). At 60 min, 22.2 and 13.4% of the solid dispersion and the reagent phenytoin, respectively, were dissolved. After 180 min the percent dissolved in both preparations was almost equal: 29.4% for the reagent and 29.2% for the dispersion. The commercial prompt phenytoin sodium was 91.5% dissolved at 60 min.

The faster dissolution rate of the dispersion, when compared with the reagent phenytoin, may be due to the particle size reduction as previously noted in the electron micrographs. The X-ray diffraction data indicate that any change in the solubility of the two phenytoin samples cannot be due to a more-soluble polymorph existing in the dispersion. Comparison of the rate of dissolution of each preparation is presented in Fig. 3. Each point represents six capsules sampled and assayed in duplicate.

The USP states that at least 85% of a commercial prompt phenytoin sodium capsule should be dissolved in 30 min. Two of the size 1 capsules containing the transferred commercial prompt phenytoin sodium did not meet this specification. Thus, an additional study was undertaken. Six intact 100-mg capsules from the same lot were tested using the USP basket dissolution method as specified for phenytoin sodium capsules. At 30 min duplicate samples were taken and filtered through a 0.45-μm filter. Samples were kept in a water bath at ~37°C and assayed within 1 h after sampling. Each sample was assayed in duplicate. The six intact capsules showed an average dissolution of 81.5%, with SD = 14.5 and CV = 17.8%. The large variation noted in the six capsules may be due to two samples that had capsule-shaped masses which remained in the rotating basket apparatus after 30 min. The presence of these masses after a dissolution test has been noted in a previous study done with commercial phenytoin sodium products (25). A Student's t test was done to compare the data obtained from the transferred capsules *versus* the intact capsules. No significant difference was found (α = 0.05).

***In Vivo* Studies**—Each animal received 750 mg of the 40% solid dispersion, 300 mg of the commercial prompt phenytoin sodium, or 300 mg of the commercial intravenous phenytoin sodium. The oral doses were administered in three hard gelatin capsules. The 300-mg dose of each oral formulation was used to represent actual dosage strengths commercially available and dosing practices. The individual plasma levels obtained from these treatments are represented in Figs. 4 and 5. The plasma levels of the phenytoin sodium were normalized according to the phenytoin. It should be noted that dog 3 exhibits the highest blood levels in both Figs. 4 and 5. The difference in the curves demonstrates the effect of dog 3 on the data. Therefore, the t tests on C_{max}, t_{peak}, and $AUC_{0\rightarrow12}$ were done with and without the data obtained from dog 3. These data are presented in Table I. All areas were calculated using the trapezoidal rule. The probability values in the t_{peak}, C_{max}, and AUC were the same regardless of whether or not dog 3 was included. In all cases, $p > 0.2$.

Speculation on the cause of the large difference in the C_{max} found in dog 3 should include the observation that phenytoin exhibits nonlinear kinetics in dogs (26). Dog 3 was also the smallest dog and, therefore, received the largest mg/kg dose since all subjects received the same amount. It is possible that the small increase in the amount of phenytoin in the dispersion, when

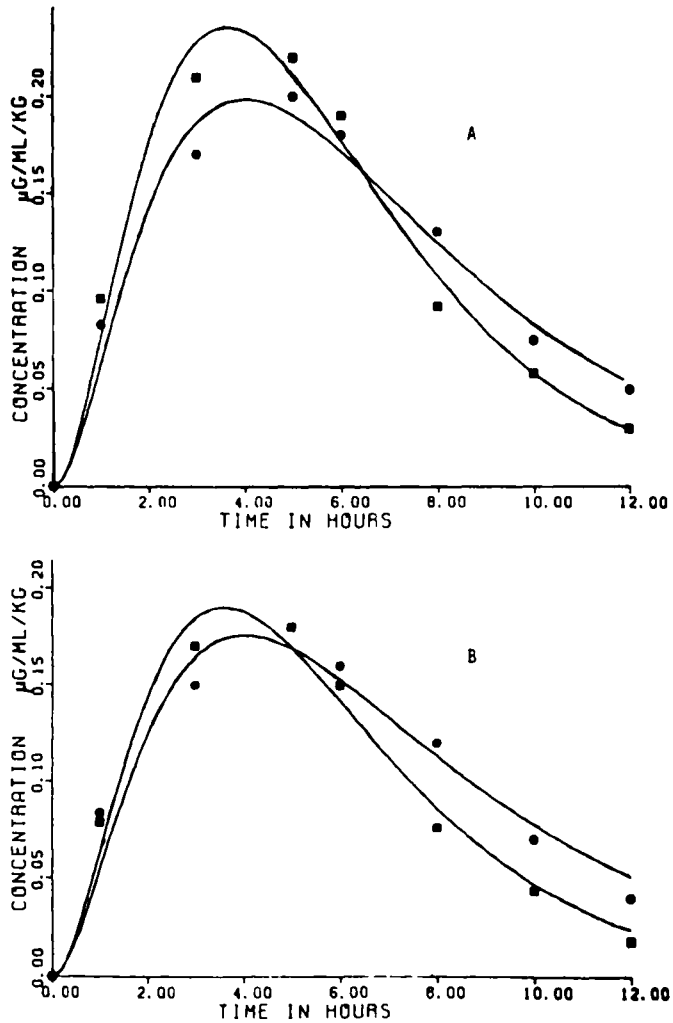

Figure 6— *Plots obtained from fitting averaged data to Eq. 2. Plot A represents the fit of all six animals, plot B represents the fit without the data from dog 3. Key: (■) 40% phenytoin dispersion; (●) commercial prompt phenytoin sodium.*

Table II—Estimates of the Parameters Obtained from the Averaged Phenytoin Plasma Concentrations Utilizing Eq. 2

Parameter	Treatment[a] A	B	C	D
k_1 (h^{-1})	0.557	0.434	0.419	0.447
k_2 (h^{-1})	0.721	0.820	1.20	1.19
k_e (h^{-1})	0.414	0.482	0.268	0.241
C_0 ($\mu g/mL/kg$)	0.673	0.632	0.460	0.379

[a] Key: (A) 750 mg of 40% phenytoin solid dispersion, $n = 6$; (B) 750 mg of 40% phenytoin solid dispersion, $n = 5$ (without dog 3); (C) 300 mg of commercial prompt phenytoin sodium, $n = 6$; (D) 300 mg of commercial prompt phenytoin sodium, $n = 5$ (without dog 3).

compared with the same milligram dose of the salt, may have been enough to cause this animal to enter the nonlinear kinetics range.

The averaged data were fitted to a model with two first-order input steps:

$$A \xrightarrow{k_1} B \xrightarrow{k_2} C \xrightarrow{k_e} \quad \text{(Eq. 1)}$$

where k_1 and k_2 are the apparent first-order rate constants for the overall absorption process and k_e is the apparent elimination rate constant. The equation used to calculate the theoretical line is:

$$C_t = k_1 k_2 C_0 \left[\frac{e^{-k_1 t}}{(k_2 - k_1)(k_e - k_1)} + \frac{e^{-k_2 t}}{(k_1 - k_2)(k_e - k_2)} + \frac{e^{-k_e t}}{(k_1 - k_e)(k_2 - k_e)}\right] \quad \text{(Eq. 2)}$$

where C_0 is the fraction of the dose absorbed divided by the volume of distribution.

The estimates for k_1, k_2, k_e, and C_0 were obtained using a nonlinear digital computer program (27) and are presented in Table II. The plots of the average data and the lines generated from Eq. 2 are represented in Fig. 6. Other equations representing biexponential or triexponential oral absorption models, including those that utilized a lag time, were attempted; however, this fit resulted in a smaller sum of squared deviations and larger r and r^2 values. Weights of 1 were used. The parameters obtained were used to calculate the $AUC_{0\to12}$, C_{max}, and t_{peak}. Good agreement is observed between the estimates obtained from the computer fits and the observed data, as seen in Table I. The relative bioavailability of the observed data is 1.01 for all subjects and 0.90 when excluding dog 3.

The data indicate that the dispersion is bioequivalent to the commercial prompt phenytoin sodium whether or not the data from dog 3 are included in the statistical analysis. Since the solubility of the salt and the acid are very different, the formulation method must be partially responsible for the increased acid solubility. The particle size reduction, as verified by the micrographs, of the phenytoin has been shown to increase plasma levels in dogs (18). The polyethylene glycol 6000 may have also affected the solubility of the dispersion. Previous studies have stated possible vehicle effects: a solubilizing effect by the vehicle (13), increased wettability (5), and a decrease in aggregation and agglomeration in hydrophobic drugs (28).

In this study, the combined effects of phenytoin crystal size reduction and any vehicle effects demonstrated bioequivalency with the much more water-soluble salt. This contradicts the *in vitro* dissolution study, which demonstrated a fivefold difference in the percent dissolved at 30 min, and a fourfold difference at 60 min. If the absorption of phenytoin is dissolution rate limited, then a significant difference should exist in the blood levels obtained from these two products. But according to the C_{max}, t_{peak}, and AUC data obtained from the animal studies, no statistical difference exists. This implies that the dispersion method must have increased the bioavailability of phenytoin.

It is possible that the particle size reduction and any vehicle effects on the *in vivo* microenvironment may be responsible for the increased dissolution rate of phenytoin. It is also possible that in an aqueous acidic environment, the relatively high concentration of free phenytoin provided by the dissolution of the salt may result in some precipitation of the free acid, as has been previously postulated (29). If this occurred, then the rate of absorption of the precipitated crystals may be comparable to the rate of absorption of the reduced crystals found in the 40% solid dispersion, and thus, demonstrate bioequivalency. If, indeed, this is a valid consideration, then any conclusions based on the greater dissolution rate of the salt implying better bioavailability must be reexamined.

The results of this study indicate that the phenytoin solid dispersion dissolution profile does not meet the criteria used by the USP XX to define a "prompt" phenytoin sodium, yet the dispersion was found to be bioequivalent to the prompt phenytoin sodium. Unless the vehicle played a very significant part in the phenytoin-microenvironment interaction *in vivo*, the use of a more representative dissolution medium to simulate the gastric fluid should be considered to improve the *in vitro–in vivo* correlation of the different phenytoin products. This study demonstrates once again the difficulties that may be encountered when selecting appropriate dissolution criteria to predict bioavailability.

Received July 19, 1982, from the *School of Materials Science and the ‡Research Center for Chemometrics, Toyohashi University of Technology, Tempaku-cho, Toyohashi 440, Japan. Accepted for publication April 15, 1983.

Abstract □ Pattern recognition techniques have been applied to the study of structure–taste correlations for perillartine derivatives. The structure of each compound was described by hydrophobicity (log P), logarithm of water solubility (log S), and topological descriptors relating to some positions which were assigned by superposing each compound on a "template" structure. The fragment molecular connectivities were calculated as the topological descriptors. The discriminant functions between the sweet and bitter taste classes were computed by the use of the simplex optimization technique, which correctly recognized most of the compounds under investigation. It was found that the hydrophobicity and one or two topological descriptors concerned with a specific part of the molecules contributed significantly to the discrimination. The discriminant function obtained correctly classified seven of nine compounds (which were not involved in the data set for developing the function) into the taste class to which they belonged.

Keyphrases □ Structure–taste relationships—discriminative structural analyses using pattern recognition techniques, perillartine derivatives □ Perillartine derivatives—taste, discriminative structural analyses using pattern recognition techniques □ Topology—structure–taste relationships, perillartine derivatives, pattern recognition techniques

Inspection of various classes of sweet-tasting substances shows a very diverse group of chemical compounds having common activity. To establish a structure–taste relationship, a large number of compounds have been tested, and several hypotheses for the sweet taste impression have been proposed by different groups (1). Shallenberger and Acree (2) postulated the first glucophore for sweet-tasting compounds. Their model is referred to as AH—B theory, where A and B are electronegative atoms and H is a hydrogen atom. This AH—B system was extended by Kier (3), who pointed out that the third feature was a nonpolar region, X, which was capable of interacting with a corresponding site on a receptor by dispersion forces. Although there are many exceptions, it seems that the extended theory, the AH—B—X system, is the most sophisticated model among the various theories. However, there remain many problems to be solved for developing new synthetic sweeteners, including that sweet-tasting compounds are often accompanied by bitter and/or other unpreferable tastes. This fact has puzzled chemists interested in searching for new sweeteners. Relating to this taste dichotomy, Belitz and his co-workers (4) suggested the presence of a sweet–bitter receptor, which could be given by formal representation as a hydrophobic pocket with a bipolar system.

Recently, Acton and Stone (5) synthesized 51 perillartine derivatives to develop new potent sweeteners. In their article, taste potencies and taste qualities (sweetness, bitterness, and other tastes) for the perillartines are represented by relative potencies to sucrose and percentages for total taste potencies, respectively. Using this data set, Iwamura (6) implemented the regression analysis with physicochemical and the STERIMOL parameters (7) of the compounds. From the results, he suggested that sweet and bitter receptors have common features. Furthermore, we (8) have shown that the sweet taste receptor might be more restricted (from the viewpoint of spatial shape) than the bitter receptor, by means of class discrimination using the STERIMOL parameters. On the other hand, Kier tried to discriminate between these sweet- and bitter-tasting compounds using discriminant analysis with molecular connectivities (9). He pointed out that unsaturation or heteroatoms are not critical to the structures that influence the sweet and bitter tastes.

In this article, we discuss the results of a discriminative structural analysis of perillartines using pattern recognition techniques; to describe the topological features of these molecules, molecular connectivity indices are also used. However, they are not calculated for whole molecules, but for the fragments related to some specific positions based on a template structure. The use of the indices may give some local topological information on a molecule.

In view of the class discrimination between the sweet and bitter tastes of perillartines, these indices are used in developing the best discriminant function together with two other descriptors. In such classification problems, statistical discriminant analysis (9–11) is frequently used. But the results of such statistical analysis is less reliable when the size of the data set available is not large enough. In contrast, nonparametric pattern recognition is applicable for such small data sets with proper reliability. Therefore, we employed the simplex pattern recognition method for the present study.

EXPERIMENTAL

Data Selection—In the present study, 22 compounds (11 sweet and 11 bitter) were selected as representative compounds from those previously reported by Acton (5). Each possesses >50% of the total taste potency with respect to only the most potent taste quality (Fig. 1). Nine compounds were used as a prediction set for discriminating the taste classes of unknowns by the use of the discriminant function, which was obtained by the former set of compounds. All of the compounds selected are aldoximes.

Template Structure and Fragment Molecular Connectivity—For generating the structural descriptors, a template structure was considered based on the chemical structure of perillartine and related compounds (Fig. 2). Ten positions of interest were considered. Assignments of the positions on the structure for the topological descriptors were made as shown in Fig. 2. For each compound to be analyzed, the positions a–j were assigned by superposing the structure in the manner of planar representation on the template structure. The α,β-unsaturated bonds of skeletons always correspond to the edge between a and b on the template structure. Three positions (h, i, and j) were designated in the descending order of the bulkiness or size of the side chains on each position. As topological descriptors, 20 fragment molecular connectivity (FMC) indices (${}^1\chi_a$–${}^1\chi_j$, ${}^1\chi^v_a$–${}^1\chi^v_j$) related to the 10 positions were adopted for use in this study. These indices are those for path 1 fragments with respect to the given position, which were calculated as the sum of the first-order terms for each edge joining the position of interest (12). Thus, for this study, the path 1 FMC value ${}^1\chi$ (or ${}^1\chi^v$) for the vertex k is given by:

$$\mathrm{FMC}_k = \sum_l (\delta_k \cdot \delta_l)^{-1/2} \qquad \text{(Eq. 1)}$$

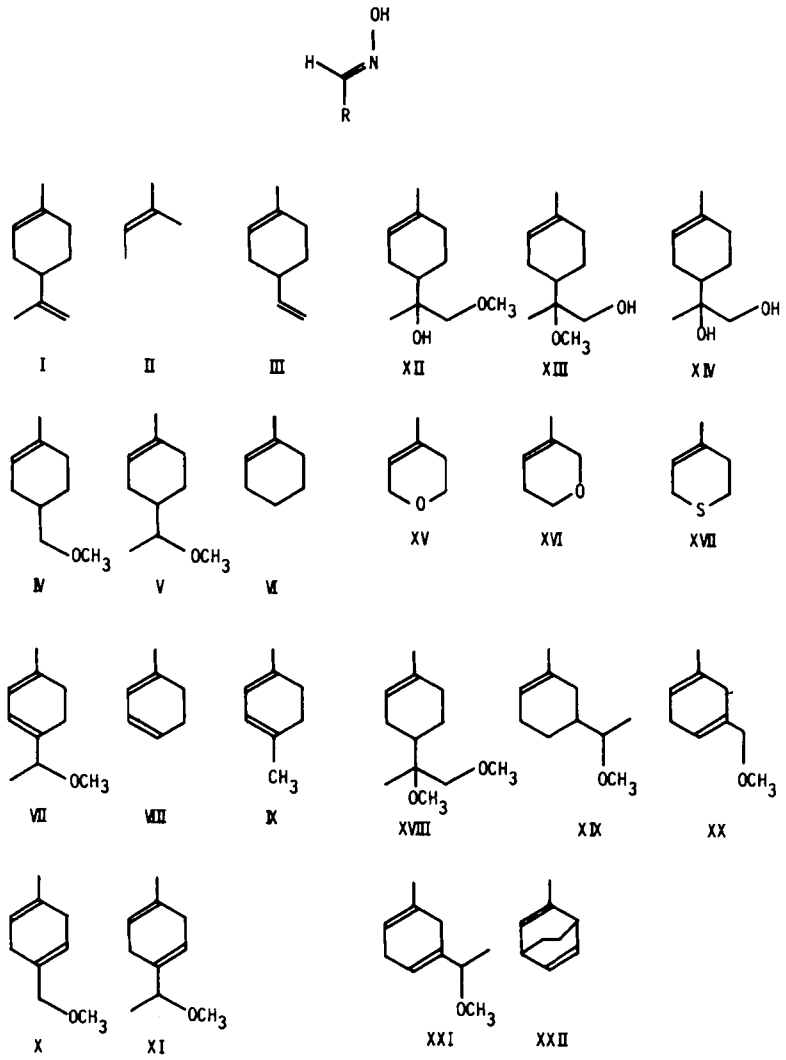

Figure 1—*Perillartine analogues.*

where δ is the valence of a vertex which corresponds to an atom and l is a vertex adjacent to k on the template structure. As a convention, positions were coded with zero for FMC if there were no substituents at the given positions. These structural descriptors were used to describe local topological features of the molecules.

In addition, two other descriptors were used in this study, hydrophobicity (log P) and the logarithm of water solubility (log S) of the compounds. These values were taken from the literature (5, 6). The values of ${}^{1}\chi_a - {}^{1}\chi_j$, log P, and log S for the compounds are shown in Table I.

In the present study, each value of the descriptors employed was normalized in such manner that the mean value was zero and the standard deviation was one for each of 22 descriptors. This process, which is sometimes called autoscaling, will not alter any of the classification results since no change of the relative positions of the pattern points occurs.

Feature Selection—Descriptors not relevant to the classification problem should be eliminated because they may disturb the correct classification or enlarge the computational work. An exhaustive search for the best subset of features is only possible for a small number of descriptors. In this study, the number of original features is too large, and it was necessary to reduce the dimensionality due to the reason mentioned above.

Feature (descriptor) selection was performed with the Fisher ratio (13). The Fisher ratio is a quantitative estimate of the significance of a given parameter for separating two classes. The Fisher ratio of the descriptor k (F_k)

[a] Compounds with (sweet/total taste) ≥0.5 are taken as sweet and those with (bitter/total taste) ≥0.5 as bitter. [b] Taken from Ref. 6. [c] Taken from Ref. 5.

is calculated from Eq. 2; it is the ratio between the square of the difference in interclass means and the sum of squared intraclass standard deviations:

$$F_k = \frac{(\bar{x}_k^{(1)} - \bar{x}_k^{(2)})^2}{\sigma_k^{(1)2} + \sigma_k^{(2)2}} \qquad \text{(Eq. 2)}$$

where $\bar{x}_k^{(1)}$ and $\bar{x}_k^{(2)}$ are the mean values of the descriptor k in classes 1 and 2, respectively, and $\sigma_k^{(1)}$ and $\sigma_k^{(2)}$ are the standard deviations of those classes. The features are ranked according to their importance, and less important features are discarded.

Development of the Discriminant Function—The simplex pattern recognition method was applied to develop a near optimum discriminant function for discrimination between the sweet- and bitter-tasting compounds. The simplex method is an approach to optimize an objective function (*e.g.*, discriminant function). This optimization technique was previously applied to the optimization of linear discriminant functions for chemical applications by Ritter *et al.* (14). In the present work, the simplex pattern recognition program(SPLX), which was developed in our laboratory according to their algorithm with a small modification, was used.

In the case of two classes, if pattern points on one side of a discriminant surface always belong to class 1 and those on the other side belong to class 2, the data are linearly separable by a linear discriminant function of the following form:

$$g(\mathbf{X}) = w_1x_1 + w_2x_2 + \ldots + w_dx_d = |\mathbf{W}||\mathbf{X}|\cos\theta \qquad \text{(Eq. 3)}$$

where x_i is the ith component of a pattern $\mathbf{X}$ and w_i is the weight assigned to that component. Hence, the classification into two categories can be implemented with the sign of $g(\mathbf{X})$ given by the dot product of a pattern vector $\mathbf{X}$ and a weight vector $\mathbf{W}$. The optimization problem of that function, in this case, can be placed in that of the corresponding weight vector in the weight space.

A simplex is a geometric figure in d-dimensional space, which consists of $d + 1$ vertices. For example, a two-dimensional simplex is a triangle, a three-dimensional simplex is a tetrahedron, *etc.* Figure 3 shows a two-dimensional simplex superimposed on a contour map, which represents the various equiresponse lines of a function of two variables. In this case, the search variables are the components of the weight vector. On the other hand, two criterion functions are evaluated in terms of the response. These are given by:

$$R = N_c/N_t \qquad \text{(Eq. 4)}$$

$$P = \sum_{\mathbf{X}_i \in S_E} |\mathbf{W} \cdot \mathbf{X}_i| \qquad \text{(Eq. 5)}$$

In Eq. 4, N_t is the total number of compounds tested and N_c is that of compounds correctly classified, so R is a recognition rate. On the other hand, in Eq. 5, S_E is the set of all patterns misclassified by $\mathbf{W}$. Thus, P is the sum of the absolute values of the dot products of all misclassified patterns by the use of the weight vector $\mathbf{W}$. In general, the value of P will become small if few compounds are misclassified or if those misclassified lie close to the discriminant surface. This criterion is used only as a smoothing function, so that the ultimate solution will be given by the minimum P value for a weight vector giving maximum recognition rate.

The optimization procedure begins by locating initial simplex (initial weight vectors) on the d-dimensional weight vector space. These were generated as follows:

$$\begin{aligned}
\mathbf{W}_1 &= (w_1, w_2, w_3, \ldots, w_d, w_{d+1}) \\
\mathbf{W}_2 &= (w_1 + \delta_1, w_2, w_3, \ldots, w_d, w_{d+1}) \\
\mathbf{W}_3 &= (w_1, w_2 + \delta_2, w_3, \ldots, w_d, w_{d+1}) \\
&\vdots \\
\mathbf{W}_{d+1} &= (w_1, w_2, w_3, \ldots, w_d + \delta_d, w_{d+1})
\end{aligned} \qquad \text{(Eq. 6)}$$

where $w_{d+1} = -1$ and δ_j was defined as:

$$\delta_j = \alpha w_j \qquad \text{(Eq. 7)}$$

The constraint of $w_{d+1} = -1$ describes a unique weight vector for a given decision surface (14). In Eq. 7, α is an arbitrary constant parameter concerned

$^1\chi_j$	−0.39	0.16	−0.19	−0.03	1.00

with a kind of size on the initial simplex. In the present study, α was selected to be 0.5.

A prototype weight vector (initial weight vector) $\mathbf{W}_1$, in generating the initial simplex, was determined by the use of the bisecting approach in which the linear discriminant surface might be approximate as the hyperplane bisecting two class centers (14). Once the initial simplex was located in the objective space, optimization of the simplex (or weight vectors) by a certain moving algorithm was attempted. Moving the simplex in the optimization process was performed according to the algorithm suggested by Nelder and Mead (15), which is a logical algorithm consisting of reflection, expansion, and contraction rules. Since this procedure has been described in detail elsewhere (14–16), it will not be repeated here.

In addition, another approach was also employed for the development of discriminant functions. Ordinary statistical discriminant analysis was implemented to the same data set for comparison with the above method.

RESULTS AND DISCUSSION

The correlations between the descriptors under investigation were examined. The results of the correlation analysis showed that the values of descriptors $^1\chi$ and $^1\chi^v$ were highly correlated (correlation coefficients = 0.78–1.00) with each other on the same position of the molecule. In such classification problems, the use of highly correlated pairs among descriptors may lead to the reduction of reliability of discriminant functions, decreasing the intrinsic dimensionality in the pattern space and increasing the probability of chance classification. Thus, in the present work $^1\chi$ values were taken as the topological variables relating to each position on the template structure. Furthermore, for the purpose of reducing the number of descriptors, preselection of the descriptors was implemented by the use of the Fisher ratio, which is a measure of the significance of a given parameter for differentiating between the taste classes. Each descriptor was ranked in decreasing order of the Fisher ratio (Table II). According to the ranking, the descriptors were eliminated one at a time and then a linear discriminant function was developed with the descriptor set using the simplex method or statistical discriminant analysis. The plots of recognition rate R *versus* the number of descriptors are illustrated in Fig. 4.

As shown in Fig. 4, in most cases the results for discriminant analysis were not as good as those for the simplex method. This would be anticipated because the $^1\chi$ FMC indices show noticeably non-normal distributions (Table I). It seemed that the simplex pattern recognition was more suitable for the discriminative analysis for the present data set, rather than the other method.

It was shown, in this case, that only two or three descriptors were enough to discriminate between the two taste classes from the result of the simplex method: log P, $^1\chi_c$, and $^1\chi_j$. During the analysis described above, only the Fisher ratios were used for the feature selection. However, because the Fisher ratio is based on the global class separation information of the data structure, it is not always true that the obtained result is the best. Thus, further examinations would be required for the descriptors. Five of the best descriptors were selected on the basis of the Fisher ratio, log P, log S, $^1\chi_c$, $^1\chi_h$, and $^1\chi_j$. The cross-correlation table among the descriptors is shown in Table III. These descriptors were used in the following studies.

To develop a discriminant function with the best set of variables among the combinations of the above descriptors, implementations were performed. The best linear discriminant function with three or two descriptors is shown as follows:

$$g_3(\mathbf{X}) = 0.595 \cdot \log P - 0.773 \cdot {}^1\chi_c - 0.220 \cdot {}^1\chi_j - 0.882 \times 10^{-5} \quad \text{(Eq. 8)}$$

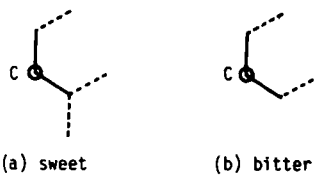

Figure 5—*Characteristic topological fragments for the sweet or bitter compounds.*

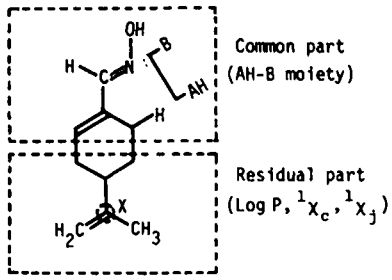

Figure 6—*AH—B—X postulation for perillaldehyde oxime (3).*

$$g_2(\mathbf{X}) = 0.696 \cdot \log P - 0.718 \cdot {}^1\chi_c - 0.220 \times 10^{-5} \quad \text{(Eq. 9)}$$

$$g(\mathbf{X}) \begin{cases} \geq 0 \text{ implies sweet class} \\ < 0 \text{ implies bitter class} \end{cases}$$

Equation 8 correctly classified all compounds into the observed classes. On the other hand, Equation 9 correctly discriminated all of the 11 sweet-tasting compounds and 10 of the 11 bitter-tasting compounds. The average recognition rate was 95%; only XVIII was misclassified.

Equations 8 and 9 suggest that the log P and fragment molecular connectivity index, $^1\chi_c$, are significant characteristics that influence whether a compound is sweet or bitter. In the two equations, as the hydrophobicity of a compound increases, the $g(\mathbf{X})$ values are larger due to the positive value of that coefficient. The compound then tends to be classified as sweet.

The negative coefficient for the $^1\chi_c$ term suggests that a smaller value of $^1\chi_c$ enhances the sweet-taste impression. For the data set employed in the present work, however, the values of $^1\chi_c$ do not vary much. In this case, it is helpful to consider the contribution of $^1\chi_c$ in terms of topological features. The $^1\chi_c$ index describes the branching information or the topological form concerned with the path 1 fragment at position c. Although each value does not always correspond to a unique fragment, it is meaningful to examine the topological fragment. The topological fragments concerned with those positions are illustrated in Fig. 5. Most compounds in the sweet class involve a fragment such as a in Fig. 5; the compounds in another class involve fragment b, excepting some compounds. It should be noted that fragment b is embedded in another fragment.

Furthermore, the third term (which was weighted by a negative coefficient in Eq. 8) suggests that bulky side chains on the j position may prevent the impression of sweetness. Alternatively, because $^1\chi_j$ is zero except for four compounds in the bitter class, this variable could be replaced by an indicator variable related to the presence of a quaternary carbon at the g position. Thus, it is postulated that the occupancy by a substituent at the position j may influence the taste quality of these compounds.

In the present data set, since the aldoxime moiety is a common part of all molecules, the variation of log P is due to the residual part. Thus, the observations are consistent with Kier's postulation of perillartine in his AH—B—X

theory (3). The AH—B—X system of perillartine is illustrated in Fig. 6. Furthermore, the aforementioned results suggest that the shape of the moiety concerned with the third site (X) plays an important role in the taste impression (especially, sweetness). This insight would be clear in the following predictive analysis.

The discriminant ability of the linear discriminant function obtained in the present study can be tested by predicting the taste classes of compounds not used in the development of the function. For this test, as shown in Fig. 7, nine compounds were selected from a previous study (5). These compounds are not dominant in one taste class, as seen by the total taste potency (Table IV). However, on the basis of the sweet-bitter taste ratios, each compound could be assigned to either the sweet or bitter taste class. The first five compounds (XXIII-XXVII) are categorized as sweet, and the other compounds (XXVIII-XXXI) are categorized as bitter. The prediction results of their taste classes are shown in Table V. Both discriminant functions, $g_2(X)$ and $g_3(X)$, correctly predicted the class of seven of the tested compounds.

Compounds XXIII and XXIX were misclassified (Fig. 7). They are the smallest in terms of the difference between the sweet and bitter taste ratios (Table IV). Considering that the compounds tested were not so typically sweet or bitter, this result may be more favorable.

The results of this prediction encouraged us to apply the methodology of this study to the structure-taste problem for the series of perillartines. In such a discrimination, the influence of hetero atoms or unsaturated bonds on a structure was examined in the same manner by the use of FMC indices ($^1\chi^v_{a-j}$) with the weighted valences. The values of the weighted valences were obtained from a previous paper (12). But, the result was not as favorable, as shown in Fig. 8. Furthermore, an additional analysis in which $^1\chi$ and $^1\chi^v$ FMC indices were used together in developing the best discriminant function had the same results as using only $^1\chi$ FMC indices. These examinations suggest that the hetero atoms and unsaturated bonds are not so critical in the aforementioned residual part.

CONCLUSION

The structural discriminative analysis of the sweet and bitter perillartines using a template structure was successfully performed by pattern recognition techniques. It was shown that the fragment molecular connectivity indices are useful in describing the local features of molecules in terms of topological structure.

The results for the series of perillartines offer some explanations of the structure-taste correlation. The hydrophobicity of the residual part except for the AH—B moiety in the analogues influenced the taste quality, and furthermore the topological shape of the residual part is also predominantly concerned with the sweet or the bitter taste impression. The information obtained from the best discriminant functions was used to examine additional molecules, and it improved predictions of their taste classes. This study confirms Kier's original postulation (3) of the sweet pharmacophore for perillartine.

Table V—Prediction Results from Simplex Pattern Recognition

Membrane Solubility Parameter and *In Situ* Release of Theophylline

A. ADJEI *, J. NEWBURGER, S. STAVCHANSKY, and A. MARTIN ˣ

Received December 6, 1982, from the *University of Texas, College of Pharmacy, Drug Dynamics Institute, Austin, TX 78712.* Accepted for publication February 2, 1983. * Present address: Pharmaceutical Products Division, Abbott Laboratories, North Chicago, IL 60064.

Abstract □ The solubility of theophylline in polyethylene glycol 400–water binary mixtures was analyzed in terms of solute-solvent interaction using the solubility parameter principle of Hildebrand. Preliminary *in situ* (rat gut permeation) studies with the solvent mixtures having varying polarity as expressed by the solubility parameter showed that (*a*) the more alike the solubility parameter of theophylline (δ_2 = 14, as obtained from solubility studies) and the solubility parameter of the solvent mixture, the greater was the attraction of solvent for the drug (*b*) sufficient similarity must exist between the solubility parameter of theophylline and that of the intestinal mucosa to promote bioabsorption, and (*c*) from the above, it follows that there exists a competition between solvent and rat gut membrane for the drug. The solubility parameter of the solvent vehicle must be such that it does not impede absorption of the molecules into the intestinal mucosa.

Keyphrases □ Solubility parameter—theophylline in propylene glycol 400–water, *in situ* release in the rat gut, membrane solublity parameter □ Release rate—theophylline in propylene glycol 400–water, *in situ* rat gut model, membrane solubility parameter □ Solute-solvent interactions—effect on the solubility of theophylline in propylene glycol 400–water, *in situ* release in the rat gut, membrane solubility parameter

The principle of solute–solvent interaction and its influence on drug solubility and solubilization has been studied extensively (1–10). Recent works (11–13) have extended the Hildebrand–Scatchard model (1, 2) to handle solubility predictions of drugs in polar solvents.

This report examines the influence of solvent polarity, solvent attraction for the solute (theophylline), and the effect of this interaction on theophylline release. The method of Doluisio *et al.* (14), in which drug absorption is followed using an *in situ* rat gut preparation, was employed to monitor theophylline disappearance from various polyethylene glycol 400–water mixtures into the rat intestinal membrane. The results of this study are analyzed according to the postulates of previous work (3–5, 15–17).

EXPERIMENTAL

***In Situ* Rat Gut Method**—Male Sprague–Dawley rats, 220–250 g, were fasted for 16 h with free access to water and housed in mesh screen cages to prevent coprophagy. The rats were anesthetized with 75 mg/kg ip injections of sodium pentobarbital. After the onset of anesthesia, a midline incision was made to expose the intestines. Two L-shaped glass cannulae were inserted into the intestine and ligated. The proximal cannula, which was placed just below the bile duct, and the distal cannula were spaced ~61 cm apart. Four-centimeter lengths of Tygon tubing were attached to each cannula, and a 30-mL hypodermic syringe was connected to each Tygon tube using a three-way stopcock as a connector. The proximal syringe was filled with a pH 7 phosphate buffer, previously warmed to 37°C, and the intestine was flushed until the perfusate was observed to be clear as it left the distal cannula. Nine milliliters of various polyethylene glycol 400–water mixtures, having a range of solubility parameters and resulting in varing solubility for the drug, were formulated with each containing 2 mg/mL of theophylline and 1200 cpm of ^{14}C-labeled polyethylene glycol 4000, which was used as a nonabsorbable marker to monitor water flux. These solutions were placed in the prepared gut *via* the distal cannula and flushed back and forth through the intestines several times to effect uniform mixing. Two time zero samples (0.1 mL each) of the solution were then removed. After sampling, the solution was returned to the intestine and the stopcocks were closed to maintain the solution in place. A stop watch was activated, and serial time samples were removed thereafter. The stop watch was stopped during sampling time and restarted when the solution was returned to the gut. Samples were removed from alternate syringes at each time period. One of the two samples removed was placed in a 20-mL vial, 15 mL of scintillation cocktail was added, and the sample was counted in a liquid scintillation counter utilizing single-channel counting to monitor water flux. The second sample was added to a 10-mL volumetric flask, brought to volume with the same solvent that the drug was dissolved in, and the absorbance measured in a spectrophotometer[1] at 272 nm.

Solubility Studies—Data from an earlier investigation (11) on the solubility of theophylline in dioxane–water mixtures were utilized in the study to obtain the solubility parameter of theophylline and to assess its solubility in solvent mixtures of varying solubility parameters (δ values).

RESULTS

Rate Constants for Absorption—The disappearance of theophylline from the solvent provided semilogarithmic plots, as observed in Fig. 1, which when analyzed, suggested the following model:

$$D_G \underset{k_2}{\overset{k_1}{\rightleftharpoons}} D_M \xrightarrow{k_3} D_B \qquad \text{(Eq. 1)}$$

The quantity D_G represents the concentration of drug in the intestine, D_M is the drug concentration in the membrane, k_1, k_2, and k_3 are the rate constants for transfer of drug between the compartments, and D_B is the drug concentration in the blood.

Differential equations for the process represented by the above model were written from which the following solutions were obtained:

$$D_G = D\frac{(k_2 + k_3 - \alpha)e^{-\alpha t}}{(\beta - \alpha)} + D\frac{(k_2 + k_3 - \beta)e^{-\beta t}}{(\alpha - \beta)} \qquad \text{(Eq. 2)}$$

where D represents the concentration of drug in the solution that was perfused into the intestine. The general form of Eq. 2 may be written as:

$$D_G = X_1 e^{-\alpha t} + X_2 e^{-\beta t} \qquad \text{(Eq. 3)}$$

where α is the slope of the residual line feathered from the nonlinear initial phase of the curve in Fig. 1, and β is the slope of the terminal log-linear phase. The respective intercepts of these two straight lines are X_1 and X_2, and are written as:

$$X_1 = D\frac{(k_2 + k_3 - \alpha)}{\beta - \alpha} \qquad \text{(Eq. 4)}$$

$$X_2 = D\frac{(k_2 + k_3 - \beta)}{\alpha - \beta} \qquad \text{(Eq. 5)}$$

where D_G is defined at time zero, *i.e.*, D_{G0}, by the expression:

$$D_{G0} = X_1 + X_2 \qquad \text{(Eq. 6)}$$

k_1, k_2, and k_3 are obtained from the identities:

$$\alpha + \beta = k_1 + k_2 + k_3 \qquad \text{(Eq. 7)}$$

and:

$$\alpha\beta = k_1 k_3 \qquad \text{(Eq. 8)}$$

Substituting Eqs. 6 and 7 into Eq. 4 and rearranging yields:

$$k_1 = \frac{X_2\beta + X_1\alpha}{X_1 + X_2} \qquad \text{(Eq. 9)}$$

which enables one to calculate k_3 from Eq. 8 and k_2 from Eq. 7.

Biological Partition Parameter and a Membrane Solubility Parameter—From the shape of the experiemental curve of Fig. 1, it is assumed that equilibrium of theophylline exists between compartments G and M due to a par-

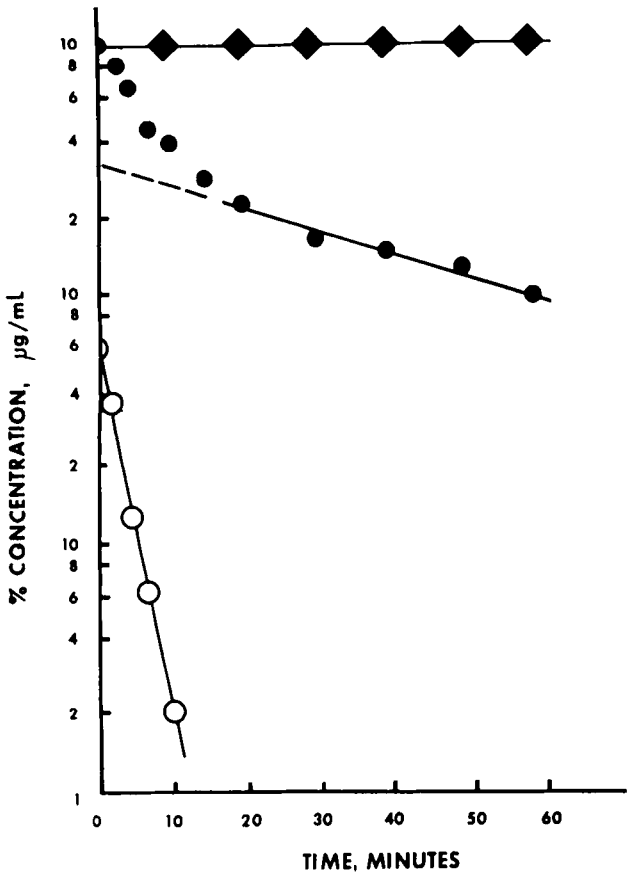

Figure 1—*Semilogarithmic plot showing first-order biexponential absorption of theophylline from the rat small intestine. Key: (◆) water flux as monitored using the nonabsorbable marker [^{14}C]polyethylene glycol 4000; the straight line shows concentration of the pure binary solvent in the rat intestine after correction for water flux; (●) theophylline concentrations in the rat intestine, $\beta = 0.021$; (○) residual feathered line representing the equilibrium phase of drug between contents of the gut and the rat intestinal membrane, $\alpha = 0.348$.*

titioning of the drug. The partition parameter, K_p, for this process (absorption and desorption of theophylline in the intestinal membrane) is written as:

$$K_p = \frac{k_1}{k_2} \qquad \text{(Eq. 10)}$$

The parameter K_p of Eq. 10, obtained from *in situ* rat gut data, should be related to the physicochemical properties of the drug–solvent carrier system. An equation, written in different forms by Davis (15), Cammarata and Rogers (18), Weimer and Prausnitz (19), Yeh and Higuchi (20), and Srebrenik and Cohen (21), and introducing δ_0 as the solubility parameter representing the rat gut membrane, is shown below:

$$\log K_p = \frac{V_2 \phi_1^2}{2.303RT}[(\delta_1 - \delta_2)^2 - (\delta_0 - \delta_2)^2] \qquad \text{(Eq. 11)}$$

This equation may be used to analyze the data of the current study. The quantity R is the gas constant, T is the absolute temperature, and V_2 is the liquid molar volume of the solute, which for theophylline is 124 mL/mol. The terms ϕ_1 and δ_1 are, respectively, the volume fraction and the solubility parameter of the solvent, and δ_2 is the solubility parameter of the solute. Mullins (16) has reviewed various methods by which δ_0 for biological membranes may be obtained. He estimated from thermodynamic considerations that the δ_0 value of the frog sciatic nerve ranges from ~10.0 to 13.0. Mullins also noted for the frog nonsynaptic membrane that a value of 11.5 was in agreement with experimental results, whereas a value of 10.0 seemed more favorable for the δ value of synaptic nerve membranes. Cammarata *et al.* (17), using the erythrocyte membrane as a model for drug partitioning in biological systems, obtained a value of 8.05 as the apparent solubility parameter for the erythrocyte membrane.

Equation 11 does not account for entropic effects such as molecular size differences between solvent, solute, and membrane. Flory (22, 23) and Huggins (24, 25) introduced such size differences, *i.e.*, the molar volumes of solute and solvent, to account for deviations of solution phenomena from ideality. The inclusion of these factors together with corrections for possible membrane metabolism and changes in solute molar volume across the biomembrane would seem warranted. Nevertheless, the present simplified approach was attempted as a first approach to the calculation of solute–solvent attractions and the estimation of δ_0 values in biological systems.

Table I—Solubility of Theophylline, $\delta_2 = 14.0$ (cal/mL)$^{1/2}$, $V_2 = 124$ mL/mol, in Selected Polyethylene Glycol 400–Water Mixtures at 25°C

Perecentage of Polyethylene Glycol 400	δ_1	ϕ_1	$(\delta_1 - \delta_2)^a$	Solubility, mg/mL	*SD*
100	10.5	0.9893	−3.5	15.539	±0.174
90	11.8	0.9879	−2.2	17.594	±0.102
80	13.1	0.9876	−0.9	17.937	±0.257

65	15.0	0.9920	1.0	11.660	±0.058
60	15.7	0.9928	1.7	10.445	±0.034

[a] δ_1 is the solubility parameter of the mixed solvent; δ_2 is the solubility parameter of the solute, theophylline.

Solubility Parameters, Drug Release, and Bioabsorption—The terms of Eq. 11describe solute–solvent and solute–membrane interaction forces due to polar interactions, in addition to dispersion or van der Waals forces as expressed by the classical Hildebrand equation (1). Analysis of the data using Eqs. 1, 3, and 7–10 provided pharmcokinetic parameters, which were correlated with solubility of theophylline and its release from the respective polyethylene glycol 400–water mixtures. A listing of these parameters is found in Tables I and II. Figure 2 shows that the closer the solubility parameter of theophylline (14.0)[2] and the solubility parameter of the particular solvent mixture (polyethylene glycol 400–water), the greater the attraction of solvent vehicle for the drug. A solvent whose solubility parameter is identical to that of theophylline would, according to regular solution theory, lead to the greatest solubility of the drug, barring solute–solvent interactions.

One would also expect an interplay of multiple physicochemical attractive forces in the drug release process due to differences between the membrane solubility parameter and that of the solvent and solute (Eq. 11). In this case,

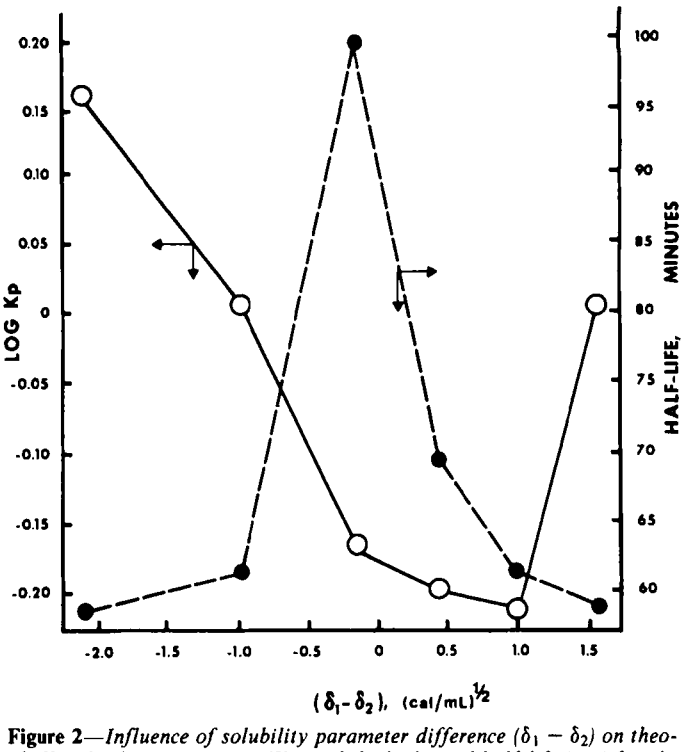

Figure 2—*Influence of solubility parameter difference ($\delta_1 - \delta_2$) on theophylline* in situ *partitioning (K_p) and the biological half-life ($t_{1/2}$) for absorption across the rat gut membrane. δ_1 is the solubility parameter of the mixed solvent; δ_2 is the solubility parameter of the drug, theophylline. Key: (●) half-life for theophylline absorption; (○) partition coefficient for theophylline absorption from solvent mixtures of varying solubility parameters.*

[2] The solubility parameter of theophylline was taken from Ref. 12.

[a] $K_p = k_1 \div k_2$. [b] Membrane solubility parameters were calculated from the quadratic Eq. 11, and the two roots designated high and low are reported here.

Eq. 11 seems to suggest that δ_0, the membrane solubility parameter, would be important in evaluating the effects of solvent solubility parameters on drug absorption. Figure 2 shows that as the solubility parameter of the solvent gets closer to that of the solute, there is a rapid fall in the *in situ* partition parameter and a significant increase in the half-life for absorption (disappearance from the intestine) of theophylline. This is considered to be due to stronger interactions of solute and solvent. Conversely, when the solubility parameter of the solvent and solute are significantly different, the extent to which the drug and solvent molecules interact would be expected to be small. In such case, drug solubility would be reduced, resulting in greater release from the vehicle and a larger absorption rate constant.

Inspection of the lines in Fig. 2 and the parameters of Eq. 11 reveals a dependence of K_p (drug partitioning parameter) on δ_2 and δ_0, the membrane solubility parameter. A solvent mixture for optimum theophylline release and bioabsorption would have a solubility parameter that operates in conjunction with δ_2 and δ_0 so that solubility and partitioning effects were simultaneously changed. That is to say, the solubility parameter of drug and solvent (vehicle) must be sufficiently different to allow ready release of theophylline from the solvent, yet be similar enough to provide a reasonable concentration of the drug. And δ_2 and δ_0 must be sufficiently alike to favor drug absorption into the membrane.

To obtain quantitative measurements for the solubility parameter δ_0 of the rat gut membrane, the data summarized in Tables I and II were substituted into Eq. 11 for each polyethylene glycol 400–water solvent mixture, assuming $\phi_1^2 \cong 1.00$. Average values for the two roots of the resulting quadratic equations were found to be 15.4 and 12.6. A δ_0 value of 12.6 for the rat gut membrane would seem to be more reasonable, since it is generally accepted that the intestinal membrane has low polarity. It is in fair agreement with the value of 11.6 suggested by Mullins (16) for synaptic nerve tissue. A value of 15.4 would suggest a polar membrane in conflict with the relatively lipophilic character of the intestinal mucosa (26).

Membrane solubility parameters may play a critical role in drug permeation and partitioning studies. The values may differ depending on the part of the intestines under consideration, such as for some antibiotics (27–29) for which "windows" or regions exist in the upper intestines where the drug is more readily absorbed.

DISCUSSION

Attempts have been made by some workers (30–32) to analyze the movement of drugs across cell membranes. These authors studied the kinetics of absorption of sulfonamides and barbiturates in the intestinal, gastric, and rectal regions of the GI tract. Utilizing theoretical models and introducing physical dimensions, some of which are associated with various membranes and others determined by *in vitro* experiments, these authors attempted to calculate physical constants consistent with the experimental data.

Khalil and Martin (5) studied the kinetics of [^{14}C]carboxyl salicylic acid through model membranes and observed that the closer the δ value of the drug molecule to that of the lipoidal barrier, the faster the disappearance of the drug from an aqueous buffer layer of pH 2 (representing stomach contents) and the slower its appearance in an aqueous buffer of pH 7.4 (representing plasma). Khalil *et al.* (33, 34) employed the solubility parameter as an index of drug activity of several barbiturates. In their investigation, these authors observed that there was a linear relationship between the solubility parameter and logarithm of the partition coefficient reported in the literature for the various barbituric acid derivatives studied. They also observed a good correlation between solubility parameters of the barbiturates and their reported activities, and suggested that the solubility parameter concept might be a possible substitute for the partition coefficient in structure-activity relationships. Pagay *et al.* (35) studied the influence of acetaminophen bioavailability and the dielectric properties of the vehicle. These studies, like those presented here, are attempts to understand the many factors that affect the solubility of drugs and their absorption properties.

Some workers (3–5, 33–38) have suggested that solubility parameters and dielectric requirements affect the bioavailability of drugs *in vivo*. Others (18, 19, 39–44) have concluded that permeability and the partition coefficient are useful parameters to be employed in monitoring drug absorption. Hansch *et al.* (45) have reported on a optimum log P for drug partitioning or penetration into the central nervous system which appears to be remarkably constant at a value of 2.0. The work reported in this paper suggests that not only the solubility parameter of the drug and solvent (drug carrier) but also the δ_0 of biological membranes should be considered by formulators in drug design work. However, the solubility parameter for the membrane as well as for the solute and solvent will probably have to be redefined to reflect the polar and hydrogen-bonding interactive forces involved in solute-solvent attraction and the permeation of the membrane by the solute. This problem has been studied (11–13) and is the subject of continuing work.

CONCLUSIONS

A method has been developed to optimize *in vivo* release characteristics of drug molecules based on solute-solvent interactive forces and use of the Hildebrand solubility parameter. A solubility parameter of 12.6 for the rat gut membrane has been estimated and is used to demonstrate the role of solute-solvent interactive forces in drug release studies. This method for obtaining the solubility parameter of a membrane uses an *in situ* drug absorption approach and a living membrane (rat gut) as the permeation barrier. The results obtained from this preliminary work are encouraging. However, further work must be done with various pharmaceutical drug-solvent systems before definitive conclusions can be made. Extended testing may provide improved solubility and penetration parameters characteristic of various living membranes and tissues which would prove useful in physical medicinal chemistry and quantitative drug design. It is suggested that theophylline, and possibly other poorly soluble drugs whose solubility and biological activity require careful control for optimum therapeutic effects, may be formulated using a generalized solubility parameter approach. Relative interaction of drug molecules with the vehicles in which they are formulated and the biological membranes they penetrate must be assessed in a number of systems before fundamental principles can be established.

Synthesis and Properties of Some 13-*cis*- and All-*trans*-retinamides

Y. FULMER SHEALY *x, JERRY L. FRYE *, C. ALLEN O'DELL *, MARTHA C. THORPE *, MARION C. KIRK *, W. C. COBURN, JR. *, and MICHAEL B. SPORN ‡

Received March 15, 1982, from the **Southern Research Institute, P.O. Box 55305, Birmingham, AL 35255-5305* and the ‡*Laboratory of Chemoprevention, National Cancer Institute, Bethesda, MD 20205.* Accepted for publication March 1, 1983.

Abstract □ Several 13-*cis*-retinamides were synthesized from 13-*cis*-retinoic acid *via* either 13-*cis*-retinoyl chloride or 13-*cis*-1-retinoylimidazole. All-*trans*-retinoylglycine was prepared from all-*trans*-retinoyl chloride and ethyl glycinate. Detailed procedures were developed for the preparation of other all-*trans*-retinamides on a large scale for studies of the chemoprevention of cancer.

Keyphrases □ 13-*cis*-Retinamides—synthesis and chemical properties □ All-*trans*-retinamides—synthesis and chemical properties □ Synthesis—13-*cis*- and all-*trans*-retinamides, chemical properties

Compounds of the vitamin A group (retinoids) are essential for normal cellular differentiation and for the growth of epithelial tissues (1–4). During recent years, many studies, reviewed by Sporn and co-workers (3–9) and Bollag and co-workers (10–12), have shown that retinoid deficiency in animals enhances susceptibility to chemical carcinogenesis, that epithelia in certain organ cultures develop preneoplastic lesions in the absence of retinoids, and that administration of certain retinoids may prevent or reduce carcinogen-induced neoplasia in epithelial tissues of animals, as well as preneoplasia (6, 13–16) in organs in culture. In particular, certain derivatives and analogues of all-*trans*-retinoic acid (tretinoin, also known as vitamin A acid; Ia) exert a prophylactic (and, in some cases, a therapeutic) effect on the development of preneoplastic and malignant epithelial lesions (*e.g.*, 11, 16–25). Among the more interesting derivatives of retinoic acid and its analogues are the amides (retinamides and retinamide analogues). The purpose of this report is to describe the preparation of several all-*trans*-retinamides (II) and 13-*cis*-retinamides (IV) for long-term studies of chemoprevention in animals. Only one 13-*cis*-retinamide, the primary amide (IV, R = H), had been previously described (without a synthesis procedure) in the literature (26).

RESULTS AND DISCUSSION

The preparation of all-*trans*-retinamides IIa–d (27) and IIe (28) has been briefly outlined in the patent literature, but the characterization data (mp, UV) were sparse. The 4-hydroxyphenyl amide (all-*trans*-*N*-(4-hydroxyphenyl)retinamide; IIm) was synthesized originally by Gander and co-workers (24, 28). The preparation of IIf–l has not been described previously, but IIf–i

Synthesis and Properties of Some 13-*cis*- and All-*trans*-retinamides

Y. FULMER SHEALY *x, JERRY L. FRYE *, C. ALLEN O'DELL *, MARTHA C. THORPE *, MARION C. KIRK *, W. C. COBURN, JR. *, and MICHAEL B. SPORN ‡

Received March 15, 1982, from the **Southern Research Institute, P.O. Box 55305, Birmingham, AL 35255-5305* and the ‡*Laboratory of Chemoprevention, National Cancer Institute, Bethesda, MD 20205.* Accepted for publication March 1, 1983.

Abstract □ Several 13-*cis*-retinamides were synthesized from 13-*cis*-retinoic acid *via* either 13-*cis*-retinoyl chloride or 13-*cis*-1-retinoylimidazole. All-*trans*-retinoylglycine was prepared from all-*trans*-retinoyl chloride and ethyl glycinate. Detailed procedures were developed for the preparation of other all-*trans*-retinamides on a large scale for studies of the chemoprevention of cancer.

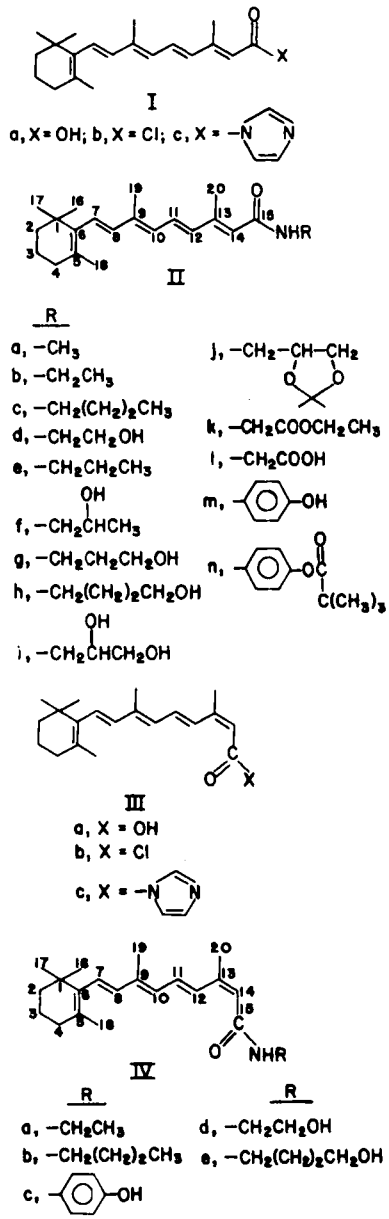
Keyphrases □ 13-*cis*-Retinamides—synthesis and chemical properties □ All-*trans*-retinamides—synthesis and chemical properties □ Synthesis—13-*cis*- and all-*trans*-retinamides, chemical properties

Compounds of the vitamin A group (retinoids) are essential for normal cellular differentiation and for the growth of epithelial tissues (1–4). During recent years, many studies, reviewed by Sporn and co-workers (3–9) and Bollag and co-workers (10–12), have shown that retinoid deficiency in animals enhances susceptibility to chemical carcinogenesis, that epithelia in certain organ cultures develop preneoplastic lesions in the absence of retinoids, and that administration of certain retinoids may prevent or reduce carcinogen-induced neoplasia in epithelial tissues of animals, as well as preneoplasia (6, 13–16) in organs in culture. In particular, certain derivatives and analogues of all-*trans*-retinoic acid (tretinoin, also known as vitamin A acid; Ia) exert a prophylactic (and, in some cases, a therapeutic) effect on the development of preneoplastic and malignant epithelial lesions (*e.g.*, 11, 16–25). Among the more interesting derivatives of retinoic acid and its analogues are the amides (retinamides and retinamide analogues). The purpose of this report is to describe the preparation of several all-*trans*-retinamides (II) and 13-*cis*-retinamides (IV) for long-term studies of chemoprevention in animals. Only one 13-*cis*-retinamide, the primary amide (IV, R = H), had been previously described (without a synthesis procedure) in the literature (26).

RESULTS AND DISCUSSION

The preparation of all-*trans*-retinamides IIa–d (27) and IIe (28) has been briefly outlined in the patent literature, but the characterization data (mp, UV) were sparse. The 4-hydroxyphenyl amide (all-*trans*-*N*-(4-hydroxyphenyl)retinamide; IIm) was synthesized originally by Gander and co-workers (24, 28). The preparation of IIf–l has not been described previously, but IIf–i

© 1984, American Pharmaceutical Association



and II l were among the retinoids evaluated in organ culture by Newton *et al.* (16) and were synthesized, originally, elsewhere[1].

All-*trans*-retinamides have been prepared (24–31) from retinoic acid (Ia) *via* all-*trans*-retinoyl chloride (Ib) in benzene (29), benzene–dimethylformamide (24, 28), or ether (27). The acid chloride (Ib) was prepared initially from Ia and phosphorus trichloride in benzene (29) and subsequently from Ia and thionyl chloride in pyridine–ether (30). Most of the retinamides described here were obtained by modifying the phosphorus trichloride method and adapting it to large-scale syntheses. The volume of benzene may be reduced considerably below that used in the original procedure (29) for the preparation of a retinamide. Although IIa–i and IIk have the same general structure, the isolation procedures used to obtain good yields of the various retinamides differ in detail. Compound IIh could also be obtained *via* Ib, but it was more conveniently prepared from 1-(all-*trans*-retinoyl)imidazole (Ic), which was prepared from Ia and 1,1′-carbonyldiimidazole (32). The dihydroxypropyl amide (IIi) was prepared by both methods; the isopropylidene derivative (IIj) was prepared from IIi by a procedure adapted from nucleoside chemistry (33). All-*trans*-*N*-retinoylglycine (II l) was prepared by treating IIb with an excess of ethyl glycinate free base and saponifying the resulting ester (IIk).

Differences among some of the all-*trans*-retinamides in their sensitivity to atmospheric oxygen were observed. Since all have the same basic retinoid structure, these differences are probably due principally to differences in crystal structure and particle size (*Experimental*). The 2,3-dihydroxypropyl amide (IIi) appeared to be the most sensitive of the all-*trans*-retinamides to deliberate exposure to air, whereas the ethyl amide (IIb) and 4-hydroxyphenyl amide (IIm) appeared to be among the least susceptible to atmospheric oxygen.

The 13-*cis*-retinamides (IV) were prepared from 13-*cis*-retinoic acid (IIIa) by way of either 13-*cis*-retinoyl chloride (IIIb) or 1-(13-*cis*-retinoyl)imidazole (IIIc). In initial runs, it was shown by NMR and HPLC that 13-*cis*-retinoic acid (IIIa) could be converted to 13-*cis*-retinoyl chloride (IIIb) and thence to 13-*cis*-*N*-ethylretinamide (IVa) without causing isomerization of the 13-*cis* structure to the all-*trans* isomer. Compounds IVa–c could be prepared *via* IIIb in yields of 74–82% from IIIa. 1-(13-*cis*-Retinoyl)imidazole (IIIc) was prepared from IIIa and 1,1′-carbonyldiimidazole by a procedure similar to that employed for the preparation of the all-*trans* isomer. A specimen of IIIc was purified, but less pure specimens, which might have contained varying amounts of imidazole, were satisfactory for the formation of 13-*cis*-retinamides. The conversion *via* IIIc was quite satisfactory, and superior to the acid chloride method, for the preparation of the hydroxyalkyl amides (IVd,e). In later, large-scale runs, IIIc was prepared and used *in situ;* consequently, the use of IIIc for the preparation of 13-*cis*-retinamides is comparable in simplicity to the acid chloride method. Yields of IVd,e were 60–70%.

Although amides are simple derivatives and IVa–e are all representatives of the same general structure, the preparation of these 13-*cis*-retinamides was not without difficulties. The most serious problem was the occasional formation during the preparation or isolation of IVa and IVb of considerable amounts (10–25%) of the all-*trans* isomer. The reasons for these occasional lapses were not apparent, but it is evident that the synthesis of a 13-*cis*-retinamide should be carefully monitored by HPLC and NMR to ensure the absence of significant amounts of the corresponding all-*trans* isomers. Other operational difficulties were caused by idiosyncracies of individual structures. The 4-hydroxybutyl derivative (IVe) could be crystallized initially only from cyclohexane; it then retained cyclohexane (~1:1) tenaciously (*Experimental*). Once a crystalline specimen was obtained free of cyclohexane, IVe could be readily recrystallized from acetonitrile–water. The 2-hydroxyethyl amide (IVd), which is isolated as a syrup, dissolves in hexane at room temperature and crystallizes. The crystalline solid is then only sparingly soluble in boiling hexane, but it is soluble in cyclohexane and can be recrystallized from the latter solvent. Compound IVc showed a tendency to retain benzene, the reaction solvent. The butyl amide (IVb) resisted crystallization and appeared to undergo considerable degradation during attempts to purify and crystallize it until seed crystals were finally obtained.

Other than differences owing to absorptions of the R groups, there is little, or no, variation in the NMR spectra[2] of the all-*trans*-retinamides (II) or of the 13-*cis*-retinamides (IV). The major differences between the 100-MHz ^{1}H-NMR spectra of the all-*trans* (IIa–l) and the 13-*cis* amides (IVa, b, d, and e) are the pronounced downfield shift of the C-12 proton signal and the upfield shifts of the C-14 and C-20 proton signals in the spectra of the 13-*cis* amides. For example, the C-12 proton signal in the spectrum of all-*trans*-*N*-ethylretinamide (IIb) is part of a multiplet (CH of C-7, C-8, C-10, and C-12 + NH) at δ 6.0–6.4 ppm, and the C-20 and C-14 proton signals are approximate singlets at δ 2.37 and δ 5.71 ppm, respectively; whereas the corresponding proton signals in the spectrum of the 13-*cis* isomer (IVa) are δ 7.84 (d, C-12), 2.01 (s, C-20), and 5.57 ppm (s, C-14). The ^{13}C-NMR spectra of the all-*trans*-retinamides are in excellent agreement with one another and with data from spectra of other all-*trans*-retinoids determined by Englert (35) and assigned with the use of lanthanide shift reagents. The greatest differences in the ^{13}C-NMR spectra (obtained in $CDCl_3$) of the 13-*cis*-retinamides (IVa, b, d, and e) relative to the spectra of the all-*trans* amides (IIa–l) are the downfield shift of C-20 (~7.2 ppm) and the upfield shift of C-12 (5–6 ppm). Significant upfield shifts were also observed in the C-13 (1.8–2.1 ppm), C-14 (1.7–1.8 ppm), and C-15 (0.4–0.5 ppm) peaks in the 13-*cis*-retinamide spectra. These differences are exemplified by chemical shifts in the ^{13}C-NMR spectra of the all-*trans*- and 13-*cis*-*N*-ethyl amides: C-20, δ 13.54 (IIb) and 20.73 ppm (IVa); C-12, δ 135.79 (IIb) and 129.7–130.6 ppm [one of four closely spaced peaks (C-5, C-10, C-11, and C-12) in the spectrum of IVa]; C-13, δ 147.89 (IIb) and 145.98 ppm (IVa); C-14, δ 121.95 (IIb) and 120.23 ppm (IVa); C-15, δ 167.12 (IIb) and 166.66 ppm (IVa).

The UV spectra[2] of the aliphatic all-*trans*-retinamides have an absorption maximum at 347–348 nm with a molar absorptivity (ϵ) of ~50,000–51,000. This maximum is shifted slightly (2–4 nm) to longer wavelengths in the spectra of the 13-*cis*-retinamides, and the molar absorptivity is lower (range: 42,200–47,700). Both the absorption maxima and the absorptivity are greater in the *N*-aryl amides. The IR spectra[2] of all of these retinamides (II and IV)

[1] Compounds IIf–i were first supplied for biological evaluation (16) by BASF Aktiengesellschaft, Ludwigshafen am Rhein, West Germany, and compounds IIm,n, by Johnson and Johnson, New Brunswick, N.J.

[2] Detailed spectrometric data for the individual retinamides (IIa–n and IVa–e) are listed in a complementary publication (34).

show at least one strong band in the region of 965–985 cm^{-1}. This band is due to the C—H out-of-plane vibrations of the *trans*-disubstituted ethylene groups (36). The molecular ion (M) is one of the most intense peaks observed above *m/z* 200 in the mass spectra of the retinamides (II and IV) when the spectra[2] are measured in the electron-impact mode at a direct-probe temperature of ~20°C. Additional characteristic, though less intense, peaks observed are M − 15, loss of a methyl group; M − 123, loss of the 2,6,6-trimethyl-1-cyclohexenyl group; and M − R, *m/z* 298, loss of the R group, when R is not an aryl group. In all of the spectra in the region above *m/z* 200, other characteristic peaks that are usually more intense than the peak at M − 15 or at *m/z* 298 are *m/z* 282 (M − NHR − H), 267 (282 − CH_3), 255 (M − CONHR), 241 (M − CH_3 − CONHR + H), 240, 239, 225 (240 − CH_3), 213, 211, and 201. Other prominent peaks, as well as less intense peaks, also appear in the region above *m/z* 200, and numerous strong peaks are present in all of the spectra in the region below *m/z* 200.

Most of these retinamides have been evaluated in the hamster trachael organ assay and are highly active (16). Several have been shown to have chemopreventive activity (24, 25) *in vivo* and to be significantly less toxic than is all-*trans*-retinoic acid (37). All-*trans*-retinoylglycine, (II l) like all-*trans*- and 13-*cis*-retinoic acids, is a strong inducer of retinoic acid metabolism (38) and is more active against hyperplasia in mouse prostate organ cultures than is all-*trans*-retinoic acid (39).

EXPERIMENTAL

All operations involved in the preparation, isolation, purification, and transfer of retinoids were performed in an atmosphere, or under a current, of dry nitrogen or argon. All such operations were also performed in dim light or photographic darkroom light and, insofar as possible, with containers wrapped with aluminum foil or with black cloths. All retinoids were stored in an atmosphere of argon or nitrogen in hermetically sealed containers at −20°C or −80°C.

Melting temperatures were determined in capillary tubes[3]. UV spectra[4] were determined with ethanol solutions (except for IIm, where methanol was employed). IR spectra[5,6] were determined from specimens in pressed potassium bromide disks. Mass spectral data were taken from low-resolution, electron-impact spectra determined at 70 eV[7]; the direct-probe temperature was 20°C. ^{1}H-NMR spectra were determined at 100 MHz[8]. ^{13}C-NMR spectra were determined at 25.2 MHz[8] or 100.6 MHz[9]. Both the ^{1}H- and ^{13}C-NMR spectra were recorded from $CDCl_3$ solutions except for the spectra of IIm and IVc, which were recorded from Me_2SO-d_6 solutions. The more salient spectroscopic data are summarized in the discussion.

TLC was performed on plates of fluorescing silica gel[10], and developed plates were examined with UV lamps (254 and 365 nm) unless otherwise indicated in parentheses. Other pertinent information (amount applied, developing solvent, other methods of detection) is given parenthetically at the appropriate places in the experimental procedures.

HPLC was performed with a components system[11] and an integrator[12] or with a complete system[13] and was monitored by UV at 340 nm, unless otherwise indicated. Reverse-phase HPLC was performed on columns of octadecylsilane (ODS) chemically bonded to silica: column A, μBondapak[11] C_{18}, 10-μm particle size; column B, Spherisorb[14] ODS, 5-μm particle size; column C, Partisil[15] ODS-2, 10-μm particle size. HPLC eluting solvents were: solvent A, gradient 60:40 acetonitrile–water (solution *a*) → 98:2 acetonitrile–water (solution *b*), 0% solution *b* → 100% solution *b*; solvent B, 85:15 acetonitrile–1% aqueous ammonium acetate, isocratic; solvent C, 80:20 acetonitrile–1% aqueous ammonium acetate, isocratic.

All-*trans*-retinoyl Chloride (Ib)—All-*trans* retinoic acid (Ia, 400 g, 1.33 mol) was suspended in 4 L of dry, reagent-grade benzene in a dry 12-L, 3-necked, round-bottom flask fitted with a motor-driven stirrer, thermometer, addition funnel, and inlet and exit tubes for nitrogen. A solution of 129.3 g (0.94 mol) of phosphorus trichloride in 1.6 L of dry benzene was added in a fast, continuous stream to the vigorously stirred mixture at ~25°C. No increase in temperature was observed during the addition; stirring was continued under a brisk current of nitrogen and with occasional warming to maintain the temperature at 25–30°C. The retinoic acid slowly dissolved, and the mixture changed from a suspension to an orange solution plus a gummy precipitate (phosphorus compounds) that generally collected on the walls of the flask. On this scale, all of the retinoic acid dissolved within ~3 h. The solution was stirred for an additional 1 h, stirring was discontinued, and the gummy precipitate was allowed to settle.

While the retinoyl chloride solution was being prepared, a dry benzene or benzene–dimethylformamide solution of the amine required for the desired retinamide was prepared under nitrogen and cooled. The retinoyl chloride solution was decanted under nitrogen into an addition funnel for introduction into the appropriate amine solution.

All-*trans*-*N*-methylretinamide (IIa)—By the procedure described for the preparation of IIb (below), methylretinamide IIa was prepared from Ib and methylamine, recrystallized from methanol, and dried *in vacuo* at room temperature to yield 11.3 g from 15 g of Ia (72%), mp 175–176°C. Since TLC revealed a trace impurity and NMR showed the presence of a small amount of methanol, the product was recrystallized from ethanol (300 mL) to yield 8.6 g (55%), mp 175–176°C [lit. (27) mp 174–175°C]; TLC: 1 spot (99:1 chloroform–methanol); HPLC: 100% (column A, solvent A, monitored at 345 and 254 nm).

Anal.—Calc. for $C_{21}H_{31}NO$: C, 80.47; H, 9.97; N, 4.47. Found: C, 80.42; H, 10.03; N, 4.40.

