Humidity aging of tablets was accomplished by manipulating water vapor pressure in closed tanks using saturated salt solutions (12). Standard all-glass aquariums (50 × 26 × 30 cm) with glass covers were used for constant humidity chambers. A saturated solution of potassium sulfate was prepared in deionized, distilled water and placed in the bottom of the tank to a depth of 2–3 cm (~2.6 L) to produce 98% relative humidity (rh). Solutions of sodium dichromate or potassium carbonate were used for 60% rh and sodium chloride was used for 75% rh. A galvanized rack was placed in the tank to hold aluminum foil-lined petri dishes 7 cm above the surface of the liquid. Air circulation was maintained within the tank by a small electrical fan mounted inside the tank. Humidity was monitored daily with a wet and dry bulb hygrometer. No attempt was made to regulate temperature within the chambers as temperature variability within the laboratory was small and temperature dependence of relative humidity using the salt solutions is small (12). The average relative humidity chamber temperature during the experiments was 20.1°C with a maximum range of 1.1°C. The chamber was made airtight by the use of foam strips impregnated with petroleum as a seal between the glass cover and the aquarium.

Tablets were subjected to the aging process by placing four tablets of each lot in aluminum foil-lined petri dishes without covers, taking care that no tablet

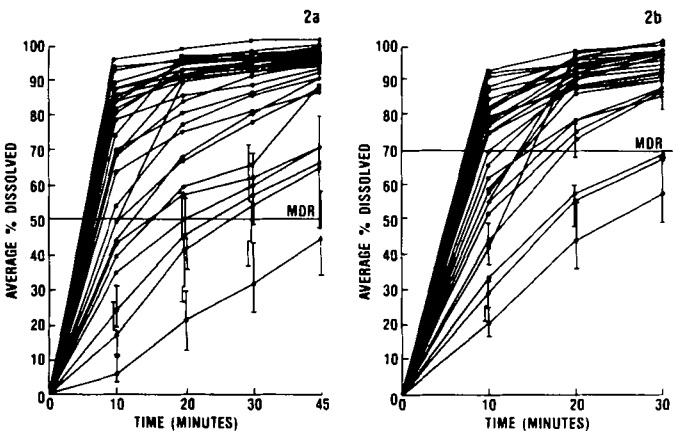

Figure 2—*Average percent of labeled tolbutamide dissolved from 500 mg of P tolbutamide tablets using the rotating-basket method (a) and the paddle-stirrer method (b). Each data point is the average of six tablets and each line is for a different lot, except tablets which failed the test. The lots which failed (2b) are the same lot number of the same manufacturer (P) but distributed under different private labels.*

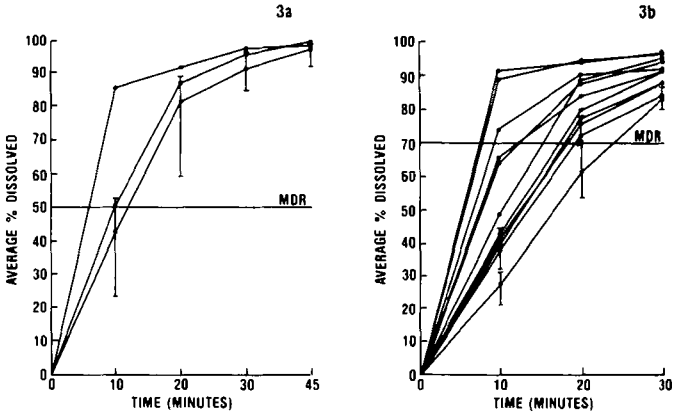

Figure 3—*Average percent of labeled tolbutamide dissolved from 500 mg of M tolbutamide tablets using the rotating-basket test (a) and the paddle-stirrer test (b).*

touched another. The chamber was then sealed and not opened until the end of the aging period.

Dissolution tests wherein the products were exposed to enzyme-free simulated gastric fluid (acid pretreatment) utilized 9.6 mL of concentrated hydrochloric acid per liter of water (pH ~1.1–1.2). Tablets of each product were allowed to separately dissolve, each in 900 mL of the simulated gastric fluid, in a USP rotating-basket apparatus at 150 rpm for 30 min. After 30 min the baskets were raised and allowed to drain. The acid dissolution medium was filtered under vacuum and then the filter paper with any retained solids was placed in a dissolution resin kettle (containing 900 mL of pH 7.4 phosphate buffer) fitted for paddle-stirrer dissolution. The contents of the basket were transferred to the phosphate buffer by gently dipping the basket (using forceps) into the buffer. Then the paddle was lowered and stirred at 75 rpm and samples were collected over time to determine the amount of tolbutamide dissolved.

RESULTS AND DISCUSSION

All lots passed the disintegration, assay, content uniformity, and tablet weight variation tests. However, there was considerable variation in dissolution characteristics among and within some lots.

Figure 1 shows that dissolution of tolbutamide from the innovators' (U) tablets[2] is relatively uniform within and among lots in both the rotating-basket and paddle-stirred apparatus. Figure 2 for the P product[3] shows wide interlot and intralot variation in dissolution. One lot (Fig. 2a) failed the USP rotating-basket test. The same lot number sold under a private label also failed the paddle-stirrer test (Fig. 2b) but passed the rotating-basket test. The cause of this dissolution variation is unknown. This lot is not the one reported earlier which also failed USP requirements (7). Figures 3–4 show dissolution profiles for tolbutamide products of some other manufacturers[4].

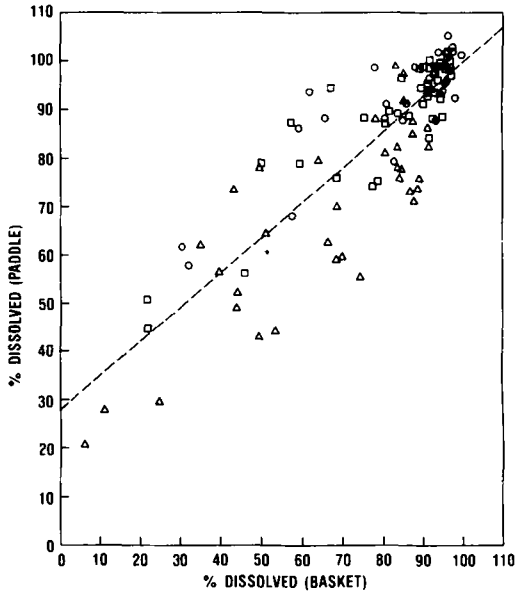

Figure 6—*Comparison of tolbutamide dissolved in paddle stirrer method* versus *rotating basket method. The generated regression line is F(x) = 27.95 + 0.705 x with $r^2 = 0.7444$; r^2 was not improved substantially by fitting to a polynomial of degree two or three. Key: (△) 10 min results; (□) 20 min results; (○) 30 min results.*

It is clear that interlot and intralot variation is manufacturer specific. For example, generic product in Fig. 3b is more variable than product in Fig. 1b, but some of the generic products in Fig. 4 produce dissolution profiles similar to those shown in Fig. 1b. Unfortunately, only a few product lots were available and these were only evaluated according to paddle-stirrer requirements (1). More lots should be tested to fully define the dissolution profiles of these products.

Figure 5 expands the information in Fig. 2a regarding both interlot and intralot variation for product P dissolution. The amount of drug released is highly dependent on the bottle (lot) used and the tablet within a bottle (lot) tested. The time to 50% dissolution was reported by Levy (6) to be related to clinical effectiveness for tolbutamide. The three lots in Fig. 5 required 1.9 min, 21.4 min, and 51.1 min, respectively, to average 50% dissolution in the USP rotating basket test. It must be noted that this test differs from the Levy (6) test, and the 51.1-min dissolution time does not necessarily imply the product will fail clinically. However, slow dissolution with wide intralot and interlot variations in dissolution rate are indicative of degree of quality control (1, 2).

The time to 50% (rotating-basket) and 70% (paddle-stirrer) dissolution for some lots of tolbutamide tested are shown in Table I. Intralot and interlot variability is manufacturer specific. The U product reached 50% and 70% dissolution ~40% faster and with 25–50% of the variation of P and M products. Products U, S, and Z were about equal in time to 70% dissolution, but too few S and Z lots were tested to be conclusive. In general, products dissolving most slowly or most rapidly in the rotating basket also dissolved slowly or rapidly, respectively, in the paddle-stirred test (Table I, Fig. 6) which indicates the two tests are correlated. However, the range of percent dissolved shows more

[a] Estimate based on interpolation between closest time intervals sampled. [b] Product identification: U, Upjohn; P, Premo; M, Mylan; PH, Pharmadyne; Z, Zenith; S, Smith Kline & French. [c] Method requires at least 50% dissolution in 45 min. [d] Method requires at least 70% dissolution in 30 min. Some lots in different-size bottles or received at different times were evaluated twice (U3, U12; U4, U13; U2, U14; M3, M6; S3, S4).

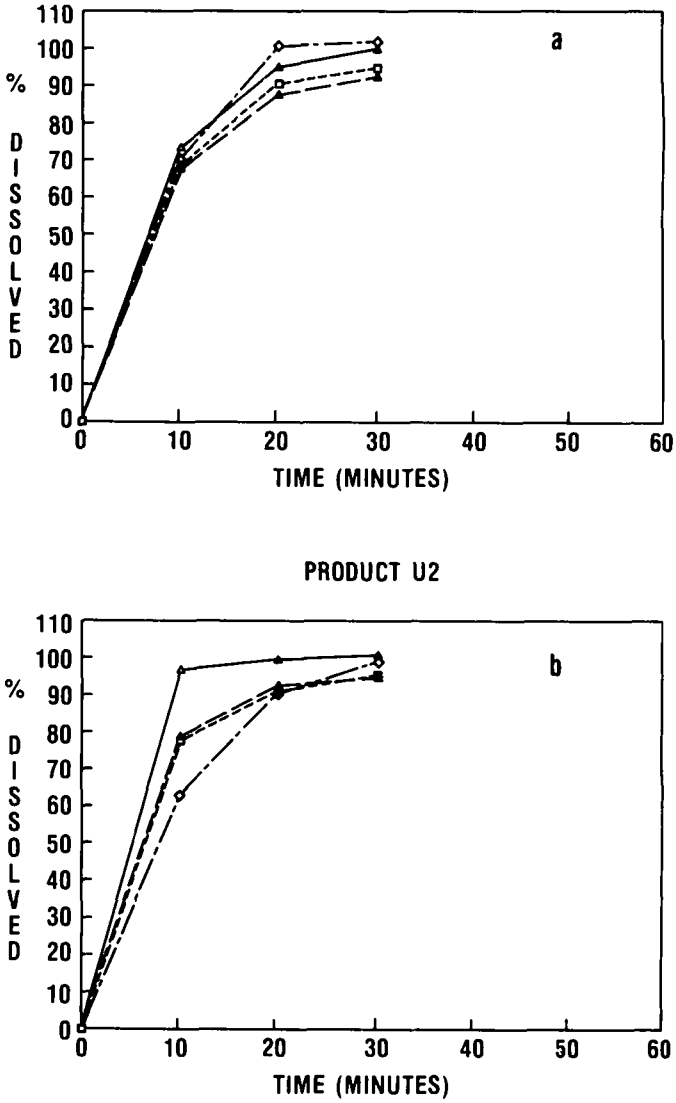

Figure 8—*Effect of aging tolbutamide tablets for various times at 98% relative humidity for two lots (a, b) of U products. Key: (△) fresh; aged (□) 3 weeks, (◇) 6 weeks, (▲) 12 weeks.*

variation in the basket-stirrer tests at each sampling time. This may be because more rapid dissolution occurs with paddle stirring and there is a natural compression of the possible range of percent dissolved drug on the upper end (*i.e.*, 100% is an upper boundary). Thus, one comparative effect is that intralot variation is compressed or more difficult to identify in the paddle-stirring test than in the rotating-basket test.

Khalil *et al.* (8) reported that humidity aging may be used to identify tolbutamide tablets which were not equivalent in their dissolution responses. The effects of humidity aging on tolbutamide lots selected for a paddle-stirrer dissolution study (based on their range of dissolution profiles when fresh) are shown in Fig. 7. Dissolution profiles of U tablets were little affected by aging ≤12 weeks at rh values of 60, 75, or 98%. The other manufacturers' products were not affected by 60% rh, but two lots failed the dissolution test after 75% and three lots failed after 98% rh. Lots P2 and P3 failed to pass the test even after 18 h of dissolution following 12 weeks at 98% rh; these tablets remained intact, or nearly intact.

Figures 8 and 9 show the combined time and rh effects on tablet dissolution. The U products were only slightly affected for all times at 98% rh (Fig. 8b). Lesser effects occurred with 60 and 75% rh. For P and PH products, 98% rh aging variously affected dissolution depending on the lot (Figs. 9). Both 60 and 75% rh affected lot P2 but not lot P1 tablets (Figs. 10). The reason for this lot-specific variable response is unknown. The *CV* for percent tolbutamide dissolved at all rh values is low when the percent of labeled drug dissolved is high (>90%) and sometimes when the percent is low (<10%). Products that are dissolved 20–80% at any given sampling time show differences in both intralot and interlot variation among manufacturers; the same is seen with unaged tablets. Thus, since the innovator's products (U) dissolve quickly

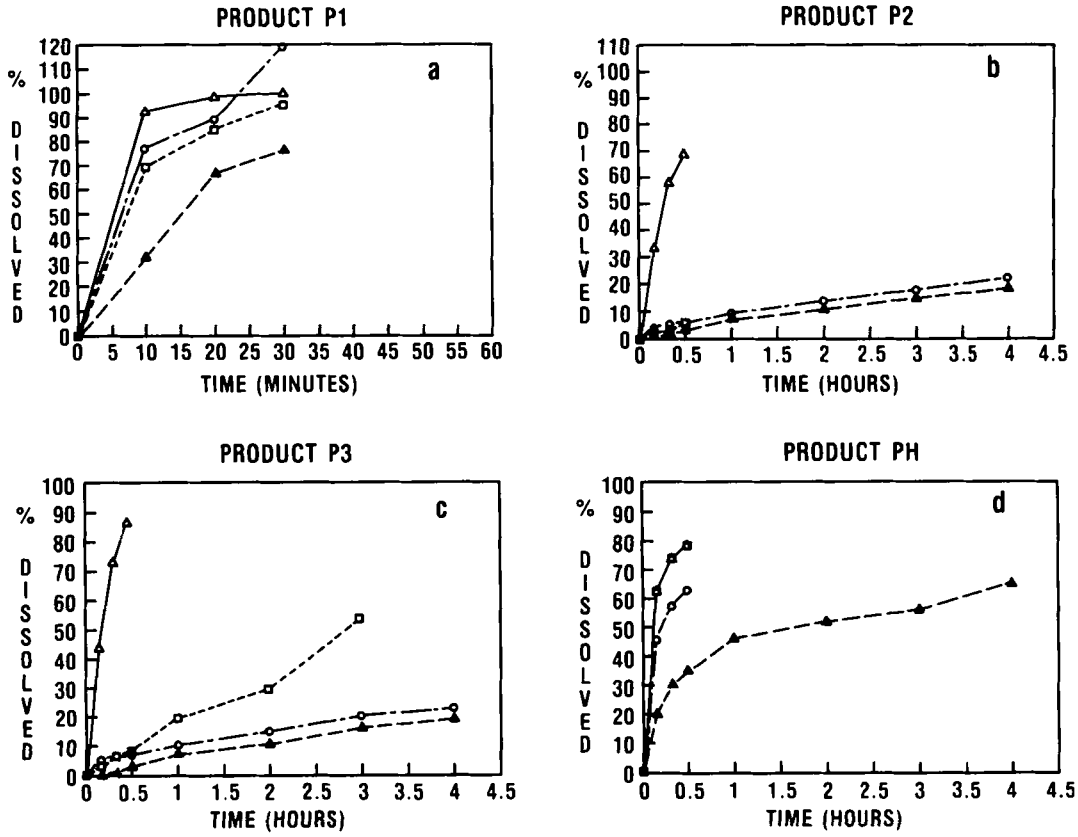

Figure 9—*Effect of aging tolbutamide tablets for various times at 98% relative humidity for P and PH products. P1 (a), P2 (b), and P3 (d) are different lots of P. For PH (d), fresh tablets and tablets aged for 3 weeks aging gave nearly identical values. Key: (△) fresh; aged (□) 3 weeks, (○) 6 weeks, (▲) 12 weeks.*

(>95% after 30 min for fresh and humidity-aged tablets), the dissolution *CV* for U products was generally much lower than for the generic products which dissolved more slowly (for fresh tablets and humidity-aged tablets).

The finding that tolbutamide tablets from different manufacturers and different lots from the same manufacturer did not dissolve equivalently after as little as 3 weeks of aging at different rh values prompted investigation of the effects of shorter exposure. There was no effect on product U (Fig. 11).

Dissolution of P products continued to be variable and effects ranged from marked depression of dissolution (after only 24 h exposure to 98% rh) to virtually no effect, depending on the lot tested. The effects of humidity were lot specific for M (Fig. 12), dramatically depressing dissolution for one lot but not the other. No effect was observed for S products and both lots of Z products were depressed.

One product, reported to fail the USP dissolution test (7), has been evalu-

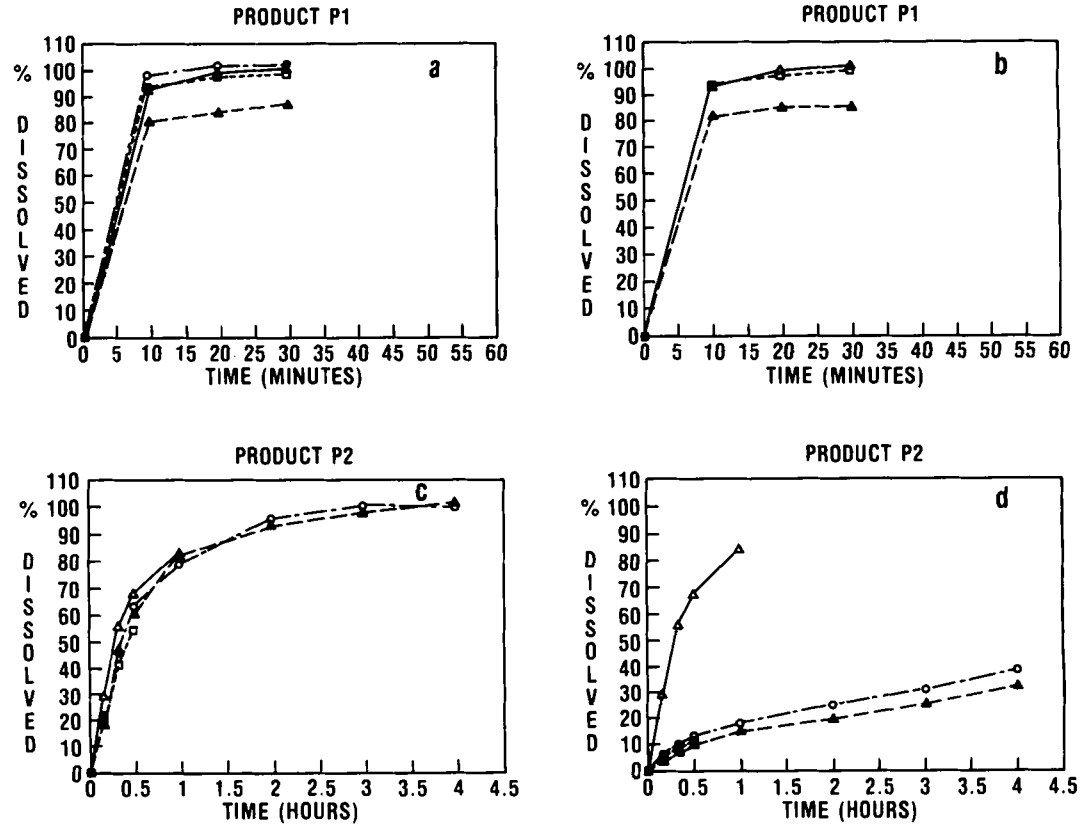

Figure 10—*Dissolution response of two lots of generic product P to 60% (a and c) and 75% (b and d) relative humidity aging for different time periods. Key: see Fig. 9.*

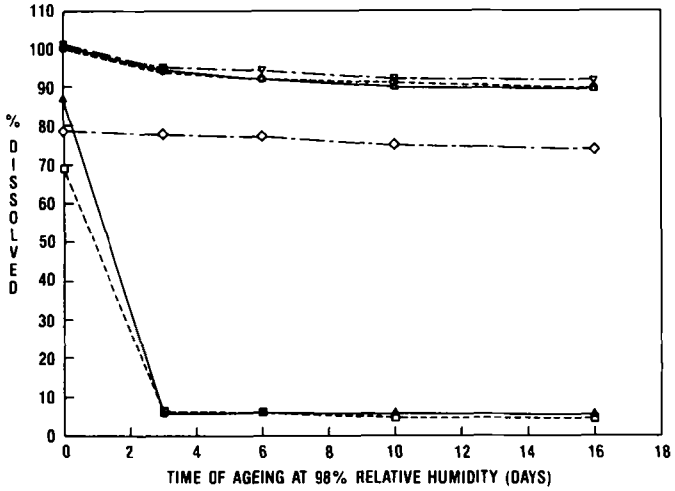

Figure 11—*Effect of short time aging on paddle-stirred dissolved drug at 30 min of different lots of U, P, and PH tolbutamide at 98% relative humidity. Key: (△) P1; (□) P2; (▲) P3; (◇) PH; (○) U1; (▽) U2.*

ated in 4 human subjects (13). The cause of the large *in vivo* variability in such a small study can not be precisely assigned. It may be due to product formulation and variable dissolution or subject variation. The variation observed *in vivo*, although larger for product P than U, was less than one might expect based on the USP dissolution test. That may be because the test does not simulate the normal exposure of tablets to the gastric acid of the stomach followed by exposure to intestinal fluid. Tuttle *et al.* (9) have reported that some tolbutamide tablets require exposure to an acidic environment in order to disintegrate and dissolve. It was proposed that these tablets contain inert formulation ingredients which are pH sensitive. Therefore, some tablets were pretreated in 0.1 M HCl for 30 min and then allowed to dissolve in pH 7.4 phosphate buffer using the USP paddle-stirrer test described in the *Experimental Section.*

Acid pretreatment produced a dramatic effect on dissolution time of P, but

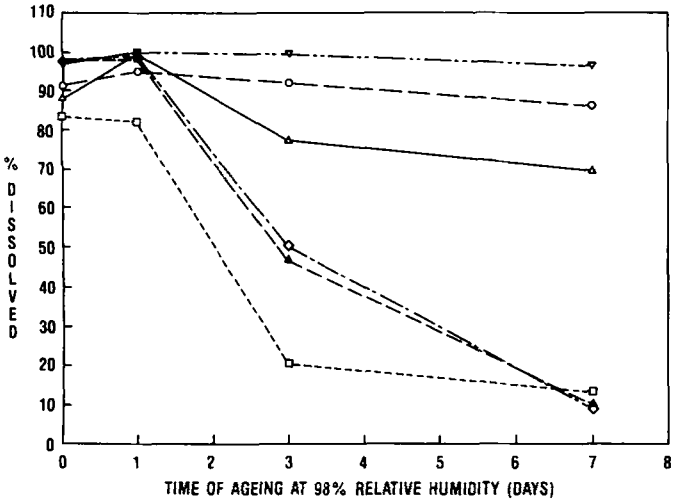

Figure 12—*Variation in paddle-stirred dissolved drug at 30 min of M, S, and Z after short-time aging at 98% relative humidity. Key: (△) M1; (□) M2; (◇) Z1; (▲) Z2; (○) S1; (▽) S2.*

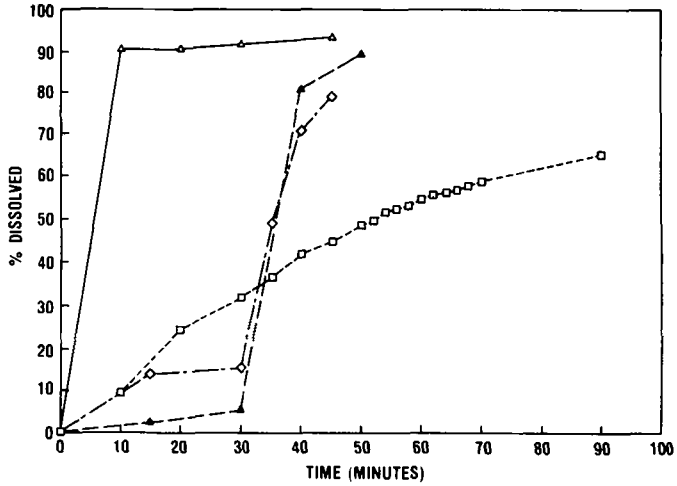

Figure 13—*Effect of pretreatment with simulated gastric fluid on U and P tolbutamide tablet products. The "no pretreatment" dissolution [(△)U; (□)P] was in phosphate buffer (pH 7.4) from time zero. The "acid pretreatment" dissolution [(◇)U; (▲)P] was in acid from time zero to 30 min and then in phosphate buffer from time 30 min to the last data point.*

had practically no effect on U (Fig. 13). That is, after acid pretreatment, both P and U dissolved at about the same rate as U without acid pretreatment. This dependence of the generic product on acid pretreatment may be undesirable (9).