All-*trans*-*N*-ethylretinamide (IIb)—The general procedure (25) for the preparation of IIb and similar all-*trans*-retinamides is illustrated by the following procedure. A solution of all-*trans*-retinoyl chloride (Ib) prepared, as described above, from 400 g (1.33 mol) of Ia was added during 0.5 h to a stirred solution of 595 g (13.2 mol) of ethylamine in 1100 mL of dry, reagent-grade benzene at 10°C. The temperature was maintained at 10–15°C with an ice–salt bath, and the reaction mixture was stirred an additional 0.5 h at 10°C. Cold water (4 L) was added during ~10 min, stirring was continued for 15 min, and the mixture was concentrated *in vacuo* with a large rotating evaporator to remove the benzene and excess ethylamine. The yellow, crystalline solid suspended in the aqueous mixture was collected by filtration, pressed by suction with a rubber sheet to remove a yellow, oily material, washed thoroughly on the filter with water, pressed again with a rubber sheet to remove as much water as possible, and dried further *in vacuo*. The solid was dissolved in hot methanol (~5 L), the solution was filtered, and the hot filtrate was diluted with warm water to the cloud point. The mixture was allowed to cool to room temperature and was then stored in a refrigerator overnight. The yellow, crystalline product was collected by filtration, washed with cold methanol–water (4:1), and dried *in vacuo* to constant weight to yield 356 g (82%), mp 138–140°C [lit. (27) mp 137–138°]; TLC: 1 spot (99:1 chloroform–methanol); HPLC: 99.7–100% (column B with solvent B or column A or C with solvent C, monitored at 350 and 254 nm).

All-*trans*-*N*-butylretinamide (IIc)—Compound IIc was prepared by the procedure described for IIb from butylamine (580 mL in 1 L of dry benzene) and a solution of Ib (prepared from 400 g of Ia, 81.3 mL of phosphorus trichloride, and 5 L of dry benzene). The mixture was stirred for 45 min and then washed thoroughly with cold water (1.5 L). The organic layer was washed again with cold water (1 L), concentrated to ~1 L, filtered to collect a yellow precipitate, and concentrated further to obtain a second crop[16]. The crude product (450 g) obtained by combining the two crops was recrystallized from methanol–water (9:1, 2.7 L). The yellow, crystalline solid was collected by filtration, washed with cold methanol–water, and dried *in vacuo* at room temperature to yield 376 g (79%) of IIc, mp 92–94°C [lit. (27) mp 92–93°C]; TLC: 1 spot (99:1 chloroform–methanol); HPLC: >99.9% (column B, solvent B).

Anal.—Calc. for $C_{24}H_{37}NO$: C, 81.07; H, 10.49; N, 3.94. Found: C, 81.03; H, 10.68; N, 3.75.

All-*trans*-*N*-(2-hydroxyethyl)retinamide (IId)—Compound IId was prepared by the procedure described for IIb from ethanolamine (dried over molecular sieves, 600 mL in 1 L of dry benzene) and a solution of Ib (prepared from 350 g of Ia in 4.8 L of dry benzene). After a reaction period of 45 min at 10°C, the product (pasty solid) was isolated (difficult filtrations) as was IIb, washed with cold methanol–water (1:1), triturated with cold methanol–water (2:1, 400 mL), and recrystallized (*cf.*, IIb) twice from methanol–water (3:1). The yellow crystals were dried *in vacuo* at room temperature to yield 335 g (84%) of IId, mp 139–141°C [lit. (27) mp 138–139°C]; TLC: 1 spot with tailing (95:5 chloroform–methanol); HPLC: 99.8–100% (column B and solvent B or column C and solvent D).

Anal.—Calc. for $C_{22}H_{33}NO_2$: C, 76.93; H, 9.68; N, 4.08. Found: C, 76.63; H, 9.88; N, 3.98.

[16] Compound IIc could also be isolated by evaporating benzene and butylamine from the water-organic mixture (*cf.*, IIb) after addition of the second portion of water and then including the yellow, oily layer to crystallize.

All-*trans*-*N*-propylretinamide (IIe)—Compound IIe was prepared from Ia (50 g) and *n*-propylamine (59 g) by the procedure described for IIb. The crude product (51 g) was recrystallized from ethanol-water (5:1, 600 mL) to yield 45.8 g (81%), mp 113–114°C [lit. (28) mp 113–115°C]; HPLC: 99.4% (column B, solvent B).

Anal.—Calc. for $C_{23}H_{35}NO$: C, 80.88, H, 10.33; N, 4.10. Found: C, 81.18; H, 10.69; N, 3.89.

(±)-All-*trans*-*N*-(2-hydroxypropyl)retinamide (IIf)—Compound IIf was prepared by the procedure described for IIb from (±)-1-amino-2-propanol (420 mL in 1.8 L of dry benzene) and a solution of Ib (prepared from 300 g of Ia, 60.8 mL of phosphorus trichloride, and 3.8 L of dry benzene). After a reaction time of 1 h at 10–15°C and concentration of the reaction mixture to ~50% of the original volume, the addition of cold water (1.5 L) to the stirring mixture caused precipitation of the product. The mixture was allowed to stand in an ice bath, and the precipitate was then collected by filtration, pressed with a rubber sheet by suction on the filter, washed with water, and dried. The benzene layer was separated from the filtrate, concentrated, and diluted with cold water (500 mL). A second portion of IIf was separated by filtration as above. The two portions were combined (279 g) and recrystallized from 2:1 acetonitrile-water (3 L). The pale yellow, crystalline product was collected by filtration and dried at room temperature to yield 237 g (67%) of IIf, mp 116–117°C; TLC: 1 spot (95:5 chloroform-methanol); HPLC: 99.4–99.9% (column B, solvent B).

Anal.—Calc. for $C_{23}H_{35}NO_2$: C, 77.27; H, 9.87; N, 3.92. Found: C, 77.58; H, 10.11; N, 4.08.

All-*trans*-*N*-(3-hydroxypropyl)retinamide (IIg)—A mixture of Ia (200 g, 0.67 mol), 1,1′-carbonyldiimidazole (124 g, 0.79 mol), and anhydrous benzene (2 L) was stirred at room temperature for 2 h. The resulting solution was warmed at 50°C in a water bath for 15 min, cooled to room temperature, and slowly added to a cold (10°C), stirred solution of 3-amino-1-propanol (260 mL, 3.6 mol) in anhydrous benzene (1 L). The reaction mixture was stirred at 10°C for 2 h, allowed to stand at room temperature overnight, and diluted with ether (~1 L) to minimize emulsification. The resulting solution was washed with water (2 × 1 L), and the organic layer was dried over sodium sulfate and concentrated to a low volume. The yellow, finely divided precipitate was collected by filtration, washed with small amounts of benzene and ether, and dried *in vacuo* to yield 195 g. A second crop (18 g) was obtained from the filtrate (total yield of crude IIg = 89.4%). The two portions were combined and dissolved in hot ethyl acetate (1 L). The pale yellow precipitate was filtered from the cool mixture and dried *in vacuo* to yield 154 g (65%) of IIg, mp 110–111°C (cap., inserted at 95°C); TLC: 1 spot (95:5 chloroform-methanol); HPLC: 99.7–100% (column B, solvent B).

Anal.—Calc. for $C_{23}H_{35}NO_2$: C, 77.27; H, 9.87; N, 3.92. Found: C, 77.30; H, 10.05; N, 4.14.

All-*trans*-*N*-(4-hydroxybutyl)retinamide (IIh)—The procedure was similar to that described for the preparation of IIg except that the ratio of the amine (4-aminobutanol, 0.97 mol) to Ia (0.33 mol, 100 g) was lower. After the benzene-ether solution had been washed with cold water (3×), it was concentrated to a viscous oil that crystallized after seed crystals were added. The yellow, crystalline solid was triturated with cyclohexane-hexane (1:2, 100 mL), collected by filtration, dried *in vacuo* (weight, 96 g), and recrystallized from acetonitrile (hot). The pale yellow crystals were filtered from the cold mixture and dried *in vacuo* at room temperature to yield 93 g (73%) of IIh, mp 111–113°C (cap., inserted at 80°C); TLC: 1 spot (95:5 chloroform-methanol); HPLC: 99.8% (column B, solvent B).

Anal.—Calc. for $C_{24}H_{37}NO_2$: C, 77.58; H, 10.04; N, 3.77. Found: C, 77.76; H, 10.30; N, 3.65.

A polymorphic form of IIh was also obtained (from cyclohexane or acetonitrile), mp 95–96°C. The solid-state IR spectrum differed from, but was similar to, that of the higher-melting form. The two forms were shown to be identical by TLC, HPLC, ^{1}H-NMR, and ^{13}C-NMR.

(±)-All-*trans*-*N*-(2,3-dihydroxypropyl)retinamide (IIi)—A solution of all-*trans*-retinoyl chloride (prepared from 100 g of Ia, 21 mL of phosphorus trichloride, and 1300 mL of dry benzene) was added to a solution of 200 g of (±)-3-amino-1,2-propanediol in 1200 mL of dry benzene and 300 mL of dimethylformamide at a rate that did not cause the mixture temperature to exceed 20°C. The orange, two-phase mixture was stirred overnight at room temperature. The supernatent solution was decanted from the gummy amine hydrochloride and divided into approximately equal amounts in two 5-L separatory funnels, each containing 1 L of water and 1.5 L of ethyl acetate. The emulsions separated during standing, and the aqueous layers were removed. The organic layers were extracted repeatedly (5–8 times) with 600-mL portions of water. Additional amounts of ethyl acetate and small portions of sodium chloride were added, as needed, during these extractions to cause separation of the emulsions. The two organic layers were combined, and the solution was chilled in an ice bath, dried over anhydrous magnesium sulfate, and concentrated *in vacuo* to ~1 L. (Much magnesium sulfate was required to dry the solution and considerable heat was evolved.) Finely divided, yellow crystals formed, and 1 L of cyclohexane was added. After the mixture had been stored in a freezer overnight, IIi was collected by filtration, washed with 1:1 ethyl acetate-cyclohexane, and dried *in vacuo* at room temperature to constant weight to yield 103 g (83%), mp 101–104°C. Polymorphic forms of IIi were obtained: mp 83–85°C from acetonitrile; mp 101–104°C from ethyl acetate. The specimen described above (103 g) was recrystallized from acetonitrile to yield 98 g (79%) of IIi, mp 83–85°C; HPLC: 98–100% (column B, solvent B).

Anal.—Calc. for $C_{23}H_{35}NO_3$: C, 73.96; H, 9.44; N, 3.75. Found: C, 73.21; H, 9.64; N, 3.63.

Preparation of Derivative IIj—A solution prepared by carefully adding 16.74 mL of 60% perchloric acid to a stirred solution of 11.16 mL of 2,2-dimethoxypropane and 415 mL of anhydrous acetone was stirred for 5 min, (±)-all-*trans*-*N*-(2,3-dihydroxypropyl)retinamide (12.5 g) was added in one portion, and the resulting solution was stirred for 50 min. Pyridine (16.75 mL) was added, and the solution was concentrated *in vacuo* to a gummy residue that was partitioned between chloroform (500 mL) and saturated aqueous sodium bicarbonate (500 mL). The aqueous layer was reextracted twice with 250-mL portions of chloroform, and the chloroform solution (3 portions combined) was dried over magnesium sulfate and concentrated *in vacuo* to an orange syrup. A solution of the residual syrup in petroleum ether (125 mL, bp 30–60°C) was filtered and then refrigerated. A yellow precipitate was collected by filtration, washed with cold petroleum ether, and dried *in vacuo* at room temperature to give 11.8 g. Since TLC showed that this material still contained some of the starting material, it was chromatographed on a column of silica gel. The column was eluted with 95:5 chloroform-methanol, and the fractions containing IIj were located by TLC. Concentration of these fractions *in vacuo* left a yellow syrup (8.2 g) that was crystallized from petroleum ether (150 mL). Yellow crystals were filtered from the cold mixture, washed with petroleum ether, and dried *in vacuo* at room temperature to yield 6.02 g (43.5%) of IIj, mp 106–110°C; HPLC: 97.2% (column B, solvent B); UV_{max} (ethanol): 348 nm (ϵ 47,500).

All-*trans*-*N*-retinoylglycine Ethyl Ester (IIk)—A solution of 196 g (1.40 mol) of glycine ethyl ester hydrochloride in 200 mL of water was covered with 400 mL of ether. The mixture was cooled to 0°C in an ice bath, and 160 mL of 33% aqueous NaOH was added at such a rate that the temperature of the reaction mixture did not exceed 4°C. Immediately after the sodium hydroxide had been added, anhydrous potassium carbonate was added until the water layer was a pasty mass. The ether layer was decanted, and the residual mass was extracted twice with 250-mL portions of ether. The combined, cold, ether extracts were dried over a 9:1 mixture of anhydrous potassium carbonate and barium hydroxide and filtered through a pad of anhydrous magnesium sulfate. The total volume of the combined filtrate and ether washings was 900 mL. The solution was cooled to 5°C and used in the coupling reaction with Ib. (In an earlier, small-scale reaction, concentration of the dried, ether extracts afforded a fluid, colorless oil; examination of this product by MS and by ^{1}H-NMR indicated that little or no diketopiperazine was present.)

A solution of Ib in 450 mL of dry benzene (prepared from 45 g of Ia) was added to the vigorously stirred ethyl glycinate solution (described above) at a rate that did not cause the temperature to exceed 10°C. The mixture was then stirred at 10°C for 1 h. Ice-cold water (450 mL) was added in a dropwise manner, the two-phase mixture was concentrated *in vacuo* at ~35°C to remove the ether and benzene, and the fluid yellow syrup that remained in suspension was extracted into a minimum amount of ether. The ether layer was stirred vigorously with water (400 mL) to ensure thorough mixing, the mixture was concentrated *in vacuo* to remove the ether, and the water was decanted from the viscous syrup. This process was repeated, but the water-syrup mixture was refrigerated overnight before the water was decanted. An ether solution of the residual syrup was dried ($MgSO_4$) and concentrated *in vacuo* at 35°C to constant weight to yield 55 g (95%) of a yellow glassy material. Crystalline IIk was obtained by dissolving the glassy material in warm ethanol and storing the filtered solution at −15°C; mp 91–93°C; TLC: 1 spot (10:1 chloroform-acetone); HPLC: 99% (column A, solvent A).

Anal.—Calc. for $C_{24}H_{35}NO_3$: C, 74.76; H, 9.15; N, 3.63. Found: C, 74.39; H, 8.95; N, 3.36.

All-*trans*-*N*-retinoylglycine (II l)—A stirred solution of 15.0 g (38.9 mmol) of crude *N*-retinoylglycine ethyl ester in 265 mL of ethanol that contained 15.0 g of 85% KOH was heated at 60°C for 1 h. The reaction mixture was poured into 600 mL of water at 0°C, and the solution was extracted with ether (3 × 250 mL) to remove neutral and basic impurities. When the aqueous layer was acidified to pH 3 with 1.5 M sulfuric acid, a fluid oil separated. The mixture was extracted with 250 mL of ether, and the extract was washed twice with water and dried over anhydrous magnesium sulfate. Concentration of the dried extract afforded 13.5 g (97%) of a viscous orange syrup. Crystallization of the crude product twice from acetonitrile (about 10 ml/g) gave yellow microcrystals, mp 94–97°C; TLC: 1 spot (8:2:1 butanol-acetic acid-

water); HPLC: >98% (column A, solvent 1:1 acetonitrile–1% ammonium acetate).

Anal.—Calc. for $C_{22}H_{31}NO_3$: C, 73.91; H, 8.74; N, 3.92. Found: C, 73.68; H, 8.21; N, 3.78.

All-*trans*-*N*-(4-hydroxyphenyl)retinamide (IIm)—The preparation of IIm was based on the procedure of Gander and co-workers (24, 28) and is similar to the preparation of other all-*trans*-retinamides from IIb. The literature procedure (24, 28) was modified to adapt it to large-scale synthesis as follows. The precipitate of 4-aminophenol hydrochloride was filtered from the reaction mixture; the filtrate was washed with water, concentrated, and chilled; and the crude, crystalline product was collected (1–3 crops). These modifications obviate the need for the large quantities of ether used in the original procedure and permit the preparation of 300–400 g of IIm per run. (Some ether was added during the workup of some of the preparations of IIm in order to minimize emulsification.) The crude product was recrystallized from methanol–water and then from ethanol–water, mp 173–175°C; TLC: 1 spot (95:5 chloroform–methanol); HPLC: 99.9% (column B, solvent B).

Anal.—Calc. for $C_{26}H_{33}NO_2$: C, 79.77; H, 8.50; N, 3.58. Found: C, 79.55; H, 8.75; N, 3.54.

This compound evidently crystallizes in several polymorphic or solvated forms. Among many specimens prepared by the procedure outlined above, the mp of 173–175°C was typical, and the IR spectra of most of these specimens were identical; however, the solid-state IR spectra of a few specimens that melted over a 1–2°C range between 171°C and 176°C differed in fine structure from the typical spectrum. Therefore, there may be more than one form with a melting point in this range. Also, a form obtained by slow crystallization of IIm from methanol melted at 178–181°C and retained methanol. The form reported by Gander and co-workers (24) melted at 162–163°C and apparently is more soluble in chloroform than the typical form described above. All of these forms, including a specimen with mp 162–163°C (24), were shown by UV, ^{1}H-NMR, ^{13}C-NMR, MS, TLC, and HPLC to be identical with one another and to be IIm of high purity.

All-*trans*-*N*-[4-(pivaloyloxy)phenyl]retinamide (IIn)—This compound was prepared by acylating IIm with pivaloyl chloride in benzene–pyridine, pouring the reaction mixture into water, and recrystallizing the yellow precipitate from methanol–water and then from ethanol–water, mp 158–160°C; TLC: 1 spot (99:1 chloroform–methanol); HPLC: 99.9–100% (column B, solvent B).

Anal.—Calc. for $C_{31}H_{41}NO_3$: C, 78.28; H, 8.69; N, 2.94. Found: C, 78.23; H, 8.72; N, 2.71.

1-(13-*cis*-Retinoyl)imidazole (IIIc)—A mixture of 13-*cis*-retinoic acid (20 g, 66 mmol) and 1,1′-carbonyldiimidazole (12.4 g, 76 mmol) in benzene (300 mL) was stirred at room temperature for 3 h; gas evolution had ended by this time. The solution was warmed to 50°C for 15 min and then concentrated *in vacuo* to an orange syrup. A mixture of the residue and cyclohexane (250 mL) was stirred at room temperature, filtered to remove a beige solid, and concentrated to dryness under reduced pressure. A solution of the residue in cyclohexane (150 mL) was diluted with hexane (50 mL) and cooled with stirring in an acetone–dry ice bath at −10°C. A yellow precipitate was collected by filtration and dried to yield 18 g (77% yield of crude product). Recrystallization of a 13-g portion of this material from cyclohexane and refrigeration of the mixture afforded 7 g of a yellow solid, mp 70–85°C; HPLC: 98%. A second crop of 2.4 g (mp 75–80°C; HPLC: 96.6%) was obtained after the filtrate was diluted with hexane and refrigerated. A cyclohexane (150 mL) solution of 6.9 g of this material (crop 2 plus part of crop 1) was washed with water (2 × 50 mL), dried ($MgSO_4$), concentrated to ~30 mL, and stored at −15°C. A yellow crystalline solid was collected by filtration and dried *in vacuo* to yield 5.0 g of IIIc, mp 85–86°C (cap., inserted at 65°C); HPLC (column B, solvent B): 98.2% IIIc (retention time, 20.2 min) and 1.2% of an impurity (retention time, 17.6 min). A spike at δ 1.42 ppm on the upfield side of a multiplet in the ^{1}H-NMR spectrum indicated the presence of a small amount of cyclohexane in this specimen. A portion was crushed to a powder and dried thoroughly *in vacuo* prior to microanalysis.

Anal.—Calc. for $C_{23}H_{30}N_2O$: C, 78.82; H, 8.63; N, 7.99. Found: C, 78.94; H, 8.79; N, 8.26.

From another run beginning with 40 g of 13-*cis*-retinoic acid, compound IIIc was obtained in three crops of crystals from cyclohexane–hexane: 2.4 g, mp 77–80°C; 22.6 g, mp 73–83°C; and 13.3 g, mp 82–84°C. The total yield of IIIc satisfactory for use as an intermediate was 82%.

13-*cis*-*N*-Ethylretinamide (IVa)—13-*cis*-Retinoic acid (IIIa, 75 g, 0.25 mol, dried *in vacuo* over P_2O_5) was suspended in 700 mL of dry, reagent-grade benzene, and a solution of 15.2 mL of phosphorus trichloride in 200 mL of dry benzene was added rapidly to the vigorously stirred mixture. The reaction mixture was then stirred at 25°C for 3 h. During this time, 13-*cis*-retinoic acid slowly dissolved and a gummy precipitate formed. Stirring was discontinued, the precipitate was allowed to settle, and the supernatant solution was decanted into an addition funnel.

The acid chloride (IIIb) solution was added slowly to a stirring solution of 130 mL of ethylamine in 300 mL of dry benzene at 10°C, and stirring was continued for 0.5 h. Cold water (250 mL) was added with stirring, the layers were separated, and the aqueous layer was discarded. The benzene layer was washed with two more 250-mL portions of water and concentrated *in vacuo* to a viscous, yellow syrup. The syrup was dissolved in methanol (175 mL), and the solution was diluted slowly with water just short of the cloud point and then seeded with previously obtained crystals of IVa. After some crystallization had occurred, more water was added slowly with stirring (50–75 mL), and the mixture was refrigerated overnight. The precipitate (68 g) was collected by filtration, dried, and recrystallized by dissolving it in refluxing acetonitrile and adding water (~6:1 acetonitrile–water) to yield 64 g (78%), mp 114–115°C (cap., inserted at 95°C); TLC: 1 spot (99:1 chloroform–methanol); HPLC (column B, solvent B): >99.9%.

Anal.—Calc. for $C_{22}H_{33}NO$: C, 80.68; H, 10.16; N, 4.28. Found: C, 80.75; H, 10.44; N, 4.41.

13-*cis*-*N*-Butylretinamide (IVb)—A solution of 13-*cis*-retinoyl chloride (IIIb) [prepared as described above (IVa) from 40 g (133 mmol) of 13-*cis*-retinoic acid in 400 mL of dry benzene and 8.1 mL (93 mmol) of phosphorus trichloride in 155 mL of dry benzene] was added slowly to a vigorously stirred, cold (10°C) solution of 64 mL (650 mmol) of *n*-butylamine in 300 mL of dry benzene. Stirring was continued for 1 h, the mixture was extracted with cold water (2 × 500 mL), and the benzene layer was dried with anhydrous sodium sulfate and concentrated *in vacuo* to give a viscous, orange syrup. A solution of the syrup in 95% acetonitrile at room temperature was seeded with previously obtained crystals of IVb and refrigerated. The pale yellow, crystalline solid was collected by filtration, washed sparingly with cold 95% acetonitrile, and dried *in vacuo* to yield 35 g (74%), mp 77–78°C (cap., inserted at 50°C); TLC: 1 spot (98:2 chloroform–methanol); HPLC (column B, solvent B): >99.9%.

Anal.—Calc. for $C_{24}H_{37}NO$: C, 81.07; H, 10.49; N, 3.94. Found: C, 81.11; H, 10.69; N, 4.03.

13-*cis*-*N*-(4-Hydroxyphenyl)retinamide (IVc)—A solution of 13-*cis*-retinoyl chloride in benzene was prepared by the procedure described above for IVa from 65 g of 13-*cis*-retinoic acid (dried *in vacuo* overnight over P_2O_5), 13.2 mL of phosphorus trichloride, and 750 mL of dry benzene. The benzene solution of IIIa was added slowly to a cold (10°C), stirring solution of 100 g of 4-aminophenol in 400 mL of dimethylformamide (spectral grade), and the reaction mixture was allowed to warm to room temperature and stirred overnight. The mixture, containing precipitated 4-aminophenol hydrochloride, was stirred in an ice bath for 1 h before it was filtered to remove the precipitate. Water (400 mL) was added to the stirring filtrate, and the aqueous layer was separated and discarded. (Much of the product sometimes precipitated during the water extraction or during a second water washing.) The benzene layer was concentrated under reduced pressure to ~300 mL, cooled in an ice bath, and filtered to remove the yellow precipitate, which was washed with benzene and dried. This material (66 g) was combined with a second crop (14 g), obtained similarly from the filtrate and washings, and the total product was recrystallized from methanol–water. A refluxing ethanol solution of the recrystallized material (72 g) was diluted with water well past the point at which crystallization began, and the mixture was cooled to room temperature and then refrigerated. The yellow, crystalline precipitate was collected and dried to yield 70 g (82%) of IVc; mp 186–188°C (cap., inserted at 165°C); TLC: 1 spot (95:5 chloroform–methanol); HPLC (column B, solvent B): >99.7%.

Anal.—Calc. for $C_{26}H_{33}NO_2$: C, 79.77; H, 8.50; N, 3.58. Found: C, 79.99; H, 8.86; N, 3.66.

13-*cis*-*N*-(2-Hydroxyethyl)retinamide (IVd)—*From Isolated IIIc*—A solution of 5 g (14.3 mmol) of 1-(13-*cis*-retinoyl)imidazole (IIIc) in 50 mL of dry benzene was added slowly to a stirring mixture of 6.4 mL (105 mmol) of ethanolamine and 50 mL of benzene at 5–10°C. The mixture was stirred vigorously at 5°C for 2 h and then diluted with cold water (50 mL). Ether (100 mL) was added to cause separation of the emulsion. The benzene–ether layer was separated, washed with saturated aqueous sodium chloride, dried (Na_2SO_4), and concentrated under reduced pressure to a viscous syrup. The syrup was dissolved in hexane (50 mL) at room temperature, and the solution was filtered and stored at 5°C. A yellow, crystalline precipitate was collected by filtration and dried to give 3.5 g (71%). The crystalline product was only sparingly soluble in hexane, but it could be recrystallized by dissolving it in hot cyclohexane and cooling: yield 2.8 g (57%) of IVd; mp 107–109°C (cap., inserted at 95°C); HPLC (column B, solvent B): 98.8%.

From IIIc In Situ—A mixture of 13-*cis*-retinoic acid (50 g), 1,1′-carbonyldiimidazole (31 g), and dry benzene (500 mL) was stirred for 3 h at 20–25°C and then heated to 50°C for 15 min. The dark orange solution was slowly added to a stirring mixture of ethanolamine (62 mL) in benzene (500 mL) at ~10°C. This mixture was stirred for 2 h at 10–20°C; at this time TLC showed the absence of starting material. Cold, saturated, aqueous sodium chloride solution (500 mL) and then ether (500 mL) were added to the stirring

reaction mixture. The organic layer was separated and washed again with saturated aqueous NaCl. The benzene–ether solution was dried (Na_2SO_4) and concentrated *in vacuo* to a viscous syrup that was dissolved in hexane (450 mL) and refrigerated overnight. A yellow, crystalline precipitate was separated by filtration, slurried with hot hexane (400 mL) in which it was only slightly soluble, and recrystallized from cyclohexane to yield 38 g (66%) of IVd, mp 107–109°C (cap., inserted at 80°C); TLC: major spot and two slower, trace impurities (95:9 chloroform–methanol); HPLC (column B, solvent B): 99% IVd, retention time 6.6 min; 0.5% impurity, retention time 5.1 min; and 0.5% impurity, retention time 8 min.

Anal.—Calc. for $C_{22}H_{33}NO_2$: C, 76.93; H, 9.68; N, 4.08. Found: C, 76.82; H, 9.65; N, 3.94.

13-cis-*N*-(4-Hydroxybutyl)retinamide (IVe)—Compound IVe was prepared from 35 g (117 mmol) of IIIa, 21.7 g (134 mmol) of 1,1′-carbonyldiimidazole, and 350 mL of benzene by the second procedure described for the preparation of IVd, but the reaction mixture was concentrated under reduced pressure to a viscous syrup without first adding water. An ether (500 mL) solution of the syrup was extracted with water (2 × 250 mL), dried (Na_2SO_4), and evaporated to a viscous, orange syrup. A solution of the syrup in warm acetonitrile (200 mL) was filtered, diluted with warm water (~50 mL), seeded with IVe previously induced to crystallize from acetonitrile–water, cooled (with scratching) to room temperature, and stored in a refrigerator overnight. The pale yellow, crystalline precipitate was collected by filtration, washed sparingly with acetonitrile–water (2:1), and dried *in vacuo* to yield 26 g (60%) of IVe; mp 53–57°C (cap., inserted at 45°C); TLC: 1 spot with streaking (95:5 chloroform–methanol); HPLC (column B, solvent B): 99.3% IVe (retention time 6.8 min); 0.2% impurity, retention time 5.3 min; and 0.3% impurity, retention time 8.4 min.

Anal.—Calc. for $C_{24}H_{37}NO_2 \cdot 0.5H_2O$: C, 75.76; H, 10.07; N, 3.68. Found: C, 75.82; H, 10.08; N, 3.56.

Compound IVe was first obtained as a solvate with cyclohexane. The syrup obtained by the procedure described above from the ether solution was dissolved in warm cyclohexane. The solution was cooled to room temperature, refrigerated, and filtered to remove a yellow, crystalline product, mp 71–76°C (63% yield calculated as a 1:1 solvate). The solvate was recrystallized from cyclohexane (92% recovery) mp 73–76°C (cap., inserted at 65°C); TLC: IVe as a strong spot and a trace impurity (95:5 chloroform–methanol); HPLC: 99%. ^{1}H-NMR (δ 1.42, s, $CDCl_3$) and mass spectra (*m/z* 284) revealed the presence of cyclohexane; elemental analysis, UV, and ^{1}H-NMR indicated that the molar ratio of cyclohexane to IVe was ~1:1.

Anal.—Calc. for $C_{24}H_{37}NO_2 \cdot C_6H_{12}$: C, 79.08; H, 10.83; N, 3.08. Found: C, 78.87; H, 10.86; N, 3.00.

A specimen (43 g) kept in a high vacuum (continuous pumping, oil pump) at room temperature for 5 d did not lose weight. A specimen recrystallized from 90% acetonitrile appeared to retain at least some of the cyclohexane (mp 54–75°C; MS, *m/z* 84). A solution of the solvate in ethanol was evaorated to dryness *in vacuo*, and this process was repeated four times. The residual syrup was crystallized from acetonitrile–water, mp 53–57°C; HPLC: 98%. ^{1}H-NMR, UV, and MS indicated that the cyclohexane had been removed.

Stability and Storage—Observations of the sensitivity of several all-*trans*-retinamides in the crystalline state to atmospheric oxygen indicated that there are differences among compounds with this structure. The 2,3-dihydroxypropyl amide (IIi, polymorph with mp 83–85°C) appeared to be the most susceptible to deterioration during deliberate exposure to air. The crystalline material became amorphous, and the UV maximum decreased markedly. Eventually, the UV spectrum became a broad plateau with very low absorbance from 220–360 nm and slight elevations centered near 340 and 240 nm. HPLC analyses monitored by UV and based on relative areas may give grossly inaccurate (and high) assays of retinoids that have deteriorated in this manner. However, IIi could be stored for long periods in a liquid-nitrogen freezer, at low temperatures in flame-sealed ampules containing an inert atmosphere, or at low temperatures in heat-sealed, impervious plastic bags (below) containing an inert atmosphere. Crystalline specimens of the 2-hydroxyethyl (IId), 2-hydroxypropyl (IIf), and 4-hydroxybutyl (IIh) all-*trans* amides were also susceptible, but less so, to absorption of atmospheric oxygen; the ethyl (IIb) and 4-hydroxyphenyl (IIm) amides appeared to be more stable. These differences probably arise from differences in crystal form and particle size. For example, as expected, a finely crushed specimen of IIi (lower-melting polymorph) absorbed oxygen more rapidly than did an uncrushed specimen; also, the lower-melting polymorph of IIi absorbed oxygen more rapidly than did the higher-melting polymorph. Storage of retinoids at very low temperatures does not necessarily prevent deterioration unless the retinoids are continuously in an inert atmosphere such as that provided by a liquid-nitrogen freezer, flame-sealed ampules containing nitrogen or argon, or heat-sealed plastic bags containing argon or nitrogen. If a retinoid is placed in a container sealed at room temperature with a screw cap and if the container contracts more than the cap, crevices may develop at low temperatures that would permit the exchange of outside air with the container atmosphere.

Crystalline specimens of the retinamides (II and IV) were stored in an argon atmosphere in flame-sealed, all-glass ampules or in a liquid-nitrogen freezer. The ampules were the freeze-drying type, so they could withstand evacuation with a vacuum pump. The retinamide were put into ampules in a nitrogen atmosphere in a controlled-atmosphere box. After the ampules were loaded with the retinoids, the ampule necks were cleared of adhering crystals to prevent decomposition of small amounts of the retinoids during flame-sealing. The ampules were then attached to a system that included a manometer and a vacuum pump and evacuated; argon was then admitted into the ampules to atmospheric pressure. This process was repeated five times. After the final admission of argon, the neck of the ampule (still attached to the closed system) was sealed with a torch while the body of the ampule containing the retinoid was kept cool. The seals of the ampules were examined with a stereoscope (magnification 30×). The ampules were then placed in dry ice or in a freezer at −80°C at least overnight. The seals were then reexamined with the stereoscope to see if cracks had developed because of stresses during storage at low temperatures. If the retinoid was to be stored for extended periods, the ampules were kept either at −20°C or at −80°C. Retinoids stored for short periods of time were put in brown, screw-cap bottles. Argon or nitrogen was admitted into these bottles in an evacuated desiccator. Each sealed bottle, with tape around the cap, was then placed in an impervious plastic bag. The bag was heat-sealed except for a hole in a corner, flushed with nitrogen or argon with a tube through the corner, and then sealed completely. The sealing was done with a heat-pressure device.

UV and IR spectra and microelemental analyses were determined by Christine Richards, and HPLC was performed by Anita T. Shortnacy and Sheila R. Campbell. Some of the NMR spectra were determined with a Bruker WH-400 spectrometer, through the courtesy of Dr. Jerry D. Glickson, at the NMR Core Facility, Comprehensive Cancer Center, University of Alabama in Birmingham. 13-*cis*-Retinoic acid (synthesized by BASF Aktiengesellschaft, Ludwigshafen am Rhein, West Germany) was supplied by the Laboratory of Chemoprevention, National Cancer Institute.

Analysis of Oxprenolol in Formulations by High-Performance Liquid Chromatography

ADNAN EL-YAZIGI

Received December 6, 1982, from the *Department of Cancer and Radiation Biology Research, King Faisal Specialist Hospital and Research Centre, Riyadh 11211, Saudi Arabia.* Accepted for publication May 10, 1983.

Abstract □ A simple, accurate, and rapid high-performance liquid chromatographic method for the analysis of oxprenolol in commercial formulations is described. The analysis was performed on a cyano radial compression cartridge, with 0.0539 M, pH 3 phosphate buffer–acetonitrile–methanol (76:15.6:8.4) as the mobile phase. The flow rate was 5 mL/min, with detection at 272 nm; the mobile phase was employed for extraction. The assay was applied to the content uniformity test of three oxprenolol hydrochloride tablet formulations of different strengths and the contents of a 2-mg dry ampule for intravenous/intramuscular injection. The percent of label claim for each formulation tested was within 91.7–110%. The applicability of this assay to the analysis of some other β-blocking drugs was investigated. It was found that under the above conditions, atenolol, metoprolol, oxprenolol, and propranolol can be fully resolved in <3 min.

Keyphrases □ Oxprenolol—tablet and dry ampule formulations, assay alone or simultaneously with other β-adrenergic drugs, HPLC □ β-Adrenergic drugs—oxprenolol, propranolol, atenolol, and metoprolol, individual and simultaneous assay in formulations, HPLC

Oxprenolol, (±)-1-[*o*-(allyloxy)phenoxy]-3-(isopropylamino)-2-propanol (I), is a β-adrenergic drug frequently used in the treatment of hypertension (1), cardiac arrhythmias (2), and angina pectoris (3). The low dosage of I, particularly when administered intravenously, and its susceptibility to light and other storage conditions require assurance of potency and content uniformity of its dosage forms.

Several methods have been reported for the analysis of I in biological fluids including GC (4–8), TLC with fluorescence detection (9), and high-performance liquid chromatography (HPLC) (10, 11). While the GC assays involve prechromatography derivatization and multiple-step extraction, the TLC method includes derivatization of I to a fluorescing compound. The utilization of HPLC for the analysis of I provides a real advantage, since it does not involve lengthy derivatization steps and the compound is detected directly. However, the previously reported HPLC methods, in addition to lacking a high chromatographic efficiency, have not been applied to the analysis of I in formulations. No pharmacopeial assay of I is available.

The present report describes an expedient, accurate, and specific HPLC method for the analysis of I in formulations. The procedure can be applied for the chromatography of some other β-blocking drugs (atenolol, metoprolol, nadolol, and propranolol) under the same conditions employed for I.

EXPERIMENTAL

Materials—Methanol[1], acetonitrile[1], hexane[2], monobasic sodium phosphate[2], and 85% phosphoric acid[2] were either analytical or HPLC grade. Purified water[3] was used as obtained. The oxprenolol hydrochloride formulations[4] tested (20-, 40-, and 80-mg tablets and 2-mg dry ampules) were obtained in-house. Propranolol hydrochloride[5], nadolol[6], atenolol[5], and metoprolol tartrate[7] were used as received. Oxprenolol (I) was first extracted from a saturated solution of oxprenolol hydrochloride in 5 M NaOH with boiling hexane and was recrystallized several times (mp 77.1°C) from hexane.

Apparatus—The chromatograph used consisted of dual solvent delivery systems[8] with a mixing chamber, automatic sample injection processor[9], printer-plotter integrator data module[10], variable-wavelength UV detector[11], and radial compression module[12]. The analysis was performed on a 10-μm, 8-mm × 10-cm cartridge[13].

Chromatography Conditions—The mobile phase was methanol–acetonitrile–0.0539 M sodium phosphate buffer solution at pH 3 (8.4:15.6:76) filtered twice and deaerated before use. A flow rate of 5 mL/min was used throughout (pressure = 1100 psi). The UV detector was set at 272 nm, and the volume injected into the cyano cartridge was 40–60 μL.

1	0.0193	3.031	0.99995
2	0.00945	3.043	0.99999
3	0.0138	3.031	0.99999
4	0.0159	3.027	0.99999
5	0.0139	3.033	0.99999

[a] Peak area ratio *versus* concentration plots obtained by linear regression analysis; mean of four determinations (two samples in duplicate injections).

Preparation of the Buffer and Standard Solutions—The buffer solution was prepared by adding dropwise (≅0.45 mL/drop) 85% phosphoric acid to 1 L of 0.05 M monobasic sodium phosphate to adjust the pH to 3. The final buffer concentration was ≅0.0539 M.

Fifty milligrams of I or propranolol hydrochloride (internal standard) was weighed and carefully transferred into a 50-mL volumetric flask with fresh mobile phase. The solution was shaken until a complete dissolution was obtained, then brought to volume with a fresh mobile phase.

Calibration Curves—Calibration curves were constructed by transferring 1, 3, 5, 10, and 20 mL of the I standard solution into 25-mL volumetric flasks, and 5 mL of the internal standard solution was added to each flask. The solutions were brought to volume with fresh mobile phase and thoroughly mixed. An aliquot (~3 mL) of each solution was transferred into an autosampler vial and placed on the tray. The automatic sample injection processor was programmed to inject 50 μL of each vial in duplicate. Standard curves were prepared on different days, to establish linearity, and prior to each assay, for the calculation of I in the samples analyzed.

Combined Tablet Sample Assay—Fifteen tablets of each strength, *i.e.*, 80, 40, and 20 mg, were weighed and pulverized into a fine powder. An aliquot equivalent to 20 mg of oxprenolol hydrochloride (17.58 mg of I) was accurately weighed and carefully transferred to a 100-mL volumetric flask with fresh mobile phase. The flask was then shaken for 2 min, and the fluid was brought to volume with fresh mobile phase. The suspension was filtered through a filtration unit[14], and ~20 mL of the filtrate was transferred to a 25-mL volumetric flask containing 5 mL of the internal standard solution. The solution was then shaken and brought to volume with an adequate aliquot of the above filtrate. An aliquot (~3 mL) of this solution (theoretical final concentration is 0.14 mg/mL of I) was transferred to an autosampler vial and analyzed as described earlier. This assay was performed on eight replicate samples in duplicate injections.

Combined 2-mg Dry Ampule Samples Assay—The contents of five dry ampules were carefully transferred to a 50-mL volumetric flask with a syringe after reconstitution with fresh mobile phase. The ampules and syringe were thoroughly rinsed with mobile phase, and the rinse was added to the flask.

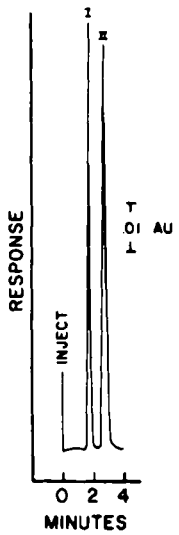

Figure 1—*Representative chromatogram of a calibration curve sample containing oxprenolol (I) with propranolol (II) as internal standard at a concentration of 0.2 mg/mL each. The mobile phase was pH 3 phosphate buffer–acetonitrile–methanol (76:15.6:8.4) at a flow rate of 5 mL/min; the stationary phase was a cyano cartridge.*

[14] Millipore.

Table II—Analyses of the Combined Dosage Unit Samples Showing the Reproducibility of the Assay

Sample	Percent of Label Claim[a] 80-mg Tablet	40-mg Tablet	20-mg Tablet	2-mg Dry Ampule

8	105.9	99.9	104.3	—
Mean	105.1	100.9	101.6	107.2
SD	2.85	1.79	1.70	2.56
CV	2.71	1.78	1.67	2.39

[a] Mean value of two injections.

After the volume was brought to the mark with mobile phase, 8 mL of the solution was transferred to a 10-mL volumetric flask containing 2 mL of the internal standard solution. The flask was then shaken, and an aliquot (~3 mL) of this solution (theoretical final concentration 0.14 mg/mL of I) was transferred to an autosampler vial and analyzed as described earlier. This assay was performed on five replicate samples in duplicate injections.

Content Uniformity Test—*Tablet Formulations*—The tablet was pulverized into a fine powder and carefully transferred to a 100-mL volumetric flask with fresh mobile phase, and 20 mL of the internal standard solution was added. The suspension was then brought to volume with fresh mobile phase and shaken vigorously for 2 min. A sufficient aliquot of the suspension was filtered through a filtration unit[14], and the filtrate was transferred to an autosampler vial and analyzed in duplicate as described earlier.

Dry Ampule for Intravenous/Intramuscular Injection—The content of the dry ampule was reconstituted with 2-mL aliquots of fresh mobile phase and transferred with a syringe to a 10-mL volumetric flask containing 2 mL of the internal standard solution. The ampule and syringe were rinsed with small aliquots of the mobile phase, and the rinse was added to the 10-mL volumetric flask. The solution was then shaken and brought to volume with

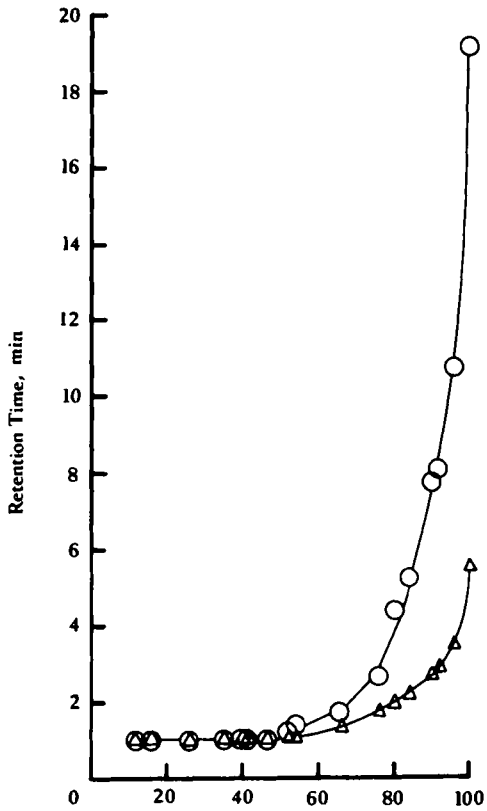

Figure 2—*Effect of the 0.0539 M phosphate buffer (pH 3) concentration in the mobile phase on the retention times of oxprenolol (Δ) and propranolol (○).*

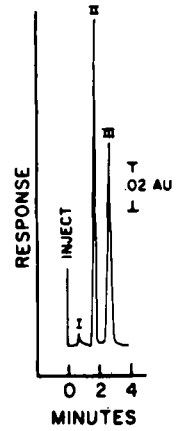

Figure 3—*Typical chromatogram obtained from the analysis of powdered 80-mg tablets. Key: (I) impurity; (II) oxprenolol; (III) propranolol.*

fresh mobile phase. An aliquot of this solution was transferred to an autosampler vial and analyzed in duplicate as described earlier.

Recovery of I from Tablets—Six accurately weighed 50-mg aliquots of a combined tablet powder (80-mg tablets) were transferred to 100-mL volumetric flasks. To five of these flasks, 5 mg of I was added; the remaining flask received no I. These samples were analyzed according to the procedure described under combined tablet sample assay using the sample which did not receive the additional 5 mg of I as a blank.

Chromatograph of Other β-Blockers—Dilute solutions of nadolol, atenolol, and metoprolol tartrate in fresh mobile phase were prepared and transferred to autosampler vials. The retention time of each drug was then determined under the same chromatographic conditions employed for I. A combined solution of atenolol, metoprolol tartrate, I, and propranolol hydrochloride in mobile phase was also prepared and chromatographed.

RESULTS AND DISCUSSION

A typical chromatogram of I and propranolol under the conditions employed is depicted in Fig. 1. As can be seen in this figure, a high efficiency (sharp, symmetrical peaks) and full resolution between I and propranolol are obtained in <3 min. Using C_{18} packing, the retention times under the conditions used were excessive, and although at high concentrations of methanol–acetonitrile in mobile phase the elution was quite rapid, tailing prevailed, suggesting strong binding of both compounds to silanol groups of the C_{18} packing. With the 0.0539 M phosphate buffer (pH 3)–acetonitrile–methanol mixture as the mobile phase, these compounds seemingly favor cyano packing, where both the normal- and reverse-phase modes of chromatography operate.

In an attempt to optimize the chromatography conditions of I and propranolol, the effect of the composition of the mobile phase on the retention times of these compounds was studied (Fig. 2). At zero concentration of the organic mixture (acetonitrile–methanol; 65:35) in the mobile phase the retention times of I and propranolol were 5.58 and 19.15 min, respectively, but the peaks were broad. As the concentration of the organic phase was increased, shorter retention times and sharper peaks were obtained; however, at an inorganic phase concentration of ≤46% (v/v), both compounds were eluted concomitantly without an appreciable change in retention times.

Based on these findings, it was concluded that the 76% phosphate buffer concentration in the mobile phase is an ideal composition for performing the chromatography, since it yields a high chromatographic efficiency and full resolution between I and propranolol in the shortest possible time; this was therefore selected for the analysis.

Table III—Content Uniformity Test of Oxprenolol Hydrochloride Formulations According to the Described Assay

Sample	Percent of Label Claim[a] 20-mg Tablet	40-mg Tablet	80-mg Tablet	2-mg Dry Ampule
1	102.5	94.8	103.5	101.7
2	103.2	105.8	104.3	105.0
3	94.8	105.7	102.3	100.4
4	107.8	104.5	103.3	97.0
5	91.6	104.3	99.5	100.0
6	103.0	104.1	102.1	104.0
7	108.7	107.3	101.7	109.4
8	98.6	104.0	103.8	105.4
9	106.3	106.0	105.2	107.0
10	103.3	101.5	103.5	110.0
Mean	102.0	104.0	102.9	104.0
SD	5.50	3.60	1.60	4.22
Range	91.6–108.7	94.8–107.3	99.5–105.2	97.0–110.0

[a] Mean of four determinations (two samples in duplicate injections).

The peak area ratio (I/internal standard) *versus* concentration calibration curves were linear ($r > 0.9999$) in the concentration range employed in this study (0.04–0.8 mg/mL) and were utilized to calculate I concentrations in the samples analyzed. The day-to-day variations in the slope and intercept were very small (Table I), indicating excellent concentration–response reproducibility.

The chromatogram presented in Fig. 3 is representative of a combined 80-mg tablet sample assay. The small front peak (retention time = 0.7 min) is an impurity or tablet excipient peak and does not interfere with the assay, since it is fully resolved from the peaks in question. The two minor peaks (retention times 0.86 and 1.15 min) which appear in the chromatogram of a single dry ampule analysis (Fig. 4) were also fully resolved.

The recovery of I from tablets was determined by adding 5 mg of I to 50 mg of powdered 80-mg oxprenolol hydrochloride tablets, equivalent to ~14 mg of I. The analysis of five such samples yielded the following recoveries: 100.8, 98.5, 98.3, 99.2, and 99.1% with a mean of 99.2% and a coefficient of variation of 0.991%. These data indicate that the assay precision is excellent and that the extraction procedure (using mobile phase and 2 min of shaking) employed is adequate, yielding a full recovery of I from tablets.

The reproducibility of the assay to analyze I in commercial formulations is clearly evident from the results of the combined tablets or dry ampule assay (Table II) where eight replicate analyses of each tablet lot and five replicate analyses of the combined dry ampule were performed. At no instance did the coefficient of variation exceed 2.7%, which indicates excellent assay reproducibility.

The results of the content uniformity test of commercial oxprenolol hydrochloride formulations are provided in Table III. The data were obtained from the application of the assay to three different-strength tablet formulations and a dry ampule for injection. Ten samples of each lot were analyzed individually, and the percent of label claim for each was calculated using an oxprenolol hydrochloride to I conversion factor of 0.879. As demonstrated in

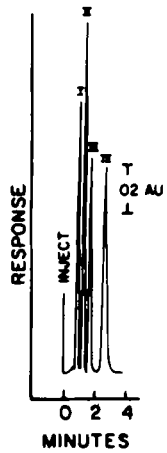

Figure 5—*Chromatogram obtained for a solution containing atenolol (I), metoprolol (II), oxprenolol (III), and propranolol (IV) in mobile phase.*

Table IV—Relative Retention Times[a] of Various β-Adrenergic Blocking Drugs

β-Blocking Drug	Relative Retention Time
Atenolol	0.340
Metoprolol	0.479
Nadolol	0.394
Oxprenolol	0.641
Propranolol	1.000

[a] Retention time of the β-blocking drug/retention time of propranolol.

Table III, the percent of label claim for all formulations tested were within the range of 91.6–110%. Unfortunately, no official USP or BP assay for I is available and, therefore, a comparison between the content uniformity test results obtained according to this method and those of an official assay was not possible. However, if this assay is to be used for such a test, it is clear that all the formulations investigated meet the USP content uniformity requirements (100 ± 15%).

The applicability of this assay for the analysis of some other β-blocking drugs was investigated, and the relative retention times (retention time of drug/retention time of propranolol) of these agents are listed in Table IV. It is clear that, with the exception of nadolol–atenolol (due to poor resolution), it is possible to analyze these drugs under the described chromatography conditions using one drug as the internal standard and the other as the unknown. Indeed, without changing a single chromatography condition, this assay can be utilized for the chromatography of atenolol, metoprolol, I, and propranolol simultaneously with a high efficiency and good resolution (Fig. 5) in <3.0 min.

Improved Liquid Chromatographic Assay for the Analysis of Pirmenol in Plasma and Urine

E. L. JOHNSON and L. A. PACHLA ˣ

Received September 7, 1982, from the *Department of Pharmacokinetics/Drug Metabolism, Warner-Lambert/Parke-Davis Pharmaceutical Research, Ann Arbor, MI 48105.* Accepted for publication April 22, 1983.

Abstract □ A sensitive, specific, and rapid high-performance liquid chromatographic procedure was developed for the determination of pirmenol in human biological fluids. Plasma or urine samples were alkalinized and extracted with cyclohexane. The organic extract was evaporated to dryness, reconstituted with the mobile phase, and then chromatographed on a microparticulate spherical trimethylsilane stationary phase with UV detection at 254 nm. The procedure for the assay of pirmenol in plasma was linear from 0.125 to 5.0 μg/mL. The reproducibility of the peak area ratios of the standard curves had relative standard deviations between 7.7 and 1.8% and a relative error of 0–4.6% over the linear range. The accuracy for the determination of pirmenol in human plasma containing 0.5, 2.5, and 4.0 μg/mL had relative errors of 9.0, 3.8, and 3.6%, respectively. Thirty compounds were tested and found not to interfere in the assay of the drug in plasma, and the method was found to be suitable for clinical samples. The urine procedure was linear between 1.0 and 30.0 μg/mL. The reproducibility of the peak areas of the standard curves had relative standard deviations that ranged from 1.9 to 6.2% over the linear range. The accuracy for the determination of pirmenol in human urine containing 5.0, 17.5, and 25.0 μg/mL had relative errors of 1.4, 0.5, and 2.8%, respectively.

Keyphrases □ Pirmenol—improved HPLC assay, plasma and urine, cyclohexane extraction □ HPLC—improved assay for pirmenol, plasma and urine, cyclohexane extraction

Pirmenol hydrochloride, (±)-*cis*-α-[3-(2,6-dimethyl-1-piperidinyl)propyl]-α-phenyl-2-pyridinemethanol monohydrochloride (I), a new antiarrhythmic drug currently being tested in Phase 1 clinical trials, is a promising agent because of its therapeutic response, lack of toxicity, and relatively long half-life (1). This report describes an improved procedure for the analysis of pirmenol when compared to a recently reported procedure (2). The present method is more accurate and precise due to the choice of extraction solvent and internal standard. The method has been validated for human biological samples, and various potential interfering compounds have been evaluated to demonstrate method specificity.

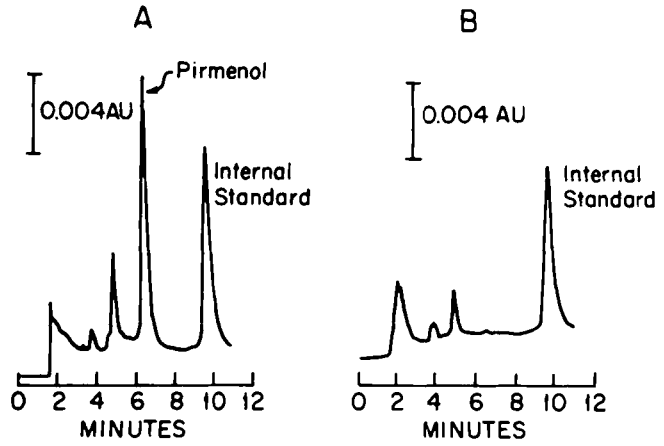

Figure 1—*Typical chromatograms for pirmenol and the internal standard in plasma. Key: (A) pirmenol in a 40-min plasma sample following infusion (150 mg iv at 5 mg/min) was estimated to be 1.7 μg/mL); (B) preinfusion plasma sample.*

chromatographic grade. Monobasic sodium phosphate[4], triethylamine[4], phosphoric acid[4], hydrochloric acid[5], and sodium hydroxide[5] were analytical reagent grade and were used as received.

Apparatus—The liquid chromatographic system was equipped with a constant-volume pump[6], valve-type injector[7], 254-nm fixed-wavelength detector[8], and a data acquisition system[9]. Separations were performed on a 25 cm × 4.6 mm i.d. stainless steel column containing 6-μm spherical trimethylsilane stationary phase[10].

Mobile Phase—The mobile phase was prepared by diluting 150 mL of acetonitrile to 1 L with phosphate buffer containing 0.5% triethylamine. The phosphate-triethylamine buffer was prepared by adding 6.9 g of monobasic sodium phosphate monohydrate and 5.0 mL of triethylamine to water, adjusting the pH to 2.6 with phosphoric acid, and then diluting to 1 L with water. The mobile phase was filtered through a 0.2-μm filter and deaerated by vacuum. The flow rate of the mobile phase was 1.5 mL/min, which produced a pressure of ~2700 psi. All separations were performed at ambient temperature. A 50-μL aliquot of extracted sample was injected into the chromatographic system.

Standard and Stock Solutions—Stock solutions of pirmenol (110.7 mg of pirmenol hydrochloride/10 mL of 0.05 M HCl) and the internal standard (II) (11.1 mg of II/100 mL of 0.05 HCl) were prepared. Standard solutions for plasma containing 0.25, 1.0, 2.0, 4.0, 6.0, 8.0, and 10 μg/mL and standard solutions for urine containing 4, 20, 40, 60, 80, 100, and 120 μg/mL were prepared by serial dilution of the stock pirmenol solution with 0.05 M HCl. The internal standard solution was further diluted 3:100.

Pirmenol Plasma and Urine Seeded Control Pools—One milliliter of 50-, 250-, or 400-μg/mL solutions of pirmenol (in 0.05 M HCl) was added to a 100-mL volumetric flask and brought to volume with control plasma to yield seeded control samples of 0.5, 2.5, and 4.0 μg/mL of pirmenol. Urine seeded controls were prepared by adding 0.5, 1.75, and 2.5 mL of a 1.0 mg/mL standard solution and diluting to 100 mL with control urine to yield 5.0-, 17.5-, and 25.0-μg/mL samples. The plasma and urine samples were then divided into 2.5-mL portions and frozen.

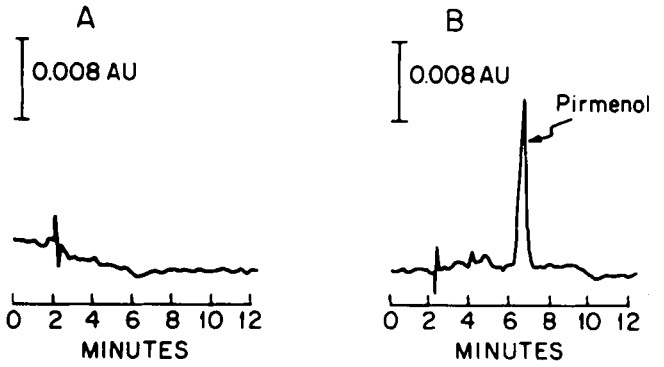

Figure 2—*Typical chromatograms for pirmenol in human urine. Key: (A) predrug urine sample; (B) pirmenol in an 18-h postdose urine sample of a patient administered 150 mg of pirmenol was estimated to be 4.0 μg/mL.*

[a] Peak area used for urine samples.

Assay for Pirmenol in Plasma and Urine—To a 1-mL sample in a 10-mL screw-top test tube were added 0.5 mL (0.25 mL for urine samples) of either 0.05 M HCl or pirmenol standard solution, 0.5 mL of internal standard solution (no internal standard is used for urine samples), 4 mL of cyclohexane, and 0.15 mL (0.2 mL for urine samples) of 1 M NaOH. After shaking for 10 min on a horizontal shaker and centrifuging[11] at 206×*g* for 5 min, 3 mL of the organic phase was transferred to a clean tube and evaporated to dryness. The residue was reconstituted in 0.2 mL (1 mL for urine samples) of the mobile phase by vortexing, and 50 μL (100 μL for urine samples) was injected into the chromatograph.

Interference Study—The specificity of the plasma procedure was assessed by direct injection of a number of potentially interfering compounds. If a compound eluted in the void volume or had a retention time >12 min, then the compound was deemed not to interfere in the assay. Those compounds having a retention time similar to either pirmenol or the internal standard were further tested in the following manner. Plasma containing 1 μg/mL of pirmenol was spiked with 100 μg/mL of the potentially interfering compounds. These samples were then assayed for pirmenol. If the pirmenol concentration deviated >±5% of the established value, than the compound was considered to interfere in the assay.

Method Application—To test the suitability of the procedure, samples from a clinical trial were assayed. In this trial, patients received a 150-mg dose of pirmenol intravenously or orally. For the intravenous dosing, patients were infused over a 30-min period with the drug dissolved in 5% dextrose. Blood samples were drawn at 15, 30, 32, 35, 40, 50, 60, 75, 90 min, and 2, 3, 5, 7, 9,

12, 16, 20, and 24 h into heparinized tubes, and the plasma was harvested following centrifugation. For the oral study, the same patients were administered 150-mg capsules 48 h after the intravenous dose. Blood samples were taken at 0, 0.25, 0.50, 0.75, 1, 1.25, 1.5, 2, 3, 4, 5, 7, 12, 16, 20, and 24 h following drug administration. The plasma was harvested following centrifugation. Timed urine collections of 2 h were collected for the first 6-h period followed by 6-h collections for 48 h postdose.

RESULTS AND DISCUSSION

The present procedure for the analysis of pirmenol in human plasma and urine involves a single-step alkaline extraction with cyclohexane. The supernatant is evaporated to dryness and reconstituted with the mobile phase. Cyclohexane was found to give improved extraction recoveries and cleaner sample extracts compared with ether (2). An internal standard was found not to be necessary in the urine procedure due to the high pirmenol concentration and simple sample preparation (3). The validity of the assay was established through a careful study of linearity of response, reproducibility of standard curve, extraction recovery, accuracy, precision, and potential interference studies.

The retention times for pirmenol and the internal standard were 6.4 and 9.5 min, respectively. Figure 1 illustrates typical chromatograms for control human plasma and that from the plasma of a patient who received an intravenous dose of pirmenol. Figure 2 illustrates typical chromatograms for blank urine and an 18-h postdose urine sample. The total time required for the plasma and urine assays was 12 and 7 min, respectively.

The linearity of response of the amount of pirmenol added to control human plasma and urine was found to be linear over a range of 0.125–5.00 μg/mL for plasma and 1–30 μg/mL for urine. These ranges cover the projected therapeutic plasma and urine concentration ranges. The best-fit line was obtained using linear regression analysis with weighting factors of 1/concentration squared (4). The results of a typical regression analysis were: peak area ratio = 0.563 × plasma concentration + 0.0357 (r = 0.9987) and peak area = 0.367 × urine concentration + 0.0067 (r = 0.9948).

The reproducibility of the calibration curves was assessed by assaying triplicates of each plasma and urine standard over a 3-d period. The relative standard deviations of the peak area ratios for plasma and peak areas for urine between the lowest and highest concentrations were found to range from 7.7 to 1.8% and from 1.9 to 6.2%, respectively. The accuracy for these standards had relative errors of 0–4.6% and 0–4.3% for plasma and urine, respectively. These data are summarized in Table I.

The extraction efficiency for tritium-labeled pirmenol was determined using liquid scintillation counting[12] and is given in Table II. These data show that the extraction efficiency of pirmenol from plasma and urine ranges from 85 to 87% and 82 to 90%, respectively.

The relative error of the plasma procedure was determined by assaying seeded control plasma pooled samples containing 0.5, 2.5, and 4.0 μg of pirmenol/mL over a 3-d interval and was found to be 9.0, 3.8, and 3.6%, respectively. The relative error of the urine procedure was assessed by assaying seeded control urine pooled samples containing 5.0, 17.5, and 25.0 μg/mL and was found to be 1.4, 0.5, and 2.8%, respectively (Table III).

The specificity of the plasma assay was assessed by determining the chromatographic behavior of a number of potentially interfering compounds. The following compounds were found not to interfere with the quantification of pirmenol based on retention time: acetaminophen, clonidine hydrochloride, diazepam, disopyramide, ethacrynic acid, fenoprofen sodium, furosemide, hydralazine hydrochloride, hydrochlorothiazide, ibuprofen, methotrimeprazine, methyldopa, prazepam, prazosin hydrochloride, procainamide, propranolol hydrochloride, propoxyphene hydrochloride, reserpine, and tolmetin sodium. Compounds that had a similar retention time as primenol, but were found not to interfere were: aspirin, bretylium tosylate, chlorthalidone, naproxen, oxazepam, quinidine, salicylate, triamterene, and zomepirac sodium. To date, over 650 human plasma samples and 200 urine samples have been assayed for pirmenol using this methodology, and no apparent interfering compounds have been detected. Figure 3 illustrates typical plasma time courses for pirmenol after intravenous and oral dosing.

The method provides several improvements over a previous procedure (2). The improvements include cleaner sample extracts, improvement in chromatographic baseline due to choice of reconstitution solvent, an internal standard for plasma that is structurally similar to pirmenol, and increased sample throughput and ability to reinject samples if required. The data for the procedure are in agreement with the predicted precision expected for the internal or external calibration technique (3).

Characteristics of Drug–Phospholipid Coprecipitates I: Physical Properties and Dissolution Behavior of Griseofulvin–Dimyristoylphosphatidylcholine Systems

S. VENKATARAM and J. A. ROGERS ˣ

Received February 24, 1983, from the *Faculty of Pharmacy and Pharmaceutical Sciences, University of Alberta, Edmonton, Alberta, Canada.* Accepted for publication May 11, 1983.

Abstract □ Solid dispersions of griseofulvin and dimyristoylphosphatidylcholine (lecithin) have been prepared as both coprecipitates and physical mixtures, and their physical characteristics and dissolution behavior compared with pure griseofulvin. The dissolution of the physical mixtures was similar to pure drug, but the coprecipitates yielded a 3.5-fold greater initial dissolution rate and a limiting concentration after 60 min which was 72% greater at a griseofulvin–lecithin weight ratio of 19:1. Increasing the lecithin content to 1.5:1 compositions resulted in only a further 50% increase in the initial dissolution rate and a further 12% increase in the limiting concentration. The effect of the pH of the medium on dissolution was slight, but varied with the composition of the system. The phase diagram indicated that these systems have no significant eutectic or solid solution formation. X-ray diffraction spectra further showed that freshly prepared or aged coprecipitates contained griseofulvin crystals, and photomicrographs showed that the crystals essentially retained their characteristic shapes and sizes in all systems. Differential thermal analysis yielded heats of fusion that gave a good linear correlation with the percent of griseofulvin dissolved from coprecipitates at all time intervals, but not with physical mixtures. Furthermore, aged coprecipitates underwent a slower rate of dissolution compared with fresh samples. The results are interpreted to suggest that griseofulvin undergoes improved dissolution from coprecipitates due to the formation of crystals of lower stability. In addition, the rapid dispersion of lecithin in the aqueous medium (as seen microscopically) entraps griseofulvin in myelinic structures and liposomes and effectively increases the saturation concentration of drug in the diffusion layer during the dissolution process.

The dissolution of solid drugs having low water solubility is often a rate-limiting step in obtaining bioavailability. Thus, several formulation approaches have been explored to improve bioavailability of such drugs, including the use of lipid vehicles and the preparation of solid dispersions. In those cases where lipids have been used, the dissolution and bioavailability of drugs have been found to be dependent on the nature of the lipids used in the formulation, being either increased (1–4), decreased (1, 3–5), or unaffected (1). In most instances, the dosage form contains a large proportion of lipid. Likewise, solid dispersions involving water-soluble carriers require a large proportion of carrier to be effective. On the other hand, it would be advantageous to incorporate a minimal amount of carrier to produce either rapid dissolution or sustained release of a drug from a solid dosage form.

Phospholipids spontaneously disperse in aqueous media to form bilayer structures which have the capacity to entrap or sequester solutes. This dual behavior could prove beneficial for improving bioavailability of drugs in a number of ways. According to the Nernst film theory of dissolution, an increased saturation concentration of drug in the stationary layer leads to an increase in the dissolution rate. It is not important that the concentration achieved is due to the intrinsic solubility of the drug in the medium of the stationary layer or due to a partitioning process. Encapsulated or entrapped drug within the bilayer structures (myelinic or liposomal) during the dissolution process may be transported, first to the stationary or diffusion layer, then to the bulk solution, then to the site of absorption to yield rapid delivery of a drug to the general circulation. Furthermore, for drugs which may be susceptible to degradation or solubility changes within the GI fluids, entrapment may afford a degree of protection (6, 7).

The system of griseofulvin–dimyristoylphosphatidylcholine has been chosen to test these hypotheses and to evaluate the performance of a phospholipid in a solid dispersion formulation. The purpose of the present report is to present some preliminary data for this system and to evaluate its potential in controlled-release dosage form design.

EXPERIMENTAL

Materials—Micronized griseofulvin[1] (I) was pretreated by dissolving it in chloroform then removing the solvent by warming slightly over a water bath and applying a gentle stream of air. Drying of the crystals was carried out under vacuum over desiccants. The melting points of untreated and treated I were identical. Pure I and all binary mixtures were passed through an 80-mesh sieve[2] prior to testing.

L-α-Dimyristoylphosphatidylcholine[3] (II), claimed to be 98% pure, was used as received. All solvents and chemicals were reagent grade, and distilled water was used to prepare the dissolution media.

	Coprecipitates	Physical Mixtures	Coprecipitates	Physical Mixtures
1:0	0.36	0.36	15.0	15.0
19:1	1.26	—	25.8	—
9:1	1.68	0.60	24.9	15.3
4:1	1.67	—	35.3	—
1.5:1	1.86	0.48	28.8	13.7

Preparation of Coprecipitates and Physical Mixtures—Solid dispersions of I–II compositions were prepared by the solvent method from chloroform, yielding coprecipitates which were subsequently dried under vacuum over desiccants as before. Coprecipitates were usually examined within 48 h after preparation. Physical mixtures were prepared by triturating appropriate quantities of I and II using a mortar and pestle, then transferring to a vacuum desiccator until ready for use.

Thermalmicroscopic Method—The thaw and melt temperatures of all samples were determined by the hot-stage microscopic technique[4]. The heating rate was set at 2°C/min. just below the predetermined thaw temperature.

Differential Thermal Analysis—The differential thermal analyzer[5] was calibrated with indium[6], tin[6], and lead[6] using a 15-mg sample against an empty pan as reference. The heating rate was set at 10°C/min, the differential temperature sensitivity was 0.3°C/2.54 cm, and the reference temperature sensitivity was 13.7°C/2.54 cm. Heats of fusion were determined from the areas under the endothermic peaks (planimeter method), and the corresponding calibration coefficients were obtained from the fusion temperatures (taken at the peak of the endothermic event) and the calibration curve (8).

X-ray Diffraction Studies—Samples for low-angle powder X-ray diffraction studies (~50 mg) were uniformly dispersed on a glass slide. A piece of transparent cellulose tape was then used to secure the powder in position. X-ray diffraction spectra[7] were obtained employing CuK_α radiation and run at 2°/min and a 2θ angle.

Dissolution Studies—The spin-filter dissolution test apparatus[8] employing a 1-μm porosity filter screen was used (9). Filter rotation speed was maintained at 600 rpm in 900 mL of dissolution medium, which was either HCl–KCl buffer at pH 2.0 or phosphate buffer at pH 5.0, at 37°C. Measurement of concentrations of I in the dissolution medium was carried out employing automated UV spectrometry at $\lambda = 293$ nm (10). A 50-mg sample was dispersed in the dissolution medium in each instance. The presence of II in the dissolution medium did not interfere with the analysis of I. Experiments were run in duplicate and the results averaged, although at no time was a significant difference found between duplicates.

Photomicrographic Analysis—Representative samples of powders were examined microscopically[9], 320× magnification, in either light mineral oil or water. Photomicrographs[10] were obtained for comparison of crystal shape and size and to record the various stages of dissolution.

RESULTS

Dissolution Studies—The dissolution of I from a multiparticulate I–II coprecipitate was found to be considerably greater than from physical mixtures or pure I. Typical dissolution profiles are given in Fig. 1, where it is apparent that the initial dissolution rates and the amount of I dissolved after 60 min from the coprecipitates exceeded those of pure I or the corresponding physical mixtures. Furthermore, the dissolution of 1.5:1 coprecipitates was greater than that of the 9:1 composition, whereas the dissolution behavior of the corresponding physical mixtures was in the reverse order. The initial dissolution rates (IDR) (computed over the first 5 min of dissolution) and concentrations of I achieved after 60 min, which were essentially limiting after this period (LDC), are compared in Table I. The IDR of the I–II coprecipitate exhibits an increase of 3.5-fold with as little as 5% of II in the total sample (19:1 weight ratio) and an increase of 5-fold for samples containing 40% of II (1.5:1 weight ratio). In contrast, the IDR of I from physical mixtures increased only slightly with a higher content of II. Values of LDC obtained from coprecipitates clearly indicate a substantial increase in the apparent solubility of I in the dissolution medium. On the other hand, an increased fraction of II in the physical mixture compositions does not increase the apparent solubility of I and, indeed, at 40% II the LDC is somewhat lower than that for pure I. The superior dissolution of I–II coprecipitates is further exemplified by the data in Table II. Percent dissolved of I from coprecipitates is more than twice that dissolved from physical mixtures at corresponding times.

The dissolution of I appears to have a slight dependency on the pH of the dissolution medium. This is more pronounced after the first 10 min of dissolution and is reflected in the LDC as shown in Table III. In all cases, except the 9:1 coprecipitate, the LDC is less at pH 5.0 than pH 2.0 which is consistent with other reports of the dissolution of griseofulvin coprecipitates at various pH values (4). However, the 9:1 coprecipitate displayed a reverse and significant pH dependency in its dissolution profile which is not readily explained. This result, together with the unusually greater LDC of the 4:1 coprecipitates, suggest that the physical characteristics of the crystals formed in the coprecipitates differ from sample to sample and are dependent on the proportions of I and II.

Solid-State Analysis—Differential thermal analysis (DTA) of I pretreated with chloroform yielded a sharp major endothermic peak at 221°C [lit. (4) mp 220–222°C]. However, a distinct, broad peak also occurred at 120–126°C.

Table II—Comparison of Percent Dissolved from Griseofulvin–Dimyristoylphosphatidylcholine Coprecipitates, Physical Mixtures, and Pure Griseofulvin

Composition (Weight Ratio)	Coprecipitates				Physical Mixtures			
	5 min	20 min	40 min	60 min	5 min	20 min	40 min	60 min
1:0	3.2	15.8	23.8	27.0	3.2	15.8	23.8	27.0
9:1	16.8	43.1	48.7	49.8	5.6	18.5	24.5	17.5
1.5:1	27.9	72.8	83.9	86.4	7.0	25.1	35.7	41.1

It also appeared in the thermograms of coprecipitates and physical mixtures, but its height varied in proportion to the I content of the sample. This peak did not appear in thermograms of I pretreated with methanol or acetone or untreated I. Chloroform solvates of I have been reported (11, 12) and, therefore, it is concluded that the unexpected peak was due to chloroform, in spite of fairly rigorous drying of each treated sample.

Thermograms of the binary systems contained two peaks: a peak corresponding to the melting of I and a peak corresponding to the melting of II. Determination of the thaw and melt temperatures from each peak enabled construction of the phase diagram (Fig. 2). The line for the solid indicates a slight depression of the melting point of II as the composition increases with respect to I. Likewise, the line for the liquid displays a slight decrease in the melting point of I as the composition decreases with respect to I. Hot-stage microscopy permitted visualization of the melting of each component and confirmed the thaw and melt temperatures. Above 70% II, the I peak on the DTA thermogram was too small to accurately measure, so hot-stage microscopy results are recorded only. The phase diagram is typical of a monotectic system (13), which indicates the absence of eutectic or solid solution formation. Thus, no strong interaction between I and II exists.

The relevant fusion temperatures and heats of fusion (ΔH_f) for systems examined for their dissolution behavior are given in Table IV. It can be seen that the fusion temperatures are similar for coprecipitates and physical mixtures, but the heats of fusion differ. There is a gradual and uniform decrease in ΔH_f with coprecipitate compositions, whereas an abrupt decrease in ΔH_f occurs with the 19:1 physical mixture; it remains essentially constant for all other compositions.

The dissolution studies demonstrated that the dissolution of I from the 19:1 coprecipitate was nearly as dramatic as from other coprecipitates containing a larger fraction of II (Table I). Thus, the physical state of the 19:1 composition was studied in detail in order to gain an insight into the mechanisms of dissolution of these systems. Several possibilities exist which may account for the increased dissolution of I–II coprecipitates. Therefore, X-ray diffraction spectra were prepared to attempt to resolve some of these issues. Typical X-ray diffraction patterns of powdered samples of II, chloroform-treated I, and the 19:1 coprecipitate are shown in Fig. 3. The crystalline properties of I are characterized by two major and four minor peaks in the spectrum, whereas the II spectrum displays the properties of an amorphous material. The identifiable peaks of I are also visible in the spectrum of the 19:1 coprecipitate even though there appears that some broadening and loss of detail of the peaks has occurred. The positions of the diffraction peaks of I were not altered compared with that of the pure compound. Physical mixtures and 19:1 coprecipitates all exhibited the identifiable peaks of I in their spectra 2 h, 1 week, and 2 weeks after preparation although there were variations in the shapes and intensities of the peaks. These clearly indicate that I does not exhibit polymorphism, complex formation, eutectic, or solid solution formation with II in the coprecipitate.

DISCUSSION

When the solid dispersion system has been employed to formulate drugs having low water solubility, invariably the inert carrier is one which either undergoes rapid dissolution (*e.g.*, urea, polyethylene glycol, or polyvinylpyrrolidone) to increase the dissolution of the drug (14) or it is one which undergoes slow dispersion in aqueous media to provide sustained release [*e.g.*, tristearin, cholesterol, or cholesteryl ester (3, 7)]. If the lipid has significant surface activity [*e.g.*, cholesteryl stearate (3) or polyoxyl 40 stearate (4)] usually an increase in dissolution of drug due to wetting is observed. Solubilization of the drug during dissolution may also play a role (4). Phospholipids have not previously been employed to prepare solid dispersions of drugs. Yet these nontoxic agents have the ability to both increase the wetting of hydrophobic drug particles and to spontaneously disperse into colloidal aggregates, with the capacity to sequester substantial quantities of drug in lipidic or aqueous compartments.

The best solid dispersion systems from the point of view of rapid release of drug have been those containing large ratios of carrier to drug (15), although compositions high in drug content have been chosen in some instances as

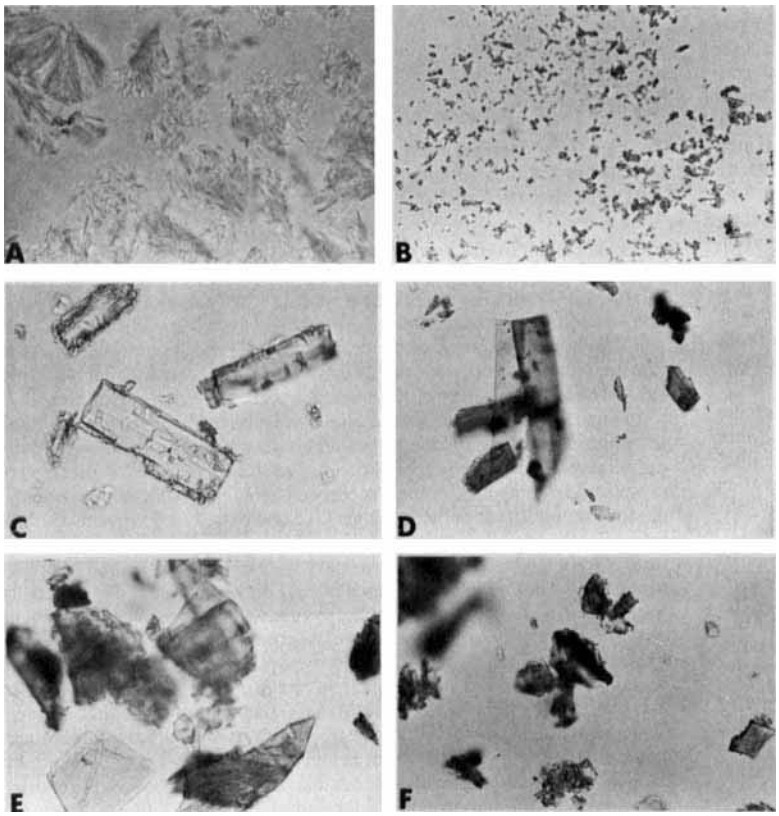

Figure 4—*Photomicrographs of various test samples dispersed in light mineral oil (320× magnification). Key: (A) untreated II; (B) untreated, micronized I; (C) chloroform-treated I; (D) 9:1 I–II coprecipitate; (E) 4:1 I–II coprecipitate; (F) 1.5:1 I–II coprecipitate.*

Table III—Effet of pH on the Dissolution of Coprecipitates of Griseofulvin and Dimyristoylphosphatidylcholine

Composition (Weight Ratio)	Initial Dissolution Rate, mg/L/min		Limiting Conc. After 60 min, mg/L	
	pH 2.0	pH 5.0	pH 2.0	pH 5.0
1:0	0.36	0.40	15.0	12.4
19:1	1.26	1.21	25.8	25.4
9:1	1.68	1.53	25.9	28.8
4:1	1.67	1.63	35.3	34.0
1.5:1	1.86	1.56	28.8	26.2

representing eutectic mixtures (16-18). However, it has now been demonstrated that high rates of dissolution are possible from coprecipitates with drug content as high as 95% using a phospholipid carrier. Furthermore, as the carrier content of the coprecipitate is increased, the IDR of I increases by a further 50%, while the apparent solubility of I at pH 2.0 (LDC) increases by a further 12%, following an 8-fold increase in the percentage of phospholipid in the sample (see Table I). Thus, unlike the griseofulvin-succinic acid solid dispersion (19), decreasing the carrier content, when it is phospholipid, does not necessarily result in the formation of larger crystals of I.

The X-ray diffraction spectra and the phase diagram for the I-II system clearly indicate the lack of any specific I-II interaction. This is substantiated by the observation that under the microscope crystals of I and I-II coprecipitates have approximately the same shape and size (Fig. 4C-F).

In view of the above discussion, there are two possible mechanisms which may be responsible for the greater dissolution behavior of coprecipitates than for pure drug or physical mixtures. In the first instance, it is reasonable to assume that on coprecipitation of I and II from chloroform, crystals are formed having mainly characteristics of chloroform-treated I, at least with medium to high I compositions. The chloroform solvate of I is an important factor in its physical state, as described earlier in the DTA results and previously by others (11, 12, 20). However, it would appear that the packing arrangement of the molecules in the coprecipitate crystal is different than in the absence of II, leading to a major change in the stabilization energy of the crystals. This packing arrangement would appear to be ideal for rapid release of I and its transfer from the solid state to the solution state. A good linear correlation was found between the percent of I dissolved and ΔH_f for coprecipitates ($r > 0.97$) at all dissolution times, but not with physical mixtures after 5 min. Furthermore, aging of the coprecipitates resulted in reduced dissolution rates, although X-ray diffraction patterns of aged samples were essentially unchanged. The dissolution behaviors of untreated micronized I, treated I, and aged treated I were essentially identical.

According to the film theory of dissolution (21) factors influencing the rate of dissolution include the diffusion coefficient, the stationary or diffusion layer thickness, the surface area, and the difference between the saturation concentration in the diffusion layer and the bulk solution concentration. Under identical conditions of dissolution testing for the same compositions of I-II, differences in dissolution behavior between coprecipitates and physical mixtures or pure drug are likely to originate from changes in the total surface area during the dissolution process and the diffusion layer concentration-bulk solution concentration difference at any given time. In the case of the coprecipitate, very fine crystallites of I may become available as the original crystals fracture and break up in the dissolution medium, thereby increasing the total surface area of I. The situation is obviously different with regard to the physical mixtures, where the phospholipid, which may not undergo rapid dispersion, provides very little wetting of the crystals of I and only a minor increase in the effective surface area. The result is a slight increase in the IDR as seen in Table I.

The solubilization effect in the diffusion layer surrounding the particles may be exerting the most substantial effect in the dissolution process. More specifically, it is the rapid, spontaneous dispersion of II into colloidal aggregates of phospholipid bilayers (liposomes) and the simultaneous incorporation

Table IV—Fusion Temperatures and Heats of Fusion of Griseofulvin and Griseofulvin-Dimyristoylphosphatidylcholine Compositions

of I molecules into this partitioning system that is analogous to an increase in the saturation concentration in the diffusion layer. In the case of physical mixtures, II is not in as desirable a physical state for spontaneous dispersion and, in addition, I molecules must be dissociated from the solid state by solvent and then become sequestered by the liposomes. The vigorous agitation of the dissolution medium coupled with its large volume decrease the chances of any substantial sequestering of I molecules adjacent to the particle surfaces.

In an attempt to determine the validity of this reasoning, microscopic observation of coprecipitate crystals undergoing dissolution in water was carried out. Figure 5 shows a sequence of photomicrographs of a 1.5:1 coprecipitate sample undergoing dissolution. As early as 2 min following mixing, it is apparent that multitudes of long, finger-like bodies (myelinic structures) had formed at the crystal surfaces. These could be seen as growing and extending further outward into the medium as part of a rapid, dynamic process of dispersion and what may be considered as part of the process of dissolution. It was interesting to note that a similar picture was observed when a physical mixture was examined, but the formation and dispersal of the myelinic structures was much slower. Although these observations are based on what must be considered as a static system, in relative terms, it demonstrates that phospholipids can play a role in solid dispersion formulations that is much different than that observed with other lipids or surfactants. Studies are continuing along these lines to determine the potential of phospholipids in developing formulations which have the dual roles of controlled release of drug and bioavailability improvement following oral administration.

Model-Independent Steady-State Plasma Level Predictions in Autonomic Nonlinear Pharmacokinetics I: Derivation and Theoretical Analysis

PETER VENG-PEDERSEN

Received January 17, 1983, from the *Divison of Pharmacokinetics, School of Pharmacy and Pharmacal Sciences, Purdue University, West Lafayette, IN 47907.* Accepted for publication May 21, 1983.

Abstract □ Current drug level predictions in nonlinear pharmacokinetics are based on specific pharmacokinetic models in contrast to the model-independent (structureless), dose-linearity, and superposition principles used in linear pharmacokinetics. Such model-dependent methods may not provide reliable predictions due to their inherent nonuniqueness, computational complexity, and often unrealistic kinetic assumptions. Some novel model-independent methods for predicting the steady-state drug levels of extravascular, intravenous bolus, and intravenous infusion administrations are presented that should overcome such disadvantages. The methods only assume an autonomic nonlinear kinetic behavior, which implies that following an intravenous bolus administration the derivatives of the drug concentration–time profile at arbitrary drug levels are independent of the dose given. Such a kinetic behavior is found for any nonlinear pharmacokinetic system when the rate of change of the drug level following an intravenous bolus administrations depends only on the drug level, *i.e.*, $dC/dt = -q(C)$, where q can be any function dependent only on C and time-invariant kinetic parameters. The basic approach presented represents a novel alternative which avoids the very difficult and often impractical task of identifying and incorporating the numerous kinetic parameters and processes responsible for the observed drug concentration data into a useful pharmacokinetic model. The focus in the kinetic analysis is instead on two much simpler processes: (*a*) fitting empirical functions to estimate the mean drug disposition behavior of the subject or population and (*b*) testing the validity of the assumptions involved.

Keyphrases □ Pharmacokinetics—nonlinear, model independent, steady-state plasma drug-level predictions, theory and mathematical models □ Plasma drug levels—prediction at steady state, model-independent nonlinear pharmacokinetics, theory and mathematical models

Steady-state plasma level predictions in linear pharmacokinetics are done by extrapolations using the dose-linearity and superposition principles or by using the convolution property of linear pharmacokinetics. The plasma level profiles used for the predictions are most commonly determined by fitting suitable model-independent[1] equations, typically of an exponential type, to available plasma level data. Such model-independent methods cannot be used for drugs showing nonlinear pharmacokinetics because the superposition and dose-linearity principles do not apply. Consequently, drug level predictions in nonlinear pharmacokinetics have been based on model-dependent methods, which may not provide reliable predictions due to their inherent nonuniqueness, computational complexity, and often unrealistic model assumptions. A model-independent approach is presented which overcomes some of these disadvantages.

THEORETICAL

The proposed methodology applies to drugs showing what will be called *autonomic nonlinear pharmacokinetics; i.e.*, the drug-concentration profile resulting from an intravenous bolus dose adheres to the autonomic differential equation:

$$\frac{dC}{dt} = -q(C) \qquad \text{(Eq. 1)}$$

where q stands for any function only dependent on the drug concentration C and time-invariant kinetic parameters. It is assumed that q is such that the solution of Eq. 1, $C(t)$, is monotonically decreasing with time. Autonomic nonlinear pharmacokinetics is readily identified in a model-independent manner from "the horizontal superposition property" (Fig. 1). Different intravenous bolus doses result in drug-concentration profiles with identical slopes

[1] The terminology "model-independent" is used here to denote a general approach not based on a specific structured (model-dependent) kinetic analysis of the individual kinetic components of the pharmacokinetics.

Model-Independent Steady-State Plasma Level Predictions in Autonomic Nonlinear Pharmacokinetics I: Derivation and Theoretical Analysis

PETER VENG-PEDERSEN

Received January 17, 1983, from the *Divison of Pharmacokinetics, School of Pharmacy and Pharmacal Sciences, Purdue University, West Lafayette, IN 47907.* Accepted for publication May 21, 1983.

Abstract □ Current drug level predictions in nonlinear pharmacokinetics are based on specific pharmacokinetic models in contrast to the model-independent (structureless), dose-linearity, and superposition principles used in linear pharmacokinetics. Such model-dependent methods may not provide reliable predictions due to their inherent nonuniqueness, computational complexity, and often unrealistic kinetic assumptions. Some novel model-independent methods for predicting the steady-state drug levels of extravascular, intravenous bolus, and intravenous infusion administrations are presented that should overcome such disadvantages. The methods only assume an autonomic nonlinear kinetic behavior, which implies that following an intravenous bolus administration the derivatives of the drug concentration–time profile at arbitrary drug levels are independent of the dose given. Such a kinetic behavior is found for any nonlinear pharmacokinetic system when the rate of change of the drug level following an intravenous bolus administrations depends only on the drug level, *i.e.*, $dC/dt = -q(C)$, where q can be any function dependent only on C and time-invariant kinetic parameters. The basic approach presented represents a novel alternative which avoids the very difficult and often impractical task of identifying and incorporating the numerous kinetic parameters and processes responsible for the observed drug concentration data into a useful pharmacokinetic model. The focus in the kinetic analysis is instead on two much simpler processes: (*a*) fitting empirical functions to estimate the mean drug disposition behavior of the subject or population and (*b*) testing the validity of the assumptions involved.

Keyphrases □ Pharmacokinetics—nonlinear, model independent, steady-state plasma drug-level predictions, theory and mathematical models □ Plasma drug levels—prediction at steady state, model-independent nonlinear pharmacokinetics, theory and mathematical models

Steady-state plasma level predictions in linear pharmacokinetics are done by extrapolations using the dose-linearity and superposition principles or by using the convolution property of linear pharmacokinetics. The plasma level profiles used for the predictions are most commonly determined by fitting suitable model-independent[1] equations, typically of an exponential type, to available plasma level data. Such model-independent methods cannot be used for drugs showing nonlinear pharmacokinetics because the superposition and dose-linearity principles do not apply. Consequently, drug level predictions in nonlinear pharmacokinetics have been based on model-dependent methods, which may not provide reliable predictions due to their inherent nonuniqueness, computational complexity, and often unrealistic model assumptions. A model-independent approach is presented which overcomes some of these disadvantages.

THEORETICAL

The proposed methodology applies to drugs showing what will be called *autonomic nonlinear pharmacokinetics; i.e.*, the drug-concentration profile resulting from an intravenous bolus dose adheres to the autonomic differential equation:

$$\frac{dC}{dt} = -q(C) \qquad \text{(Eq. 1)}$$

where q stands for any function only dependent on the drug concentration C and time-invariant kinetic parameters. It is assumed that q is such that the solution of Eq. 1, $C(t)$, is monotonically decreasing with time. Autonomic nonlinear pharmacokinetics is readily identified in a model-independent manner from "the horizontal superposition property" (Fig. 1). Different intravenous bolus doses result in drug-concentration profiles with identical slopes

[1] The terminology "model-independent" is used here to denote a general approach not based on a specific structured (model-dependent) kinetic analysis of the individual kinetic components of the pharmacokinetics.

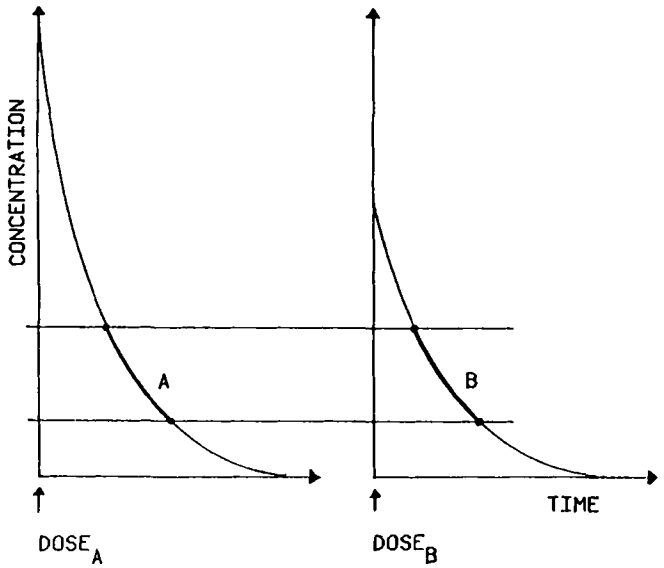

Figure 1—*Illustration of the horizontal superposition property of autonomic nonlinear pharmacokinetics (A = B), which is characterized by an intravenous bolus disposition behavior that follows to the general autonomic differential equation (Eq. 1).*

at the same concentration levels. Thus, a horizontal shift of the curves will result in their exact superposition (Fig. 1). For example, a parallel first-order and Michaelis–Menten elimination:

$$\frac{dC}{dt} = -KC - \frac{V_m C}{K_m + C} \qquad \text{(Eq. 2)}$$

will result in this behavior; so will any pharmacokinetic system incorporating nonlinear binding, excretion, metabolism, *etc.*, as long as the kinetics can be described in the general form of Eq. 1. However, due to the model-independent nature of the method proposed, there is no need to postulate a specific kinetic relationship.

The most studied nonlinear drug, phenytoin, appears quite consistent to show autonomic disposition kinetics (1). The fall-off curves studied for 10 subjects for a period of 4 consecutive days after different daily doses of phenytoin were discontinued seem to agree well with Eq. 1 (1). Other examples of the horizontal shift and the superposition concept include the pharmacokinetics of alcohol (2).

Steady-State Prediction of Extravascular Dosing—In linear pharmacokinetics, steady-state predictions can be made solely from a single dose, without using the information about the basic disposition of the drug provided by an intravenous drug administration. For example, if data from a single extravascular dose is well approximated by a sum of exponentials:

$$C(t) = \sum_{i=1}^{m} A_i e^{-\alpha_i t} \qquad \text{(Eq. 3)}$$

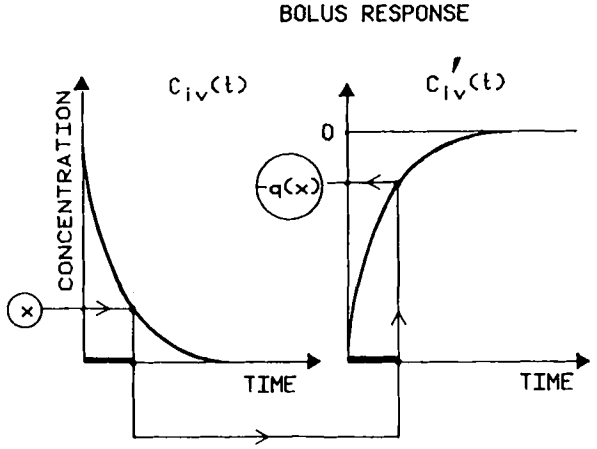

Figure 2—*Empirical evaluation of the disposition function* q *(Eq. 1) according to Eq. 9. The function* $C_{iv}(t)$ *denotes a suitable, monotonically decreasing function fitted to data from an intravenous bolus injection;* $C'_{iv} = dC_{iv}(t)/dt$.

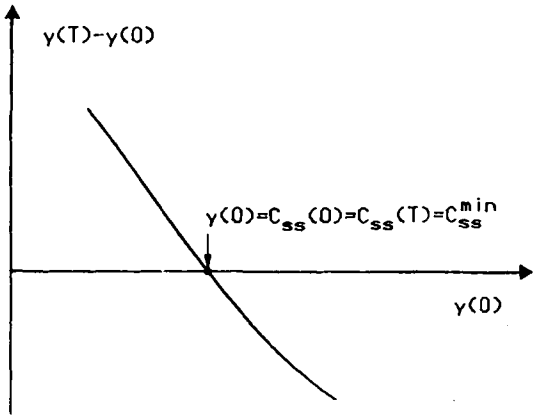

Figure 3—*Boundary value behavior of Eq. 14 (Eq. 13 simplified). An initial value for* y(0) *is chosen and improved by an iterative procedure until the corresponding* y(T) *value, obtained by numerical integration of Eq. 14, is the same as* y(0), *in which case the steady-state solution* $C_{ss}(t) = y(t)$ *is obtained.*

where $\Sigma A_i = 0$, then the steady state can be predicted by:

$$C_{ss}(t) = \sum_{i=1}^{n} \frac{A_i e^{-\alpha_i t}}{1 - e^{-\alpha_i T}} \qquad \text{(Eq. 4)}$$

where T is the dosing interval.

To make predictions in nonlinear pharmacokinetics in a model-independent way, it is, contrary to the linear case above, always necessary to have data available from a known intravenous administration to evaluate and properly account for the basic disposition behavior[2]. In the present case, data from an intravenous administration are used to empirically determine the functional behavior of the disposition function q (Eq. 1) without knowing its functional (algebraic) form. This is done as follows. Let $C_{iv}(t)$ denote a suitable monotonically decreasing equation that fits the intravenous bolus data well (*e.g.*, by least-squares regression):

$$C = C_{iv}(t) \qquad \text{(Eq. 5)}$$

then:

$$\frac{dC}{dt} = dC_{iv}(t)/dt = C'_{iv}(t) \qquad \text{(Eq. 6)}$$

Since $C_{iv}(t)$ is monotonically decreasing its inverse $C_{iv}^{-1}(C)$ exists, and can be found algebraically or numerically:

$$t = C_{iv}^{-1}(C) \qquad \text{(Eq. 7)}$$

Substituting Eq. 7 into Eq. 6 gives:

$$\frac{dC}{dt} = C'_{iv}[C_{iv}^{-1}(C)] \qquad \text{(Eq. 8)}$$

Comparing Eqs. 8 and 1, it is seen that the disposition function q can be evaluated empirically from the function $C_{iv}(t)$ fitted to the intravenous bolus data:

$$q(x) = -C'_{iv}[C_{iv}^{-1}(x)] \qquad \text{(Eq. 9)}$$

The simple evaluation of $q(x)$ is illustrated graphically in Fig. 2.

Consider now a single extravascular dosing, which results in some arbitrary systemic drug input $f(t)$ (mass/time). The differential equation relating to this input is:

$$\frac{dC}{dt} = -q(C) + \frac{f(t)}{v} \qquad \text{(Eq. 10)}$$

where v is a constant of dimension volume. Let $C_f(t)$ denote a suitable arbitrary equation that fits the data from the extravascular dosing well, then $C_f(t)$ should satisfy Eq. 10 to give:

$$f(t) = v[q(C_f(t)) + C'_f(t)] \qquad \text{(Eq. 11)}$$

[2] This may seem as a disadvantage in comparison with the model-dependent methods, where such predictions can be made without this additional information. However, such predictions will be highly inaccurate and unreliable because the disposition parameters in such models are allowed to "float" in an unconstrained way in the curve fitting. There is only hope for reasonable predictions if additional data from an intravenous administration are available, so the disposition parameters can be estimated without the confounding interference from the absorption process.

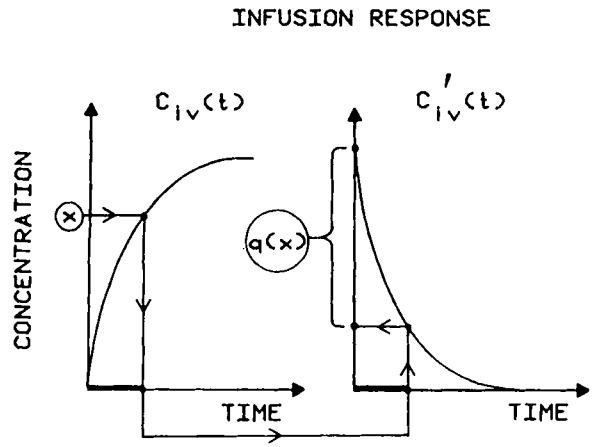

Figure 4—*Empirical evaluation of the disposition function* q *(Eq. 1) according to Eq. 17. The function* $C_{iv}(t)$ *denotes a suitable monotonically increasing function fitted to data from a constant-rate intravenous infusion;* $C'_{iv}(t) = dC_{iv}(t)/dt$.

Consider next the same extravascular dose given to the same subject at regular dosing intervals, T. Let the following assumptions be made:

1. The drug disposition kinetics do not change (kinetic parameters of q are time invariant).
2. The drug absorption $f(t)$ from each dose is reproducible.
3. The drug is absorbed quickly enough in comparison with the dosing interval T, so that the absorption is completed before a new dose is given.

The steady-state drug level profile will, under these assumptions, follow Eq. 10:

$$\frac{dC_{ss}}{dt} = -q(C_{ss}) + \frac{f(t)}{v} \qquad \text{(Eq. 12)}$$

The drug absorption is assumed reproducible; thus, $f(t)$ in Eq. 12 can be substituted with the expression in Eq. 11 to give:

$$\frac{dC_{ss}}{dt} = -q(C_{ss}) + q[C_f(t)] + C'_f(t) \qquad \text{(Eq. 13)}$$

Equation 13 is the final differential equation from which the steady-state drug level profile $C_{ss}(t)$ can be calculated, when data from a single extravascular dose are available in addition to data from an intravenous bolus administration. Mathematically $C_{ss}(t)$ is the solution, $y(t)$, to a boundary value problem, which can be stated in its most simplified form as follows. Find the particular solution $y(t)$ of the differential equation:

$$\frac{dy}{dt} = -q(y) + g(t) \qquad \text{(Eq. 14)}$$

which satisfies the boundary condition:

$$y(0) = y(T) \qquad \text{(Eq. 15)}$$

Equation 14, which is a simplified restatement of Eq. 13, is recognized as a simple first-order differential equation which can be integrated numerically using a suitable algorithm[3]. The initial value $y(0)$ of Eq. 14 is unknown. An initial estimate for $y(0)$ is therefore required as a tentative solution which can be improved in an iterative manner as follows. Integration of Eq. 14 (from $t = 0$ to tT) produces a $y(T)$ corresponding to the current $y(0)$. If $y(T) > y(0)$, then $y(0)$ is too small and must be increased in the next iteration. Similarly if $y(T) < y(0)$, then $y(0)$ should be decreased in the next iteration. The $y(0) - y(T)$ *versus* $y(0)$ relationship is sketched in Fig. 3. The above so-called "shooting method" is a standard approach to solve nonlinear boundary value problems and is easily implemented on a computer. When the process converges, *i.e.*, $y(0) = y(T)$, then the steady-state profile $C_{ss}(t) = y(t)$ is given by the integration of Eq. 14 in the last iteration. The steady-state minimum and maximum levels are simple "by-products" of the process; *i.e.*, $C_{ss}^{min} = y(0) = y(T)$ and C_{ss}^{max} is the maximum value of $y(t)$ reached in the last integration. The mean steady-state level can readily be calculated by integrating the $y(t)$ points (*e.g.*, using a trapezoidal or log-trapezoidal rule) and dividing the area by the dosing interval (4):

$$\bar{C}_{ss} = \int_0^T y(t)dt/T \qquad \text{(Eq. 16)}$$

[3] A Runge-Kutta method (3) appears to be a suitable first choice because of its simplicity and economical evaluation. However, it must be expected that in some cases Eq. 14 may be numerically unstable in the integration region (which varies during the boundary value iterations), in which case the Runge-Kutta method is inaccurate. This inaccuracy can readily be detected by comparing the integration results to those obtained using a substantially smaller (*e.g.*, 1/10) step size. In such cases, it is necessary to switch to a more elaborate and accurate multistep predictor-corrector type algorithm (3).

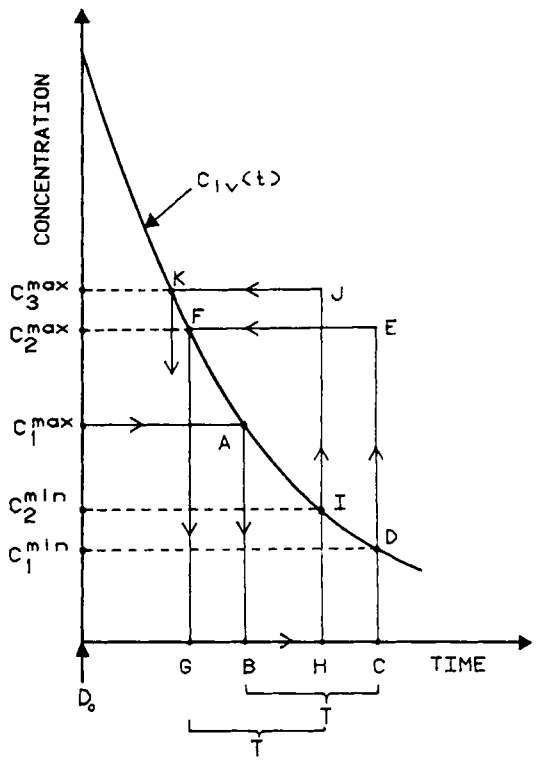

Figure 5—*Hysteresis iteration method (Eqs. 19–24) to predict peak and trough plasma levels in multiple intravenous bolus dosing. The steady-state drug level is reached at convergence when* $C_{n+1}^{max} \simeq C_n^{max}$ *and* $C_{n+1}^{min} \simeq C_n^{min}$. *The function* $C_{iv}(t)$ *denotes a suitable monotonically decreasing function fitted to data from an intravenous bolus administration, and* T *is the dosing period.*

In summary, the steps required to predict the steady-state plasma levels are:

1. Suitable arbitrary equations $C_{iv}(t)$ and $C_f(t)$ are fitted to data from a single intravenous bolus and extravascular (*e.g.*, oral) administration, respectively.
2. The intravenous bolus response approximation, $C_{iv}(t)$, and the absorption response approximation, $C_f(t)$, are differentiated algebraically to define $C'_{iv}(t)$ and $C'_f(t)$.
3. An initial estimate for $y(0)$ is chosen (*e.g.*, zero) and Eq. 14 (*i.e.*, Eq. 13) is integrated repeatedly in an iterative manner that improves the $y(0)$ value until it closely agrees with its corresponding $y(T)$ value. When converged the steady-state drug level is given by the integrated equation, $C_{ss}(t) = y(t)$.

Not all drugs can be given by an intravenous bolus administration due to excessive side effects resulting from a too rapid systemic input. However, Eq. 13 can still be applied if the drug in question can be administered by a constant-rate intravenous infusion. In this case it can be shown (Appendix I) that the disposition function q in Eq. 13 can be evaluated empirically according to:

$$q(x) = C'_{iv}(0) - C'_{iv}[C_{iv}^{-1}(x)] \qquad \text{(Eq. 17)}$$

where C_{iv} (contrary to C_{iv} in Eq. 8) is an arbitrary monotonically increasing function which provides a good fit to the data from the constant-rate drug infusion. The evaluation of $q(x)$ in this case is illustrated graphically in Fig. 4.

A simple precaution must be taken in the initial ($t = 0$) evaluation of q during the numerical integration of Eq. 14 (Eq. 13). An evaluation of $q(0)$ according to Eq. 9 may cause floating point overflow. For example, if a monotonically decreasing function $C_{iv}(t)$ which asymptotically approaches zero for $t \to \infty$ has been chosen for the intravenous bolus approximation, then $C_{iv}^{-1}(x) \to \infty$ for $x \to 0$ and $C_{iv}^{-1}(0)$ is not defined. Thus, $q(0)$ cannot be evaluated according to Eq. 9 in this case. However, by setting $q(0) = 0$ (see Appendix I) the problem is readily solved. Subsequent evaluations of $q(x)$ for $x > 0$ should not cause any numerical problems.

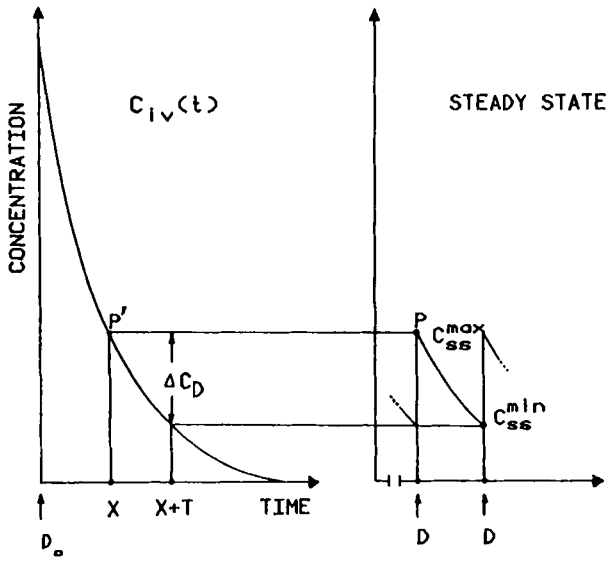

Figure 6—*Solution configuration of the root-solving method (Eq. 30) to determine the steady-state peak and trough drug levels in intravenous bolus administration. The function $C_{iv}(t)$ denotes a suitable, monotonically decreasing function fitted to data from an intravenous bolus administration, and T is the dosing period.*

The evaluation of the inverse $C_{iv}(t)$ function (Eq. 7) is done in a straightforward manner by numerically finding the root, t, of the expression:

$$C - C_{iv}(t) = 0 \qquad \text{(Eq. 18)}$$

for given values of C, where $C_{iv}(t)$ is the function previously fitted to the data from the intravenous drug administration. Most scientific computer program libraries (5-7) and many books dealing with numerical analysis (3, 8) have general programs for finding the root of an arbitrary nonlinear equation, suitable for solving Eq. 18 in a routine manner. The same root-finding algorithm used to solve Eq. 18 can also be used in the "shooting method" to find the root of the boundary value function (Fig. 3).

It is evident from Eq. 13 that in order to calculate the steady-state drug levels, the single-dose response function $C_f(t)$ only needs to be evaluated in the time interval $t = 0$ to $t = T$. This is a definite advantage, since the difficult problem of evaluating or extrapolating $C_f(t)$ beyond $t = T$ is avoided. This would not be the case for a method that makes use of area under the curve (AUC) or total clearance.

Steady-State Prediction of Intravenous Bolus Dosing—The following derivation shows how the plasma level profile in any drug interval in multiple dosing can be predicted from data from a single intravenous bolus dosing. Let $C_{iv}(t)$ denote an arbitrary monotonically decreasing function that provides a good fit to data from an intravenous bolus dose D_0. If after the drug is eliminated the same subject is given an intravenous bolus dose D every T hours,

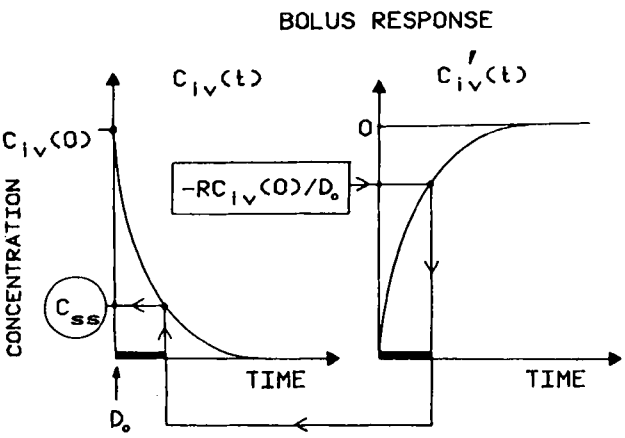

Figure 7—*Method to predict the steady-state drug level, C_{ss}, resulting from a constant rate, R, drug infusion. The prediction is done according to Eq. 36 on the basis of data from an intravenous bolus (D_0) administration. The function $C_{iv}(t)$ denotes a suitable monotonically decreasing function fitted to the intravenous bolus data; $C'_{iv}(t) = dC_{iv}(t)/dt$.*

then the predicted initial concentration C^{max} will be $DC_{iv}(0)/D_0$ if it is assumed that the autonomic nonlinear pharmacokinetics show a dose-linear initial behavior. This appears a reasonable assumption, since the nonlinearity is more likely to be due to secretion and metabolic processes than to the initial distribution.

The decline in the drug level from C_1^{max} will, due to the horizontal superposition property (Fig. 1), follow the $C_{iv}(t)$ curve. Thus, if point A in Fig. 5 is the point on the $C_{iv}(t)$ curve at the C_1^{max} level, then the first dosing profile is predicted by the curve segment AD which stretches over T hours (BC, Fig. 5). When the second dose is given at point D, then the drug level rises to point E where ED = AB = C_1^{max} (Fig. 5). Point E (C_2^{max}) is projected to point F on the $C_{iv}(t)$ curve. Point F now becomes the new point replacing the original point A and the same procedure is iterated, *i.e.*, GH = T hours, I = C_2^{min}, J = C_3^{max}, *etc.*

The peak and trough levels C_n^{max} and C_n^{min} ($n = 1, 2, \ldots$) can quickly be predicted graphically according to this hysteresis iteration method. However, it is more accurate to evaluate these quantities on a computer according to the corresponding algorithm, specified by Eqs. 19-24:

$$C_1^{max} = DC_{iv}(0)/D_0 \qquad \text{(Eq. 19)}$$

$$n = 1 \qquad \text{(Eq. 20)}$$

$$t = C_{iv}^{-1}(C_n^{max}) + T \qquad \text{(Eq. 21)}$$

$$C_n^{min} = C_{iv}(t) \qquad \text{(Eq. 22)}$$

$$n = n + 1 \qquad \text{(Eq. 23)}$$

$$C_n^{max} = C_{n-1}^{min} + C_1^{max} \qquad \text{(Eq. 24)}$$

The peak and trough levels are obtained sequentially when iterating Eqs. 21-24 as indicated. The iterations will eventually converge such that $C_{n+1}^{max} \simeq C_n^{max}$ and $C_{n+1}^{min} \simeq C_n^{min}$, in which case, by definition, the steady-state drug level profile has been reached. The mean steady-state drug level can subsequently be calculated from:

$$\bar{C}_{ss} = \int_{t-T}^{t} C_{iv}(u)du/T \qquad \text{(Eq. 25)}$$

where t in Eq. 25 is the t value calculated in Eq. 21 at convergence.

The steady-state drug levels can be calculated more directly without having to evaluate the inverse $C_{iv}(t)$ function (Eq. 21) according to the following alternative method. The peak level at steady state is equal to the trough level plus the concentration increment ΔC_D resulting from the dose injected at the end of the dosing interval:

$$C_{ss}^{max} = C_{ss}^{min} + \Delta C_D \qquad \text{(Eq. 26)}$$

As previously discussed, it is assumed that the pharmacokinetics show a dose-linear initial value behavior, so that ΔC_D is proportional to the dose:

$$\Delta C_D = D/V \qquad \text{(Eq. 27)}$$

Equation 26 can, as illustrated in Fig. 6, be transformed into an equivalent expression involving C_{iv}:

$$C_{iv}(X) = C_{iv}(X + T) + \Delta C_D \qquad \text{(Eq. 28)}$$

The proportionality term V in Eq. 27 is given by:

$$V = D_0/C_{iv}(0) \qquad \text{(Eq. 29)}$$

Combining Eqs. 27-29 yields the expression:

$$C_{iv}(X + T) + \frac{D}{D_0} C_{iv}(0) - C_{iv}(X) = 0 \qquad \text{(Eq. 30)}$$

Solving Eq. 30 for X numerically using any suitable general purpose root-finding program will subsequently give the steady-state peak, trough, and mean drug levels:

$$C_{ss}^{max} = C_{iv}(X) \qquad \text{(Eq. 31)}$$

$$C_{ss}^{min} = C_{iv}(X + T) \qquad \text{(Eq. 32)}$$

$$\bar{C}_{ss} = \int_{X}^{X+T} C_{iv}(u)du/T \qquad \text{(Eq. 33)}$$

The root-solving method (Eq. 30) is the most suitable because of its simplicity when the primary interest is to predict the steady-state quantities $\bar{C}_{ss}$, C_{ss}^{max}, and C_{ss}^{min}. However, if additionally it is desirable to evaluate how long (nT) it will take to reach 90% of steady state, then the hysteresis iteration method (Eqs. 19-24) must be used.

Steady-State Prediction of Constant-Rate Infusion—The differential

equation describing the drug level profile resulting from a constant-rate (R) intravenous infusion is given by Eq. 1A (see Appendix I). At steady state, $dC/dt = 0$, in which case Eqs. 1A and 29 give:

$$q(C_{ss}) = RC_{iv}(0)/D_0 \qquad \text{(Eq. 34)}$$

Let $q^{-1}(x)$ denote the inverse of the disposition function; then, the steady-state level is obtained by inversion of Eq. 34:

$$C_{ss} = q^{-1}(RC_{iv}(0)/D_0) \qquad \text{(Eq. 35)}$$

The problem is now to evaluate the $q^{-1}(x)$ function, which is best illustrated graphically as "q evaluated in reverse." If $-q(x)$ in Fig. 2 is set equal to $-RC_{iv}(0)/D_0$, then x will be $q^{-1}(RC_{iv}(0)/D_0)$, *i.e.*, x will be C_{ss} (Eq. 35). From this it is seen (Fig. 2) that:

$$C_{ss} = C_{iv}\,[C_{iv}^{-1}(-RC_{iv}(0)/D_0)] \qquad \text{(Eq. 36)}$$

where $C_{iv}^{-1}(\ )$ denotes the inverse of the $C_{iv}'(\ )$ function. Equation 36 enables the steady-state drug level resulting from a constant-rate (R) drug infusion to be predicted in a model-independent manner when data from an intravenous bolus dose (D_0) are available. The procedure is simply:

1. A suitable monotonically decreasing function $C_{iv}(t)$ is fitted (*e.g.*, by least-squares technique) to the intravenous bolus data to appropriately approximate the bolus response.
2. The function is differentiated to give $C_{iv}'(t)$.
3. The predicted steady-state drug level is calculated according to Eq. 36.

The evaluation procedure is graphically illustrated in Fig. 7. The evaluation of the inverse of $C_{iv}'(t)$ (Fig. 7) can be done readily in the same way as the inverse of $C_{iv}(t)$, as previously discussed (Eq. 18).

DISCUSSION

The above derivations and theoretical analysis have shown how steady-state predictions can be made for extravascular, intravenous bolus, and intravenous infusion administrations for drugs showing autonomic nonlinear pharmacokinetics. The methodology is certainly not a general solution to the very difficult prediction problems in nonlinear pharmacokinetics. However, the methodology does seem appealing because it is model independent and requires few assumptions, which can be tested readily (*e.g.*, the horizontal superposition property, Fig. 1). It represents a novel alternative that appears less academic and more practical than the model-dependent methods with their often unrealistic kinetic assumptions and computational complexity. The methodology avoids the very difficult and often impractical task of identifying and incorporating the numerous kinetic parameters and processes responsible for the observed drug concentration data into a useful mathematical model. The focus in the kinetic analysis is instead on two much simpler processes: (*a*) fitting empirical functions to drug concentration data to estimate the mean drug disposition behavior of the subject or population (*i.e.*, the disposition function q) and (*b*) testing the validity of the assumptions involved.

The empirical sum of exponentials, which are fitted quite successfully in linear pharmacokinetics, apparently do not fit nonlinear pharmacokinetic data properly. Preliminary investigations were therefore carried out to identify a suitable type of function that could be used. It was found that the following function:

$$C_{iv}(t) = \frac{p_1 e^{-p_2 t}}{1 + e^{(p_3 - p_4 t)}} \qquad p_i > 0 \qquad \text{(Eq. 37)}$$

produced very excellent fits to all typical Michaelis-Menten type intravenous bolus data investigated. Extensions of the numerator and denominator in Eq. 37 to include more exponential terms seem to hold some promise for other types of administrations and other types of nonlinearities. Alternatively, the use of least-squares splines may provide a more general and flexible approximation approach (9). Work is in progress to experimentally investigate the methodology proposed.

APPENDIX I

The differential equation describing the drug level profile resulting from a constant-rate (R) intravenous infusion is:

$$\frac{dC}{dt} = -q(C) + \frac{R}{V} \qquad \text{(Eq. 1A)}$$

Let $C_{iv}(t)$ denote an arbitrary monotonically increasing function which fit the data from a constant-rate infusion well; then, dC/dt can be determined according to Eq. 8 as previously described. By comparing Eqs. 1A and 8, it is seen that the disposition function q can be estimated empirically from the function $C_{iv}(t)$ fitted to the intravenous infusion data according to:

$$q(x) = \frac{R}{V} - C_{iv}'(C_{iv}^{-1}(x)) \qquad \text{(Eq. 2a)}$$

It is evident from Eq. 1 that $q(0) = 0$ since $dC/dt = 0$ for $C = 0$ following an intravenous bolus administration. Thus, the volume term in Eq. 2A can be evaluated from the initial condition of Eq. 1A to give:

$$V = R/C_{iv}'(0) \qquad \text{(Eq. 3A)}$$

Inserting this expression for V into Eq. 2A gives Eq. 17.

APPENDIX II: GLOSSARY

A_i, α_i = Constants (parameters) of an empirical equation (Eq. 3)
C = Drug concentration
$C_f(t)$ = Drug concentration-time profile resulting from an arbitrary rate of systemic input $f(t)$
$C_f'(t)$ = $dC_f(t)/dt$
$C_{iv}(t)$ = Drug concentration-time profile resulting from an intravenous bolus dose or a constant-rate drug infusion (as indicated)
$C_{iv}^{-1}(\ )$ = Inverse function of $C_{iv}(t)$
$C_{iv}'(t)$ = $dC_{iv}(t)/dt$
$C_{iv}^{-1}(\ )$ = Inverse function of $C_{iv}'(t)$
C_n^{max}, C_n^{min} ($n = 1, 2, \ldots$) = Peak and trough drug concentrations, respectively, in the nth dosing period in an intravenous bolus dosing regimen
C_{ss} = Steady-state drug concentration
$\bar{C}_{ss}$ = Mean steady-state drug concentration
D = Intravenous bolus dose in multiple administration
D_0 = Intravenous bolus dose in a single administration
$f(t)$ = Arbitrary rate of systemic drug input (mass/time) resulting from an extravascular dose
$g(t)$ = $q[C_f(t)] + C_f'(t)$ (Eq. 14)
K = Constant kinetic parameter (Eq. 2)
K_m = Michaelis-Menten parameter (Eq. 2)
p_i = Constants (parameters) of an empirical equation (Eq. 37)
$q(\ )$ = Disposition function (Eq. 1)
$q^{-1}(\ )$ = Inverse of the disposition function q
R = Constant rate of intravenous drug infusion
t = Time
T = Dosing interval
v = Constant of dimension volume
V_m = Michaelis-Menten parameter (Eq. 2)
y = Variable defined by Eqs. 13 and 14

Self-Association of Doxorubicin and Related Compounds in Aqueous Solution

MILENA MENOZZI ˣ, LUIGI VALENTINI, ELISABETTA VANNINI, and FEDERICO ARCAMONE

Received January 24, 1983, from *Farmitalia Carlo Erba, Ricerca e Sviluppo Chimico, Via dei Gracchi 35, 20146 Milano, Italy.* Accepted for publication May 11, 1983.

Abstract □ The dimerization of doxorubicin, daunorubicin, and their 4-demethoxy, 4′-epi, and 4′-deoxy analogues was studied spectrophotometrically. Self-association was found to be influenced by buffer composition and ionic strength. K_d values were 1.3×10^4 and 2.3×10^4 M^{-1} for doxorubicin and daunorubicin, respectively, and ranged from 3.8×10^3 to 6.1×10^3 M^{-1} for the 4-demethoxy analogues. For 4′-epi- and 4′-deoxydoxorubicin, tetramerization has also been considered. On this basis, values of 2.0×10^4 and 2.2×10^4 M^{-1} were found, respectively, for the formation constant of the dimerization process. Stability of the dimeric species appears to be strongly influenced by substitution of the chromophore moiety.

Keyphrases □ Doxorubicin—self-association, 4-demethoxy, 4′-epi, 4′-deoxy, 4-demethoxy-4′-epi, analogues, effect of buffer concentration and ionic strength □ Daunorubicin—self-association, 4-demethoxy analogues, effect of buffer concentration and ionic strength □ Dimerization—doxorubicin, daunorubicin, and their 4-demethoxy, 4′-epi, and 4′-deoxy analogues, effect of buffer concentration and ionic strength

During investigations carried out in this laboratory on doxorubicin–biopolymer interactions, knowledge of the drug dimerization process under the conditions used was necessary. The self-association of doxorubicin (I) and daunorubicin (II) in aqueous solutions has been the subject of several studies; such self-association was generally considered to be of the same type as that shown by actinomycin (1), acridine dyes (2, 3), and purine derivatives (4). The cooperative-type phenomena related to the effect of ligand dimerization on the manifestation of the binding process have been well documented (3, 5, 6).

For this reason, and also because the available literature data (7–15) exhibited large variations apparently related to the different experimental conditions used, we have determined the dimerization constants of these clinically important anthracyclines in three aqueous buffer systems, employing a spectrophotometric technique with the elimination of interference due to fluorescence. Figure 1 shows the differences among specific absorption spectra of doxorubicin at various concentrations in Tris buffer plus NaCl. These differences are considered to be due to dimerization (8, 10, 12). New second generation antitumor anthracyclines, showing more favorable pharmacological properties, have also been included in the study.

EXPERIMENTAL

Chemicals—Doxorubicin (I), daunorubicin (II), 4-demethoxydoxorubicin (III), 4-demethoxydaunorubicin (IV), 4′-epidoxorubicin (V), 4′-deoxydoxorubicin (VI), and 4-demethoxy-4′-epidoxorubicin (VII) were used as hydrochlorides. All the drugs were isolated or synthesized in our laboratories and purified by crystallization as hydrochloride salts. The chemical titers of I–VII were ≥97% as determined by an HPLC procedure (16). Phosphate and Tris buffer solutions at pH 7.0 were prepared at the same ionic strength (μ = 0.05). Tris buffer plus NaCl was prepared by adding NaCl (final concentration: 0.15 M) to pH 7.0, 0.05 M Tris-HCl in order to make the ionic strength 0.196 M.

Apparatus—Spectrophotometric measurements[1] were carried out at 477 nm (22°C), and interferential filters were placed beyond the cells to cut off the emitted fluorescence. The concentration range of the drugs was 1×10^{-6}–5×10^{-4} M, and 5-, 2-, and 1-cm path length cells were used. The wall adsorption effect, as already described by others (11), prevents the use of cells of small volume (such as 0.1-cm path length) for which the surface to volume ratio is very unfavorable.

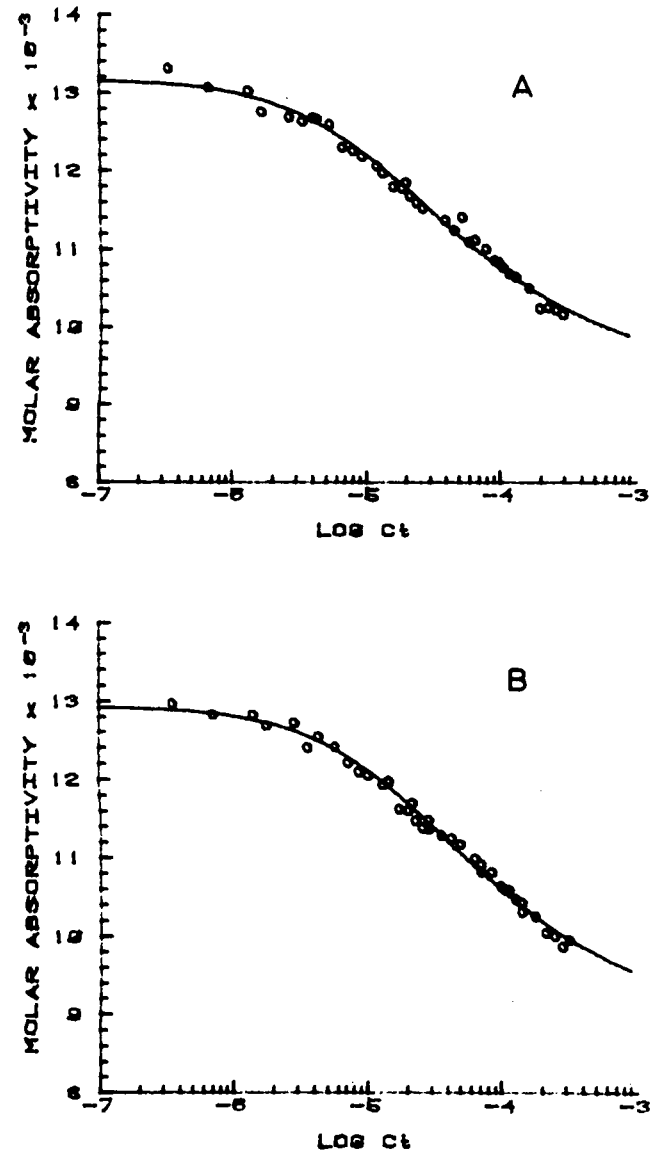

Figure 3—*Molar absorptivity* versus *log* C_t *for I (A) and II (B) in pH 7.0 Tris buffer + NaCl, according to the direct procedure. The solid lines represent the best fit of experimental points according to Eq. 5.*

Direct Procedure—Different amounts of a stock drug aqueous solution were diluted with the buffer up to the desired concentrations. The absorbance of each sample was measured without delay in 5- and 1-cm path length cells according to the concentration used. Each sample was prepared at least in triplicate.

Incremental Procedure—Increasing amounts of buffered stock drug solution were pipetted into the cell containing a predetermined volume of the same buffer. For concentration values ranging from 8×10^{-7} to 3×10^{-5} M, 15-mL cells of 2-cm path length were employed, with a starting volume of 10 mL of buffer solution, to which from 200 to 900 μL of buffered stock drug solution was added. For concentration values ranging from 6×10^{-6} to 2×10^{-4} M, 1-cm path length cells containing 2 mL of buffer were used. Absorbance was measured after the addition of increasing amounts (from 50 to 200 μL) of the drug solution.

True Spectra of Monomer and Dimer—The true spectra of monomer and dimer were obtained by differential measurements, using two cuvettes of different path length (5 and 1 cm) in order to allow subtraction of the absorption contribution due to the other species.

THEORETICAL

The absorbance of a monomeric species in equilibrium with its dimeric form is defined by:

$$A = \epsilon_m[C_m] + 2\epsilon_d^*[C_d] \qquad \text{(Eq. 1)}$$

where A is the experimental absorbance divided by the cell path length (in centimeters) at a stated wavelength; ϵ_m and ϵ_d^* are the molar absorptivities of monomer and dimer, respectively, calculated using the monomer molecular weight; and $[C_m]$ and $[C_d]$ are the molar concentrations of the monomer and dimer, respectively. For the mass balance, the total concentration is:

$$[C_t] = [C_m] + 2[C_d] \qquad \text{(Eq. 2)}$$

where $[C_t]$ is the total molar concentration expressed as monomeric units. The dimerization constant is defined by:

$$K_d = \frac{[C_d]}{[C_m]^2} \qquad \text{(Eq. 3)}$$

[a] pH 7.0, μ = 0.196, Tris buffer + NaCl. [b] pH 7.0, μ = 0.05, Tris buffer. [c] The large value of SE is due to the high correlation coefficients found between the parameters of the model.

Equations 1–3 can provide the evaluation of the dimerization constant (5, 11). Solving the system of Eqs. 1–3 for the absorbance in terms of the total concentration, one obtains:

$$A = \epsilon_d^*[C_t] + \frac{\Delta\epsilon}{4K_d}\sqrt{1 + 8K_d[C_t]} - \frac{\Delta\epsilon}{4K_d} \qquad \text{(Eq. 4)}$$

where $\Delta\epsilon = \epsilon_m - \epsilon_d^*$. Dividing Eq. 4 by $[C_t]$ the result is:

$$\frac{A}{[C_t]} = \epsilon_d^* + \frac{\Delta\epsilon}{4K_d[C_t]}(\sqrt{1 + 8K_d[C_t]} - 1) \qquad \text{(Eq. 5)}$$

and by derivation of Eq. 4 with respect to $[C_t]$ we obtain:

$$\frac{dA}{d[C_t]} = \frac{\Delta\epsilon}{\sqrt{1 + 8K_d[C_t]}} + \epsilon_d^* \qquad \text{(Eq. 6)}$$

The unknown parameters of Eqs. 4–6 are K_d, ϵ_m, and ϵ_d^*. They can be simultaneously estimated by a nonlinear least-squares fitting procedure from each of the three preceeding equations. Theoretical behavior of functions 5 and 6 is shown in Fig. 2. Data obtained following the direct procedure were treated by Eq. 5, applying a modified version of the Fletcher and Shrager program (17). The incremental procedure was employed for I and II in phosphate buffer. The data obtained, together with those from the direct procedure, were simultaneously treated by a nonlinear fitting, taking into account both Eqs. 5 and 6. The parameters describing the tetramerization process were obtained by the same fitting procedure, employing a suitable extension of Eqs. 1–3 to obtain the solving equation corresponding to Eq. 5.

RESULTS

Doxorubicin and Daunorubicin—Figure 3 shows the molar absorptivities of I and II as a function of the total concentration in pH 7.0 Tris buffer plus NaCl, μ = 0.196, following the direct procedure. Estimates of K_d, ϵ_m, and ϵ_d^*, obtained from the best fitting of Eq. 5 for the three buffers employed, are reported in Table I. Different K_d values were found for the three conditions.

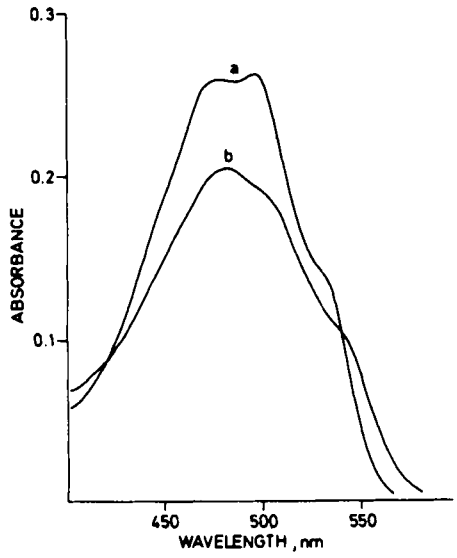

Figure 4—*True spectra of I monomer (a) and dimer (b), obtained by differential measurements, at 2.14 × 10⁻⁵ M × cm in pH 7.0 Tris buffer + NaCl. Key: (a) 1.05 × 10⁻⁵ M solution in a 5-cm cuvette against 3.10 × 10⁻⁵ M solution in a 1-cm cuvette; (b) 5.10 × 10⁻⁵ M solution in a 1-cm cuvette against 5.92 × 10⁻⁶ M solution in a 5-cm cuvette.*

Figure 4 shows the differential spectra, in Tris buffer plus NaCl, of the monomeric and dimeric species of I. The concentrations were calculated using the corresponding parameters reported in Table I.

Figure 5 reports the molar absorptivities obtained from the direct and incremental procedure for I and II in phosphate buffer. The two sets of experimental data were treated simultaneously as described above. The values of the parameters K_d, ϵ_m, and ϵ_d^* so obtained were found to be in close agreement with those presented in Table I. To evaluate the influence of the ionic strength on K_d values, measurements were performed in pH 7.0 phosphate buffer, with concentrations ranging from ~1.8×10^{-3} to 1.8×10^{-1} M. K_d values were

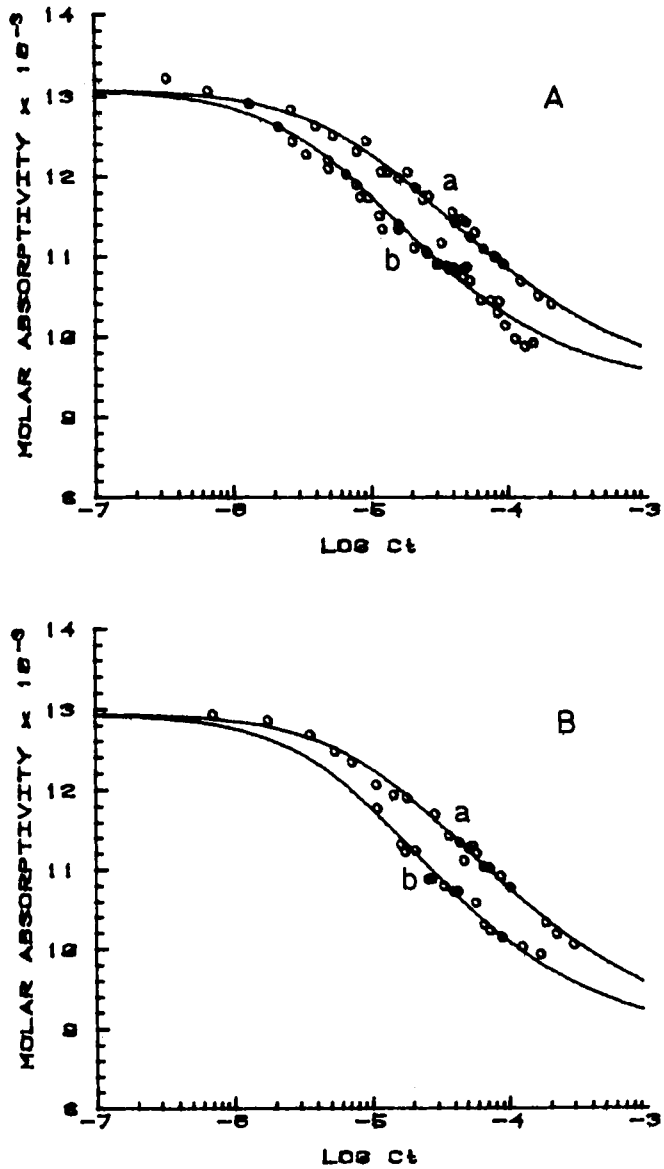

Figure 5—*Molar absorptivity (a) and incremental molar absorptivity (b) versus log C_t for I (A) and II (B), in pH 7.0 phosphate buffer, according to the direct and incremental procedures.*

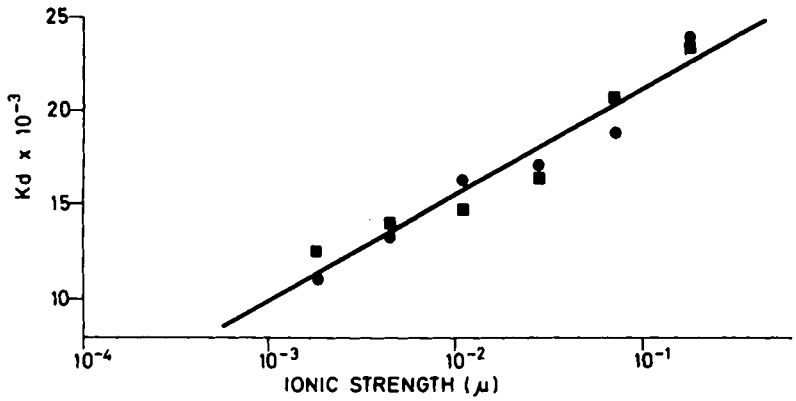

Figure 6—*Variation of the* K_d *as a function of the ionic strength.*

obtained from the absorbance measurements applying Eqs. 1-3 and using the ϵ_m and ϵ_d^* values previously determined. The dependence of K_d on the ionic strength is reported in Fig. 6.

4'-Epi, 4'-Deoxy, and 4-Demethoxy Analogues—As shown in Table II, V and VI exhibit apparent ϵ_d^* and K_d values significantly lower than those of the parent drug. The corresponding dimerization curves are presented in Fig. 7. Table II also shows the results obtained for V and VI when a tetramerization process is taken into account. The occurrence of such a process is strongly suggested by the behavior of the curves of Fig. 7 and by the low value of ϵ_d^* calculated on the basis of a simple dimerization.

A clearly lower dimerization constant is also shown by the analogues carrying a modification in the chromophore portion of the molecule, namely the 4-demethoxy derivatives (III, IV, and VII). Figure 8 shows the dimerization curves of the latter compounds.

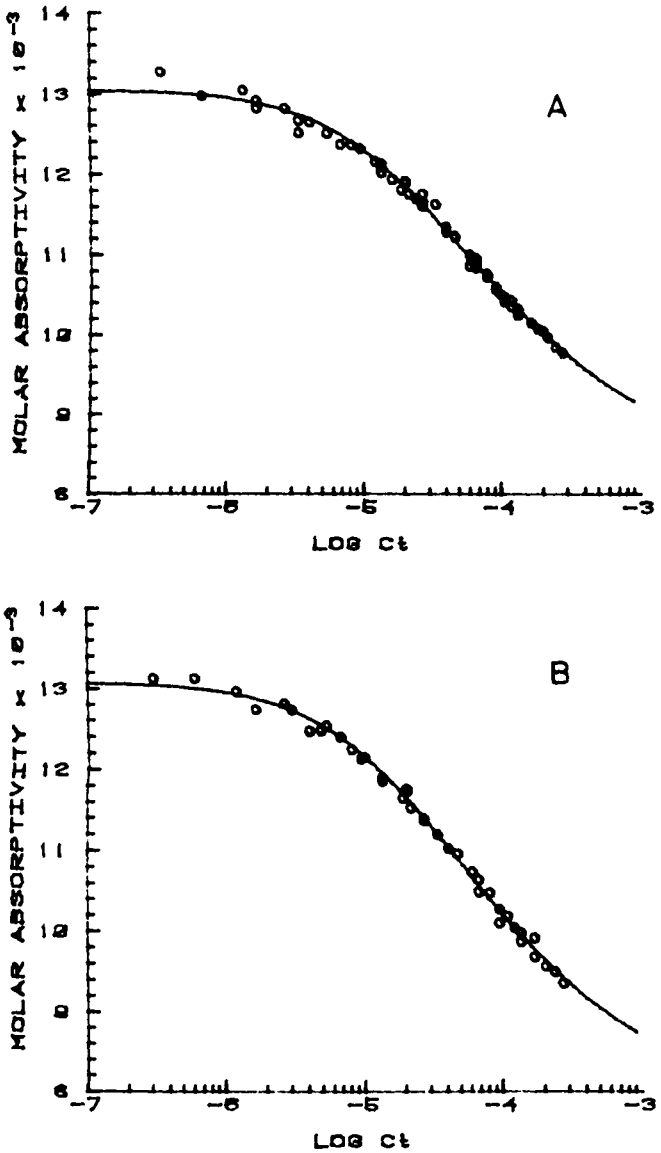

Figure 7—*Molar absorptivity* versus *log* C_t *for V (A) and VI (B). The conditions were the same as those in Fig. 3.*

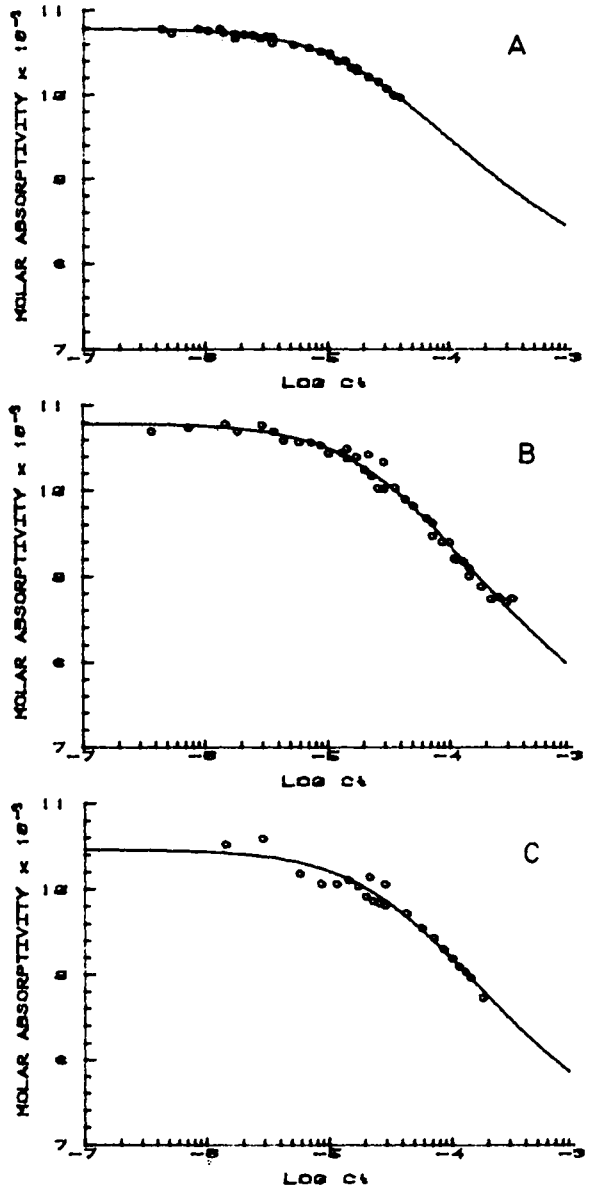

Figure 8—*Molar absorptivity* versus *log* C_t *for III (A), IV (B), and VII (C). Compound VII was in 0.05 M Tris buffer; all other conditions were the same as those in Fig. 3.*

DISCUSSION

The spectrophotometric behavior of I and II, as shown by the curves of Figs. 3 and 5, is near to that theoretically expected for a simple dimerization process. The values of the parameters obtained in different conditions (Table I) indicate that the dimerization constant is dependent on both the buffer composition and ionic strength. The K_d values observed for I seem to experience, on increase of the ionic strength, a larger variation than the corresponding K_d values of II, strongly suggesting an involvement of the 14-hydroxyl group in the dimerization process, either directly (*e.g.*, by formation of hydrogen bonds) or indirectly (*e.g.*, dipole effects). The dimerization constant values of I and II, as found in this study, are generally larger than those reported by others. Indeed the K_d values we found are twice as large as those reported by Stutter *et al.* (14) and Martin (12) for I and II, respectively, although the latter author worked with a lower buffer ionic strength. The results we obtained are practically identical to those reported by Eksborg (9), but markedly differ from those of Schütz *et al.* (11) and Chaires *et al.* (15) for II. No explanation can be given at this point for these differences, and it may be noted that the values of the molar extinction coefficients of both monomer and dimer given by these authors are not in agreement with the values reported in the present study.

Among the hundreds of doxorubicin analogues, V and VI have been selected for further development toward clinical evaluation because of their favorable pharmacological properties (18, 19). In this connection, a comparison of their properties at the molecular level with those of I is of particular interest. As regard to self-aggregation in solution, the two analogues either give rise to a somewhat less stable dimeric species or show a higher tendency toward the formation of tetramers. In both cases the latter interpretation of the results would give a slightly better fitting of the experimental data (RMS[2] = 70.2 for V and 75.8 for VI) than does the former (RMS = 75 and 81 for V and VI, respectively). The greater ability to form tetrameric species can be tentatively related to the lower hydrophilicity of V and VI as compared with I, favoring hydrophobic stacking aggregation. Accepting the tetramerization hypothesis, the dimerization constants for V and VI are very near to that found for I, in agreement with the identical electronic structure of the chromophoric moiety.

A clearly different situation exists in the case of the 4-demethoxy analogues. Compounds III, IV, and VII show a distinctly lower tendency toward dimerization when compared with the parent drugs. The reduced dimer stability appears to be a consequence of the substitution of the C-4 methoxyl group with a hydrogen atom, a modification that strongly influences the electronic structure of the chromophore. The demethoxy analogues are up to 10 times more potent than the corresponding methoxylated derivatives in different biological systems (20, 21); this property is not based on a higher affinity for the DNA receptor (22). Whether the lower tendency to self-aggregation mirrors a diminished tendency to other aspecific interactions and therefore increases, for instance, the rate of accumulation within the cells and correspondingly the availability at the receptor site, remains to be established.