Prolonged contact of tolbutamide with the GI tract, due to poor dissolution, may cause nausea, vomiting, or cramps (14). Constant patient monitoring appears prudent when products with highly variable interlot and intralot rates of dissolution are employed.

Liquid Chromatographic Analysis of Sulfaquinoxaline and Its Application to Pharmacokinetic Studies in Rabbits

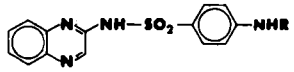
J. G. EPPEL and J. J. THIESSEN ˣ

Received September 9, 1983, from the *Faculty of Pharmacy, University of Toronto, Toronto, Canada M5S 1A1.* Accepted for publication February 24, 1984.

Abstract □ A specific, sensitive high-performance liquid chromatographic method is described for sulfaquinoxaline (I) and its major metabolite, the N^4-acetyl metabolite (II), in biological fluids. Detection limits for I and II were 0.25 and 0.50 μg/mL in plasma and 0.10 and 0.20 μg/mL in urine, respectively. The pharmacokinetics of sulfaquinoxaline and its metabolite were studied in New Zealand White rabbits after individual doses of 50 mg/kg of sulfaquinoxaline and its metabolite were administered intravenously. Mean (±*SD*) plasma half-lives were 12.7 (8.0) h for sulfaquinoxaline and 15.4 (3.5) h for the metabolite. After administration of the *N*-acetyl metabolite sulfaquinoxaline appeared in the plasma and urine indicating that deacetylation had occurred. The repercussions of this observation are briefly discussed with respect to two rabbits in which plasma analyses and complete urine collections were made. As sulfaquinoxaline is administered prophylactically to rabbits by some breeders, it is recommended that investigators allow a washout period of about one week after receipt of the animals.

Keyphrases □ Sulfaquinoxaline—HPLC, pharmacokinetics, rabbits □ Pharmacokinetics—sulfaquinoxaline, rabbits, HPLC

Laboratory animal breeders frequently use sulfaquinoxaline (I) on a chronic basis in feed or water to prevent outbreaks of coccidiosis in rabbits. Measurable quantities of sulfaquinoxaline or its metabolite may therefore be present in the blood or tissues of these animals after delivery to the laboratory. This report examines the hitherto unreported pharmacokinetics of the drug and its major metabolite, the N^4-acetyl metabolite (II), in rabbits, to determine the washout period needed to avoid incorrect conclusions from pharmacokinetics or pharmacodynamic studies.



I R·H
II R·COCH$_3$

BACKGROUND

A number of analytical procedures have been used to detect sulfaquinoxaline and related compounds. These include spectrophotometry (1-4), GC (5), TLC and column chromatography (6-10), and high-performance liquid chromatography (HPLC) (11-15). A new HPLC assay has been developed for both sulfaquinoxaline and its major metabolite in order to improve upon the specificity, sensitivity, simplicity, and/or analysis time of available methods, and to explore the pharmacokinetics of the drug and its metabolite in selected species.

Pharmacokinetic studies of sulfaquinoxaline and/or its metabolites have been conducted in a number of species but not, surprisingly, in rabbits. Elimination half-lives for sulfaquinoxaline reportedly range from 6 to 15 h in cattle (16, 17), to ≥1 d in rats (18-20) and dogs (19, 20). This wide range of half-lives obviates a reliable estimate of the washout time required for sulfaquinoxaline or its metabolites in rabbits. This report, therefore, provides information on the pharmacokinetics of sulfaquinoxaline and its N^4-acetyl metabolite in rabbits.

EXPERIMENTAL SECTION

Instrumentation—A high-pressure pump[1], a high-pressure injector[2], a UV detector[3] (252 or 360 nm), and a recorder[4] comprised the chromatographic apparatus. Chromatography was performed on a reverse-phase column[5], using a reverse-phase precolumn[6] to extend column life. The mobile phase, at a flow rate of 1.7 mL/min, consisted of 35 parts methanol[7] and 65 parts 0.2 M KH_2PO_4-Na_2HPO_4 buffer[8] (pH 7). Prior to use, the mobile phase was sonicated for 5 min to remove trapped gas.

Preparation of Standards—An alkaline, aqueous stock solution (pH ~11) was prepared containing 0.2 and 0.4 mg/mL of sulfaquinoxaline[9] and the N^4-acetyl metabolite[9], respectively. Appropriate dilutions with water were prepared to yield standards ranging in concentration from 0.5 to 200 μg/mL for sulfaquinoxaline and 1.0 to 400 μg/mL for the metabolite. At the time of analysis, 50 μL of the standards was added to blank rabbit plasma (100 μL), or 100 μL of the standards was added to blank rabbit urine (500 μL).

Sample Preparation—A fixed plasma volume (100 μL) was used for all samples. Acetone[8] (300 μL) was added slowly, while vortexing, to precipitate proteins. The mixture was centrifuged (1700×*g*) for 4 min, 100 μL of the supernatant was evaporated to dryness at 65°C under a nitrogen stream, and the residue was reconstituted with 200 μL of mobile phase. An appropriate volume (20-100 μL) was injected. Glacial acetic acid-sodium acetate buffer[10] (3 M, pH 6, 500 μL) was added to a fixed volume of urine (500 μL). After mixing, the solution was extracted with methylene chloride[11] (4.0 mL). The organic phase (0.5-1.5 mL) was evaporated to dryness, following which the sample was prepared for chromatography as described above.

Pharmacokinetic Studies in Rabbits—Sulfaquinoxaline or its metabolite (50 mg/kg) was administered as an intravenous bolus dose to male New Zealand White rabbits[12] receiving 150 g of rabbit feed[13] daily and water *ad libitum*. The sulfonamide solution was prepared by dissolving sulfaquinoxaline or its metabolite in a minimum of base and back-titrating with acid to a pH of ~9 and ~10 for the drug or the metabolite, respectively. A portion of the filtered[14] solution was retained for analysis. After dose administration *via* a marginal ear vein, blood was collected from the contralateral vein through a catheter[15]. Harvested plasma from heparinized blood was frozen until analyzed. Complete, quantitative urine collections were accomplished with an indwelling bladder catheter[16] for the first 8 h followed by further recovery from a metabolic cage[17]. The urine samples were carefully mixed, centrifuged, and the supernatant was frozen until analyzed.

Data Analysis—Calibration curves of sulfaquinoxaline or the N^4-acetyl metabolite were based upon absolute peak heights obtained from a fixed HPLC injection volume. Unknown concentrations were obtained by interpolation from these linearized curves. Pharmacokinetic parameters were computed by standard methods (21). Data were analyzed[18] with a nonlinear regression program developed by D'Argenio and Schumitsky (22). The weighting factor throughout was the inverse-square of the observed data. The required number of exponentials was established by the method of Boxenbaum *et al.* (23).

RESULTS AND DISCUSSION

Development of Assay—Figure 1 illustrates chromatograms of sulfaquinoxaline and its metabolite obtained after processing rabbit plasma and urine samples. The drug and its metabolite eluted in a reasonable period of time, were well resolved, and well separated from materials inherently present in biological fluids. A number of compounds, including nine other sulfonamides,

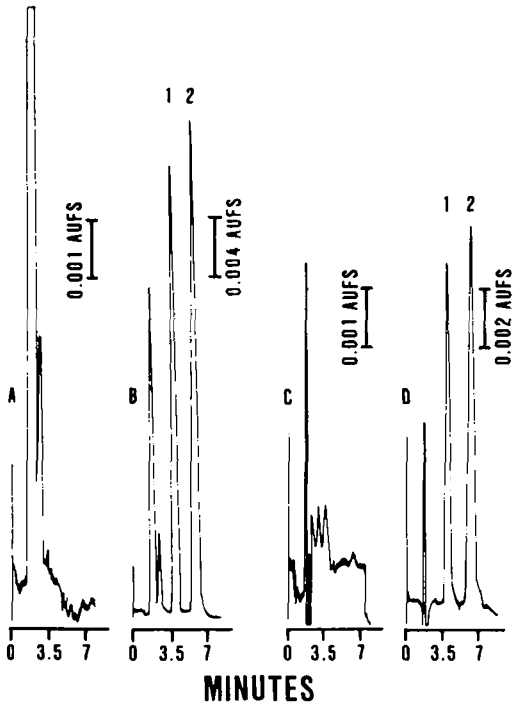

Figure 1—*Chromatograms obtained for sulfaquinoxaline (1) and the* N^4*-acetyl metabolite (2) in rabbit plasma and urine. The mobile phase consisted of 35 parts methanol and 65 parts 0.2 M, pH 7, phosphate buffer flowing at 1.7 mL/min through an* RP_{18} *column (250 × 4.6 mm i.d.). Detection was at 252 nm for plasma and 360 nm for urine. Key: (A) blank rabbit plasma; (B) sulfaquinoxaline (52.25 μg/mL) and the* N^4*-acetyl metabolite (100.5 μg/mL) in blank rabbit plasma; (C) blank rabbit urine; (D) sulfaquinoxaline (39.80 μg/mL) and the* N^4*-acetyl metabolite (83.40 μg/mL) in blank rabbit urine.*

were tested as potential internal standards. Invariably they eluted too quickly or interfered with the quantitation of I and II which exhibited retention times of ~3.6 and 5.5 min, respectively. Since no suitable internal standard was found, a fixed-volume injection method was employed. The absolute limits of detection, expressed as a measurable peak at least three times the baseline noise, were 2.8 and 5.5 ng for I and II, respectively. Using the aforementioned sample preparation methods, the limits became 0.25 and 0.50 μg/mL in plasma and 0.10 and 0.20 μg/mL in urine, respectively.

The composition of the mobile phase was examined and it was found that decreasing the methanol concentration increased the retention times for both compounds. However, the retention time of II increased at a faster rate than I. Buffer strength had little effect on the range from 0.10 to 0.25 M. The pH of the buffer had a pronounced effect on I and II. Increases in pH >4 led to rapid decreases in times, especially for II. The results for sulfaquinoxaline are in keeping with its reported pK_a of ~6 (11, 19). Surprisingly, pH 7 proved to be a good compromise between short times and well-resolved peaks, even though it exceeded the pK_a.

Table I—The Effect of Urine pH Buffered With 3 M Acetate Buffer on the Recovery of Sulfaquinoxaline (I) and the N^4-Acetyl Metabolite (II)

Compound	Buffer-Urine pH	Relative Compound Peak Height[a]	Relative Interference Peak Height[b]
I	4.49	0.91	0.0275
	4.94	0.95	0.0221
	5.42	0.97	0.0176
	5.95	0.89	0.0097
	6.52	0.85	0.0024
II	4.49	0.97	0.0056
	4.94	1.00	0.0069
	5.42	1.00	0.0080
	5.95	0.88	0.0100
	6.52	0.42	0.0123

[a] Ratio of the peak height of the compound, after adjusting for interference peaks, to the height from a standard prepared in water. [b] Ratio of the interference peak height observed in blank urine to the peak height of the compound corrected for the interfering peak; measured at 252 nm.

Table II—Intra-assay Variability in the Analysis of Plasma or Urine Sulfaquinoxaline (I) and the N^4-Acetyl Metabolite (II) Standards[a]

Compound	Conc., μg/mL		CV, %	
	Plasma	Urine	Plasma	Urine
I	0.2662	0.2130	26.04	8.97
	2.662	1.065	2.89	19.04

	207.0	82.80	1.41	1.36[b]

[a] $n = 5$. [b] $n = 4$.

Acetone, acetonitrile, anhydrous ethanol, methanol, and perchloric acid were examined as plasma protein precipitating agents. Perchloric acid was eliminated because the evaporation step was too time-consuming. Peak heights obtained for the drug and the metabolite after acetone treatment were consistently higher (4–8%) than those seen after treatment with the other agents. Furthermore, acetone provided the finest, most stable precipitate, clearest supernatant after centrifugation, and has been shown to be thorough in removing proteins (24). It was, therefore, the agent of choice.

It was initially anticipated that the plasma assay for sulfaquinoxaline and the N^4-acetyl metabolite could simply be extended to urine analysis. However, it was found that unknown, apparently endogenous components appeared as interfering peaks in the chromatograms. Consequently, various approaches were used with the following observations: (*a*) methylene chloride was chosen as an extracting solvent because solubility tests indicated that the drug and its metabolite were about four times more soluble in this solvent than in acidic water, and this ratio exceeded that observed for ether;. (*b*) because of its high buffering capacity, a strong buffer was needed to acidify the normally alkaline [pH 8–9 (25)] rabbit urine. Phosphate buffer was unsuitable due to solubility problems at concentrations >1 M. Acetate buffer, 3 M, provided the most accurate and predictable buffering of the urine. Table I indicates the degree of recovery of the drug and the metabolite in urine with this buffer; (*c*) a pH of 6 was selected as a compromise between adequate recovery of the sulfonamides and minimal solvent front and interference peak heights. To eliminate the latter, the secondary maximum, 360 nm ($\epsilon = 7.2 \times 10^3$ for the drug and the metabolite), was chosen as the detection wavelength even though 252 nm ($\epsilon = 3.2 \times 10^4$ for the drug and its metabolite), as used for plasma samples, was preferred.

Calibration curves were highly linear ($r > 0.99$) over the concentration ranges in plasma and urine of 0.25–200 μg/mL and 0.10–40 μg/mL, respectively, for sulfaquinoxaline and 0.50–400 μg/mL and 0.20–80 μg/mL, respectively, for the N^4-acetyl metabolite. Intra-assay variability is summarized in Table II and, except for the lowest concentrations, was <10%. Interassay analysis of the calibration curves in plasma provided mean (±*SD*) slopes and intercepts of 0.395 (0.166) and 0.00405 (0.0236), respectively, for sulfaquinoxaline ($n = 9$) and 0.348 (0.0261) and −0.00385 (0.0138), respectively, for the N^4-acetyl metabolite ($n = 4$). Such variability, when based on peak-height analysis without an internal standard, reflects changes in column characteristics. However, this presents no difficulty if calibration curves are generated with each set of samples. As only two calibration curves were prepared for urine samples, interassay results are not available.

Of the reported HPLC assays for sulfaquinoxaline (11–15), none describes the simultaneous measurement of the drug and its N^4-acetyl metabolite. Only one of these assays (14) has been developed to measure sulfaquinoxaline in plasma or tissues, and it employs inconvenient extraction methods and yields

Table III—Mean (±*SD*) Pharmacokinetic Parameters Obtained From Plasma Analysis of Sulfaquinoxaline (I) and the N^4-Acetyl Metabolite (II) After Single Intravenous Doses of I and II, Respectively

Variable	I	II
n	11	4
Dose, mg/kg	49.64 (0.76)	49.94 (1.29)
AUC, μg·h/mL[a]	836.1 (363.6) 737.3 (166.6)[b]	2769.9 (326.6)
TBC, (mL/h/kg)[c]	66.47 (19.75) 70.36 (15.78)[b]	18.18 (1.82)
V_1, mL/kg[d]	210.7 (41.85)	140.2 (59.37)
Terminal Constant, h^{-1}	0.0645 (0.0188)	0.0494 (0.0174)
Terminal Half-Life, h	12.67 (7.99)	15.96 (7.40)

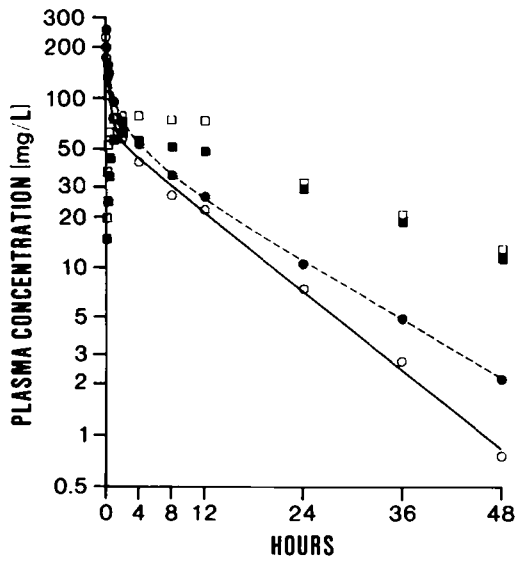

Figure 2—*Plasma sulfaquinoxaline (○) and the* N^4*-acetyl metabolite (□) observed in two rabbits following intravenous sulfaquinoxaline administration. Key: rabbit 143 (○,□) bolus dose was 49.03 mg/kg [(—) indicates the best fit of the data to a biexponential equation]; rabbit 150 (●,■) bolus dose was 49.51 mg/kg [(- - -) indicates the best fit of the data to a triexponential equation].*

a retention time of 13 min. The new method described herein was simple, reproducible, and had the requisite sensitivity to measure the drug and its metabolite in animal tissues or fluids. Also, interference from potential metabolites was not encountered.

Pharmacokinetic Studies in Rabbits—The intravenous administration of I to rabbits provided multiexponential profiles for the drug and the metabolite in plasma. Table III includes the mean (±*SD*) pharmacokinetic parameters for the drug obtained after fitting the data to bi- or triexponential equations. Seven rabbits required three exponentials while four required only two exponentials. Plasma profiles for two of the rabbits are shown in Fig. 2.

One rabbit (No. 83) displayed a total body clearance for the drug that was one-third as great as the mean clearance observed for the remainder of the rabbits. Plasma levels of the drug in this animal were elevated, while plasma levels of the metabolite were reduced. Also, the terminal phase of the metabolite profile was parallel to that of the parent drug. All of the other rabbits displayed nonparallel terminal phases with a mean (±*SD*) metabolite half-life of 15.4 (3.5) h. The data would suggest that rabbit 83 is a slow acetylator, although the clearances of the other animals could not be allocated to definable

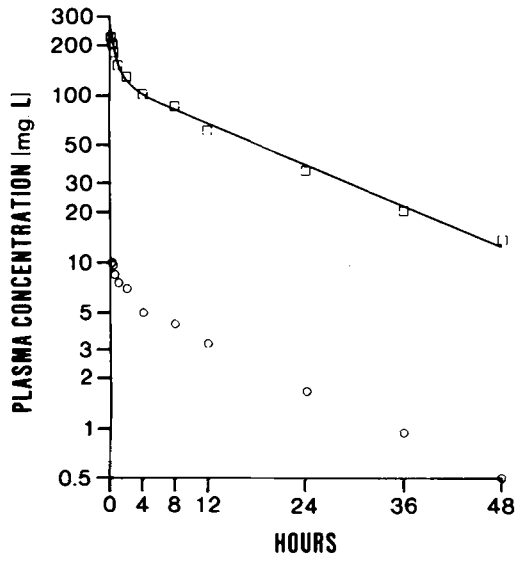

Figure 3—*Plasma sulfaquinoxaline (○) and the* N^4*-acetyl metabolite (□) observed in rabbit 143 after an intravenous bolus dose (51.16 mg/kg) of the acetylated compound. The solid line represents the best fit of the data to a biexponential equation.*

Table IV—Urinary Excretion Data Observed in Two Rabbits Given Both Sulfaquinoxaline (I) and Its Metabolite (II) on Separate Occasions

Rabbit	Compound Administered	Dose, mg/kg	Amount Excreted, mg/kg[a]		Renal Clearance, mL/h/kg[b]	
			I	II	I	II
179	I	48.96	3.172	13.36	5.978	8.054
	II	49.71	5.343	32.06	61.35	10.85
184	I	49.08	3.035	16.47	5.421	8.477
	II	48.21	3.588	31.83	32.06	13.42

groups. While the phenomenon of fast and slow acetylation has been widely reported and reviewed (26), no known studies have used sulfaquinoxaline as a probe.

Rabbits reportedly lack the ability to deacetylate (27) whereas such metabolism has been observed in other species (27–30). The N^4-acetyl metabolite was, therefore, administered intravenously to 4 rabbits. Unexpectedly, a plasma chromatographic peak was observed with a retention time corresponding to sulfaquinoxaline. Initially it was felt that the presence of sulfaquinoxaline reflected contamination of the metabolite dose by the drug. However, HPLC analysis of the filtered metabolite solution administered to the rabbits confirmed the absence of the drug. Figure 3 illustrates the profiles observed in one of the experiments. Table III also includes the mean (±*SD*) pharmacokinetic parameters obtained for the metabolite after its administration to four rabbits. The mean terminal half-life of the metabolite in these experiments agrees well with that observed after sulfaquinoxaline administration. Two animals (Nos. 179 and 184) were studied in greater detail by monitoring both plasma and urine for 96 h after administering the drug and the metabolite on different occasions, two weeks apart. The results in Table IV indicate a sizeable urinary excretion of the drug following administration of the metabolite. The results also demonstrate that urinary recovery of the drug and the metabolite do not account for either administered dose. Perhaps the sulfonamides undergo partial elimination *via* the feces (18) and/or alternate routes of metabolism (17, 19, 31). Finally, the renal clearances of sulfaquinoxaline are notably different when sulfaquinoxaline or the N^4-acetyl metabolite are administered. This anomaly remains to be explored.

From the total body clearance of rabbits 179 and 184 (90.52 and 86.17 mL/h/kg, respectively), one might surmise that the rabbits disposed of the drug in an identical manner and that they might even be identical genetic acetylators. Analysis of the plasma data from these rabbits according to the technique proposed by Wagner *et al.* (32) for prednisone-prednisolone interconversion *in vivo*, provided intriguing results. The method, which permits a calculation of each clearance in the interconversion, pointed to a 40% greater acetylation clearance in rabbit 184 accompanied by a 32% greater deacetylation clearance. The obvious effect of these parallel differences would to be provide an identical total body clearance of the drug in the two rabbits. This preliminary observation has important implications in defining the genetic acetylation characteristics of humans and animals.

The primary purpose in developing an HPLC assay for sulfaquinoxaline and the N^4-acetyl metabolite was to monitor their presence in purchased rabbits. The relatively high single dose of the drug administered in this study required ~4 d to reach plasma levels of the drug and the metabolite, <0.25 and 0.50 μg/mL, respectively. Even though animal breeders undoubtedly use lower chronic daily doses for prophylactic treatment, it would seem prudent for investigators to avoid using rabbits for 1 week after receipt from a supplier.

Preparation of 7,8-Dimethoxy-3,4-dihydroisoquinoline, Facile Route to 7,8-Dioxygenated-3,4-dihydroisoquinolines

A. M. EL-FISHAWY, D. J. SLATKIN, J. E. KNAPP, and P. L. SCHIFF, JR. ˣ

Received January 17, 1983, from the *Department of Pharmacognosy, School of Pharmacy, University of Pittsburgh, Pittsburgh, PA 15261.* Accepted for publication October 17, 1983.

Abstract □ Oxidation of 7,8-dimethoxy-1,2,3,4-tetrahydroisoquinoline with potassium permanganate in acetone afforded 7,8-dimethoxy-3,4-dihydroisoquinoline as the primary product. Hence, oxidation of the appropriate secondary nonphenolic 7,8-dioxygenated tetrahydroisoquinoline alkaloid is thus a facile method for the generation of the corresponding imine. The imine is not easily prepared *via* the usual synthetic route involving ring closure of β-phenethylamine derivatives.

Keyphrases □ 7,8-Dimethoxy-1,2,3,4-tetrahydroisoquinoline—oxidation with potassium permanganate □ 7,8-Dimethoxy-3,4-dihydroisoquinoline—synthesis, secondary amine, oxidation with potassium permanganate □ 7,8-Dioxygenated-3,4-dihydroisoquinoline—secondary amine, oxidation with potassium permanganate

As a continuation of our studies of the alkaloids of *Tiliacora dinklagei* and of the synthesis of various 7,8-dioxygenated-1,2,3,4-tetrahydroisoquinolines (1), it was considered appropriate to attempt to prepare the isoquinolone analogues of these bases. Thirteen simple isoquinolones have been isolated from higher plants to date with most of these alkaloids possessing 6,7-dioxygenation while a few possess 5,6,7-trioxygenation (2). Although no examples of naturally occurring 7,8-dioxygenated isoquinolone alkaloids could be found in the literature, it was felt that preparation of these bases from their isoquinoline counterparts would provide a ready source of physicochemical and spectral data in anticipation of the possible ultimate isolation of these isoquinolones from natural sources.