High-Performance Liquid Chromatographic Determination of Diltiazem and Six of Its Metabolites in Human Urine

J. P. CLOZEL, G. CAILLÉ ˣ, Y. TAEYMANS, P. THÉROUX, P. BIRON, and F. TRUDEL

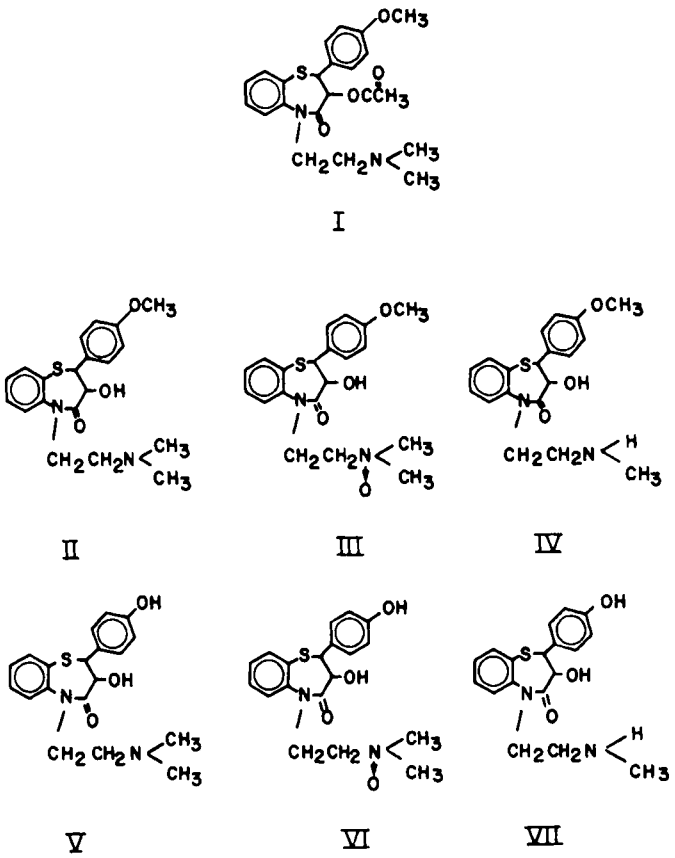
Received February 24, 1982, from the *Département de pharmacologie, Faculté de médecine, Université de Montréal, Case postale 6128, Succursale "A", Montréal, Québec H3C 3J7, Canada.* Accepted for publication May 5, 1983.

Abstract □ The use of the calcium antagonist diltiazem (I) is increasing, particularly in treating unstable angina. This study describes a simple and specific high-performance liquid chromatographic method for the determination of I and six of its metabolites in urine. Diltiazem and its conjugated and unconjugated metabolites were assayed in the urine of patients treated with a dose of 120 mg po of diltiazem tid. Sensitivity of the method was 100 ng/mL for I and the metabolites desacetyldiltiazem (II), *N*-desmethyldesacetyldiltiazem (IV), *O*-desmethyldesacetyldiltiazem (V), *O*-desmethyl-*N*-desmethyldesacetyldiltiazem (VII), *N*-oxide desacetyldiltiazem (III), and *O*-desmethyl-*N*-oxide desacetyldiltiazem (VI). In the urine of patients, the extent of conjugation of six metabolites was >80%.

Keyphrases □ Diltiazem—HPLC determination, six metabolites, human urine □ HPLC—diltiazem and six metabolites, human urine

Diltiazem, (+)-*cis*-3-(acetyloxy)-5-[2-(dimethylamino)-ethyl]-2,3-dihydro-2-(4-methoxyphenyl)-1,5-benzothiazepin-4(5*H*)one monohydrochloride, is a new calcium antagonist which has been shown to be useful in the treatment of unstable angina (1, 2). Limited data are available on the metabolism and pharmacokinetics of this new drug, but the recent development of sensitive and specific analytical methods will advance understanding in these areas. A GC method (3, 4) has been published, but it did not separate diltiazem (I) from its six metabolites and required a derivatization of the principal metabolite, desacetyldiltiazem (II). A spectrophotometric method has also been published (5), but it has limited specificity and sensitivity.

The present article describes a simple method for the determination of I and its six metabolites in urine using high-performance liquid chromatography (HPLC). This method has been applied to the measurement of urine metabolites (conjugated and unconjugated) of I in two patients receiving 120 mg po of I tid.



EXPERIMENTAL

Materials—Diltiazem[1] (I), the six metabolites (II–VII)[1], and loxapine[2] (the internal standard) were used as hydrochloride salts. All solvents and reagents were of analytical grade except acetonitrile and water, which were HPLC grade.

Apparatus—The assays were performed on a liquid chromatograph[3] equipped with a variable-wavelength UV detector set at 210 nm with attenuation at 128 AU × 10^{-4} cm. The 25 × 0.46 cm i.d. C_{18} column[4] packed with 5-μm Spherisorb ODS was eluted with acetonitrile–0.01 M phosphate buffer, pH 3 (72:28). The mobile phase had a flow rate of 2.5 mL/min from 0 to 5.5 min, increasing to 3 mL/min from 5.5 to 13 min.

Extraction—*Unconjugated Metabolites*—To 1 mL of urine, contained in a culture tube, were added 1 mL of 0.1 M acetate buffer adjusted to pH 5 and 100 μL of internal standard solution (100 μg/mL). The solution was vortexed for 30 s and extracted with 10 mL of chloroform containing 1% isoamyl alcohol. The mixture was agitated for 10 min on a reciprocating shaker and then centrifuged at 2500 rpm. The organic phase was transferred to a second culture tube and evaporated to dryness on a hot plate at 60°C under a nitrogen stream. The aqueous phase was then passed over a C_{18} cartridge[5] (previously prepared with 2.5 mL of H_2O, 2.0 mL of methanol, and another 2.5 mL of H_2O, fol-

lowed by 2 mL of 0.1 M phosphate buffer at pH 3.0 and finally 3 mL of acetonitrile). The filtrate (acetonitrile) was transferred to the tube containing the residue of the organic phase. The solution was vortexed for 30 s and the solution was evaporated to dryness. The residue was dissolved in 0.3 mL of 0.01 M HCl, and a 150-μL aliquot was analyzed by HPLC.

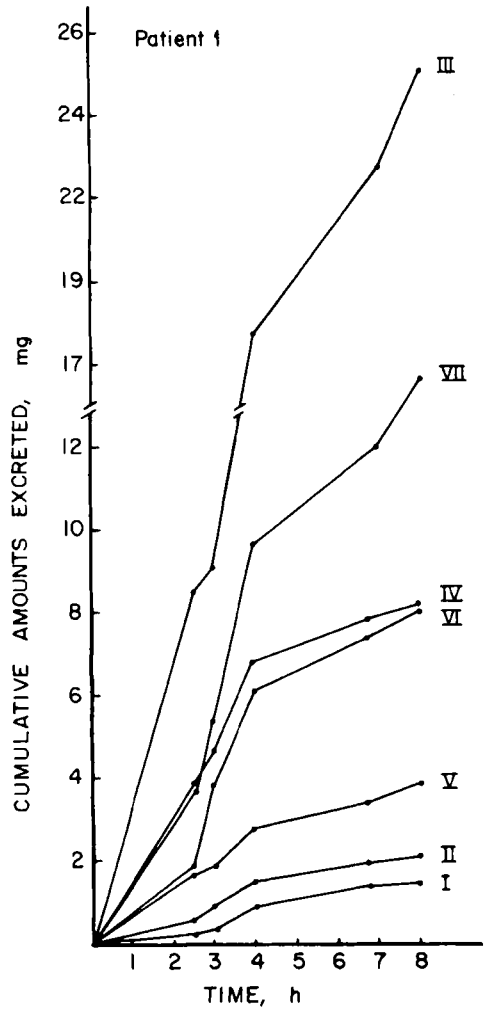

Figure 2—*Cumulative amounts of I and its metabolites excreted in urine after a single oral 120-mg dose.*

Conjugated Metabolites—To determine the total amount of I and metabolites excreted in urine, the conjugated products were hydrolyzed. The optimum conditions necessary for complete hydrolysis were evaluated. The conditions chosen consisted of incubation of 1 mL of urine containing 100 μg of loxapine with 0.1 mL of β-glucuronidase-sulfatase solution[6] at 37°C for 16 h. After incubation, the extraction was done as described above for unconjugated metabolites.

Calibration Curves—Standard samples were prepared by spiking human urine samples with increasing concentrations (0.1, 0.2, 0.4, 0.8, 1.6, 4.0, and 4.8 μg/mL) of I and the six metabolites. Calibration curves were constructed by plotting the ratios of the peak areas of I–VII to that of the internal standard

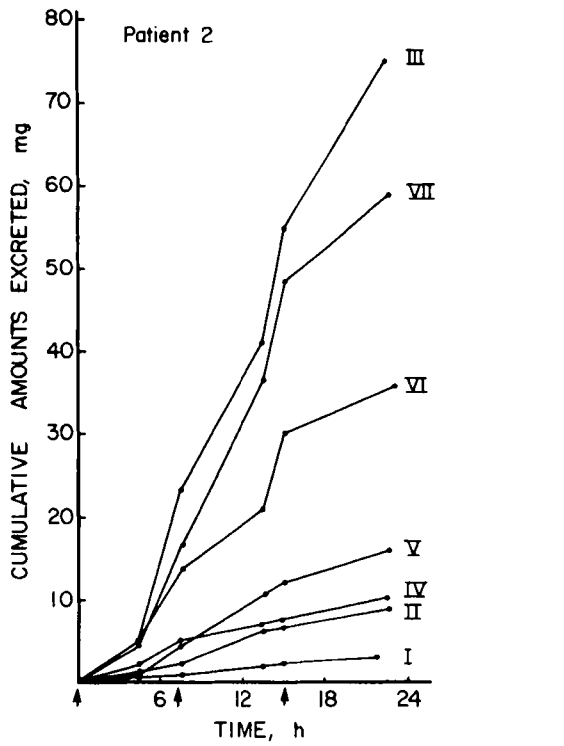

Figure 3—*Cumulative amounts of I and its metabolites excreted in urine after administration of the first three doses (120 mg tid). Arrows indicate the times of dosing.*

Table III—Reproducibility of the Assay of Diltiazem and Metabolites

Compound	Urine Conc., μg/mL	N	CV, %
Diltiazem (I)	0.8	12	3.0
	4.8	12	3.2
II	0.8	9	4.1
	4.8	9	3.9
IV	0.8	9	4.7
	4.8	9	4.5
V	0.8	9	5.1
	4.8	9	2.8
VII	0.8	9	6.1
	4.8	9	3.7
III	1.6	9	6.2
	4.8	9	4.7
VI	1.6	9	7.4
	4.8	9	3.3

against the respective concentrations I–VII. Five samples were run for each of the seven concentrations.

Analytical recoveries of I and metabolites were determined by comparing the peak areas obtained by direct injection of standard aqueous solution with those obtained after the extraction procedure. This procedure was done for each concentration of I and metabolites used in the calibration curves.

Clinical Study—Urine samples were taken from two patients treated for unstable angina with 120 mg po tid of diltiazem. In patient 1, the urine samples were taken at 2.5, 3, 4, 7, and 8 h after the first dose. In patient 2, the urine samples were taken over a period of 24 h, during and after the first three doses, at 5, 6, 14, 15, and 24 h following the first dose.

RESULTS AND DISCUSSION

A typical chromatogram showing the separation of I and the metabolites is presented in Fig. 1. Table I gives the retention time, sensitivity of the method, and results obtained for the calibration curve of I and its metabolites. The standard curves were linear throughout the range studied, and the limit of sensitivity of I and its metabolites was 100 ng/mL. Analytical recovery of I and its metabolites is presented in Table II. The day-to-day reproducibility of replicate analyses of standard urine samples containing different concentrations of I and metabolites is presented in Table III and shows a very good precision, with a coefficient of variation of 3–7.4%. Standard solutions of I and metabolites were freshly prepared and stored in darkness at low temperature (refrigerator) for short periods of time. New standard solutions were made every week, and particular attention was given to stock solutions of metabolites IV, V, and VII, which showed degradation products after a few hours at room temperature.

Cardiovascular drugs that may be given to patients without producing interferences in the assay of I and metabolites are: digoxin, propranolol, procainamide, nitroglycerin, isosorbide dinitrate, and furosemide. On the other hand, benzodiazepines (flurazepam and diazepam) interfere with the metabolites of I, but not with I itself.

Table IV—Percent of Conjugated Diltiazem and Metabolites in the Urine of Two Patients

	Patient 1	Patient 2
Diltiazem (I)	0%	0%
II	70%	77%
IV	80%	75%
V	90%	96%
VII	95%	96%
III	98%	95%
VI	97%	98%

In Figs. 2 and 3 the cumulative amounts of I and metabolites excreted in urine are presented, and Table IV gives the ratio of conjugated to free products in the urine of two patients. In fact, >80% of each metabolite excreted in urine is conjugated, and only a small amount of I was found unchanged in the urine (Table II). More than 50% of the dose was excreted in the first 8 h.

After a single oral 120-mg dose, metabolites III and VII appeared to be the main metabolites in urine, followed by successively smaller amounts of IV, VI, V, and II. The same metabolic pattern is observed during chronic administration (120 mg tid) with the exception of IV, which did not show a significant increase (Fig. 3). In fact, the cumulative amounts of IV excreted were 8 mg after a single dose and 10 mg after chronic administration. For I and other metabolites, there is a three- or fourfold difference in concentrations between single and chronic dosing.

This method was applied to the measurement of plasma concentrations of I and metabolites, but the lack of sensitivity does not permit adequate pharmacokinetic studies when concentrations are as low as 20 ng/mL.

Fluid Shifts and Other Factors Affecting Plasma Protein Binding of Prednisolone by Equilibrium Dialysis

F. DOUGLAS BOUDINOT and WILLIAM J. JUSKO ˣ

Received February 9, 1983, from the *Department of Pharmaceutics, School of Pharmacy, State University of New York at Buffalo, Buffalo, NY 14260.* Accepted for publication April 22, 1983.

Abstract □ The effects of drug stability, radioactive tracer purity, buffer composition, protein concentration, and fluid shifts on the nonlinear plasma protein binding of prednisolone were examined by equilibrium dialysis. Prednisolone exhibits a concentration-dependent degradation; however, the limited extent of this does not affect protein binding. Impure tritiated prednisolone used as a tracer produces incorrect, low fractional binding values with the binding parameters generated for transcortin affected more than those for albumin. Isotonic sodium phosphate and Krebs original Ringer phosphate buffers yield similar fractional binding of prednisolone and identical protein binding parameters. Fractional binding of the steroid decreases with total plasma protein concentration, but the association constants remain constant over a twofold dilution of plasma proteins. Further dilution increases these parameters. A time-dependent colloidal osmotic fluid shift during dialysis causes dilution of plasma protein concentrations and diminished drug binding. Theoretical simulations show that the osmotic fluid shifts produce the largest changes in fractional binding for compounds that are bound by low-capacity proteins with low association constants ($K < 10^6$ M^{-1}). A mathematical equation was developed to correct bound drug concentrations and fraction bound for protein dilution caused by this effect. The fluid shifts can be prevented by the addition of dextran (mol. wt. 70,000) to the dialysis buffer in a concentration of 55% of the total protein concentration. Multiple factors can diminish the nonlinear prednisolone binding as artifacts during equilibrium dialysis, but the changes are relatively modest.

Keyphrases □ Plasma protein binding—prednisolone, equilibrium dialysis, effects of drug stability, radiotracer purity, buffer composition, and fluid shifts □ Prednisolone—plasma protein binding, equilibrium dialysis, effects of drug stability, radiotracer purity, buffer composition, and fluid shifts □ Equilibrium dialysis—plasma protein binding of prednisolone, effects of drug stability, radiotracer purity, buffer composition, and fluid shifts

Determinants of the plasma protein binding of ligands can be separated into two categories: authentic and experimental. Authentic factors include drug concentrations, plasma protein concentrations, competitors or inhibitors of binding that may be present in plasma, and other natural physiological factors such as pH. Experimental determinants are due to the manipulations that are necessary to obtain *in vitro* measurements. These factors are often characteristic of the experimental method employed. The most widely used method of determining the extent of drug plasma protein binding is equilibrium dialysis. Protein binding by this method can be affected by drug stability, radioactive tracer purity, time of equilibration, dilution, temperature, pH, buffer composition, and colloidal osmotic fluid shifts caused by plasma proteins.

The interaction of glucocorticoids with proteins and the examination of factors affecting binding have been the subject of numerous publications over the past 25 years. These steroids are bound in plasma principally by transcortin, albumin, and α_1-acid glycoprotein. Hydrocortisone, corticosterone (1), and prednisolone (2) are bound strongly to transcortin, but this protein is easily saturated due to its low binding capacity (2, 3). Albumin has a large capacity, but low affinity for binding these steroids. α_1-Acid glycoprotein exhibits both weak affinity for binding hydrocortisone (4) and prednisolone (5), as well as low binding capacity. Its contribution to overall steroid binding in plasma can be neglected (5).

Saturation of transcortin binding sites results in a nonlinear relationship between the fraction bound and the plasma prednisolone concentration. There is a decrease in the fraction of prednisolone bound at higher drug concentrations. Thus, one concern in measuring prednisolone binding by equilibrium dialysis has been the effects of dilution of the original plasma drug concentration, which shifts binding to a greater fraction bound than exists at the original *in vivo* concentration (6, 7). In addition, lower plasma albumin concentrations produce less drug binding, but increase the number of binding sites or affinity constants (*i.e.*, $N{\cdot}K$), of several drugs (8) including hydrocortisone (9, 10). The net movement of fluid from buffer to plasma that occurs during equilibrium dialysis results in a dilution of the plasma proteins. Thus, fluid shifts that occur during equilibrium dialysis may yield unpredictable changes in prednisolone binding. Equations for correcting for such dilution effects on thyroxine binding were originally proposed by Oppenheimer and Surks (11).

The composition of the buffer used in equilibrium dialysis can have a marked influence on drug binding. For example, the fractional binding of quinidine to albumin is higher when isotonic phosphate rather than Krebs–Ringer phosphate buffer is used (12, 13).

Impure radioactive tracer or degradation of ligand during dialysis may lead to inaccurate results (14). Impurities in a radioactive tracer, more likely than not, bind differently than the ligand being examined. Degradation products of an unstable ligand may also either interfere with the protein binding of the ligand itself or decrease the amount of ligand in the dialysis system. The latter also occurs if the drug binds nonspecifically to the membrane or cell.

The purpose of the present study was to assess the effects of drug stability, radioactive tracer purity, time of equilibration, buffer composition, protein concentration, and volume shifts on prednisolone binding by equilibrium dialysis. A mathematical approach to correct for protein dilution caused by fluid shifts was developed. Physically preventing fluid shifts from occurring by adding dextran to the buffer was examined. Simulations were performed to assess the expected degree of perturbation in binding caused by fluid shifts for drugs and proteins with diverse association constants.

EXPERIMENTAL

Equilibrium Dialysis—Prednisolone[1] was added to pooled human plasma, treated with charcoal to remove endogenous steroids, to yield concentrations ranging from 0 to 1000 ng/mL (2.8 μM). Total plasma protein and albumin concentrations were measured chemically[2]. Acrylic[3] dialysis cells, checked to ensure that no leakage occurred, and dialysis membrane[4] with a 12,000–14,000 molecular weight cutoff were used. Tritiated prednisolone[5] (41 Ci/mmol) was purified by HPLC (15). Plasma (0.8 mL) with trace amounts

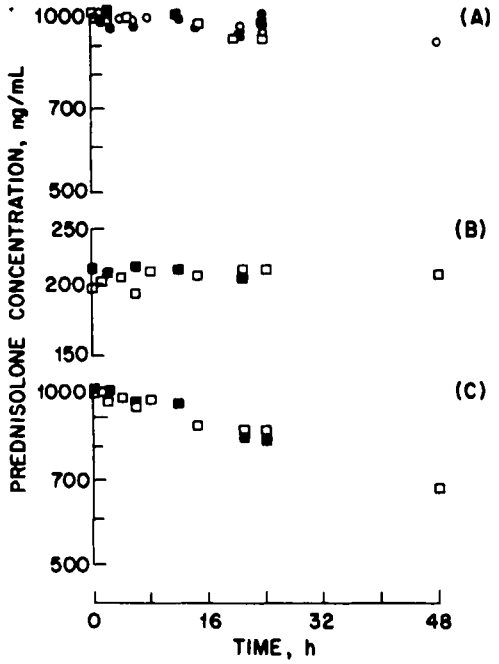

Figure 1—*Stability of prednisolone as a function of time at 37°C. Key: (A) Stability profiles for prednisolone in normal (○) and nephrotic (□) serum contained in glass tubes and normal (●) and nephrotic serum (■) in the dialysis cells. The initial concentration of each set of samples was 1000 ng/mL. (B) Stability profiles for prednisolone in normal serum contained in glass tubes (□) and normal serum in the dialysis cells (■). The initial concentration of each set of samples was 200 ng/mL. (C) Stability profiles for prednisolone in isotonic phosphate buffer, pH 7.4, contained in glass tubes (□) and in the dialysis apparatus (■) at an initial concentration of 1000 ng/mL.*

(10,000 cpm) of tritiated prednisolone was dialyzed against isotonic sodium phosphate buffer, pH 7.4, (0.8 mL) at 37°C for 16 h. Postdialysis plasma and buffer volumes were measured using a syringe[6]. Aliquots (0.5 mL) of plasma and buffer were added to water (2.5 mL) and scintillation cocktail[7] (10 mL) and counted with a scintillation counter[8]. Counts per minute were converted to disintegrations per minute using the external standard ratio method (16). Experiments were done in duplicate or triplicate.

Stability and Membrane Binding—The stability of prednisolone was assessed in normal and pooled nephrotic patient serum and in isotonic phosphate buffer, pH 7.4. Prednisolone was dissolved in each of these fluids to produce concentrations of 200 or 1000 ng/mL. Serum and buffer samples were gently shaken in glass tubes maintained at 37°C with samples of each solution taken at 0, 1, 2, 4, 6, 8, 14.5, 21, 24, and 48 h after placement into a water bath.

To determine the stability and extent of adsorption of prednisolone in the presence of dialysis membranes and dialysis cells, aliquots of the above solutions were added to the dialysis apparatus. The cells were gently shaken in a water bath at 37°C, with removal of samples at 0, 2, 6, 12, 21, and 24 h after initiation of the study.

All samples were frozen (−20°C) immediately on removal from the water bath. Prednisolone concentrations were determined in all samples using the HPLC technique of Rose and Jusko (15).

Radioactive Tracer Purity—Equilibrium dialysis experiments were carried out using tritiated prednisolone, which had been maintained in a freezer (−20°C) in benzene-ethanol (9:1) for 6 months. The material was purified by HPLC, and the dialysis experiments were repeated. The same plasma was used for both experiments.

Equilibrium Rate—The time required to obtain equilibration of free prednisolone concentrations between the plasma and buffer compartments of dialysis cells was evaluated at both low (50-ng/mL) and high (1000-ng/mL) plasma prednisolone concentrations. Plasma, with prednisolone added, was dialyzed against either isotonic sodium phosphate buffer or isotonic buffer with dextran added. At various times after the initiation of dialysis, plasma and buffer samples were removed from the cells. The volumes of the samples were measured and aliquots placed in scintillation vials for counting of the radioactive tracer. Samples were obtained over a 24-h period. Fractional binding of prednisolone was calculated at each sampling time.

[8] Packard.

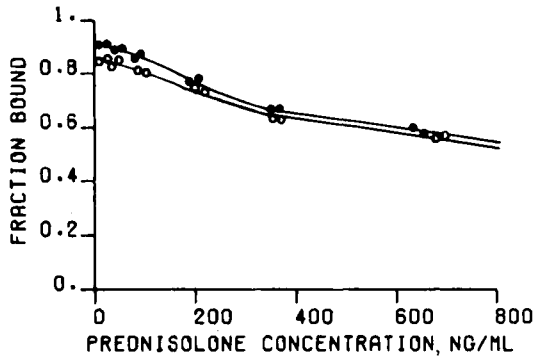

Figure 2—*Fraction bound* versus *postdialysis plasma prednisolone concentration before (○) and after (●) purification of the tritiated prednisolone tracer by HPLC.*

Influence of Buffer Composition—Krebs original Ringer phosphate, pH 7.4 (0.14 M), was prepared according to Dawson *et al.* (17). Isotonic sodium phosphate buffer, pH 7.4 (0.14 M), was composed of 0.054 M Na_2HPO_4, 0.013 M KH_2PO_4 and 0.075 M NaCl. Both buffers were prepared in distilled deionized water. Plasma, with prednisolone added, was dialyzed against the Krebs and phosphate buffers.

Effect of Protein Concentration—The total protein concentration of pooled human plasma (total protein = 5.5 g/dL, albumin = 3.7 g/dL) was defined as 100%. This plasma was diluted with various volumes of isotonic sodium phosphate buffer, pH 7.4, to yield total protein concentrations of 87.5% (4.8 g/dL), 75% (4.1 g/dL), 50% (2.8 g/dL), and 25% (1.4 g/dL). Prednisolone was added to each protein dilution (0–1000 ng/mL) and dialyzed as described previously.

Fluid Shifts—*Mathematical Correction*—The concentration of drug bound was corrected for protein dilution due to fluid shifts by:

$$D_B = (D_{Te} - D_F) \cdot \frac{V_{pe}}{V_{pi}} \qquad \text{(Eq. 1)}$$

where D_F and D_B are the free and protein-bound plasma prednisolone concentrations, D_{Te} is the total plasma prednisolone concentration at equilibrium, and V_{pi} and V_{pe} are the initial and equilibrium plasma volumes. The fraction of prednisolone bound to plasma proteins (F_B) can be calculated by:

$$F_B = \frac{(D_{Te} - D_F) \cdot \frac{V_{pe}}{V_{pi}}}{\left[(D_{Te} - D_F) \cdot \frac{V_{pe}}{V_{pi}}\right] + D_F} \qquad \text{(Eq. 2)}$$

The derivation of these equations is provided in the *Appendix*.

Dextran—Dextran[9] with an average mol. wt. of 70,000 was added to the isotonic sodium phosphate buffer to offset osmotic fluid shifts caused by plasma proteins. Various concentrations of dextran (0–5 g/dL) in buffer with prednisolone (0–2000 ng/mL) added were dialyzed against buffer to assess whether binding of prednisolone to dextran occurs. To develop an equation to predict the concentration of dextran needed to prevent fluid shifts, dextran (0–5 g/dL) in buffer was dialyzed against plasma (total protein = 5.5 g/dL),

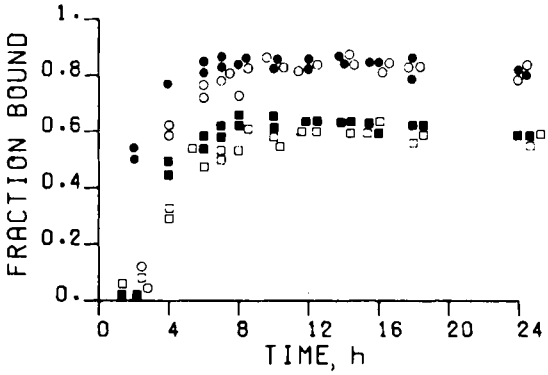

Figure 3—*Apparent fraction bound* versus *equilibration time for prednisolone plasma concentrations of 50 ng/mL (○,●) and 1000 ng/mL (□,■), dialyzed against isotonic sodium phosphate buffer (closed symbols) and phosphate buffer with dextran added (open symbols).*

[9] Pharmacia Fine Chemicals AB, Uppsala, Sweden.

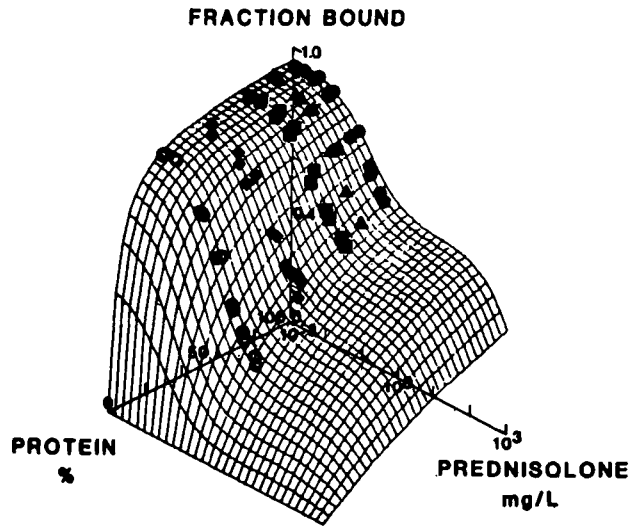

Figure 4—*Relationship between the plasma protein binding of prednisolone, unbound drug concentrations, and protein concentrations of 100% (●), 87.5% (▲), 75% (■), 50% (◆), and 25% (○).*

and postdialysis plasma and buffer volumes were measured. Mean postdialysis plasma and buffer volumes were plotted as a function of dextran concentration. The intersect of ordinary least-squares regression lines drawn through the postdialysis plasma and buffer volumes *versus* dextran concentration points occurs at the dextran concentration (3.0 g/dL) needed to offset perfectly fluid shifts caused by a total protein concentration of 5.5 g/dL. Rearrangement of the direct proportionality:

$$\frac{[\text{Dextran}]}{[\text{Total Plasma Protein}]} = \frac{3.0\ \text{g/dL}}{5.5\ \text{g/dL}} \qquad \text{(Eq. 3)}$$

yields

$$[\text{Dextran}] = [\text{Total Plasma Protein}] \times 0.5455 \qquad \text{(Eq. 4)}$$

which can be used to predict the dextran concentration required to prevent fluid shifts based on total plasma protein concentration. The predictive value of Eq. 4 was examined over a wide range of total plasma protein concentrations by employing plasma from 10 normal volunteers and 9 patients with nephrotic syndrome, a condition that results in hypoproteinemia. Total plasma protein concentrations were measured, and the appropriate dextran concentrations were determined using Eq. 4. Samples were dialyzed against buffer containing the calculated dextran concentrations, and postdialysis plasma and buffer volumes were measured. To examine the effect of dextran on prednisolone binding, plasma containing prednisolone was dialyzed against buffer in the absence and presence of dextran.

Data Analysis—When radioactive tracer methods are employed to determine the fractional binding, Eq. 2 can be written as:

$$F_B = \frac{(\text{DPM}_p - \text{DPM}_B) \cdot \frac{V_{pe}}{V_{pi}}}{(\text{DPM}_P - \text{DPM}_B) \cdot \frac{V_{pe}}{V_{pi}} + \text{DPM}_B} \qquad \text{(Eq. 5)}$$

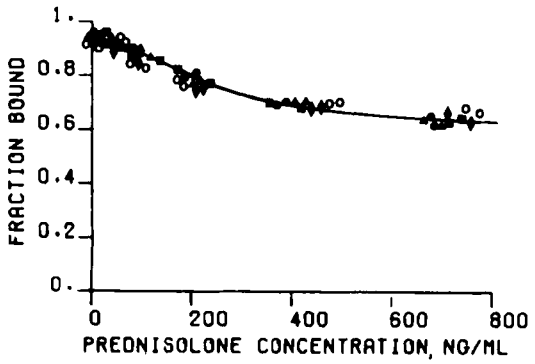

Figure 5—*Fraction of prednisolone bound* versus *postdialysis plasma prednisolone concentrations showing results of correction for protein dilutions. Symbols represent experimental data at protein concentrations of 100% (●), 87.5% (▲), 75% (■), 50% (◆), and 25% (○).*

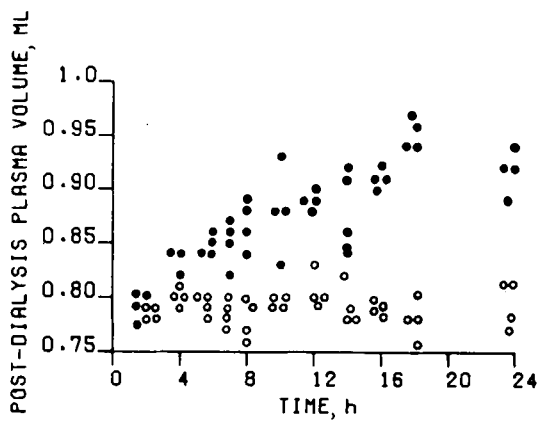

Figure 6—*Postdialysis plasma volume* versus *time where plasma was dialyzed against isotonic sodium phosphate buffer (●) and buffer with dextran (○).*

where DPM_P and DPM_B are disintegrations per minute in the plasma and buffer after background counts have been subtracted. When fluid shifts were observed, Eq. 5 was used to calculate the fraction of prednisolone bound. In the absence of fluid shifts (*i.e.*, when dextran was added to the dialysis buffer), the fraction bound was calculated by:

$$F_B = \frac{\text{DPM}_P - \text{DPM}_B}{\text{DPM}_P} \qquad \text{(Eq. 6)}$$

The plasma protein binding of prednisolone can be described by the relationship:

$$D_B = \frac{N_T K_T P_T D_F}{1 + K_T D_F} + \frac{N_A K_A P_A D_F}{1 + K_A D_F} \qquad \text{(Eq. 7)}$$

where N_T and N_A are the number of binding sites on transcortin and albumin, K_T and K_A are the association constants for transcortin and albumin, P_T and P_A are the plasma concentrations of transcortin and albumin, and D_B and D_F are the plasma concentrations of bound and free prednisolone. Least-squares estimates of $N_T K_T P_T$, K_T, and $N_A K_A P_A$ were obtained by the method of Priore and Rosenthal (18). Since P_A was measured chemically, $N_A K_A$ could be calculated. P_T was calculated assuming an N_T value of one. The total prednisolone concentration at equilibrium was generated using a variation of the methods of Behm and Wagner (6) and Rose *et al.* (7).

Statistics—The paired *t* test was used to determine whether there were any differences in the binding parameters obtained with phosphate and Krebs buffers. Regression lines for protein concentration *versus* postdialysis volumes were fitted by the weighted perpendicular least-squares method assuming error in both variables (19).

RESULTS AND DISCUSSION

Stability—The results from the stability study are presented in Fig. 1. At initial prednisolone concentrations of 1000 ng/mL, degradation in normal serum, nephrotic serum, and buffer at the end of 24 h was 6.7, 14.2, and 16.5% as determined by log-linear regression of concentration–time data. This degradation appears to be concentration dependent since no significant loss occurred in normal serum at initial drug concentrations of 200 ng/mL (Fig. 1B). The extent of this degradation does not appear to present any problem in analyzing prednisolone binding data. While the protein binding of the steroid was examined at concentrations as high as 1000 ng/mL, most samples have concentrations that were much lower and, therefore, may be subject to less degradation. There was no significant difference between the loss of prednisolone as a function of time from solutions contained in glass tubes *versus* solutions studied in the dialysis cells. This suggests that adsorption of prednisolone onto dialysis membranes and cell walls does not occur.

Radioactive Tracer Purity—The effects on binding of using aged *versus* freshly purified tritiated prednisolone tracer are shown in Fig. 2. The use of pure radioactive tracer resulted in fractional binding data higher than the data obtained using impure tracer. The binding parameters $N_T K_T P_T$, K_T, and $N_A K_A P_A$ were 5.33, $1.21 \times 10^7\ M^{-1}$, and 0.84 when impure radioactive tracer was used and 8.56, $2.16 \times 10^7\ M^{-1}$, and 0.85 when purified tracer was employed. Thus, the products of both radiolysis and of chemical degradation bind less readily, if at all, to transcortin and albumin, resulting in an increased apparent free drug concentration and incorrect, low fractional binding data. We have found that purification of tritiated prednisolone approximately every 3 months is required to obtain valid binding results.

Table I—Plasma Protein Binding Parameters for Prednisolone Related to Protein Concentration Without and With Correction for Dilution

Protein Conc., g/dL	$N_TK_TP_T$ Without Correction	$N_TK_TP_T$ With Correction	K_T, $M^{-1} \times 10^{-7}$ Without Correction	K_T, $M^{-1} \times 10^{-7}$ With Correction	$N_AK_AP_A$ Without Correction	$N_AK_AP_A$ With Correction	N_AK_A, $M^{-1} \times 10^{-3}$ Without Correction	N_AK_A, $M^{-1} \times 10^{-3}$ With Correction
5.5	11.4	13.2	2.87	3.26	0.917	1.12	1.94	2.06
4.8	11.6	14.4	3.16	3.35	0.793	1.03	1.88	1.89
4.1	8.91	12.6	2.62	3.28	0.704	1.11	1.88	2.04
2.8	6.98	13.8	3.10	4.86	0.566	1.36	2.18	2.50
1.4	4.93	15.8	4.37	7.40	0.359	1.61	2.64	2.96

Equilibration Rate—The results of the equilibration study are presented in Fig. 3. When isotonic sodium phosphate buffer is used as the dialysate, equilibration of free prednisolone occurs within 8 h and is independent of the prednisolone concentration. The inclusion of dextran in the buffer results in a slower equilibration rate (10–14 h), with the higher prednisolone concentrations requiring a longer time to attain equilibrium. This may be due to obstruction of pores in the dialysis membrane by dextran. Fractional binding values remain constant from the minimum time required to reach equilibrium of free prednisolone to at least 18 h, reinforcing our conclusion that prednisolone degradation during dialysis is minimal.

Buffer Composition—Isotonic sodium phosphate buffer and Krebs original Ringer phosphate yield similar binding of prednisolone. The mean (*SD*) $N_TK_TP_T$, K_T, and $N_AK_AP_A$ obtained were 8.59 (2.53), 1.71×10^7 (0.35×10^7) M^{-1}, and 0.92 (0.15) when isotonic phosphate buffer was used and 8.17 (3.02), 1.73×10^7 (0.48×10^7) M^{-1}, and 0.91 (0.15) when Krebs buffer was employed. There were no statistically significant differences between the binding parameters obtained using the two buffers.

These protein binding parameters agree well with previously reported values for prednisolone (2, 20–22). Chan and Slaunwhite (23) noted small decreases in the binding of hydrocortisone and progesterone to transcortin as dialysate NaCl concentrations decreased below 0.15 M. However, lower NaCl concentrations in the isotonic sodium phosphate buffer than in Krebs original Ringer phosphate (0.075 *versus* 0.118 M) did not produce this effect with prednisolone.

Protein Concentration—Figure 4 illustrates the fraction of prednisolone bound as a function of unbound prednisolone concentration and plasma protein concentration. The surface was calculated using binding parameters obtained by fitting fractional binding data from the 75–100% protein concentration range, where no differences were found in the binding parameters (see below). The data from the 25% protein concentration deviates slightly from the predicted values. Nonlinear binding is seen at all protein concentrations examined, with less fractional binding of prednisolone at lower plasma protein concentrations. The fractional binding of prednisolone diminished as the total protein concentration decreased as a result of lower plasma transcortin and albumin concentrations. At higher prednisolone concentrations, the drug is predominantly bound to albumin. Because the affinity of albumin for prednisolone is low (10^3 M^{-1}), the diminished fractional binding is proportional to the reduced protein concentration (24). At low prednisolone concentrations, where transcortin is the major protein responsible for binding prednisolone, the change in the fractional binding is less marked owing to the high affinity of transcortin for prednisolone (24). At the middle range (100–300 ng/mL) of prednisolone concentrations, the fractional binding changes are also appreciable because of the saturation of transcortin binding. Figure 5 presents the fractional binding data shown in Fig. 4 after corrections for the protein dilutions have been made. All the corrected data, except that from the 25% protein concentration, cluster together.

Decreases in albumin concentrations in albumin solutions (9, 10) and in serum (10) have resulted in increases in the binding parameter $N{\cdot}K$. Increases in α_1-acid glycoprotein concentrations, on the other hand, result in increases in the binding affinity for hydrocortisone and corticosterone (4), but not for prednisolone (5). The computer-fitted binding parameters obtained at each protein concentration, before and after correcting for plasma dilution, are listed in Table I. Without any correction, K_T remains constant over the protein concentration range of 100–50%, but increases at the 25% protein concentration. The N_AK_A values remain constant between 100 and 75% protein concentrations, but increase at lower protein concentrations. After correcting the binding data for the plasma protein dilutions, the K_T and N_AK_A values remain constant above the 75% protein concentration, but increase at lower total protein concentrations. Inspection of Table I shows that the correction for protein dilution in the protein concentration range of 75–100% does not appreciably affect K_T and N_AK_A values.

The magnitude of the increases in K_T and N_AK_A at low protein concentration is not particularly great, yet helps explain the deviations noted at the 25% protein concentration (Figs. 4 and 5). The N_AK_A for prednisolone, which does not increase until the albumin concentration has decreased to 50% ($P_A = 2.7 \times 10^{-4}$ M), appears to be more resistant to changes in albumin concentration than hydrocortisone, which shows increases in N_AK_A at albumin concentrations $<9 \times 10^{-4}$ M (10). No change occurs in K_T until protein concentrations are reduced to 25% ($P_T = 1.1 \times 10^{-7}$ M). When diluting plasma, the possibility arises that the increases seen in the binding parameters

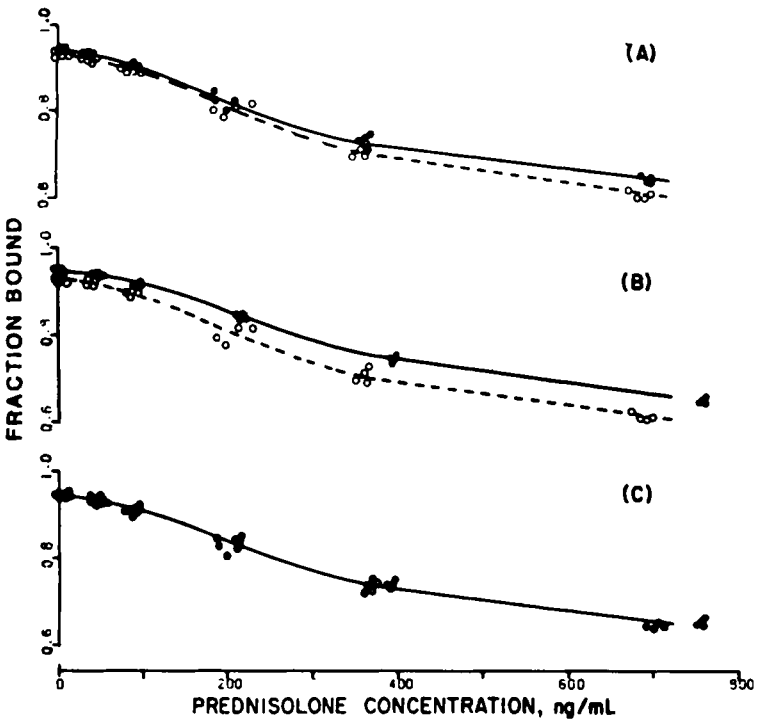

Figure 7—*Plasma protein binding of prednisolone in relation to free drug concentrations under the following conditions: (A) without (○) and with (●) mathematical correction for fluid shifts using Eq. 5, maximum difference 6%; (B) without (○) and with (●) dextran added to prevent fluid shifts; (C) with dextran added to buffer (●) and after mathematical correction (Eq. 5) for the fluid shifts that occur with buffer alone (○).*

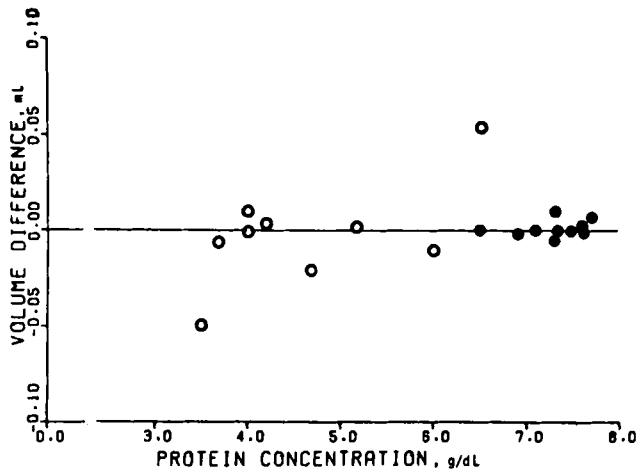

Figure 8—*Postdialysis volume differences (plasma side minus buffer side) observed when plasma containing various total protein concentrations were dialyzed against buffer, with dextran content calculated by Eq. 4. Key: (●) normal subjects; (○) patients with nephrotic syndrome; (—) no fluid shift.*

are due to lower concentrations of binding inhibitors, although these were probably removed by the charcoal. Another explanation might be that conformational changes in the albumin molecule may make available binding sites that were previously inaccessible (25). This may explain the increases in N_AK_A, but no increase occurs in the number of binding sites on the transcortin molecule. The trimer-polymer form of albumin has been shown to have a lower binding affinity for progesterone than the monomer or dimer forms (26). The binding affinity of transcortin in the rat (27) and rabbit (28) has also been shown to decrease owing to polymer formation. Whether or not human transcortin forms polymers is still being debated (29–31). A decrease in polymer formation at low protein concentrations may explain the increases seen in K_T and N_AK_A. It is important to note that K_T and N_AK_A remain constant up to a twofold dilution of the plasma proteins.

The colloidal osmotic pressure of plasma proteins tends to pull fluid into the plasma compartment of a dialysis cell, resulting in lower postdialysis protein concentrations. A decrease in the fractional binding of ligand to protein may also occur. Linear relationships were observed between postdialysis plasma ($r = 0.994, p < 0.005$) and buffer ($r = 0.966, p < 0.01$) volumes and plasma protein concentration. Fluid shifts were greatest with undiluted plasma and decreased as plasma protein concentration decreased. The decreases in protein concentration caused by these fluid shifts resulted in decreases in the fractional binding of prednisolone. As the protein binding parameters for prednisolone are constant over the range of dilutions that result from fluid shifts, this low fractional binding of prednisolone can be corrected mathematically.

Volume Shifts—*Mathematical Correction*—Equal volumes (0.8 mL) of plasma and isotonic sodium phosphate buffer were placed in each equilibrium dialysis cell. Figure 6 presents measured postdialysis plasma volumes as a function of time, showing progressive increases in the plasma volume between 2 and 14 h. Plasma volumes were static after 14 h. Mean (*SD*) plasma and buffer volumes typically found at 16 h are 0.91 (0.04) mL and 0.67 (0.04) mL, respectively. Volume shifts of similar magnitude were noted when plasma was dialyzed against Krebs original Ringer phosphate and with both hypotonic and hypertonic sodium phosphate buffers. This produces postdialysis protein concentrations that are ~86% of the initial concentrations. Equation 5 was employed to correct for this fluid shift, and Fig. 7A presents the binding results with (Eq. 5) and without (Eq. 6) this adjustment. The dilution of plasma proteins caused by fluid shifts results in lower values for the fractional binding of prednisolone. The K_T and N_AK_A were $2.83 \times 10^7\ M^{-1}$ and $2.06 \times 10^3\ M^{-1}$ without correction and $3.55 \times 10^7\ M^{-1}$ and $2.28 \times 10^3\ M^{-1}$ with correction.

Oppenheimer and Surks (11), in the first attempts to correct protein binding data for dilution of plasma proteins, corrected the free drug concentration for dilution in terms of the total volume of the dialysis system. Our method differs in that we correct the bound drug concentration for dilution of proteins using pre- and postdialysis volumes of the plasma compartment only. The bound drug concentration was corrected since this is the variable that is dependent on drug and protein concentrations (Eq. 7). Correction of the free drug concentration would appear to introduce an artifact into the system, particularly when binding is nonlinear.

Volume shifts that occur in our equilibrium dialysis system yield postdialysis protein concentrations that are ~86% of their initial value. As shown previously, protein dilutions of this magnitude have no effect on $N_TK_TP_T$, K_T, or N_AK_A. If D_F is held constant, the only changing variables in Eq. 7 are P_T and P_A. These can be corrected for by use of a dilution factor and D_B can then be calculated. This dilution factor can be expressed as the ratio of the equilibrium plasma volume (V_{pe}) to the initial plasma volume (V_{pi}). The higher D_B and F_B obtained after correction are then functions of the initial protein concentration. A dilution factor could also be calculated from directly assayed pre- and postdialysis protein concentrations. Mathematical correction for fluid shifts cannot be used if the binding parameters are highly dependent on protein concentration.

Dextran—Dextran, when added to dialysis buffer, alters the magnitude and direction of fluid shifts. Equation 4 was found to be useful for calculating the dextran concentration required to prevent fluid shifts, based on total plasma protein concentration. As shown in Fig. 8, 19 samples dialyzed against buffer containing dextran resulted in fluid shifts of <0.05 mL, while 16 resulted in shifts of <0.01 mL. No binding of prednisolone to dextran occurred.

The results of dialyzing plasma containing prednisolone against buffer alone and buffer with dextran added are shown in Fig. 7B. The fractional binding of prednisolone determined by dialyzing plasma against plain buffer is lower as a result of the dilution of plasma proteins. When dextran was added to the buffer, no fluid shifts occurred. The K_T and N_AK_A values were $2.38 \times 10^7\ M^{-1}$ and $2.06 \times 10^3\ M^{-1}$ for plain buffer and $3.54 \times 10^7\ M^{-1}$ and 2.25×10^3

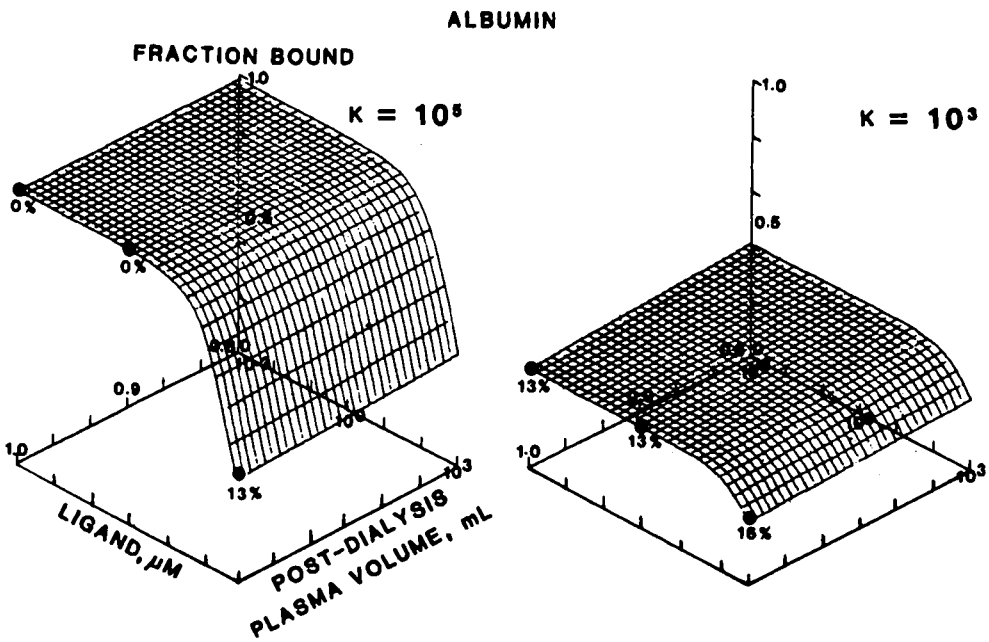

Figure 9—*Relationship between the fraction of ligand bound to albumin, free ligand concentration, and postdialysis plasma volume. Dots indicate the percent decrease in fractional binding due to volume shifts at ligand concentrations of 10^{-3}, 10^0, and 10^3 μM.*

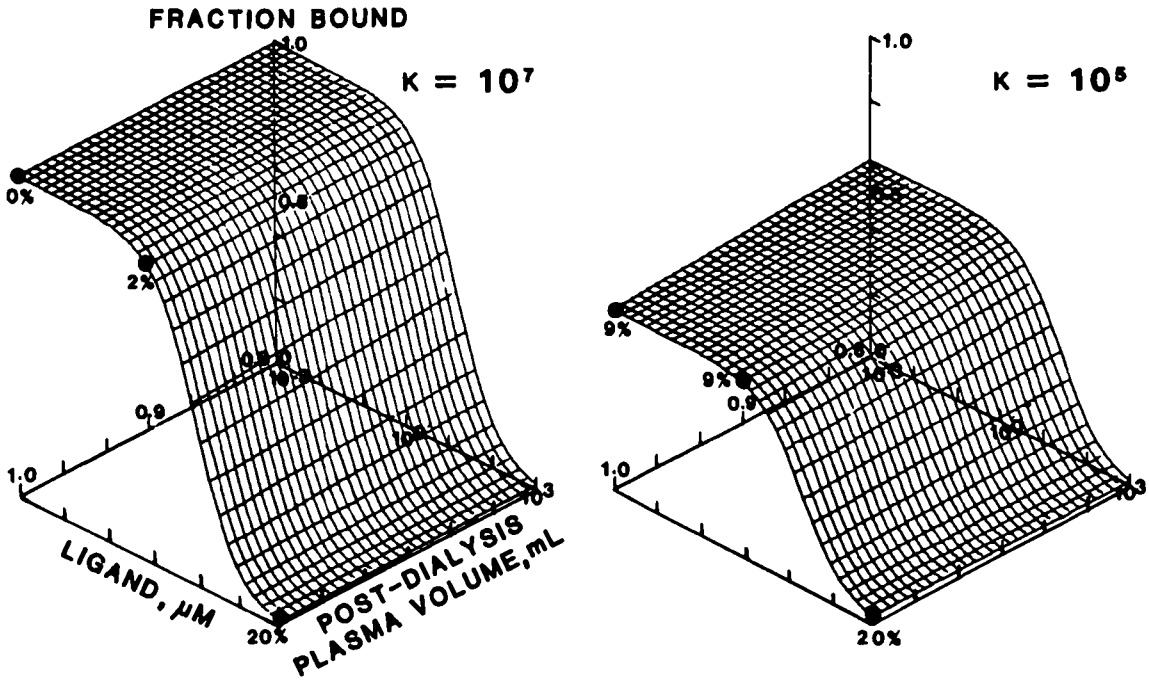

Figure 10—*Relationship between the fraction of ligand bound to α_1-acid glycoprotein, free ligand concentration, and post-dialysis plasma volume. Dots indicate the percent decrease in fractional binding due to volume shifts at ligand concentrations of 10^{-3}, 10^{0}, and 10^{3} μM.*

M^{-1} for buffer with dextran. Figure 7C shows the same data with correction for the typical volume shifts. The results with dextran and those obtained with the mathematical correction coincide on the same binding curve, although the latter are shifted slightly to the left as a result of the increased plasma volume (6, 7). The computer-fitted K_T and $N_A K_A$ were 3.54×10^7 M^{-1} and 2.25×10^3 M^{-1} for results obtained with dextran and 3.55×10^7 M^{-1} and 2.28×10^3 M^{-1} for the mathematically corrected binding data.

Dextran, when added to buffer in appropriate amounts, prevents the occurrence of any fluid shift, so that the binding results obtained are then directly related to the initial protein concentration. Inhibitors of binding also remain undiluted. The concentration of dextran (mol. wt. 70,000) required to prevent volume shifts is 55% of the total plasma protein concentration.

The use of other dialysis membranes or systems may also prevent volume shifts. Lima *et al.* (32) found that a thicker membrane with a molecular weight cutoff of 6000–8000 will diminish the fluid shift. We also examined equilibrium dialysis of prednisolone with cells that have a larger membrane-to-volume surface area[10]. Equilibration was obtained by 2 h, and no volume shifts were observed. Prednisolone binding data in these cells were identical with results obtained by mathematical correction or addition of dextran in the present system.

Calculated Effects of Volume Shifts—Simulations were employed to illustrate the effects of volume shifts on the protein binding (D_B) of ligands at various protein concentrations (P), association constants (K), and free ligand concentrations (D_F). Normal values of albumin (4.8 g/dL) and α_1-acid glycoprotein (70 mg/dL) concentrations were used to depict high and low protein concentrations. Association constants employed were 10^3 M^{-1} and 10^5 M^{-1} for albumin and 10^5 M^{-1} and 10^7 M^{-1} for α_1-acid glycoprotein. The number of binding sites per protein molecule (N) was assigned as 1 for both proteins. It was assumed that neither N nor K changed as a result of increases in the postdialysis plasma volume. The equation used for these simulations is:

$$D_B = \frac{N \cdot K \cdot P \cdot D_F \cdot \frac{V_{pi}}{V_{pe}}}{1 + K \cdot D_F} \qquad \text{(Eq. 8)}$$

where ligand concentration ranged from 10^{-9} to 10^{-3} M. Postdialysis plasma volumes (V_{pe}) ranged from 0.8 mL (no volume shift, V_{pi}) to 1.0 mL.

Simulations depicting drug binding to albumin in relation to volume changes are shown in Fig. 9. The fractional binding calculated with both association constants is linear over a wide range of ligand concentrations due to the high binding capacity of albumin. The higher association constant ($K = 10^5$ M^{-1}) yields higher fractional binding at all ligand concentrations. When $K = 10^5$ M^{-1}, an increase in the plasma volume from 0.8 mL to 1.0 mL produces <1% decrease in the fraction bound over a ligand concentration range of 10^{-3}–10^1 μM. At higher ligand concentrations, volume shifts produce progressively larger decreases in fractional binding. At a ligand concentration of 10^3 μM, a shift in plasma volume from 0.8 to 1.0 mL results in a 13% decrease (from 0.41 to 0.36) in fraction bound. When $K = 10^3$ M^{-1}, the same volume shift produces a 13% (0.05 absolute F_B) decrease in fractional binding up to a ligand concentration of 10^2 μM. A similar 16% decrease (from 0.26 to 0.22) in fractional binding occurs at a ligand concentration of 10^3 μM.

Simulations illustrating binding of ligand to α_1-acid glycoprotein are presented in Fig. 10. Saturation of this low-capacity protein at $D_F > 10^{-2}$ μM produces marked nonlinearity in the fractional binding. As expected, the higher association constant yields greater fractional binding of the drug. When $K = 10^7$ M^{-1}, volume shifts produce no change in fractional binding when ligand concentrations range from 10^{-3} to 10^{-1} μM. At a ligand concentration of 10^0 μM, the 20% increase in plasma volume results in a 2% decrease (0.94 to 0.92) in fractional binding. As the ligand concentration increases further, the percent decrease in fractional binding caused by volume shifts progressively increases. The largest absolute change in fractional binding (0.05) as a result of fluid shifts occurs at a ligand concentration of 10^1 μM. When $K = 10^5$ M^{-1}, volume shifts produce a 9% (0.05 absolute) decrease in fractional binding over a ligand concentration range of 10^3–10^1 μM. At higher ligand concentrations the absolute changes in fractional binding are extremely small.

These theoretical simulations show that changes in protein binding of a ligand are dependent on the protein concentration, the association constant, the free ligand concentration, and the magnitude of the volume shift. In general, the decrease in fractional binding is greatest with lower initial protein concentrations, lower association constants, higher free drug concentrations, and larger fluid shifts. The fluid shifts can be either corrected for mathematically or prevented with dextran.

With prednisolone, the binding results obtained by correction or dextran addition agree well. The mathematical approach requires that binding parameters remain constant and also that possible competitors or inhibitors of binding are not influenced by fluid shifts. The equations used can easily be written into a computer program. The dextran approach requires an accurate measurement of the total plasma protein concentration for each compound. For prednisolone, the fluid shifts produce a slight decrease in the fractional binding and do not present any major errors in binding results.

APPENDIX: Correction for Volume Shifts in Protein Binding

The amount of protein (AP_i) initially placed in the dialysis cell is:

$$AP_i = P_i \cdot V_{pi} \qquad \text{(Eq. A1)}$$

[10] Spectrum Medical Industries Inc., Los Angeles, Calif.

where P_i is the initial protein concentration and V_{pi} is the initial dialysate volume. After equilibration of free drug, the amount of protein (AP_e) in the plasma compartment is:

$$AP_e = P_e \cdot V_{pe} \qquad \text{(Eq. A2)}$$

where P_e is the postdialysis protein concentration and V_{pe} is the postdialysis dialysate volume. Assuming there is no loss of protein from the protein compartment:

$$AP_i = AP_e \qquad \text{(Eq. A3)}$$

and therefore:

$$P_i \cdot V_{pi} = P_e \cdot V_{pe} \qquad \text{(Eq. A4)}$$

Rearranging:

$$P_e = P_i \cdot \frac{V_{pi}}{V_{pe}} \qquad \text{(Eq. A5)}$$

In the absence of volume shifts, the concentration of bound drug (D_{Bi}) for m classes of binding sites can be predicted by:

$$D_{Bi} = \sum_{i=1}^{m} \frac{N \cdot K \cdot P_i \cdot D_F}{1 + K \cdot D_F} \qquad \text{(Eq. A6)}$$

given the number of binding sites per protein molecule (N), the association constant (K), the free drug concentration (D_F), and P_i. When volume shifts occur, the same equation applies, except for the change in protein concentration. Thus, the bound drug concentration (D_{Be}) is given by:

$$D_{Be} = \sum_{i=1}^{m} \frac{N \cdot K \cdot P_e \cdot D_F}{1 + K \cdot D_F} \qquad \text{(Eq. A7)}$$

Substituting for P_e:

$$D_{Be} = \sum_{i=1}^{m} \frac{N \cdot K\left(P_i \cdot \frac{V_{pi}}{V_{pe}}\right) D_F}{1 + K \cdot D_F} \qquad \text{(Eq. A8)}$$

If it is assumed that N and K do not vary with changes in P, then:

$$D_{Be} \cdot \frac{V_{pe}}{V_{pi}} = \sum_{i=1}^{m} \frac{N \cdot K \cdot P_i \cdot D_F}{1 + K \cdot D_F} = D_{Bi} \qquad \text{(Eq. A9)}$$

Note that the same value for the independent variable, D_F, is used with and without volume shifts. However, the measured D_F would differ from the D_F obtained had no fluid change occurred. This causes the corrected binding curve to shift up and to the right when plotting fraction bound *versus* equilibrium total drug concentration (see Fig. 7).

The fraction of drug bound at the initial protein concentration is calculated by:

$$F_{Bi} = \frac{D_{Bi}}{D_{Bi} + D_F} \qquad \text{(Eq. A10)}$$

From Eq. A9:

$$D_{Bi} = D_{Be} \cdot \frac{V_{pe}}{V_{pi}} \qquad \text{(Eq. A11)}$$

Substituting for D_{Bi}:

$$F_{Bi} = \frac{D_{Be} \cdot \frac{V_{pe}}{V_{pi}}}{D_{Be} \cdot \frac{V_{pe}}{V_{pi}} + D_F} \qquad \text{(Eq. A12)}$$

The values of D_{Te} and D_F are obtained experimentally. Since:

$$D_{Te} = D_{Be} + D_F \qquad \text{(Eq. A13)}$$

then:

$$D_{Be} = D_{Te} - D_F \qquad \text{(Eq. A14)}$$

thus:

$$F_{Bi} = \frac{(D_{Te} - D_F) \cdot \frac{V_{pe}}{V_{pi}}}{(D_{Te} - D_F) \cdot \frac{V_{pe}}{V_{pi}} + D_F} \qquad \text{(Eq. 2)}$$

as presented in the text.

Effect of Compressional Force on Tablets Containing Cellulosic Disintegrators I: Dimensionless Disintegration Values

E. B. VADAS ˣ, G. R. B. DOWN, and R. A. MILLER

Received July 22, 1982, from *Merck Frosst Canada Inc., Pharmacy Research & Development, P.O. Box 1005, Pointe Claire-Dorval, Quebec, H9R 4P8, Canada.* Accepted for publication May 11, 1983.

Abstract □ Spray-dried lactose tablets containing cellulosic disintegrators or microcrystalline cellulose were compressed at different compressional forces. USP disintegration times were measured as a function of pH and compressional force. Two dimensionless quantities were derived from the experimentally determined disintegration times, and their utility in the study of tablet formulations was demonstrated. These dimensionless quantities were used to assess the effect of compressional force and pH on distintegration behavior as well as to compare disintegrator efficiency. Two internally cross-linked sodium carboxymethylcellulose disintegrators were found to be the most efficient; their efficiency increased with increasing compressional force at all pH values.

Keyphrases □ Compressional force—effect on tablets containing cellulosic disintegrators, dimensionless disintegration values □ Disintegrators, cellulosic—effect of compressional force on tablets, dimensionless disintegration values □ Disintegration—dimensionless values, effect of compressional forces on tablets containing cellulosic disintegrators

Considerable knowledge has been accumulated in the past concerning the behavior and mechanism of action of disintegrators, particularly those belonging to the starch family (1, 2). With the introduction of several new disintegrators in recent years, interest has become focused on methods of evaluation of disintegrator function and on the elucidation of their mechanism of action (3–7). The one basic measurement generally used in evaluating disintegrators in a tablet formulation, regardless of all other aspects of the study, is the measurement of disintegration time.

It is the aim of this paper to define two dimensionless quantities which can be derived from the experimentally determined disintegration times and, furthermore, to illustrate by the use of a simple tablet formulation that their application gives access to a wealth of information concerning the performance of disintegrators under a variety of processing and testing conditions. Also, our aim is to demonstrate that information inherent, but not immediately evident, in disintegration times can be extracted by a simple and considerably underutilized technique of data analysis. Compressional force was chosen as the processing variable and pH as the testing variable to demonstrate the utility of dimensionless disintegration values. The importance of pH in the evaluation of disintegrator behavior has been demonstrated by Shangraw *et al.* (4).

EXPERIMENTAL

Materials—The tablet matrix consisted of spray-dried lactose[1] containing 0.25% magnesium stearate[2] as the lubricant. The disintegrators used were two sodium carboxymethylcellulose derivatives (croscarmellose sodium type A[3] and type B[4]) and low-substituted hydroxypropyl cellulose[5]. Microcrystalline cellulose[6] was included for comparison in an additional series of tablets. All excipients were used at a fixed concentration of 3%.

Methods—A portion of the spray-dried lactose (~90%) was mixed with the disintegrator in a laboratory-scale twin-shell blender[7] for 7 min. The remaining spray-dried lactose was mixed with the magnesium stearate, the mix passed through a 60-mesh screen, and added to the bulk material. The entire mixture was then blended for 7 min.

Tablets were compressed on an instrumented rotary tablet machine (8) tooled with 12.7-mm round flat-faced punches. The tablet weight of each formulation was 725 mg. Samples of each tablet formulation were compressed at four different compressional forces. Although the forces were not identical in each series, their values were comparable (Table I). Values for tablet hardness were determined using a Schleuniger hardness tester[8] and are reported in kiloponds (kp, 1 kilogram-force) as the average of 10 measurements.

Disintegration times were measured according to USP XX method. Besides distilled water (pH 6.0), USP simulated gastric fluid (pH 1.5) and intestinal fluid (pH 7.5) without enzymes were also used to assess the effect of pH. All measurements were carried out using 1-day-old tablets.

RESULTS AND DISCUSSION

Physical Properties and USP Disintegration Times—The compressional forces used and the resulting physical properties of the control matrix and tablets containing the disintegrators are listed in Table I. Tablet hardness showed typical compressional force-dependent behavior as expected; *i.e.*, tablet breaking strength increased with increasing compressional force within each tablet formulation. Tablets containing low-substituted hydroxypropyl cellulose or microcrystalline cellulose had breaking strengths considerably higher than the control matrix. The increase was found to be approximately the same with these two excipients.

Since spray-dried lactose is soluble in aqueous media, its behavior in the absence of disintegrators should be properly described as slow dissolution rather than disintegration. However, for sake of uniformity and for purposes of comparison, the term disintegration will be used throughout the paper to describe the behavior of the control matrix.

Disintegration times of the control tablets were found to be both compressional force and pH dependent, as indicated by the values listed in Table II. Regardless of the pH of the test fluid, disintegration times increased with increasing compressional force and at each compressional force, the shortest disintegration time was measured at pH 1.5.

Tablets containing croscarmellose sodium, type A or B, had disintegration times apparently independent of both the processing and testing variable, *i.e.*, within both series, disintegration times were approximately the same at all compressional forces and at all pH values. A somewhat similar insensitivity of disintegration times to compressional force was found by Miller *et al.* (9) when studying the behavior of acetaminophen tablets containing these disintegrators. The disintegration times of tablets containing low-substituted hydroxypropyl cellulose were relatively insensitive to pH, but varied with compressional force exhibiting a minimum at 92.9 MN/m^2 (sample 2) and then increasing with increasing compressional force. The presence of 3% microcrystalline cellulose resulted in a decrease in disintegration times for the lower compressional forces (samples 1 and 2), followed by a considerable increase at higher compressional forces (samples 3 and 4) at all pH values.

Except for the control matrix, disintegration times did not correlate with tablet hardness in any of the tablet formulations. Such a lack of correlation has been reported recently (10) for theobromine tablets containing cornstarch, microcrystalline cellulose, or crospovidone as disintegrators.

tablets of different compositions, the disintegration times were normalized to that of tablets compressed at the lowest compressional force (sample 1) in each series according to the definition given by Eq. 1A (see *APPENDIX*). Values of T_N are plotted in Fig. 1.

The use of a dimensionless quantity such as T_N allows direct comparison of trends in tablet behavior with compressional force or with any other variable affecting disintegration times, *e.g.*, concentration of disintegrator, concentration of other excipients such as materials to improve the powder flow and lubricants, and the length of time of mixing of tablet ingredients prior to compression. In such a comparison the disintegration time of the first tablet of the series (in this case the tablet compressed at the lowest compressional force) becomes unity. Values of $T_N < 1$ are indicative of a beneficial effect of the variable on disintegration, whereas values of $T_N > 1$ indicate a detrimental effect.

In addition to overall trends, small differences in disintegration properties due to the presence of different disintegrators in the tablet matrix become immediately apparent, as illustrated in Fig. 1. Admixing of croscarmellose sodium type A is shown to result in a complete insensitivity of disintegration behavior to both pH and compressional force, at least within the limits used in this study. The addition of croscarmellose sodium type B results in complete pH insensitivity and an apparent slight compressional force dependence. This behavior was found to be reproducible.

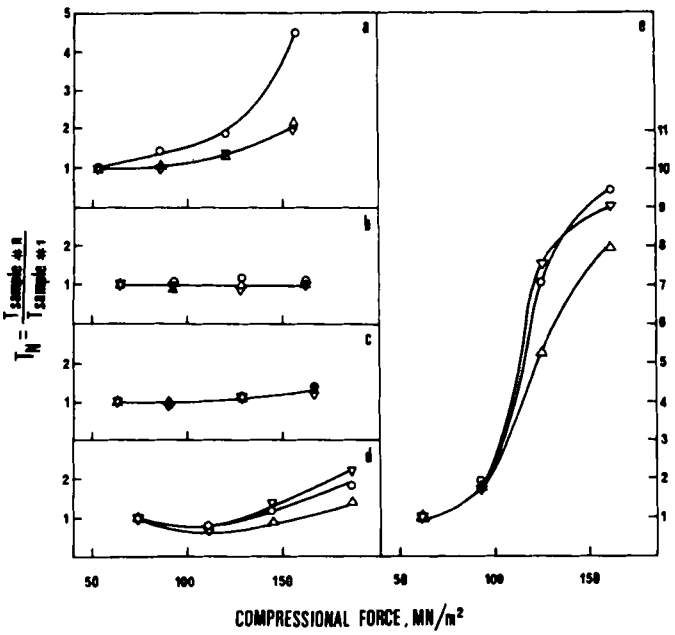

Figure 1—*Plots of the dimensionless disintegration quantity (Eq. 1A) as a function of compressional force and pH of test fluid. Values of* T_N *were calculated from the experimentally determined USP disintegration times for spray-dried lactose tablets containing (a) no disintegrant, (b) croscarmellose sodium, type A, (c) croscarmellose sodium, type B, (d) low-substituted hydroxypropyl cellulose, and (e) microcrystalline cellulose. Key: (○) pH 1.5; (△) pH 6.0; (▽) pH 7.5.*

Dimensionless Disintegration Value, T_C—A second dimensionless quantity may be derived from the experimentally determined disintegration times according to Eq. 2A (see *Appendix*). Here, the disintegration times of tablets containing a variety of disintegrators are normalized to the disintegration times of a common matrix. The quantity so obtained allows one to quantitatively assess and compare disintegrator efficiency.

Values of T_C are plotted in Fig. 2. While the previously discussed dimensionless quantity T_N allows direct comparison of the disintegration behavior of tablets of widely different disintegration times, T_C gives clear indications of disintegrator performance with respect to pH, *i.e.*, whether the tablet is effectively designed to disintegrate in a particular medium.

To illustrate this point one may compare the behavior of tablets compressed at ~90 MN/m^2 (sample 2) and containing either croscarmellose sodium (type

Table II—Disintegration Times [a] as a Function of Compressional Force and pH of Test Fluid

[a] The average of the longest disintegration times measured on two sets of six tablets is given.

A or B) or low-substituted hydroxypropyl cellulose. In simulated gastric fluid, the tablet containing croscarmellose sodium type A has a T_C value of 0.6; *i.e.*, due to the presence of the disintegrator, the disintegration time of the tablet is 60% of that of the control matrix in a highly acidic medium. The tablet containing croscarmellose sodium type B has a T_C value of 0.42, and that containing low-substituted hydroxypropyl cellulose has $T_C = 0.60$. Clearly, the most efficient disintegrator in this case is croscarmellose sodium type B, since its presence in the tablet formulation results in a larger reduction of disintegration time than the inclusion of either of the other two cellulosic disintegrators.

In simulated intestinal fluid, however, the behavior of all three tablet formulations is very nearly identical, as indicated by the values of T_C. For the tablet containing croscarmellose sodium type A, $T_C = 0.30$ (*i.e.*, a 70% reduction in disintegration time in a near neutral medium), and for those containing croscarmellose sodium type B or low-substituted hydroxypropyl cellulose, $T_C = 0.24$. Here, then, any of the three disintegrators would be similarly efficient.

In addition to allowing the formulator to assess disintegrator efficiency, the dimensionless disintegration quantity, T_C, has further utility. It was noted earlier that the absolute values of disintegration times were independent of compressional force when either croscarmellose sodium type A or B were used as the disintegrator. When describing the behavior of these tablet formulations in terms of T_C, the effect of compressional force becomes evident. In fact, values of T_C indicate that all tablet formulations used in this study exhibited compressional force as well as pH-dependent behavior from the point of view of disintegrator efficiency. In all tablet formulations the disintegrators were found to be the least efficient at pH 1.5, where the spray-dried lactose matrix disintegrated most readily, and were about equally efficient at pH 6.0 and 7.5, except low-substituted hydroxypropyl cellulose, which seemed to be most efficient at pH 7.5 in tablets processed at low compressional forces.