Isoquinolones are known to arise in nature *via* the oxidation of benzylisoquinolines or from the *in vivo* oxidation of protoberberines, phthalideisoquinolines, or spirobenzylisoquinolines (2). The use of potassium permanganate as an oxidizing agent in the conversion of isoquinoline-derived alkaloids to isoquinolones is well documented (3–5) and it was thus felt that a facile method for the preparation of 7,8-dimethoxyisoquinolone (1-oxo-7,8-dimethoxy-1,2,3,4-tetrahydroisoquinoline) (I) would be the analogous oxidation of 7,8-dimethoxy-1,2,3,4-tetrahydroisoquinoline (II) with potassium permanganate. In fact, oxidation of isoquinoline II with potassium permanganate in acetone afforded, instead, the imine, 7,8-dimethoxy-3,4-dihydroisoquinoline (III) [as characterized by its physicochemical properties, preparation of the methiodide (IV), and sodium borohydride reduction back to II]. This oxidation was repeated on two additional occasions with the same imine being produced in each case. Although 6,7-dioxygenated imines of this series are easily prepared *via* formylation of the parent β-phenethylamine followed by ring closure (6, 7), this same simple procedure is not possible for the 7,8-dioxygenated series since ring closure always proceeds in a less hindered fashion to afford the 6,7-analogues (6). Hence, oxidation of the appropriate secondary nonphenolic 7,8-dioxygenated alkaloids (7,8-dimethoxy or 7,8-methylenedioxy) with potassium permanganate should be a facile method for generating the corresponding imines. It can be assumed that preparation of phenolic alkaloids of this series would require protection of the phenolic group, *e.g.*, *via* the benzyl ether, to prevent further oxidation during the reaction. Examples of this include the use of sodium hypochlorite in the oxidation of 6,7-dimethoxy-8-benzyloxy-1,2,3,4-tetrahydroisoquinoline to the corresponding imine (8) and mercuric acetate in the oxidation of 2-methyl-7-methoxy-8-benzyloxy-1,2,3,4-tetrahydroisoquinoline to its corresponding quaternary imine (9).

EXPERIMENTAL SECTION[1]

7,8-Dimethoxy-3,4-dihydroisoquinoline (III)—To a stirred solution of 7,8-dimethoxy-1,2,3,4-tetrahydroisoquinoline (II) (145 mg) (1) in acetone (40 mL) was slowly added a solution of potassium permanganate (5%) (10 mL) over a period of 1 h. The reaction was stirred for an additional 48 h after which time TLC [silica gel G; benzene–acetone–methanol–ammonium hydroxide (16:16:4:1)] indicated that all of the starting material II (R_f 0.37) had been oxidized to a second product (R_f 0.63) with no other spots appearing on the chromatogram. Other solvent systems used indicated the same results [chloroform–ethyl acetate–methanol–ammonium hydroxide (20:20:4:0.5)—starting material R_f 0.38 and oxidized product R_f 0.83; chloroform–methanol–ammonium hydroxide (90:10:1)—starting material R_f 0.64 and oxidized product R_f 0.85]. The resulting suspension was filtered and the residue of manganese dioxide washed with hot acetone (20 mL) (4×). The filtrate and washings were combined and evaporated to afford 7,8-dimethoxy-3,4-dihydroisoquinoline (III) as a pale-yellow residue (131 mg; 91% yield). The residue was dissolved in chloroform (2 mL) and passed through a column of silicic acid (10 g). Elution with chloroform (5 mL) followed by chloroform–methanol (95:5) (10 mL) afforded the imine III as the same pale-yellow residue (128 mg) which was crystallized as its methiodide salt. The imine III exhibited the following spectral properties: UV λ_{max} (MeOH) (log ε): 320, (3.34), 262 (3.92), and 227 (4.42) with no bathochromic shift on the addition of 3 drops of 0.1 M methanolic KOH; λ_{max} (MeOH–0.1 M HCl) (log ε): 375 (3.41), 297 (4.04), 237 (sh) (4.10), and 218 (sh) (4.17); IR ν_{max} (KBr): 1625, 1580, 1490, 1455, 1420, 1345, 1295, 1270, 1240, 1085, 1060, 1007, 985, 855, 810, 775, and 750 cm^{-1}; ^{1}H-NMR ($CDCl_3$): δ 2.64 (2 closely overlapping triplets, 4, J = 8 Hz, C-3 and C-4), 3.89 (s, 3, C-7 $ArOCH_3$), 3.93 (s, 3, C-8 $ArOCH_3$), 6.90 (s, 2, C-5 and C-6 ArH), and 8.7

[1] Melting points were determined on a Fisher–Johns hot-stage melting point apparatus and are uncorrected. UV absorption spectra were obtained on a Perkin-Elmer Model 552 UV/VIS spectrophotometer. Infrared absorption spectra were taken on a Perkin-Elmer model 267 Grating Infrared Spectrophotometer. ^{1}H-NMR spectra were recorded on a Hitachi Perkin-Elmer Model R-24 High Resolution Spectrometer with deuterochloroform or deuteromethanol as solvent, and with tetramethylsilane as the internal standard; chemical shifts were reported in δ (ppm) units. ^{13}C-NMR spectra were recorded on a JEOL FX-900 high resolution spectrometer with deuterochloroform as solvent. Low resolution mass spectra were taken on a Finnegan EI Mass Spectrometer (Extranuclear Laboratories, Inc., Spectrel). Silica gel G (Camag) was used for TLC and spots were visualized by spraying with $KMnO_4$ (1%) in Na_2CO_3 (1%). Silicic acid (Mallinckrodt) was used for column chromatography.

ppm (br s, 1, C-1 ArH); ^{13}C-NMR: 24.5 (C-4), 47.4 (C-3), 56.0 (C-7 OCH_3), 61.8 (C-8 OCH_3) 115.0 (C-6), 121.7 (C-8a), 122.4 (C-5), 129.2 (C-4a), 147.2 (C-7), 151.3 (C-8), and 155.8 ppm (C-1) (10-12); MS M^+: *m/z* 191 (83%) (calc. for $C_{11}H_{13}NO_2$, 191.0946; obs., 191.0947), 176 (65), 161 (66), 146 (70), 133 (35), 116 (79), 105 (26), 89 (49), 77 (86), 62 (47) and 51 (100).

7,8-Dimethoxy-3,4-dihydroisoquinoline Methiodide (IV)—To 7,8-dimethoxy-3,4-dihydroisoquinoline (**III**) (100 mg) in acetone (5 mL) was added methyl iodide (0.25 mL), and the resulting solution was allowed to stand overnight. The resulting yellow crystals were removed by filtration, washed with cold acetone, and recrystallized twice from acetone–methanol to afford IV as yellow needles (112 mg), mp 165–166°C; UV λ_{max} (MeOH) (log ϵ): 375 (3.03), 297 (3.77), and 218 (4.06); IR ν_{max} (KBr): 1668, 1582, 1498, 1270, 1254, 1080, 1033, 954, and 820 cm^{-1}; ^{1}H-NMR (CD_3OD): δ 3.39 (2 closely overlapping poorly defined triplets, 4, J = 8 Hz), 3.86 (s, 3, N-2 N^+CH_3), 3.95 (s, 3, C-7 $ArOCH_3$), 4.10 (s, 3, C-8 $ArOCH_3$), 7.15 (d, 1, J = 8 Hz, C-5 ArH), 7.52 (d, J = 8 Hz, C-6 ArH), and 9.27 ppm (br s, 1, C-1 ArH); MS M^+: *m/z* 191 (100%) ($M^+ - CH_3I$), 142 (52), 127 (57), and 77 (23).

7,8-Dimethoxy-1,2,3,4-tetrahydroisoquinoline (**II**)—To 7,8-dimethoxy-3,4-dihydroisoquinoline (III) (60 mg) in methanol (30 mL) was added, with stirring, sodium borohydride (200 mg) over a period of 30 min. The mixture was stirred for an additional 8 h and was then filtered. The filtrate was evaporated to give a residue which was dissolved in HCl (5%) (20 mL), basified with NH_4OH to pH 8–9, and extracted with chloroform (50 mL) (4×). The chloroform extracts were combined, dried (anhydrous sodium sulfate), filtered, and the filtrate was evaporated to afford a residue (50 mg) which was dissolved in methanolic HCl (5%) (4 mL). The solvent was subsequently removed by evaporation and the resulting residue treated with a mixture of acetone–methanol (12:1) (3 mL) to afford yellowish-white crystals of II HCl, mp 189–191°C, identical with authentic 7,8-dimethoxy-1,2,3,4-tetrahydroisoquinoline hydrochloride by direct comparison [mp, UV, IR (1)].

Determination of Heparin Activity by a New Laser Nephelometric Method and Comparison to the USP Method

A. ESCOBAR *x, R. T. MAHER, M. L. COURTNEY ‡, and A. J. VALICENTI

Received March 22, 1982, from the *Travenol Laboratories, Inc., Morton Grove, IL 60053.* Accepted for publication October 21, 1982. Present addresses: *Arner-Stone Labs, Aquadilla, Puerto Rico 00604 and ‡Oregon State University, Corvallis, OR 97333.

Abstract □ A new method for the determination of heparin activity in solutions has been developed, based on the increase in light scattering observed during the clotting of plasma. The recalcification clotting time (RCT) of sheep plasma is measured in the presence of heparin, using a laser nephelometer. The activity of heparin in the sample is determined from a standard curve of the logarithm of RCT *versus* heparin activity. The results indicate that this method is simpler, faster, and more reproducible than the current USP grading method.

Keyphrases □ Heparin—activity, laser nephelometry method, comparison to USP method, recalcification clotting time □ Laser nephelometry—heparin activity, comparison to USP method, recalcification clotting time □ Recalcification clotting time—heparin activity, laser-nephelometry, comparison to USP method

Heparin is an anticoagulant widely used in the treatment of myocardial infarction and thromboembolic disease (1). The anticoagulant effect of the drug cannot be predicted by chemical analysis because it has not been related to any specific functional group or to molecular weight (2). Therefore, the activity of heparin, rather than its concentration, must be measured.

Evaluation of the anticoagulant activity of heparin is based on the ability of the drug to prolong the clotting of recalcified sheep plasma (*i.e.*, sheep plasma to which calcium ions are added to promote coagulation). This ability can be measured instrumentally and visually. Reed *et al.* (3) developed an instrumental method based on measurement of the time needed for a sample of recalcified sheep plasma to reach a pre-established viscosity, *i.e.*, a predetermined degree of clotting. This time is then related to the times needed for a set of standards to reach the same viscosity. The USP method, which does not use instruments, is based on the visual evaluation of the degree of clotting of samples as compared with that of a set of standards.

This work describes the development of a nephelometric method to determine heparin activity and compares this method with the USP procedure. Woziwodzki (4) used nephelometric techniques to study the clotting of plasma. More recently Tanaka (5) used laser nephelometric techniques to study the structure of polyacrylamide gels. Because a clot is essentially a gel composed of a fibrin polymer (1), it was postulated that a laser nephelometer could be used to measure the clotting time.

EXPERIMENTAL SECTION

Apparatus and Reagents—The cuvette compartment of a laser nephelometer[1] was modified to allow external circulation of water, thus maintaining

ppm (br s, 1, C-1 ArH); ^{13}C-NMR: 24.5 (C-4), 47.4 (C-3), 56.0 (C-7 OCH_3), 61.8 (C-8 OCH_3) 115.0 (C-6), 121.7 (C-8a), 122.4 (C-5), 129.2 (C-4a), 147.2 (C-7), 151.3 (C-8), and 155.8 ppm (C-1) (10-12); MS M^+: *m/z* 191 (83%) (calc. for $C_{11}H_{13}NO_2$, 191.0946; obs., 191.0947), 176 (65), 161 (66), 146 (70), 133 (35), 116 (79), 105 (26), 89 (49), 77 (86), 62 (47) and 51 (100).

7,8-Dimethoxy-3,4-dihydroisoquinoline Methiodide (IV)—To 7,8-dimethoxy-3,4-dihydroisoquinoline (**III**) (100 mg) in acetone (5 mL) was added methyl iodide (0.25 mL), and the resulting solution was allowed to stand overnight. The resulting yellow crystals were removed by filtration, washed with cold acetone, and recrystallized twice from acetone–methanol to afford IV as yellow needles (112 mg), mp 165–166°C; UV λ_{max} (MeOH) (log ϵ): 375 (3.03), 297 (3.77), and 218 (4.06); IR ν_{max} (KBr): 1668, 1582, 1498, 1270, 1254, 1080, 1033, 954, and 820 cm^{-1}; ^{1}H-NMR (CD_3OD): δ 3.39 (2 closely overlapping poorly defined triplets, 4, J = 8 Hz), 3.86 (s, 3, N-2 N^+CH_3), 3.95 (s, 3, C-7 $ArOCH_3$), 4.10 (s, 3, C-8 $ArOCH_3$), 7.15 (d, 1, J = 8 Hz, C-5 ArH), 7.52 (d, J = 8 Hz, C-6 ArH), and 9.27 ppm (br s, 1, C-1 ArH); MS M^+: *m/z* 191 (100%) ($M^+ - CH_3I$), 142 (52), 127 (57), and 77 (23).

7,8-Dimethoxy-1,2,3,4-tetrahydroisoquinoline (**II**)—To 7,8-dimethoxy-3,4-dihydroisoquinoline (III) (60 mg) in methanol (30 mL) was added, with stirring, sodium borohydride (200 mg) over a period of 30 min. The mixture was stirred for an additional 8 h and was then filtered. The filtrate was evaporated to give a residue which was dissolved in HCl (5%) (20 mL), basified with NH_4OH to pH 8–9, and extracted with chloroform (50 mL) (4×). The chloroform extracts were combined, dried (anhydrous sodium sulfate), filtered, and the filtrate was evaporated to afford a residue (50 mg) which was dissolved in methanolic HCl (5%) (4 mL). The solvent was subsequently removed by evaporation and the resulting residue treated with a mixture of acetone–methanol (12:1) (3 mL) to afford yellowish-white crystals of II HCl, mp 189–191°C, identical with authentic 7,8-dimethoxy-1,2,3,4-tetrahydroisoquinoline hydrochloride by direct comparison [mp, UV, IR (1)].

Determination of Heparin Activity by a New Laser Nephelometric Method and Comparison to the USP Method

A. ESCOBAR *x, R. T. MAHER, M. L. COURTNEY ‡, and A. J. VALICENTI

Received March 22, 1982, from the *Travenol Laboratories, Inc., Morton Grove, IL 60053.* Accepted for publication October 21, 1982. Present addresses: *Arner-Stone Labs, Aquadilla, Puerto Rico 00604 and ‡Oregon State University, Corvallis, OR 97333.

Abstract □ A new method for the determination of heparin activity in solutions has been developed, based on the increase in light scattering observed during the clotting of plasma. The recalcification clotting time (RCT) of sheep plasma is measured in the presence of heparin, using a laser nephelometer. The activity of heparin in the sample is determined from a standard curve of the logarithm of RCT *versus* heparin activity. The results indicate that this method is simpler, faster, and more reproducible than the current USP grading method.

Keyphrases □ Heparin—activity, laser nephelometry method, comparison to USP method, recalcification clotting time □ Laser nephelometry—heparin activity, comparison to USP method, recalcification clotting time □ Recalcification clotting time—heparin activity, laser-nephelometry, comparison to USP method

Heparin is an anticoagulant widely used in the treatment of myocardial infarction and thromboembolic disease (1). The anticoagulant effect of the drug cannot be predicted by chemical analysis because it has not been related to any specific functional group or to molecular weight (2). Therefore, the activity of heparin, rather than its concentration, must be measured.

Evaluation of the anticoagulant activity of heparin is based on the ability of the drug to prolong the clotting of recalcified sheep plasma (*i.e.*, sheep plasma to which calcium ions are added to promote coagulation). This ability can be measured instrumentally and visually. Reed *et al.* (3) developed an instrumental method based on measurement of the time needed for a sample of recalcified sheep plasma to reach a pre-established viscosity, *i.e.*, a predetermined degree of clotting. This time is then related to the times needed for a set of standards to reach the same viscosity. The USP method, which does not use instruments, is based on the visual evaluation of the degree of clotting of samples as compared with that of a set of standards.

This work describes the development of a nephelometric method to determine heparin activity and compares this method with the USP procedure. Woziwodzki (4) used nephelometric techniques to study the clotting of plasma. More recently Tanaka (5) used laser nephelometric techniques to study the structure of polyacrylamide gels. Because a clot is essentially a gel composed of a fibrin polymer (1), it was postulated that a laser nephelometer could be used to measure the clotting time.

EXPERIMENTAL SECTION

Apparatus and Reagents—The cuvette compartment of a laser nephelometer[1] was modified to allow external circulation of water, thus maintaining

a temperature of 37 ± 0.5°C. The following were used as received from the manufacturers: heparin sodium USP reference standard, sodium chloride[2], calcium chloride[2], and frozen sheep plasma[3].

Standard Preparation—A 3-U/mL (USP units) heparin stock solution in 0.9% NaCl was prepared from a sodium heparin reference standard. The working standards were prepared from this stock solution using 0.9% NaCl as a diluent. Because the activity range of the working standards depends on the lot of sheep plasma used, the range was determined by measuring the clotting times of several working standards having activities between 1 and 3 U/mL. For the plasma used in these studies, the activities ranged between 1.10 and 1.40 U/mL with clotting times between 100 and 200 s. Clotting times higher or lower than this range showed deviations from linearity for the logarithm of clotting time *versus* activity.

Procedure—Samples were diluted with 0.9% NaCl to an activity within the range of the standard curve. The sheep plasma was thawed at room temperature, filtered, and kept in an ice bath during the analysis.

The instrument was standardized by setting zero light scattering with a solution of 1 mL of 0.9% NaCl mixed with 0.5 mL of sheep plasma. Maximum light scattering was set at 190 using a fully clotted sample prepared by incubating a mixture of 0.5 mL of 0.9% NaCl, 0.5 mL of sheep plasma, and 0.5 mL of 0.02 M $CaCl_2$ for 5 min at 37°C.

A 0.5-mL aliquot of the diluted sample was mixed with 0.5 mL of sheep plasma in a 10 × 75-mm test tube and incubated at 37°C for at least 3 min. Immediately after addition of 0.5 mL of 0.02 M $CaCl_2$ (prewarmed to 37°C), a timer was started and the contents of the tube were remixed. The tube was placed in the nephelometer, and the time was recorded when the display reached 100. This is defined as the recalcification clotting time (RCT). Three determinations were made on each solution. The activity of the test solution was determined from a standard curve of the logarithm of mean RCT *versus* heparin activity.

Comparison of the Nephelometric and USP Methods—Three aqueous solutions of sodium heparin[4] buffered with citric acid[5] and sodium monohydrogen phosphate[3], with activities of 45.07, 49.97, and 54.91 U/mL, were prepared. These solutions were analyzed for heparin activity using both the USP XX (6) and nephelometric methods. On each of 3 d, two technicians analyzed each solution using a randomized order, making three determinations on duplicate dilutions of each sample.

RESULTS AND DISCUSSION

Figure 1 illustrates the increase in light scattering during clot formation for two levels of heparin activity. The two curves differ only in the amount of time elapsed before clot formation begins. The midpoint of the clotting curve was chosen as the end point for clotting time because it lies in the linear section of greatest slope, allowing timing instruments to be stopped with the greatest precision.

Reed *et al.* showed that the logarithm of clotting time varies linearly with heparin activity (3). The nephelometric method produced similar results. Good correlation with a straight line at the 95% confidence level was obtained with a standard curve consisting of at least four points. For the comparison study, the average correlation coefficient for the nephelometric standard curves was 0.9901.

The results indicate that the nephelometric assay is more reproducible than the USP assay. The coefficients of variation, calculated at an activity of 50 U/mL, were 2.79% for the nephelometric assay and 5.94% for the USP method. For each method, the total observed variation in assay results was statistically analyzed in terms of each of the underlying sources of assay imprecision. The results of this variance component analysis and the relative contribution of each source of variation are shown in Table I. For the nephelometric assay, determination of clotting time is the largest contributor to variance. This variability is due to normal changes in the clotting response of sheep plasma. The greatest sources of assay imprecision for the USP assay are daily shifts in assay results and technician differences. The technician variance seems to be due to the subjectivity of the grading system, indicating not only differences in the way two technicians grade, but also differences in the way a single technician grades from day to day. This factor seems to be eliminated with the instrumental method.

Table I—Comparison of the Precision of the Nephelometric and USP Methods

Variance Components	Nephelometric Method: Variance Estimate, U/mL²	Nephelometric Method: Relative Contribution to Total Variance, %	USP Method: Variance Estimate, U/mL²	USP Method: Relative Contribution to Total Variance, %

Table II—Comparison of the Accuracy of the Nephelometric and USP Methods

Technician	Theoretical Heparin Activity, U/mL	Mean Bias[a]: Nephelometric	Mean Bias[a]: USP	Recovery, %: Nephelometric	Recovery, %: USP
1	45.07	−0.64	−1.25	98.6	97.2
	49.97	−0.83	−2.87	98.3	94.3
	54.92	−0.75	−2.83	98.6	94.9
2	45.07	−0.25	1.43	99.5	103.2
	49.97	−1.91	−0.41	96.4	99.2
	54.92	−1.14	−0.82	97.9	98.5

[a] Difference between theoretical and experimentally determined activity.

The accuracy of each method was evaluated by comparing observed assay values with theoretical heparin activity (Table II). Although both methods demonstrate a negative mean bias at nearly all concentration levels for both technicians, the observed biases were within the precision limits found for each method. This negative bias is most likely a systematic error in the experimental procedure (*e.g.*, preparation of the test solutions) because it was observed in all results except one. The two methods were tested for equivalency by analyzing the ranks of the mean biases. This analysis showed no significant difference between methods ($p > 0.05$).

The nephelometric method has definite advantages over the USP method. It is faster (a single assay can be completed in less than half the time the USP method takes) and simpler (it does not involve the subjective grading, lengthy procedure, and calculations of the USP method). The nephelometric method is also more sensitive. Activities of 1 U/mL of heparin can be detected with the nephelometer *versus* 3 U/mL with the USP assay.

Comparative Pharmacokinetics of [^{65}Zn]Zinc Sulfate and [^{65}Zn]Zinc Pantothenate Injected Intravenously in Rabbits

OLIVIER GUILLARD *[x], PHILIPPE COURTOIS [‡], PATRICK MURAI *, DANIEL DUCASSOU [‡], and DANIEL REISS *

Received March 14, 1980, from the **Laboratory of Biochemistry and* [‡]*Pharmacology Jean Bernard Hospital, BP 577, 86021 Poitiers Cedex, France.* Accepted for publication December 12, 1983.

Abstract □ The pharmacokinetics of zinc sulfate were compared with those of a new zinc salt, pantothenate, in rabbits. Each salt was administered at a dosage of 3.3 μCi of zinc-65/kg of body weight. The measured pharmacokinetics of the two compounds responded to a two-compartment open model. The urinary elimination of the two salts was similar, as was their localization in the skin and fur, but zinc pantothenate was fixed by the liver to a lesser extent than was zinc sulfate.

Keyphrases □ [^{65}Zn]Zinc sulfate—intravenous administration to rabbits, pharmacokinetics □ [^{65}Zn]Zinc pantothenate—intravenous administration to rabbits, pharmacokinetics □ Pharmacokinetics—comparison of [^{65}Zn]zinc sulfate and [^{65}Zn]zinc pantothenate injected intravenously, rabbits □ Zinc salts—zinc sulfate and zinc pantothenate, comparative pharmacokinetics, intravenous administration to rabbits

Zinc sulfate is used to treat acrodermatitis enteropathica (1, 2), a condition associated with abnormal zinc metabolism. Zinc pantothenate, which we synthesized in our laboratory, had a much lower toxicity when administered orally to animals than did zinc sulfate and exhibited better gastric tolerance (3). We report here a comparative pharmacokinetic study of the intravenous injection of the two radioactive zinc salts.

EXPERIMENTAL SECTION

Reagents—[^{65}Zn]Zinc pantothenate was prepared as previously described (4). The principle of the reaction is an exchange between calcium pantothenate and [^{65}Zn]zinc sulfate with a specific radioactivity of 3.5 mCi/mg.

Animal Treatment—Six male rabbits (mean weight, 2.5 kg) were isolated in metabolism cages and placed on a water diet 12 h prior to the experiment. The necks of the animals were shaved, and a 0.5% solution of lidocaine was applied as a light topical anesthesia. The jugular vein was freed, and a catheter was inserted. Bleeding was prevented by placing a small sponge imbibed with anesthetic under the suture. The protruding catheter was fixed to the skin with a bandage, thus permitting both injection of the products tested and blood sampling.

Protocol and Analytical Procedures—Each zinc salt was injected into the jugular vein at a dose of 3.3 μCi of zinc-65/kg, and blood samples were taken at 5, 10, 15, 30, and 60 min and 2, 4, and 6 h postinjection. Blood samples (4 mL) were taken at the indicated times in a dry polypropylene tube (5), and serum was separated by centrifugation for 10 min at 3000 rpm. Animals were sacrificed 6.5 h after injection, and various organs or tissue fragments were removed and weighed: liver, kidneys, whole skin with fur, and, after washing with physiological saline, the small intestine.

Radioactivity was determined with a liquid scintillation counter[1]. Serum activity is expressed as disintegration per minute after quench correction (Fig. 1). For urine elimination and tissue and organ samples, the results are expressed as the percentage of the total quantity administered (Table I).

[1] Model 9000 γ; Beckman.