Examining the trends shown by tablets containing the sodium carboxymethylcellulose derivatives, the effect of compressional force on these two disintegrators is highlighted quite dramatically. The higher the compressional force applied to the tablets, the more efficient these two disintegrators become, *i.e.*, the reduction in disintegration times from that of control increases with increasing compressional force. This effect is most pronounced at pH 1.5, as illustrated by Fig. 2a and b. It is felt that this type of behavior is a strong indication of the importance of deformation due to compression in the mechanism of action of croscarmellose sodium.

Tablets containing microcrystalline cellulose show a biphasic trend, as already mentioned when discussing disintegration times (Table II). It is interesting to note here that in terms of disintegrator efficiency, microcrystalline cellulose (used at the unusually low concentration of 3%) did indeed act as a true disintegrator at the two lower compressional forces, where the reduction of disintegration time with respect to the control was found to be comparable with that obtained with the other disintegrators. The two samples made at higher compressional force, however, showed increased disintegration times at all pH values when compared with the appropriate controls. Here, the excipient caused retardation of disintegration rather than facilitating it. The extent to which microcrystalline cellulose facilitated or hindered disintegration is numerically expressed by values of T_C.

CONCLUSIONS

Two dimensionless quantities were defined and calculated from the experimentally determined USP disintegration times, and their use was demonstrated with a simple tablet formulation. Although the practice of using dimensionless quantities is not widespread in physical pharmacy, their utility may be considerable when comparisons must be made among systems of widely differing properties, such as those encountered during the development of pharmaceutical dosage forms.

APPENDIX—DEFINITION OF DIMENSIONLESS DISINTEGRATION VALUES

The first dimensionless quantity, T_N, facilitates comparison within a given tablet formulation and is defined as:

$$T_N = \frac{T_{\text{sample } n}}{T_{\text{sample 1}}} \qquad \text{(Eq. 1A)}$$

where $T_{\text{sample } n}$ is the disintegration time of the nth member of a series of tablets all containing the same disintegrator and compressed at different compressional forces, and $T_{\text{sample 1}}$ is the disintegration time of the tablet processed at the lowest compressional force within the series. Both disintegration times must be determined at the same pH.

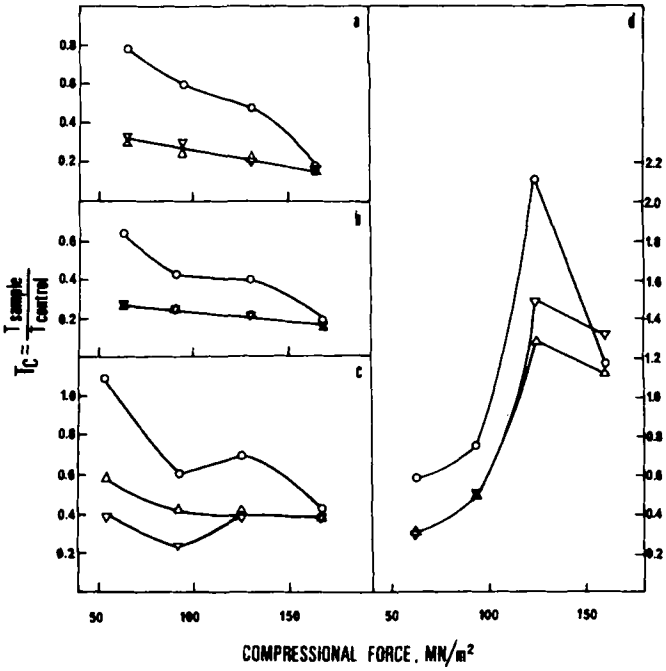

Figure 2—*Plots of the dimensionless disintegration quantity (Eq. 2A) as a function of compressional force and pH of test fluid obtained for spray-dried lactose tablets containing (a) croscarmellose sodium, type A, (b) croscarmellose sodium, type B, (c) low-substituted hydroxypropyl cellulose, and (d) microcrystalline cellulose. Key: (○) pH 1.5; (△) pH 6.0; (▽) pH 7.5.*

The second dimensionless quantity, T_C, is used to evaluate disintegrator efficiency and is given by:

$$T_C = \frac{T_{\text{sample}}}{T_{\text{control}}} \qquad \text{(Eq. 2A)}$$

where T_{sample} is the disintegration time of a tablet containing a specific disintegrator and compressed at a given compressional force, and T_{control} is the disintegration time of a tablet which contains no disintegrator and is compressed at the same compressional force. Both T_{sample} and T_{control} must be determined at the same pH.

Freeze-Drying of Oxyhemoglobin: Protection Against Oxidation in the Presence of EDTA Salts, Sulfonic Acid Buffers, and Pantothenic Acid Derivatives

A. FAUVEL *, P. LABRUDE ‡x, and C. VIGNERON *

Received February 17, 1983, from the *Laboratoire d'Hématologie et Physiologie, Faculté des Sciences, Pharmaceutiques et Biologiques, B.P. 403, 54001 NANCY Cédex and ‡Laboratoire de Chimie Hématologique, Centre Régional de Transfusion Sanguine et d'Hématologie, 54500 Vandoeuvre les Nancy, France. Accepted for publication May 4, 1983.

Abstract □ Hemoglobin was freeze-dried in the presence of salts of EDTA, sulfonic acids used as buffers, or derivatives of pantothenic acid. At 0.25 M most of the compounds effectively inhibited the formation of methemoglobin. The various model compounds used (sodium zinc EDTA, tris(hydroxymethyl)methylaminopropanesulfonic acid, and DL-pantothenol) produced similar decreases in methemoglobin formation as a function of the concentration of protective agent between 0.01 and 0.20 M. Experiments on the storage of the freeze-dried materials revealed substantial denaturation of oxyhemoglobin after 12 months at 4°C. On the whole, these compounds were less effective than amino acid salts, during both desiccation and storage. The multiplicity of compounds that inhibit the denaturation of hemoglobin during freeze-drying indicates that their mode of action is nonspecific.

Keyphrases □ Oxyhemoglobin—oxidation to methemoglobin during freeze-drying, protection by EDTA salts, sulfonic acid buffers, and pantothenic acid derivatives □ EDTA salts—protection of oxyhemoglobin during freeze-drying, prevention of methemoglobin formation □ Sulfonic acid buffers—protection of oxyhemoglobin during freeze-drying, prevention of methemoglobin formation □ Pantothenic acid derivatives—protection of oxyhemoglobin during freeze-drying, prevention of methemoglobin formation

Oxyhemoglobin has been freeze-dried under various conditions, and it has been definitely established that desiccation leads to oxidation of the heme iron and to the formation of methemoglobin (metHb) representing up to 60% of the original hemoglobin (1-3). Until now, the only way of obtaining nondenatured freeze-dried hemoglobin has been to add a sufficient concentration of a protective agent before freezing the solution. The demonstration by Smith and Pennell in 1952 (4) of a protective effect of glucose has been followed more recently by exploration of a series of chemical compounds such as amine buffers (5), carbohydrates (6), and macromolecules (7), for which dose-response relationships have been established. Better understanding of protective agents would be useful in stabilizing solutions of hemoglobin for eventual use as a blood substitute and in other biotechnologies.

We describe here experiments with representatives of three series of chemical compounds not previously studied as protective agents in freeze-drying, chosen for the following reasons: EDTA salts, because of their effects on the process of oxidation of hemoglobin (8, 9); buffer compounds, to follow up our earlier studies of Tris derivatives (5); and derivatives of pantothenic acid, because their parent molecule is structurally related to some protective compounds already known—β-alanine and quaternary carbon polyols (2, 5).

Table I—Physiological Properties of Hemoglobin after Freeze-Drying in the Presence of 250 mM of Different EDTA Salts

EDTA Salt	*n*	Oxyhemoglobin, %	Methemoglobin, %	pH	Hill coefficient
Dipotassium	3	85.3	14.0	5.31	1.96
Sodium zinc	3	91.9	6.5	7.07	2.18
Dipotassium magnesium	3	89.7	3.5	7.30	2.36
Disodium magnesium	3	92.8	2.9	7.26	2.52
Tetrasodium	3	84.4	1.5	8.56	2.88
Tripotassium	3	86.9	2.8	7.70	2.52

EXPERIMENTAL

Reagents—A solution of human hemoglobin was prepared from citrated blood samples taken 3 weeks earlier. The red blood cells were separated and washed in 0.15 M NaCl, and then hemolyzed in deionized water. The stromata were separated by centrifugation twice at 25,000×*g* for 30 min and decantation of the hemoglobin solution. This solution was dialyzed against deionized water at 4°C for 15 h, then centrifuged once again to remove the remaining stromata and adjusted to a hemoglobin concentration of 100 g/L. The EDTA salts used were: dipotassium·2 $_2O$[1], sodium zinc·4H_2O[2], dipotassium magnesium[1], disodium magnesium·H_2O[2], tetrasodium[1], and tripotassium[3]. The pantothenic acid (vitamin B_5) derivatives were: calcium D-pantothenate[4], DL-pantothenic alcohol[4], D-pantothenic alcohol[4], (−)-D-pantoyllactone[4], and sodium DL-pantoyltaurinate[4]. The buffers were 3-(*N*-morpholino)propanesulfonic acid (I)[4], *N*-(2-hydroxyethyl)-1-piperazinepropanesulfonic acid (II)[4], 2[(2-amino 2-oxoethyl)amino]ethanesulfonic acid (III)[2], *N*,*N*-bis(2-hydroxyethyl)-2-aminoethanesulfonic acid (IV)[2], *N*-tris(hydroxymethyl) methyl-2-aminoethanesulfonic acid (V)[2], and tris(hydroxymethyl)methylaminopropanesulfonic acid (VI)[2].

Procedures—In the initial series of experiments, the samples to be freeze-dried were made up of a homogeneous mixture of 5 mL of an aqueous 100-g/L solution of hemoglobin and 5 mL of an aqueous 0.5 M solution of the protective agent being studied. This made it possible to verify that these materials were indeed soluble. Next, for one agent from each of the three chemical series we looked at the dose-response relationship, plotting the percentage of methemoglobin formed *versus* the molar concentration of the protective agent, from 0.01 to 0.2 M, at a constant hemoglobin concentration as before and with a volume of 10 mL before freeze-drying. Each sample was studied in triplicate.

More detailed studies were carried out with EDTA. First, a series of excellent freeze-dried materials, obtained from 10 mL of solutions containing 100 g/L of hemoglobin and 0.25 M of each of its salts, were stored in darkness for 12 months in air at 4°C. Next, samples freeze-dried in the presence of 0.01-0.20 M sodium zinc EDTA were stored in the same conditions for 12 months. Finally, we wished to find out (as has not yet to our knowledge been systematically studied) whether the concentration of hemoglobin influenced the proportion of methemoglobin formed, at a constant concentration of protective agent chosen to give a level of oxidation that was neither zero nor too high. The experiments were carried out on 10 mL of freeze-dried material, with 0.05 M sodium zinc EDTA and 250-1000 mg of hemoglobin.

The freeze-drying was carried out in a freeze-drying apparatus[5] under the following conditions. Samples (10 mL) were frozen at −40°C in the bottom of 100-mL flasks in the apparatus, followed by desiccation with the control set at 70% (heating of shelf 70% of time) and final temperature displayed as 4°C. The vacuum was broken and the freeze-dried materials were immediately stoppered in air. The samples were macroscopically examined (for appearance and color) and dissolved in 10 mL of Sörensen's 0.066 M phosphate buffer of pH 6.4, 7.4, or 7.8, depending on the pH before freeze-drying. The other examinations carried out were:

2. Measurement of oxyhemoglobin in the aqueous solution with an oximeter[6], without correction for the concentrations of methemoglobin.

3. Determination of the pH[7] of the reconstituted hemoglobin solution.

4. Plotting of the dissociation curve[8] of the hemoglobin at 37°C and $P\,CO_2$ of 40 Torr, and calculation of the Hill coefficient.

5. Plotting of the spectrum[9] of the hemoglobin from 500 to 700 nm.

6. Calculation of the concentration-protection relationships using a programmable calculator[10] linked to a plotter.

RESULTS AND DISCUSSION

In all our previous experiments on freeze-drying carried out under similar conditions, unprotected hemoglobin contained 49 ± 8% of methemoglobin (metHb) after freeze-drying (n = 45). Its oxygen saturation was 56 ± 5% (n = 29), and its cooperativity was lost (Hill coefficient = 1.76 ± 0.07, compared with a normal value of >2.6).

Protection Due to EDTA Salts—On coming out of the freeze-drier, the samples were red and powdery; they dissolved rapidly and totally. All the EDTA salts studied here, except for dipotassium EDTA, seemed to be protective agents that inhibited the formation of methemoglobin, giving <10% methemoglobin (Table I). The tetrasodium salt was the most effective, but it led to the lowest saturation values and a pH very different from physiologic values. Least-squares best estimates were calculated for straight lines on Hill plots; the Hill coefficients obtained demonstrated that the physiological properties of the hemoglobin were well preserved, except with the dipotassium salt.

We arbitrarily chose the sodium zinc salt for the other studies. The color of the dry freeze-dried materials, ranging from brown to red, indicated decreasing proportions of methemoglobin as the concentration of protective agent increased. The samples showed no turbidity when reconstituted with a pH 7.4 buffer, but the more altered the hemoglobin, the slower they were to dissolve. The relationship between the percentage of methemoglobin (y-axis) and the percentage of oxyhemoglobin (x-axis) fitted the equation $y = -x + 97.1$ (n = 33, $r = -0.97$, $p < 0.001$). There was a linear relationship between the logarithm of the proportion of methemoglobin and the molar concentration of protective agent: $y = -4.12x + 1.51$ (n = 33, $r = -0.903$, $p < 0.001$) (Fig. 1). After 12 months, the freeze-dried materials obtained with the EDTA salts showed methemoglobin levels between 8.8% (with the tetrasodium salt) and 64.7% (with the dipotassium salt). The order of effectiveness of the various salts was the same as at time zero. The saturations were low (56–70%), especially in the presence of tetrasodium EDTA, although the spectrum of the hemoglobin of this sample was altered very little.

The samples containing various concentrations of sodium zinc EDTA displayed proportions of methemoglobin between 50.9 and 26.8%, yielding the correlation line $y = -185.6x + 58.9$ (n = 10, $r = -0.918$, $p < 0.001$); this line cuts the x-axis at 0.32 M, which is the hypothetical concentration of EDTA in a hemoglobin solution that will prevent any oxidation to methemoglobin during both desiccation and storage. This concentration is much higher than those we found with other protective agents under similar conditions (11), which indicates that EDTA salts are much less effective. The proportion of methemoglobin varied greatly with the concentration of hemoglobin, as seen in Fig. 2 ($y = 0.026x + 2.89$; n = 14, $r = 0.98$, $p < 0.001$). This relationship between hemoglobin and protective agent is in accordance with the previous relationship (Fig. 1): both show that hemoglobin was correctly protected only in certain narrowly defined conditions of concentration. This sensitivity of hemoglobin to small changes in concentration was found also for the other classic protective agents (such as glucose or sucrose) for which we have established equations of the same type[11].

Table II—Physiological Properties of Hemoglobin after Freeze-Drying in the Presence of 250 mM of Buffer Compounds

Buffer	n	Oxyhemoglobin, %	Methemoglobin, %	pH	Hill coefficient
I	3	93.6	2.2	6.15	2.90
II	3	99.0	1.9	6.65	2.40
III	3	65.5	47.1	6.35	—
IV	3	94.6	4.6	6.23	2.01
V	3	96.0	2.2	6.33	2.07
VI	3	97.6	3.5	7.13	3.00

Protection Due to Buffer Compounds—Buffer III is poorly soluble in aqueous media and had no protective effect, whereas the five other buffers gave satisfactory protection (Table II). The structure of these compounds (sulfonic acids) and their concentrations produced acid solutions despite their being dissolved in an alkaline buffer solution. At these pH values, the Barcroft curve was displaced towards low affinities and the $p50$ values were high (21–45 Torr).

The dose-response relationship was studied with VI. At concentrations of ≥0.075 M it gave satisfactory levels of methemoglobin, *i.e.* <10%. The relationship between the logarithm of the percentage of methemoglobin and the concentration of VI took the form $y = -5.76x + 1.52$ (n = 33, $r = -0.867$, $p < 0.001$) (Fig. 3). Here too, the correlation between methemoglobin and oxyhemoglobin was very significant: $y = -0.75x + 75.62$ (n = 33, $r = -0.975$, $p < 0.001$). Two samples of hemoglobin freeze-dried in the presence of VI or V were stored for 12 months at 4°C; the levels of oxyhemoglobin and methemoglobin were then found to be 76% and 22%, respectively, and their respective Hill coefficients were 2.13 and 1.66. As with the EDTA salts, these protective agents seemed to be greatly inferior to the amino acid salts and sucrose studied previously (11).

Protection Due to Derivatives of Pantothenic Acid—These derivatives were quite difficult to study, because D-pantothenol is very viscous and dissolves poorly in water, while (−)-D-pantoyllactone yielded a poorly soluble freeze-dried material, whose solution was slightly turbid, brown, and in need of centrifugation. Calcium pantothenate yielded even greater turbidity, which prevented any precise estimation of methemoglobin in the centrifugation supernatant. Nevertheless these compounds were effective protective agents, as seen in Table III. The correlations established above were again found for log (methemoglobin percentage) *versus* molarity of the protective agent

DL-pantothenol [$y = -7.19x + 1.64$ (Fig. 4) ($n = 33, r = -0.95, p < 0.001$)] and for methemoglobin *versus* oxyhemoglobin [$y = -0.86x + 84.6$ ($n = 33$, $r = -0.98, p < 0.001$)].

CONCLUSIONS

This study has demonstrated the protective effect during the freeze-drying of hemoglobin of representatives of three different chemical series, adding to those already known (5–7). With EDTA salts, where only the cation and the pH differed, the proportion of oxyhemoglobin was generally low, and pH seemed to be involved, since the extreme pH values gave both the best and the worst results. With one exception, the sulfonic acids used as biological buffers were effective protective agents. The same was true for the pantothenate family that we have investigated, since they derive from both β-alanine and a quaternary carbon alcohol. This remark suggests that there may be possible structure-activity relationships in this series.

On the other hand, three reasons lead us instead to conclude that a nonspecific antioxidant action is present: (*a*) the multiplicity and the variety of chemical families in which protective agents for hemoglobin have already been found—carbohydrates, amine buffers, macromolecules, amino acids, *etc.*, (*b*) the observation by ESR that glucose, β-alanine, or Tris, taken as models, do not interact with heme iron and its environment (12), and (*c*) the result with the same models using circular dichroism (CD) that the absence of protector only weakly influences the conformation in the vicinity of the heme and alters the secondary structure by slightly increasing the helicity. The CD spectra also suggest that the protector may not enter into the heme pocket, since one would then observe much greater spectral changes in the visible region and the Soret band (13).

Table III—Physiological Properties of Hemoglobin after Freeze-Drying in the Presence of 250 mM of Pantothenic Acid Derivatives[a]

Derivative	*n*	Oxyhemoglobin, %	Methemoglobin, %	pH	Hill's Number
D-Pantothenic acid, hemicalcium salt	3	97.4	—	5.61	—
DL-Panthenol	3	99.3	2.3	7.29	2.51
D-panthenol	3	98.3	3.4	7.35	2.49
(−)-D-Pantoyllactone	3	75.3	23.3	7.28	2.11
DL-Pantoyltaurine sodium salt	3	100.0	2.0	8.28	2.53

[a] Derivatives were dissolved in buffer, pH 6.38.

Taking in account the preceding remarks, it appears that the oxidation of ferrous iron remains the main denaturer of hemoglobin and that the estimation of methemoglobin is the first and one of the best tests to evaluate the effects of freeze-drying on hemoglobin. The mechanism of action of the protectors is still poorly understood, but our current experiments link this action with concomitant effects of vacuum and removal of water. It is not impossible that

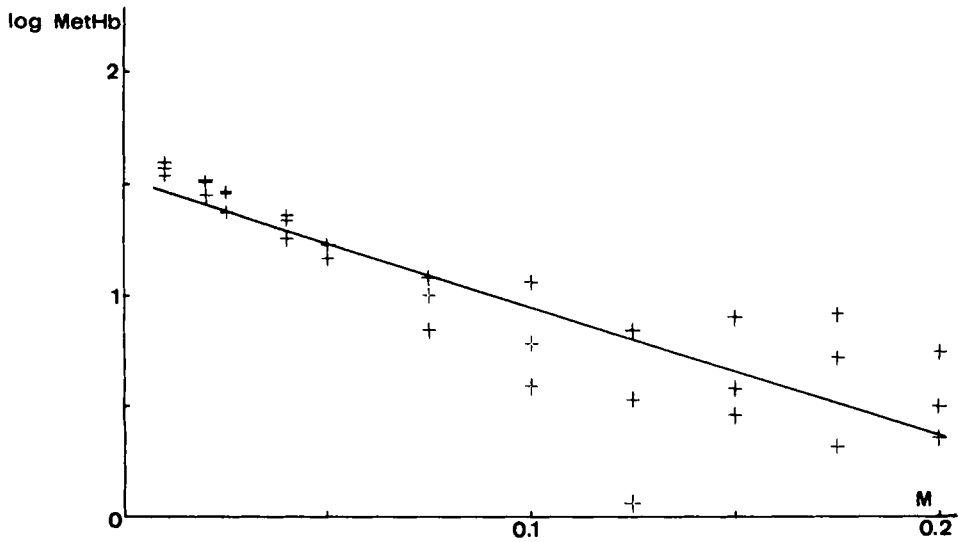

Figure 3—*Linear regression between the log of methemoglobin (%) and molar concentration (0.01 to 0.20 M) of VI.*

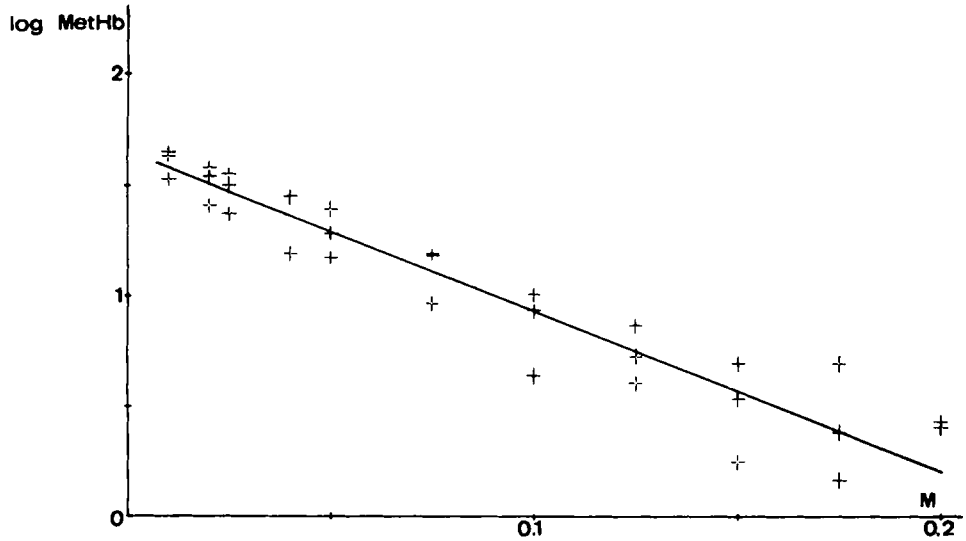

Figure 4—*Linear regression between the log of methemoglobin (%) and molar concentration (0.01 to 0.20 M) of* DL-*panthenol.*

such protectors "modify" the structure of globin as has been described for some proteins and glycerol by Gekko and Timasheff (14).

The changes in the proportion of methemoglobin as a function of concentration of the protective agent always fitted a hyperbola that could be linearized by a logarithmic transformation, giving a straight line with a negative slope. The three correlation lines thus obtained had slopes of the same order of magnitude, which indicates that these three model compounds are fairly similar in effectiveness. However, they are much less effective, during both freeze-drying and storage, than the amino acid salts that we have studied previously. This difference in behavior, which undoubtedly derives from quite specific physicochemical properties of the protective agents, remains unexplained.

Disposition Kinetics of Ethambutol in Nephrectomized Dogs

CHING-SAN C. LEE ˣ **and ABRAHAM VARUGHESE**

Received March 14, 1983, from the *Department of Pharmaceutics, College of Pharmacy, University of Houston, Houston, TX 77030.* Accepted for publication May 9, 1983.

Abstract □ The effect of nephrectomy on the disposition of ethambutol was investigated in seven adult mongrel dogs: five were nephrectomized and two served as the control. Each dog was intravenously administerd 500 mg ethambutol, followed by blood sample collection for 12 h. Total urine was collected over 24 h from the normal control dogs. Ethambutol contents in plasma and urine were assayed by a GC method. The nephrectomized group and the control group exhibited differences in the following pharmacokinetic parameters: half-life, 5.0 *versus* 4.1 h (significant at $p < 0.1$); total body clearance, 8.4 *versus* 13.2 mL/min/kg (significant at $p < 0.1$); and volume of distribution, 2.7 *versus* 3.8 L/kg (significant at $p < 0.1$). Comparison of pharamacokinetic parameters among rabbits, dogs, and humans revealed distinct interspecies differences with regard to total body clearance, renal clearance, volume of distribution, and fractional renal excretion. One comparable parameter shared by all species is the β-phase half-life.

Keyphrases □ Ethambutol—disposition, pharmacokinetics in the dog, effect of nephrectomy, interspecies comparison □ Pharmacokinetics—ethambutol disposition in the dog, effect of nephrectomy, interspecies comparison □ Distribution—ethambutol in the dog, effect of nephrectomy, pharmacokinetics, interspecies comparison

Ethambutol (I), an antitubercular agent, is used alone or in combination with other drugs for the treatment of tuberculosis. The absorption and excretion of I has been studied in rats and mice (1), dogs (2, 3), and human subjects (4–6). In mice receiving single oral doses of I, peak serum concentrations were reached within 1 h of administration, and the compound

[a] Ethambutol was administered to each dog at a dose of 500 mg iv.

was rapidly excreted (1). The medium lethal dose of I varied considerably for the different routes of drug administration to mice (1), suggesting a first-pass metabolism of the drug when administered nonparenterally. The first-pass effect was demonstrated for I using a rabbit model in which a low bioavailability of 28% was observed[1], in comparison with the nearly 80% oral bioavailability in humans (5).

After a single oral 100-mg/kg dose of I to dogs, absorption was rapid and the drug was cleared from the blood with a half-life of 1.5 h (2). Within 8 h of an intravenous injection of [^{14}C]I, 57% of the radioactivity appeared in the urine as the unchanged drug, determined after separation of metabolites by counter-current distribution (3). Arnaud *et al.* (7) reported a substantial urinary excretion of the unchanged I in two dogs, up to 50% of the dose within 2 h of a rapid intravenous injection. Limited studies of I in dogs make it difficult to relate the pharmacokinetic similarities between dogs and humans, especially with respect to renal excretion. This study was intended to investigate the effect of nephrectomy on the disposition of I in dogs and to compare the pharmacokinetics of I in rabbits, dogs, and humans.

$$HOCH_2CH(R)NH(CH_2)_2NHCH(R)CH_2OH$$

I R = C_2H_5
II R = CH_3

EXPERIMENTAL

Materials—Ethambutol[2] and the methyl analogue of ethambutol (II)[2] were supplied as the dihydrochloride salts. Trifluoroacetic anhydride[3] and pyridine[3] were used as derivatizing agents. Chromatographic-grade chloroform[4] and benzene[4] were used as supplied.

Animal Experiments—Seven adult mongrel dogs weighing 13.6–24.5 kg were used in the study. Five dogs were bilaterally nephrectomized, while two normal dogs served as the control. Dogs were surgically prepared after being anesthetized with 50 mg/kg of pentobarbital. The jugular and anticubital veins were cannulated for blood drawing and drug infusion, respectively. Normal dogs were allowed sufficient time to recover from anesthesia before drug administration. In the nephrectomized group, the drug study was not initiated until 2 d after the nephrectomization. During the waiting period, dogs were allowed limited access to food and water. Sham operations were not performed on the normal control dogs; otherwise, both groups of dogs were similarly treated prior to and during the experiment. Each dog was intravenously administered 500 mg of I *via* the anticubital vein of the forelimb over a 3-min period. Blood samples were collected at various times for 12 h. In the control dog study, total urine was collected by natural voiding over a 24-h period and aliquots were pooled. Plasma and urine samples were frozen at −20°C until analysis.

Analytical Procedure—Plasma and urine samples, to which a specific quantity of II (the internal standard) was added, were extracted with chloroform, derivatized with trifluoroacetic anhydride, and subjected to a GC analysis (8). A gas chromatograph[5] equipped with a ^{63}Ni electron-capture detector, a 61-cm × 32-mm i.d. glass column, and a 5% liquid[6] on solid support[6] stationary phase was used. The carrier gas was nitrogen at 20 mL/min; temperatures for the oven, injector, and detector were 155°C, 210°C, and 240°C, respectively.

Pharmacokinetic Analysis—Plasma data were fitted to a two-compartment open body model using the NONLIN program (9). The β-phase half-life ($t_{1/2,\beta}$) and the total body clearance (CL_t) were determined as:

$$t_{1/2,\beta} = \ln 2/\beta \quad \text{(Eq. 1)}$$

$$CL_t = D_0/AUC_\infty \quad \text{(Eq. 2)}$$

where β is the slope of the log-linear phase of the plasma decay curve, D_0 is the dose, and AUC_∞ is the area under the plasma concentration (C_p) *versus* time curve, calculated by the trapezoidal rule in conjunction with an area extrapolation method. The steady-state volume of distribution (Vd_{ss}) was determined using the model-independent expression of Benet and Galeazzi (10):

$$Vd_{ss} = D_0 \cdot (AUMC_\infty)/(AUC_\infty)^2 \quad \text{(Eq. 3)}$$

where AUMC is the area under the first moment of the plasma curve.

The fraction of renal excretion (f_e) in normal dogs was calculated as

$$f_e = (A_{e,24} + CL_r \int_t^\infty C_p dt)/D_0 \quad \text{(Eq. 4)}$$

where $A_{e,24}$ is the amount of I excreted in the 24-h urine sample and CL_r is the renal clearance determined by A_e/AUC using parameter values of up to 12 h. The integration term actually represents the extrapolated urinary recovery of the drug from the last plasma sampling point to infinite time. In this study, the last plasma datum at 24 h was extrapolated since the assay sensitivity could not allow accurate detection of plasma concentration <0.25 μg/mL.

Difference in mean pharmacokinetic parameters of the control and nephrectomized dogs was tested for significance by nonpaired Student's t statistics.

RESULTS AND DISCUSSION

Table I records the mean plasma data obtained for the five nephrectomized and two normal dogs. The normal group appeared to maintain higher plasma levels of I during the first hour of intravenous drug injection, whereas the nephrectomized group retained substantially greater plasma concentrations after 1.5 h. At the end of the blood sampling period of 12 h, the mean plasma concentrations observed were 1.21 μg/mL for the nephrectomized group and 0.33 μg/mL for the control group. Figure 1 depicts the time profiles for mean plasma levels in the normal and nephrectomized dogs. A distinct distribution phase was noted in the normal control dogs, and the distribution equilibrium was not reached until 2.5 h after the drug injection. In the nephrectomized

Mean	22.2	4.12	13.2	3.8
SD	3.3	0.85	4.6	0.9

group, the distribution phase was apparent, but less extensive. The rapid and extensive distribution phenomena of I have also been noted in rabbits[1] and in human subjects (5).

Since a distinct distribution phase was noted after drug injection, plasma concentrations of I were subjected to computer analysis using a two-compartment open body model. Table II lists the pharmacokinetic parameters, and Table III compares the mean parameter values. Half-lives in the nephrectomized group varied from 4.29 to 5.93 h and those of the normal dogs were 3.52 and 4.72 h. The difference in the mean half-life of the two groups represented a 20.9% prolongation of half-life, presumably caused by nephrectomization, and was statistically significant ($p < 0.1$). Mean total body clearances of the nephrectomized (8.4 ± 3.4 mL/min/kg) and the normal dogs (13.2 ± 4.6 mL/min/kg) showed a significant difference of 36.33% ($p < 0.1$). In the limited number of dogs studied, nephrectomy induced a general trend for the increased half-life and reduced total body clearance of I, reflecting the renal excretory feature of the drug. The effect of nephrectomy on the elimination of I has not been reported in dogs, perhaps because such an effect is generally regarded as obvious. In humans, chronic renal failure caused a reduction of total body clearance from 500 mL/min to <10 mL/min (4). A prolongation of the half-life of I to ~10 h was also reported in renal failure (11).

Nephrectomized dogs were found to have a smaller volume of distribution (mean, 2.7 L/kg) than normal dogs (mean, 3.8 L/kg); the difference was statistically significant ($p < 0.1$). Nephrectomy would presumably cause a decreased volume of distribution due, in part, to the organ removal and the ligation of the vascular system. Chronic renal failure has been reported to alter the apparent volume of distribution for a number of drugs, notably digoxin (12) and phenytoin (13). It should be noted, however, that the nephrectomized dogs used in this study could only be deemed as approaching the chronic uremic state, since the drug investigation was initiated 2 d after the surgical preparation. Had the study been carried out at the steady state of chronic uremia, the change of pharmacokinetic parameters would have been more pronounced. Nevertheless, one can generally conclude that nephrectomy increased the half-life, decreased the total body clearance, and decreased the volume of distribution of I in dogs.

In a recent study of the effect of aluminum hydroxide on the absorption of I in rabbits[1], a substantially lower bioavailability of 28% was observed in comparison with the 80% bioavailability in humans, suggesting a first-pass metabolism of I in rabbits. With respect to renal excretion, rabbits excreted <5% of the intravenous dose as the unchanged compound in 24 h; the equivalent values were 30% for normal dogs and 70% in healthy human volunteers (Table IV). The observations of renal excretion of I in rabbits and dogs are contradictory to the general belief that I is predominantly excreted unchanged in all animal species. Arnaud *et al.* (7) reported a substantial urinary excretion of up to 50% for I; however, the urine assay was performed by a relatively

Table III—Comparison of Mean Pharmacokinetic Parameter Values for Half-Life, Total Body Clearance, and Volume of Distribution Between the Nephrectomized and Normal Dogs

Dog	$t_{1/2,\beta}$, h	CL_t, mL/min/kg	Vd_{ss}, L/kg
Nephrectomized	4.98	8.4	2.7
Normal	4.12	13.2	3.8
Percent change[a]	20.9	36.3	28.9
t value	1.54	1.51	1.81

[a] All differences are significant at $p < 0.1$.

Table IV—Comparison of Half-life, Total Body Clearance, Renal Clearance, Volume of Distribution, and Fractional Renal Excretion among Rabbits, Dogs, and Humans

Parameter	Rabbit[a]	Dog[b]	Human
$t_{1/2,\beta}$ (h)	3.87	4.12	4.21[c]
CL_t (mL/min/kg)	43.7	13.2	8.6[c]
CL_r (mL/min/kg)[d]	2.2	4.0	6.0
Vd_{ss} (L/kg)	8.5	3.8	3.9[c]
f_e (%)	5	30	70[c,e]

[a] C. S. Lee *et al.*, unpublished results. [b] Present study with normal dogs. [c] From Ref. 5. [d] Calculated as f_e-CL_t based on the f_e values listed. [e] From Ref. 3.

nonspecific and less sensitive colorimetric method (14). With regard to volume of distribution, rabbits exhibited the highest value (13.6 L/kg), followed by dogs (4.6 L/kg), and humans had the smallest distribution volume (2.3 L/kg) of the three species. In all cases, the volume of distribution exceeded total body weight, suggesting a localized distribution of I in the dogs. Pujet and Pujet (15) have noted a preferential distribution of I in the deep layers of the lung. In addition, I has been demonstrated, both *in vivo* and *in vitro*, to have a preference for partition into red blood cells (3, 16).

Total body clearance followed the same rank order as that of distribution volume: 43.7 mL/min/kg in rabbits, 13.2 mL/min/kg in dogs, and 8.6 mL/min/kg in humans, respectively. Since all clearance values listed in Table IV were calculated independent of a pharmacokinetic model ($CL = D_0/AUC$), compartmentalization would not have contributed to the difference in clearances observed among the three species. Assuming a renal excretion of 5% in rabbits, 30% in dogs, and 70% in humans, the respective renal clearances can be calculated as $CL_r = f_e \cdot CL_t$ and values of 2.2, 4.0, and 6.0 mL/min/kg would be obtained. In all cases, the renal clearance would exceed the glomerular filtration rate normalized to the body weight, indicating a net renal tubule secretion of the drug in all species. The active secretory mechanism of I has been demonstrated in humans, whose renal clearance was ~400 mL/min (4, 16). Since half-life is a function of both clearance and volume of distribution ($t_{1/2} = 0.693V/CL$), the three species actually shared similar half-lives—3.87 h in rabbits, 4.12 h in dogs, and 4.21 h in humans. However, there were distinct differences in other pharmacokinetic parameters, including total body clearance, renal clearance, volume of distribution, and fractional renal excretion.

Solubility Parameter and Hydrophilic–Lipophilic Balance of Nonionic Surfactants

HANS SCHOTT

Received January 24, 1983, from the *School of Pharmacy, Temple University, Philadelphia, PA 19140.* Accepted for publication May 4, 1983.

Abstract □ The solubility parameters of various polyoxyethylated nonionic surfactants were compared with their hydrophilic–lipophilic balance (HLB) numbers. The compounds included three homologous surfactant series based on dodecanol, octylphenol, and fatty acid esters of sorbitan, respectively, a polyoxyethylated sorbitol ester, and a polyethylene glycol. Solubility parameters were calculated from measured heats of vaporization for the polyoxyethylated dodecanol series and from molar attraction constants for all three surfactant series. The values remained nearly constant and independent of the degree of polyoxyethylation, increasing at most by 1 $(cal/cm^3)^{1/2}$ while the HLB increased from 0 to 10. This discrepancy arose because HLB values are based on emulsification experiments, in which the polyoxyethylene or polyol moiety of the surfactants is hydrated, while the solubility parameter was calculated for anhydrous conditions. When the solubility parameter was corrected for hydration by including a hydrogen-bonding component, plots of HLB *versus* this new solubility parameter were nearly linear and parallel for the three series of surfactants, with slopes of 5.0 ± 0.2. The three lines were spaced apart only ~1.2 $(cal/cm^3)^{1/2}$ despite structural differences among the surfactants, indicating that the chemical nature of the hydrocarbon moiety exerts only a limited effect on the solubility parameter. The HLB, which considers only the weight percent of the hydrocarbon moieties of nonionic surfactants and completely disregards differences in structural features, is, therefore, not as bad an approximation as had previously been thought.

Keyphrases □ Solubility parameter—polyoxyethylated nonionic surfactants, comparison with hydrophilic-lipophilic balance □ Hydrophilic-lipophilic balance—polyoxyethylated nonionic surfactants, comparison with solubility parameter □ Surfactants, nonionic—polyoxyethylated, solubility parameters compared with hydrophilic-lipophilic balance values

The hydrophilic–lipophilic balance (HLB) system was developed by Griffin to characterize the emulsifying efficiency of nonionic surfactants (1). Because the experimental determination of HLB values through emulsification experiments is laborious and not very accurate, the following equation was developed (2, 3):

$$HLB = \frac{E + P}{5} \qquad \text{(Eq. 1)}$$

where E is the percent (w/w) of polyoxyethylene and P the percent (w/w) of polyhydric alcohols in the surfactant molecule.

A criticism leveled against the HLB concept, as embodied in Eq. 1, was that it disregards the effect of the chemical nature of the hydrocarbon moiety of the surfactants (4). The purpose of this work is to investigate the application of the solubility parameter concept (5–7) to nonionic surfactants, because it takes into consideration the nature of their hydrophilic as well as their hydrophobic moieties. Even though the solubility parameter is the subject of much current pharmaceutically oriented research (8, 9), it has been investigated only briefly in connection with nonionic surfactants (10, 11).

[a] Average number of oxyethylene units per molecule. [b] Calculated by Eq. 1. [c] Calculated by Eq. 2 from experimental ΔH values (12). [d] Calculated by Eq. 2 from ΔH values extrapolated with Eq. 3. [e] Calculated from molar attraction constants in Table II and Eq. 7. [f] Calculated by Eq. 8.

BACKGROUND

The solubility parameter, δ, is the square root of the cohesive energy density, *i.e.*, the molar internal energy of vaporization ΔE per unit volume:

$$\delta = \sqrt{\frac{\Delta E}{V_l}} = \sqrt{\frac{(\Delta H - RT)d}{M_r}} \qquad \text{(Eq. 2)}$$

where $V_l = M_r/d$ is the molar volume in the liquid state, d is the density, and M_r is the molecular weight. The molar heat of vaporization ΔH refers to constant pressure P. Therefore, it exceeds the molar energy of vaporization, which refers to constant volume, by the expansion term during vaporization $P(V_g - V_l) \cong PV_g = RT$; V_g is the molar volume in the gaseous state, R is the gas constant, and T is the absolute temperature (5–7).

RESULTS

Solubility Parameters from Heats of Vaporization—Vapor pressure measurements from which heats of vaporization can be calculated require such high temperatures that all but homologues with the lowest degrees of oxyethylation undergo decomposition. For polyoxyethylated dodecanol surfactants, $C_{12}H_{25}O(CH_2CH_2O)_pH$, heats of vaporization were measured for p values up to 4 (12). A plot of the ΔH values for surfactants with $p = 2$, 3, and 4 fall on a straight line represented by the equation:

$$\Delta H = 8.4 + 5.65p \qquad \text{(Eq. 3)}$$

where the units of ΔH are kcal/mol.

The densities, d, of polyoxyethylated dodecanols at 25°C are related to the logarithm of the average number, p, of oxyethylene units per molecule by the equation:

$$\log p = -6.64 + 7.63d \qquad \text{(Eq. 4)}$$

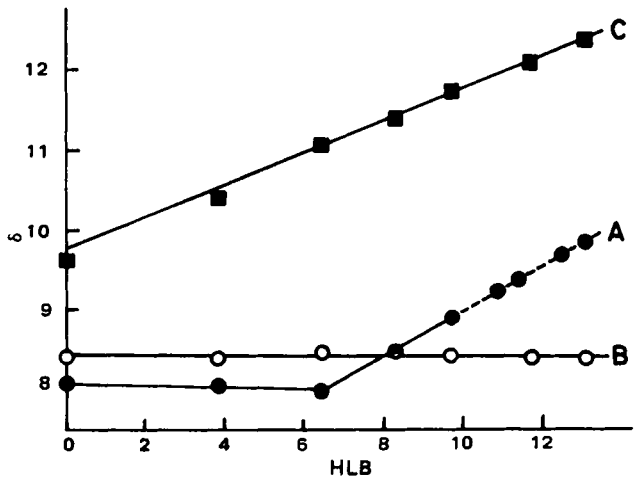

Figure 1—*Solubility parameters of polyoxyethylated dodecanols obtained by three methods* versus *HLB. For polyoxyethylated *p-tert*-octylphenols, the following linear relation holds for p values <20:

$$\log p = -12.53 + 12.72d \qquad \text{(Eq. 5)}$$

Applying Eq. 2 to the measured heats of vaporization (12) of dodecanol-based surfactants with p values of 0–4 and to the heats of vaporization extrapolated by Eq. 3 for surfactants with p values of 6 and 8 results in the δ values in the third and fourth columns of Table I, respectively, and curve A of Fig. 1. The curve consists of two segments. The first is nearly horizontal. The second, for HLB values >5 ($p \geq 2$), is linear and represented by the equation:

$$\delta = 6.16 + 0.283 \cdot \text{HLB} \qquad \text{(Eq. 6)}$$

The slopes of both segments are unrealistically small. For the second segment, a change of 1 HLB unit produces a change of only 0.3 $(\text{cal/cm}^3)^{1/2}$. The two parameters actually span similar ranges of values: the HLB scale extends from 0 to 20 (Eq. 1) and the δ scale from 5 to 23 (13).

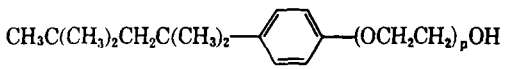
The HLB values of the surfactants in Table I range from 0 to 15, *i.e.*, from surfactants primarily soluble in liquids of low polarity such as vegetable or mineral oils ($\delta \cong 8$) to surfactants primarily soluble in polar liquids like ethyl alcohol ($\delta = 12.8$), propylene glycol ($\delta = 15.0$), and water ($\delta = 23.6$) (1–3). Compounds are most soluble in solvents whose δ values match their own most closely. Since the δ values of the best solvents for the surfactants in Table I cover the range from 8 to at least 15, the δ values of the surfactants should cover a similar range, rather than the more limited range of 8–10 obtained from heats of vaporization. The 8–10 range would indicate highest solubility in liquids of intermediate polarity, such as esters, amines, and ketones (13), for all surfactants. One possible explanation for this discrepancy is that the linear extrapolation by Eq. 3 is unwarranted.

Solubility Parameters from Molar Attraction Constants—Small (14) treated the solubility parameter as an additive-constitutive property. He noted that the so-called molar attraction constants, $F = (\Delta e \cdot v_1)^{1/2}$, were additive; Δe and v_1 are the contributions of the organic functional groups to the molar energy of vaporization and to the molar volume in the liquid state at 25°C, respectively. Therefore, the solubility parameter of a compound can be calculated from the F values of its functional groups according to the following equation (14):

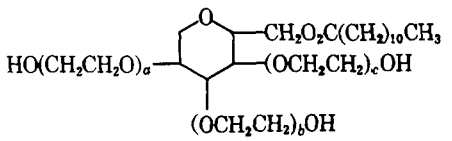
$$\delta = \frac{d\Sigma F}{M_r} \qquad \text{(Eq. 7)}$$

The F values used here, selected from the various published sets (14, 15), are listed in Table II.

The structures for the three classes of surfactants investigated are $CH_3(CH_2)_{11}(OCH_2CH_2)_pOH$, and I and II (shown below). In addition to the lauric acid ester of sorbitan shown (II), the stearic and oleic acid esters are also included. The total number of ethylene oxide molecules added during oxyethylation of the sorbitan monoesters are $a + b + c = p$. As long as the value of p remains constant, the value of ΣF is not changed if a polyoxyethylene chain is inserted by transesterification between the ester group of the fatty acid and the hexitan ring during the oxyethylation reaction (16). Sorbitan is a mixture of 5- and 6-membered rings. These two ring structures make the same contribution to ΣF.



I



II

For dodecanol derivatives, the δ values are represented by curve B in Fig. 1 and the fifth column of Table I. For octylphenol and polyol derivatives, the results are listed in the third columns of Tables III and IV, respectively.

The δ values of the dodecanol derivatives based on heats of vaporization are in good agreement with those calculated from molar attraction constants for derivatives with HLB ≤ 10 ($p \leq 4$) (compare the solid portion of curve A with curve B in Fig. 1). As the number, p, of oxyethylene units increases, the calculated δ values remain constant for the dodecanol derivatives: curve B of Fig. 1 is horizontal. The δ values actually decrease slightly for the octylphenol and sorbitan derivatives. Similar observations have been published (10, 11).

Table II—Molar Attraction Constants F for Functional Groups of Nonionic Surfactants

Group	F, $(\text{cal/cm}^3)^{1/2}$/mol
$-CH_3$	179
$-CH_2-$	133
$CH\lessgtr$	67
$>C<$	0
$-CH=CH-$	231
$-C_6H_4-$ (o-, m-, or p-phenylene)	658
Saturated 5- or 6-membered ring	105
—OH aliphatic hydroxyl	240
—C(=O)O— ester	303
—O— ether	70

An empirical parameter, the product of the contribution of the hydrocarbon moiety to ΣF times the weight fraction of that moiety, was developed as a consequence. It was inversely proportional to the HLB (11) and offers, therefore, no advantage over that parameter.

The reason that the solubility parameters obtained from these two approaches are nearly independent of the percentage of oxyethylene in the surfactant molecule or its HLB is that they were computed for anhydrous systems. In the absence of water, the molar attraction constant for the ether oxygen is only 70, *i.e.*, not much larger than that of a hydrogen atom. Consequently, the polyoxyethylene moiety increases the polarity of the nonionic surfactant molecule little or not at all above that of its hydrophobic moiety. It is only in the presence of water, where the ether groups are extensively hydrated, that the polyoxyethylene moiety becomes polar and raises the effective δ of the surfactant.

Emulsification experiments measure the HLB values of hydrated surfactants. Even surfactants dissolved in oil have their polyoxyethylene or polyol moieties immersed in water when they are concentrated at the oil–water interface during emulsification. Hydrogen bonding between water and the ether oxygens and/or hydroxyl groups of nonionic surfactants is responsible for their water solubility or, in the case of oil-soluble surfactants, for their surface activity. The two treatments underestimate the solubility parameters because they do not take into account these intermolecular hydrogen bonds.

Solubility Parameters Corrected for Hydrogen Bonding—Intermolecular forces affecting the cohesive energy density of surfactants in the presence of water include not only the dispersion forces (subscript D), which constitute the major components of the F values of Table II, but also the dipole–dipole forces (subscript P) and the hydrogen-bonding forces (subscript H). The overall solubility parameter δ_O is calculated from these three components according to (7, 15, 17, 18):

$$\delta_O = \sqrt{\delta_D^2 + \delta_P^2 + \delta_H^2} \qquad \text{(Eq. 8)}$$

The contribution of the polar forces, δ_P, can be neglected because it is small in relation to the hydrogen-bonding forces (18, 19). Furthermore, the p oxygen–carbon dipoles in a randomly coiled polyoxyethylene moiety weaken each other to the point of annihilation (15).

On the assumptions that each hydrogen bond contributes 5000 cal/mol to the energy of vaporization and that each of the p ether groups and each hydroxyl group forms one hydrogen bond with water, the hydrogen-bonding component of the solubility parameter is calculated (20) as:

$$\delta_H = \sqrt{\frac{5000(p+1)d}{M_r}} \qquad \text{(Eq. 9)}$$

Table III—Values of Hydrophilic–Lipophilic Balance and Solubility Parameters for Polyoxyethylated Octylphenols

p[a]	HLB[b]	δ[c]	δ_O[d]
0	0	8.85	10.06

3	7.81	8.87	11.80
4	9.21	8.83	12.06
6	11.23	8.77	12.44
8	12.61	8.73	12.70
10	13.62	8.70	12.89
13	14.70	8.67	13.10

[a] Average number of oxyethylene units per molecule. [b] Calculated by Eq. 1. [c] Calculated from molar attraction constants in Table II and Eq. 7. [d] Calculated by Eq. 8.

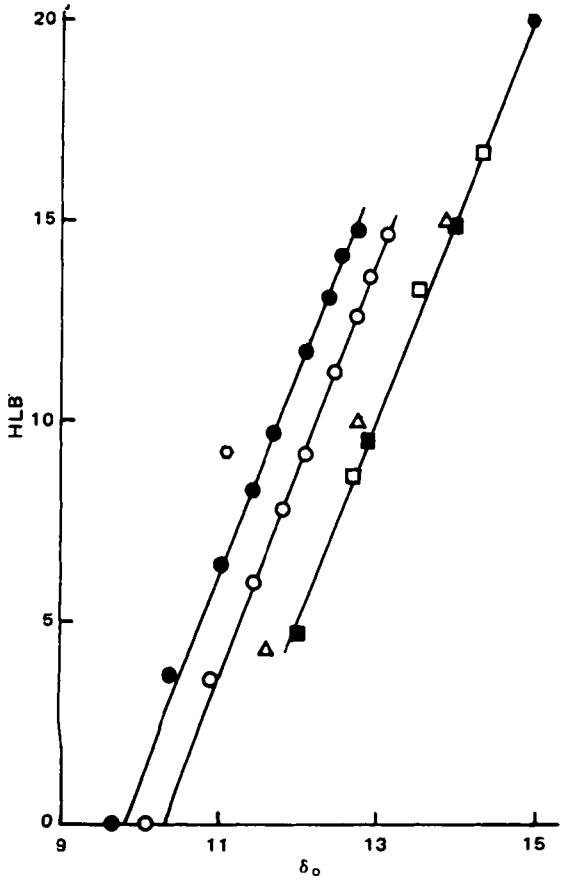

Figure 2—*Relationship between HLB and δ_O for three classes of polyoxyethylated surfactants. Key: (●) dodecanol derivatives; (○) octylphenol derivatives; (△) sorbitan monooleate derivatives; (■) sorbitan monostearate derivatives; (□) sorbitan monolaurate derivatives; (○) polyoxyl 40 sorbitol septaoleate; (●) polyethylene glycol 3350.*

for the dodecanol and octylphenol derivatives, which have one hydroxyl group per molecule. For sorbitan derivatives containing p oxyethylene units, the coefficient is $p + 4$ to account for the ether linkage in the ring and the three hydroxyl groups. For a polyethylene glycol formed by adding p ethylene oxide molecules to one water molecule, it is $p + 1$ since the compound contains $p - 1$ ether linkages and two hydroxyl groups.

Because hydrogen bonding is an unsymmetrical interaction, two δ_H parameters are sometimes employed, one for proton donation or acid character, the other for acceptor or base effects (18). In the present study, almost all donors are water molecules and all acceptor groups are ether linkages. Therefore, the acid nature of the donor groups and the basic nature of the acceptor groups were constant in all surfactant systems, justifying the use of a single δ_H parameter and the assumption of a constant contribution of 5000 cal/mol for all hydrogen bonds to the molar energies of vaporization (20).

The overall solubility parameter δ_O was calculated according to Eq. 8 as follows. The δ values based on the molar attraction constants and Eq. 7 were used as the dispersion component δ_D; δ_P was neglected, and δ_H was calculated by Eq. 9. The δ_O values for the three classes of surfactants are listed in the last columns of Tables I, III, and IV. For the dodecanol derivatives, they are plotted in Fig. 1 on curve C. They include the effect of hydration on the polarity of the nonionic surfactants, *i.e.*, they are corrected for intermolecular hydrogen bonds.

For polyethylene glycol 3350[1], δ or δ_D is 9.28 and δ_O is 14.96. These two values are in good agreement with the experimental δ values determined for this compound, namely, 8.9 as the lower end of the range in poorly hydrogen-bonded solvents and 14.5 as the upper end of the range in strongly hydrogen-bonded solvents, especially, water (18). The former value corresponds to δ_D and the latter to δ_O. This agreement validates the methods for computing δ_O, δ_D, and δ_H.

CONCLUSIONS

The δ_O values for the nonionic surfactants based on dodecanol, octylphenol, and sorbitan are plotted against their HLB values in Fig. 2. The points for the three classes of sorbitan esters based on lauric, stearic, and oleic acid, respectively, nearly fall on a single straight line which also includes polyethylene glycol 3350. The curves for the dodecanol and octylphenol derivatives are linear down to HLB values of 6. The three straight lines are parallel with slopes, $d\text{HLB}/d\delta_O$, of 5.0 ± 0.2; the ± sign precedes the range of values.

The surprising fact is that the three curves belonging to three different categories of surfactants are spaced only ~1.2 $(\text{cal/cm}^3)^{1/2}$ apart despite the structural differences. This observation indicates that the nature of the hydrocarbon moiety of nonionic surfactants affects their solubility parameter only to a limited extent. The objection that the HLB calculated by Eq. 1 does not take into account the nature of the hydrocarbon moiety but only its weight percentage (or the weight percentage of the polyoxyethylene or polyol moiety, E or P) (4) has only limited validity. The solubility parameter takes the nature of the hydrocarbon moiety into account. Yet, at comparable HLB values, solubility parameters for different classes of surfactants based on different types of hydrocarbons are identical within limits that are narrower than ±1 $(\text{cal/cm}^3)^{1/2}$.

Effect of Inorganic Additives on Solutions of Nonionic Surfactants VI: Further Cloud Point Relations

HANS SCHOTT ˣ and ALAN E. ROYCE

Received September 4, 1982, from the *School of Pharmacy, Temple University, Philadelphia, PA 19140.* Accepted for publication May 4, 1983.

Abstract □ Disperse dosage forms stabilized with nonionic surfactants frequently contain electrolytes as active ingredients or adjuvants. Salting out of the surfactants by these electrolytes may cause breakdown of the dosage forms. The cloud point of an aqueous solution of octoxynol 9 was used to measure the salt effects. Electrolytes which salt octoxynol 9 out lower its cloud point, while salting-in electrolytes raise it. The observed cloud point effects are discussed according to the mechanisms involved. Salting out by dehydration in competition with octoxynol 9 for the available water was observed with sulfate and phosphate anions, sodium, potassium, and ammonium tribasic cations, and the nonelectrolyte sorbitol. The extensive self-association of water by hydrogen bonds at and below room temperature weakens its solvent power. Ions which reduce this self-association, breaking the structure of water, increased the cloud point of octoxynol 9. Among them were the iodide, thiocyanate, and nitroprusside anions. Ions which tighten the structure of water and enhance its self-association salted the surfactant out, lowering its cloud point. Among these were the fluoride and hydroxide anions. Complex formation between the ether linkages of octoxynol 9 and the following cations increased its cloud point: hydrogen (from strong acids), silver, magnesium, and zinc. Including published data, the only cations which do not form complexes with polyoxyethylated surfactants (and are, therefore, unable to salt them in) were the alkali metal ions sodium, potassium, and cesium and the ammonium ion. The cloud point increases produced by a weak organic base and acids are ascribed to the formation of mixed solvents with water. The hydrotropes sodium salicylate, phenobarbital sodium, and sodium benzoate raised the cloud point appreciably even at low concentrations. The most efficient cloud point boosters were the three surfactants studied, namely, two ionic and a nonionic surfactant with an elevated cloud point. They formed mixed micelles with octoxynol 9. The changes in cloud point caused by electrolytes having a common ion were compared at equal values of a concentration parameter chosen to produce cloud point additivity. By using the nitrate ion as a reference and arbitrarily equating its change in cloud point to zero, cloud point shift values could be assigned to other individual ions. For the anions, these cloud point shift values were related by a smooth function to the lyotropic numbers in the Hofmeister series. There was no correlation between the cloud point shift values and the lyotropic numbers of cations, presumably because of complexation between the ether groups of octoxynol 9 and many of the cations.

Keyphrases □ Surfactants, nonionic—octoxynol 9, effect of inorganic additives, cloud point relations □ Octoxynol 9—effect of inorganic additives on nonionic surfactants, cloud point relations □ Cloud point relations—effect of inorganic additives on nonionic surfactants, octoxynol 9

The influence of electrolytes on the solubility of nonionic polyoxyethylated surfactants can be assessed by their effect on the cloud point (1–5). The present work extends cloud point measurements of a representative nonionic surfactant to solutions containing electrolytes with anions and/or cations used in dosage forms. It also presents a numerical system for rating the capacity of various ions to salt the polyoxyethylated surfactant in or out.

BACKGROUND

Dosage forms consisting of micellar solutions and of disperse systems—suspensions, emulsions, ointments, and aerosols—are commonly stabilized with surfactants. Electrolytes may be present as active ingredients, adjuvants, or impurities. They frequently have an adverse effect on stability. Salting out of the surfactants by the electrolytes may cause breakdown of the dosage form.

The method generally used to study the effect of electrolytes on the solubility of nonelectrolytes is to determine that solubility in water (S_n^o) and in aqueous solutions containing C_e mol/L of electrolyte (S_n). These parameters are related by the Setschenow equation (6):

$$\log (S_n^o/S_n) = K \cdot C_e \qquad \text{(Eq. 1)}$$

where the magnitude and sign of the salt parameter, K, indicate the extent of salting in or out.

Solubility measurements of nonionic surfactants in water or aqueous salt solutions are difficult to perform because of the high values and the appearance, in concentrated systems, of viscous mesomorphic phases (7). The cloud point of these surfactants is sensitive to electrolytes (1–5), but insensitive to surfactant concentration within rather wide limits (8, 9). It can be measured readily and reproducibly and serves, therefore, as a convenient parameter for salt effects.

Electrolytes that raise the cloud point expand the region in the surfactant–water phase diagram between the upper consolute temperature, represented by the cloud point curve, and either the Krafft point curve or the freezing point curve. In this region (Region II of Fig. 1 in Ref. 10), which contains a single phase, the surfactant exists in an undersaturated isotropic solution. Such electrolytes increase the solubility of the surfactant, salting it in ($K < 0$). Electrolytes that depress the cloud point reduce the region in which the surfactant is soluble, *i.e.*, they salt it out ($K > 0$).

Information on the effect of electrolytes on the cloud point of nonionic surfactants also has practical uses. Dosage forms stabilized with nonionic surfactants frequently break down when heated above the cloud point, *e.g.*, during thermal sterilization.

EXPERIMENTAL

Materials—The surfactant, octoxynol 9 NF[1], was an anhydrous, viscous liquid. The following reagents were USP/NF grade: boric acid, citric acid, light magnesium carbonate, phenobarbital sodium, sodium benzoate, sodium fluoride, sorbitol, and trolamine (2,2′,2″-nitrilotriethanol). Sodium bromide was purified[2], tribasic sodium phosphate was technical grade[2], and sodium salicylate was certified[3]. Sodium dodecyl sulfate, triethanolamine hydrochloride, hexadecane, and xylenes were research chemical grade[4]. Another nonionic surfactant, polyoxyl 20 oleyl ether[5] (oleyl alcohol with 20 ethylene oxide units), was solid at room temperature. All other chemicals were ACS reagent grade.

A stock solution of dibasic magnesium citrate, $MgH(C_6H_5O_7)$, was made by dissolving light magnesium carbonate in a citric acid solution. Stock solutions of the sodium citrates were made by neutralizing citric acid solutions

with sodium hydroxide solutions to varying degrees. The water used was double distilled.

Methods—Concentrated stock solutions of the electrolytes were analyzed as reported (4, 5) or by the official USP methods. Octoxynol 9 solutions were aged for at least 48 h before mixing with the electrolyte solutions to permit complete hydration and breakdown of mesomorphic phases and large micelles.

Cloud points were determined at the 2.00% octoxynol 9 level (4, 5). All concentrations in the ternary mixtures are based on the weight of water.

An analysis of the errors incurred in weighing out stock solutions and water and in measuring cloud points indicates that the reported electrolyte molalities are accurate to three significant figures, resulting in an accuracy for the cloud points of ±0.5°C or better.

RESULTS AND DISCUSSION

Five lots of octoxynol 9 were used. Their cloud points ranged from 64.5°C to 67°C. Therefore, the changes in the cloud point of 2.00% octoxynol 9 solutions, Δ, were calculated as the difference between the cloud point of the solutions containing octoxynol 9 plus the additive and the cloud point of the corresponding blank octoxynol 9 solution. A positive Δ indicates salting in, and a negative Δ indicates salting out. The data are listed in Tables I–VI and plotted in Figs. 1–8.

Cloud points usually varied monotonically with increasing additive concentrations. The main exceptions were magnesium chloride and sulfuric acid. The plot of Δ *versus* molality for the former (Fig. 6) went through a minimum of −16°C at 2 *m*. However, at 3.4 *m*, Δ was only −11°C, the same value as at 0.7 *m*. The chloride ion probably acts as a ligand for magnesium in competition with the ether groups of octoxynol 9. The upturn in the curve is ascribed to increasing complexation with the latter at higher salt concentrations, either as a result of the law of mass action or because the coordination number of magnesium is increased to 6. Sulfuric acid depressed the cloud point of octoxynol 9 by 2°C at 0.10 *m*, but raised it considerably more at higher concentrations (4). The Δ values of ammonia cover the narrow interval from 2°C to −6°C in the broad concentration range extending to 10 *m* (Table IV, Fig. 5).

Some of the plots of Δ *versus* concentration were curved, indicating that the tendency towards salting octoxynol 9 in or out increased less than proportionally with the additive concentration. Linear plots of Δ *versus* concentration were observed for the following additives in the entire concentration range investigated: trolamine, acetic acid, dibasic sodium citrate, and tribasic sodium phosphate. Linearity for most of the plots was observed for citric acid (Fig. 3) and sodium nitrate (4). Sodium, ammonium, and magnesium sulfates had linear plots over 50–67% of the concentration ranges investigated (Fig. 7).

The numbers in the first columns of Tables I–VI rank the salting-in or salting-out efficiency of the additives. Increasing numbers from 1 to 19 indicate that progressively higher additive molalities were required to boost the cloud point of octoxynol 9 by 10°C. These numbers thus rank the additives in order of decreasing salting-in capacity. Increasing numbers from 20 to 40 indicate that progressively lower additive concentrations were required to reduce the cloud point of octoxynol 9 by 10°C. These numbers rank the additives in order of increasing salting-out capacity. Thus, additive no. 1 is the most efficient salting-in agent, and additive no. 40 is the most efficient salting-out agent on a molal basis. Boric acid was not assigned a number because its solubility was too low to produce a Δ value of 10°C. The tabulated Δ values at the listed additive molalities were either measured directly or interpolated. No extrapolated values were used.

Mechanisms of Electrolyte–Octoxynol 9 Interaction— Polyoxyethylated surfactants are soluble in water because of the hydration of their ether linkages. Studies with model ethers have shown that a maximum of two water molecules are bound directly to each oxygen by hydrogen bonding (11). The hydration

of small and nearly spherical nonionic micelles varies between 0.4 and 6.3 water molecules per micellar ether linkage (12). Water solubility and cloud point increase with the number of ether groups and the hydrophilic–lipophilic balance (HLB) of the surfactants. The various mechanisms by which electrolytes affect hydration, cloud point, and solubility of octoxynol 9 are discussed below and used to interpret present and previously published data.

Salting Out by Dehydration—Many cloud point-depressing electrolytes act through water binding or dehydration, reducing the amount of water available for the hydration of the polyoxyethylene moiety of the surfactant by tying up water through their own hydration. The sulfate and phosphate anions are examples of ions that salt out octoxynol 9 by competing with the surfactant for water of hydration (see Table V, Figs. 4 and 7) (1–4).

Dehydration is probably the most important salting-out mechanism for nonelectrolytes. Additional mechanisms include dielectric effects and electrostriction. Their application to nonionic surfactants has been discussed (5).

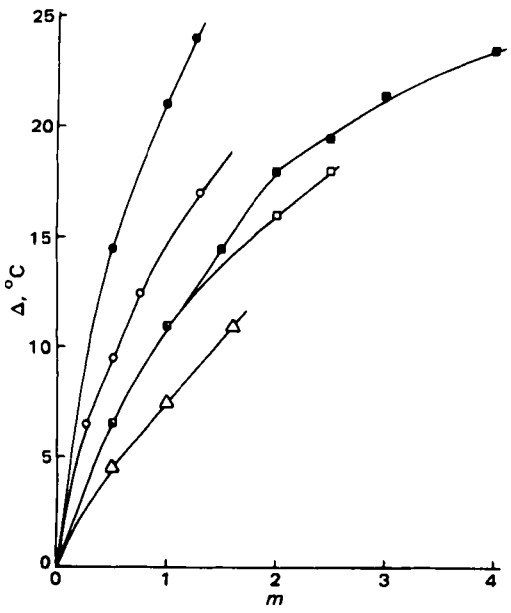

Figure 4—*Cloud point increases by salting-in electrolytes as a function of their molal concentrations. Key: (●) NaSCN; (○) $Na_2[Fe(CCN)_5NO]$; (■) $AgNO_3$; (□) NaI; (△) $Zn(NO_3)_2$.*

Sorbitol also depresses the cloud point through water binding or dehydration (Table IV, Fig. 6). Although not an electrolyte, it was included among the additives because it is so hygroscopic that it is used as a humectant.

Modification of Water Structure—At and below room temperature, water molecules are extensively self-associated by hydrogen bonding into "icebergs" or "flickering clusters" (13). Ions that reduce the self-association among water molecules, depolymerizing water and reducing its viscosity, are designated as structure breakers (13, 14). Only monomeric or nonassociated water molecules can hydrate the ether linkages of octoxynol 9 effectively. Therefore, structure-breaking ions increase the solubility of octoxynol 9 (raising its cloud point) by increasing the hydrogen bonding between ether groups and nonassociated water molecules at the expense of the hydrogen bonding among water molecules.

Examples of structure breakers are the large and polarizable iodide, thiocyanate, and nitroprusside anions (13). These anions were also efficient cloud point boosters (Table III, Fig. 4). The nonelectrolyte urea has also been found effective in breaking the structure of water and in raising the cloud point of nonionic surfactants (5).

The mucolytic action of potassium iodide and sodium thiocyanate (15, 16) is probably due to the same mechanism as their salting-in of octoxynol 9. By breaking the structure of water and making the aqueous environment a better solvent, the gel structure and viscoelasticity of mucus are reduced.

Ions that tighten the structure of water and increase its viscosity are designated as structure promoters. They include the fluoride and hydroxide ions (13). These anions salt octoxynol 9 out by enhancing the self-association of water molecules, thereby reducing the association of water molecules with the ether linkages of the surfactant (Table V, Figs. 6 and 7). The tetramethylammonium cation, which enhances the hydrogen bonding among water

	0.132	2.90	2.91	1.4

[a] At 26°C; pH of 2.00% (0.032 *m*) octoxynol 9 solution was 5.32.

molecules and the structure of water by hydrophobic bonding (17) also salts the surfactant out (18).

Complex Formation—The ether oxygen atoms of model ethers like dioxane, ethyl ether, and eucalyptol act as ligands for most cations, forming adducts similar to hydrates. Nonionic polyoxyethylated surfactants, with their multiplicity of ether groups, act as polydentate ligands and may, therefore, even displace water of hydration from these cations (4). Solid, water-soluble complexes with calcium chloride were isolated (19).

When octoxynol 9 solutions and silver nitrate solutions were combined to produce mixtures containing 2.00% octoxynol 9, a white precipitate formed when the silver nitrate concentration exceeded 1.50 *m*. Higher silver nitrate concentrations produced larger amounts of precipitate. This precipitate, which is probably a complex between the two compounds, dissolved when the mixture was heated for the cloud point determination. Mixtures containing 2.5 and 3.0 *m* $AgNO_3$ turned clear at ~38°C and 43°C, respectively. The precipitate reappeared on cooling.

Complex formation between octoxynol 9 and metal ions salts the octoxynol 9 in, raising its cloud point. The only cations unable to form complexes with model ethers and to raise the cloud point of nonionic surfactants were sodium, potassium, cesium, ammonium (Tables IV and V, Figs. 5 and 7) (4), and presumably rubidium. Among other monovalent cations, lithium, silver, and especially the hydrogen ion, which forms oxonium ions with ether linkages, as well as all di- and trivalent cations raised the cloud point of nonionic surfactants (Tables II and III, Fig. 3) (4, 5). Zinc and magnesium ions are in this category. Their nitrates raised the cloud point of octoxynol 9, while magnesium sulfate and citrate lowered it (Tables V and VI, Figs. 7 and 8). The nitrate anion has an intermediate lyotropic number (20); it has a slight tendency towards salting in. Unlike the chloride ion, it does not tend to act as a ligand for metal ions in competition with ether linkages. The cloud point-depressing effect of the citrate and sulfate anions, which have low lyotropic numbers, overcame the cloud point-raising effect of the magnesium cation.

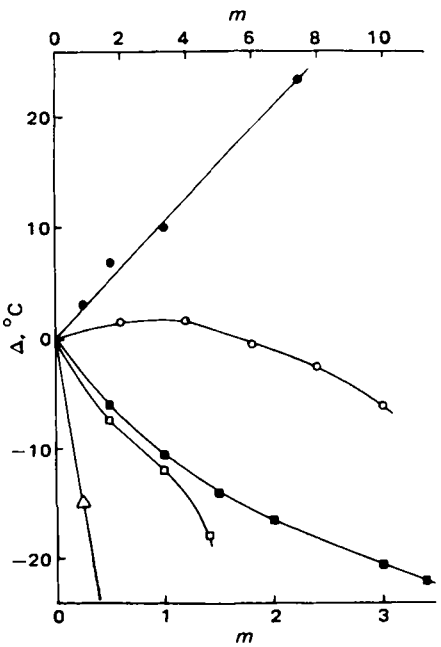

Figure 5—*Cloud point changes by weak bases and their salts as a function of their molal concentrations. Upper abscissa scale refers to molality of ammonia (○), lower abscissa scale refers to molality of trolamine (●), trolamine hydrochloride (□), ammonium chloride (■), and ammonium sulfate (△).*

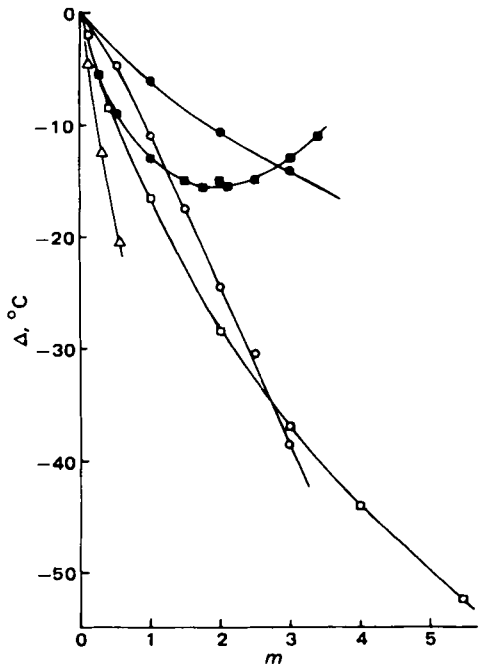

Figure 6—*Cloud point decreases by salting-out additives as a function of their molal concentrations. Key: (●) NaBr; (○) sorbitol; (□) NaCl; (■) $MgCl_2$; (△) NaF.*

On the other hand, in sulfuric acid, the cloud point-boosting effect of the two hydrogen ions overcame the cloud point-depressing effect of the sulfate ion. The cloud point-depressing action of the chloride anion when combined with the cloud point-raising lithium (1, 2), calcium (1-3), magnesium (2), or aluminum cation (1) is ascribed to its tendency to act as a ligand, displacing the ether group. This mechanism may also apply to the fluoride ion, which forms more stable complexes with some of these cations than the chloride ion.