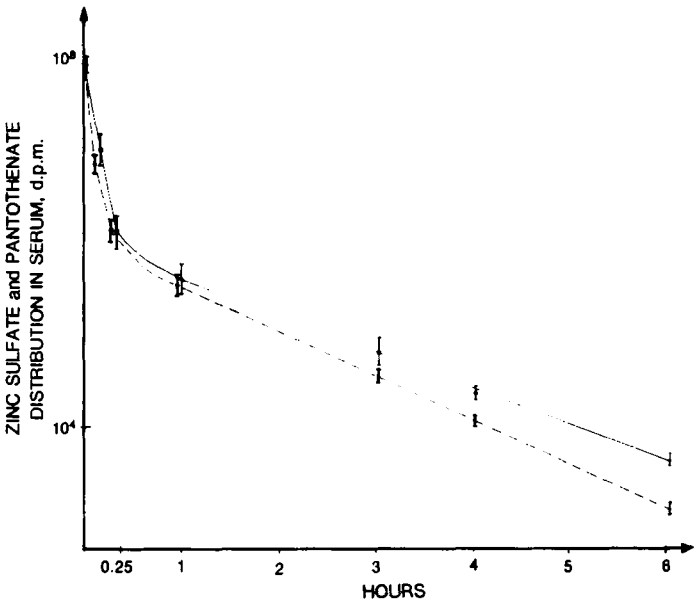

Figure 1—*Kinetics of the blood distribution of [^{65}Zn]zinc sulfate (—) and [^{65}Zn]zinc pantothenate (- -) after intravenous injection to six rabbits. The radioactivity is expressed as disintegrations per minute (d.p.m.). Results are expressed as the mean* ± SE.

RESULTS AND DISCUSSION

The pharmacokinetic data indicate that the distribution half-life (α) of zinc pantothenate is shorter (0.11 h^{-1}) than that of zinc sulfate (0.134 h^{-1}) (Fig. 1). Urinary elimination is very low and does not exceed 1% of the administered dose, which confirms results of previous studies with rats (6) and dogs (7) with zinc sulfate alone.

Both salts exhibit a similar distribution in the kidneys, the small intestine, the skin, and the fur. In the present study, there is a clear difference in hepatic

Table I—Tissue Distribution and Urine Elimination of [^{65}Zn]Zinc Pantothenate and [^{65}Zn]Zinc Sulfate after Intravenous Administration [a]

Tissue or Fluid	Radioactivity, Percentage of Total	
	[^{65}Zn]Zinc Pantothenate	[^{65}Zn]Zinc Sulfate
Liver	8	17
Kidney	2	2
Whole skin and fur	4	2
Small Intestine	1	1
Urine elimination	1	1

[a] Results were obtained 6.5 h after administration to six rabbits; results are expressed as percentage of the total activity.

The necks of the animals were shaved, and a 0.5% solution of lidocaine was applied as a light topical anesthesia. The jugular vein was freed, and a catheter was inserted. Bleeding was prevented by placing a small sponge imbibed with anesthetic under the suture. The protruding catheter was fixed to the skin with a bandage, thus permitting both injection of the products tested and blood sampling.

Protocol and Analytical Procedures—Each zinc salt was injected into the jugular vein at a dose of 3.3 μCi of zinc-65/kg, and blood samples were taken at 5, 10, 15, 30, and 60 min and 2, 4, and 6 h postinjection. Blood samples (4 mL) were taken at the indicated times in a dry polypropylene tube (5), and serum was separated by centrifugation for 10 min at 3000 rpm. Animals were sacrificed 6.5 h after injection, and various organs or tissue fragments were removed and weighed: liver, kidneys, whole skin with fur, and, after washing with physiological saline, the small intestine.

Radioactivity was determined with a liquid scintillation counter[1]. Serum activity is expressed as disintegration per minute after quench correction (Fig. 1). For urine elimination and tissue and organ samples, the results are expressed as the percentage of the total quantity administered (Table I).

[1] Model 9000 γ; Beckman.

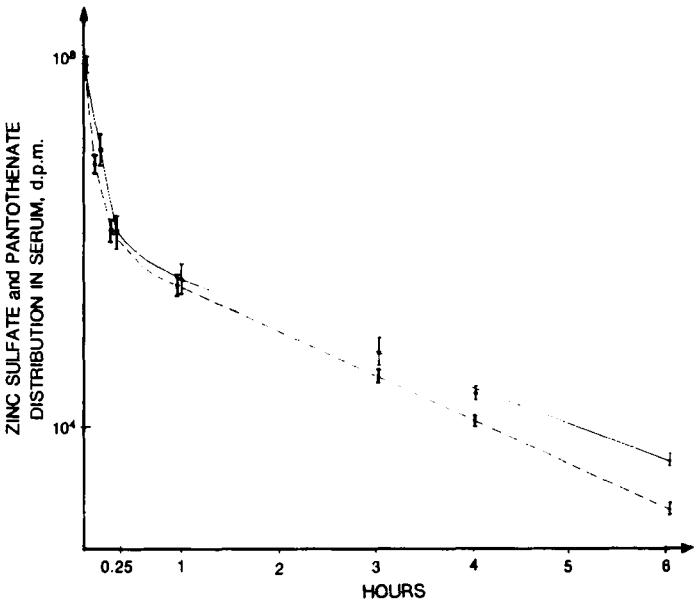

Figure 1—*Kinetics of the blood distribution of [^{65}Zn]zinc sulfate (—) and [^{65}Zn]zinc pantothenate (- -) after intravenous injection to six rabbits. The radioactivity is expressed as disintegrations per minute (d.p.m.). Results are expressed as the mean* ± SE.

RESULTS AND DISCUSSION

The pharmacokinetic data indicate that the distribution half-life (α) of zinc pantothenate is shorter (0.11 h^{-1}) than that of zinc sulfate (0.134 h^{-1}) (Fig. 1). Urinary elimination is very low and does not exceed 1% of the administered dose, which confirms results of previous studies with rats (6) and dogs (7) with zinc sulfate alone.

Both salts exhibit a similar distribution in the kidneys, the small intestine, the skin, and the fur. In the present study, there is a clear difference in hepatic

Table I—Tissue Distribution and Urine Elimination of [^{65}Zn]Zinc Pantothenate and [^{65}Zn]Zinc Sulfate after Intravenous Administration [a]

Tissue or Fluid	Radioactivity, Percentage of Total	
	[^{65}Zn]Zinc Pantothenate	[^{65}Zn]Zinc Sulfate
Liver	8	17
Kidney	2	2
Whole skin and fur	4	2
Small Intestine	1	1
Urine elimination	1	1

[a] Results were obtained 6.5 h after administration to six rabbits; results are expressed as percentage of the total activity.

binding of the two salts: the zinc sulfate is fixed to a greater extent than is the zinc pantothenate (17 *versus* 8%).

The efficient distribution and diffusion of zinc pantothenate in the skin and the fur, as well as its less important retention in the liver, would suggest a therapeutic use in the treatment of disorders of the skin and scalp.

Epiandrosterone- and Dehydroepiandrosterone-3β-alkanesulfonates as Inhibitors of Mouse Glucose-6-phosphate Dehydrogenase Activity

MAGID ABOU-GHARBIA *[x], ELAINE N. CHEESEMAN, LAURA PASHKO, ARTHUR SCHWARTZ, and DANIEL SWERN [†]

Received September 15, 1983, from the *Fels Research Institute and Department of Chemistry, Temple University, Philadelphia, PA 19122.* Accepted December 14, 1983. *Present address: Wyeth Laboratories, Philadelphia, PA 19101. [†]Deceased.

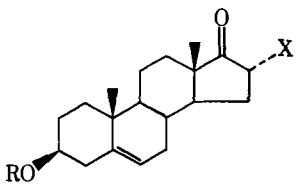
Abstract □ 3β-Alkanesulfonates of dehydroepiandrosterone, 16α-bromodehydroepiandrosterone, epiandrosterone, and 16α-bromoepiandrosterone were prepared in 54–95% yield *via* the reaction of long chain alkanesulfonyl chlorides with the corresponding dehydroepiandrosterone, and epiandrosterone analogues. These compounds inhibit mouse glucose-6-phosphate dehydrogenase activity.

Keyphrases □ 3β-Alkanesulfonates—synthesis, screened as glucose-6-phosphate dehydrogenase inhibitors □ Long-chain alkanesulfonyl chlorides—synthesis, antitumor agents

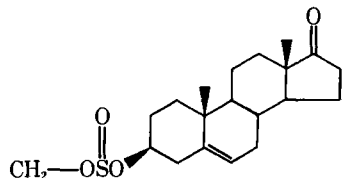
In a series of clinical and epidemiological studies several investigators have found that women with subnormal plasma concentrations of the adrenal steroid dehydroepiandrosterone (Ia) have a high risk of developing breast cancer (1–3). We have found that long-term treatment of various mouse strains with Ia inhibits the development of spontaneous breast cancer (4) and chemically induced lung (5) and colon tumors (6). It also blocks the 12-*O*-tetradecanoylphorbol-13-acetate (tumor promoter) stimulation of DNA synthesis in mouse epidermis (7) and inhibits the rate of [^{3}H]thymidine incorporation in various cell lines in culture (4).

Compound Ia is a potent noncompetitive inhibitor of mammalian glucose-6-phosphate dehydrogenase (G6PDH) (8, 9). Inhibition of this enzyme and the pentose-phosphate shunt, a major source of extramitochondrial NADPH, may account for the reduction in DNA synthesis rate by the steroid (10). Dehydroepiandrosterone in human plasma is largely sulfated. According to Oertel and Hoppe-Seyler, the predominant sulfated form of Ia in human plasma is not dehydroepiandrosterone sulfate (Ib), but an ester of Ib and a diglyceride, known as dehydroepiandrosterone sulfatide (II) (11). The sulfatide was found to be a more potent inhibitor of G6PDH than Ia (9).

We have observed that II is more effective than Ia in inhibiting mouse epidermal G6PDH as well as in blocking 12-*O*-tetradecanoylphorbol-13-acetate stimulation of DNA synthesis in mouse epidermis (7). On the other hand II is a labile material and decomposes readily within a few days, even



Ia, R = H, X = H
Ib, R = SO_3H
Ic, R = H, X = Br
Id, R = $SO_2(CH_2)_7CH_3$, X = H
Ie, R = $SO_2(CH_2)_7CH_3$, X = Br
If, R = $SO_2(CH_2)_{15}CH_3$, X = H
Ig, R = $SO_2(CH_2)_{15}CH_3$, X = Br



II

when stored at −5°C, to the sulfate Ib, resulting in loss of biological activity. Replacement of the sulfate functionality with sulfonate should lead to more stable analogues. In the search for stable and potent derivatives of II, we decided to incorporate the long chain alkanesulfonates into compounds which have already demonstrated a greater activity as inhibitors of glucose-6-phosphate dehydrogenase such as 16α-bromoepiandrosterone (7). Accordingly, 3β-alkanesulfonates of Ia, 16α-bromodehydroepiandrosterone (Ic), epiandrosterone (IIIa), and 16α-bromoepiandrosterone (IIIb) were prepared.

RESULTS AND DISCUSSION

Chemistry—3β-Alkanesulfonates of dehydroepiandrosterone and epiandrosterone (I and V) were synthesized by the reaction of a long chain alkanesulfonyl chloride IVa–e with the corresponding dehydroepiandrosterone or epiandrosterone analogue in the presence of dry triethylamine (Scheme I).

Long-chain alkanesulfonyl chlorides IVa–e were prepared in 60–85% yields from the corresponding fatty alcohol *via* a modification of the King and Aslam procedure (12) in which the hydroxyl group was replaced by the isothiuronium functionality and then the sulfur moiety was oxidized with chlorine in aqueous medium (Scheme II).

Biological Activity—The compounds listed in Table I were evaluated for their abilities to inhibit mouse epidermal glucose-6-phosphate dehydrogenase (Table II). Among the 3β-alkanesulfonates, compound Vf and its 16α-bromo analogue (Vg), both with the hexadecanesulfonyl side chain attached to the 3β-position of the epiandrosterone molecule, are the most potent inhibitors.

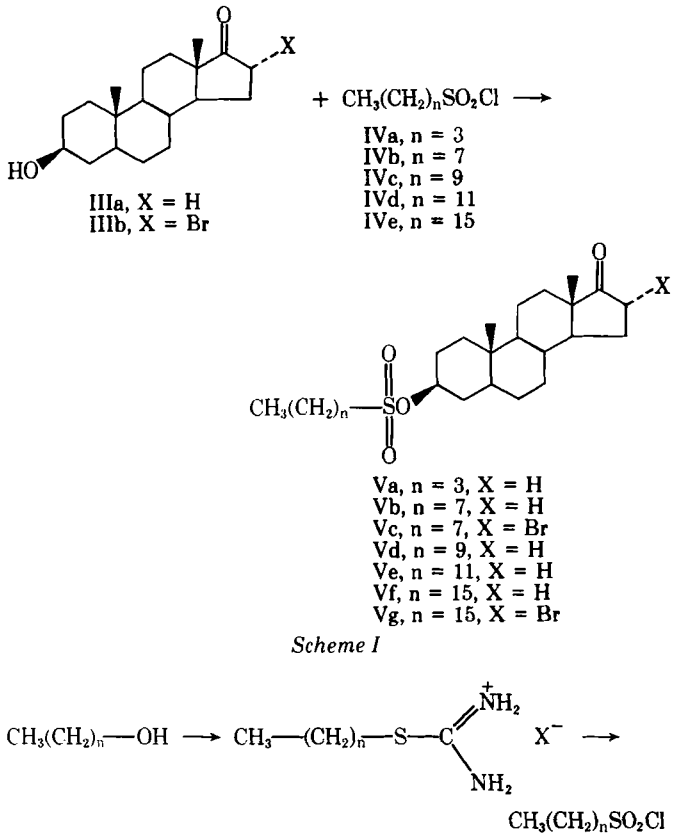

Scheme I

IVa–e (X = halogen)

Scheme II

Compound Vg is twice as active as the parent steroid Ia, showing 88% inhibition compared with the 46% inhibition produced by Ia.

Inhibition of this enzyme will consequently inhibit the pentose-phosphate shunt which generates ribose-phosphate and the bulk of extramitochondrial reduced nicotinamide adenine diphosphate (NADPH) (13), both of which are necessary for deoxyribonucleotide and fatty acid syntheses.

EXPERIMENTAL SECTION

Chemical Syntheses—All melting points were determined on apparatus[1] and are uncorrected. IR spectra were recorded on a spectrophotometer[2]. Elemental analyses were performed by Galbraith Laboratories.

Dehydroepiandrosterone Sulfatide (II)—This compound was prepared in 68% yield from the reaction of Ia-silver sulfate with dipalmitoyl-L-2-iodopropylene glycol following a reported procedure (14).

Alkanesulfonyl Chlorides IVa–d—These compounds were prepared from long-chain fatty alcohols following reported procedures (7). Dodecansulfonyl chloride IVe was similarly prepared in 75% yield, bp 126–130°C at 4 mm Hg.

Anal.—Calc. for $C_{12}H_{25}ClO_2S$: C, 53.60; H, 9.27; Cl 13.18; S, 11.92. Found: C, 53.75; H, 9.42; Cl, 12.90; S, 11.83.

General Procedure for the Preparation of 3β-Alkanesulfonates I, V, and VI—A modified procedure of Tesser and Balvert-Geev (15) was used in which 0.05 mol of the steroid was dissolved in 25 mL of dichloromethane and stirred. To this solution was added 0.65 g of dry triethylamine. The solution was cooled in an ice bath for 15 min and 0.006 mol of the appropriately substituted alkanesulfonyl chloride was added over a period of 10 min. The mixture was stirred for an additional 5 min, then was washed four times with cold water, dried (sodium sulfate), and evaporated under reduced pressure. The white solid formed was recrystallized from a suitable solvent (Table I).

Glucose-6-phosphate Dehydrogenase Assay—Epidermal G6PDH was prepared by a modification of the procedure of Ziboh *et al.* (16). Male ICR mice (6–8 weeks old) in hair resting phase were shaved 2–3 d before use. Only those mice showing no hair regrowth were used. Mice were sacrificed and a depilatory[3] was applied to the shaved area. After 5 min, the depilatory was washed off, the skin was cut out, placed in 55°C water for 30 s and the epidermis was scraped off with a scalpel. The scrapings were frozen and thawed three times in liquid nitrogen and then homogenized in 10 volumes of 0.25 M sucrose. The homogenate was centrifuged at 105,000×*g* for 1 h at 0°C. The supernatant was concentrated to one-fifth of its original volume[4] and the concentrated cytosol was used in the G6PDH assay. Steroid inhibition of G6PDH activity was determined according to the procedure of Oertel and Rebelein (9). Steroids were dissolved in dioxane immediately before testing. The reaction medium consisted of 3 mL of 0.05 M triethanolamine–0.005 M EDTA buffer (pH 7.6), 0.01 M NADP[5] solution, and 0.02 mL of dioxane or steroid in dioxane. The reaction was run at 25°C and was initiated by the addition of 0.005 mL of a 0.03 M glucose-6-phosphate[5] solution. Activity was measured in minutes from changes in absorbance at 366 nm on a recording spectrophotometer[6]. The inhibition produced by the added steroid was expressed as percent of control value. (The inhibition values in Table II were obtained by subtracting the percent control activity from 100.)

Nalmefene: Radioimmunoassay for a New Opioid Antagonist

ROSS DIXON [¶x], JANE HSIAO [*], WILLIAM TAAFFE [‡], ELLIOTT HAHN [§], and RONALD TUTTLE [¶]

Received December 5, 1983, from [¶]*Key Pharmaceuticals, Inc., Miami, FL 33169*, [*]*Innotech Laboratories, Inc., Ft. Lauderdale, FL 33314*, the [‡]*Institute for Clinical Pharmacology, St. James Hospital, Dublin, Ireland*, and [§]*Rockefeller University, New York, NY 10021.* Accepted for publication February 3, 1984.

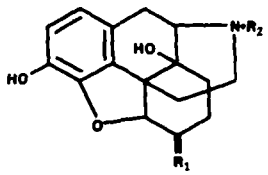
Abstract □ A specific radioimmunoassay (RIA) has been developed for the quantitation of a new opioid antagonist, nalmefene, in human plasma. The method employs a rabbit antiserum to an albumin conjugate of naltrexone-6-(*O*-carboxymethyl)oxime and [^{3}H]naltrexone as the radioligand. Assay specificity was achieved by extraction of nalmefene from plasma at pH 9 into ether prior to RIA. The procedure has a limit of sensitivity of 0.2 ng/mL of nalmefene using a 0.5-mL sample of plasma for analysis. The intra- and interassay coefficients of variation did not exceed 5.6 and 11%, respectively. The specificity of the RIA was established by demonstrating excellent agreement (r = 0.99) with a less sensitive and more time consuming HPLC procedure in the analysis of clinical plasma samples. The use of the RIA for the pharmacokinetic evaluation of nalmefene is illustrated with plasma concentration profiles of the drug in humans following intravenous and oral administration.

Keyphrases □ Nalmefene—human plasma, RIA, compared with HPLC □ RIA—compared with HPLC, nalmefene, human plasma

Nalmefene [17-(cyclopropylmethyl)-4,5α-epoxy-6-methylenemorphinan-3,14-diol] is a potent, orally active narcotic antagonist (1) which is undergoing clinical evaluation in humans. The drug is a structural analogue of naltrexone with an exocyclic methylene group in the 6-position. Hahn *et al.* (1) indicated in preliminary pharmacology studies that orally administered nalmefene was about 50 times more potent than naloxone in its ability to antagonize the antinociceptive activity of an ED_{95} dose of morphine in either the mouse hot-plate or tail-clip procedures. Furthermore, nalmefene was 16 times more potent than naloxone in precipitating narcotic withdrawal in morphine-dependent rhesus monkeys. Recently, nalmefene has been shown to decrease the food and water intake and weight gain in obese and lean Zucker rats, lending further support to a possible role for opioids in the control of food intake (2).

The present study was undertaken to develop a simple and specific radioimmunoassay (RIA) for nalmefene which would provide greater sensitivity and ease of operation than a recently reported high-performance liquid chromatographic (HPLC) procedure (3). It was hoped that the RIA might be utilized in a wide variety of human tolerance and pharmacokinetic studies that are under way with nalmefene.

The initial approach taken in the development of the RIA was to produce an antiserum which would cross-react almost equally well with nalmefene and naltrexone. In this way, high specific activity, commercially available [^{3}H]naltrexone could be used as the radioligand for the assay. Furthermore, the hapten which was likely to elicit the production of such an antiserum could be readily prepared from naltrexone in a fashion similar to the recently reported synthesis of naloxone-6-(*O*-carboxymethyl)oxime (4).



Nalmefene, R_1 = CH_2, R_2 = CH_2—◁
Naltrexone, R_1 = O, R_2 = CH_2—◁

Hapten, R_1 = N—O—CH_2COOH, R_2 = CH_2—◁

EXPERIMENTAL SECTION

Preparation of Immunogen and Antibody Production—The hapten, naltrexone-6-(*O*-carboxymethyl)oxime[1], was covalently coupled to bovine serum albumin using the mixed anhydride procedure of Erlanger *et al.* (5). The resulting conjugate was dialyzed against 0.05 M $NaHCO_3$, then water, and was then isolated by lyophilization. UV analysis of the immunogen indicated that ~17 moles of hapten were covalently coupled to 1 mol of albumin.

Two New Zealand White rabbits were immunized intradermally and boosted intravenously with the immunogen as previously described by Dixon and Crews (6). The antiserum with the highest titer of antibodies to nalmefene, obtained following the second booster immunization, was used for all subsequent studies. The antiserum was divided into 1-mL aliquots, lyophilized, and stored at −20°C.

Radioimmunoassay Procedure—Plasma samples (0.1–0.5 mL) containing

[1] Synthesized according to the procedure reported for naloxone-6-(*O*-methyl)oxime (4). The NMR, IR, and mass spectra were compatible with the proposed structure.

Nalmefene: Radioimmunoassay for a New Opioid Antagonist

ROSS DIXON [¶x], JANE HSIAO [*], WILLIAM TAAFFE [‡], ELLIOTT HAHN [§], and RONALD TUTTLE [¶]

Received December 5, 1983, from [¶]*Key Pharmaceuticals, Inc., Miami, FL 33169*, [*]*Innotech Laboratories, Inc., Ft. Lauderdale, FL 33314*, the [‡]*Institute for Clinical Pharmacology, St. James Hospital, Dublin, Ireland*, and [§]*Rockefeller University, New York, NY 10021.* Accepted for publication February 3, 1984.

Abstract □ A specific radioimmunoassay (RIA) has been developed for the quantitation of a new opioid antagonist, nalmefene, in human plasma. The method employs a rabbit antiserum to an albumin conjugate of naltrexone-6-(*O*-carboxymethyl)oxime and [^{3}H]naltrexone as the radioligand. Assay specificity was achieved by extraction of nalmefene from plasma at pH 9 into ether prior to RIA. The procedure has a limit of sensitivity of 0.2 ng/mL of nalmefene using a 0.5-mL sample of plasma for analysis. The intra- and interassay coefficients of variation did not exceed 5.6 and 11%, respectively. The specificity of the RIA was established by demonstrating excellent agreement (r = 0.99) with a less sensitive and more time consuming HPLC procedure in the analysis of clinical plasma samples. The use of the RIA for the pharmacokinetic evaluation of nalmefene is illustrated with plasma concentration profiles of the drug in humans following intravenous and oral administration.

Keyphrases □ Nalmefene—human plasma, RIA, compared with HPLC □ RIA—compared with HPLC, nalmefene, human plasma

Nalmefene [17-(cyclopropylmethyl)-4,5α-epoxy-6-methylenemorphinan-3,14-diol] is a potent, orally active narcotic antagonist (1) which is undergoing clinical evaluation in humans. The drug is a structural analogue of naltrexone with an exocyclic methylene group in the 6-position. Hahn *et al.* (1) indicated in preliminary pharmacology studies that orally administered nalmefene was about 50 times more potent than naloxone in its ability to antagonize the antinociceptive activity of an ED_{95} dose of morphine in either the mouse hot-plate or tail-clip procedures. Furthermore, nalmefene was 16 times more potent than naloxone in precipitating narcotic withdrawal in morphine-dependent rhesus monkeys. Recently, nalmefene has been shown to decrease the food and water intake and weight gain in obese and lean Zucker rats, lending further support to a possible role for opioids in the control of food intake (2).

The present study was undertaken to develop a simple and specific radioimmunoassay (RIA) for nalmefene which would provide greater sensitivity and ease of operation than a recently reported high-performance liquid chromatographic (HPLC) procedure (3). It was hoped that the RIA might be utilized in a wide variety of human tolerance and pharmacokinetic studies that are under way with nalmefene.

The initial approach taken in the development of the RIA was to produce an antiserum which would cross-react almost equally well with nalmefene and naltrexone. In this way, high specific activity, commercially available [^{3}H]naltrexone could be used as the radioligand for the assay. Furthermore, the hapten which was likely to elicit the production of such an antiserum could be readily prepared from naltrexone in a fashion similar to the recently reported synthesis of naloxone-6-(*O*-carboxymethyl)oxime (4).