Mixed Micelles and Micellar Solubilization—The two ionic and the nonionic surfactants listed in Table I were the most effective cloud point boosters (Fig. 1). Ionic surfactants exhibit no cloud points; their solubilities increase with temperature. The nonionic surfactant, polyoxyl 20 oleyl ether,

[a] In systems containing 2.00% octoxynol 9 + 0.50% hydrocarbon + electrolyte. [b] Calculated as the sum of the Δ values of the systems containing 2.00% octoxynol 9 + 0.50% hydrocarbon and 2.00% octoxynol 9 + electrolyte, respectively.

has an HLB of 15.3 and a cloud point above 100°C. The great salting-in effectiveness of surfactants has been ascribed to mixed micelles (1). The formation of mixed micelles between anionic and nonionic surfactants has been substantiated by various techniques (21, 22).

An alternate mechanism for the increase in cloud point of octoxynol 9 by other surfactants is the following. At temperatures well above its cloud point, the nonionic surfactant precipitates from its aqueous solution due to insufficient hydration. The precipitated octoxynol 9 is then solubilized by micelles of the more soluble surfactants. The two mechanisms are related because micelles of the soluble surfactant containing solubilized octoxynol 9 molecules are, in effect, mixed micelles.

A third mechanism, compatible with the previous two, to explain the increase in cloud point of octoxynol 9 by the other surfactants is complex formation. Anionic surfactants are bound far more extensively to polyethylene oxide and to its low molecular weight analogue, polyethylene glycol, than cationic surfactants (23–25). The strong interaction of sodium lauryl sulfate with polyethylene oxide has been investigated by various techniques (26–28). Presumably, the binding or complexation of one nonionic surfactant by another is the weakest of the three classes of surfactants. Accordingly, sodium lauryl sulfate was 5–7 times more efficient in raising the cloud point of octoxynol 9 than decylammonium chloride and 13–27 times more efficient than polyoxyl 20 oleyl ether.

Hydrotropy—The pronounced increases in cloud point produced by sodium salicylate, sodium benzoate, and phenobarbital sodium (Table I, Fig. 2) are ascribed to hydrotropy (18). The first two of these compounds are recognized as typical hydrotropes (29).

Mixed Solvents—As the temperature of nonionic surfactant solutions is increased, the critical micelle concentrations decrease and the micellar molecular weights increase. The cloud point can be regarded as the temperature at which the micelles have become infinitely large, resulting in macroscopic phase separation. The addition of increasing amounts of ethanol, dioxane, methanol, or propanol to aqueous solutions of nonionic surfactants at constant temperature progressively increased the critical micelle concentration and decreased the micellar size (30–34), thereby lowering the cloud point (30, 33, 34). For instance, 5% (v/v) or 0.90 *m* ethanol decreased the micellar molecular weight of nonoxynol 10 by 18% and increased its cloud point by 12°C (33). These reductions in cloud point are analogous to the effect of several water-miscible solvents, whose addition to water increases the solubility of compounds poorly soluble in water but appreciably soluble in the solvent. Mixed solvents act through reductions in the dielectric constant, solubility parameter, or structure of water. The cloud point-boosting action of acetic acid, trolamine, and possibly also of citric acid (Table II, Fig. 3) is attributed to the formation of such mixed solvent systems with water. At the pH values prevailing in their solutions, these compounds exist mainly in the un-ionized form (see Table VII for the two acids).

Alternate salting-in mechanisms for the two acids are discussed below. Less soluble carboxylic acids, such as benzoic, *p*-hydroxybenzoic, and salicylic acids, formed complexes with polyethylene glycol (35) and were solubilized in micelles of nonionic surfactants (36). The extent to which citric and acetic acids are distributed between the polyoxyethylene shell of octoxynol 9 micelles and water will be the subject of future investigations. Table VII shows only insignificant increases in the pH of citric and acetic acid solutions on the addition of 2.00% or 0.032 *m* octoxynol 9. Since the bulk of the two acids exists in the un-ionized form, the hydrogen ion activity is not a sensitive indicator for their binding to micellar octoxynol 9.

Increasing ionization of citric acid converted it progressively from an effective cloud point booster to an effective cloud point depressant (Table VI, Fig. 8). The tribasic citrate ion was the third most powerful salting-out additive. Tribasic magnesium citrate was not investigated because of its low solubility. In the dibasic magnesium citrate, the salting-out capacity of the $C_6H_6O_7^{2-}$ anion outweighed the salting-in capacity of the magnesium cation, making the salt a cloud point depressant.

Whereas ammonia exerted only a weak action on the cloud point of octoxynol 9, trolamine boosted it substantially. This observation is in keeping with the pronounced salting-in capacity of ethanol for polyoxyethylated surfactants and the similarity in structure between trolamine and ethanol. The hydrochlorides of both bases reduced the cloud point of octoxynol 9 substantially (Table IV, Fig. 5).

Additivity of Cloud Point Effects of Electrolytes and Hydrocarbons—Organic liquids of low water solubility either lowered or raised the cloud points of nonionic surfactants (1, 9). The additivity of these effects with the cloud point-lowering or -boosting effects of electrolytes is examined below.

The effect of solubilized hexadecane and xylene on the cloud point of octoxynol 9 is shown in Fig. 9. The onset of turbidity on heating and the disappearance of turbidity on cooling were more gradual in the presence of the two hydrocarbons, especially at higher levels. The recorded cloud points, corresponding to the temperatures at which the solutions turned substantially cloudy on heating or cleared appreciably on cooling, were as much as 3–4°C above the temperatures at which the first cloudiness appeared or at which the last cloudiness disappeared. The arrow in Fig. 9 indicates the solubility limit of hexadecane in 2.00% octoxynol 9 solution at room temperature. Systems with higher hexadecane concentration separated visible oil droplets at room temperature. On heating, these droplets largely dissolved before the systems became cloudy due to octoxynol 9 separation. The solubility limit of xylene in 2.00% octoxynol 9 was over twice as large as that of hexadecane.

The solvent systems in Table VIII contained either 0.5 g of hexadecane/100 g of octoxynol 9 solution (0.023 *m*) or 0.5 g of xylene/100 g of octoxynol 9 solution (0.048 *m*). The table compares the Δ values produced by the joint addition of hydrocarbon plus electrolyte (Δ_{obs}) with the sum of the Δ values

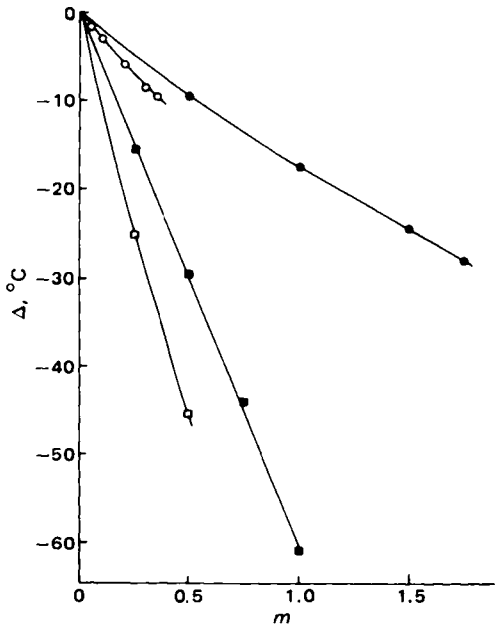

Figure 8—*Cloud point decreases by various citrates as a function of their molal concentrations. Key: (●) NaH_2; (○) MgH; (■) Na_2H; (□) Na_3.*

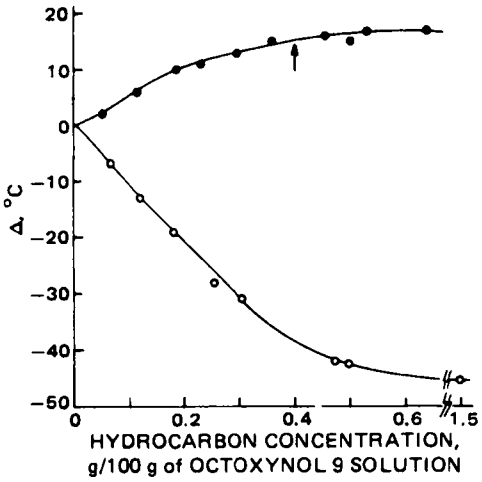

Figure 9—*Cloud point changes by two solubilized hydrocarbons as a function of their concentrations. Arrow indicates solubilization limit of hexadecane at 25°C. Key: (●) hexadecane; (○) xylene.*

produced when the hydrocarbon and the electrolyte were added to separate octoxynol 9 solutions (Δ_{calc}). All systems contained 2.00% (w/w) octoxynol 9 based on the weight of water.

Table VIII indicates that the cloud point-raising effect of hexadecane was approximately additive with the cloud point-raising or -lowering effects of salting-in and salting-out electrolytes. However, the cloud point lowering by xylene was between 6°C and 12.5°C smaller in the presence of salting-in as well as salting-out electrolytes than in their absence.

Additivity of Cloud Point Effects of Electrolyte Mixtures and Ionic Cloud Point Shifts—The effects of mixtures of electrolytes on the cloud point of octoxynol 9 were approximately additive. For instance, $\Delta MgSO_4$ at 0.25 *m* was −15°C, ΔNa_2SO_4 at 0.25 *m* was −19°C. A solution containing both 0.25 *m* $MgSO_4$ and 0.25 *m* Na_2SO_4 had $\Delta = -33$°C compared with the additive value of −34°C. Similarly, a mixture containing 0.5 *m* NaCl and 0.5 *m* NH_4Cl has a Δ value of −16°C, identical to the sum of the Δ values of the two salts at 0.5 *m* concentrations. The Δ value of a mixture of 1.0 *m* NaCl and 1.0 *m* NaBr was −21°C compared with an additive Δ value of −22.5°C.

The only discrepancies arose when one component was hydrochloric or sulfuric acid, presumably because they had slightly negative Δ values at low concentrations which became large and positive at higher concentrations. A solution containing 1.0 *m* NaCl and 1.0 *m* HCl had a Δ value of −8°C compared with an additive value of −11°C. A solution containing 0.25 *m* $MgSO_4$ and 0.25 *m* H_2SO_4 had a Δ value of −11°C compared with an additive Δ of −16°C.

Since the effects of individual ions on the cloud point are approximately additive, it is possible to assign a "cloud point shift" or Δ value to each ion.

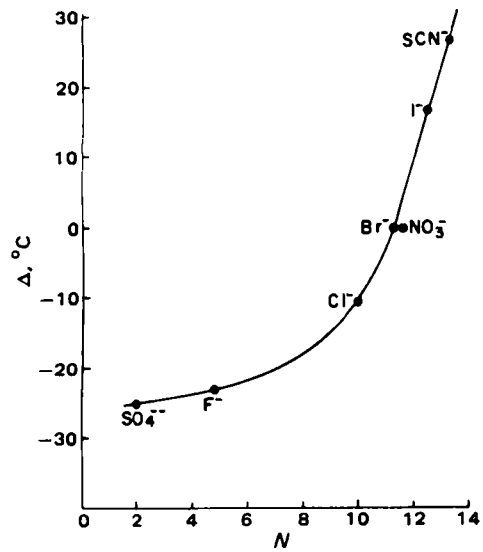

Figure 10—*Ionic cloud point shift values, Δ, of various anions at* W = 2 *as a function of their lyotropic numbers,* N.

Table IX—Effect of Various Ions on the Cloud Point of Octoxynol 9 at W = 2

Ion	Cloud Point Shift Δ, °C: From Sodium Salt	From Ammonium Salt	From Magnesium Salt
PO_4^{3-}	−18		
Cl^-	−10.5	−9.5	−7[a]

Ag^+	11		
	From H_2SO_4	From HCl	From HNO_3
H^+	13	15	15

[a] Probably low due to complexation, see text.

To do this, the Δ values of different electrolytes must be compared at identical values of some concentration parameter. Various parameters, including ionic strength, were investigated by trial and error. The following two criteria must be satisfied when comparisons of Δ values are made at equal values of a concentration parameter that is suitable:

1. The cloud point shift values calculated for various individual ions must add up to the changes in cloud point observed for the electrolytes containing these ions.
2. Different electrolytes containing a common ion must furnish the same cloud point shift value for that ion. A self-consistent set of ionic cloud point shift values can then be calculated.

The simplest concentration parameter that satisfied these conditions, designated molal strength (*W*), is defined by:

$$W = \Sigma mz \qquad \text{(Eq. 2)}$$

where *m* is the molality and *z* is the valence of the ions that constitute the electrolyte. According to this equation, a molal strength value of $W = 2$ corresponds to the following molalities: for sodium chloride (a 1:1 electrolyte), 1.0; for sodium sulfate (a 1:2 electrolyte) and magnesium nitrate (a 2:1 electrolyte), 0.50; for magnesium sulfate (a 2:2 electrolyte), 0.50; and for tribasic sodium phosphate (a 1:3 electrolyte) and aluminum nitrate (a 3:1 electrolyte), 0.33. It is necessary to assign an arbitrary Δ value to one given ion to serve as reference. Accordingly, the cloud point shift value for the nitrate anion, ΔNO_3^-, was set equal to zero.

The following calculations illustrate how the data in Table IX were obtained. At $W = 2$, sodium nitrate (no. 23, Table V) has a molality of 1.0. A solution containing 1.0 *m* $NaNO_3$ and 2.00% octoxynol 9 had a cloud point of 59°C, while a 2.00% solution of octoxynol 9 from the same batch had a cloud point of 65°C. Hence, $\Delta NaNO_3 = 59 - 65 = -6$°C. Since $\Delta NaNO_3 = \Delta Na^+ + \Delta NO_3^-$ and ΔNO_3^- was arbitrarily set equal to zero, $\Delta Na^+ = -6$°C. The molality for sodium sulfate at $W = 2$ is 0.50 according to Eq. 2. The Δ value of 0.50 *m* Na_2SO_4 was −37°C (no. 37, Table V). Therefore, $\Delta SO_4^{2-} = \Delta Na_2SO_4 - 2\Delta Na^+ = -37 - (2)(-6) = -25$°C. Since the Δ value of 0.50 *m* H_2SO_4 was 1°C, $\Delta H^+ = \frac{1}{2}(\Delta H_2SO_4 - \Delta SO_4^{2-}) = \frac{1}{2}[1 - (-25)] = 13$°C.

Data at $W = 1$ and 4 were also calculated. To conserve space, they were not included in Table IX, but they showed trends comparable with the data at $W = 2$. As expected from the shape of the Δ *versus m* plots and Eq. 2, as the *W* values increase, the absolute values of the ionic cloud point shifts increase commensurately.

The ΔCl^- values obtained from magnesium chloride were consistently lower than those obtained from sodium chloride or ammonium chloride. This discrepancy is ascribed to the fact that the chloride ion acts as a ligand for magnesium, in competition with the ether groups of octoxynol 9, whereas the nitrate and sulfate ions do not.

The ionic cloud point shift values of the anions are related by a smooth function to their lyotropic numbers in the Hofmeister series (20), shown in Fig. 10. As the lyotropic numbers of the anions decrease, the negative values of the standard free energies of formation of the aqueous anions at 25°C increase (37). A plot of the ionic cloud point shift values *versus* the standard free energies of formation of the anions in water has a shape similar to Fig. 10 and can almost be superimposed on it.

For cations, the points of ionic cloud point shift values *versus* either lyotropic numbers or standard free energies of formation in water are scattered and do not fall on a single curve. This lack of correlation is ascribed to the fact that all cations except sodium, potassium, ammonium, rubidium, and cesium form complexes with the ether groups of octoxynol 9. The cloud points of polyoxyethylated surfactants are thus affected by cations in two ways. First, all cations tend to become hydrated, binding water and altering its structure. Second, there is a specific interaction by complexation between the ether groups of the surfactants and most cations, which predominates over their dehydrating effect to various degrees, resulting in net salting in or positive Δ values (4, 5). The ionic cloud point shift values for the complexing cations are probably related to the stability constants of the complexes they form with the ether linkages of the polyoxyethylated surfactants and the standard free energy changes of complexation.

Anions do not form complexes with the ether groups. Therefore, their effect on the cloud points of nonionic surfactants depends entirely on their interaction with water, which is also the dominant factor in ranking the anions in the Hofmeister series.

The ionic cloud point shift values of Table IX refer to octoxynol 9. They are higher than the corresponding absolute Δ values for polyoxyethylated surfactants having practically the same average number of ethylene oxide units per molecule and the same HLB but lacking an aromatic ring. Calculating the ionic cloud point shift values with the aid of Eq. 2 from the data of Ref. 5, it was found that polyoxyl 10 cetyl ether and polyoxyl 10 stearyl ether had the lowest absolute Δ values. Those of polyoxyl 10 oleyl ether were somewhat higher, but still well below the corresponding values for octoxynol 9. As the polarity of the hydrocarbon moiety of the surfactants decreased, the ionic cloud point shift values at a given W also decreased. Since the HLB values of the four surfactants were the same within one unit, this observation points up the major shortcoming of the HLB system, namely, that it does not take into account the nature of the hydrophobic moiety of the surfactants (8, 38).

Dissolution Profile Determination of a Multicomponent Product Using a Rapid Liquid Chromatographic Analysis

RICHARD SOLTERO *x, JOHN ROBINSON ‡, and DENNIS ADAIR §

Received June 9, 1982, from the *Research and Development Department, Pharmaceuticals Division, Ciba-Geigy Corporation, Summit, NJ 07901.* Accepted for publication May 9, 1983.

Present address: *Berlex Labs., 110 E. Hanover Ave., Cedar Knolls, NJ 07927; ‡Varian Corp., Florham Park, NJ; §Schering Corp., Bloomfield, NJ 07003.

Abstract □ A system was developed which is capable of monitoring the dissolution profiles of each of the active components in a two-component combination product. The UV spectra of the two drugs (metoprolol and hydrochlorothiazide) overlap considerably, making conventional UV analysis of either component unrealistic. By resolving the two drugs on a high-performance liquid chromatographic (HPLC) system both can be quantitated after separation. The analysis is sufficiently short to allow for the use of a six-station dissolution tester in tandem with an HPLC for determination of dissolution profiles. The HPLC system and equipment, can monitor six samples of this product at 5-min intervals in real analysis time.

Keyphrases □ Dissolution—multicomponent product, rapid HPLC, metoprolol, hydrochlorothiazide □ Metoprolol—dissolution profile, multicomponent product with hydrochlorothiazide, rapid HPLC □ Hydrochlorothiazide—dissolution profile, multicomponent product with metoprolol rapid HPLC.

The determination of the release rate of an active drug from pharmaceutical dosage forms has become a standard technique in pharmaceutical development, research, and quality control testing laboratories. useful for predicting bioavailability, and at times it is possible to employ dissolution to satisfy the FDA requirements concerning the bioavailability of a product.

Many dissolution techniques have been proposed, and several are in general usage. The most frequently used techniques are the USP rotating basket and USP rotating paddle methods (1). Other methods that have been employed are the spin filter (2, 3), the rotating flask (4), and the USP disintegration basket (5). Typically, samples of the test solution are taken at one or more time points, and the concentrations of the active component(s) are determined. Various analytical techniques are employed for evaluation concentrations. Wet chemistry techniques can be used to prepare the sample for analysis, or the samples can be analyzed directly without preparation depending on the particular drug excipients and the relative concentration ranges. Several automated dissolution methods have been proposed (6–8). In addition, several commercial instruments are available which will sample, store, and prepare samples for UV analysis[1]. The development of high-performance liquid chromatographic (HPLC) techniques and equipment has simplified the analysis of aqueous samples. This method can be employed for analyzing samples taken from the dissolution medium using a fraction collector, or the solution can be sampled automatically (9).

This paper presents HPLC techniques and equipment which can be used in conjunction with most dissolution test methods. The system is capable of sequentially sampling six streams from the dissolution apparatus and subjecting these samples to chromatographic analysis in <5 min. In operation, all six streams from a dissolution test unit[2] are continuously pumped, through in-line filters, into a six-way rotary valve[3], which selects one stream to be diverted to the injection loop of a chromatograph, while the other streams are returned to the dissolution flasks. Kent *et al.* (10) used a similar valve to monitor the UV absorbance of six dissolution streams. This system has the advantage of performing an HPLC separation and analysis of several components of a multicomponent product during the dissolution experiment.

EXPERIMENTAL

Equipment—An HPLC[4] with programmable external events and a pneumatic loop valve injector was used. The position of the injection valve was controlled by a program in the chromatograph that used solenoids to control the pneumatic pressure to the valve. "Tee" fittings were placed in the pneumatic lines to control the action of a 60° stepping actuator. This actuator was used to rotate a six-way rotary valve[5]. As shown in Fig. 1, each of six streams of dissolution medium from a dissolution unit is pumped to the six-way valve, where one stream is selected to go to the injection valve and the rest are returned through polytef tee fittings to the dissolution unit. The stream going to the injection valve flows through the injection loop and then to waste (~2–3 mL of medium is lost in a 30-min analysis).

On program command (external event), the injection valve switches from the load position to the inject position, and the sample is washed onto the analytical column. At the same time, the pneumatic pressure switches the 60° stepping actuator to the return position. The next external events command causes the injector valve to return to the load position, and the stepping actuator is advanced simultaneously to select the next stream from the dissolution unit and send it through the injection loop. The injection loop is thus continuously flushed with new sample throughout the time required for the chromatographic separation.

Chromatographic Conditions—Since rapid turnaround is required for this application, the chromatography was optimized with a short (5-cm) column and a high flow rate. An analysis time of 30–45 s/sample was the targeted range.

The rapid HPLC method used a 50 × 2.5-mm column packed with nucleosil 5 SA. At ambient temperature, an isocratic mobile phase composed of 0.015 M $KMeSO_3$, 0.025 M tetramethylammonium chloride, and 50% acetonitrile was employed at a flow rate of 2.7 mL/min (~150 atm) with a 10-μL injection loop. The detection was at 212 nm, with 0.2 AUFS attenuation; resolution of the two components was achieved within 0.8 min. The samples in the dissolution experiment were started at 0.8-min intervals so that the timing of the analysis would be synchronized with the dissolution time. This process allowed six samples to be analyzed in sequence within 5 min.

Additionally, as an alternate system, a microprocessor[6] was used to control the sequence of steps and provide the timing in an automated HPLC system. All of the instrument conditions were kept constant, except for the pneumatic actuation and the HPLC pumping system. In this case, two solenoid valves[7] were used under the control of the microprocessor. The microprocessor has 16 I/O ports, which are extensions of a resident versatile interface adapter. Two of these ports were used to control the solenoid valves. The pneumatic pressure released by the solenoid valves was used to simultaneously power an automatic injector and 60° stepping actuator[8]. The timing and the sequence

of steps were programmed in BASIC. Driving the injector to the load or inject positions was done by sending the appropriate signals through the I/O port to the appropriate solenoid (one for inject position, one for load position). System delays were easily accomplished by sending the BASIC program into a loop for the appropriate period of time.

The advantages of the microprocessor-based system are that (*a*) it can be retrofitted to an existing HPLC pump and detector, (*b*) all of the hardware is commercially available and is relatively inexpensive, and (*c*) the programming on the microprocessor can be tailored to specific applications and is independent of another operating system (such as the timed event functions necessary on the chromatograph for this procedure).

Dissolution Apparatus and UV Analyses—The USP paddle method was used at 50 rpm employing 1 L of distilled water as the dissolution medium. The dissolution profiles were determined by continuously monitoring the absorbance of the media through a series of flow cells in a UV-visible spectrophotometer[9]. The media were circulated through polytef tubing with an in-line filter holder[10] using a thick prefilter[11]. A wavelength of 252 nm was selected, where the sum of the absorbance is due to the hydrochorothiazide and the absorbance due to the metoprolol will be in a convenient range for analysis.

RESULTS AND DISCUSSION

This system is applicable for either single-component products (which have low extinction coefficients or some inactive material in the formulation that interferes with normal analysis) or multicomponent products. The obvious advantage is that the release rate profiles of the individual components in multicomponent products can be determined. The system proposed here can analyze six separate dissolution samples within a 5-min turnaround time. This allows for the dissolution experiment and the HPLC analysis of the active components to be conducted simultaneously.

In developing an HPLC method for use in conjunction with a standard six-sample dissolution apparatus, analysis time is the prime consideration. For example, if the required dissolution profile allows for 5-min time intervals between groups of six samples for this apparatus, ~0.8 min is available for each chromatogram. For separations which cannot be performed this quickly, longer sampling intervals such as 10 or 15 min would be required.

The product, metoprolol-hydrochorothiazide, was prepared in three strengths: 50:25, 100:25, and 100:50 mg. Each of the strengths was analyzed for dissolution profiles and each compared using the two different analytical methods. All results are the mean of six tests.

The UV spectra of metoprolol and hydrochorothiazide are shown in Fig. 2. The spectra are seen to overlap at all points of the UV spectrum. It would nearly be impossible to develop an accurate multiple-wavelength analysis for this combination product. HPLC analysis would be an obvious method of choice in this case.

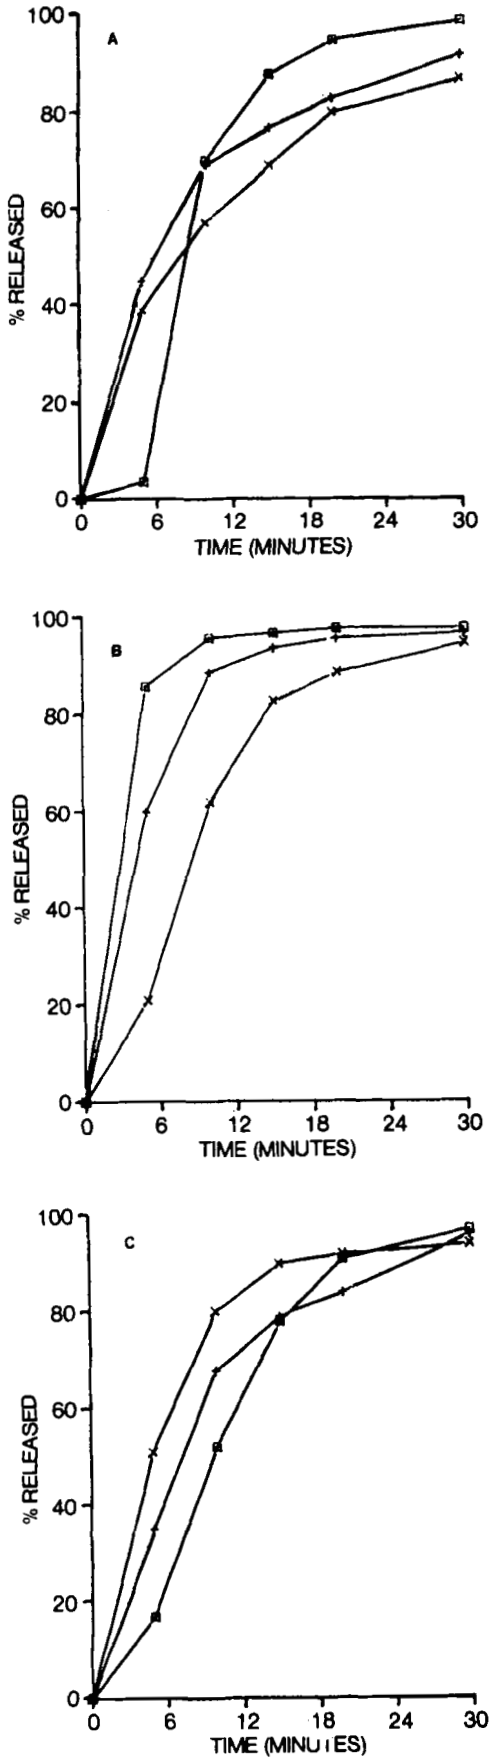

Figure 3—*Comparison of the dissolution rates of (A) 50:25-, (B) 100:25-, and (C) 100:50-mg combinations of metoprolol-hydrochlorothiazide. Key: (+) UV analysis (combination); (x) HPLC analysis of metoprolol; (□) HPLC analysis of hydrochlorothiazide.*

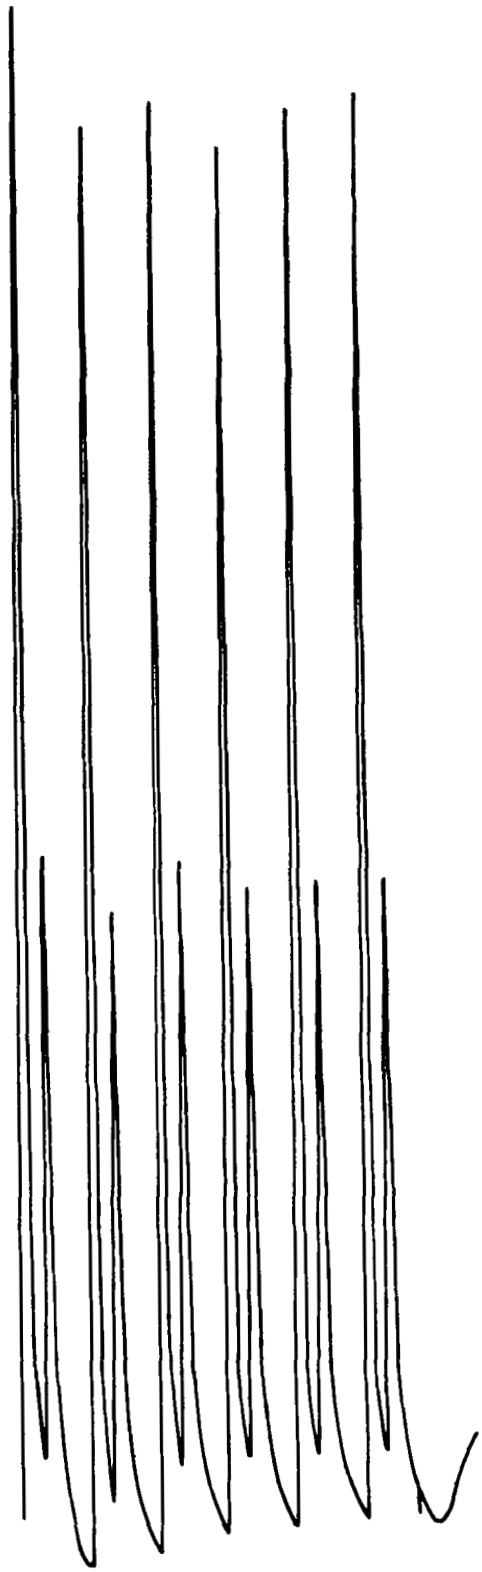

Figure 4—*Chromatogram showing six injections made in a 5-min period.*

The three strengths of metoprolol-hydrochlorothiazide were tested using this rapid HPLC method, and comparison data were generated using the UV analysis method (Fig. 3). It can be seen that the UV analysis yields a dissolution profile which is a composite of the individual release rates measured by the rapid HPLC method. For these sets of experiments, the analysis time for each batch of tablets required ~1.5 h using the rapid HPLC technique. For a conventional HPLC analysis technique, the time required to pull manual aliquots and analyze each sample is much greater. Before this technique was introduced into our laboratory, it required ~5 h to analyze a similar dissolution.

[a] MET, metoprolol. [b] HCT, hydrochlorothiazide.

The advantage of a rapid screening technique for monitoring individual release rates of the active components of a multicomponent product is shown in Fig. 3. The composite release from the 100:25- and 100:50-mg formulations appear similar; however, the hydrochlorothiazide is the faster component in Fig. 3B (100:25 mg) and the slower component in Fig. 3C (100:50 mg).

A typical chromatogram is shown in Fig. 4, where six analyses were completed. Peak height measurements for a series of standards are listed in Table I. Linear regression analysis on the mean peak height values of metoprolol and hydrochlorothiazide *versus* concentration yielded correlation coefficients of 0.9996 and 0.9994, respectively.

The intent of these experiments was to demonstrate the utility of a novel approach to analyzing the dissolution rate profile of combination products. For this article, we selected an example of a dual-entity product which was manufactured in several strengths. The ease of operation and facility of this technique is demonstrated in the reduced time required for quantitative analysis of each of the two components of this combination product. The progress being made in HPLC techniques and equipment should allow this technique to be developed for other combination products and for single-entity products which have excipients that interfere in normal UV analyses.

Some Effects of 1-(2,4-Dichlorophenyl)-4-dimethylaminomethyl-1-nonen-3-one Hydrochloride on *Escherichia coli* GK-19

G. G. KHACHATOURIANS *‡ˣ, P. K. HOLMLUND ‡, and J. R. DIMMOCK §

Received December 27, 1982, from the **Department of Applied Microbiology and Food Science, College of Agriculture*, ‡*Department of Microbiology, College of Medicine*, and §*College of Pharmacy, University of Saskatchewan, Saskatoon, Saskatchewan S7N 0W0, Canada.* Accepted for publication April 26, 1983.

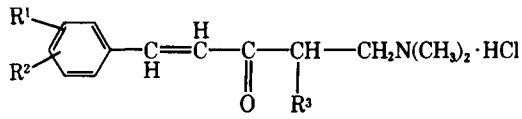
Abstract □ 1-(2,4-Dichlorophenyl)-4-dimethylaminomethyl-1-nonen-3-one hydrochloride (Id) was shown to inhibit the growth of *Escherichia coli* GK-19 at a concentration of 50 μg/mL in a medium of pH 6.5. Maximal antibacterial activity was found during the logarithmic growth phases rather than at the early stationary phase. Electron microscopy revealed that Id caused lysis, and inhibition of respiration and retardation of RNA and protein syntheses occurred in the bacteria with this compound at 50 μg/mL.

Keyphrases □ 1-(2,4-Dichlorophenyl)-4-dimethylaminomethyl-1-nonen-3-one hydrochloride—antibacterial activity in *Escherichia coli*, effects of concentration, temperature, and medium pH □ Antibacterial activity—1-(2,4-dichlorophenyl)-4-dimethylaminomethyl-1-nonen-3-one hydrochloride against *Escherichia coli*, effects of concentration, temperature, and medium pH

Previous work from these laboratories showed that a number of Mannich bases derived from conjugated styryl ketones had antibacterial properties (1–3). The aim of the present investigation was twofold. First, it was hoped to unravel some of the factors affecting the action of a representative Mannich base on bacterial growth, and second, to discern the site or sites of action of the compound toward the bacteria.

EXPERIMENTAL

Synthesis of Compounds—Compound Ia was prepared by the literature method (4); Ib, d–f were synthesized by a previously described procedure (5), as was Ic (6).



Ia: $R^1 = R^2 = R^3 = H$
Ib: $R^1 = R^2 = H$; $R^3 = (CH_2)_4CH_3$
Ic: R^1 = 3-OH; $R^2 = H$; $R^3 = (CH_2)_4CH_3$
Id: R^1 = 2-Cl; R^2 = 4-Cl; $R^3 = (CH_2)_4CH_3$
Ie: R^1 = 2-Cl; R^2 = 6-Cl; $R^3 = (CH_2)_4CH_3$
If: R^1 = 3-Cl; R^2 = 4-Cl; $R^3 = (CH_2)_4CH_3$

Measurement of Bacterial Growth—In this study, an isolate of *Escherichia coli* K-12 strain designated GK-19 (7) was employed. The bacteria were grown in a minimal salts medium (8) to which casamino acids (0.5% w/v) and thiamine (7.5 μg/mL) had been added. Adjustment of the pH was made using Sörensen's buffer solutions (9). The cultures were grown in Erlenmeyer flasks

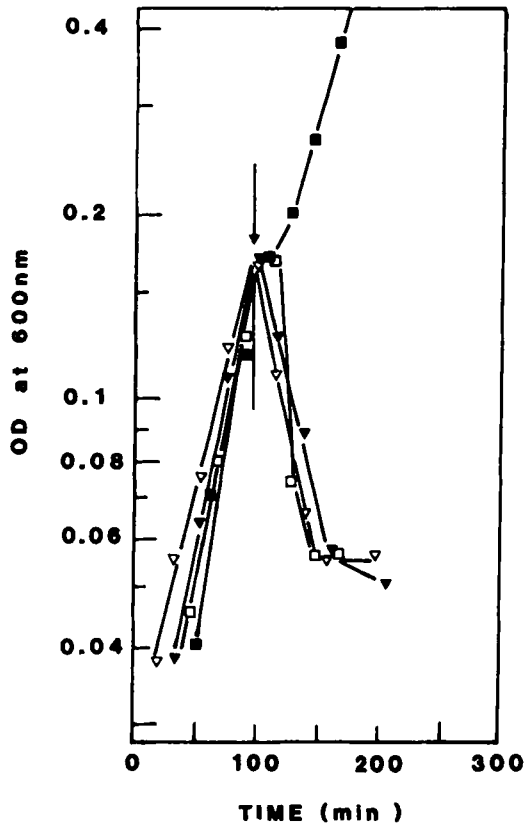

Figure 1—*Effect of Id (50 μg/mL) on the growth of* E. coli *GK-19 at pH 7.0 (■), 6.5 (□), 6.0 (▼), and 5.0 (▽). Compound Id was added (arrow) after exponential growth of the bacteria had commenced.*

at 37°C (unless otherwise stated) with a culture-to-flask volume of 1:5 or 1:10, using a gyratory shaker incubator[1]. The growth of the cultures was monitored by determining the absorbancy at 600[2] and 610[3] nm. The determination of cell viability was made by the appropriate dilutions of the culture being placed onto nutrient agar[4] and incubated at 37°C for 24–36 h. Colony-forming units were determined by plating. The compounds were dissolved in water prior to the addition of the medium unless otherwise indicated.

Electron Microscopy—A pellet of bacterial cells was prepared[5] by centrifugation (9650×*g* for 3 min), and the cells were fixed in a solution of glutaraldehyde (2.5% w/v) in 0.1 M cacodylate buffer, pH 7.4. After this process (105 min), the cells were embedded in a resin[6], and ultrathin sections were prepared[7] and stained with uranyl acetate solution in methanol (1% w/v) followed by lead citrate solution (2.66% w/v). Negative staining was accomplished by placing the cells prior to the fixation process, on 200-mesh grids followed by treatment with phosphotungstic acid solution (3% w/v). The samples obtained by these procedures were examined by electron microscopy[8].

Measurement of Respiration—Compound Id was added to *E. coli* GK-19 at log phase in standard biological oxidation-demand bottles attached to a polarographic dissolved-oxygen electrode[9]. The addition and mixing process was complete within 30 s and oxygen consumption was measured[10] every 2 min at 22–23°C.

Effect of Id on DNA and RNA Syntheses—Compound Id (50 μg/mL) was added to a culture of *E. coli* GK-19 at an optical density of 0.44, and the extent of incorporation of [^{3}H]thymidine (1 μCi/mL of culture) and [^{3}H]uracil (0.1 μCi/mL of culture) into DNA and RNA, respectively, was made by the batch method described previously (8) using a scintillation counter[11]. The experiments examining the rates of DNA and RNA syntheses were undertaken once and in triplicate (±5%), respectively.

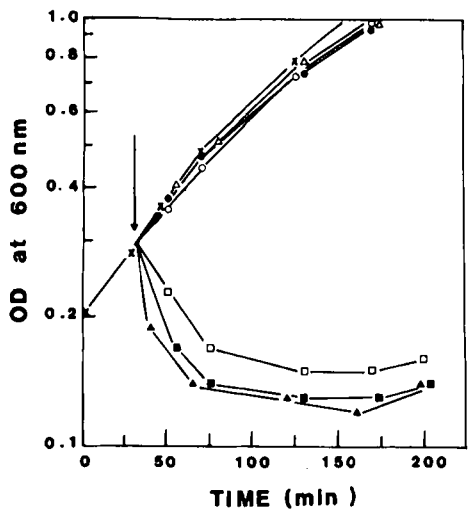

Figure 2—*Effect of Ia–f (100 μg/mL) on the growth of* E. coli *GK-19. The arrow indicates the time of addition of Ia (○), Ib (●), Ic (△), Id (▲), Ie (□), and If (■); (X) untreated controls.*

RESULTS AND DISCUSSION

Six candidate antibacterial agents I were considered in which the substitution pattern of the aromatic ring varied, while the *n*-pentyl group present in Ib–f was absent in Ia. A laboratory strain of *E. coli* K-12, designated as strain GK-19, was used as the test organism.

The initial experiments were designed to examine some of the factors affecting the bacterial growth by a representative Mannich base. Since Mannich bases are known to be unstable under alkaline conditions (5, 10), one of the derivatives (Id) was evaluated against *E. coli* GK-19 at neutral pH and in media which was mildly acidic (Fig. 1). At pH 7.0, a transient reduction of the growth rate of the bacteria was observed after the addition of Id, but afterward virtually normal growth resumed. Under acidic conditions (pH values of 6.5, 6.0, and 5.0) minimum absorbancy was noted after 1 h. Changes in pH can affect the ratio of un-ionized and ionized molecules (11), and it is conceivable that lowering the pH increases the percentage of Id existing in the ionic form, which may be the bioactive species.

The six Mannich bases were also examined at pH 6.5 for their effect on bacterial growth (Fig. 2). Compounds Ia–c were virtually bereft of antibacterial activity, while the dichlorinated derivatives (Id–f) caused a marked decrease in culture turbidity. Mannich base Id was selected for further studies. Reduction of the concentration of Id showed that the antibacterial effect was detectable at the lowest concentration examined, *i.e.*, 5 μg/mL (Fig. 3), while at 35 μg/mL substantial antibacterial activity was observed. However, this effect reversed after ~1 h, and colony-forming ability returned. At 35 μg/mL, Id was bacteriostatic (Fig. 3A) and at 50 μg/mL it was bactericidal (Fig. 3A and B). Figure 3B shows that at 50 μg/mL, the bactericidal activity is >99.9%.

Compound Id was dissolved in three different solvents to observe the effect of solvent on the antibacterial activity of Id (Fig. 4). When Id was dissolved in water and ethanol, minimal absorbancy was attained more rapidly than when a solution of Id in dimethyl sulfoxide was administered to a culture of the microorganisms. Gradual recovery occurred with solutions of Id in dimethyl sulfoxide and ethanol, but not when water was used.

The effect of the antibacterial effect of Id on *E. coli* GK-19 at different temperatures is seen in Fig. 5. At 6°C, little bacterial growth is observed, in contrast to that seen at 23°C, 37°C, and 40°C. At 23°C, addition of Id virtually abolished growth, but it was only after 1 h that the lytic effect was noted. At 37°C and 40°C, lysis began on addition of Id. This observation is of interest insofar that a reduction in the respiration-inhibitory properties of some related Mannich bases on mitochondrial function was noted at 20°C compared with 37°C (12) and, hence, the present study is germane to recent reports in changes of biochemical function with variation in temperature (13–15). In addition, the fatty acid composition of a yeast membrane varied with temperature (16). In summary, unless otherwise indicated subsequent experimentation utilized compound Id at a concentration of 50 μg/mL in a medium of pH 6.5 and a temperature of 37°C.

A further question posed was the effect of Id on the age of the culture of

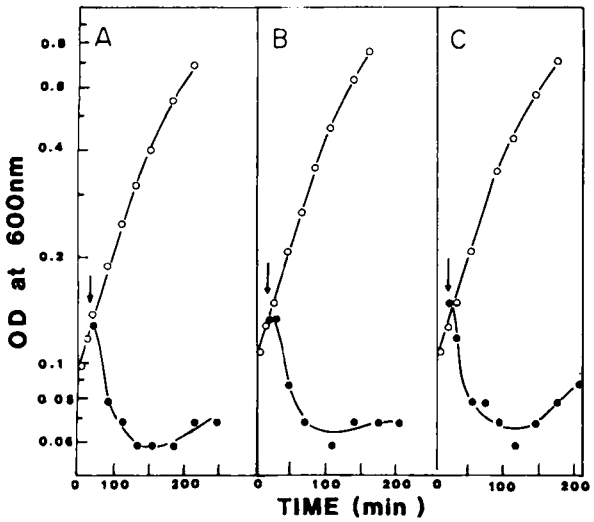

Figure 4—*Effect of the addition (arrow) of Id (50 μg/mL) dissolved in dimethyl sulfoxide (A), water (B), and ethanol (C) on the growth of treated (●) and untreated (○) cultures of* E. coli *GK-19.*

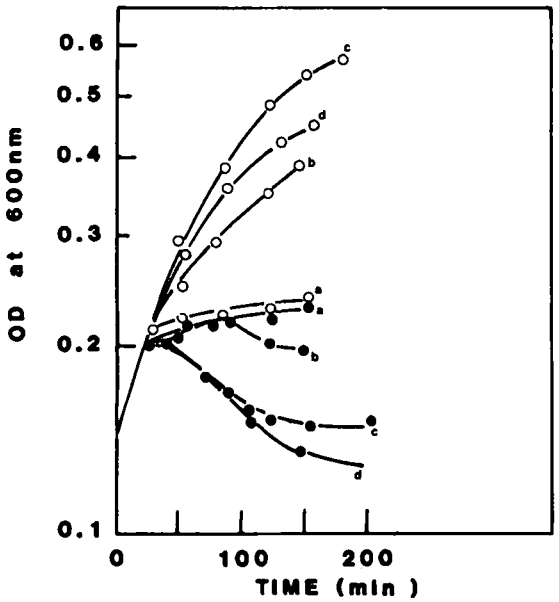

Figure 5—*Effect of the addition of Id (50 μg/mL) on treated (●) and untreated (○) cultures of* E. coli *GK-19 at 6°C (a), 23°C (b), 37°C (c), and 40°C (d).*

E. coli GK-19. Figure 6 shows that after a short lag phase of ~0.5 h, the bacteria entered their logarithmic (log) growth phase, which continued for 5 h. Compound Id was added to culture aliquots at times corresponding to early log, mid log, late log, and early stationary phases; antibacterial activity was demonstrated on all four occasions, although greater activity was seen during the logarithmic growth phases. However, the larger number of cells present in the early stationary phase could be an explanation for the reduced antimicrobial activity of Id at this point in time. To examine such a possibility, a culture of *E. coli* GK-19 was grown to early-mid log phase and concentrated fivefold by centrifugation; two quantities of Id (50 μg/mL) were added, separated by a 40-min period, and then the turbidity of the culture was followed for a further 90 min. No different effect was observed to that found for the early stationary phase shown in Fig. 6. In addition, the difference in the culture growth phase sensitivity to Id could be due to changes in the growth media, *i.e.*, the concentration of certain nutrients could have diminished by the time the bacteria had entered the stationary phase or, alternatively, new compounds could have formed and be present in the media. To test this possibility, cells at the mid log phase were harvested by centrifugation and resuspended in both freshly prepared media and also in media from which bacteria at the early stationary phase had been removed. The bacteria in both media responded to Id in an identical manner and, hence, the differential

sensitivity of Id at various growth stages was not due to changes in content of the media occurring during the growth of the bacteria.

The second phase of the investigation consisted of attempts to delineate the site(s) of action of Id on *E. coli* GK-19. An initial question posed was whether there was retention of the integrity of the cell membrane and cellular constituents after treatment with Id or whether a lytic process occurred, in which case rupture of the cell membrane and leakage of intracellular material would take place. Figure 7A is an electron micrograph of *E. coli* GK-19 cells taken from a culture of cells in the mid log growth phase, while Fig. 7B shows the effect of Id on these cells. After addition of Id, there are distortions of the cell shapes, loss of surface layer, and altered stainability compared with the untreated cells as noted in Fig. 7. Thin sections of some of the untreated cells revealed the cell membrane and the cytoplasmic regions containing ribonucleoprotein complexes (Fig. 8); regions of nuclear material are shown as lighter areas. After treatment with Id, there is the appearance of condensation of nuclear material, disorganization of the cell membrane, disappearance of the ribonucleoprotein structures, and appearance of pockets of small rounded vesicles inside cells, as well as in aggregate forms outside the cells (Fig. 9). Lysed cells of *E. coli* GK-19 after treatment with Id showed an increased loss of cellular constituents (Fig. 10). Hence, the Mannich base Id exerts a lytic effect on these bacteria at 50 μg/mL.

It is conceivable that Id could exert antibacterial activity in addition to lysis. In other words, while the lysis was in progress, Id could also act, for example, on the respiration apparatus and the macromolecular synthetic pathways of the bacteria. Figure 11 shows the effect of the addition of various concentrations of Id on oxygen consumption; at 50 μg/mL, there is complete inhibition of respiration. A plot of the rate of oxygen consumption at the end of 20 min *versus* concentration of Id (on linear paper) is shown as an inset in Fig. 11.

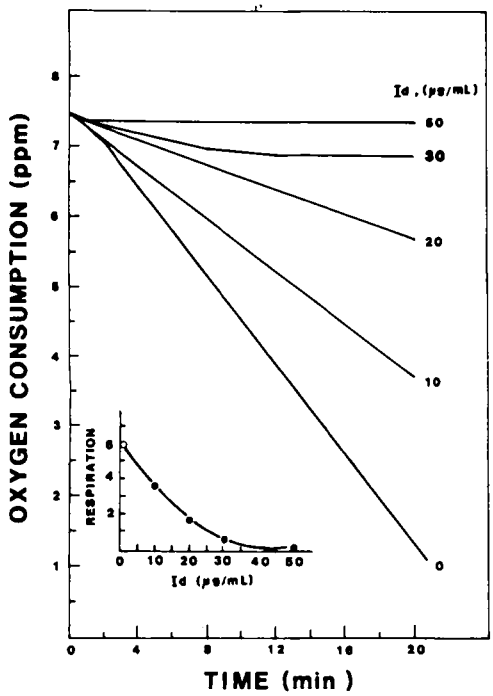

Figure 11—*Effect of Id on oxygen consumption in* E. coli *GK-19.*

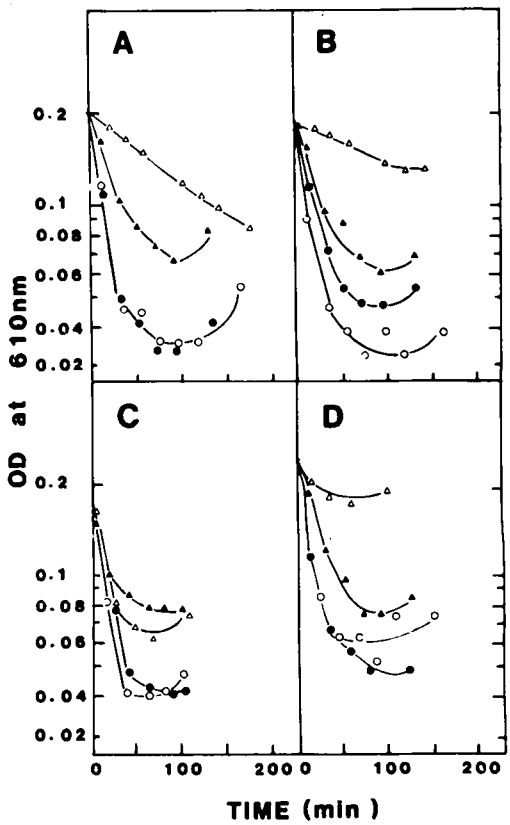

Figure 12—*Effect of the sensitivity of* E. coli *GK-19 to Id (50 μg/mL) by treatment with metabolic inhibitors. Key: (A) potassium cyanide (1950 μg/mL); (B) sodium azide (1950 μg/mL); (C) 2,4-dinitrophenol (18.4 mg/mL); (D) chloramphenicol (150 μg/mL). Compound Id was added simultaneously (●), 5 (○), 30 (△), or 120 (▲) min after the addition of the metabolic inhibitor.*

Table I—Effect of Id (50 μg/mL) on the Incorporation of [^{3}H]Thymidine and [^{3}H]Uracil into the DNA and RNA of *E. coli* GK-19.

Time, min	Counts per Minute of [^{3}H]-Thymidine[a]		Counts per Minute of [^{3}H]-Uracil[a]	
	Control	Treated	Control	Treated
5	100	100	100	100
10	102	100	294	193
20	106	99	650	224
30	108	97	650	237
40	112	96	650	255

[a] Figures in the table are relative to the counts per minute of labeled precursor in control experiments at the end of 5 min.

In addition, treatment of *E. coli* GK-19 with potassium cyanide, sodium azide, and 2,4-dinitrophenol, which are known inhibitors of respiration and energy production, was undertaken; Id was added simultaneously or at varying times after the addition of the inhibitors. The results are portrayed in Fig. 12A-C. With pretreatment times of 30 and 120 min, the antibacterial effect of Id is markedly reduced, which further indicates that cellular respiration or energy, in part at least, is likely required for the lytic effect of Id on *E. coli* to be manifested.

A similar study with chloramphenicol, which is an inhibitor of protein synthesis, showed that protein synthesis is required for the lysis of cells (Fig. 12D). It is concluded that in order for Id to exert its maximum lytic effect, normal respiration, energy production, and protein synthesis are required. Because of the cellular physiological functions that were affected by Id, it was suspected that macromolecular synthesis, in general, could also be affected. The conviction that protein synthesis was a site of action of this Mannich base was strengthened by its inhibition of the biosynthesis of the enzyme β-galactosidase. In *E. coli* GK-19, it is possible to induce the synthesis of this enzyme within 2-3 min with isopropylthiogalactoside (17), but addition of Id to a culture of this microorganism abolished the ability of the cells to synthesize this enzyme.

The effect of Id on the synthesis of DNA and RNA was measured using radioactively labeled thymidine and uracil, respectively, and the results are shown in Table I. The data indicate that while the synthesis of DNA is virtually unaffected, the inhibition of RNA synthesis commences after 5 min and is reduced by 66% after 20 min.

In conclusion, this study has unearthed some of the factors which affect the antibacterial activity of 1-(2,4-dichlorophenyl)-4-dimethylaminomethyl-1-nonen-3-one hydrochloride (Id) against *E. coli* GK-19. In addition, the bioactivity of this compound is due, at least in part, to its causation of lysis, and adverse effects on respiration, as well as protein and RNA biosynthesis, take place.

Determination of Amphetamine, Norephedrine, and Their Phenolic Metabolites in Rat Brain by Gas Chromatography

RONALD T. COUTTS ˣ, DANIEL B. PRELUSKY, and GLEN B. BAKER

Received March 29, 1982, from the *Neurochemical Research Unit, Faculty of Pharmacy and Pharmaceutical Sciences* and *Department of Psychiatry, University of Alberta, Edmonton, Alberta T6G 2N8, Canada.* Accepted for publication April 25, 1983.

Abstract □ A specific analytical procedure for the quantitation of amphetamine (I), norephedrine (III), and their amphoteric metabolites, *p*-hydroxyamphetamine (II) and *p*-hydroxynorephedrine (IV), in biological samples using electron-capture gas chromatography (GC-EC) is described. The procedure utilizes the ion-pairing reagent, bis(2-ethylhexyl)phosphoric acid, which frees the amines from most contaminants and permits the efficient extraction of the amphoteric compounds (as acetates) from the aqueous solution. Amines I and III and acetylated amines II and IV were perfluoroacetylated prior to GC-EC analysis. Metabolism of I, II, and III in the rat brain was studied. Results indicate that both *in vivo* and *in vitro* amines I and III are *p*-hydroxylated to II and IV, respectively, and II is β-hydroxylated to give IV. Norephedrine (III) was not detected as a rat brain metabolite of amphetamine (I).

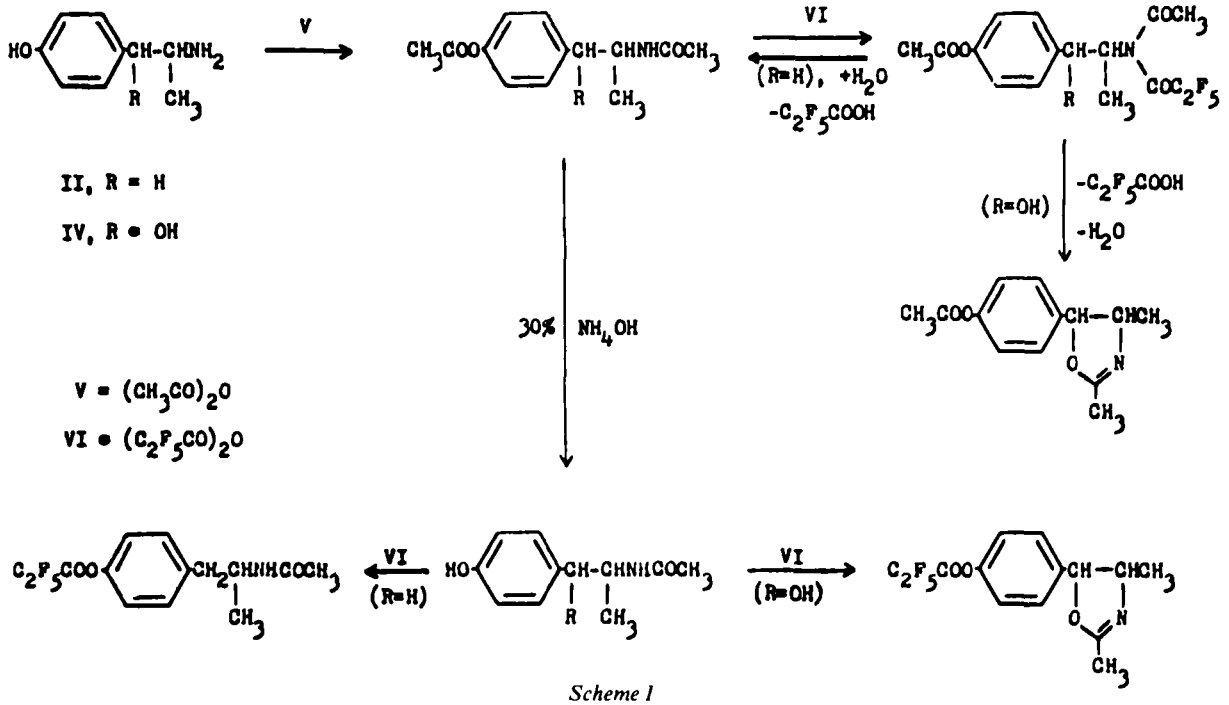

Scheme I

determined (1–11). It has been suggested (2, 5, 12, 13) that amphetamine (I) is first *p*-hydroxylated in the liver, and trace amounts of the resulting *p*-hydroxyamphetamine (II) penetrate the blood–brain barrier and accumulate in brain tissue where β-hydroxylation of II to *p*-hydroxynorephedrine (IV) occurs (14, 15). However, there is alternative evidence from *in vitro* studies to suggest that *p*-hydroxylation of I can also occur in the brain (9).

In a continuation of our studies on trace amines in the brain, we wished to determine whether analytical techniques previously developed (16–18) could be applied to the measurement of amphetamine (I), *p*-hydroxyamphetamine (II), norephedrine (III), and *p*-hydroxynorephedrine (IV) and provide information on the extent to which *p*- and β-hydroxylation occur in the brain tissue.

Current analytical procedures rely on the extraction of the amines into an organic solvent followed by derivatization with a reagent sensitive to electron-capture detection (EC) (2, 11, 19) or utilize technically more complex procedures involving tritiated compounds (1, 6, 8, 9, 11, 13, 14, 20) or mass fragmentography (3, 7). The simple extraction procedure is adequate for the analysis of many amines but usually demonstrates a poor gas chromatographic (GC) detection linearity over wide concentration ranges, as well as a poor sensitivity for phenolic amines, which are normally inefficiently extracted from aqueous solution.

We now report a rapid analytical method that permits the identification and efficient quantitation of amphoteric compounds (II and IV) in tissues and that can be employed to improve the GC sensitivity limits of simple amines (I and III). By utilizing this analytical procedure the levels of I–IV in rat brain tissues were determined after intraperitoneal administration of each amine. The results of an *in vitro* study on the metabolism of I–III with rat brain homogenate is also reported.

EXPERIMENTAL

Animal Studies—Male Sprague-Dawley rats (150 ± 20 g) were used. For the *in vivo* studies, rats were injected intraperitoneally with equimolar quantities (74 μmol/kg) of amphetamine hydrochloride[1], *p*-hydroxyamphetamine hydrobromide[1], norephedrine hydrochloride[2], and *p*-hydroxynorephedrine hydrobromide[2], (*i.e.*, 10.0, 11.19, 11.19, and 12.37 mg/kg, respectively, calculated as the free bases). Physiological saline was used as the vehicle, and injection volumes of ~0.3 mL were employed. Control rats received the same volume of vehicle without drug. All animals were sacrificed exactly 60 min after injection. The complete brain was rapidly removed, homogenized in three volumes of cold 0.4 M perchloric acid, and centrifuged at 10,000×*g* for 15 min. Supernatant equal to 1.0 g of whole brain tissue was used in the analyses.

For the *in vitro* studies, the whole brains from untreated rats were removed, homogenized in three volumes of ice-cold 1.15% KCl solution, and centrifuged at 10,000×*g* for 20 min. Supernatant corresponding to 0.5 g of the original tissue was incubated at 37°C with shaking in open 15-mL Erlenmeyer flasks containing an NADPH-generating system (20 μmol of glucose 6-phosphate[3], 20 μmol of magnesium chloride, and 4.4 μmol of NADP[4]) in Tris-HCl buffer (pH 7.4) and 1.0 μmol of the appropriate substrate (total volume 3.8 mL). Incubations were terminated after 60 min by the addition of 0.2 mL of 2.0 M perchloric acid. *In vitro* experiments were performed in triplicate.

Extraction and Derivatization—The samples [*in vivo* brain supernatant (4 mL) or *in vitro* incubation mixture (4 mL)], to which 1.0 μg of 2-(*p*-chlorophenyl)ethylamine[5] was added as internal standard, were adjusted to pH 7.8 by the addition of solid potassium bicarbonate and centrifuged (2000×*g*) to remove any precipitate formed. The supernatant was then extracted with 5.0 mL of a 2.5% solution of bis(2-ethylhexyl)phosphoric acid[6] in chloroform. After separation of the two phases, the aqueous layer was discarded and the chloroform layer was back-extracted with 3.0 mL of 0.5 M HCl.

Method a—For the analysis of I and III, the acid layer was adjusted to a pH value of >10.5 and extracted with 4.0 mL of ethyl acetate. The organic layer was evaporated to dryness under a stream of nitrogen, and the residue was pentafluoroacylated and treated further as described below.

Method b—For the analysis of II and IV, the acid layer was made slightly basic by addition of solid sodium bicarbonate, 300 μL of acetic anhydride (V) was added to the basified solution followed by small additional quantities of sodium bicarbonate with shaking until all effervescence ceased, and the so-

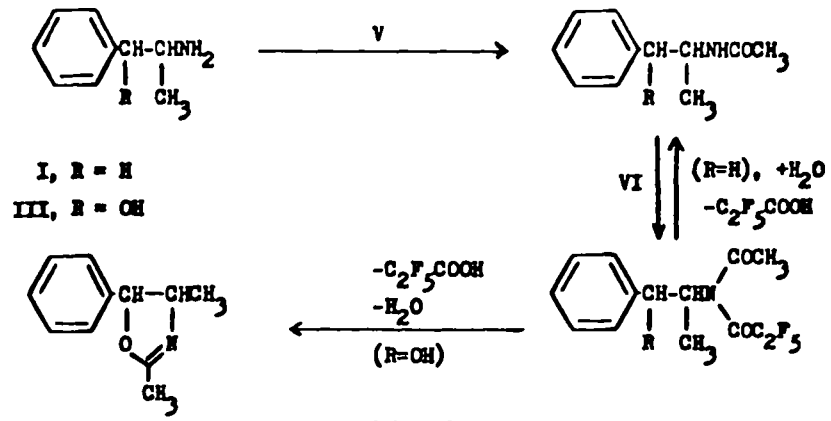

Scheme II

lution was extracted with 4.0 mL of ethyl acetate. To the separated organic layer, 300 μL of a 30% NH_4OH solution was added and the mixture was vortexed for 40 min. After neutralization of the NH_4OH solution, the layers were separated by centrifugation. The ethyl acetate layer was then evaporated to dryness in a stream of nitrogen.

The residues obtained from each of the methods were separately dissolved in a mixture of 35 μL of ethyl acetate and 75 μL of pentafluoropropionic anhydride (VI)[7], and the ensuing reaction was allowed to proceed at 85°C for 1 h. Each mixture was reduced in volume under a stream of nitrogen and partitioned between toluene (200 μL) and 0.1 M sodium phosphate buffer (200 μL; pH 7.4). Each organic layer was retained for GC analysis.

Instrumentation—Analyses were performed with a gas chromatograph[8] equipped with a 15-mCi ^{63}Ni-source linear EC detector. A fused silica capillary column (Carbowax 20M, 12 m) was used with temperature programming, 80–220°C at 20°C/min, and injection port and detector temperatures of 250°C. The carrier gas was helium at 7 psi; argon–methane (95:5) at a flow rate of 36 mL/min was used as the make-up gas at the detector. The mass spectrometer[9] separator and ionization source temperatures were 180°C with an ionization energy of 70 eV. The gas chromatographic column and operating conditions were as described above. All spectra were consistent with the structures assigned; the mass spectra are described elsewhere[10].

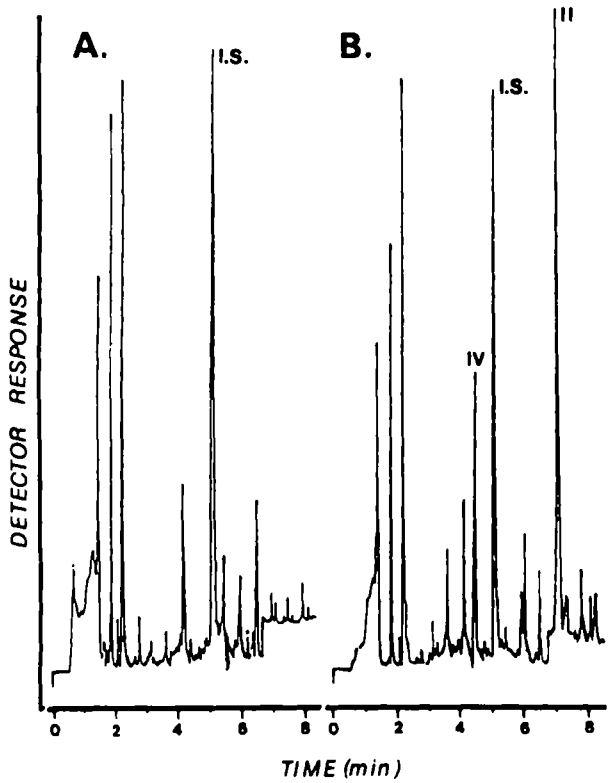

Figure 1—*Typical chromatograms of rat brain extracts which have been derivatized by method b. Key: (A) from rats injected with physiological saline; (B) from rats injected with norephedrine; (II) derivatized norephedrine; (IV) derivatized p-hydroxynorephedrine; (I.S.) derivatized internal standard.*

RESULTS AND DISCUSSION

Amphetamine (I), norephedrine (III), and their metabolites, *p*-hydroxyamphetamine (II) and *p*-hydroxynorephedrine (IV), were present in brain samples in trace concentrations. An analytical technique was required which would not only permit the adequate extraction of I–IV from aqueous solution, but also eliminate the interference created by the simultaneous extraction of endogenous contaminants. Such interference was found to be a particularly troublesome problem when utilizing GC–EC detection methods following the perfluoroacylation of sample extracts.

The described method proved to be a suitable analytical procedure. The four amines were efficiently extracted from brain supernatant or *in vitro* incubation mixtures with chloroform containing the ion-pairing reagent, bis(2-ethylhexyl)phosphoric acid (21) and were recovered from the organic solution by extracting the latter with dilute hydrochloric acid. The amine-containing aqueous solution was now free of most contaminants. The reextraction of the amphoteric metabolites II and IV into an organic solvent was made possible by their prior acetylation in the basified aqueous medium with acetic anhydride (V) to lipophillic *N,O*-diacetates (Scheme I). This acetylation procedure also converted amphetamine (I) and norephedrine (III) to their *N*-acetates (Scheme II). The β-hydroxyl group of either III or IV did not undergo acetylation.

Attempts were made to pentafluoroacylate the extracted acetates to increase their sensitivities to GC–EC. However, the *N*-pentafluoropropionyl derivatives of all four *N*-acetylated derivatives proved to be unstable. The derivatives of I and III rapidly lost the pentafluoroacetate moiety by hydrolysis, and the derivatives of III and IV cyclized to GC–EC-insensitive oxazoline products (Schemes I and II). The problem of insufficient sensitivity was overcome for II and IV by the preferential hydrolysis of the *O*-acetate moiety of their *N,O*-diacetates using ammonium hydroxide. This treatment freed the phenolic hydroxyl group for reaction with VI and resulted in the formation of the final derivatives identified in Scheme I. These *O*-pentafluoroacetyl derivatives were stable for at least 2 weeks if refrigerated. Typical GC traces are shown in Fig. 1.

Since neither amphetamine (I) nor norephedrine (III) contains a phenolic group, the analytical procedure just described for the analysis of II and IV was not applicable to the quantification of I and III; a separate analytical procedure was necessary for the latter two amines. They were directly removed from the aforementioned dilute hydrochloric acid solution containing I–IV by basifying the solution and extracting it with ethyl acetate. The extracts were treated with VI and the resulting *N*-pentafluoropropionyl derivatives (Scheme III) proved to be both stable to hydrolysis and GC–EC sensitive. This procedure permitted effective recovery and detection of both I and III without interference from the amphoteric metabolites.

Overall recoveries for the compounds (based on 100-ng amounts), using the methods described above, were as follows: I (87.7 ± 0.6%), II (65.0 ± 2.7%), III (80.3 ± 1.2%), IV (52.7 ± 2.5%), and internal standard (80.1 ± 1.7%); values represent mean ± *SD* ($n = 3$). The structures of all final de-

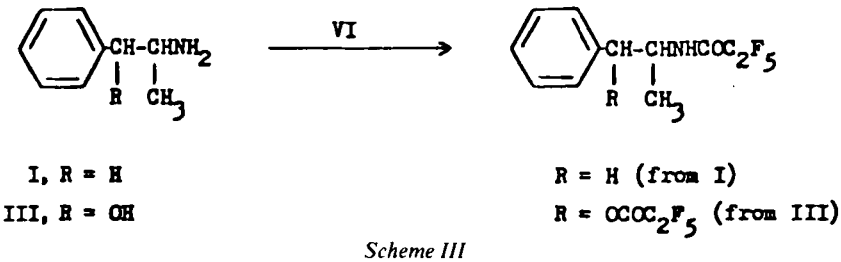

Scheme III

rivatized products were confirmed by mass spectrometric analysis. Calibration plots of the derivatized form of all four amines were constructed using varying quantities of each amine and 2-(*p*-chlorophenyl)ethylamine as internal standard. All plots were linear over a 10–10,000-ng range. The minimal detection level of each amine was 10 ng/g of tissue sample.

The levels of substrates and metabolites found in whole brain tissue after intraperitoneal injection of rats with equimolar quantities of each amine are given in Table I. Levels of I, II, and IV after administration of amphetamine (I) are comparable to values obtained in other studies (2, 4, 5, 19, 20). Rat whole brain levels of III and IV after intraperitoneal injection of norephedrine (III), of *p*-hydroxynorephedrine (IV) after its intraperitoneal injection, and of II and IV after intraperitoneal injection of *p*-hydroxyamphetamine (II) have apparently not been determined previously.

Rat whole brain levels of *p*-hydroxyamphetamine (II) (114.1 ng/g), resulting from the administration of amphetamine (I) were significantly higher ($p < 0.025$; Student's t test) than those obtained (74.9 ng/g) when II was injected directly. Thus, even if all the intraperitoneally injected I had been metabolized to II in the liver (and this had not occurred—see Table I), this would not account for the levels of II observed. One possible explanation of these is that *p*-hydroxylation of I to II occurs in the rat brain to an appreciable extent. Similar results were observed when norephedrine (III) was the substrate. Although 80.9 ng/g of *p*-hydroxynorephedrine (IV) was measured in brain tissue after injection of IV, this does not fully account for the significantly higher ($p < 0.01$) brain levels (131.7 ng/g) of IV detected after injection of III.

Attempts to show that norephedrine (III) was an *in vivo* rat brain metabolite of amphetamine (I) were unsuccessful. If any III was so formed, it was in an amount which was below the detection limit of the assay (10 ng/g). This failure to detect III in rat tissues after intraperitoneal injection of I agrees with previous reports (6, 9, 15). In contrast, Lewander (2) detected [^{14}C]III in rat brain after injection of [^{14}C]I, although the levels measured (<10 ng/g of tissue) were below the detection limits of most other analytical procedures. Kuhn *et al.* (9) found appreciable amounts of III in brain following the intracisternal injection of amphetamine (I).

In vitro studies using rat brain 10,000×*g* homogenate supernatant confirmed that both *p*- and β-hydroxylating enzymes are present in brain tissue (Table II). Metabolism of amphetamine (I) (1.0 μmol) produced trace amounts of II (0.744 nmol) and IV (0.498 nmol), but no norephedrine (III). The incubation of III (1.0 μmol) similarly produced IV (0.789 nmol); conversion of II (1.0 μmol) to IV (1.117 nmol) was also demonstrated. These metabolic conversions were not observed *in vitro* in the absence of brain homogenate supernatant.

CONCLUSIONS

A sensitive analytical procedure has been developed that permits extraction and analysis of amphetamine, norephedrine, and their *p*-hydroxylated metabolites from rat brain. The phenolic metabolites are derivatized by a combination of aqueous acetylation, specific basic hydrolysis of phenolic acetyl groups, and perfluoroacylation under anhydrous conditions. The procedure permits the analysis of *p*-hydroxyamphetamine and *p*-hydroxynorephedrine without interference from amphetamine or norephedrine; this is particularly important in the study reported here, since in the *in vitro* investigation concentrations of the parent compounds were many times higher than those of the metabolites. The results obtained with this procedure suggest that (*a*) both amphetamine (I) and norephedrine (III) are *p*-hydroxylated to some extent in rat brain, both *in vivo* and *in vitro*, (*b*) *p*-hydroxyamphetamine (II) undergoes intracerebral conversion to *p*-hydroxynorephedrine (IV), and (*c*) norephedrine (III) could not be detected as either an *in vivo* or an *in vitro* brain metabolite. Thus, the results of this preliminary study suggest that a β-hydroxylation of *p*-hydroxyamphetamine, but not of amphetamine, occurs in rat brain. Factors such as differential metabolism and elimination rates in brain and liver must be considered, and future comprehensive time studies in these two organs may yield additional information on the formation of amphetamine metabolites.