EXPERIMENTAL SECTION

Preparation of Immunogen and Antibody Production—The hapten, naltrexone-6-(*O*-carboxymethyl)oxime[1], was covalently coupled to bovine serum albumin using the mixed anhydride procedure of Erlanger *et al.* (5). The resulting conjugate was dialyzed against 0.05 M $NaHCO_3$, then water, and was then isolated by lyophilization. UV analysis of the immunogen indicated that ~17 moles of hapten were covalently coupled to 1 mol of albumin.

Two New Zealand White rabbits were immunized intradermally and boosted intravenously with the immunogen as previously described by Dixon and Crews (6). The antiserum with the highest titer of antibodies to nalmefene, obtained following the second booster immunization, was used for all subsequent studies. The antiserum was divided into 1-mL aliquots, lyophilized, and stored at −20°C.

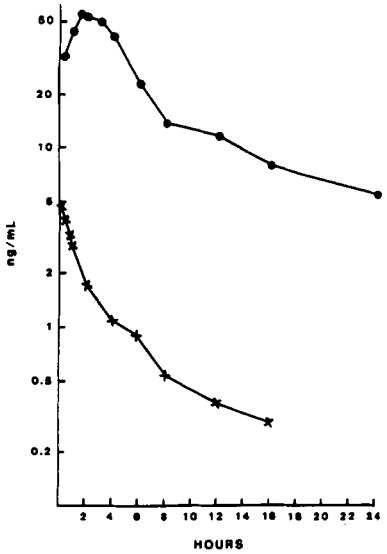

Figure 1—*Plasma concentrations of nalmefene following an intravenous injection (×) of 0.5 mg of nalmefene hydrochloride and an oral dose (●) of 64 mg of nalmefene hydrochloride.*

either known or unknown concentrations of nalmefene were diluted with 0.1 mL of 1 M borate buffer (pH 9) and extracted by vortexing with 2.5 mL of ether in a 12 × 75 mm disposable glass culture tube. Following brief centrifugation, the tubes were immersed in a shallow bath of 2-propanol–dry ice and the aqueous phases were frozen. The organic phase was decanted into a 12 × 75 mm tube and the ether was evaporated using a water bath at 50°C.

Each residue was dissolved in 0.1 mL of methanol and diluted with 0.4 mL of assay buffer[2]. Duplicate 0.2-mL aliquots of each extract were added to 12 × 75 mm tubes followed consecutively by 30,000 dpm of [^{3}H]naltrexone[3] in 0.2 mL of buffer and 0.2 mL of antiserum diluted 1:10,000 with buffer. After incubation at 4°C for 30 min, 0.5 mL of a well stirred suspension of dextran-charcoal[4] at 4°C was added to each tube, the contents were briefly vortexed and then allowed to stand at 4°C for ~10 min. The tubes were centrifuged at 4°C for 10 min at 1200×*g* and each supernatant, containing the antibody-bound radioligand, was decanted into a containing vial. After the addition of 10 mL of scintillation fluid[5], the vial was assayed in a liquid scintillation counter.

A calibration curve was generated using a four-parameter logistic curve-fitting program for a desk-top calculator[6] (7). Both the plasma standards and unknown samples were taken through the entire extraction and RIA procedure.

RESULTS AND DISCUSSION

Radioimmunoassay Characteristics—Depending on the degree of sensitivity required, two different ranges of calibration curves were used. The more sensitive assay ranged from 0.2 to 8 ng/mL using a 0.5-mL sample of plasma for analysis, while the other used a 0.1-mL sample and ranged from 2 to 100 ng/mL. In both instances, the logit-log plots were linear and the interday coefficients of variation ($n = 6$) for both standard curves did not exceed 11% for any individual standard (range, 2.4–11%). Linear regression analysis of the mean concentrations of nalmefene found *versus* the amount of nalmefene present in each plasma standard ($n = 6$) gave correlation coefficients of 0.999 and slopes within 6% of unity for both calibration curves. If necessary, unknown plasma samples with concentrations of nalmefene >100 ng/mL were appropriately diluted to bring the concentrations within the range of the 2–100-ng/mL calibration curve.

Using dextran-charcoal for the separation of antibody-bound and free radioligand, ~50% of the [^{3}H]naltrexone was bound in the presence of diluted antiserum alone while the nonspecific binding (no antiserum) was ~4%. The recovery of nalmefene from plasma using the present extraction procedure was 85 ± 4%; however, since both the standard and unknown plasma samples were handled in an identical fashion, no correction for recovery was necessary.

Assay Specificity—As mentioned previously, nalmefene and naltrexone were expected to cross-react about equally well with the antiserum, thereby allowing the use of commercially available [^{3}H]naltrexone as the radioligand for the quantitation of nalmefene. Cross-reactivity studies confirmed these expectations in that nalmefene exhibited an apparent cross-reactivity of 90% relative to naltrexone. At the same time 6β-naltrexol, the major metabolite of naltrexone found in plasma (8), cross-reacted 40%. The latter observation is not surprising since little antigenic specificity can be expected at the 6 position where the hapten was coupled to albumin. Thus, this antiserum would be of little value for use in a specific RIA for naltrexone due to the extensive cross-reactivity of 6 β-naltrexol. Naloxone, which only differs from naltrexone by having an *N*-allyl function, cross-reacted 20% with the antiserum, an indication that the *N*-cyclopropylmethyl group on the hapten was not a potent antigenic determinant.

During the initial developmental stages of the RIA, the apparent plasma concentrations of nalmefene in clinical samples were considerably higher when the plasma was assayed directly than following the extraction procedure outlined above. This was probably due to high concentrations of nalmefene glucuronide, in the presence of unconjugated nalmefene, cross-reacting to some extent with the antiserum. Therefore, the extraction step became a critical component of the assay procedure since nalmefene glucuronide would not be extracted into ether at alkaline pH.

A definitive and rigorous evaluation of the specificity of the RIA was made by comparing it with a recently established HPLC procedure (3). Clinical plasma samples obtained from four subjects who had received single oral doses of nalmefene hydrochloride (32 or 64 mg) were assayed by both analytical procedures and the joint determinations ($n = 21$) were subjected to linear regression analysis (RIA = y). Over a concentration range of 4–58 ng/mL, the correlation coefficient, regression-line slope, and y-intercept were 0.998, 0.996, and 0.38, respectively, which demonstrated excellent agreement between the two procedures and validated the specificity of the RIA for the quantitation of intact nalmefene in clinical plasma samples.

Nalmefene Plasma Concentrations in Humans—To illustrate the utility of the RIA, some typical plasma concentration profiles of nalmefene in subjects who had received various intravenous and oral doses of the drug are shown in Fig. 1.

Following intravenous administration of 0.5 mg of nalmefene hydrochloride, the plasma concentrations of the intact drug declined rapidly over the first 2 h, followed by a slower elimination phase up to 16 h, at which time the plasma concentration approached the limit of sensitivity of the assay (0.2 ng/mL). For the subject who received a 64-mg dose orally in solution, a peak plasma concentration of 55 ng/mL was reached 1.5 h after dosing and declined to 6 ng/mL after 24 h.

In conclusion, a simple and specific RIA for the quantitation of nalmefene in human plasma has been developed and validated by comparison with an established HPLC procedure. The RIA provides adequate sensitivity to obtain pharmacokinetic profiles of the drug following both intravenous and oral administration to humans. By virtue of its simplicity, the assay can facilitate the analysis of the ever increasing number of plasma samples which are being generated during new drug development studies.

Determination of the Partition Coefficient and Acid Dissociation Constants of Iodochlorhydroxyquin by an Improved Partition Method

HIROSHI TANAKA ˣ and ZENZO TAMURA

Received January 4, 1983, from the *Faculty of Pharmaceutical Sciences, University of Tokyo, 7-3-1 Hongo, Bunkyo-ku, Tokyo 113, Japan.* Accepted for publication September 29, 1983.

Abstract □ A simple and precise method for determining partition coefficients was developed utilizing a disposable injector. The method was used to determine the partition ratio of iodochlorhydroxyquin between *n*-decane and phosphate-buffered saline, pH 7.4. The partition ratio was found to be 1750 with a coefficient of variation of 3%. Moreover, it was found that iodochlorhydroxyquin did not associate in *n*-decane at a concentration $< 1 \times 10^{-3}$ M. The acid dissociation constants and the partition coefficient of the undissociated species were determined. These values corresponded well with the values obtained from spectrophotometric methods.

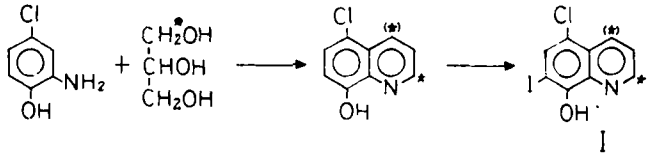
Keyphrases □ Iodochlorhydroxyquin—partition coefficients, acid dissociation constants □ Improved partition method—partition coefficients, dissociation constants, iodochlorhydroxyquin

Iodochlorhydroxyquin (5-chloro-7-iodo-8-quinolinol; I), an amphoteric molecule sparingly water soluble at neutral or slightly acidic pH values, has been studied *in vivo* using a radionuclide-labeled compound (1). Repeated administrations of I to beagle dogs led to neurological disorders with concomitant demonstration of I in the central nervous system (CNS) by quantitative GC measurements (2). Intestinal absorption, renal excretion, and the distribution of I to various tissues, especially to the CNS, were thought to be influenced by the concentration of the undissociated species. The acid dissociation constants and partition coefficient of the undissociated species have not been reported, primarily because I is extremely insoluble in water and is strongly adsorbed onto glassware.

Special glassware was used to determine the partition ratio of long-chain fatty acids between *n*-heptane and an aqueous phosphate buffer (3); however, accurate values >1000 were not determined. Using a disposable injector, we have developed a more precise and convenient method for determining large partition ratios. This methodology has been used to determine the partition coefficient of the undissociated species and acid dissociation constants of I.

EXPERIMENTAL SECTION

Syntheses of Tritiated Analogues of 5-Chloro-7-iodo-8-quinolinol—Tritiated I was synthesized according to the method reported by Urakubo and Kido (4) (Scheme I). To a mixture of 2-amino-4-chlorophenol[1] (14.4 mg, 0.1 mmol), 4-chloro-2-nitrophenol[1] (8.8 mg, 0.05 mmol), glycerol[2] (0.11 mmol), and [1(3)-^{3}H]glycerol[3] (1.6 mCi, 2.3 Ci/mmol) was added 21 μL of concentrated sulfuric acid. The mixture was refluxed at 125°C for 2 h, and then the remaining 4-chloro-2-nitrophenol was removed by sublimation (the temperature was increased to 160°C for 15 min). The residual material was extracted twice with 1.5 mL of distilled water and with the same volume of 7% H_2SO_4. The total aqueous phase was adjusted to pH 5 with 30% NaOH, and the resulting precipitate was removed by centrifugation and washed with distilled water to give 5-chloro-8-[2(4)-^{3}H]quinolinol as a gray powder, which was purified by sublimation at 140°C. This afforded 10.7 mg (60% yield) of crystalline material, mp 129°C (a radiochemical yield of 26%). 8-[2(4)-^{3}H]Quinolinol was synthesized in a similar manner (30% yield), mp 76°C.



Scheme I

Preparation of 5-Chloro-7-iodo-8-[2(4)-^{3}H]quinolinol—5-Chloro-8-[2(4)-^{3}H]quinolinol (8.6 mg) was dissolved in 3 mL of 60 mM glycine buffer (pH 1.35) and was iodinated with iodine monochloride as described by Hales and Randle (5). The excess reagent was decomposed by adding 0.5 M $Na_2S_2O_3$, the precipitate was washed twice with the buffer, twice with distilled water, and was then dried under reduced pressure over phosphorus pentoxide to give 12.1 mg (83% yield) of 5-chloro-7-iodo-8-[2-(4)-^{3}H]quinolinol as a white solid, mp 173°C (dec.).

The chromatographic behavior (TLC, silica gel) and the melting points of these labeled compounds were identical with those of authentic cold materials (6). The radiochemical purity of tritiated I was determined to be 99.3% by an isotopic recrystallization method.

Other Chemicals—*n*-Decane[1], reagent grade, was purified by shaking several times with concentrated sulfuric acid until the acidic layer became colorless, and was then distilled under reduced pressure. The buffers were 0.02 M, containing 0.13 M NaCl and 5 mM EDTA to prevent the interference of metal ions; pH values of the buffer were adjusted with an accuracy of ±0.01. The scintillation cocktail consisted of 5 g of 2,5-diphenyloxazole (PPO)[4] and 134 mg of 2,2′-*p*-phenylene-*bis*(4-methyl-5-phenyloxazole) (dimethyl POPOP)[5] per liter of toluene[2]. All other chemicals were of the highest purity available.

The General Procedure for the Measurement of Partition Ratios—A glass tube (19 mm i.d. × 37 mm depth) containing 3.5 mL of buffer was covered with a polyethylene cap with two holes (4 mm i.d. and 1 mm i.d., respectively). A 25-gauge disposable needle[6] was inserted into the tube through the larger

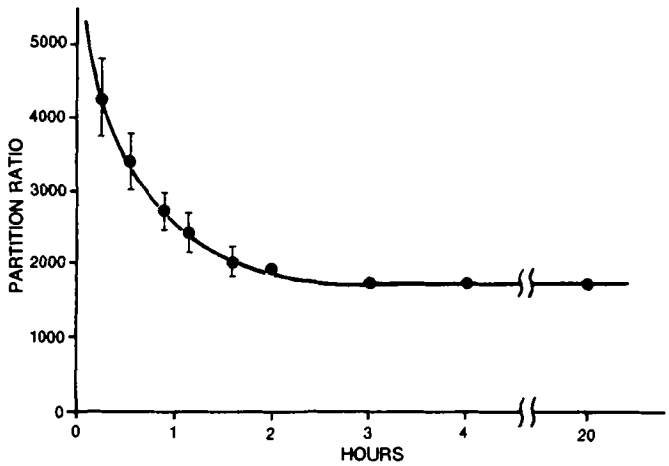


Figure 1—*Time course of partition equilibrium of iodochlorhydroxyquin between n-decane and 0.02 M phosphate-0.13 M NaCl-5 mM EDTA buffer (pH 7.4) at 25°C. [^{3}H]Iodochlorhydroxyquin was initially added to the organic layer.*

hole of the cap and fixed so that the tip of the needle almost reached the bottom. A disposable tuberculine syringe (2.5 mL)[6] was connected to the needle. The *n*-decane solution of [^{3}H]iodochlorhydroxyquin (0.2 mL) was gently placed on the aqueous layer with a microsyringe through the smaller hole of the cap. The tubes were gently shaken by a reciprocating shaker[7] 73 times per min for 3 h at 25 ± 0.5°C. After the equilibration, 2 mL of the aqueous layer was removed (with the tuberculine syringe) and the solution was transferred to a weighed scintillation vial. The vial was weighed again to accurately determine the volume of the sample. After removal of the polyethylene cap with the needle, 50 μL of the organic layer was removed and transferred to a weighed scintillation vial. The volume was again determined by weighing the vial. Ten milliliters of the scintillation cocktail was added to each vial and the radioactivity was counted with a liquid scintillation counter[8]. The vial containing the aqueous sample was shaken 100 times before counting.

RESULTS AND DISCUSSION

Determination of the Partition Ratio of I by the Partition Method—The partition ratio is defined as follows:

$$\text{Partition ratio} = \frac{\text{Radioactivity in organic phase}}{\text{Radioactivity in aqueous phase}} \qquad \text{(Eq. 1)}$$

Figure 1 shows that the partition equilibrium was reached after 3 h and was maintained for ≥17 h with a variation of ±3%. As shown in Fig. 2, the partition ratios of I, 8-quinolinol, and 5-chloro-8-quinolinol at pH 7.4 were measured over a wide concentration range. Since the partition ratios remained constant, it appeared that the 8-quinolinols did not associate in a manner similar to the fatty acids (3). The partition ratio of I was 1750, while those of 8-quinolinol and 5-chloro-8-quinolinol were 24.1 and 247, respectively.

Determination of the Dissociation Constants of I by the Partition Method—The partition ratio (Eq. 2) assumes that the ionized forms of I are not found in the organic phase and that un-ionized molecules of I are found in both phases.

$$\text{Partition ratio} = \frac{[CF]_o}{[CF^+]_w + [CF]_w + [CF^-]_w} = \frac{K_p}{\frac{(H^+)_w}{K_1'} + 1 + \frac{K_2'}{(H^+)_w}} = \frac{K_p}{10^{(pK_1'-pH)} + 1 + 10^{(pH-pK_2')}} \qquad \text{(Eq. 2)}$$

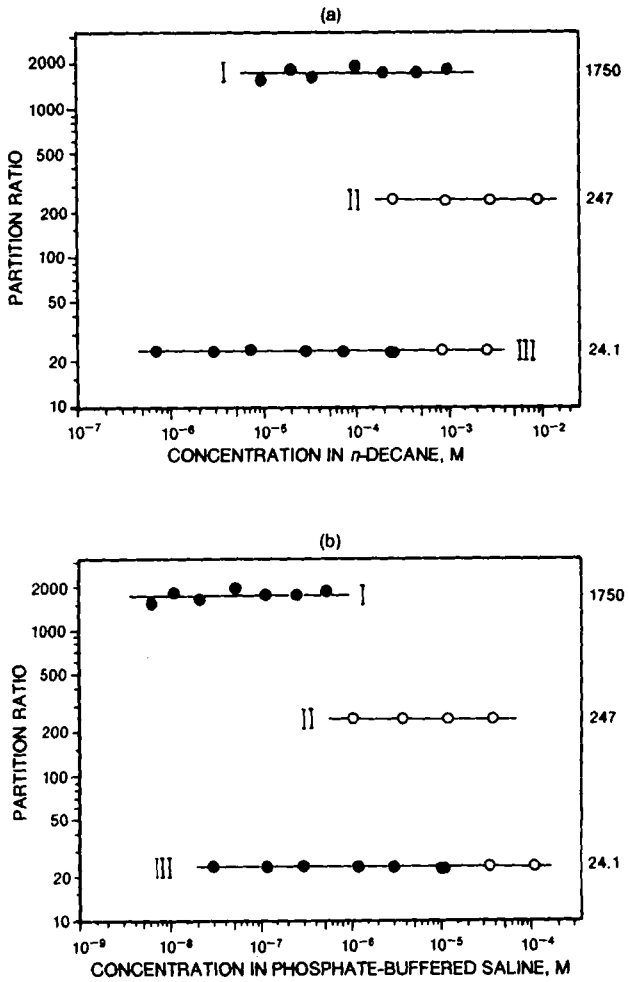

Figure 2—*Effect of concentration on the partition ratio of iodochlorhydroxyquin (I), 5-chloro-8-quinolinol (II), and 8-quinolinol (III) between n-decane and phosphate-buffered saline (pH 7.4) at 25°C. Key: (●) radioisotope method; (○) values from the spectrophotometric measurement.*

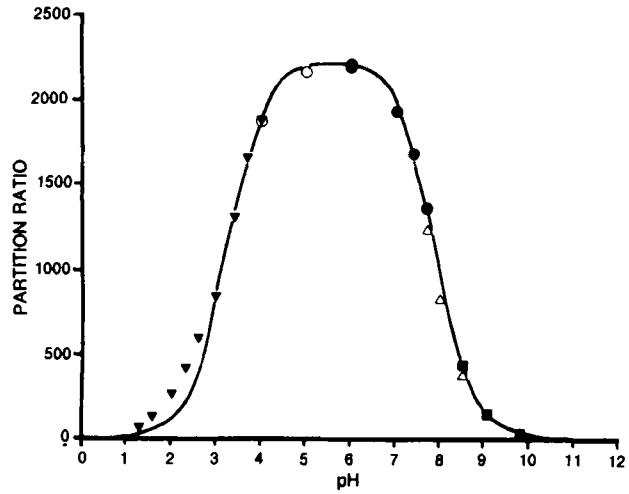

Figure 3—*Effect of pH on the partition ratio of iodochlorhydroxyquin between n-decane and the 0.02 M buffer–0.13 M NaCl–5 mM EDTA system at 25°C. Key: (▼) glycine–hydrochloric acid; (○) acetate; (●) phosphate; (△) Tris-HCl and (■) glycine–sodium hydroxide; (—) hypothetical curve for Eq. 3.*

In Eq. 2, the subscripts o and w indicate the organic and the aqueous phases, respectively. [CF], [CF$^+$], [CF$^-$], and (H$^+$) represent the concentration of the molecular, the cationic, and the anionic forms of I, and the activity of the hydrogen ion, respectively. The partition coefficient, K_p, is expressed as $K_p = [CF]_o/[CF]_w$. The dissociation constants of I in acidic and basic media are expressed as $K_1' = [CF]_w(H^+)/[CF^+]_w$, and $K_2' = [CF^-]_w(H^+)/[CF]_w$, respectively. Accordingly, those constants may be calculated from the pH profile of the partition ratio.

The partition ratio at various pH values (1.2–9.8) was measured using five buffer systems. Figure 3 shows that the pH profile of the partition ratios in I was a bell-shaped curve with a maximum at pH 5.6. The constants, K_p, K_1', and K_2' were estimated from the data in Fig. 3 as follows: $K_p = 2230 \pm 43$ (CV 1.9%), $n = 11$; $K_1' = 5.6 \times 10^{-4}$, $pK_1' = 3.25$; $K_2' = 1.29 \times 10^{-8}$, $pK_2' = 7.89$. Consequently, Eq. 2 can be expressed as:

$$\text{Partition ratio} = \frac{2230}{10^{(3.25-pH)} + 1 + 10^{(pH-7.89)}} \qquad \text{(Eq. 3)}$$

The solid line in Fig. 3 is the hypothetical curve for Eq. 3, and it agrees well with the observed values in the pH range of 3–10.

Inquiry of the Partition Method by a Spectrophotometric Approach—Compound I and its ionized forms show characteristic UV absorption. The dissociation constants of such compounds, in general, can be calculated from the spectral data. The spectrophotometric method is based on the general equation:

$$A = [CF^+]\epsilon^c + [CF]\epsilon^n + [CF^-]\epsilon^a \qquad \text{(Eq. 4)}$$

where A, total absorbance, is the sum of the respective absorbance of each species, and ϵ^n, ϵ^c, and ϵ^a represent the molar extinction coefficients of the un-ionized, cationic, and anionic forms of I, respectively. When the pH value is lower than $pK_2' - 2$ or higher than $pK_1' + 2$, the term [CF$^-$] or [CF$^+$] can be neglected, respectively. In this case, pK_1' and pK_2' are as follows:

$$pK_1' = pH + \log\frac{[CF^+]}{[CF]} \qquad \text{(Eq. 5)}$$

$$pK_2' = pH + \log\frac{[CF]}{[CF^-]} \qquad \text{(Eq. 6)}$$

Both the anionic and cationic forms of I showed an absorption maximum at 266 nm, and the values of ϵ_{266}^a or ϵ_{266}^c, calculated from the spectrophotometric data by dissolving I in 1 mM sodium carbonate buffer or in diluted hydrochloric acid, were 3.81×10^4 and 2.80×10^4, respectively. However, the value of ϵ^n could not be determined because I was sparingly soluble in the neutral aqueous solution. Accordingly, we estimated $\epsilon_{\lambda_{max}}^n$ (252.5 nm) and ϵ_{266}^n as 1.2×10^4 and 0.42×10^4, respectively, by extrapolating the ϵ values measured in the various concentrations of methanol (Fig. 4). $\epsilon_{252.5}^c$ and $\epsilon_{252.5}^a$ were found to be 2.00×10^4 and 1.92×10^4, respectively. Thus, Eqs. 5 and 6 may be expressed as follows:

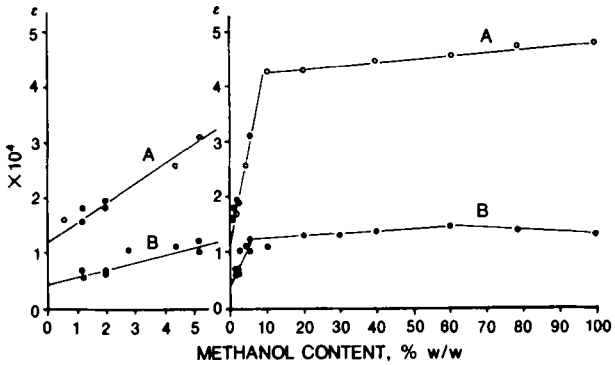

Figure 4—*Effect of methanol content in aqueous solution on the ε of iodochlorhydroxyquin at 252.5 (A) and 266(B) nm.*

$$pK_1' = pH + \frac{1.20 \times A_{266}/A_{252.5} - 0.42}{2.80 - 2.00 \times A_{266}/A_{252.5}} \qquad \text{(Eq. 7)}$$

$$pK_2' = pH + \frac{1.92 \times A_{266}/A_{252.5} - 3.81}{0.42 - 1.20 \times A_{266}/A_{252.5}} \qquad \text{(Eq. 8)}$$

The dissociation constants of I were calculated from the data listed in Table I. Similarly $pK_{1,0}$ and $pK_{2,0}$, calculated from the following Debye-Hückel equations, were 2.25 and 8.33 at 25°C, respectively.

$$pK_1' = pK_{1,0} + 0.509\sqrt{I} \qquad \text{(Eq. 9)}$$

$$pK_2' = pK_{2,0} - 0.509\sqrt{I} \qquad \text{(Eq. 10)}$$

where I represents the ionic strength.