Hypolipidemic Activity of 4-Phenyl-5,5-dicarbethoxy-2-pyrrolidinone in Rodents

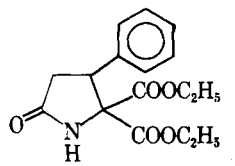
I. H. HALL ˣ, G. H. COCOLAS, and P. J. VOORSTAD

Received March 11, 1983, from the *School of Pharmacy, University of North Carolina at Chapel Hill, Chapel Hill, NC 27514.* Accepted for publication May 12, 1983.

Abstract □ A series of pyrrolidinones have been reported to possess hypolipidemic activity in mice. The most active agent, 4-phenyl-5-5-dicarbethoxy-2-pyrrolidinone, effectively lowered both serum cholesterol and triglyceride levels at 20–30 mg/kg/d. The agent suppressed liver mitochondrial citrate exchange, phosphatidate phosphohydrolase, and *sn*-glycerol-3-phosphate acyl transferase activities. Lipid content of the liver, small intestine, and serum lipoprotein fractions was reduced by drug treatment, but lipid levels increased in the bile and fecal samples, suggesting the drug accelerated lipid excretion. The mode of action of the pyrrolidinone appears similar to that of the cyclic imides.

Keyphrases □ 4-Phenyl -5,5- dicarbethoxy -2- pyrrolidinone—hypolipidemic activity, rodents □ Hypolipidemic agents—potential, 4-phenyl-5,5-dicarbethoxy-2-pyrrolidinone, rodent screen

A series of substituted 2-pyrrolidinones have previously been examined for hypolipidemic activity in mice and have been observed to be active between 20–30 mg/kg/d. Similarly, types of moieties such as succinimide (1) also have hypolipidemic activity in the dosage range. One particular compound, 4-phenyl-5,5-dicarbethoxy-2-pyrrolidinone (2), demonstrated potent activity and lowered serum cholesterol and triglycerides >40% at 30 mg/kg/d after 16 d. The current study involves the mode of action of 4-phenyl-5,5-dicarbethoxy-2-pyrrolidinone in lowering lipid levels of the body.



4-Phenyl-5,5-dicarbethoxy-2-pyrrolidinone

EXPERIMENTAL

Antihyperlipidemic Screens in Normal Rodents—4-Phenyl-5,5-dicarbethoxy-2-pyrrolidinone was suspended in 1% aqueous carboxymethylcellulose and administered to male CF_1 mice (~25 g) intraperitoneally for 16 d or male Holtzman rats (~350 g) orally by an intubation needle for 14 d. On days 9 and 14 or 16, blood was obtained by tail vein bleeding, and the serum was separated by centrifugation for 3 min. The serum cholesterol levels were determined by a modification of the Liebermann–Burchard reaction (3). Serum was also collected on day 14 or 16, and the triglyceride content was determined using a commercial kit[1].

Testing in Atherogenic Mice—Male CF_1 mice (~25 g) were placed on a commercial diet[2] which contained butterfat (400 g), cellulose[3] (60 g), cholesterol (53 g), choline dihydrogen citrate (4 g), salt mixture oil[4] (40 g), sodium cholate (20 g), sucrose (223 g), vitamin-free casein (200 g), and total vitamin supplement for 10 d. After the cholesterol and triglyceride levels were assayed and observed to be elevated, the mice were administered the test drug at 20 mg/kg/d ip for an additional 12-d period. Serum cholesterol and triglyceride levels were measured after 12 d of drug administration.

Animal Weights and Food Intake—Periodic animal weights were obtained during the experiments and expressed as a percentage of the animals' weights on day 0. After dosing for 14 d with the test drug, selected organs were excised, trimmed of fat, and weighed.

Toxicity Studies—The acute toxicity (LD_{50} value) (4) was determined in male CF_1 mice by administering the test drug intraperitoneally from 100 mg to 2 g/kg as a single dose. The number of deaths were recorded over a 7-d period for each group.

Enzymatic Studies—*In vitro* enzymatic studies were determined using 10% homogenates of male CF_1 mouse liver with 50–200 μmol of the test drug. *In vivo* enzymatic studies were determined using 10% homogenates of liver obtained from male CF_1 mice after administering the agents for 16 d at a dose ranging from 10 to 60 mg/kg/d ip. The liver homogenates for both *in vitro* and *in vivo* studies were prepared in 0.25 M sucrose plus 0.001 M EDTA.

Acetyl CoA synthetase (5) and ATP-dependent citrate lyase (6) activities were determined spectrophotometrically at 540 nm as the hydroxamate of acetyl CoA formed after 30 min at 37°C. Mitochondrial citrate exchange was determined by the procedure of Robinson *et al.* (7, 8) using sodium [^{14}C]-bicarbonate (41 mCi/mmol) incorporated into mitochondrial [^{14}C]citrate after isolating rat mitochondria (9000×*g* for 10 min) from the homogenates. The exchanges of the [^{14}C]citrate were determined after incubating the mitochondrial fraction, which was loaded with labeled citrate and test drug for 10 min. The radioactivity was then measured in the mitochondrial and supernatant fractions in scintillation fluid[5] and expressed as a percentage. Cholesterol side-chain oxidation was determined by the method of Kritchevsky and Tepper (9) using [26-^{14}C]cholesterol (50 mCi/mmol) and mitochondria isolated from rat liver homogenates. After 18 h of incubation at 37°C with the test drug, the generated $^{14}CO_2$ was trapped in the center well in {2-[2-(*p* - 1,1,3,3-tetramethylbutylcresoxy)ethoxy]ethyl}dimethylbenzylammonium hydroxide[6] and counted[5]. 3-Hydroxy-3-methylglutaryl CoA reductase (HMG CoA reductase) activity was measured using [1-^{14}C]acetate (56 mCi/mmol) and a postmitochondrial supernatant (9000×*g* for 20 min) incubated for 60 min at 37°C (10). The digitonide derivative of cholesterol was isolated and counted (11). Acetyl CoA carboxylase activity was measured by the method of Greenspan and Lowenstein (12). Initially, the enzyme had to be polymerized for 30 min at 37°C and then the assay mixture containing sodium [^{14}C]bicarbonate (41.0 mCi/mmol) was added and incubated for 30 min at 37°C with the test drug. Fatty acid synthetase activity was determined by the method of Brady *et al.* (13) using [2-^{14}C]malonyl CoA (37.5 mCi/mmol), which was incorporated into newly synthesized fatty acids that were extracted

with ether and counted[5]. *sn*-Glycerol-3-phosphate acyl transferase activity was determined with L-[2-^{3}H]glycerol-3-phosphate (7.1 Ci/mmol) and the microsomal fraction of the liver homogenates (14). The reaction was terminated after 20 min, and the lipids were extracted with chloroform–methanol (1:2) containing 1% concentrated HCl and counted. Phosphatidate phosphohydrolase activity was measured as the inorganic phosphate released after 15 min by the method of Mavis *et al.* (15). The released inorganic phosphate after development with ascorbic acid and ammonium molybdate was determined at 820 nm.

Liver, Small Intestine, and Fecal Lipid Extraction—In male CF_1 mice that had been administered the test drug for 16 d, the liver, small intestine, and fecal materials (24-h collection) were removed and a 10% homogenate in 0.25 M sucrose–0.001 M EDTA was prepared. A 2-mL aliquot of the homogenate was extracted by the methods of Folch *et al.* (16) and Bligh and Dyer (17), and the number of milligrams of lipid was determined. The lipid was taken up in dichloromethane and cholesterol level (3), triglyceride levels[7], neutral lipid (18), and phospholipid content (19) were determined.

[^{3}H]Cholesterol Distribution in Rats—Male Holtzman rats (~350 g) were administered the test agent orally for 14 d. On day 13, 10 μCi of [^{3}H]cholesterol was administered intraperitoneally in mice and orally in rats, and feces were collected after 24 h. Twenty-four hours after cholesterol administration, the major organs were excised and samples of blood, chyme, and urine were obtained. Homogenates (10%) were prepared of the tissues, which were combusted[8] and counted[5]. Some tissue samples were plated on filter paper[9], dried, and digested for 24 h in base[6] at 40°C and counted[5]. Results were expressed as dpm per total organ.

Cholesterol Absorption Study—Male Holtzman rats (~400 g) were administered the test drug intraperitoneally for 14 d at 20 mg/kg/d. On day 13, 10 μCi of [1,2-^{3}H]cholesterol (40.7 mCi/mmol) was administered to the rat orally. Twenty-four hours later, the blood was collected and the serum separated by centrifugation (20). Both the serum and the precipitate were counted[5].

Bile Cannulation Study—Male Holtzman rats (~400 g) were treated with the test drug at 20 mg/kg/d orally for 14 d. The rats were anesthetized with chlorpromazine[10] (25 mg/kg ip) followed after 30 min by pentobarbital[11] (22 mg/kg ip). The duodenal section of the small intestine was isolated, and ligatures were placed around the pyloric sphincter and distally to a site approximately one-third down the duodenum. Sterile isotonic saline was injected into the sectioned-off duodenal segment. The saline expanded the duodenum and the common bile duct. Once the bile duct was identified, a loose ligature was placed around it, an incision was made, and plastic tubing[12] was introduced into the duct. Once past the ligature, the tubing was tied in place, and the ligatures around the duodenum were removed. Once bile was freely moving down the cannulated tube, [1,2-^{3}H]cholesterol (40.7 mCi/mmol) was injected subcutaneously into the rats. The bile was collected over the next 6 h and the volume was measured. Aliquots were counted[5] as well as analyzed for cholesterol (3), neutral lipid (18), and phospholipid (19) content[13].

Plasma Lipoprotein Fractions—Male Holtzman rats (~400 g) were administered the test drug at 20 mg/kg/d for 14 d. On day 14, blood was collected from the abdominal aorta. The serum was separated from whole blood by centrifugation at 3500 rpm. Aliquots (3 mL) were separated by density gradient ultracentrifugation according to the method of Hatch and Lees (21) and Havel *et al.* (22) into the chylomicrons and very low-density, high-density, and low-density lipoproteins. Each fraction was analyzed for cholesterol (3), triglycerides[7], neutral lipids (18), phospholipids (19), and protein levels (23).

RESULTS

Data are expressed in the tables as mean percent of control ± *SD*. The probable significant level (p) between each test group and the control group was determined by the Student's t test.

4-Phenyl-5,5-dicarbethoxy-2-pyrrolidinone proved to be a potent hypolipidemic agent in both mice and rats by the oral route as well as intraperitoneally (Table I). A dose-response curve showed that cholesterol levels were lowered approximately the same, 47–50%, at 10, 30, and 60 mg/kg/d. Serum triglyceride levels were reduced 52% maximally at 30 mg/kg/d in mice. In rats the serum cholesterol and triglyceride levels were approximately the same at 20 mg/kg/d as those observed in mice. After inducing a hyperlipidemic state in mice, in which case serum cholesterol levels were elevated 183% (354 mg%) above control values (125 mg%), drug treatment at 20 mg/kg reduced serum cholesterol to 184 mg%, 47% above normal. Serum triglyceride levels in the hyperlipidemic mice were elevated 168% (367 mg/dL) above control values. Drug administration lowered triglycerides to 176 mg/dL, which was 28% above normal triglyceride values (138 mg/dL).

In vitro enzyme assays (Table II) showed that the presence of the drug caused a decrease in mitochondrial citrate exchange to the cytoplasm, with 200 μM resulting in a 31% reduction. Cholesterol side-chain oxidation was reduced 44% at 100 μM. Phosphatidate phosphohydrolase activity was suppressed in a dose-dependent manner, with 200 μM resulting in 74% inhibition. *sn*-Glycerol-3-phosphate activity was lowered 31% at 200 μM.

In the *in vivo* enzymatic studies (Table III), marginal inhibition was observed in ATP-dependent citrate lyase at 60 mg/kg (13%) and in acetyl CoA synthetase at 10 (22%) and 60 mg/kg (32%). HMG CoA reductase activity was slightly inhibited at 40 and 60 mg/kg by 16–17%. Acetyl CoA carboxylase activity was suppressed 16% at 40 mg/kg/d. The maximum effect of the drug appeared to be on phosphatidate phosphohydrolase and *sn*-glycerol-3-phosphate acyl transferase activities. 4-Phenyl-5,5-dicarbethoxy-2-pyrrolidinone reduced phosphatidate phosphohydrolase activity 57% at 40 mg/kg/d and 41% at 60 mg/kg/d. *sn*-Glycerol-3-phosphate acyl transferase activity was reduced in a dose-dependent manner, with 60 mg/kg/d causing 48% reduction.

In an attempt to determine if the lipids were being removed from the blood compartment and being deposited in the tissues, the liver and small intestine were examined for lipid content after drug treatment (Table IV). In the liver, cholesterol was lowered 27%, triglycerides 29%, neutral lipids 45%, and phospholipids 24%. In the small intestine, cholesterol levels were reduced 12%; however, marked reduction of triglyceride levels was evident (80%). The drug treatment did not affect [^{3}H]cholesterol absorption from the intestine over a 24-h period after oral administration. Nevertheless, biliary excretion of lipids

Table V—Effects of 4-Phenyl-5,5-dicarbethoxy-2-pyrrolidinone on Rat [^{3}H]Cholesterol Distribution 24-h After Administration and Organ Weights After 14 d of Administration Orally

	Organ Weight, g		[^{3}H]Cholesterol/Total Organ, dpm	
	Control	Treated	Control	Treated
Brain	1.97	1.97	5877	1232
Lung	2.60	1.70	7069	3632
Heart	1.33	1.20	4004	1280
Liver	14.47	12.67	47429	25328
Kidney	3.37	3.13	8170	2592
Spleen	0.67	0.77	2315	2633
Adrenal	0.0504	0.050	—	—
Stomach	2.97	2.43	11375	1440
Small intestine	10.17	6.33	41656	73152
Large intestine	4.10	3.57	14104	10832
Chyme	2.57	7.58	9226	30048
Feces	2.63	5.03	8349	9664

was altered by drug treatment. Cholesterol excretion was elevated 12%, neutral lipids 37%, and phospholipids 21%. The fecal sample also demonstrated increases in lipid content, *i.e.*, 17% and 37% increases in cholesterol and triglycerides, respectively, and a 21% reduction in phospholipids.

Examination of the lipoprotein fractions of the blood showed reduction of cholesterol content in all four fractions. Triglycerides were lowered in chylomicrons and in the very low-density fraction, which contain most of the triglyceride content of the lipoprotein fractions. Neutral lipids were also lowered in the chylomicron, very low-, and low-density lipoprotein fractions. Phospholipid content was elevated in these three fractions. Examination of the effects of drug treatment on [^{3}H]cholesterol distribution in the body shows that there is a reduction of cholesterol in the brain, lung, heart, liver, kidney, and stomach (Table V). However, high concentrations of labeled material were found in the small intestine (76%), chyme (226%), and feces (16%). The organ weights of the treated animals were lower than those of the control animals. The LD_{50} in mice was >2 g/kg ip.

DISCUSSION

4-Phenyl-5,5-dicarbethoxy-2-pyrrolidinone proved to be a potent hypolipidemic agent, lowering serum cholesterol and triglyceride levels >45%. The agent was more active than clofibrate, which is inactive at 10–60 mg/kg/d. Clofibrate requires dosages of 150–200 mg/kg/d to reduce cholesterol ~15% and triglyceride levels 25%. The pyrrolidinone was active in the dosage range where succinimide (1) had proven to be active as well as the cyclic imide, phthalimide, saccharin, and 1,8-naphthalimide (24). In fact, its mode of action of lowering serum lipids seems to be similar to the cyclic imides. For example, inhibition of mitochondrial citrate exchange would lower the cytoplasmic levels of acetyl CoA, a key intermediate precursor in the *de novo* synthesis of cholesterol and fatty acids. Two regulatory enzymes of the triglyceride pathway, phosphatidate phosphohydrolase and *sn*-glycerol-3-phosphate acyl transferase activities, were inhibited by the pyrrolidinones as well as the cyclic imides. Positive correlations between the inhibition of the activities of these enzymes with the lowering of serum triglyceride levels have been made previously (14).

Removal of lipids from the blood was not related to an increase in organ lipids. Three observations support this thesis: (*a*) the lipid content of liver and small intestine was actually reduced; (*b*) there was no increase in organ weights over the control values; (*c*) the [^{3}H]cholesterol content was lower in the major organs of the treated animals compared with the control animals.

The lipids appeared to be excreted in the bile at an accelerated rate after drug treatment. This excretion of [^{3}H]cholesterol was also reflected in the higher radioactive content observed in the small intestine, chyme, and feces. Similar observations have been made with phthalimide and saccharin (25).

Cholesterol, triglycerides, and neutral lipid content of rat serum lipoprotein fractions were also lowered by treatment with the pyrrolidinones. Cholesterol content probably did not change when examining the high-density to low-density ratio. High cholesterol in the high-density lipoprotein fraction and low content in the low-density lipoprotein supposedly protects against myocardial infarction. Nevertheless, lowering the cholesterol content of the low-density lipoprotein fraction is probably beneficial since this is the lipoprotein fraction which deposits lipids in the atherosclerotic plaque. These preliminary studies do suggest that pyrrolidinones may have potential as hypolipidemic agents and are worthy of further study.

Novel Device for Quantitatively Collecting Small Volumes of Urine from Laboratory Rats

ANDRE J. JACKSON *x and JOHN C. SUTHERLAND‡

Received November 5, 1982, from the *Department of Pharmaceutics, School of Pharmacy and the ‡ University of Maryland Cancer Center, University of Maryland, Baltimore, MD 21201. Accepted for publication May 26, 1983.

Abstract □ A reusable urinary collection device suitable for quantitative collection of uncontaminated urinary samples from rats without using a metabolism cage has been designed. The device can be attached to the pelvic skin within 5 min with minimum handling and discomfort to the unanesthetized rat using an adhesive. The suitability of this device was investigated by collecting and analyzing urine over a 48-h period following the intraperitoneal injection of [^{14}C]inulin. A two-way crossover study was done with samples from one of the two experiments being collected while the animal was housed in a commercially available metabolism cage equipped to separate urine and feces. The percent of the dose excreted, food and water consumption, and the urinary output were not statistically different for rats housed in the metabolism cages or with the collection device attached. Histopathological examination of the rats revealed no pathology after a 24-h period except minor skin inflammation which occurred both in controls and animals to which the device was attached. These studies demonstrate the comparability of the new urine collection device to a commercially available metabolism cage in the quantitative collection of small (0–7 mL) urine samples with less contamination of the samples from the environment.

Keyphrases □ Urine collection—quantitative, rats, reusable device, comparison with metabolism cages

The preclinical evaluation of a drug requires that the acute and chronic toxicity, metabolic pattern, and bioavailability be evaluated in animal species. Two of the primary species utilized in preclinical screening are rats and mice. These species have proven useful because of their low cost, minimal holding space, relatively short life span, and defined genetic lineage. Several recent reports have presented data related to the bioavailability of drugs in rats and mice comparing gavage with administration in the diet (1, 2).

Despite the reported results, a major concern in these and other studies that require analysis of urinary and fecal data is the possible contact and resultant contamination of these excreta by each other or by the environment. A new commercially available cage[1] has made progress in this area, but it still cannot completely eliminate contamination of urine by either animal fur-containing food particles or contact between urine and feces, especially if the animal has diarrhea.

There are currently several modified metabolism units which have been presented in the literature (3, 4). The general approach to the construction of these units has been to place the animal in a cage with a stainless steel floor and then, utilizing either another screen of smaller mesh or a funnel with various designs, to effect the separation and collection of urine and feces. However, flat-bottom and polycarbonate metabolism cages have proven unsatisfactory because of food contamination of urine and contamination of samples for GC analysis by leached plastics following repeated washes of the polycarbonate cage with benzene (3). The modified unit, which is quite similar to those commercially available, still utilizes the same basic principles and in addition has metal in direct contact with the urine prior to collection (3).

A urine-collecting device (patent pending) has been developed in our laboratory that (*a*) prevents contact and assures 100% separation of urine and feces, (*b*) gives a quantitative collection of small (0–7 mL) urine samples comparable with those obtained with a commercially available metabolism cage, (*c*) is devoid of metal in its design, and (*d*) is resistant to organic solvents. The application of this device to the quantitative collection of urine from rats is described in this report.

EXPERIMENTAL

Materials—[Carboxy-^{14}C]inulin[2] had a specific activity of 2.02 μCi/mg. Phosphate-buffered saline contained 92 mM sodium chloride, 23 mM dibasic sodium phosphate, and 11 mM monobasic sodium phosphate. A commercially available metabolism cage[3] was used for comparison to the urine collection device[4].

Urine-Collecting Device Design—A perspective side photograph of a rat with the collection device attached to the pelvic region is presented in Fig. 1. The collection device apparatus is shown schematically in Fig. 2, with portions represented in phantom.

The mounting plate has a projecting funnel which receives the penis of the rat (or urethral region for female animals), with the plate being adhered to the pelvic skin by a quick-drying methylcyanoacrylate adhesive[5]. The mounting plate is made from either acetal resin[6] or acetal resin coated with polymethyl methacrylate[7] with the container being constructed of either material. The urine collector and funnel are separate units joined by screw threads disposed around a cylindrical projection or annulus at the mouth of the funnel. Screw threads couple with screw threads in an opening through the top wall of the container, with the container being essentially a chamber that is vented in the top wall.

To empty the container, a drain is positioned in the end wall. The drain is threaded and plugged with a nylon screw. Urine can be sampled with a syringe or by merely removing the container from the funnel. A metal set screw, which is not in contact with the collecting chamber, is utilized as a detent to keep the longitudinal axes of the container and mounting plate aligned. The set screw is advanced to set in an indentation formed in the bottom surface of the funnel mounting plate. When the screw is advanced to set tightly in the indentation, the container rotates with difficulty about the axis of the funnel. Consequently, the container remains in place and thus eliminates urine loss and the amount of gnawing which the rat can do to the mounting plate.

Attachment of the Urine Collecting Device—The hair was removed from the region around the penis using small animal clippers[8] fitted with a size 40 blade, without the use of soap since surfactants interfere with subsequent bonding of the funnel to the skin. In addition, the abdomen of female animals was shaven using a disposal razor (again without soap). The skin was then cleaned with isopropyl alcohol, and the methyl cyanoacrylate glue was applied as a thin film to the mounting plate to effectively bond it to the skin. Attachment was accomplished by having the rat restrained by hand while the mounting plate was positioned. (During the attachment the animal can be restrained by hand with careful alignment of the penis or urethral opening (female rats) with the funnel opening; contact between the respective urethral opening and the adhesive should be avoided.) Bonding was rapid (1–5 min). Curing occurs best at a relative humidity of 58–68%. Once the plate was firmly attached, the container was screwed onto the funnel.

Although still in place at 24 h, the edges of the mounting plate may not be as securely bonded to the skin due to normal turnover of epidermal cells and the animals tendency to gnaw at this surface, but the device can be rebonded

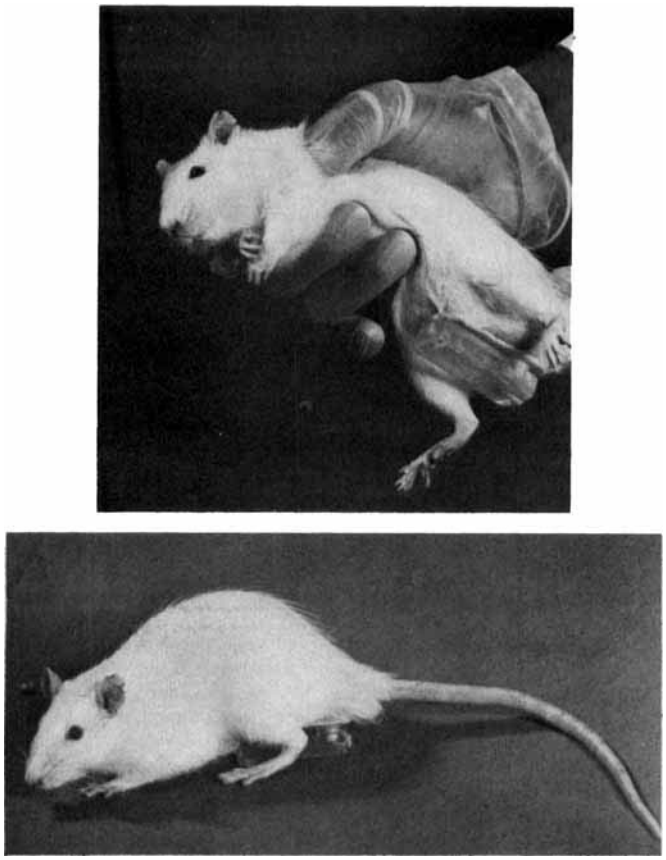

Figure 1—*Photographs (lateral and ventral views) of a rat which has had the urine-collection device attached to the pelvic skin for a 48-h period.*

readily by application of the adhesive to the mounting plate in any exposed area. Although not done in these studies, the animal can be lightly anesthetized with ether and the funnel sutured around the edges after attachment with the glue[9]. Either acetone or nail polish remover can be applied to the skin to remove the device at the termination of the study if only glue is used for attachment. The collection device can also be gently pulled from the abdomen with some minor discomfort to the animal.

Experimental Design—The comparison of the urinary excretion of [^{14}C]inulin administered in phosphate-buffered saline (pH 7.4) to 12 male Dub (SDD) rats[10] was investigated using the metabolism cage and the urine collection device. The animals were divided into three groups (50–200 g; 200–400 g; >400 g) with four animals in each group. A comparative excretion study was also done in eight female rats (four/group) with weights ranging between 50–200 g and 200–400 g. One microcurie of [^{14}C]inulin was administered intraperitoneally (0.5 mL) using a 1-mL plastic syringe fitted with a 27-gauge needle. Animals were housed in a metabolism cage (after being prepared similar to device-carrying rats) or in a regular stainless steel cage while the urinary collection device was attached. Food pellets[11] and distilled water were provided *ad libitum*. Urine was sampled by restraining the rat by hand, removing the drain screw, and collecting the samples using a syringe.

All samples were analyzed by liquid scintillation counting. The collection period for all studies was 48 h with animals randomly receiving either treatment. Following a 7-d washout period, the rats received the other treatment, *i.e.*, those animals that had been housed in metabolism cages had the urine collection device attached while animals that had urine collected with the urine device were housed in metabolism cages for urine collection. Food and water consumption, urinary output, and percent inulin recovered in urine were determined for each collection method at 48 h.

Histopathology—In a separate study using nine male rats (150–550 g) and nine female rats (100–400 g), the attachment area was examined for evidence of pathology. The rats were equally divided into three groups, with the rats in control groups I and II having their pelvic region shaven or shaven with glue (identical lot) applied, respectively. Animals in treatment group III were

shaven with the urine collection device attached for a 24-h period. After 24 h the animals in groups I and II were anesthetized with ether and necropsied. Sections were taken of the skin of the lower abdomen adjacent to the penis, the urinary bladder, and one testicle for male animals. For female animals, the skin adjacent to the urethral opening, vagina, uterus, ovaries, and urinary bladder were evaluated.

Rats from treatment group III were similarly examined following removal of the urine in the urine collection device. Sections of the aforementioned tissues were fixed in 10% formaldehyde, embedded, sectioned, and stained with hematoxylin and eosin for histopathological examination.

RESULTS

Urinary Excretion of Inulin—Data for the urinary collection of [^{14}C]inulin over the 48-h period is presented in Table I. Food and water consumption, urinary volume, and percent inulin recovered were not significantly different for the two methods of urine collection. Urine samples collected with the device were free from contamination, while those collected while the animal was housed in the cage contained elements from the environment such as food, hair, and feces.

Histopathology—*Male Rats*—Intradermal abscesses were observed in the skin from six rats. Four of these animals were controls: one was from control group II, shaven plus adhesive, while the other three were from control group I, in which the animals were only shaven. The abscesses were usually superficial, although a rat from control group II exhibited more extensive abscesses extending into the superficial dermis with a mild infiltration of polymorphonuclear leucocytes into the superficial fat. Such infiltration was also seen in one of the rats carrying the collection device and in one control animal from group II. Inflammation was always localized, never extending beyond the boundaries of the shaved area of skin.

A slight infiltrate of eosinophilic leucocytes was seen in the subcutaneous tissue of the penis for two rats in control group II and one animal in treatment group III. The urinary bladders all appeared normal, except in two of the animals in control group I where there was a small amount of blood in each bladder. The testicles in all animals were unremarkable. Two of the animals that had the collection device attached showed dilated preputial glands, and in one of these animals a plug was found that appeared to be desquamated squamous cells from a preputial gland. These results are summarized in Table II.

Female Rats—No pathological findings were noted in the ovaries or the urinary bladder. The chief findings were those in the skin. Like the male rats, there were epidermal abscesses noted in one rat which was only shaven and in all of those shaven with glue applied and the cup-bearing rats. Inflammation increased, extending into the dermis, for both rats to which glue had been applied and the cup-bearing rats. Also two rats from each of these groups showed abscesses in the dermis. Inflammation continued into the fat for these two groups. Sections of the vaginas showed a few polymorphonuclear leucocytes in the mucosa of all rats. Two rats, both shaven with glue applied, appeared to have long-standing vaginal infections with pus. In the second and third groups (shaven with glue and cup-bearing), there were a few more polymorphonuclear leucocytes in the wall of the vagina as compared with those only shaven.

Eosinophils were found in the wall of all vaginas, with two rats having more

eosinophils than the others. One of these was a rat which had been shaven with glue applied and another was a cup-bearing rat. Otherwise, the eosinophilic distribution seemed about equal. Examination of uteri showed eosinophils in the submucosa and muscularis of the uteri of all rats with very little difference between the three groups. A summary of these pathological findings is presented in Table II.

DISCUSSION

The accurate collection and evaluation of data from experimental animals utilized in toxicity feeding, pharmacokinetic, and metabolic studies is essential in the preclinical screening of biologically active drug products. Current methods of collecting urinary samples are somewhat compromised because of the tendency of these samples to become contaminated by the environment. The method presented in this report provides a means of accomplishing this objective with overall rat response similar to that of those housed in a standard metabolism cage. Based on the results of the study, it would appear that the device is well tolerated by laboratory rodents and did not appear to alter their food and water consumption nor their excretion of inulin. The urinary collection device is suitable for male and female rats as evidenced by the results from the current study.

Table II—Number of Rats in which Pathological Abnormalities were Found *versus* the number of Rats Examined

Pathological Observation	Treatment: Shaven Only	Treatment: Shaven Plus Adhesive	Urine Collecting Device Attached
Intraepidermal abscess(es), cup site	4/6	4/6	5/6
Abscess(es) in superficial dermis, cup site	2/6	2/6	5/6
Acute inflammation of dermis, diffuse	4/6	4/6	4/6
Acute inflammation of penile skin	1/3	1/3	2/3
Acute vaginitis	3/3	3/3	3/3
Eosinophilia in skin, cup site	0/6	2/6	1/6

Preparing the abdominal region for device attachment appears to be a limitation, since hair removal of this area with clippers resulted in intradermal abscesses of the abdominal and, in some cases, penile skin. The presence of abcesses in both control and treated groups (male and female) indicates that the preparation of the area was the primary cause, not device attachment. The presence of the mild infiltrate of eosinophilic leucocytes suggested a slight hypersensitivity to the adhesive, which is consistent with the manufacturer's report of a mild irritant effect to the skin from the adhesive. Dilation of the preputial glands (male and female rats) was the only histological observation that was exclusive to device-carrying animals. Therefore, one would conclude that the acute pathology associated with the device is indeed minor.

Because of the limited capacity of this self-contained unit, it will not allow quantitative collection over 24 h without intermittent collections. Nevertheless, judicious utilization of the urine collection device in conjunction with other established methods of rodent urine collection could prove a valuable tool. It would be especially applicable in validating urinary excretion data obtained from rodents by conventional methods during toxicological feeding, pharmacokinetic, or metabolic studies without removing the animals from their normal environment.

Abstract □ The stability of aqueous solutions of luteinizing hormone-releasing hormone (LHRH) after extended storage at various temperatures was investigated using a newly developed HPLC assay and an *in vitro* dispersed pituitary cell culture bioassay. Good correlations were obtained between the potency obtained by HPLC and bioassay in samples stored at 37°C or subjected to different stress conditions. No significant decrease in activity of LHRH was observed in aqueous solutions stored at 37°C for up to 10 weeks, at 4°C for 2 years, or subjected to repeated freezing and thawing for 5 d. Heating to 60°C in sterile pH 9.0 buffer up to 11 d and storage at ambient temperature in nonsterile solution for 4 months produced well-distinguished degradation products and a decrease in potency. It is concluded that sterile aqueous solutions of LHRH are stable for at least 10 weeks at 37°C and, thus, could be reliably used for chronic administration when long-term stability at body temperature is important.

Keyphrases □ Luteinizing hormone-releasing hormone—stability, aqueous solutions, *in vitro* bioassay, HPLC □ Stability—LHRH, aqueous solutions, *in vitro* bioassay, HPLC □ Degradation—LHRH aqueous solutions, *in vitro* bioassay, HPLC

Luteinizing hormone-releasing hormone (LHRH), isolated from porcine hypothalami by Schally *et al.* (1), was found to release both luteinizing hormone and follicle-stimulating hormone from the pituitary of several species, including humans (1, 2). LHRH has recently been found to be clinically useful in stimulating gonadotropin release, testicular development (3–5), and follicular maturation and ovulation (6, 7) in hypogonadotropia in humans, especially when small doses of LHRH are administered chronically by intermittent intravenous injection (8–10) or by a portable infusion pump (11–13).

We have evaluated the stability of LHRH solutions under commonly used storage conditions and after long-term exposure to body temperature (37°C) to determine how long and under what conditions LHRH solutions might be utilized for chronic hormone administration. LHRH activity was assayed by *in vitro* pituicyte bioassay as well as a newly developed HPLC technique.

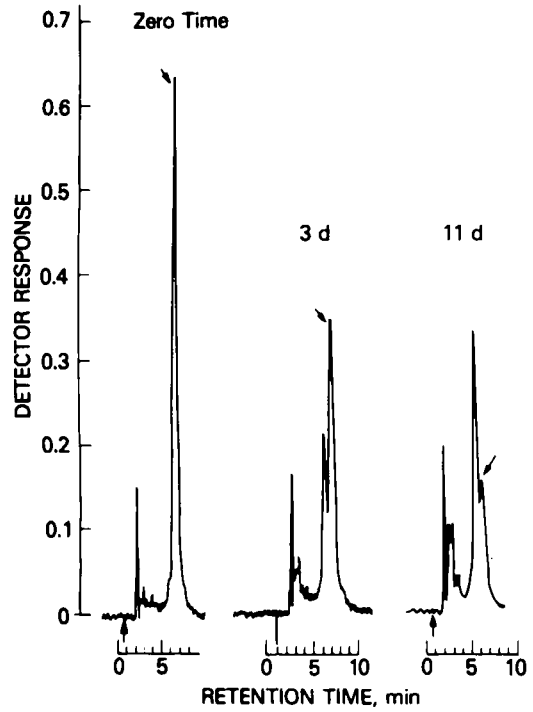

Figure 1—*HPLC profile of LHRH solutions prepared in 0.01 M borate buffer (pH 9.0) kept at 60°C for 0, 3, and 11 d. The arrows indicate intact LHRH peaks.*

EXPERIMENTAL

General Experimental Protocol—Sterile stock solutions of synthetic LHRH[1] were prepared at a concentration of 1 mg/mL in distilled water or 0.01 M borate buffer (pH 9.0). Aliquots (1 mL) of the stock solution were dispensed into 2-mL glass vials and sealed with polytef-lined stoppers. The samples were stored at various temperatures as specified below. At selected time intervals, two individual vials were removed and stored at −20°C for

Table I—Stability of LHRH at 60°C

	Day	Potency, % HPLC	Potency, % Bioassay	
	0	100	100	
Distilled water	3	96	118	($p > 0.25$)
	11	96	142	($p > 0.25$)
Buffer pH 9.0	3	40	15	($p < 0.02$)
	11	5	7	($p < 0.01$)

subsequent analysis: one was analyzed by HPLC and the other by an *in vitro* bioassay using dispersed rat anterior pituitary cells in culture. The potency of all treated samples was compared with freshly prepared LHRH solutions.

Experiment 1—To check the specificity of the HPLC analysis, stock solutions of LHRH in distilled water and in borate buffer pH 9.0 were heated to 60 ± 2°C in a constant-temperature oven for 0, 3, and 11 d. The potency of the samples was anlayzed by both HPLC and bioassay.

Experiment 2—To provide a different set of degradation products to test the specificity of HPLC assay, a degraded LHRH solution was prepared by leaving a nonsterile solution of LHRH at ambient temperature for 4 months. Three mixtures of LHRH solutions were then prepared: (A) 90% fresh LHRH + 10% degraded LHRH, (B) 90% fresh LHRH + 10% normal saline, and (C) 100% degraded LHRH solution. Solution B was used as the control sample.

Experiment 3—To determine the long-term stability at body temperature, stock LHRH solutions in distilled water were kept at 37 ± 0.1°C in a constant-temperature water bath, and the activity of LHRH was assayed by HPLC and pituitary cell culture. Samples were incubated for 0, 4, 6, and 10 weeks in the first experiment and for 0, 10, and 27 weeks in a second study.

Experiment 4—To obtain the long-term shelf life, sterile solutions of LHRH were stored for 2 years at 4°C. The LHRH potency was determined by the HPLC method alone.

Experiment 5—To evaluate the effect of accidental freezing and thawing, one set of samples was stored at −20°C in a freezer but subjected to a 1-h thaw at room temperature every day for 5 d. The potency of the frozen and thawed samples was compared with the original control vials, which remained frozen until HPLC assay.

Liquid Chromatographic Assay of the LHRH Solution— HPLC was performed on a 25 cm × 4-6 mm i.d. reverse-phase column[2] using a liquid chromatograph[3] equipped with a variable-wavelength detector[4] and a fixed-volume injector[5]. A mobile phase of acetonitrile–acetic acid–sodium hexylsulfonate–water (35:0.1:0.2:64.7) at a flow rate of 1.6 mL/min was used as the eluant. Retention time of LHRH was 6.0 min under these conditions.

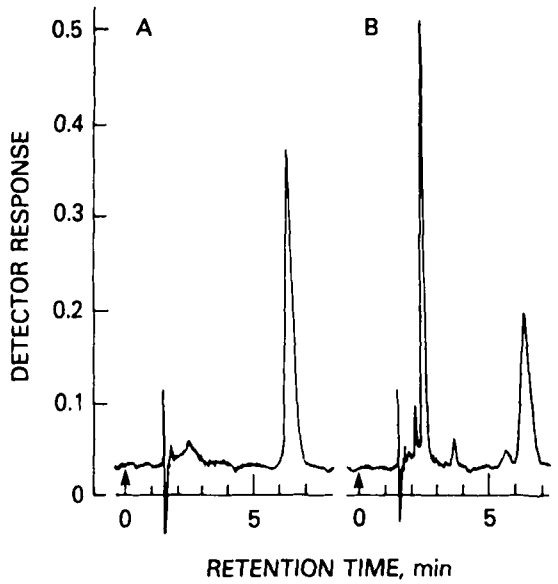

Figure 3—*HPLC profile of nonsterile LHRH solutions stored at ambient temperature. Key: (A) time zero; (B) 4 months.*

Table II—Specificity of the HPLC Assay

Solution	Potency, % HPLC	Potency, % Bioassay	
A	106	106	($p > 0.25$)
B	100	100	($p < 0.001$)
C	55	31	

Testosterone, which was used as internal standard in a few runs to check the quantitation accuracy, had a retention time of 11.5 min. The wavelength for quantitation was 220 nm.

Solutions of LHRH were diluted quantitatively to 20 μg/mL, and 50 μL of this solution was injected using the fixed-loop injector. Testosterone, when added to check the accuracy, was added at a concentration of 10 μg/mL in the mobile phase used for dilution of stock LHRH solutions. Either the peak height of LHRH or peak height ratio of LHRH to testosterone was used for quantitation. The potency of the treated samples was compared with the freshly prepared samples.

Bioassay of the LHRH Solutions—The bioactivity of LHRH was assessed by quantitating the release of luteinizing hormone into the media of dispersed rat anterior pituitary cells placed into short-term monolayer culture according to the method of Vale *et al.* (14). The control and experimental LHRH samples were added to the cell culture in the dose range of 10^{-7}–10^{-10} M for 3 h, and the medium was then aspirated, centrifuged to remove any suspended cells, and the luteinizing hormone concentration was measured by double-antibody RIA using LHRH-1 as standard (15). Reagents were provided by the NIAMDDK National Hormone and Pituitary Program. All samples from one experiment were measured individually in duplicate in a single assay to eliminate between-assay variation. The assay detection limit was 2 ng/mL.

Statistical Analysis—All bioassay results are presented as the mean ± *SEM*. Potency estimates were determined within each cell culture experiment relative to the LHRH stock solution prepared on day 0. Each LHRH dose-response curve was first tested for linearity (*t* test) and then for parallelism (*F* test) to the control curve prior to the estimation of potency. The relative precision (x) for symmetrical experimental designs was determined according to the method of Finney (16).

RESULTS AND DISCUSSION

Specificity of the Liquid Chromatographic Method and Its Correlation with the Bioassay—The HPLC method gave sharp and reproducible peaks for LHRH, and the height of the LHRH peak was directly proportional to the concentration of LHRH in a series of freshly prepared solutions. The HPLC profile of LHRH in borate buffer pH 9.0 heated to 60°C showed a degradation product peak which was well separated from the intact LHRH peak (arrow, Fig. 1). The small shoulder (corresponding to the retention time of the degradation product) in the time-zero sample in Fig. 1 is, however, attributible to a chromatographic artifact. Purity of the LHRH peak was verified by comparison of the retention times and peak height ratios at 210, 220, and 230 nm of the sample peaks to those from a freshly prepared solution of LHRH. Solutions of LHRH in distilled water were stable after being heated to 60°C for up to 11 d. By contrast, significant loss of integrity was observed at pH 9.0 during the same time interval. The results of the HPLC assay correlated well with those obtained by bioassay (Fig. 2, Table I). The potency of the mild

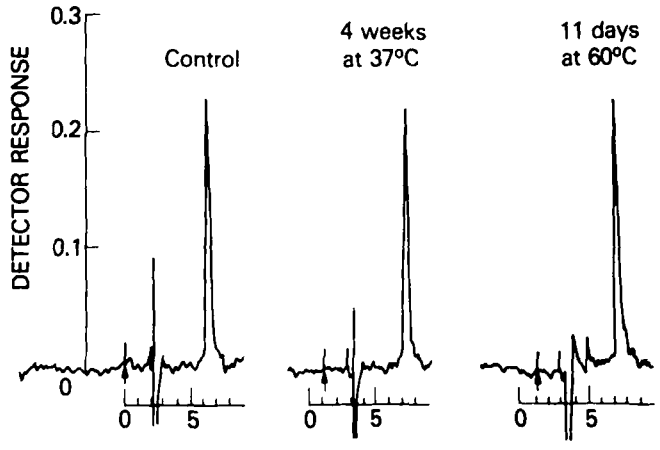

Figure 4—*HPLC profile of LHRH solutions prepared in distilled water kept at 60°C for 11 d or at 37°C for 4 weeks.*

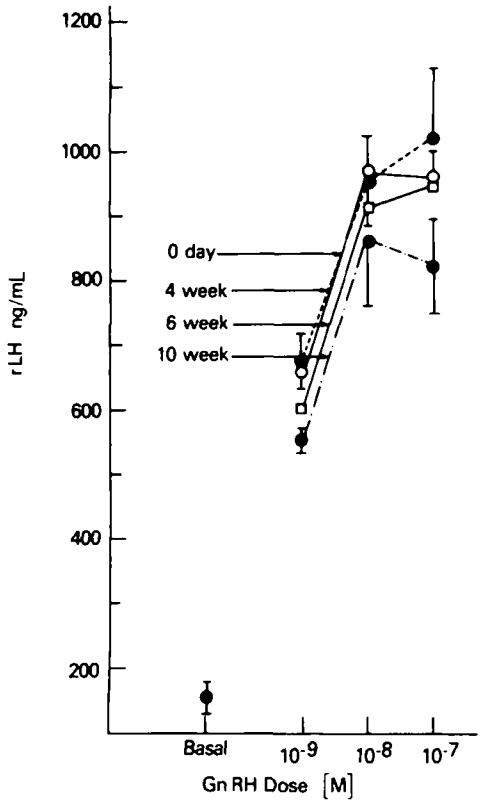

Figure 5—*Luteinizing hormone release from dispersed rat pituitary cells in culture following incubation with LHRH solutions prepared in distilled water (pH 6) and kept at 37°C for 0, 4, 6, and 10 weeks.*

alkaline solution of LHRH stored at 60°C for 11 d was 5% by the HPLC assay and 7% by bioassay.

The HPLC profile of the degradation product of the nonsterile LHRH solution stored at ambient temperature for 4 months was different from that obtained from LHRH solution stored at 60°C in borate buffer (Fig. 3). The potencies of this degraded LHRH product were 55 and 31% when assayed by HPLC and pituitary cell culture, respectively (Table II). There was no significant difference in the potency between LHRH solutions mixed with normal saline or the degradation product at a final concentration of 10% (Table II).

Analysis of the HPLC assay shows that under the conditions tested in this study (*a*) it gives reproducible LHRH peaks both in terms of retention time and peak height ratio at three different wavelengths, (*b*) the intact LHRH peak can be distinguished from the degradation peak(s) produced from two separate stress conditions, and (*c*) the chemical integrity of LHRH obtained by HPLC assay correlates well with the biological potency obtained by pituitary cell culture. It is concluded, therefore, that the reported HPLC method can be used as a rapid and reliable assay.

Stability of the LHRH Solution—The HPLC chromatograms and the LHRH response curves of pituitary cultures of some representative solutions of LHRH in distilled water kept at 37°C are shown in Figs. 4 and 5 and Table III. The potency of LHRH in samples stored at 37°C for 27 weeks was reduced 10% as measured by HPLC, but showed a 40–50% decrease by bioassay between 10–27 weeks. The significant difference between the HPLC and bioassay results for the 27-week sample is real, as confirmed by reassaying samples from the same vial by both HPLC and bioassay (experiment 2, Table III). Bacterial contamination cannot be completely ruled out as a possible cause of this difference.

LHRH stored at 4°C for up to 2 years and that subjected to repeated freezing and thawing for 5 d retained 94 ± 2% and 95 ± 2%, respectively, of their chemical integrity by HPLC. These results indicate that LHRH survived for at least 10 weeks at 37°C and for at least 2 years when refrigerated. Accidental freezing and thawing causes no change in the HPLC profile, and short-term exposure to 60°C does not induce significant deterioration of the peptide hormone in distilled water as assayed by either HPLC or the biological response of pituitary cell culture. It appears that a sterile LHRH solution is adequately stable for formulation and storage either frozen or refrigerated and could be reliably used in pumps for at least 10 weeks.

Our results also demonstrate that a nonsterile solution of LHRH at ambient temperature was chemically degraded 45% in 4 months. Based on HPLC assay

Table III—Stability of LHRH in Distilled Water at 37°C

Experiment	Weeks	Potency, % HPLC	Potency, % Bioassay	
1	0	100	100	
	4	98	100	$p > 0.25$
	6	96	65	$p < 0.2$
	10	90	47	$p < 0.02$
2	0	10	100	
	10	92	66	$p < 0.2$
	27	89	60	$p < 0.05$

values of sterile LHRH solutions at 4°C or 37°C, storage for 4 months at ambient temperature of LHRH should produce little degradation. The increased degradation is probably attributable to bacterial contamination, which causes a dramatic loss of activity of polypeptides[6]. This might also explain the shorter stability of LHRH solutions observed by Dermody *et al.* (17) at 4°C (stable for 14 weeks at 4°C compared with 2 years in our experiments). They observed bacterial contamination in their solutions stored at 4°C, and the rather abrupt loss of activity reported by them between 14 and 23 weeks suggests that LHRH degradation was catalyzed by bacteria. One should, therefore, be careful in extrapolating the stability data presented in this paper to nonsterile solutions of LHRH.

Identification and isolation of degradation products was not attempted in this investigation. However, it is known that minor changes in amino acid composition of LHRH impart marked changes in agonist or antagonist bioactivity[7]. Significant differences in the bioassay and HPLC results obtained in our experiments may be due to an altered biological activity of the degradation products.

Received October 27, 1982, from the *Product Development Department, R. P. Scherer North America, Clearwater, FL 33518.* Accepted for publication May 12, 1983.

Abstract □ A rapid and simple high-performance liquid chromatographic (HPLC) method for the analysis of dichlorophen in raw material and in dichlorophen-toluene soft gelatin capsules for veterinary use was developed using a reverse-phase technique. This HPLC system was shown to isolate dichlorophen from its major impurity (the trimer). Three formulations were assayed and were found to contain 7.14, 7.90, and 8.4% of the trimer. A C-18 column was used with a mobile phase of methanol–water (75:25). The flow rate was 1.5 mL/min, and the effluent was monitored at 290 nm for both dichlorophen and the trimer. Dichlorophen and the trimer had retention times of 6.5 and 9.0 min, respectively.

Keyphrases □ Dichlorophen—HPLC, major impurity □ HPLC—analysis of dichlorophen and its major impurity

Dichlorophen (I), 2,2′-methylenebis(4-chlorophenol), is an anthelmintic which is used mainly for the removal of ascarids and hookworms and as an aid in the removal of tapeworms from dogs and cats. Dichlorophen is used in combination with toluene and is available in a soft gelatin capsule formulation for veterinary use. The USP XX (1) does not contain an official monograph for dichlorophen or dichlorophen capsule formulations; however, the British Pharmacopoeia (2) does for dichlorophen tablets. Dichlorophen is often contaminated with a trimer (II), 4-chloro-2,6-bis(5-chloro-2-hydroxybenzyl)-phenol, which is a result of the synthesis process. The trimer constitutes 5–10% by weight of dichlorophen.

The BP (2) method for dichlorophen assay involves a nonaqueous titration. Various analytical methods have appeared in the literature (3–7) for the determination of dichlorophen. Unfortunately, these methods cannot detect the presence of the trimer impurity. The present method offers a rapid and simple high-performance liquid chromatographic (HPLC) procedure for the simultaneous determination of dichlorophen and the trimer in raw material and capsule formulations.

SD [b]	0.74	2.18	0.61

[a] Reported as a percentage. [b] Standard deviation.

EXPERIMENTAL

Materials—Dichlorophen[1] and the trimer[1], were used as received. Methanol and water were HPLC quality[2]. A gradient liquid chromatograph[3] equipped with two single-piston pumps[4] was operated in the isocratic mode. A 20-μL loop injector[5], variable-wavelength detector[6], electronic data printer-plotter[7], and nonpolar column (3.9 mm × 30 cm[8]) were used throughout. The mobile phase consisted of methanol–water (75:25) and was pumped at 1.5 mL/min. The detector was set at 290 nm and sensitivity was 0.018 AUFS.

Sample Preparation—Stock solutions of dichlorophen (60 mg/dL) and the trimer (30 mg/dL) were prepared in methanol. Solutions of dichlorophen containing 5, 9, 12, 15, and 18 μg/mL were prepared in methanol. Solutions of the trimer containing 6, 9, 12, 18, and 24 μg/mL were also prepared in methanol.

One capsule was cut, the fill material was squeezed into a 500-mL graduated cylinder, and the volume was adjusted with methanol. This was allowed to stand for 4 h, and then 8 mL of solution was diluted to 100 mL with methanol. Five milliliters of this diluted solution was further diluted to 50 mL with methanol to produce a solution having approximate concentration of 16 μg/mL. Twenty microliters of the resulting solution was used for analysis.

Calculations—Since linearity experiments indicated that the peak areas (and also peak heights) were related directly to the concentrations of dichlorophen (range 6–18 μg/mL) as well as the trimer (range 6–24 μg/mL), the results were calculated using:

$$\frac{Ph_a}{Ph_s} \times \frac{C}{L} \times D \times 100 = \text{Percent of label claim}$$

Where Ph_a is the peak area for the unknown solution, pH_s is the peak area for standard solution, C is the concentration of standard solution (g/mL), L is label claim (g), and D is the dilution factor (mL)

RESULTS AND DISCUSSION

Dichlorophen contains two phenolic groups. Use of the phenolic properties is made in several methods for the assay of dichlorophen (8); the results ob-

Table II—Analysis of Dichlorophen-Toluene Capsule Formulations by the HPLC Method[a]

Number	Formulation A		Formulation B		Formulation C	
	Dichlorophen	Trimer	Dichlorophen	Trimer	Dichlorophen	Trimer
1	93.2	7.8	99.8	7.5	97.8	9.1
2	92.8	7.4	102.1	7.2	96.4	8.8
3	95.1	7.8	98.6	6.7	97.2	8.6
4	89.9	8.4	100.7	7.3	96.3	7.9
5	93.9	8.1	99.3	7.0	95.4	7.6
Mean	92.98	7.90	100.10	7.14	96.62	8.4
SD^b	1.93	0.37	1.35	0.30	0.92	0.63

[a] Reported as a percentage of the theoretical label claim of 1 g. [b] Standard deviation.

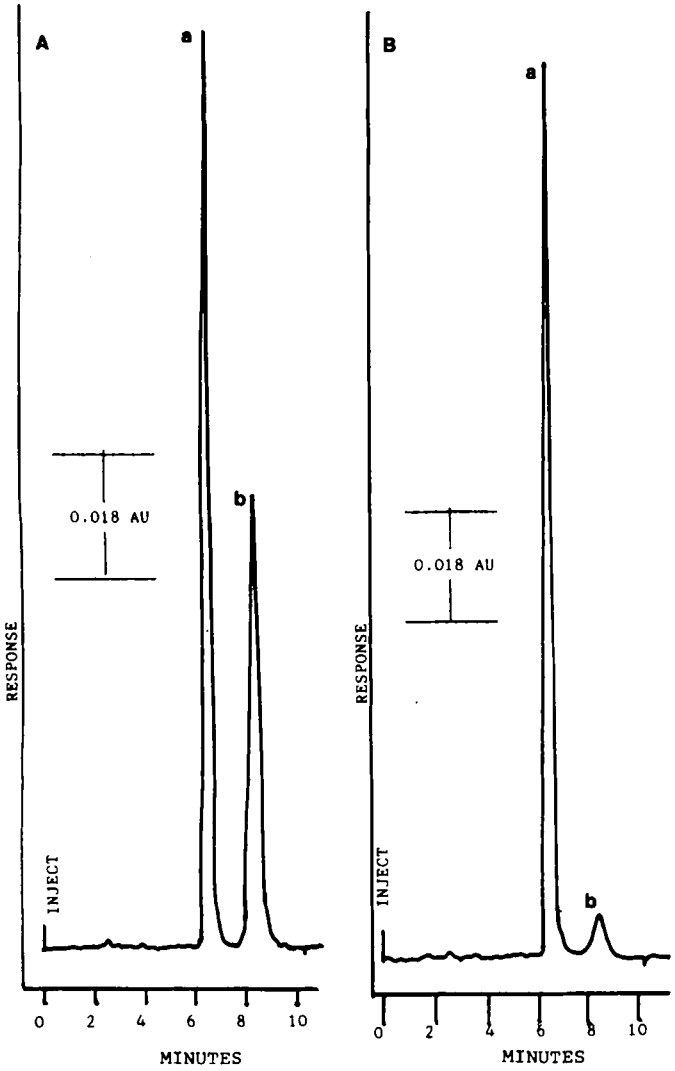

Figure 1—*Typical chromatograms of a standard solution of dichlorophen (19 μg/mL) and trimer (19 μg/mL) (A) and dichlorophen-toluene soft gelatin capsules containing 1 g of dichlorophen. Key: (a) dichlorophen; and (b) trimer.*

tained using these methods included the presence of the trimer. The chromatogram shown in Fig. 1A was obtained for a standard mixture of dichlorophen and the trimer. Figure 1B represents a chromatogram from a dichlorophen-toluene soft gelatin veterinary capsule formulation.

The calibration curve for dichlorophen was linear (r^2 = 0.99) over the concentration range of 6–18 μg/mL. The trimer calibration curve was also linear (r^2 = 0.99) over a concentration range of 6–24 μg/mL. The precision of this method was determined using 20 μL of each of a series of 10 standard solutions containing 12 μg/mL of dichlorophen and 12 μg/mL of the trimer. The coefficient of variation averaged 1.76% for dichlorophen and 2.02% for the trimer.

The recovery data for dichlorophen were determined by adding different amounts of the reference standard equivalent to one-third of the amount of dichlorophen contained in the dichlorophen-toluene veterinary capsules. The analysis of five such samples resulted in recovery values of 99.3, 100.0, 99.7, 101.0, and 99.8% of the total quantity expected. The mean and standard deviation were 99.96 and 0.64, respectively. The recovery data for the trimer were also determined by adding different amounts of the trimer equivalent to one-third of the amount of the trimer contained in the dichlorophen-toluene capsules. The analysis of five such samples resulted in recovery values of 98.2, 98.9, 98.9, 96.5, and 100.5% of the total quantity expected. The mean and standard deviation were 98.60 and 1.46, respectively. Therefore, it was determined from the above data that the assay provides satisfactory accuracy and precision.

Application of the HPLC assay to commercial source dichlorophen raw material provided the results given in Table I. The methoxide titration produced a higher percentage of dichlorophen because this value represents a summation of dichlorophen and the trimer. However, the HPLC procedure differentiated dichlorophen from the trimer, producing lower percentages.

Application of the HPLC procedure to three commercial dichlorophen-toluene soft gelatin veterinary capsules produced the results given in Table II. All formulations were labeled as having 1 g of dichlorophen. Mean dichlorophen potencies were 92.98, 100.10, and 96.62%, with respective standard deviations of 1.93, 1.35, and 0.92. The trimer means were 7.90, 7.14, and 8.40, with respective standard deviations of 0.37, 0.30, and 0.63.

The dichlorophen content for formulations A, B, and C were also determined using the methoxide titration method. This method provided mean dichlorophen potencies of 99.9, 105.0, and 103.0% for formulations A, B, and C, respectively. Again, the methoxide titration provided higher percentages of dichlorophen. The method presented here is rapid, precise, accurate, and simpler than the methoxide titration method. The trimer content in dichlorophen raw material can be easily determined.

Binding of Disopyramide to α_1-Acid Glycoprotein in Plasma Measured by Competitive Equilibrium Dialysis

R. L. G. NORRIS *x, J. T. AHOKAS ‡, P. J. RAVENSCROFT *, and M. HENRY §

Received September 7, 1982, from the *Department of Clinical Pharmacology, Princess Alexandra Hospital, ‡Department of Medicine, University of Queensland, Princess Alexandra Hospital, and the §Department of Chemistry, Queensland Institute of Technology, Brisbane, Qld 4102, Australia. Accepted for publication May 3, 1983.

Abstract □ A modification of equilibrium dialysis in which α_1-acid glycoprotein and plasma compete directly for disopyramide has been used in conjunction with binding curves to measure the extent of the α_1-acid glycoprotein–disopyramide interaction. At concentrations in the therapeutic range, 80–90% of disopyramide was bound to α_1-acid glycoprotein for plasma from each of six healthy adults. Also, equilibrium dialysis data are presented, indicating that pH does not influence the binding of disopyramide within the therapeutic range.

Keyphrases □ Disopyramide—binding to α_1-acid glycoprotein, competitive equilibrium dialysis □ Equilibrium dialysis, competitive—binding of disopyramide to α_1-acid glycoprotein □ α_1-Acid glycoprotein—binding of disopyramide, competitive equilibrium dialysis

The antiarrhythmic drug disopyramide has concentration-dependent plasma protein binding (1) and variability in therapeutic response which may be due, at least in part, to variability in protein binding. An increased number of reports have associated the binding of basic drugs with α_1-acid glycoprotein (2–10). Interindividual variability in the free concentration of the drug and its effect could conceivably be produced by differing concentrations of this protein, as even the reference range for α_1-acid glycoprotein is wide (55–140 mg/dL). As α_1-acid glycoprotein is an acute phase reactant that can approximately double in concentration following acute myocardial infarction (11, 12), its involvement in disopyramide binding may be of even greater significance in this situation.

In previous studies, parameters obtained either from Scatchard plots or the bound fraction of the drug in buffered solution of protein alone were compared with data obtained in plasma (5, 8–10). This approach was also used to implicate α_1-acid glycoprotein in the binding of disopyramide by David *et al*[1]. Others have implied the relationship from correlations of plasma protein concentration with the extent of protein binding (2–4, 6).

To assess the contribution of a specific protein to the total binding occurring in plasma, a more direct evaluation of the interaction would be desirable. The work presented here utilizes a procedure in which the moles of drug bound to protein and to macromolecules in plasma are determined while both protein and plasma compete for the drug. As this procedure is essentially a variation of equilibrium dialysis, we have called the method competitive equilibrium dialysis. The effect of pH on the binding has also been investigated because of its potential importance in binding results.

EXPERIMENTAL

Reagents—The buffer used was 0.1 M Na_2HPO_4 (0.3% NaCl) unless otherwise stated; it was prepared from analytical-grade reagents and distilled water[2]. Disopyramide and the ^{14}C-radiolabeled disopyramide were supplied[3]. The [^{14}C]disopyramide was further purified by HPLC and stored at 4°C in 0.1 M pH 7.4 Na_2HPO_4 buffer containing 0.3% NaCl. The radiochemical purity of the purified disopyramide was >98%. Human α_1-acid glycoprotein purified from Cohn's fraction VI was obtained commercially[4] and used without further treatment. A stock solution of α_1-acid glycoprotein was prepared in buffer, and the concentration was determined from the molar absorbance at 278 nm. Appropriate dilutions were then used to provide all α_1-acid glycoprotein solutions including standards for assays by radial immunodiffusion. Comparison of these standards with commercially available standard human serum[5] indicates the glycoprotein to be >90% pure.

Scintillation Counting—Sufficient [^{14}C]disopyramide was used in all samples to ensure more than 1000 cpm/vial. For all samples, 200-μL duplicates were placed in respective polyethylene vials followed by 2 mL of tissue solubilizer[6]. After mixing and standing for 30 min, 12 mL of scintilation fluid[7] containing 100 μL of glacial acetic acid was added before capping and further mixing. Scintillation counting was carried out until at least 10,000 counts were accumulated using a scintillation counter[8] with external standardization. Means of duplicate counts were used for all calculations. Samples were counted before dialysis to determine specific activities as well as sampling contents of each dialysis compartment at equilibrium.

α_1-Acid Glycoprotein Determinations—Quantitation of α_1-acid glycoprotein employed the method of Mancini *et al.* (13) using radial immunodiffusion plates[9]. Four standards were run per plate. Interassay variability was evaluated by repeated analysis of a single sample, and accuracy was estimated by duplicate analysis of standard human serum containing 92 mg/dL of the glycoprotein[8].

Dialysis—Blood from six healthy volunteers was obtained by venipuncture in plain glass syringes and immediately transferred to EDTA tubes from which the stoppers had been discarded. Plasma was obtained ~30 min later after centrifugation, and the samples assayed for α_1-acid glycoprotein before being stored at −18°C in glass tubes with polytef-lined screw caps.

Each of 20 polymethyl methacrylate dialysis cells having two 1-mL compartments were prepared using dialysis membrane[10] that had been soaked in distilled water for 30–60 min. The experiment consisted of three sections: First, plasma from each of the subjects was dialyzed against six different concentrations of disopyramide in pH 6.7 buffer (pH 7.2 at equilibrium). These results were used to prepare a binding curve for each subject. The second section involved competitive equilibrium dialysis. This was experimentally identical to the first section except sufficient glycoprotein was added to the buffer to produce approximately equal concentrations in opposing compartments of each cell at equilibrium. In the third section, the effect of pH on the binding was evaluated. Three of the disopyramide concentrations used in the binding curve were prepared in pH 6.4 buffer (equilibrium pH 6.9) and pH 7.2 buffer (equilibrium pH 7.6). These solutions were then also dialyzed against plasma. By also utilizing the data from the binding curve, three disopyramide concentrations at three pH values were investigated.

Dialysis was carried out for 5 h at 37°C. These dialysis conditions have been shown to produce equilibrium for disopyramide concentrations (at equilibrium in the plasma) across the range of 1.0–18 mg/L for equilibrium dialysis and across the range of 2.5–10 mg/L during competitive equilibrium dialysis. On conclusion of dialysis in all three sections of the experiment, the contents of each compartment were transferred to glass vials using a 500-μL syringe[11].

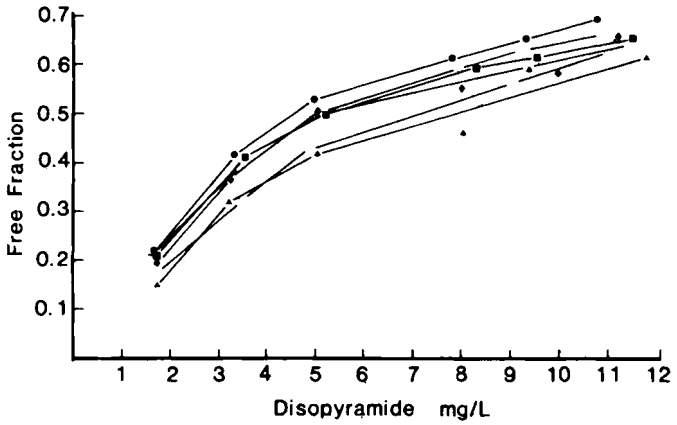

Figure 1—*Relationship of free fraction of disopyramide in plasma to total disopyramide concentration curves for disopyramide. No mathematical curve fitting procedures were used. Key: (■) subject 1; (▲) subject 2; (●) subject 3; (◆) subject 4; (□) subject 5; (○) subject 6.*

The contents of each compartment were then sampled for scintillation counting and α_1-acid glycoprotein assay.

To provide sufficient volume to determine pH, samples were combined in the following manner: For samples from sections 1 and 2, the contents of the plasma side of the dialysis unit from the three lowest disopyramide concentrations were combined; the four highest concentrations were also combined. A similar combination regimen was used for the samples from the buffer side. For samples from section 3, all three concentrations were combined, again keeping plasma side and buffer side samples separate.

RESULTS AND DISCUSSION

Interassay coefficient of variation for α_1-acid glycoprotein assays was 2.2% (n = 17; mean = 84 mg/dL). The results of duplicate analyses of standard human serum (92 mg/dL) were 97 and 100 mg/dL, indicating the accuracy of this method. Ratios of volumes of buffer compartment to plasma compartment at equilibrium were determined for all cells. The mean values ($\pm SD$) of this ratio for all cells dialyzed was 0.92 ± 0.05, illustrating the osmotic effect of the macromolecular components of plasma, as isotonic solutions were used. Total disopyramide concentrations at equilibrium and free fractions were calculated from equilibrium radiolabel concentrations and initial specific activities as per Norris *et al.* (14).

The curves of free fraction of disopyramide against total disopyramide concentration are shown as Fig. 1. These were then used as standard curves to determine the free fraction of disopyramide present after competitive dialysis in respective plasma samples at their equilibrium concentrations. From the free fraction and total drug concentration, the free and bound concentrations in the plasma were calculated. As the free concentration is the same in both compartments at equilibrium, the bound concentrations in the buffer side were also readily calculated. The contribution of α_1-acid glycoprotein to the binding in the plasma was calculated by Eq. 1. This equation assumes equal glycoprotein concentrations in both compartments at equilibrium and, under such conditions, provides direct quantitation of the relative importance of α_1-acid glycoprotein in the plasma protein binding of disopyramide:

$$\text{Fraction of binding attributable to } \alpha_1\text{-acid glycoprotein} = \frac{DISO_\beta^b}{DISO_\beta^p} \qquad \text{(Eq. 1)}$$

where $DISO_\beta^b$ and $DISO_\beta^p$ are the concentrations of disopyramide bound at equilibrium in the buffer and plasma compartments, respectively.

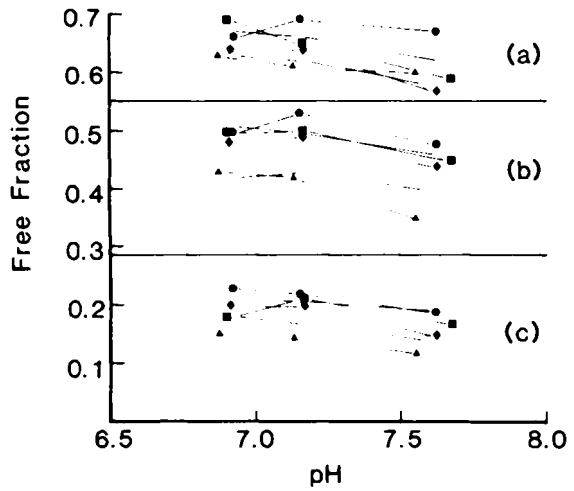

Figure 2—*Effect of pH on the binding of disopyramide to plasma. Symbols as for Fig. 1. Mean (and range) of disopyramide concentrations in plasma equilibrium: (a) 11.2 (10.5–11.8) mg/L; (b) 5.06 (4.74–5.27) mg/L; (c) 1.63 (1.3–1.75) mg/L.*

Table I—Binding Curves and Competitive Equilibrium Dialyses of α_1-Acid Glycoprotein at Equilibrium[a]

6	1.05	0.90	0.88	0.84	0.88

[a] —Missing value.

Table I reports the mean values of α_1-acid glycoprotein concentrations of compartments at equilibrium for each of the subjects. As these results do not show exact agreement in the glycoprotein concentration between compartments, some comment regarding subsequent errors in data obtained from Eq. 1 is necessary. With the relatively narrow range of α_1-acid glycoprotein concentrations being considered for plasma from each subject, it is reasonable to assume that the moles of drug bound varies linearly with the protein concentration. The percent error in data obtained using Eq. 1 is therefore given by:

$$\%\ \text{error} = 1 - \frac{[\alpha_1 AG]^b}{[\alpha_1 AG]^p} \times 100 \qquad \text{(Eq. 2)}$$

where $[\alpha_1 AG]^b$ and $[\alpha_1 AG]^p$ are the concentrations of α_1-acid glycoprotein in the buffer and plasma compartments at equilibrium, respectively.

Application of Eq. 2 to the data in Table I indicates the errors associated with the calculations from Eq. 1 to be 0.3, 12, 8, 12, 2, and 4%, respectively, for subjects 1–6. Data obtained using Eq. 1 is presented as Table II, showing that α_1-acid glycoprotein is responsible for ~80–90% of the binding of disopyramide at concentrations from 2.6 to 9.9 mg/L. Therefore, this glycoprotein is the major binding protein in plasma for disopyramide at therapeutic concentrations.

The free fraction of drug at each of three pH values for three different concentrations is presented as Fig. 2. Variations in pH within the physiological range have no important effect on the protein binding of disopyramide.

In Vitro and *In Vivo* Assessment of Hepatic and Extrahepatic Metabolism of Diazepam in the Rat

YASUTAKA IGARI, YUICHI SUGIYAMA, YASUFUMI SAWADA, TATSUJI IGA ˣ, and MANABU HANANO

Received December 30, 1982, from the *Faculty of Pharmaceutical Sciences, University of Tokyo, Bunkyo-ku, Tokyo 113, Japan.* Accepted for publication April 27, 1983.

Abstract □ Since diazepam is metabolized by many organs in the rat, the microsomal fractions of the liver, kidney, and lung from male Wistar rats were assayed for NADPH-dependent metabolism of diazepam and enzymatic parameters. The predicted extraction ratios were obtained from this *in vitro* experimental system. The organ clearances of the liver, kidney, and lung were then calculated for the determination of the relative contribution of each eliminating organ to the total body clearance (CL_{tot}) of diazepam in the rat. The liver was the most effective eliminating organ, followed by the kidney and the lung, in that order. The hepatic extraction ratio of diazepam was determined *in vivo* after portal and femoral vein administrations of diazepam. The validity of the *in vitro* experimental system for the liver was demonstrated by a good agreement between the calculated hepatic extraction ratio of diazepam from *in vitro* enzymatic parameters (0.616) and that derived *in vivo* (0.648). However, the sum of organ clearances of the liver, kidney, and lung did not account for CL_{tot} of diazepam in the rat, suggesting the possible contribution of the metabolism in the other organs or tissues, or an underestimation of the pulmonary and renal metabolism.

Keyphrases □ Diazepam -metabolism, hepatic and extrahepatic, *in vitro* assessment, comparison with *in vivo* parameters in the rat □ Metabolism—diazepam in the rat, hepatic and extrahepatic, *in vitro* assessment compared with *in vivo* parameters

Diazepam is a clinically important minor tranquilizer which is extensively metabolized by all species studied. However, there are pronounced interspecies differences in the total plasma clearance (CL_{tot}) per unit of body weight that presumably reflect differences in organ intrinsic clearances, blood flow, plasma binding, and the relative contributions of eliminating organs (1). In humans the total clearance is small [26.6 ± 4.1 mL/min (mean ± *SD*; $n = 5$)] (2) and it is assumed to reflect only hepatic metabolism. In contrast, in the rat the total clearance exceeds the liver blood flow, suggesting the involvement of extrahepatic elimination. The relative contribution of different organs to the overall metabolism of a drug may be assessed *in vivo*, but this is often difficult. Instead, comparison is often made between the *in vitro* enzymatic characteristics of an organ. This approach has recently received new impetus, since it has been shown to be readily extrapolated to the whole organ.