The values pK_1' and pK_2', obtained from the spectrophotometric results at the same temperature and the same ionic strength as the partition method, were 3.17 ± 0.11 and 8.05 ± 0.08 at 25°C, respectively, and agree well with those obtained by the partition method.

Determination of Meclocycline, a Tetracycline Analogue, in Cream Formulations by Liquid Chromatography

ANNELI M. DEPAOLIS *x, THOMAS E. BRITT ‡, ARLENE J. HOLMAN *, EUGENE J. McGONIGLE *, GERALD KAPLAN ‡, and WALTER C. DAVIES ‡

Received May 26, 1983, from the *Research Laboratories, Ortho Pharmaceutical Corp., Raritan, NJ 08869 and ‡Johnson & Johnson Research Center, New Brunswick, NJ 08902. Accepted for publication November 16, 1983.

Abstract □ A rapid and sensitive high-performance liquid chromatographic quantitation of meclocycline (I) in a cream formulation is described. The acidified methanolic extract of the sample was diluted with mobile phase and analyzed on a reverse-phase column by using a mobile phase consisting of EDTA buffer (pH 6.6)-tetrahydrofuran (85:15 v/v). The method gave linear, quantitative, and reproducible results with a detection limit of 0.4 ppm for meclocycline.

Keyphrases □ Meclocycline—tetracycline analogue, cream formulations, HPLC □ Cream formulations—meclocycline, tetracycline analogue, HPLC

Meclocycline sulfosalicylate (I), a 7-chloro-6-methylene-5-hydroxy-derivative of tetracycline, is marketed as a topical antibiotic cream formulation[1] for the treatment of acne. Methods for quantitating meclocycline and its impurities have not been reported. However, high-performance liquid chromatographic (HPLC) methods have been shown to be most effective for separating tetracyclines and their degradation products. These HPLC methods have been extensively reviewed (1). The reverse-phase mode has become the most widely used column packing for tetracyclines with a mobile phase at a low pH range (1.2–2.5), which is generally not recommended for bonded silica columns. In an additional method, a microparticulate phenyl column and single-step gradient elution at pH 2.2 are used (2). These types of systems have been found not to be applicable to the separation of meclocycline and its impurities. It has been preferred to have a system with a less acidic mobile phase, not only to prolong the lifetime of the column but to retard the degradation of tetracyclines known to occur at low pH (3). Among the various reverse-phase packings, Vydac TP C_{18} has been found to be very suitable for use with mobile phases in the near neutral region for the separation of tetracyclines and their degradation products (4). By utilizing this column and a mobile phase of tetrahydrofuran in ammonium EDTA buffer at pH 6.6, a baseline separation of meclocycline, and its potential degradation products and impurities in pharmaceutical cream was achieved. In this report is described a rapid, linear, and reproducible method for the quantitation of meclocycline in a cream formulation.

EXPERIMENTAL SECTION

Materials—Meclocycline sulfosalicylate[2] (I) (4*S*,4a*R*,5*S*,5a*R*,12a*S*)-7-chloro-4-(dimethylamino)-1,4,4a,5,5a,6,11,12a-octahydro-3,5,10,12,12a-pentahydroxy -6- methylene-1,11-dioxo-2-naphthacenecarboxamide, mono(5-sulfosalicylate), was used in all experiments as received. For the cream samples, a 1% w/w formulation of meclocycline sulfosalicylate cream[1] was used. Tetrahydrofuran[3] was HPLC grade; EDTA[4] and all the other chemicals and solvents were analytical reagent grade.

Preparation of Mobile Phase—EDTA (0.6 g) was mixed with 2 mL of methanol and dissolved in 15 mL of concentrated ammonium hydroxide. Approximately 1800 mL of distilled water was added, and the pH was adjusted to precisely 6.6 with glacial acetic acid. The solution was diluted to 2 L with distilled water. The 0.001 M ammonium EDTA buffer solution was filtered through a fluoropore membrane filter (0.5 μm), mixed with tetrahydrofuran in the ratio of 85:15 v/v, and deaerated under vacuum.

Chromatographic System—A liquid chromatograph[5] equipped with an automatic sample injector[6] was used for all HPLC work. The column was packed with octadecylsilane material bonded to microparticulate silica gel (10 μm)[7]. The columns were periodically purged with 95% ethyl alcohol (form III)[8] for optimum resolution. Since the columns were obtained from the manufacturer preserved in denatured alcohol, no column conditioning was necessary. The flow rate was 0.8 mL/min, and a 10-mV strip chart recorder was employed at a chart speed of 0.5 cm/min.

Standard Solution Preparation—A portion (30–50 mg) of the reference standard, meclocycline sulfosalicylate (I) (or 25 mg of USP meclocycline base reference standard) was weighed to the nearest 0.1 mg and dissolved in and diluted to 100 mL with methanol. A 2.0-mL aliquot of the solution described above was diluted to 50.0 mL with mobile phase. The solution was filtered through a Swinney filter with a syringe and used as an external standard. Filters[9] (0.5 μm) were used and stored in methanol prior to use.

Sample Preparation—A portion of the meclocycline sulfosalicylate cream (equivalent to ~8 mg of I or ~5 mg of meclocycline base) was weighed to the nearest 0.1 mg into a 50-mL stoppered centrifuge tube. Equal volumes of methanol (20 mL) and 0.0125 M sulfuric acid (20 mL) were added to the tube. The sample was thoroughly dispersed by a combination of sonication (~60 min) and vortexing (2 min). Inadequate dispersing produced poor recoveries. The dispersed mixture was quantitatively transferred into a 50-mL volumetric flask and diluted to volume with methanol. After centrifugation at ~2000×*g* for 10 min, a 5.0-mL aliquot of the supernatant liquid was diluted to 50.0 mL with the mobile phase. The mixture was filtered through a Swinney filter as described above. The samples should not be stored in the mobile phase solution longer than a day, or loss of meclocycline will be observed.

Analytical Procedure—Chromatograms for all standards and samples were obtained at ambient temperature by injecting 10-μL aliquots at a detector sensitivity of 0.02 AUFS. When the flow rate was 0.8 mL/min, the average retention time of meclocycline was 7 min, although depending on the column condition the retention time can vary between 5.5 and 8.5 min. By small adjustments of tetrahydrofuran in the mobile phase, the retention time may be varied to the desired value. The resolution factors are 3.0 for methacycline and meclocycline and 1.7 for C-4-epimeclocycline and meclocycline, and the tailing factor for meclocycline is 1.0. For quantitation of meclocycline, samples were injected with an automatic sample injector and bracketed with standards in the sequence: STD-1, STD-1, STD-2, STD-2, SAMP-1, SAMP-1, SAMP-2, SAMP-2, STD-1, STD-1, STD-2; STD-2 (where STD is the standard solution and SAMP is the sample solution). A basic program designed for a computer system[10] was used for quantitation of the samples of meclocycline in sequence with the standards as listed above. The percentage of meclocycline base in the cream by weight was calculated by: $(A_{samp} \times W_{std} \times P)/(A_{std} \times W_{samp} \times 50)$. The peak areas and weights, in milligrams, of sample and standard, are A_{samp}, W_{samp}, and A_{std}, W_{std}, respectively. The potency[11] (P) of meclocycline is usually equivalent to not less than 620 μg/mg

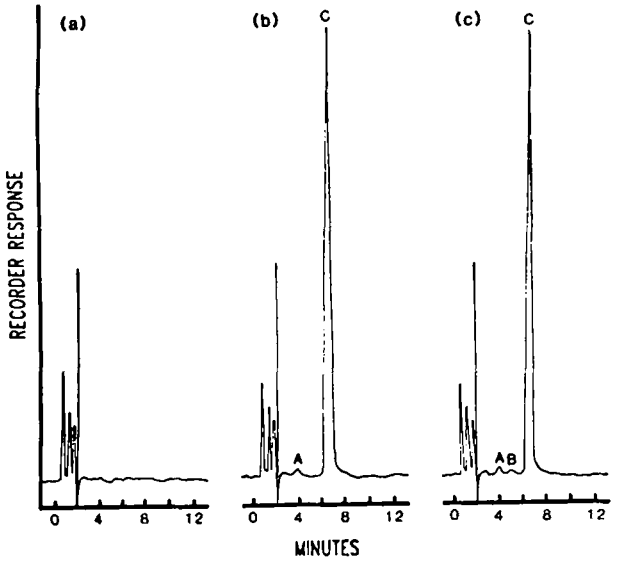

Figure 1—*Typical chromatograms of cream placebo (a), standard I (b), and a 1% cream sample preparation of I (c). Key: (A) methacycline; (B) C-4-epimer of I; (C) I. Conditions: mobile phase, 0.001 M ammonium EDTA buffer (pH 6.6)–tetrahydrofuran (85:15); column, reverse-phase*[7], *25 cm × 3.2 mm i.d.; flow rate, 0.8 mL/min; detector, UV at 340 nm.*

and usually in the area of 665-670 μg/mg[12], and for USP meclocycline base it is 1000 μg/mg.

RESULTS AND DISCUSSION

Typical chromatograms obtained for the cream placebo, standard meclocycline sulfosalicylate (I), and a 1% cream sample preparation of I are shown in Fig. 1. The system gave a baseline separation for meclocycline, methacycline, and the C-4-epimer of meclocycline at ambient temperature. Meclocycline eluted with an average retention time of 7 min. The peak at 4 min corresponded to methacycline, an impurity always present in the raw material but never present at >3% of the total weight. The peak at 5 min was identified to be the C-4-epimer of meclocycline (5). By varying the relative amount of tetrahydrofuran in the mobile phase, the retention times of meclocycline and impurities could easily be shifted. The objective was to keep the retention time of meclocycline in the range of 5.5–8.5 min. The ammonium EDTA buffer in the mobile phase was a crucial ingredient to give well-defined and sharp peaks on HPLC chromatograms. It was also necessary to dilute the sample with the mobile phase in the sample preparation. If only methanol was utilized, leading peaks were observed. The wavelength of 340 nm was selected for maximum sensitivity and for the least amount of interference from UV-absorbing components of cream excipients. The minimum detection for meclocycline was 0.4 ppm at 340 nm.

[12] The potency was determined by a microbiological assay method.

Table I—Recovery of Meclocycline Base from Spiked Cream Placebo [a]

Theoretical Label Claim, %	Percent Recovery[b] Peak Areas	Peak Heights
80	101	100
	97.0	96.2
100	96.0	98.5
	96.8	96.0
120	98.7	98.2
	96.9	97.6
Average	$\bar{X}_6$ = 97.7%	$\bar{X}_6$ = 97.8%
SD	±1.83%	±1.51%
RSD	±1.87%	±1.54%

[a] Representative of 80-120% of theoretical label claim; label claim is 1% w/w meclocycline base. [b] Meclocycline base.

The results of recovery studies performed on cream placebos spiked with I are shown in Table I. The spiking covered the range of 80-120% of the theoretical label claim, which is usually 1% meclocycline base by weight. The recoveries, ranging from 96 to 101%, were comparable whether peak areas or heights were used. The data demonstrate the method to give linear, quantitative, and reproducible results with a minimum of sample handling.

A few other commercially available reverse-phase columns (C_{18}[13,14], ODS[15], and C_8[15]) were tested under the same operating conditions but were found to be not suitable. It seems that meclocycline was bound on these columns and would not elute until purged with methanol. When the solvent system was changed to consist of 1% phosphoric acid–methanol (45:55), the C_{18}[13] reverse-phase column gave a separation of methacycline and meclocycline, but no separation of meclocycline and its C-4-epimer was observed. Since the pH of the latter mobile phase was ~2, meclocycline was assumed to be mainly in the ionic form with a protonated dimethylamino group, which is analogous to other tetracyclines (6). It therefore seems that on reverse-phase columns, the C-4 isomers of meclocycline cannot be separated as ionic species but rather as doubly charged zwitterions, the most likely form of tetracyclines between pH 3.0 and 6.5 reported previously (6).

In conclusion, the described method gives a rapid and reproducible quantitation of meclocycline in the cream formulation of meclocycline sulfosalicylate.

Preparation of Alkoxyquinoline Derivatives and Their Evaluation as Potential Central Nervous System Stimulants

M. EL-KERDAWY, A. ABOU-OUF, A. TANTAWY*[x], and I. ABOU EL-DAHAB

Received November 30, 1982, from the *Organic and Pharmaceutical Chemistry Deprtment, Faculty of Pharmacy, University of Mansoura, El-Mansoura, Egypt.* Accepted for publication April 18, 1983. *Present address: Holy Mecca, Ibn Sina Clinic, P.O.B. 1576, Saudi Arabia.

Abstract □ A variety of substituted amides of 6,7-dimethoxy-2-hydroxyquinoline-3-carboxylic acid were synthesized. Three of these compounds, tested as potential central nervous system stimulants, showed no marked biological activity.

Keyphrases □ Alkoxyquinoline derivatives—potential CNS stimulants, synthesis □ Stimulants—CNS, alkoxyquinoline derivatives, synthesis

The analeptic activity of aromatic heterocyclic tetrazoles (1), such as nikethamide, ethamivan, and their *N*-ethylamides (2, 3) is well known. In addition, the *N*,*N*-diethylamides of numerous ring systems (such as pyrazole, thiazole, isoxazole, and the imidazolopyrimidines) as well as some xanthines and pyridines show analeptic activity (2, 4). Some CNS-sympathomimetic drugs such as the benzyl-, morpholinyl-, and piperidyl-*N*-ethylamide derivatives (2, 3) are also employed as psychomotor stimulants to elevate the mood or to improve the sense of well being of patients suffering from certain psychiatric depressions. The biological effects of the aforementioned drugs could be explained by the incorporation of a nitrogen atom in the ring systems (5), possibly providing resistance to enzymatic inactivation by steric protection of the amino groups (6), as in the case of phenmetrazine or methylphenidate. Similarly, *N*-alkyl groups, which are substituted with more bulky groups than methyl, diminished activity; the absence of the aromatic nucleus or its replacement by an alkyl group resulted in compounds of little or no activity (6). On the other hand, iproniazide (7), a monamine oxidase (MAO) inhibitor, appears to reverse the action of reserpine.

Since maximum MAO inhibition and analeptic activity are shown by compounds similar to amphetamine, *e.g.*, phenipraxine and a nitrogenisostere of methamphetamine (8), the present work describes the synthesis of potential CNS-stimulating agents, which have both aminoalkane and heterocyclic structural systems, such as quinoline. A series of substituted amides derived from 2-hydroxy-6,7-dimethoxyquinoline-3-carboxylic acid, which appeared likely to possess a CNS-stimulating effect, were prepared. In addition, the unsubstituted hydrazide derivatives of the compounds were alkylated to overcome the insignificant MAO inhibitory properties of unsubstituted hydrazines (9, 10). In the present investigation, the 6,7-dimethoxyquinoline system was varied to obtain 3-carboxylic acid hydrazides and hydrazones (Scheme I) for evaluation as CNS stimulants.

EXPERIMENTAL SECTION

Chemistry—*6,7-Dimethoxy-2-hydroxyquinoline-3-carboxylic Acid Hydrazide (IX)*—Hydrazine hydrate (0.1 mol) was added to a suspension of 6,7-dimethoxy-3-ethoxycarbonyl-2-hydroxyquinoline (I) (11) (0.02 mol) in ethanol (200 mL). The mixture was heated at reflux for 3 h. The hydrazide was removed by filtration, washed with water, dried, and recrystallized (Table I).

Interaction of 6,7-Dimethoxy-3-ethoxycarbonyl-2-hydroxyquinoline and Phenylhydrazines (X and XI)—Phenylhydrazine or 2,4-dinitrophenylhydrazine (0.02 mol) was added to a suspension of 6,7-dimethoxy-3-ethoxy-

carbonyl-2-hydroxyquinoline (I) (0.01 mol) in ethanol (20 mL). The mixture was heated at reflux for 2 h. The solid was removed by filtration and recrystallized.

6,7-Dimethoxy-2-hydroxyquinoline-3-carboxylic Acid Hydrazones (XII-XVI)—The appropriate aldehyde (0.02 mol) was added to 6,7-dimethoxy-2-hydroxyquinoline-3-carboxylic acid hydrazide (IX) (0.01 mol) in glacial acetic acid. The mixture was heated at reflux for 1 h, and the material was removed by filtration and recrystallized.

Interaction of 6,7-Dimethoxy-2-hydroxyquinoline-3-carboxylic Acid Hydrazide and Acid Anhydrides (VII and VIII)—A mixture of the hydrazide (IX) (0.01 mol) and the appropriate acid anhydride (0.02 mol) in glacial acetic acid (30 mL) was heated at reflux for 3 h. The mixture was allowed to stand overnight. The material was removed by filtration and recrystallized. For VIII ^{1}H-NMR[1] ($CDCl_3$): δ 7.25 (s, 1, OH), 8.1-7.0 (m, 7, ArH), 4.3 (s, 1, NH), and 3.7 ppm (m, 6, 2 OCH_3).

Interaction of 6,7-Dimethoxy-3-ethoxycarbonyl-2-hydroxyquinoline and Different Amines (II-VI)—A mixture of 6,7-dimethoxy-3-ethoxycarbonyl-2-hydroxyquinoline (I) (0.01 mol) and the appropriate amine (0.02 mol) was heated at reflux in methanol (20 mL) for 3 h. Approximately 15 mL of the solvent was removed under reduced pressure, the residue was cooled, and the solid material was removed by filtration and recrystallized from a suitable solvent. For II, ^{1}H-NMR ($CDCl_3$): δ 6.8 (s, 1, OH), 8.1-7.03 (m, 3, ArH), 4.2 (s, 1, NH), 3.8 (m, 6, 2 OCH_3), and 1.5 ppm (s, 3, CH_3). For V [6,7-dimethoxy-3-(piperidinocarbonyl)-2-hydroxyquinoline], MS: *m/z* 316 (M^+), 232 ($M - C_5H_{10}N$), 204 [$M - (C_5H_{10}N + CO)$], 189 [$M - (C_5H_{10}N + CO + CH_3)$], and 173 [$M - (C_5H_{10}N + CO + OCH_3)$].

Biological Screening—Three compounds (III, V, and VII) of this series of alkoxyquinolines were used for preliminary pharmacological screening as CNS stimulants. Each was suspended in distilled water and administered to albino mice by oral intubation and intraperitoneal injection in doses up to 1 g/kg of body weight. The behavior and normal characteristics of the animals (heart rate, locomotor activity, reflexes, *etc.*) were recorded before and for 24 h after administration of the compounds.

RESULTS AND DISCUSSION

The animals given III showed transient increases in respiratory rate (from 198 to 300/min) 5 min after administration and returned to normal values 7 min later. Otherwise, there were no signs of CNS stimulation of the animals at the doses studied. There was no change in animal behavior, activity, and locomotion. None of the animals showed any signs of toxicity or mortality within 24 h after administration of the different compounds in the doses given.

From the biological screening, it is obvious that the tested compounds, although they are structurally related to the well-known carboxamide and *N,N*-alkylated derivatives of heterocyclic types of compounds, do not have a marked MAO inhibitory action. This leads to the conclusion that these bioisostere moieties of the fused heterocyclic systems structurally related to the quinoline series are biologically inactive as CNS stimulants.

Determination of Phenylbutazone in Tablets by Nuclear Magnetic Resonance Spectrometry

RONA STROMBERG

Received April 18, 1983, from the *Food and Drug Administration, Department of Health and Human Services, New York Regional Laboratory, Brooklyn, NY 11232.* Accepted for publication October 6, 1983.

Abstract □ A method for the quantitative analysis of phenylbutazone in tablets using NMR is reported. The method is both accurate and precise. Using synthetic mixtures, the mean recovery value $\pm SD$ was 100.5 ± 0.86%. The NMR results of commercial preparations are compared with those obtained by the USP XX procedure. The NMR spectrum, in addition, provides a very specific means of identification for phenylbutazone.

Keyphrases □ Phenylbutazone—NMR analysis, comparative analyses □ NMR—phenylbutazone, comparative analyses

Phenylbutazone, 4-butyl-1,2-diphenyl-3,5-pyrazolidinedione (I), a synthetic pyrazolone derivative chemically related to aminopyrine, has anti-inflammatory, antipyretic, analgesic, and mild uricosuric properties (1). Approaches to the quantitative determination of phenylbutazone in tablets have varied. Tomaskova (2) reported a GC method using flame-ionization detection. A quantitative IR spectroscopic method was described by Pawelcyzk and Marciniec (3). Differential spectrophotometry, relying on the differences in absorption between acidic and basic species of phenylbutazone, was employed by Bezakova *et al.* (4). Other assay techniques have included separation on an ion-exchange column followed by titration (5) and acid hydrolysis to form benzidine, which was subsequently oxidized, and determined colorimetrically (6). The method of USP XX for the assay of phenylbutazone in tablets entails an ether-based extraction with a UV spectrophotometric determination (7). All these approaches require either lengthy sample preparations and/or nonspecific determinations. In contrast, nuclear magnetic resonance spectrometry (NMR) offers the advantages of minimal sample preparation, simplicity and specificity for the active ingredient.

NMR studies on phenylbutazone have dealt with its carbon-13 spectrum (8), degradation products (9, 10), and the monitoring of its dissolution kinetics (11). However, this technique has not been applied to the quantitative determination of the drug in pharmaceuticals. This paper describes a method in which a carbon tetrachloride–nitromethane mixture is used as the solvent and hexamethylcyclotrisiloxane

0022-3549/84/1100-1653$01.00/0

carbonyl-2-hydroxyquinoline (I) (0.01 mol) in ethanol (20 mL). The mixture was heated at reflux for 2 h. The solid was removed by filtration and recrystallized.

6,7-Dimethoxy-2-hydroxyquinoline-3-carboxylic Acid Hydrazones (XII-XVI)—The appropriate aldehyde (0.02 mol) was added to 6,7-dimethoxy-2-hydroxyquinoline-3-carboxylic acid hydrazide (IX) (0.01 mol) in glacial acetic acid. The mixture was heated at reflux for 1 h, and the material was removed by filtration and recrystallized.

Interaction of 6,7-Dimethoxy-2-hydroxyquinoline-3-carboxylic Acid Hydrazide and Acid Anhydrides (VII and VIII)—A mixture of the hydrazide (IX) (0.01 mol) and the appropriate acid anhydride (0.02 mol) in glacial acetic acid (30 mL) was heated at reflux for 3 h. The mixture was allowed to stand overnight. The material was removed by filtration and recrystallized. For VIII ^{1}H-NMR[1] ($CDCl_3$): δ 7.25 (s, 1, OH), 8.1-7.0 (m, 7, ArH), 4.3 (s, 1, NH), and 3.7 ppm (m, 6, 2 OCH_3).

Interaction of 6,7-Dimethoxy-3-ethoxycarbonyl-2-hydroxyquinoline and Different Amines (II-VI)—A mixture of 6,7-dimethoxy-3-ethoxycarbonyl-2-hydroxyquinoline (I) (0.01 mol) and the appropriate amine (0.02 mol) was heated at reflux in methanol (20 mL) for 3 h. Approximately 15 mL of the solvent was removed under reduced pressure, the residue was cooled, and the solid material was removed by filtration and recrystallized from a suitable solvent. For II, ^{1}H-NMR ($CDCl_3$): δ 6.8 (s, 1, OH), 8.1-7.03 (m, 3, ArH), 4.2 (s, 1, NH), 3.8 (m, 6, 2 OCH_3), and 1.5 ppm (s, 3, CH_3). For V [6,7-dimethoxy-3-(piperidinocarbonyl)-2-hydroxyquinoline], MS: *m/z* 316 (M^+), 232 ($M - C_5H_{10}N$), 204 [$M - (C_5H_{10}N + CO)$], 189 [$M - (C_5H_{10}N + CO + CH_3)$], and 173 [$M - (C_5H_{10}N + CO + OCH_3)$].

Biological Screening—Three compounds (III, V, and VII) of this series of alkoxyquinolines were used for preliminary pharmacological screening as CNS stimulants. Each was suspended in distilled water and administered to albino mice by oral intubation and intraperitoneal injection in doses up to 1 g/kg of body weight. The behavior and normal characteristics of the animals (heart rate, locomotor activity, reflexes, *etc.*) were recorded before and for 24 h after administration of the compounds.

RESULTS AND DISCUSSION

The animals given III showed transient increases in respiratory rate (from 198 to 300/min) 5 min after administration and returned to normal values 7 min later. Otherwise, there were no signs of CNS stimulation of the animals at the doses studied. There was no change in animal behavior, activity, and locomotion. None of the animals showed any signs of toxicity or mortality within 24 h after administration of the different compounds in the doses given.

From the biological screening, it is obvious that the tested compounds, although they are structurally related to the well-known carboxamide and *N,N*-alkylated derivatives of heterocyclic types of compounds, do not have a marked MAO inhibitory action. This leads to the conclusion that these bioisostere moieties of the fused heterocyclic systems structurally related to the quinoline series are biologically inactive as CNS stimulants.

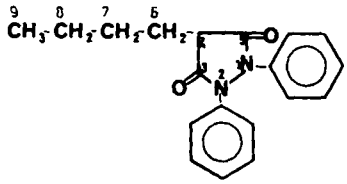
is the internal standard. Preparations containing known amounts of phenylbutazone and commercial tablets were analyzed.



EXPERIMENTAL SECTION

Materials—An NMR spectrometer[1] (90 MHz) with an ambient probe temperature of 41°C was used. Samples were placed in precision-type, 5-mm, NMR tubes[2]. Phenylbutazone[3], hexamethylcyclotrisiloxane[4], tetramethylsilane[5], carbon tetrachloride[6], and nitromethane (>99% pure)[7] were used as obtained. Tablets were obtained from various commercial sources.

Phenylbutazone Analysis—Twenty tablets were weighed and finely powdered. An accurately weighed portion of this powder, containing ~150 mg of phenylbutazone, was transferred into a glass-stoppered centrifuge tube. Hexamethylcyclotrisiloxane (~64 mg) and 2 mL of carbon tetrachloride containing two drops of nitromethane/mL were added, and the mixture was shaken for 2 min. Insoluble excipients were allowed to rise and ~0.5 mL of the bottom layer was transferred to an analytical NMR tube. (For spectrometers which require a deuterium signal for field-frequency lock, approximately three drops of Me_2SO-d_6 should be added). The spin rate was adjusted so that no spinning side bands occurred between 0.4 and 0.6 ppm (hexamethylcyclotrisiloxane region), or between 6.9 and 7.5 ppm (phenyl region of phenylbutazone). The intensity of the spectrum was maximized with the RF power and amplitude setting; care was taken to avoid saturation, particularly in the spectrum of the sharp hexamethylcyclotrisiloxane signal. The delta (δ) scale was used to express magnetic field strength and all peak field positions were referenced to hexamethylcyclotrisiloxane at 0.14 ppm. The resonance signals for phenylbutazone, which appear as a broad resonance peak centered at ~7.25 ppm, and the singlet for hexamethylcyclotrisiloxane, the internal standard, at 0.14 ppm were integrated a minimum of five times, and the results were averaged. The amount of phenylbutazone was calculated as follows: mg/tablet = $(A_p/A_h) \times (EW_p/EW_h) \times$ (mg hexamethylcyclotrisiloxane/mg sample) × mean tablet weight, where A_p is the integral value of the signal representing phenylbutazone, A_h is the integral value of the signal representing the internal standard, EW_p is the equivalent weight of phenylbutazone (formula weight/10 protons = 30.84), and EW_h is the equivalent weight of the internal standard (formula weight/18 protons = 12.35).

RESULTS AND DISCUSSION

The absence of proton resonance signals for carbon tetrachloride makes it an ideal solvent for NMR spectroscopic work. Both phenylbutazone and hexamethylcyclotrisiloxane were soluble in carbon tetrachloride, but in the proposed method, the volume of this solvent was made slightly suboptimal with respect to phenylbutazone to obtain a relatively high concentration of drug and a low instrument noise level. The addition of a few drops of nitromethane, originally intended to serve as the internal standard, improved the solubility of phenylbutazone in the NMR solvent, and compensated for the lower sample volume. The resonance signal for nitromethane appeared at δ 4.10 ppm and was well separated from any other peak. Alternatively, the amount of sample specified in the assay method may be dissolved in 3 mL of carbon tetrachloride, but an adjustment of the attenuation setting is required. The utility of hexamethylcyclotrisiloxane as an internal standard has been demonstrated (12-14). Under the described experimental conditions, its resonance peak appears as a singlet at an extreme upfield position (~δ 0.14 ppm). This combination of solvent system and internal standard provides a specific interference-free means of identification and quantitation of the active ingredient.

The amount of phenylbutazone present in the dosage form is determined by integrating the broad resonance signal pattern centered at ~δ 7.25 ppm, arising from the 10 aromatic protons at positions 1 and 2, and the singlet at ~δ 0.14 ppm, due to the 18 methyl protons of the internal standard.

Table I—NMR Determination of Phenylbutazone in Standard Mixtures[a]

Standard Mixture	Internal Standard Added, mg	Phenylbutazone Added, mg	Phenylbutazone Found, mg	Phenylbutazone Recovery, %
1	30.0	77.4	77.9	100.6
2	29.7	76.1	75.6	99.4
3	29.8	75.8	75.6	99.7
4	30.7	76.5	77.2	100.9
5	29.5	77.3	77.5	100.3
6	32.1	76.7	77.5	101.0
7	30.4	37.9	38.7	102.0
8	31.8	113.7	113.4	99.7
Mean ± *SD*				100.5 ± 0.9

[a] Half the amount of phenylbutazone specified in the method, dissolved in a similarly decreased volume of solvent, was used in order to conserve sample.

Table II—NMR and Compendial Determinations of Phenylbutazone in Commercial Tablets

Sample	Amount Declared, mg/Tablet	Amount Found, %[a] NMR	Amount Found, %[a] USP XX	Difference, %
1	100	97.9	96.7	1.2
2	100	100.5	97.3	3.2
3	100	103.0	99.7	3.3
4	100	98.7	97.6	1.1
5	100	102.7	100.4	2.3

[a] Since each tablet is declared to contain 100 mg of drug, the quantity found in mg/tablet is identical to the percent of declared values.

In addition to their utility in the quantitative analysis of phenylbutazone in dosage forms, the proton resonance characteristics of this molecule may be used for identification. The coupling of the methine proton at position 4 with the methylene protons at position 6 produces a triplet centered at ~δ 3.18 ppm. The complex splitting patterns seen in the region between δ 0.7 and 2.2 ppm may be assigned consecutively to the methyl protons at position 9 and to the methylene protons on carbons 6-8. The resonance signal pattern centered at ~δ 1.4 ppm arises from the overlapping of the peaks for the protons of the two methylene groups at positions 7 and 8.

The analysis of several known phenylbutazone mixtures is summarized in Table I. The results show that the method is both accurate and precise. The mean recovery value ±*SD* was 100.5 ± 0.9%. The relative proportions of phenylbutazone and hexamethylcyclotrisiloxane, as noted in Table I, had no significant bearing on the accuracy of the determination for the range of proportions shown.

The proposed method was also applied to commercial preparations. Table II summarizes the results of the analysis of five lots of tablets. For comparison purposes, the same composites were analyzed by the USP XX method. The data in Table II show that the results by the official method were 1.1-3.3% lower than those obtained by the NMR method. One of the possible reasons for these discrepancies may be the losses incurred with the official method during the extraction steps. Recovery studies from two commercial preparations, spiked with a known amount of phenylbutazone, gave a mean recovery value of 100.1%.

Influence of Food on the Bioavailability of Enalapril

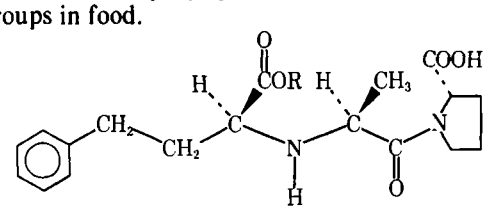
B. N. SWANSON *, P. H. VLASSES *, R. K. FERGUSON *, P. A. BERGQUIST *, A. E. TILL ‡, J. D. IRVIN ‡, and K. HARRIS ‡

Received August 25, 1983, from the **Division of Clinical Pharmacology, Jefferson Medical College of Thomas Jefferson University, Philadelphia, PA 19107* and ‡*Merck Sharp & Dohme Research Laboratories, West Point, PA 19486.* Accepted for publication December 5, 1983.

Abstract □ In a randomized, two-period crossover study in 12 normal volunteers, serum and urine concentrations of the angiotensin-converting enzyme inhibitor enalapril and its active metabolite enalaprilat were determined following administration of a single 40-mg tablet of enalapril maleate administered both in the fasting state and with a standard breakfast. A 7-d interval separated the two treatment periods. Area under the serum concentration-time curves for enalaprilat and urinary recoveries for enalaprilat and total drug did not differ significantly between the fed and fasted conditions. The mean observed maximum serum concentration of enalaprilat was slightly higher for the fasting treatment, but the time to peak concentration was almost identical for the two treatments. Enalapril maleate is unlike the prototype angiotensin-converting enzyme inhibitor captopril in that a standard meal does not appear to influence absorption of this new drug.

Keyphrases □ Enalapril maleate—bioavailability, influence of food □ Enalaprilat—metabolite of enalapril, bioavailability, influence of food □ Angiotensin-converting enzyme—enalapril maleate, bioavailability, influence of food

Food is known to alter the bioavailability of many drugs (1). The presence of food in the GI tract has been shown to reduce, by 30–40%, the absorption of the recently marketed oral angiotensin-converting enzyme (ACE) inhibitor captopril (2). Compromised absorption of captopril could affect the magnitude or duration of the antihypertensive effect of this drug (3). Enalapril maleate is a new ACE inhibitor which, like captopril, has been shown to be effective in the treatment of hypertension and congestive heart failure (4). Enalapril ((*S*)-1-[*N*-[1-(ethoxycarbonyl)-3-phenylpropyl]-L-alanyl]-L-proline; I) is a prodrug which is deesterified to an active diacid form, enalaprilat ((*S*)-1-[*N*-(1-carboxy-3-phenylpropyl)-L-alanyl]-L-proline; II) (4). Since enalapril lacks the sulfhydryl moiety of the chemical structure of captopril, it may have a more favorable benefit-to-risk ratio. Oral absorption of enalapril may also be more complete than captopril since the sulfhydryl group of the latter binds to other thiol groups in food.



I, R = CH_2CH_3
II, R = H

The purpose of this study was to investigate whether consumption of food alters the rate or extent of absorption of enalapril when a single dose is administered to healthy male volunteers.

EXPERIMENTAL SECTION

Subjects—Twelve healthy, normotensive male subjects (age, 23–37 years) volunteered to participate in this study. They were judged to be in good health on the basis of history, physical examination, routine laboratory data, standard electrocardiogram, and diastolic blood pressure (≤90 mm Hg). All subjects weighed within ±10% of the ideal body weights for their ages and heights. No medications other than enalapril maleate were taken by the subjects from 1 week prior to the study until its completion. The protocol was approved by the Committee on Research of Thomas Jefferson University.

Study Design—This was an open, randomized, two-way crossover study in which enalapril maleate (40 mg) was administered as a single dose in its market image. Subjects fasted from midnight of the previous night. On the first day of each treatment period, subjects received doses of enalapril maleate either in a fasting state or immediately after a standard prescribed breakfast by a randomized design. The breakfast consisted of one egg, two pieces of toast or bread, two strips of bacon or two sausages, 150 mL of low fat milk or 100 mL of orange juice, tea, or coffee. All volunteers resumed their normal diets each day at lunch (4 h after dosing). Treatments were separated by 7 d.

Blood was drawn at 0, 1, 2, 3, 4, 6, 8, 12, 16, 24, 36, 48, 60, and 72 h postdrug administration. Urine was collected at −1–0, 0–2, 2–4, 4–6, 6–8, 8–12, 12–24, 24–36, 36–48, 48–72, 72–96, and 96–120 h after each treatment. Blood pressure and pulse rate were measured in the supine and sitting positions at regular intervals for 24 h postadministration. Adverse effects were monitored throughout the study.

Biochemical Analysis and Statistical Methods—The assay value for the enalapril maleate tablet was 42.02 mg, equivalent to 29.88 mg of enalaprilat per tablet. A radioimmunoassay procedure (5) was used to analyze the serum and urine samples for enalaprilat and for total drug (enalaprilat after enzymatic hydrolysis of enalapril). After mixing and incubation overnight at room temperature, the hydrolysis of enalapril to enalaprilat was virtually complete. The assay was considered to be accurate and reproducible at enalaprilat concentrations >1 ng/mL in serum and 0.5 μg/mL in urine; the interassay coefficient of variation was 8%. Concentrations below these values were not considered detectable and, hence, zero for the purpose of data analysis.

All parameters were analyzed by using an analysis of variance for a two-period crossover design (6). These results were corroborated by a nonparametric method based on ranks of the data (7). The posterior probabilities were calculated by the method of Rodda and Davis (8). The power analysis was based on the *t* test.

RESULTS

The mean serum profiles for enalaprilat after administration of enalapril maleate in the fasting and fed states are depicted in Fig. 1. Profiles for the two treatments are virtually superimposable. Mean urinary excretion rate plots

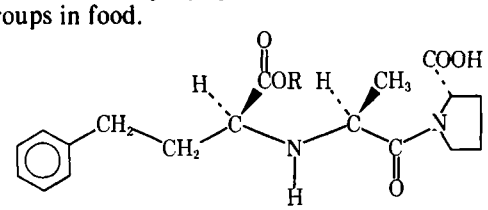
Abstract □ In a randomized, two-period crossover study in 12 normal volunteers, serum and urine concentrations of the angiotensin-converting enzyme inhibitor enalapril and its active metabolite enalaprilat were determined following administration of a single 40-mg tablet of enalapril maleate administered both in the fasting state and with a standard breakfast. A 7-d interval separated the two treatment periods. Area under the serum concentration-time curves for enalaprilat and urinary recoveries for enalaprilat and total drug did not differ significantly between the fed and fasted conditions. The mean observed maximum serum concentration of enalaprilat was slightly higher for the fasting treatment, but the time to peak concentration was almost identical for the two treatments. Enalapril maleate is unlike the prototype angiotensin-converting enzyme inhibitor captopril in that a standard meal does not appear to influence absorption of this new drug.

Keyphrases □ Enalapril maleate—bioavailability, influence of food □ Enalaprilat—metabolite of enalapril, bioavailability, influence of food □ Angiotensin-converting enzyme—enalapril maleate, bioavailability, influence of food

Food is known to alter the bioavailability of many drugs (1). The presence of food in the GI tract has been shown to reduce, by 30–40%, the absorption of the recently marketed oral angiotensin-converting enzyme (ACE) inhibitor captopril (2). Compromised absorption of captopril could affect the magnitude or duration of the antihypertensive effect of this drug (3). Enalapril maleate is a new ACE inhibitor which, like captopril, has been shown to be effective in the treatment of hypertension and congestive heart failure (4). Enalapril ((*S*)-1-[*N*-[1-(ethoxycarbonyl)-3-phenylpropyl]-L-alanyl]-L-proline; I) is a prodrug which is deesterified to an active diacid form, enalaprilat ((*S*)-1-[*N*-(1-carboxy-3-phenylpropyl)-L-alanyl]-L-proline; II) (4). Since enalapril lacks the sulfhydryl moiety of the chemical structure of captopril, it may have a more favorable benefit-to-risk ratio. Oral absorption of enalapril may also be more complete than captopril since the sulfhydryl group of the latter binds to other thiol groups in food.



I, R = CH_2CH_3
II, R = H

The purpose of this study was to investigate whether consumption of food alters the rate or extent of absorption of enalapril when a single dose is administered to healthy male volunteers.

EXPERIMENTAL SECTION

Subjects—Twelve healthy, normotensive male subjects (age, 23–37 years) volunteered to participate in this study. They were judged to be in good health on the basis of history, physical examination, routine laboratory data, standard electrocardiogram, and diastolic blood pressure (≤90 mm Hg). All subjects weighed within ±10% of the ideal body weights for their ages and heights. No medications other than enalapril maleate were taken by the subjects from 1 week prior to the study until its completion. The protocol was approved by the Committee on Research of Thomas Jefferson University.

Study Design—This was an open, randomized, two-way crossover study in which enalapril maleate (40 mg) was administered as a single dose in its market image. Subjects fasted from midnight of the previous night. On the first day of each treatment period, subjects received doses of enalapril maleate either in a fasting state or immediately after a standard prescribed breakfast by a randomized design. The breakfast consisted of one egg, two pieces of toast or bread, two strips of bacon or two sausages, 150 mL of low fat milk or 100 mL of orange juice, tea, or coffee. All volunteers resumed their normal diets each day at lunch (4 h after dosing). Treatments were separated by 7 d.

Blood was drawn at 0, 1, 2, 3, 4, 6, 8, 12, 16, 24, 36, 48, 60, and 72 h postdrug administration. Urine was collected at −1–0, 0–2, 2–4, 4–6, 6–8, 8–12, 12–24, 24–36, 36–48, 48–72, 72–96, and 96–120 h after each treatment. Blood pressure and pulse rate were measured in the supine and sitting positions at regular intervals for 24 h postadministration. Adverse effects were monitored throughout the study.

Biochemical Analysis and Statistical Methods—The assay value for the enalapril maleate tablet was 42.02 mg, equivalent to 29.88 mg of enalaprilat per tablet. A radioimmunoassay procedure (5) was used to analyze the serum and urine samples for enalaprilat and for total drug (enalaprilat after enzymatic hydrolysis of enalapril). After mixing and incubation overnight at room temperature, the hydrolysis of enalapril to enalaprilat was virtually complete. The assay was considered to be accurate and reproducible at enalaprilat concentrations >1 ng/mL in serum and 0.5 μg/mL in urine; the interassay coefficient of variation was 8%. Concentrations below these values were not considered detectable and, hence, zero for the purpose of data analysis.

All parameters were analyzed by using an analysis of variance for a two-period crossover design (6). These results were corroborated by a nonparametric method based on ranks of the data (7). The posterior probabilities were calculated by the method of Rodda and Davis (8). The power analysis was based on the *t* test.

RESULTS

The mean serum profiles for enalaprilat after administration of enalapril maleate in the fasting and fed states are depicted in Fig. 1. Profiles for the two treatments are virtually superimposable. Mean urinary excretion rate plots

0022-3549/84/1100-1655$01.00/0

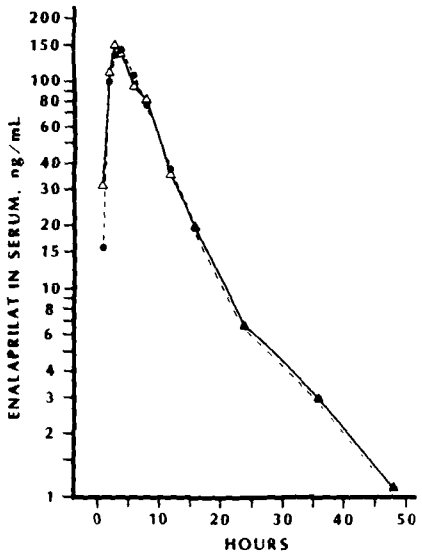

Figure 1—*Mean enalaprilat serum concentrations following administration of an enalapril maleate 40-mg tablet to fasting (●) and fed (△) healthy subjects (n = 12).*

for enalaprilat and total drug (Figs. 2 and 3, respectively) were similar for the fasting and fed states as well. Serum parameters for enalaprilat and urine parameters for enalaprilat and total drug are presented in Table I, as are power analyses and posterior probability results. Mean peak serum concentrations of enalaprilat were 154 and 147 ng/mL for the fasting and nonfasting treatments and were observed at 3.3 and 3.4 h, respectively, after administration of enalapril maleate. Mean serum $AUC_{0\text{-}24}$ values for enalaprilat obtained from the fasting and nonfasting treatments were essentially the same and accounted, on the average, for 93% of the total AUC (from time zero to the time of the lowest detectable serum concentration) for both treatments. For most subjects, the maximum serum concentration for enalapril (obtained as the difference between enalaprilat equivalents before and after sample hydrolysis) was observed at 1 h, the first sampling time, and tended to be slightly higher during the fasting state. In two subjects, the maximum was at 2 h (data not shown).

Mean urinary recoveries (0–48 h) of enalaprilat were 31 and 32% of the dose for the fasting and nonfasting treatments, respectively; recoveries of total drug after hydrolysis of urinary enalapril were 53 and 58% of the dose, respectively. The mean urinary recovery ratio of enalaprilat–total drug was 0.58 for the fasting treatment and 0.54 for the nonfasting treatment. No statistically significant differences were found between treatments for any of the serum or urine parameters considered.

Table I—Mean Serum Parameters for Enalaprilat and Urine Parameters for Enalaprilat and Total Drug [a]

Parameter[b]	Fasting (Mean ± *SD*)	Fed (Mean ± *SD*)	Comparison[c]
C_{max} (enalaprilat), ng/mL	154 ± 39	147 ± 36	NS
t_{max} (enalaprilat), h	3.3 ± 0.5	3.4 ± 0.5[d]	NS
$AUC_{0\text{-}24}$ (enalaprilat), ng·h/mL	1209 ± 203	1173 ± 212	NS
$AUC_{0\text{-}LSC}$ (enalaprilat), ng·h/mL	1304 ± 240	1262 ± 220	NS
Urinary recovery, 0–48 h (percent of administered enalaprilat equivalents)[d]			
Enalaprilat	30.5 ± 7.5	31.6 ± 8.8	NS
Total drug	53.1 ± 10.1	57.6 ± 12.4	NS
Urinary recovery ratio of enalaprilat/total drug, 0–48 h[d,e]	0.58	0.54	NS

[a] Following oral administration of enalapril maleate (40 mg) in healthy fasting and fed volunteers; $n = 12$; total drug was measured after hydrolysis, representing enalaprilat which was present in the urine as enalapril itself and that which was present as enalaprilat. [b] C_{max}, observed maximum serum concentration; t_{max}, time of observed maximum serum concentration; $AUC_{0\text{-}24}$ and $AUC_{0\text{-}LSC}$, area under the serum concentration–time curve from 0–24 h and 0–last observed serum concentration, respectively. [c] No significant differences (NS) were found for any comparison. The power of detecting a 20% difference in urinary recovery of enalaprilat and total drug, with $\alpha = 0.05$, is 0.82 and 0.81, respectively; posterior probability that the true difference is 20% or less is 0.97 for enalaprilat and 0.94 for total drug. [d] $n = 11$. [e] Geometric mean of individual ratios.

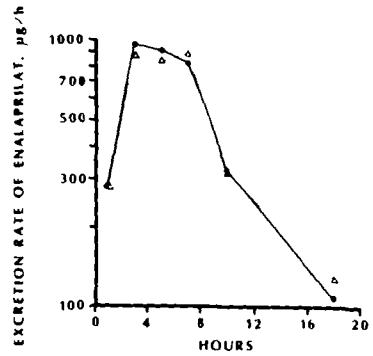

Figure 2—*Mean enalaprilat urinary excretion plots following oral administration of enalapril maleate to fasting (●) and fed (△) healthy subjects (n = 9 and 10, respectively).*

Mean diastolic blood pressure significantly decreased from predose values by 2 h after each dose, and these decreases were maintained for 4–8 h. No adverse effects were reported.

DISCUSSION

Enalapril maleate is a new nonsulfhydryl ACE inhibitor which is converted *in vivo* to an active diacid metabolite (enalaprilat). Although both enalapril and its metabolite are ACE inhibitors, it is the metabolite that exhibits the greatest potency and is the presumed active compound *in vivo*. In the present study, the effect of food on the serum concentration–time profile of enalaprilat and urinary recovery of enalaprilat and total drug (enalapril plus enalaprilat) after administration of a single dose of enalapril maleate were evaluated. This is of interest because food has been reported to decrease by 30% the extent of absorption of captopril, the currently available oral ACE inhibitor (2). In addition, maximum inhibition of ACE, as reflected by enzyme activity in serum, appears to be required for the full therapeutic effect of this class of drugs (4). Since serum ACE activity is directly related to circulating drug concentrations, this maximal degree of inhibition may not occur if drug absorption is impaired. Interestingly, food has recently been reported to decrease, by ~50%, the oral absorption of *d*-penicillamine, another sulfhydryl-containing compound (9).

This study in normal volunteers showed that a standard breakfast did not alter the serum concentration–time profile and urinary recovery of enalaprilat following a single oral dose of enalapril maleate (40 mg). We have demonstrated previously that an enalaprilat concentration of ~14 ng/mL is required to inhibit serum ACE levels by 90% (10, 11). In the current study, this serum concentration was maintained for at least 16 h after each 40-mg dose in most subjects, regardless of diet.

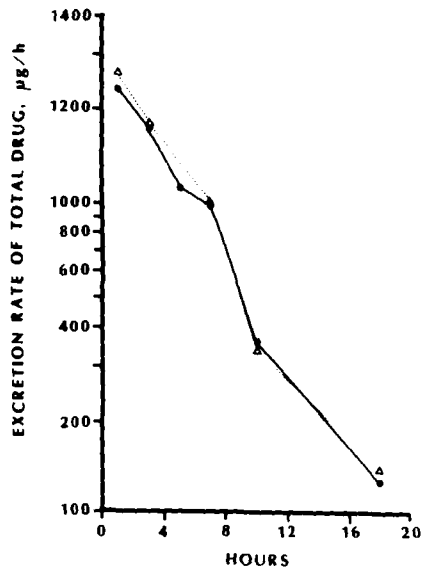

Figure 3—*Mean urinary excretion rate plots for total drug (enalaprilat measured after hydrolysis) following oral administration of enalapril maleate to fasting (●) and fed (△) healthy subjects (n = 9 and 10, respectively).*

In conclusion, the serum parameters for enalaprilat and urine parameters for enalaprilat and total drug (enalapril-enalaprilat) were similar following administration of a single enalapril maleate 40-mg tablet to healthy volunteers under fasting and nonfasting conditions. Thus, food did not appreciably alter the absorption of enalapril or the bioavailability of enalaprilat in this study.