In the present study, the *in vitro* experimental system using microsomal fractions was employed to evaluate enzymatic parameters of the hepatic and extrahepatic diazepam elimination systems in the rat. The kidney and the lung were selected as the representative extrahepatic eliminating organs, since these two organs are reported to contain considerable amounts of cytochrome P_{450} (3). Enzymatic parameters of the liver, kidney, and lung were extrapolated to those of the whole organs. Using these parameters, the relative contributions of individual disposing organs were evaluated and, in the case of the liver, compared with an *in vivo* assessment.

EXPERIMENTAL

Materials—Male Wistar rats[1], weighing 250–270 g, on a normal laboratory diet were used throughout. [2-^{14}C]Diazepam (40–60 mCi/mmoL)[2] was used. Unlabeled diazepam[3], demethyldiazepam[4], oxazepam[4], and 3-hydroxydiazepam[4] were gifts from commerical sources. NADP, glucose-6-phosphate and glucose-6-phosphate dehydrogenase were obtained commercially[5]. All other chemicals were reagent grade.

Assay of Radioactivity—[2-^{14}C]Diazepam was diluted with unlabeled drug prior to the studies. The determination of carbon-14 and the assay of labeled drug and its metabolites were described elsewhere (4). The radiochemical purity was >98–99% for [2-^{14}C]diazepam by TLC.

Tissue Preparation and Drug Metabolism Study—Each of the 3–5 separate determinations were conducted on a separate pool of organs, each pool containing organs from 2–10 individual animals. After overnight fasting, the rats were exsanguinated *via* a carotid artery and perfused *in situ* with cold physiological saline *via* the venous trunk just inferior to the renal veins and *via* the portal vein until the effusate became colorless. The liver, kidney, and lung were excised, blotted, weighed, and pooled to obtain 10–11 g of each organ. The preparation of microsomal fractions was described elsewhere (5).

Incubation mixtures for the mixed function oxidation consisted of microsomal protein, 50 mM Tris-HCl buffer (pH 7.4), the NADPH-generating system (1 mM NADP, 10 mM glucose-6-phosphate, 2 U of glucose-6-phosphate dehydrogenase, and 5 mM magnesium chloride), and various amounts of [^{14}C]diazepam diluted with unlabeled diazepam to a final volume of 1.0 mL. The NADPH-generating system, microsomal protein solution, and [^{14}C]diazepam solution were preincubated separately for 2 min at 37°C. The

In Vitro and *In Vivo* Assessment of Hepatic and Extrahepatic Metabolism of Diazepam in the Rat

YASUTAKA IGARI, YUICHI SUGIYAMA, YASUFUMI SAWADA, TATSUJI IGA ˣ, and MANABU HANANO

Received December 30, 1982, from the *Faculty of Pharmaceutical Sciences, University of Tokyo, Bunkyo-ku, Tokyo 113, Japan.* Accepted for publication April 27, 1983.

Abstract □ Since diazepam is metabolized by many organs in the rat, the microsomal fractions of the liver, kidney, and lung from male Wistar rats were assayed for NADPH-dependent metabolism of diazepam and enzymatic parameters. The predicted extraction ratios were obtained from this *in vitro* experimental system. The organ clearances of the liver, kidney, and lung were then calculated for the determination of the relative contribution of each eliminating organ to the total body clearance (CL_{tot}) of diazepam in the rat. The liver was the most effective eliminating organ, followed by the kidney and the lung, in that order. The hepatic extraction ratio of diazepam was determined *in vivo* after portal and femoral vein administrations of diazepam. The validity of the *in vitro* experimental system for the liver was demonstrated by a good agreement between the calculated hepatic extraction ratio of diazepam from *in vitro* enzymatic parameters (0.616) and that derived *in vivo* (0.648). However, the sum of organ clearances of the liver, kidney, and lung did not account for CL_{tot} of diazepam in the rat, suggesting the possible contribution of the metabolism in the other organs or tissues, or an underestimation of the pulmonary and renal metabolism.

Keyphrases □ Diazepam -metabolism, hepatic and extrahepatic, *in vitro* assessment, comparison with *in vivo* parameters in the rat □ Metabolism—diazepam in the rat, hepatic and extrahepatic, *in vitro* assessment compared with *in vivo* parameters

Diazepam is a clinically important minor tranquilizer which is extensively metabolized by all species studied. However, there are pronounced interspecies differences in the total plasma clearance (CL_{tot}) per unit of body weight that presumably reflect differences in organ intrinsic clearances, blood flow, plasma binding, and the relative contributions of eliminating organs (1). In humans the total clearance is small [26.6 ± 4.1 mL/min (mean ± *SD*; $n = 5$)] (2) and it is assumed to reflect only hepatic metabolism. In contrast, in the rat the total clearance exceeds the liver blood flow, suggesting the involvement of extrahepatic elimination. The relative contribution of different organs to the overall metabolism of a drug may be assessed *in vivo*, but this is often difficult. Instead, comparison is often made between the *in vitro* enzymatic characteristics of an organ. This approach has recently received new impetus, since it has been shown to be readily extrapolated to the whole organ.

In the present study, the *in vitro* experimental system using microsomal fractions was employed to evaluate enzymatic parameters of the hepatic and extrahepatic diazepam elimination systems in the rat. The kidney and the lung were selected as the representative extrahepatic eliminating organs, since these two organs are reported to contain considerable amounts of cytochrome P_{450} (3). Figure 1—*Lineweaver-Burk plot of metabolism of diazepam by liver microsomes. Each point represents the mean of 3–5 separate determinations with standard error. The solid line represents the best fit to these data by a least-squares method (10).*

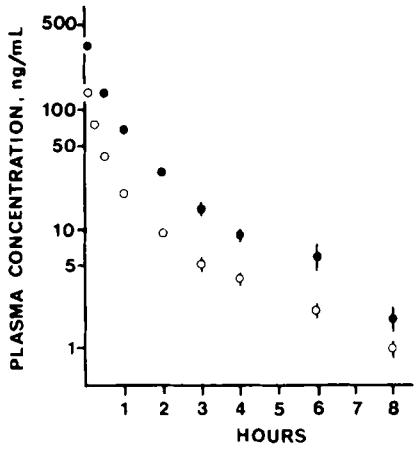

Figure 2—*Concentration-time profiles of diazepam after an injection of diazepam (1.2 mg/kg) intravenously (●) or intraportally (○) in rats (250–270 g). Each datum point represents the mean of 3–5 separate determinations ± SE. The data points without the vertical bars include the* SE *within the symbol mark.*

reaction was initiated by mixing these three solutions. The final concentration of diazepam ranged between 0.05–0.5 μg/mL. The reaction for 2 min at 37°C was stopped by transferring 0.5 mL of the incubation mixture into a stoppered glass tube containing 6 mL of cold benzene and subsequent mixing on an automatic mixer. After extraction and evaporation in boiling water (6), the amount of diazepam metabolized during 2 min was determined as previously described (4).

There are two pathways for diazepam metabolism, and the metabolites are further metabolized (7–9). Therefore, the rate of diazepam metabolized instead of the product formed was used for the enzyme assays. The spontaneous degradation of diazepam in the incubation mixture without the NADPH-generating system during incubation at 37°C did not occur. The recoveries from the extraction were determined and used for the correction. The enzymatic parameters (K_m and V_{max}) of the rat liver, kidney, and lung for diazepam metabolism were determined by Lineweaver-Burk analysis of the data of microsomal metabolism by a least-squares method (data were weighted with reciprocals of their variance) (10) using a digital computer[6].

Animal Experiments—Under light ether anesthesia, the femoral vein and artery were cannulated with polyethylene tubing[7] for intravenous drug administration and blood sampling, respectively. For intraportal venous administration, the portal vein was cannulated with polyethylene tubing[7] attached to a 27-gauge injection needle for drug administration, and the femoral artery was cannulated with polyethylene tubing[7] for blood sampling. Rats were then restrained in a Bollman cage. After 2 h of recovery from anesthesia, [^{14}C]diazepam diluted with unlabeled diazepam (1.2 mg/kg) in 0.25 mL of polyethylene glycol 300 (11) was injected, followed by 0.5 mL of physiological saline. At various times postinjection, a blood sample (0.3 mL) was withdrawn *via* a femoral artery using the cannula into a heparinized polyethylene tube followed by subsequent centrifugation[8]. Plasma samples were treated as described above.

Calculation of the Metabolic Capacity of each Disposing Organ—The enzymatic parameters (K_m and V_{max}) determined in the *in vitro* experimental system using microsomal fractions were extrapolated to those of whole organs as described previously (11–13), and the following calculations were performed. The intrinsic clearance (CL_{int}), related to the enzymatic parameters, is given as follows, assuming a single-enzyme system:

$$CL_{int} = V_{max}/(K_m + C_u) \quad \text{(Eq. 1)}$$

where C_u is the concentration of unbound drug in the water surrounding the enzyme. The CL_{int} is reduced to the following under nonsaturable conditions, *i.e.*, $K_m \gg C_u$:

$$CL_{int} \simeq V_{max}/K_m \quad \text{(Eq. 2)}$$

Assuming rapid equilibrium between organs and the effluent venous blood, the whole organ clearance (CL) of the liver or kidney is given as follows (14, 15):

$$CL = \frac{Qf_BCL_{int}}{Q + f_BCL_{int}} \quad \text{(Eq. 3)}$$

where f_B is the fraction of the drug in blood that is unbound, the Q is the blood flow supplied to the organ. The whole organ clearance of lung (CL_{Lu}) is given as follows, assuming rapid equilibrium (16):

$$CL_{Lu} \simeq f_BCL_{int(Lu)} \quad \text{(Eq. 4)}$$

The capacity of an eliminating organ to metabolize the drug can also be expressed as the extraction ratio (E). The extraction ratio of liver (E_H) derived from *in vitro* or *in vivo* experiments (17) is as follows:

$$E_H = \frac{f_BCL_{int(H)}}{Q_H + f_BCL_{int(H)}} \quad \text{(Eq. 5)}$$

$$E_H = 1 - \frac{AUC_{ip}/Dose}{AUC_{iv}/Dose} \quad \text{(Eq. 6)}$$

where AUC_{ip} and AUC_{iv} are the area under concentration-time curves of diazepam from zero to the infinity after portal venous and intravenous administration, respectively.

RESULTS

Drug Metabolism Study—The Lineweaver-Burk plot of the disappearance rates of diazepam *versus* the initial diazepam concentrations using liver microsome is shown in Fig. 1. The enzymatic parameters (K_m and V_{max}) derived from *in vitro* experiments and those extrapolated to the whole organs for the liver, kidney, and lung are listed in Table I. Since the unbound diazepam concentration in plasma was sufficiently small compared with the values of K_m of the three disposing organs (see footnote to Table I), Eq. 2 was used to

Table I—Enzymatic Parameters for Metabolism of Diazepam by Microsomes of Rat Liver, Kidney, and Lung

Organ	K_m[a], μg/mL	V_{max}, μg/min/g of Microsomal Protein	V_{max}[b], μg/min/g of Organ	CL_{int}[c], mL/min/g of Organ	CL_{org}[d], mL/min/0.25-kg rat
Liver	0.409	125.0	6.08	14.87	8.95
Kidney	0.198	18.5	0.33	1.68	0.22
Lung	0.343	27.8	0.26	0.76	0.10

[a] Michaelis–Menten constant for the unbound drug. Nonspecific binding of the drug to each microsomal suspension was low, determined by an equilibrium dialysis technique at 37°C in the absence of an NADPH-generating system (5), and was used for the correction. [b] Grams of microsomal protein per gram of liver was calculated as reported by Igari *et al.* (5) according to the methods of Lin *et al.* (12) and Smith and Bend (13), and that of kidney or lung was calculated according to the methods of Lin *et al.* (12) and Smith and Bend (13) by using the data rreported by Litterst *et al.* (3). [c] The fraction of unbound drug in plasma and the blood-to-plasma concentration ratio were 0.14 and 1.04, respectively, taken from the report by Igari *et al.* (4). The free diazepam concentrations in the systemic blood postinjection of 1.2 mg/kg iv of diazepam into the rat were below ~60 ng/mL and adequately smaller than K_m values over time, since diazepam concentration in the systemic blood declined very rapidly with time. Therefore, since the nonsaturable condition approximately holds, CL_{int} can be described by Eq. 2. [d] The values of CL_{org} of liver and kidney were calculated by Eq. 3, and that of the lung was calculated by Eq. 4. The blood flow rates of the liver and kidney were 14.7 mL/min/0.25-kg rat and 11.4 mL/min/0.25-kg rat, respectively, taken from the reports of Sasaki and Wagner (32), Dedrick *et al.* (33), and Lutz *et al.* (34).

[8] Beckman Instruments, Fullerton, Calif.

calculate CL_{int}. The calculated CL_{int} and CL are also listed in Table I. The liver is, as expected, the most potent contributor to total clearance, followed by the kidney and the lung in that order.

Evaluation of the Hepatic Extraction Ratio of Diazepam—After intravenous or intraportal administration of 1.2 mg/kg of [^{14}C]diazepam into the rat, the concentrations of diazepam in plasma declined biexponentially, as shown in Fig. 2, and could be fitted using a digital computer program (10). The AUC values are 15.4 ± 0.6 μg/mL·min (mean ± *SE*) following intravenous administration and 5.4 ± 0.7 μg/mL·min (mean ± *SE*) following intraportal administration, respectively. The extraction ratio of the liver, calculated according to Eq. 6 using the mean AUC values of postintravenous and intraportal injection, was 0.648, while that calculated according to Eq. 5 using enzymatic parameters derived from the *in vitro* experiments was 0.616 (for the hepatic blood flow rate and the blood free fraction, refer to the footnote to Table I).

The observed total clearance, calculated using CL_{tot} = Dose/AUC_{iv}, was 19.6 mL/min/0.25-kg rat.

DISCUSSION

Drug metabolism systems exist not only in the liver, but also in the kidney, intestine, lung, skin, brain, testes, placenta, adrenals, spleen, and plasma (11, 16–22); each enzyme system may have different enzymatic parameters. Since total clearance cannot be ascribed to only the liver for drugs which are metabolized by multiple organs, an accurate assessment of metabolic capacities of individual disposing organs would be indispensable in describing the drug kinetics in plasma and various tissues or organs using the physiologically based pharmacokinetic model developed by Dedrick *et al.* (23, 24). Some authors have dealt with the drug metabolism study using experimental systems prepared from the liver and the other organs. For example, Lake *et al.* (25) and Litterst *et al.* (3) reported the hepatic and extrahepatic *in vitro* metabolism of some drugs using subcellular fractions. Hayes and Brendel (26) and Devereux *et al.* (27) reported the metabolism of drugs using isolated liver and lung cell preparations, respectively. However, to incorporate the *in vitro* data into a physiologically based pharmacokinetic model, an appropriate scaling is needed to extrapolate the *in vitro* data to the *in vivo* situation, and comparison should be made between the capacity of the whole organ predicted from the *in vitro* data and observed to validate the scaling. On this point, Rane *et al.* (11) have successfully predicted intrinsic clearance and hence the extraction ratio of the liver of a wide spectrum of compounds using the values of V_{max} and K_m determined from liver homogenates, compared with those observed in the isolated liver perfusion study. Furthermore, Collins *et al.* (28) and Lin *et al.* (29) also reported the *in vitro* and *in vivo* correlation of the drug metabolism using isolated liver preparations.

In the present study, the enzymatic parameters K_m and V_{max} for the microsomal oxidation of diazepam in the liver, kidney, and lung were estimated using *in vitro* enzyme assays. It was demonstrated that the kidney and lung in addition to the liver contributed to the total clearance of diazepam in the rat. As expected, the liver was the most efficient organ for diazepam metabolism, followed by the kidney and the lung in that order. This is because there were differences in the values of V_{max} among three organs, as shown in Table I. The sum of the predicted organ clearances of the liver, kidney, and lung (9.3 mL/min/0.25-kg rat; Table I), however, was still below the observed total clearance (19.6 mL/min/0.25-kg rat). Since the predicted liver organ clearance (CL_{li}) in the present study was probably an estimate, the microsomes of the kidney and lung might not be prepared with enzymatic activity matching those of the intact kidney and lung.

Recently, the extrapolation of the *in vitro* enzymatic parameters to those *in vivo* has been demonstrated also in the lung. For example, Smith and Bend (13) and Law (30) succeeded in the extrapolation using benzo[*a*]pyrene 4,5-oxide and phencyclidine as substrates, respectively, both of which are metabolized mainly by microsomal enzymes. In the case of 5-hydroxytryptamide, which is mainly metabolized by mitochondrial monoamine oxidase, the prediction of its clearance from the *in vitro* enzymatic parameters was successful for the liver, but underestimated the observed clearance in the lung (31). Our present study using diazepam showed results similar to those for 5-hydroxytryptamine (31), although the intracellular localization of the enzymes is different.

Thus, the estimation of the enzymatic parameters of the metabolism from the *in vitro* assay systems of the liver and an appropriate scaling to the whole organ V_{max} value proved to be a useful tool for the estimation of the metabolic occurrences of diazepam *in vivo*. Since diazepam is metabolized by the kidney and lung in addition to the liver, the preparation of microsomes of the kidney and lung or experimental conditions such as components and concentrations of cofactors to yield appropriate enzymatic degradation rates should be further studied to assess the extrahepatic metabolism of diazepam.

Physicochemical and Analytical Characteristics of Amiodarone

M. BONATI ˣ, F. GASPARI, V. D'ARANNO, E. BENFENATI, P. NEYROZ, F. GALLETTI, and G. TOGNONI

Received July 14, 1982, from the *Laboratory of Clinical Pharmacology, Istituto di Ricerche Farmacologiche "Mario Negri," Via Eritrea 62, 20157 Milan, Italy.* Accepted for publication May 10, 1983.

Abstract □ Data are reported on the analytical and physicochemical characteristics of amiodarone, for use in identifying and/or assaying this antiarrhythmic agent. The drug is highly soluble in chloroform and poorly soluble in water. Its acid-base constant (pK_a) is 6.56, and its maximal lipid solubility range is from pH 3.5 to 5.5.

Keyphrases □ Amiodarone—physicochemical and analytical characteristics, HPLC and IR, UV, and mass spectrometries □ Antiarrhythmic agents—amiodarone, physicochemical and analytical characteristics, HPLC and IR, UV, and mass spectrometries

In addition to electrophysiological (1, 2) and clinical findings (3, 4), the disposition of amiodarone[1] has been extensively investigated in animals and humans (5–7). Its metabolic pathway and tissue distribution are still largely unknown, but they do offer some clues to understanding the therapeutic and toxic effects during chronic treatment (8, 9). Despite all the work done, little is known to date of the basic physical and physicochemical properties of the drug.

EXPERIMENTAL

Equipment—Amiodarone hydrochloride was synthesized, purified by recrystallization from acetone (10), and supplied by Labaz[2]. All other chemicals were reagent or UV grade.

A double-beam spectrophotometer[3] equipped with a constant-temperature control block was used for UV analysis. A high-pressure liquid chromatograph[4] was equipped with a UV-absorption detector[5] (254 nm, fixed wavelength) and a reverse-phase column[6] (7-μm particle size, 250 nm × 4 mm length). The mobile phase was acetonitrile–water–acetic acid (80:19:1, adjusted to pH 5.8 with ammonium hydroxide) at a flow rate of 2 mL/min. Melting points were determined on a hot-stage[7] and were not corrected. A mass spectrometer[8] equipped with a computer[9] was used for MS analysis. Analyses were made by the direct inlet system, scanning repetitively throughout the sample evaporation period and heating the probe to 180°C. Electron energy ranged from 20 to 60 eV. IR spectra were obtained on a spectrophotometer using potassium bromide pellets (1%, w/v).

UV Spectrometry—To obtain a spectrum and determine its molar extinction coefficient (ϵ), methanolic solutions of amiodarone were prepared in triplicate at a concentration of 10 μg/mL (14.7×10^{-6} M). UV analyses were carried out at 208, 241, 270, and 280 nm at 25°C. The molar extinction coefficient was calculated by Lambert and Beer's law:

$$\log I_0/I = \epsilon \times 1 \times C \qquad \text{(Eq. 1)}$$

where $\log I_0/I$ is the absorption intensity of the sample, 1 is the cuvette path beam length (in cm), and C is the molar concentration; hence, ϵ = Absorbance × cm^{-1} × M^{-1}.

Solubility—The percentage (w/v) of amiodarone soluble in different solvents was determined by adding an excess of drug to obtain saturation of 20 mL of each solvent tested, calculating the amount of dissolved amiodarone. The tubes were rotated end-over-end for 1 h (longer than needed to dissolve the drug in all solvents employed) at 25 ± 0.1°C in a water bath and then centrifuged at the same temperature. The supernatant was diluted and spectrophotometrically assayed for amiodarone. Three determinations were made for each solvent.

Determination of pK_a—According to a long-used method (11) the pK_a values were determined by UV titration (at λ_{max}) of aqueous solutions containing known amounts of amiodarone. A range of pH 1–5 was achieved by addition of hydrochloric acid, pH 5.8–9.2, by 0.05 M borate phosphate (adjustment being made with hydrochloric acid), while higher values were obtained by addition of sodium hydroxide solutions. Sodium chloride was used to adjust the ionic strength. All solutions were prepared immediately before use and all pH values were checked at 25°C using a standard pH-meter. In the temperature range of 20–30°C there was no substantial effect on the true pH of the solutions, but only 3–4 h after preparation we found a 10% decrease in amiodarone concentration at pH values >7.0.

The extinction coefficient was related to different hydrogen ion concentrations to check the λ_{max} shift. The dissociation constant (K_a) was determined according to the equation

$$\epsilon = \frac{A_H \times [H^+] + A_B \times K_a}{[H^+] + K_a} \qquad \text{(Eq. 2)}$$

where A_H and A_B are the extinction coefficients when amiodarone exists under acidic and basic conditions, respectively. Experimental values of ϵ *versus* pH were then fitted by a nonlinear regression iterative program on a desk computer[10]. Determinations were done in triplicate.

Partition Coefficients—According to the suggestions of Leo *et al.* (12), amiodarone was partitioned between buffer solutions saturated with 1-octanol and 1-octanol saturated with buffer solutions (as reported for the determination of pK_a). Known amounts of amiodarone were dissolved in 20 mL of buffer solution and gently shaken for 2 h (long enough to achieve equilibrium) at 25 ± 0.1°C in a shaking incubator with 5 mL of organic solvent. The two phases were separated by centrifugation, and the amount of amiodarone in the aqueous layer was determined spectrophotometrically. The apparent partition coefficient was calculated as:

$$P_{app} = \frac{C_{octanol}}{C_{buffer}} = \frac{(C_1 - C_2) \cdot a}{C_2 \cdot b} \qquad \text{(Eq. 3)}$$

where C_1 and C_2 are the amiodarone concentrations (w/v) in the buffer before and after equilibration, and a and b are the volumes of the buffer and 1-octanol layers, respectively. Each determination was made three times for each pH value checked. The true or corrected partition coefficient, knowing the pK_a value of the drug, was calculated as:

$$P_{corr} = \frac{C_{octanol}}{C_{buffer}\,(1 - \alpha)} = \frac{P_{app}}{1 - \alpha} \qquad \text{(Eq. 4)}$$

where α is the degree of ionization at a given pH and can be calculated as:

$$\alpha = \frac{1}{[1 + \text{antilog}\,(pK_a - pH)]} \qquad \text{(Eq. 5)}$$

RESULTS AND DISCUSSION

Solubility—Table I sets out the findings as percentages (w/v). The coefficient of variation was always <5% for each solvent employed. The two extremes of solubility are represented by chloroform and petroleum ether, in which the ratio of amiodarone solubility is around 30,000:1. The pH of water was 6.5, and solubility was not substantially affected by a pH range of 1.5–7.5 in aqueous solutions (physiological fluids).

UV Spectrometry—The spectrum of amiodarone in methanolic solution using 1-cm quartz cells showed λ_{max} at 208 and 241 nm. Two shoulders were resolved near 270 and 280 nm; mean ϵ values were 4.7×10^4 at 208 nm, 4.4×10^4 at 241 nm, 1.8×10^4 at 270 nm, and 1.6×10^4 at 280 nm, respectively.

Table I—Percentage Solubility (w/v) of Amiodarone in Various Solvents at 25°C [a]

Solvent	Solubility, g/100 mL
Chloroform	44.51282
Methylene chloride	19.20000
Methanol	9.98400
Ethanol	1.28000
Benzene	0.64657
Tetrahydrofuran	0.60377
Acetonitrile	0.31889
1-Octanol	0.29500
Ether	0.17436
1-Propanol	0.13435
Water	0.07164
Hexane	0.02559
Petroleum ether	0.00137

[a] Values are the average of determinations done in triplicate.

High-Performance Liquid Chromatography—The procedures described by Lesko *et al.* (13) for the preparation of biological samples were followed first. Because of the longer column life (efficiency) and greater simplicity using an aqueous mobile phase, we subsequently relied on a reverse-phase system. Values for sensitivity (0.05 μg/mL), within-day coefficients of variation (1.9% at 0.50 μg/mL and 6.5% at 5.00 μg/mL), and day-to-day coefficients of variation (7.5% at 0.50 μg/mL and 7.0% at 5.00 μg/mL) confirm the reliability of the method. The calibration curves were linear over the concentration range studied.

Melting Point—Amiodarone occurs as a white crystalline powder, with a melting point of 159 ± 2°C after recrystallization from acetone (10).

IR Spectrometry—The IR spectrum (KBr pellets) revealed characteristic bands that agreed with the suggested structure: 3000–3070 (ArCH), 2860–2960 (aliphatic CH), 2200–2700 (*tert*-amine NH^+), 1635 (diAr C=O), 1560 and 1015 (benzofuran C=C), 1380 (aliphatic CH_3), 1285 (ketonic C—C), 1250 and 1075 (ether C—O—C), and 1225 and 1025 cm^{-1} (*tert*-amine C—N).

Mass Spectrometry—The molecular peak of amiodarone was observed at *m/z* 645, corresponding to the molecular mass. The most characteristic fragments of amiodarone gave peaks at *m/z* 630 ($M^+ - CH_3$), 546, 517 ($M^+ - HI$), 420, 391, 373, 201, and 159. The peak at *m/z* 546 corresponds to cleavage of the aromatic ether with elimination of the aliphatic aminic chain. The other ions at *m/z* 420, 391, 373, 201, and 159 are all fragments of this aromatic part of the molecule.

Determination of pK_a—The UV absorption curves of amiodarone at different hydrogen ion concentrations (Fig. 1a) showed a characteristic bathochromic shift (toward the red) of λ_{max} (241 nm) from pH 6.0 to higher values. The apparent dissociation constant, calculated for amiodarone using Eq. 2, (Fig. 1b) was 6.56 ± 0.06 (*SD*). By appropriate substitution into the Henderson–Hasselbach equation of the pK_a value for amiodarone (weak acid) and considering the pH range (1.0–8.0), which encompasses the pH in all body sites, it can be affirmed that amiodarone is essentially un-ionized at acidic pH sites.

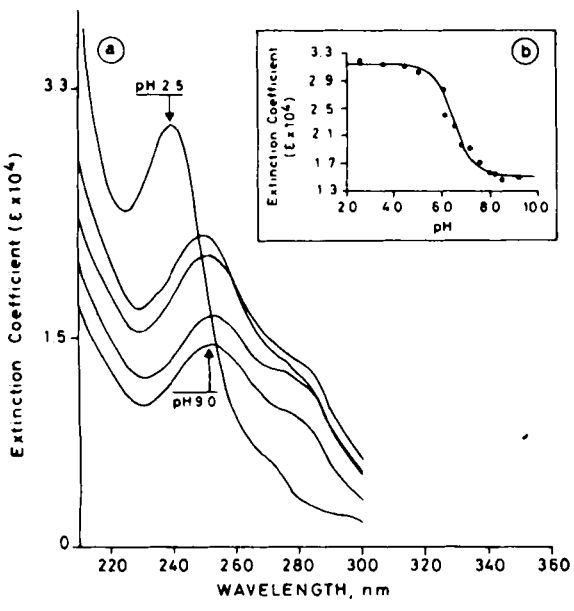

Figure 1—*Representative changes with pH in the absorption spectrum of amiodarone (a), and curve plotted to calculate the* pK_a *value for amiodarone (b).*

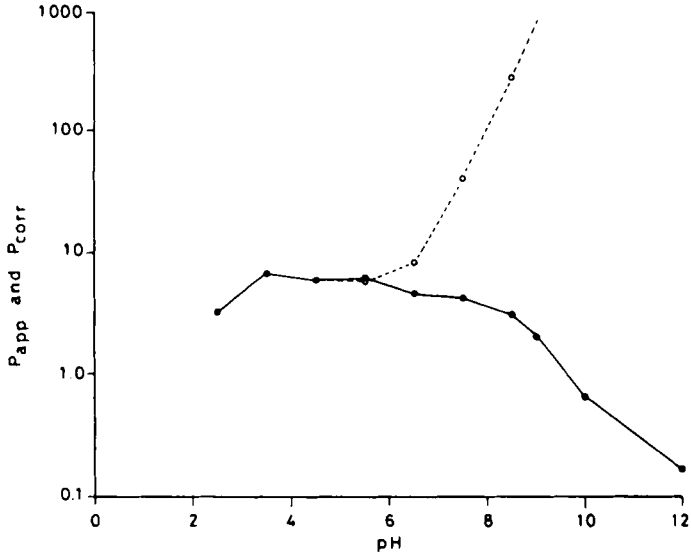

Figure 2—*Changes with pH in the apparent (●) and corrected (○) partition coefficients of amiodarone.*

Partition Coefficients—Apparent and corrected partition coefficients are plotted in Fig. 2. A typical dependence of coefficients on pH was found, with maximum lipid solubility of amiodarone between pH 3.5 and 5.5. The same behavior is described for other compounds [such as tetracycline and sulfa drugs (14, 15)].

The present findings confirm that an acidic pH (~4.5) is optimal for the extraction of amiodarone from biological specimens (7, 13). Furthermore, considering the dissociation characteristics and taking into account the "pH-partition hypothesis" (16) and Schanker's statement (17) that ". . .lipid solubility is most likely the dominant characteristic, since the relevance of the degree of ionization is probably a consequence of the poor lipid-solubility of organic ions," the absorption of amiodarone, whose extent and specific mechanism are at present unknown, should be far greater in the duodenum and jejunum than in the stomach and lower alimentary canal. Thus, gastric emptying time and changes of pH are likely to be critical in the absorption of amiodarone.

Wide variability can be expected in absorption rates and bioavailability of the drug. This is specifically relevant in protocols to investigate the correlations between amiodarone blood levels after acute and repeated oral administration and electrophysiological effects.

Liquid Chromatographic Analysis of Triamterene and Its Major Metabolite, Hydroxytriamterene Sulfate, in Blood, Plasma, and Urine

FRITZ SÖRGEL *, EMIL T. LIN, JIRO HASEGAWA ‡, and LESLIE Z. BENET ˣ

Received November 1, 1982, from the *Department of Pharmacy, School of Pharmacy, University of California, San Francisco, CA 94143.* Accepted for publication April 7, 1983. Present Addresses: *Carl-Korth Institute for Cardiovascular Research, Division of Clinical Pharmacology, 852 Erlangen, West Germany and ‡Eisai Co. Ltd., 6-10 Koishikawa 4-Chome, Bunkyo-ku, Tokyo 112, Japan.

Abstract □ The first rapid and highly sensitive high-performance liquid chromatographic (HPLC) assay for triamterene, hydroxytriamterene, and hydroxytriamterene sulfate is reported. Plasma samples were processed by protein precipitation, while urine was used untreated. Three different solvent systems were used to analyze (*a*) triamterene in plasma (30% acetonitrile, pH 4.0; internal standard: furosemide; sensitivity limit: 1 ng/mL); (*b*) hydroxytriamterene and hydroxytriamterene sulfate in plasma (12% acetonitrile, pH 5.5; internal standard: cefamandole; sensitivity limits: 20 and 2 ng/mL, respectively) and (*c*) triamterene, hydroxytriamterene, and hydroxytriamterene sulfate in urine (13% acetonitrile, pH 5.3; internal standard: hydroflumethiazide; sensitivity limits: 0.04 μg/mL, 0.5 μg/mL, and 0.1 μg/mL, respectively). Fluorescence detection of compounds was performed at 365-nm excitation and 440-nm emission wavelengths. Recovery of triamterene and its metabolites from plasma was complete, and calibration curves were linear. Intraday variation was <6% except for the lowest plasma concentration. The assay procedure has already been used in several pharmacokinetic studies.

Keyphrases □ Triamterene—HPLC analysis, major metabolites, hydroxytriamterene sulfate, blood, plasma, and urine □ Hydroxytriamterene sulfate—HPLC analysis, major metabolite of triamterene, blood, plasma, and urine

Although triamterene has been clinically available since the 1960's, the metabolic pathways for this drug have been a matter of controversy, with conflicting reports appearing up through 1982. Early work by Lehmann (1) indicated that triamterene undergoes hydroxylation and subsequent sulfation to hydroxytriamterene sulfate, which he found in urine. Pruitt *et al.* (2), using TLC separation, could only detect hydroxytriamterene, whereas Grebian *et al.* (3) and our group (4, 5) did find the sulfate ester of hydroxytriamterene using TLC techniques.

More recently, three HPLC techniques for triamterene analysis have been published (6-8). One of these research groups (6) assumed, on the basis of the work of Pruitt *et al.* (2), that hydroxytriamterene was the major metabolite of triamterene and did not develop a method to specifically measure the sulfate conjugate. The other two groups did not measure any metabolites. The first HPLC assay by which the specific measurement of hydroxytriamterene sulfate can be obtained and by which very low concentrations of unchanged triamterene and hydroxytriamterene sulfate can be quantitated is reported herein. The method is simple, fast, and accurate.

EXPERIMENTAL

Reagents—Triamterene[1], hydroxytriamterene[2], hydroxytriamterene sulfate[2], and the internal standards hydroflumethiazide[3], furosemide[4], and cefamandole[5] were used as received. Acetonitrile[6] for the HPLC measurements was glass-distilled; water was redistilled and stored in glass.

Apparatus—A high-performance liquid chromatograph[7] equipped with a sample processor[8], a fluorescence spectrophotometer[9], and a UV detector[10] was used. The assay was carried out on a 10-μm particle size, 4 × 300-mm reverse-phase column[11] at a solvent flow rate of 2 mL/min.

Mobile Phase and Retention Times—Three different solvent systems were used for the measurement of triamterene, hydroxytriamterene, and hydroxytriamterene sulfate. Each solvent system (A-C, as indicated in Table I) was used for a particular quantitation problem.

Detection Wavelengths—Triamterene, hydroxytriamterene, and hydroxytriamterene sulfate as well as the internal standards furosemide and hydroflumethiazide were analyzed using their native fluorescence at an excitation wavelength of 365 nm and an emission wavelength of 440 nm. Cefamandole, which was used as an internal standard in mobile phase B, was measured by UV detection at 254 nm. For that purpose the HPLC system was equipped with two detector systems, one for fluorescence and another for UV detection.

Methods—Each plasma or total blood sample (0.1 mL) was deproteinated by adding 0.4 mL of acetonitrile containing both furosemide (3.5 μg/mL) and cefamandole (60 μg/mL) internal standards. After mixing[12] for 1 min, the sample was centrifuged[13] for 10 min at 3200 rpm. The supernatant was transferred to a clean test tube and, if necessary, evaporated at room temperature to 0.2 mL under nitrogen when very low concentrations had to be measured. However, most of the samples could be analyzed by injection of a volume as little as 5 μL.

Urine samples ranging from 0.02 to 0.1 mL were added to 1 mL of an acetonitrile solution containing hydroflumethiazide as an internal standard (500 μg/mL). After mixing[12] and centrifugation[13], 2 μL was injected onto the HPLC system.

Human plasma, blood, and urine were stored at −20°C. Blank plasma and blood for assay development was obtained from healthy volunteers using 143 IU/10 mL of lithium heparin as anticoagulant. To test the stability of tri-

amterene and its primary metabolite over time, biological samples (over the concentrations measured) were analyzed after 6 and 12 months storage at −20°C. They did not show any degradation. On the basis of our work it appears that samples can be stored for more than 1 year at −20°C without significant degradation.

	215.0	97.4

RESULTS

Three different solvent systems were used to analyze triamterene, hydroxytriamterene, and hydroxytriamterene sulfate in plasma and urine (Table I).

Triamterene (Mobile Phase A)—Triamterene was analyzed using a 30% acetonitrile in 0.02% H_3PO_4 solvent system, adjusted to pH 4.0 with 0.5 M NaOH. As can be seen in Fig. 1a and b these conditions allowed excellent separation of triamterene (retention time 5.7 min) from endogenous materials. The internal standard, furosemide, has a retention time of 8.1 min, which means that the total run time for one sample is <10 min, allowing a large number of samples to be measured each day. Standard curves for triamterene obtained using mobile phase A exhibited linearity over the concentration range of 1–50 ng/mL. The limit of quantitation was 1 ng/mL.

Hydroxytriamterene (Mobile Phases B and C)—Hydroxytriamterene, had it been present in actual plasma or urine samples, could have been detected with solvent systems B and C. Since the retention times for hydroxytriamterene and the internal standard, cefamandole, were so close with mobile phase B (Table I), plasma samples with and without the internal standard were injected onto the column. Hydroxytriamterene peaks were not detected in either plasma or urine from healthy volunteers even when the instruments were set to the highest sensitivity. Therefore, no further attempts were made to fully establish a method of quantitation. The lower limit of quantitation was 20 ng/mL in plasma and 0.5 μg/mL in urine.

Hydroxytriamterene Sulfate (Mobile Phase B)—Hydroxytriamterene sulfate was separated from hydroxytriamterene and from endogenous compounds in solvents B and C with retention times of 5.7 and 3.2 min, respectively, in each solvent. Cefamandole used as an internal standard for mobile phase B had a retention time of 8.7 min, maintaining the total run time for hydroxytriamterene sulfate below 10 min (see representative chromatograms, Fig. 1c and d). Standard curves for hydroxytriamterene sulfate were shown to be linear over a 10–215-ng/mL concentration range. The lower limit of quantitation was 2 ng/mL.

Urine Assay (Mobile Phase C)—In urine, all three triamterene compounds can be measured simultaneously with the internal standard hydroflumethi-

Table III—Within-Day Assay Precision for Triamterene and Hydroxytriamterene Sulfate in Plasma

54.0	1.62 ± 0.10	5.9
86.4	2.52 ± 0.13	5.0
108.0	3.07 ± 0.12	4.0
215.0	6.17 ± 0.04	0.6

[a] Mean ± *SD*; *n* = 4.

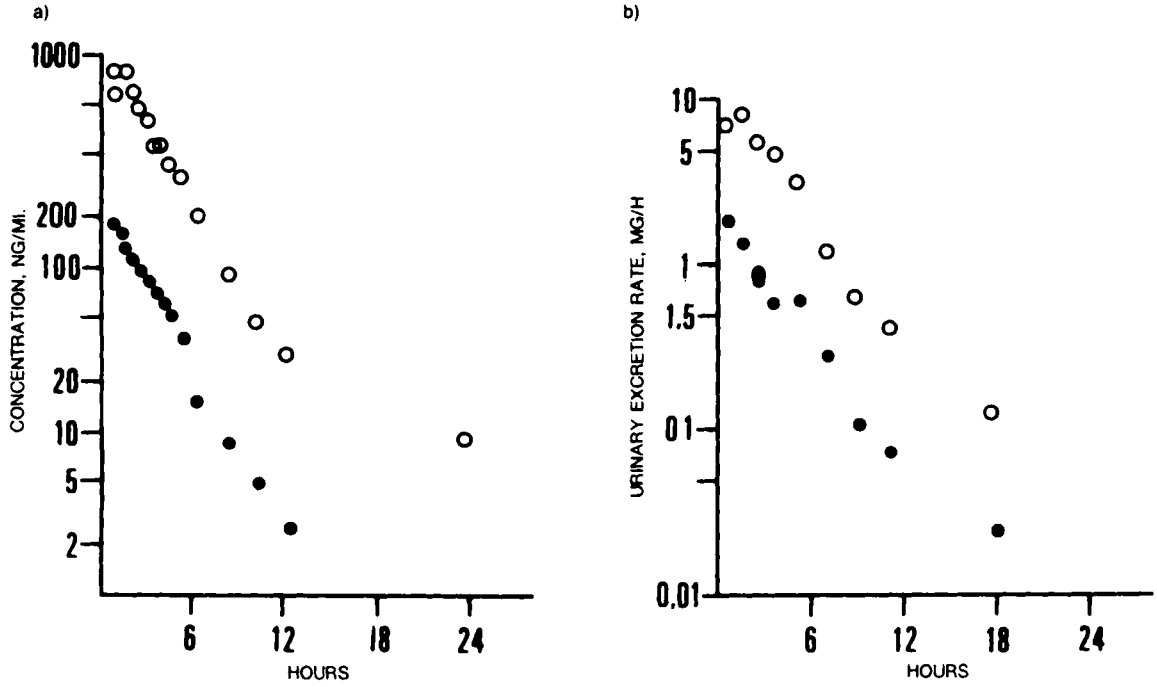

Figure 2—*Semilogarithmic plasma concentration* versus *time plot (a) and urinary excretion rate* versus *midpoint time (b) following a 100-mg oral suspension dose of triamterene to a healthy volunteer. Key: (●) triamterine; (○) hydroxytriamterine sulfate.*

azide (Fig. 1e,f); the limits of quantitation of triamterene and hydroxytriamterene sulfate were 0.04 μg/mL and 0.1 μg/mL, respectively. Standard curves for these two compounds were prepared over the following concentration ranges: triamterene, 0.15–2.35 μg/mL; hydroxytriamterene sulfate, 0.75–57.0 μg/mL.

Recovery—The recoveries of triamterene and hydroxytriamterene sulfate from plasma were determined by acetonitrile precipitation. The peak height ratios of samples prepared with plasma and water were compared. As shown in Table II, the recovery of triamterene and hydroxytriamterene sulfate was complete.

Within-Day Precision—The within-day precision was assessed by conducting replicate analyses. As shown in Table III, the coefficients of variation ranged from 0.5–6.4 for all concentrations except the lowest plasma concentration (12.6% *CV*), indicating good precision for the assay.

Blood Sample Assays—Analysis of triamterene and hydroxytriamterene sulfate were undertaken so as to determine the blood-to-plasma ratios of these compounds. The blood–plasma ratios were examined in two subjects and found to be constant over the concentration range measured following a 100-mg oral dose of triamterene (9). The ratio was 1.03 ± 0.14 for triamterene and 0.60 ± 0.07 for hydroxytriamterene sulfate.

DISCUSSION

There have been several reports in the literature regarding the quantitation of triamterene and its metabolites in humans. On the basis of a probably inappropriate TLC procedure, Pruitt *et al* (2) concluded that the major metabolite of triamterene was hydroxytriamterene rather than the sulfate conjugate (1, 3, 4).

Following the detection of hydroxytriamterene sulfate, but not hydroxytriamterene, in actual biological specimens and by using synthetic hydroxytriamterene sulfate as a reference compound, it was possible to develop a procedure to quantitatively measure hydroxytriamterene sulfate in urine and plasma. Hydroxytriamterene, the intermediate metabolite of triamterene, was not detected in any study. Had it been present, it could have been detected with our HPLC method. The most recent report on the measurement of triamterene and metabolites of Yakatan *et al.* (6) only provides information about hydroxytriamterene measurements, not mentioning the sulfate conjugate. The techniques described here have been used successfully in several pharmacokinetic studies in both humans and dogs (4, 5, 9) and are suitable to quantify triamterene and its metabolite, hydroxytriamterene sulfate.

The results of a representative experiment in a healthy volunteer receiving a 100-mg oral suspension dose of triamterene are shown in Fig. 2a and b. As indicated earlier no hydroxytriamterene could be detected in either plasma or urine. The concentration of hydroxytriamterene sulfate exceeded that of unchanged triameterene ~10-fold in plasma and ~5-fold in urine, indicating that hydroxytriamterene sulfate is the major metabolite of triamterene. Further analysis of the pharmacokinetic data in humans using the analytical techniques described here has been recently reported (9).

The authors express their gratitude to Dr. Bruce Ettinger, Kaiser Foundation, San Francisco, for donating hydroxytriamterene and hydroxytriamterene sulfate, which he had received from Röhm Pharma, Darmstadt, West Germany. They also thank Dr. P. Magnusson, Leo Pharmaceutical Products for donating hydroflumethiazide. The technical assistance of Mrs. Regina Sörgel is greatly appreciated.

Chemical Modification of Triamcinolone Acetonide to Improve Liposomal Encapsulation

ASHOK GOUNDALKAR and MICHAEL MEZEI ˣ

Received February 7, 1983, from the *College of Pharmacy, Dalhousie University, Halifax, N.S. B3H 3J5, Canada.* Accepted for publication April 18, 1983.

Abstract □ The 21-palmitate of triamcinolone acetonide was synthesized to aid in the liposomal encapsulation of the drug. Encapsulation efficiency of triamcinolone acetonide-21-palmitate was 85%, compared with 5% for the parent drug.

Keyphrases □ Triamcinolone acetonide—synthesis of the 21-palmitate ester, liposomal encapsulation □ Liposomes—encapsulation of triamcinolone acetonide-21-palmitate, synthesis

Liposomes are microscopic vesicles composed of phospholipid bilayers separated by aqueous compartments. Their potential as temporal and spatiotemporal drug delivery systems is being widely investigated (1–3). The applicability of liposomes as selective drug delivery systems for cutaneous administration of drugs has been studied (4, 5) in this laboratory using triamcinolone acetonide as the model drug. Attempts to test various types of liposomes with the same drug revealed a low level of encapsulation of the drug in the multilamellar liposomes.

A relationship between liposomal encapsulation and the structure of the derivatives of another corticosteroid, hydrocortisone, has been reported by Shaw *et al.* (6). The observation that among a variety of derivatives, hydrocortisone-21-palmitate had the maximum encapsulation in the liposomes led us to study a similar approach for enhancing encapsulation of triamcinolone acetonide. The synthesis and purification of triamcinolone acetonide-21-palmitate, based on the principles of the methods reported by Shaw *et al.* (6) and Diamanti and Bianchi (7), is described in this report.

EXPERIMENTAL

9-Fluoro-21-(1-oxohexadecoxy)-11-hydroxy-16,17-[(1-methylethylidene)-bis(oxy)]-pregna-1,4-diene-3,20-dione—Triamcinolone acetonide (435 mg, 1 mmol) was dissolved in 4 mL of *N,N*-dimethylformamide. Pyridine (160 mg, 2 mmol) and palmitoyl chloride (550 mg, 2 mmol) were added, the mixture was stirred magnetically at room temperature for 22 h, and then was poured into 0.5 M sulfuric acid (1600 mL) and stirred vigorously. The product was removed by filtration and was purified by column chromatography on silica gel (toluene–ethyl acetate–acetic acid, 90:10:1). Recrystallization from methanol, gave 471 mg (70% yield) of triamcinolone acetonide-21-palmitate, mp 143–147°C; IR (Nujol): 1760 (ester C=O), 1740 (ketone C=O), 1670 (α,β; $\alpha'\beta'$-unsaturated ketone C=O), 1620 (C=C conjugated with ketone), and 890 cm^{-1} (*cis*-CH of Δ-1,4 system); ^{1}H-NMR ($CDCl_3$): δ 0.88 (t, 3, terminal CH_3), 0.94 (s, 3, 18-CH_3), 1.25 (narrow m, 27, acetonide β-CH_3 and CH_2 chain), 1.42 (s, 3, acetonide α-CH_3), 1.55 (s, 3, 19-CH_3), 1.6–2.5 (m, 4, $CH_2CH_2CO_2$), 4.90 (s, 2, 21-CH_2O), 4.97 (br, 1, 16-CHO), 6.12 (d, 1, $J_{2,4}$ = 0.6 Hz, 4-CH), 6.44 (dd, 1, $J_{2,4}$ = 0.6 Hz, $J_{1,2}$ = 9.5 Hz, 2-CH), and 7.22 ppm (d, 1, $J_{1,2}$ = 9.5 Hz, 1-CH).

Table I—Comparative Data for Liposomal Encapsulation of Triamcinolone Acetonide and Triamcinolone Acetonide-21-Palmitate.

Procedure	Fraction	Concentration, mg/22 mL: Triamcinolone Acetonide	Concentration, mg/22 mL: Triamcinolone Acetonide-21-Palmitate
Preparation	Crude product	20	20
Filtration	Filtrate	7	19
Centrifugation	Supernatant	6	2
	Pellet (liposomes)	1	17

Preparation of Liposomes—To reliably determine encapsulation efficiency, radioactive triamcinolone acetonide-21-palmitate was prepared as above from [6,7-^{3}H]triamcinolone acetonide. Multilamellar liposomes were prepared as described by Mezei and Gulasekharam (4). Dipalmitoyl phosphatidyl choline (160 mg) and triamcinolone acetonide-21-palmitate (22 mg, 350 μCi) in chloroform–methanol (2:1) were evaporated using a rotary evaporator. The film was then dispersed with 22 mL of aqueous 8 mM $CaCl_2$ solution at 60°C. The preparation was evaluated microscopically and then filtered through a 12-μm polycarbonate filter. The filtrate was then centrifuged at 22,000×*g* for 25 min. Radioactivity in each fraction was measured after each treatment. Triamcinolone acetonide liposomes were prepared in a similar manner.

RESULTS AND DISCUSSION

Results presented in Table I indicate considerable improvement in liposomal encapsulation of triamcinolone acetonide as a result of palmitoylation. In the case of the triamcinolone acetonide liposomal preparation the first major loss occurred after filtration through a 12-μm polycarbonate filter. This filtration step is necessary with the liposomal encapsulation of a lipophilic drug. Since the drug is insoluble or very slightly soluble in the aqueous medium, only that portion is encapsulated that is in solution and intimately associated with the lipid bilayers; the remaining portion is in solid form which, although it is unencapsulated, would be present in the liposomal fraction after centrifugation. The loss of 13 mg (*i.e.*, 65%) of triamcinolone acetonide by the filtration process was due mainly to unencapsulated crystals observed in the crude preparation. Such crystals were absent in the filtrate. No crystals were seen even in the unfiltered triamcinolone acetonide-21-palmitate liposomal fraction; consequently, only 1 mg (*i.e.*, 5%) was lost by the filtration. This suggests that the palmitate form has a stronger association with the lipid layers and that almost complete encapsulation is achieved.

The second major loss in the case of triamcinolone acetonide liposomes was in the supernatant after centrifugation of the filtrate. This is due mainly to the drug in solution but not associated with liposomes. Evidence for this was demonstrated by gel filtration chromatography. Thus, the overall encapsulation of triamcinolone acetonide, determined in the final purified liposomal fraction, was only 5% while that of its palmitate derivative was found to be 85%. The encapsulation of the palmitate derivative could be close to 100%, if one considers the unavoidable loss due to the filtration and centrifugation procedures, *i.e.*, by adsorption to the filter and glassware. Another minor but inherent loss of liposomes could be due to the presence of small (<0.5-μm) liposomes, which are not completely sedimented by centrifugation. However, for comparison purposes, both preparations were analyzed by the same procedures, and consequently, the same considerations should be applied.

A possible reason for increased encapsulation of the palmitate derivative could be the change in the partition coefficient. For lipid-soluble compounds a logarithmic partition coefficient (log P) between 1.7 and 4 is unfavorable for liposomal encapsulation (8). Triamcinolone acetonide has a log P of 2.53 (9). Palmitoylation would increase this to ~11 as calculated using substituent constants (9).

The mechanism for increased encapsulation could be predicted to be analogous to that of hydrocortisone-21-palmitate (10). The palmitoyl chain may act as "hydrophobic anchor" holding the steroid head group on the surface of the lipid bilayer.

One of the drawbacks in liposomal drug delivery systems is the poor encapsulation of the drug in the liposomes. Chemical modification is likely to be a powerful approach to overcome such an obstacle, as evidenced here and elsewhere (6). Although only a small amount of the drug was associated with the liposomes, the drug disposition was altered favorably on dermal application of a triamcinolone acetonide liposomal preparation (4, 5). In light of this, the potential usefulness of this highly concentrated liposomal triamcinolone

Quantitation of Amphotericins by Reverse-Phase High-Performance Liquid Chromatography

MICHEL MARGOSIS ˣ and ADORJAN ASZALOS

Received February 26, 1982, from the *Food and Drug Administration, Division of Drug Biology, Washington, DC 20204.* Accepted for publication April 26, 1983.

Abstract □ A reverse-phase high-performance liquid chromatographic (HPLC) method was developed for simultaneous potency determination of amphotericin A and amphotericin B in bulk amphotericin B preparations. This single, rapid, specific, and simple method can be used for qualitative and quantitative analyses and is proposed to replace a combination of cumbersome official tests presently in use. This new HPLC method employs an isocratic acidic phosphate buffer–methanol mixture in a reverse mode on an octadecylsilane-bonded silica column at ambient temperature, using UV detection at 313 nm. Results obtained by HPLC compare favorably with the official assay results. During these studies, an apparent heptaenic component, not previously described, was detected in commercial amphotericin B preparations at concentrations ranging from ~6 to 14%.

Keyphrases □ Quantitation—amphotericin B, amphotericin A, reverse-phase HPLC □ Amphotericin B—quantitation with amphotericin A, reverse-phase HPLC

Amphotericin B (1) (CAS registry 1397-89-3), produced by a strain of *Streptomycetes nodusus*, is an amphoteric macrocyclic polyene antibiotic that has become a valuable therapeutic agent in the treatment of fungal and monilial infections in humans (1). Polyene antibiotics are characterized chemically by strong absorption in the UV and visible regions of the spectrum, ascribed mainly to conjugated unsaturation with four (tetraenes) to seven (heptaenes) double bonds (1, 2). These substances are relatively unstable, and the heptaenes, in particular, are insoluble in most solvents.

Bulk amphotericin B is commercially available in two forms—one is purified for use in parenteral products (type I) and the other is a cruder grade for topical applications (type II). According to the official monograph (3), the potency of each form must be ≥750 μg/mg on the anhydrous basis. Both types may also contain amphotericin A, a cofermented tetraene very similar to nystatin; however, type I may contain ≤5% amphotericin A, whereas type II may contain ≤15% amphotericin A. Characteristics of amphotericin B are extensively discussed and reviewed with respect to physicochemical and analytical properties by Asher *et al.* (1) and Thomas (2).

Official requirements for the premarketing certification of amphotericin B (3) include a microbiological agar diffusion assay, a quantitative differential UV spectrophotometric procedure for the determination of the amphotericin A content, and a qualitative UV spectrophotometric identity test for amphotericin B. The microbiological assay measures the total activity of substances responding to a particular organism in comparison with an established standard of defined activity. Selectivity, precision, and reliability of this microbiological assay are inadequate, especially because of the deleterious effect of the high pH (4, 5) needed to solubilize the substance during this assay.

Reverse-phase high-performance liquid chromatography (HPLC) was demonstrated by Mechlinski and Schaffner (6) to be well suited to the qualitative analysis of such intractable

substances as the polyene antibiotics. Subsequently, Nillson-Ehle *et al.* (7) used this technique to quantitate amphotericin B in biological fluids. An HPLC system showing a partial separation of amphotericin A and amphotericin B was also described by Asher *et al.* (1). However, none of these methods provide the separation needed for a reliable assay of the components present in the bulk material. The method described and discussed here is proposed to replace the three methods (3) that are currently used for the certification of amphotericin B bulk preparations.

Instrument—A liquid chromatograph[1] equipped with a septumless valve injector[2] and a fixed-wavelength UV detector[3] with a 313-nm filter was used for all quantitative analysis. This was connected to a recording device[4] and an electronic integrator[5]. A special system[6] described by DiCesare *et al.* (8) was used for the qualitative analysis.

Column—A stainless steel column (4.6 × 150 mm) commercially packed with fully porous 7- to 8-μm silica particles to which a monomolecular layer of octadecylsilane was chemically bonded[7] was used in the quantitative phase of this study. The inlet of this analytical column was connected to a guard precolumn (4.6 × 100 mm) gravity-packed with an octadecylsilane-bonded silica of ~40-μm particle size[8]. The column system was equilibrated and conditioned with passage of ~10–15 void volumes of mobile phase, and tested for initial performance and suitability as described previously (7). A stainless steel column (4.6 × 100 mm) commercially packed with 3-μm octadecylsilane-bonded silica especially designed for high-speed analysis[9] was used in the qualitative study.

Chemicals and Reagents—Amphotericin B[10], labeled to contain 954 μg of amphotericin B/mg of powdered standard (containing 0.24% amphotericin A), was used as the external standard. Standards of amphotericin A[11] of unknown purity and nystatin[12] were also used. The dimethyl sulfoxide was spectro grade, phosphoric acid and sodium dihydrogen phosphate were reagent grade, and methanol was distilled-in-glass quality[13]. All the water used was deionized[14].

Stock Solutions—Approximately 6.3 g of sodium dihydrogen phosphate was dissolved in 950 mL of deionized water in a 1-L volumetric flask. The pH was adjusted to 2.6 with concentrated phosphoric acid, and the solution was diluted to volume with water.

Mobile Phase—A 300-mL aliquot of the phosphate solution was diluted to 1.00 L with methanol. This solution was mixed and deaerated by passing it through a 0.5-μm filter and ultrasonicating it for 2 min before use. As an added precaution, helium was allowed to sparge perceptibly through a 2-μm metal filter into this mobile phase during analysis to ensure maximum elimination of dissolved air. If necessary, the ratio of methanol to aqueous buffer can be adjusted to obtain adequate retention and peak separation.

Standard Solution and Sample—Approximately 25 mg of the amphotericin B standard was accurately weighed into a 25-mL volumetric flask, which was then filled to volume with dimethyl sulfoxide. The solution was mixed, shaken, and ultrasonicated until totally clear. The amphotericin B samples were prepared in a manner identical with that of the standard with ~25 mg of amphotericin B type I and ~30 mg of amphotericin B type II. All solutions of amphotericin B should be prepared fresh just before use.

Conditions for Quantitation—A constant operating temperature (ambient) was maintained, and the mobile phase flow rate of 2.0–2.5 mL/min was adjusted to give peaks of satisfactory configuration. The detector sensitivity was controlled to produce peak heights >50% full scale deflection with a chart speed of 2.5 mm/min. Chromatograms used for calculating performance parameters were obtained at a chart speed of at least 25 mm/min to allow better visual measurement of peak geometry for greater accuracy. The column was rinsed with methanol for 1 min and equilibrium was reestablished with the mobile phase before each injection.

Assay and Calculations—Carefully measured 15.0-μL aliquots of standard and sample solutions were injected sequentially into the chromatograph. Quantitation was achieved by comparing peak heights (and/or areas) of samples to that of the standard according to the following equations:

tericin B sample, C_A is the concentration of amphotericin A in the amphotericin B sample solution, P_B is the height (or area) of the amphotericin B peak in the amphotericin B sample, C_B is the concentration of amphotericin B in the amphotericin B sample solution, P_S is the height (or area) of the corresponding component peak in the amphotericin B standard reference material, and C_S is the concentration of the corresponding component in the solution of amphotericin B standard reference material. An APL time-sharing computer system[15] was used to plot all graphs and to perform all calculations and data reduction.

Amphotericin B is quite insoluble in most organic solvents; for this analysis it was dissolved in neat dimethyl sulfoxide. Initial attempts to dilute the dimethyl sulfoxide solutions with methanol frequently caused gelatinous precipitates, particularly with methanol–dimethyl sulfoxide ratios >9:1. One beneficial effect of neat dimethyl sulfoxide injections was slightly better peak resolution. On the other hand, the inactivating effect of dimethyl sulfoxide and residual sample (retained solutes) in the column diminished retention time with each subsequent injection. However, the original retention time was restored rapidly with a 1-min methanol rinse. One may alternate injections of samples and methanol rinses to maximize replication of retention; however, the actual frequency of column rinsings will depend on the total amount of solute injected. For samples analyzed within 1 d, peak heights for seven injections of standard interspersed with samples and rinses showed a coefficient of variation of 1.46%.

The stability of amphotericin B is greatest at a neutral pH where it exists as a zwitterion; however, better separation was achieved with ion suppression of the acid function. The use of acidic media in the HPLC procedure tends

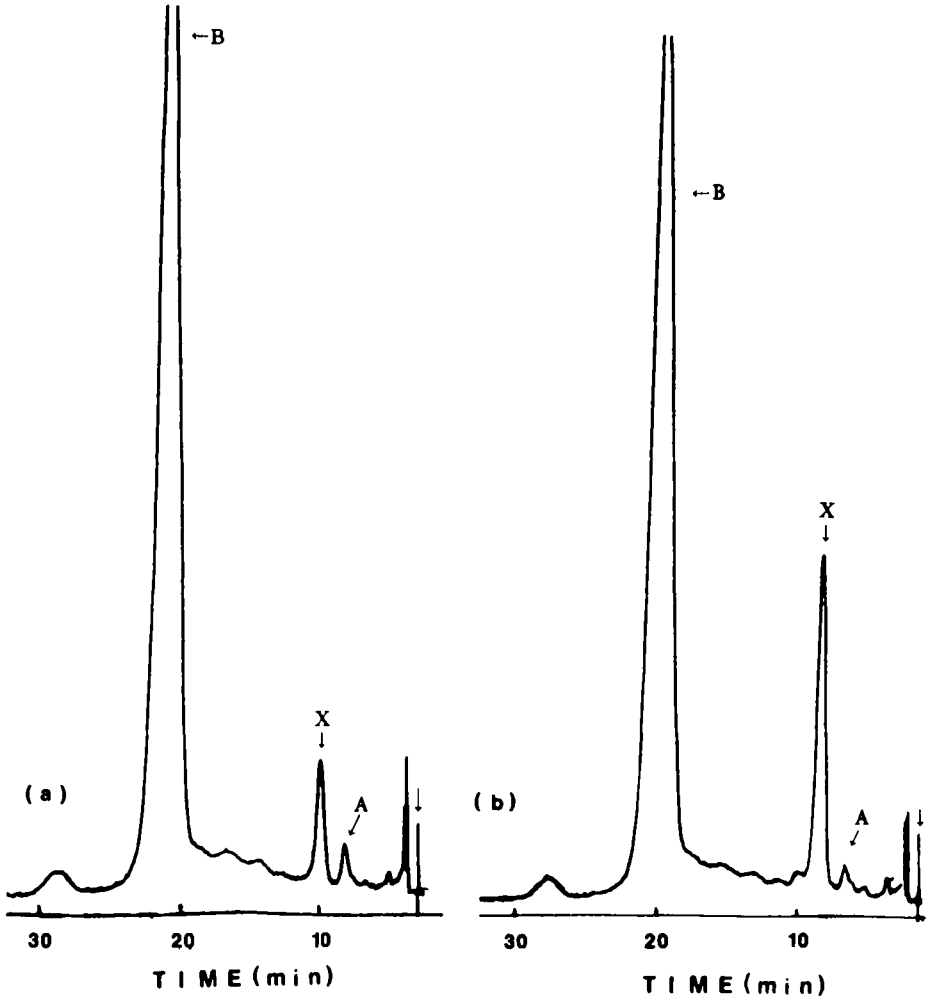

Figure 1—*Chromatograms of bulk amphotericin B from E. R. Squibb & Sons, Inc., type I (a) (batch #58022-002) and type II (b) (batch #58334-404). Key: (A) amphotericin A; (B) amphotericin B; and (X) amphotericin X.*

to approximate the method of isolation of the antibiotic from the broth in commercial production. The adverse effect of the acidity of the buffer is diminished by the high concentration of methanol in the mobile phase.

The capacity factor for amphotericin B is 25, but in spite of its magnitude, the column efficiency calculated as the reduced plate height is ~32. The separation factors for amphotericin A and amphotericin X (unidentified heptaene component) compared with amphotericin B are 4.3 and 2.7, respectively, with resolution factors of 4.4 and 3.4 between the same pairs of peaks. It is noted that although the column of 3-μm particles yielded substantially more plates, it provided about the same absolute efficiency as the column of larger particles (7–8 μm).

Qualitative Analysis—Samples of type I and type II amphotericin B yielded the chromatographic profiles shown in Fig. 1a and b, respectively, showing peaks attributed to amphotericin A and one labeled amphotericin X. These chromatograms are meant merely to provide a visual example of a separation previously unavailable from a qualitative standpoint and to indicate the relatively large quantitative difference between the two types (I and II) of commercial amphotericins. However, note that these chromatograms were not necessarily obtained the same day.

To the authors' knowledge, the presence of this newly discovered component in amphotericin B has never been described in the literature. Although the chromatograms of the type I and type II samples appear to be very similar from a qualitative standpoint, the type I sample is purer because it has a higher potency and contains less than half the amount of amphotericin X.

Amphotericin A and nystatin were believed for a long time to be identical. Consequently, because the spectral characteristics of both of these substances are so similar and because nystatin is more readily available than amphotericin A, the former is used as a standard to assay for the latter. Although these two substances had been separated under different conditions[16], they were not resolved by the method described here, demonstrating again their close similarity[17].

Chromatographic peaks were examined on-line by UV spectrophotometry (6) with the system[6] previously described. This system allows rapid elution (4 *versus* 30 min) with good resolution of peaks because of the short column packed with smaller particles (3 μm) and because of the accessory spectrophotometer especially designed with a 2.4-μL cell. This system also provides fast response time and a very low dead volume. Several peaks were subjected to UV scanning in an attempt to confirm or identify them. The resultant spectra indicated correctly that the peak attributed to amphotericin A is that of a tetraene; four other peaks including those labeled amphotericin B and amphotericin X were characterized as heptaene peaks on the basis of UV characteristics identical to those of known heptaenes.

Polyene antibiotics exhibit multiplet absorption peaks in the UV region; absorption maxima for the tetraene amphotericin A occur with decreasing intensity at 305, 318, 290, and 280 nm and at 406, 382, 363, and 356 nm for heptaenes (*e.g.*, amphotericin B) with this system[6]. The 313-nm filter of a photometer with a band spread of 10 ± 2 nm allows good sensitivity for minor tetraene peaks while simultaneously enabling adequate detection of heptaenes. Spectra of the amphotericins have also been published (1, 2).

Quantitative Analysis—Table I lists the calculated potency of several lots of commercial amphotericins; Table II gives the content of amphotericin A in the same samples.

A calibration curve for amphotericin B was obtained by plotting amounts ranging from ~5 to 26 μg of the injected drug against peak height and peak area. A rectilinear relationship was observed with corresponding correlation coefficients of 0.9999 and 0.9991 and corresponding relative percentage errors of 0.58 and 1.50. Optimum quantitation is obtained when injections of both standard and sample solutions are of approximately the same concentration and volume because errors due to nonlinearity of the detector[3] and the injector[2] are minimized (9). The addition of an internal standard to improve precision is advisable, if possible, but the complexity of the chromatogram precluded its use here.

Because the standard addition method did not prove satisfactory, the content of amphotericin A in commercial samples was calculated from peak heights by direct comparison to the content of amphotericin A in the amphotericin B standard. This standard had been established to contain 0.24% of amphotericin A by the official procedure, which is based on differential spectrophotometry of a standard solution of amphotericin B and a standard solution

of nystatin. The latter has been shown to possess spectral characteristics nearly identical to that of amphotericin A[16,17].

The paired t test was used to compare bioassay results from the manufacturer with those from the HPLC method. No significant statistical difference was found at the 95% confidence level. It would be difficult and impractical at this juncture to make further comparisons among sample results because of the poor precision of microbiological assays for antifungal substances.

It can, therefore, be concluded that the commercial bulk material is predominantly amphotericin B containing a limited amount of the A congener and several heptaenes. The potency of type I amphotericin B may measure >900 μg/mg with ~6% amphotericin X, whereas type II shows a potency of ~800 μg/mg with ~11-14% amphotericin X.

In Vitro Stability of Sodium Nitroprusside Solutions for Intravenous Administration

CHERYL MAHONY *x, JAMES E. BROWN, W. WAYNE STARGEL, CHACKO P. VERGHESE, and THORIR D. BJORNSSON

Received August 27, 1982, from the *Divisions of Clinical Pharmacology and Cardiology, Departments of Pharmacology and Medicine, Duke University Medical Center, Durham, NC 27710.* Accepted for publication March 21, 1983.

*Present address: Division of Cardiology, College of Medicine, University of Kentucky Medical Center, Lexington, KY 40536.

Abstract □ A sensitive high-performance liquid chromatographic assay for nitroprusside using an ion-exchange column and UV detection was developed to evaluate the stability of aqueous solutions of sodium nitroprusside in light-protected glass and plastic containers and during simulated infusions. The results showed that sodium nitroprusside is stable in 5% dextrose, normal saline, and lactated Ringer's solutions in light-protected glass or plastic containers. In addition, there was no decrease in the delivered potency of sodium nitroprusside solutions during simulated infusions lasting up to 24 h.

Keyphrases □ Sodium nitroprusside—*in vitro* stability, solutions, intravenous administration, HPLC □ Stability—*in vitro*, sodium nitroprusside solutions, intravenous administration, HPLC

Sodium nitroprusside [$Na_2Fe(CN)_5NO{\cdot}2H_2O$] is a valuable agent in the treatment of congestive heart failure (1), cardiogenic shock complicating acute myocardial infarction (2), and hypertensive crisis (3). This drug is also used for the production of intraoperative hypotension (4). However, there are several problems associated with the clinical use of sodium nitroprusside, including tolerance (5), tachyphylaxis (6), and the toxicity of its metabolites, cyanide and thiocyanate (7). Some of these problems might be alleviated by an understanding of the pharmacokinetics of nitroprusside in humans. To derive pharmacokinetic parameters from data collected during a constant infusion, the amount of sodium nitroprusside delivered must be known. The purpose of this study was to investigate the stability of sodium nitroprusside in various intravenous solutions and during simulated infusions.

EXPERIMENTAL

Reagents and Chemicals—Sodium nitroprusside[1] was used as received. Analytical-grade KH_2PO_4 and H_3PO_4 and deionized water were used to prepare the mobile phase. All glassware used for sampling or storage of stock solutions was silanized[2].

Instruments and Chromatographic Conditions—An anion-exchange column[3] and a 0.5 M KH_2PO_4 buffer (pH 3.0) with H_3PO_4, were used to achieve the chromatographic separation. The high-performance liquid chromatography (HPLC) was performed with a solvent pumping system[4], a variable-wavelength UV detector[5], and an injector equipped with a 50-μL sample loop[6]. The absorbance was measured at 230 nm with a 0.1 AUFS deflection and was recorded on a three-pen recorder[7]. The flow rate was 1.4 mL/min, and the mobile phase was filtered and deaerated prior to use.

Stability Studies—Sodium nitroprusside (50 mg) was dissolved in 5 mL of water and then added to 500 or 1000 mL of a test solution, resulting in a final concentration of 100 and 50 μg/mL, respectively. The stability of sodium nitroprusside was tested in 5% dextrose, normal saline (0.9% NaCl), and lactated Ringer's solutions[8] in both glass[8] and plastic[8] containers. After the addition of the sodium nitroprusside concentrate, the test solution was mixed and a sample was withdrawn for use in the construction of a standard curve. The bottle or plastic bag was wrapped in aluminum foil and left exposed to laboratory (fluorescent) light for 48 h. Sodium nitroprusside standards were protected from light and stored at 4°C. The stability of the standard solutions was verified by comparing their concentrations with freshly prepared 100-

[a] Each value represents the mean of two experiments and is expressed as percent of control.

or 50-μg/mL sodium nitroprusside standard solutions; no deterioration in the refrigerated and light-protected stock solutions was noted over a 48-h period.

Infusion Studies—A volumetric pump[9] and infusion set[8] were employed. The plastic tubing made of polyvinyl chloride was left exposed to light. The infusion set tubing was 3 m long and held a volume of 20 mL. Flow rates of 10 and 50 mL/h for 24 and 8 h, respectively, were studied. Samples were taken from both the bottle and directly from the end of the tubing at each sampling interval.

Standard Curves—The standard solution of sodium nitroprusside, serially diluted with water to yield concentrations of 6.25, 12.5, 25, and 50 μg/mL, was injected directly onto the column with measurement of peak heights to generate a calibration curve. Each sample was injected in duplicate. The coefficients of variation for the standard curves ranged from 1 to 3%. The unknown samples were analyzed immediately after withdrawal from the container or infusion set at 0, 2, 4, 8, 24, 32, and 48 h after preparation. All experiments were performed in duplicate.

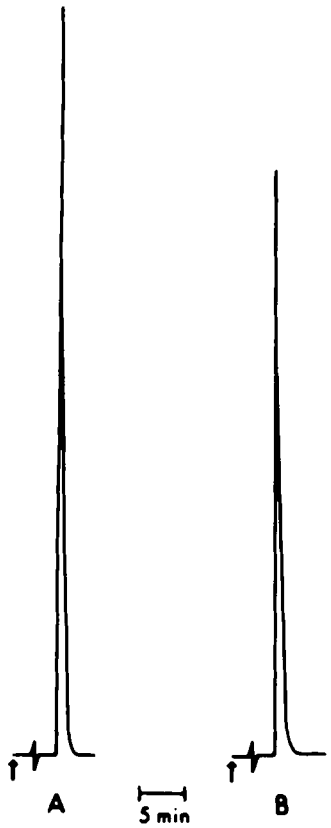

Figure 1—*Chromatogram of 5 μg of sodium nitroprusside in 5% dextrose before (A) and after exposure to light for 4 h (B). The arrow denotes the time of injection.*

[9] Life Care Pump; Abbott Laboratories, North Chicago, Ill.

Table II—Sodium Nitroprusside Stability in Intravenous Infusion Sets at Flow Rates of 10 and 50 mL/h [a]

Time, h	10 mL/h	50 mL/h
2	99.6	101.8
4	100.9	101.8
8	100.9	103.2
24	100.3	—

[a] Values represent the mean of two experiments and are expressed as percent of control.

RESULTS AND DISCUSSION