Metabolism of Salsalate in Normal Subjects

SYDNEY H. DROMGOOLE ˣ, DANIEL E. FURST, and HAROLD E. PAULUS

Received March 14, 1983, from the *Division of Rheumatology, Department of Medicine, University of California, Los Angeles, Los Angeles, CA 90024.* Accepted for publication October 26, 1983.

Abstract □ The metabolism of salsalate (I) was characterized in two normal volunteers. The drug was almost completely absorbed and was excreted primarily in the urine; only ~1% of the total dose was found in the stools. Although I is a salicylate derivative, which on hydrolysis yields two molecules of salicylic acid (II), ~7-10% of the dose was not hydrolyzed to salicylic acid and appeared in the urine either as unchanged drug or glucuronide conjugates. Thus, the incomplete availability of salicylate from salsalate that has been previously reported may not be due to incomplete absorption of the drug but to incomplete hydrolysis to salicylic acid.

Keyphrases □ Salsalate—metabolism, normal subjects □ Absorption—salsalate, normal subjects

Salsalate (I) is a salicylate derivative which on hydrolysis yields two molecules of salicylic acid (II). The results of several studies have indicated that the availability of salicylate from salsalate is lower than from either choline magnesium trisalicylate (1) or aspirin (2, 3). It has been suggested that the lower availability of salicylate from salsalate may be due to incomplete absorption (1). However, the recovery of total salicylate in the urine samples of patients receiving equivalent doses of salsalate and aspirin indicated that the absorption of the two salicylate formulations was essentially complete. The hydrolysis of salsalate to salicylate was incomplete, with <1% of the dose being excreted as unchanged salsalate and ≤13% of the dose being excreted in the urine as conjugates of salsalate (3). The only limitation of this latter study was the fact that the biological samples had been stored for several months prior to analysis, during which time salsalate (both nonconjugated and conjugated) may have partially hydrolyzed to salicylic acid.

The purpose of this study was to characterize the metabolism of salsalate in two normal volunteers following the administration of 2000 mg of salsalate containing ^{14}C-labeled salsalate.

EXPERIMENTAL SECTION

Two normal healthy male volunteers (age 29 and 35) entered into the 4-d study after initial screening procedures. The volunteers fasted for 12 h prior to and 4 h after drug administration. They ingested 2000 mg (four 500-mg capsules) of salsalate containing ^{14}C-labeled salsalate[1] (64 μCi) with water. Compound I was radiolabeled at both carboxyl positions.

Blood samples were taken just before drug ingestion, at hourly intervals up to 12 h, and then at 16, 20, 24, 30, 36, 48, 60, and 72 h following drug administration. Immediately after the blood samples were drawn into heparinized tubes, they were centrifuged, and the plasma was frozen until analysis. Urine samples were collected during the following intervals: 0-1, 1-2, 2-4, 4-6, 6-8, 8-12, 12-16, and 16-24 h. For the next 3 d, urinary output was collected as consecutive 12-h aliquots. The volume of urine and pH were recorded for each period, and aliquots were frozen in plastic containers until analysis. All stools were collected, weighed, and frozen until analysis. Due to the possibility of hydrolysis of salsalate and its conjugates to salicylic acid, all assays were completed within 2 weeks of collection.

Aliquots of plasma (0.1 mL with 0.9 mL of water) or urine (1.0 mL) were transferred into scintillation vials containing scintillation fluid[2] and counted in a scintillation counter[3]. Standards containing 500 μg of the radiolabeled salsalate[1] in propanol were also counted. All counts were corrected for quenching.

The plasma and urine samples were assayed for unchanged salsalate and salicylic acid by a previously reported HPLC technique (4). Salsalate[1], salicylic acid[4], and α-phenylcinnamic acid[4], the internal standard, were extracted from acidified plasma and urine samples. Methylene chloride[5] was used to extract plasma, whereas urine was extracted into hexane[6]. The organic phases were evaporated to dryness, redissolved in methanol (0.5 mL)[7], and analyzed by HPLC with an automatic sample injector accessory[8]. The mobile phase of methanol-1% acetic acid (60:40, v/v) was pumped at a rate of 2.0 mL/min through a 4.6 × 150-mm column[9]. Peaks were detected with a UV detector[10] (300 nm) coupled to a recorder[11] and peak integrator[12]. Plasma samples were assayed for total salicylate by HPLC after heating with HCl (18 M) overnight at 100°C. Extraction and chromatographic conditions were the same as described above for unchanged I.

Total urinary salicylate was determined by a modification of the colorimetric method described by Chiou and Onyemelukwe (5). Aliquots of urine

Metabolism of Salsalate in Normal Subjects

SYDNEY H. DROMGOOLE ˣ, DANIEL E. FURST, and HAROLD E. PAULUS

Received March 14, 1983, from the *Division of Rheumatology, Department of Medicine, University of California, Los Angeles, Los Angeles, CA 90024.* Accepted for publication October 26, 1983.

Abstract □ The metabolism of salsalate (I) was characterized in two normal volunteers. The drug was almost completely absorbed and was excreted primarily in the urine; only ~1% of the total dose was found in the stools. Although I is a salicylate derivative, which on hydrolysis yields two molecules of salicylic acid (II), ~7-10% of the dose was not hydrolyzed to salicylic acid and appeared in the urine either as unchanged drug or glucuronide conjugates. Thus, the incomplete availability of salicylate from salsalate that has been previously reported may not be due to incomplete absorption of the drug but to incomplete hydrolysis to salicylic acid.

Keyphrases □ Salsalate—metabolism, normal subjects □ Absorption—salsalate, normal subjects

Salsalate (I) is a salicylate derivative which on hydrolysis yields two molecules of salicylic acid (II). The results of several studies have indicated that the availability of salicylate from salsalate is lower than from either choline magnesium trisalicylate (1) or aspirin (2, 3). It has been suggested that the lower availability of salicylate from salsalate may be due to incomplete absorption (1). However, the recovery of total salicylate in the urine samples of patients receiving equivalent doses of salsalate and aspirin indicated that the absorption of the two salicylate formulations was essentially complete. The hydrolysis of salsalate to salicylate was incomplete, with <1% of the dose being excreted as unchanged salsalate and ≤13% of the dose being excreted in the urine as conjugates of salsalate (3). The only limitation of this latter study was the fact that the biological samples had been stored for several months prior to analysis, during which time salsalate (both nonconjugated and conjugated) may have partially hydrolyzed to salicylic acid.

The purpose of this study was to characterize the metabolism of salsalate in two normal volunteers following the administration of 2000 mg of salsalate containing ^{14}C-labeled salsalate.

EXPERIMENTAL SECTION

Two normal healthy male volunteers (age 29 and 35) entered into the 4-d study after initial screening procedures. The volunteers fasted for 12 h prior to and 4 h after drug administration. They ingested 2000 mg (four 500-mg capsules) of salsalate containing ^{14}C-labeled salsalate[1] (64 μCi) with water. Compound I was radiolabeled at both carboxyl positions.

Blood samples were taken just before drug ingestion, at hourly intervals up to 12 h, and then at 16, 20, 24, 30, 36, 48, 60, and 72 h following drug administration. Immediately after the blood samples were drawn into heparinized tubes, they were centrifuged, and the plasma was frozen until analysis. Urine samples were collected during the following intervals: 0-1, 1-2, 2-4, 4-6, 6-8, 8-12, 12-16, and 16-24 h. For the next 3 d, urinary output was collected as consecutive 12-h aliquots. The volume of urine and pH were recorded for each period, and aliquots were frozen in plastic containers until analysis. All stools were collected, weighed, and frozen until analysis. Due to the possibility of hydrolysis of salsalate and its conjugates to salicylic acid, all assays were completed within 2 weeks of collection.

Aliquots of plasma (0.1 mL with 0.9 mL of water) or urine (1.0 mL) were transferred into scintillation vials containing scintillation fluid[2] and counted in a scintillation counter[3]. Standards containing 500 μg of the radiolabeled salsalate[1] in propanol were also counted. All counts were corrected for quenching.

The plasma and urine samples were assayed for unchanged salsalate and salicylic acid by a previously reported HPLC technique (4). Salsalate[1], salicylic acid[4], and α-phenylcinnamic acid[4], the internal standard, were extracted from acidified plasma and urine samples. Methylene chloride[5] was used to extract plasma, whereas urine was extracted into hexane[6]. The organic phases were evaporated to dryness, redissolved in methanol (0.5 mL)[7], and analyzed by HPLC with an automatic sample injector accessory[8]. The mobile phase of methanol-1% acetic acid (60:40, v/v) was pumped at a rate of 2.0 mL/min through a 4.6 × 150-mm column[9]. Peaks were detected with a UV detector[10] (300 nm) coupled to a recorder[11] and peak integrator[12]. Plasma samples were assayed for total salicylate by HPLC after heating with HCl (18 M) overnight at 100°C. Extraction and chromatographic conditions were the same as described above for unchanged I.

Total urinary salicylate was determined by a modification of the colorimetric method described by Chiou and Onyemelukwe (5). Aliquots of urine

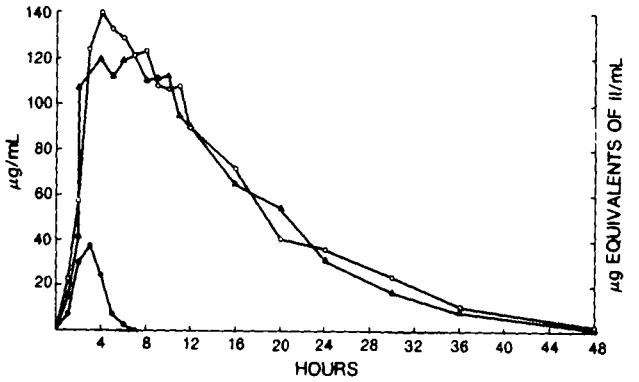

Figure 1—*Plasma levels of free salicylic acid (▲), salsalate (●), (in micrograms per milliliter), and radioactivity (○) (in microgram equivalents of salicylic acid per milliliter) in subject 1 following oral administration of 2000 mg of salsalate.*

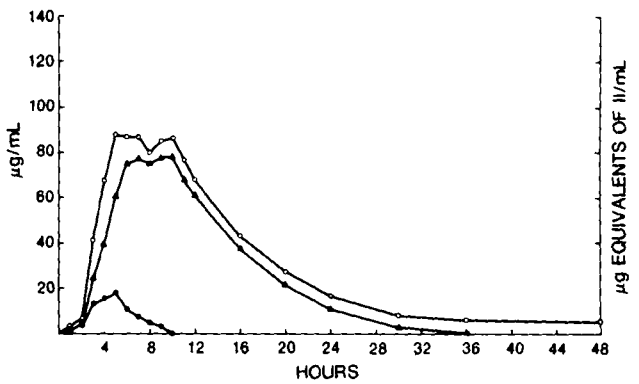

Figure 2—*Plasma levels of free salicylic acid (▲), salsalate (●), (in micrograms per milliliter), and radioactivity (○) (in microgram equivalents of salicylic acid per milliliter) in subject 2 following oral administration of 2000 mg of salsalate.*

were incubated overnight with concentrated HCl at 100°C. The tubes were then extracted with chloroform[13], an aliquot of the organic phase was shaken with the modified Trinder reagent (5), and the absorbance of the aqueous phase was measured at 540 nm. A standard curve was constructed by using known concentrations of sodium salicylate[4] from 0 to 100 mg %.

Plasma and urine samples were assayed for conjugated salsalate and salicylic acid by HPLC following incubation of the samples with β-glucuronidase[14] (5000 U/mL) in acetate buffer (pH 4.5) for 3 h at 37°C. Results of preliminary experiments indicated that partial hydrolysis of salsalate occurred during the incubation period; to correct for this hydrolysis, standards of salsalate, ranging from 20 to 300 μg/mL, were incubated and analyzed with each batch of samples. After incubation, the urine and plasma samples were analyzed for salsalate and salicylic acid by the HPLC method described above for unchanged I.

The urine samples were also assayed for nonconjugated gentisic, salicyluric, and salicylic acid levels by HPLC. Aliquots (1 mL) of standards and samples were transferred into screw-cap tubes, *o*-methoxybenzoic acid[4] (200 μg) was added as an internal standard in addition to 1.0 mL of HCl (0.6 M). The samples were extracted with ether[15] (6 mL). After centrifugation, the aqueous layer was frozen in dry ice–propanol. The ethereal phase was transferred to a tube and the solvent was removed under a stream of nitrogen at 10°C. The residue was then resuspended in 0.5 mL of mobile phase and injected into the HPLC *via* the automatic sampler. The mobile phase of methanol–1% acetic acid (15:85, v/v) was pumped at the rate of 2.0 mL/min through the reverse-phase column[9]. UV absorbance was measured at 300 nm[10]. The retention times for gentisic acid, salicyluric acid, anisic acid, and salicylic acid were 280, 600, 900, and 1190 s, respectively. A small peak was eluted between gentisic acid and salicyluric acid in the samples obtained at early times. This probably corresponds to the glucuronide(s) of salicylic acid and has been described by others (6). Under these chromatographic conditions, unchanged salsalate was not eluted.

Preliminary radioactive counting of aliquots of urine samples after HPLC indicated that not all the radioactivity could be accounted for following chromatography. This problem was resolved by using gradient elution chromatography.

Standards and urine samples (1.0 mL) were transferred into screw-cap tubes and extracted with ether[15] after acidification with 0.6 M HCl as described above. The ethereal layer was taken to dryness with nitrogen at 10°C, and the residue was resuspended in the initial mobile phase. The initial mobile phase was methanol–1% acetic acid (15:85, v/v). A solvent programmer[16] was used to change the relative pumping rates of two pumps to enable the initial phase to change linearly from its initial condition to a final composition of methanol–1% acetic acid (60:40, v/v). The gradient time was 30 min. This was followed by a 15-min elution while maintaining the final gradient conditions, after which the initial conditions were reestablished. UV absorbance was measured at 300 nm[10]. Under these conditions, the retention times were 280 s (gentisic acid), 500 s (salicyluric acid), 650 s (anisic acid), 780 s (salicylic acid), and 1800 s (salsalate). Two additional peaks were eluted at 1380 and 1590 s.

Each stool specimen was homogenized with a known amount of water. Weighed aliquots (0.5–1.0 g) were treated with the decolorizing agents perchloric acid[17] (0.4 mL) and hydrogen peroxide[18] (0.8 mL) and incubated for 24 h at 37°C, and four drops of 15% ascorbic acid[19] and 10 mL of scintillation fluid[2] were added. The treated specimens were then counted in a scintillation counter, corrected for quenching, and converted into micrograms of ^{14}C-labeled salsalate.

RESULTS AND DISCUSSION

Changes in total radioactivity of unconjugated salsalate and salicylic acid in plasma *versus* time for each subject is shown in Figs. 1 and 2. For subject 1, a peak plasma level of II (120 μg/mL) was reached after 4 h (Fig. 1), whereas with the results for subject 2, a lower peak level of 77.6 μg/mL 7 h after drug administration was attained (Fig. 3). Peak levels of I were seen in subject 1 at 3 h (37.9 μg/mL) and in subject 2 at 5 h (18.3 μg/mL).

The areas under the plasma level *versus* time curves for total radioactivity of salsalate and salicylic acid indicated that 86.6% of the area under the curve of total radioactivity was accounted for by the area under the curves of nonconjugated salsalate and salicylic acid in subject 1 and 67.3% in subject 2.

Acid hydrolysis of the plasma samples by incubation overnight at 100°C made the plasma concentrations of II congruent with the amount of radioactivity in the samples (expressed as microgram equivalents of salicylic acid per milliliter), indicating the presence of other metabolites of salicylic acid and/or salsalate in the plasma of these normal volunteers. The ratio of AUC radioactivity-$AUC_{total\ II}$ was 1.01 in subject 1 and 1.02 in subject 2.

The urinary excretion of radioactivity demonstrated that 45.8 and 56.6% of the dose was excreted after 12 h in subjects 1 and 2, respectively, whereas the amount of radioactivity in urine (expressed in microgram equivalents of salsalate) accounted for 95.5 and 101.8% of the drug dose after 84 h. Only ~1% of the total radioactivity was found in the stools of these subjects. The

Table I—Urinary Excretion of Salsalate and Its Metabolites

Compound	Urinary Excretion	
	Subject 1	Subject 2
Total radioactivity, mg equivalents of salsalate	1909.0 (95.4)[a]	2036.0 (101.8)[a]
Free salicylic acid, mg	90.5 (4.2)	50.7 (2.4)
Conjugated salicylic acid, mg	328.6 (15.4)	264.3 (12.4)
Free salsalate, mg	3.4 (0.2)	6.2 (0.3)
Conjugated salsalate, mg	136.0 (6.8)	200.0 (10.0)
Gentisic acid, mg	75.4 (3.2)	58.7 (2.5)
Salicyluric acid, mg	1514.7 (50.3)	1797.2 (59.6)
Total salicylate, mg	1961.4 (91.7)	2014.0 (96.2)

[a] Numbers in parentheses indicate the percentage of administered dose recovered in the urine.

urinary excretion of nonconjugated salsalate and salicylic acid during the study period is shown in Table I; nonconjugated salicylic acid accounted for 2–4% of the total dose, whereas <1% of the dose was excreted as nonconjugated salsalate. These results agree with those reported by Harrison *et al.* (2). Conjugates of both salsalate and salicylic acid were present in significant amounts in both volunteers (Table I). Approximately 12–15% of the dose was excreted as conjugates of salicylic acid, whereas the conjugates of salsalate accounted for 6.8 and 10% of the dose in subjects 1 and 2, respectively. The majority of the conjugates of salsalate were excreted within 12 h after the administration of the drug. A typical HPLC tracing of a urine sample before and after β-glucuronidase treatment is shown in Fig. 3. This chromatogram shows the disappearance of peak 4 and the increase in salsalate (peak 6) after incubation with glucuronidase. Peak 1 also disappeared on treatment with glucuronidase, whereas the salicylic acid peak (peak 3) increased, indicating that peak 1 was one or both of the glucuronides of salicylic acid.

The urinary excretion of nonconjugated gentisic acid, salicyluric acid, and salicylic acid is tabulated in Table I. The amount of nonconjugated gentisic acid excreted in the urine of these subjects was 2.5% (subject 1) and 3.2% (subject 2) of the total dose, whereas excretion as nonconjugated salicyluric acid accounted for 50.0% of the dose in subject 1 and 59.6% in subject 2. The total salicylate recovered in the urine (as percentage of the dose) was 91.7% in subject 1 and 96.2% in subject 2. These values do not include the gentisate excreted since this metabolite is not hydrolyzed to salicylic acid. Thus, urinary salicylate plus gentisic acid levels accounted for 94.9% (subject 1) and 98.7% (subject 2) of the administered dose of salsalate (Table I).

This study of the metabolism of salsalate in two normal volunteers clearly demonstrates the essentially complete absorption of the drug (as indicated by the almost complete recoveries of doses in the urine) and the incomplete hydrolysis of salsalate to salicylic acid (as indicated by the presence of glucuronide conjugates of salsalate in the urine). Formation of the glucuronide conjugates of salsalate may occur either during its passage through the GI tract (7) or in the liver. Regardless of the site of glucuronidation, however, in this study 7–10% of the dose was excreted as glucuronide conjugates of salsalate. Attempts to identify the structures of the glucuronide conjugates by mass spectrometry were unsuccessful. However, mass spectrometric analysis[20] of peak 4 (Fig. 3) following treatment with β-glucuronidase showed that the aglycone was salsalate.

The presence of the glucuronide conjugates, however, suggests that the lower plasma levels of salicylic acid achieved with salsalate, as compared with aspirin or choline magnesium salicylate in previous studies (1–3), are due to a decreased amount of salicylic acid in the body caused by the rapid conjugation of some salsalate (before its hydrolysis to salicylic acid) and its subsequent excretion into the urine.

Although the percentages of the dose excreted as conjugates of salsalate in the two volunteers in this study do not fully explain the 15–23% lower than expected plasma levels of salicylic acid observed in patients (3) and normal volunteers (1, 2) after the administration of salsalate, it should be pointed out that a 10% decrease in the dose of available salicylate may be accompanied by a disproportionate decrease in serum salicylate levels. Such disproportionality follows from the observation that a 50% increase in the dosage of aspirin can almost triple the serum salicylate levels (8).

It should be noted that the decreased availability is only with respect to salicylate, however, since salsalate is essentially completely absorbed and the rapid glucuronidation and excretion prevents complete hydrolysis of salsalate to salicylic acid *in vivo*, thus decreasing the amount of salicylic acid that reaches the systemic circulation.

The results of the present study in normal volunteers supports the results of our multiple dose study in patients with rheumatoid arthritis (3) and indicates that the reduced availability of salicylic acid from salsalate is due to the incomplete hydrolysis of the prodrug.

The clinical implication of these studies is that the dose of salsalate needed to achieve equal plasma salicylate levels will be greater than that predicted from an equivalent dose of aspirin. Preliminary data from multiple dose studies in normal volunteers (2, 9) suggest that the availability of salicylate from one 500-mg tablet of salsalate[21] is approximately equivalent to that available from two 325-mg tablets of aspirin. These doses contain 535 and 500 mg equivalents of salicylic acid, respectively. However, for optimal salicylate therapy of inflammatory arthritis, plasma salicylate concentrations should be determined periodically and used as the basis for dosage adjustment.

High-Performance Liquid Chromatographic Method for the Determination of Esmolol Hydrochloride

YING-CHI LEE, DAVID MICHAEL BAASKE ˣ, and ABU S. ALAM

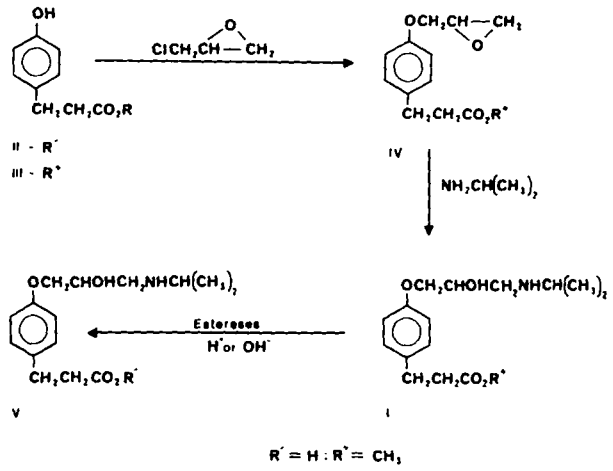
Received September 14, 1983, from the *Pharmaceutical Development Department, Research and Development Division, American Critical Care, McGaw Park, IL 60085.* Accepted for publication January 13, 1984.

Abstract □ A rapid high-performance liquid chromatographic method for the determination of esmolol hydrochloride, a new ultra-short-acting beta blocker, is described. The stability-indicating nature of the method was demonstrated by resolving esmolol from synthetic intermediates, potential impurities, and the product of decomposition. Reverse-phase liquid chromatography was performed with a microparticulate (10-μm) cyano-bonded silica-packed column, a fixed-wavelength UV absorbance detector (λ = 280 nm), and a mobile phase of acetonitrile–0.005 M sodium acetate–acetic acid (15:84:1) pumped at 2 mL/min. The internal standard was 2-*p*-chlorophenyl-2-methylpropanol. A percent *RSD* of <1.7% and an accuracy (100% − mean error) of >98.6% were achieved over the concentration range studied (100–500 μg/mL), with correlation coefficients >0.9996.

Keyphrases □ HPLC—determination of esmolol hydrochloride □ Esmolol hydrochloride—HPLC

Esmolol hydrochloride (methyl 3[4-[2-hydroxy-3-[(2-methylethyl)amino]propoxy]phenyl]propionate hydrochloride; I) is the first of a new class of beta blockers, known as ultra-short-acting beta blockers, to enter clinical trials. The ultra-short-acting beta blockers were designed to extend the usefulness, safety, and efficacy of beta blockers in critical cardiac therapy through controlled and titratable intravenous therapy (1). This was accomplished by designing chemical instability into the molecule. The ester functionality of the molecule is susceptible to cleavage by the nonspecific serum esterases to the free acid 3[4-[2-hydroxy-3-[(2-methylethyl)amino]-propoxy]phenyl]propionic acid.

Esmolol hydrochloride was synthesized (2) from 3-(*p*-hydroxyphenyl)propionic acid (II) *via* a four-step process (Scheme I). In this report the development and validation of a high-performance liquid chromatographic (HPLC) method for the quantitation of esmolol in the presence of synthetic intermediates (II–IV) and free acid (V) is described.



Scheme I

EXPERIMENTAL SECTION

Materials—Compounds I, III, IV, V, and VI were synthesized in this laboratory. 2-(*p*-Chloro-phenyl)-2-methyl propanol[1], compound II, glacial acetic acid[2], and sodium acetate[2] were used as received. Glass-distilled acetonitrile and methanol were used for all procedures[3]. Purified water[4] was used throughout.

Chromatography—A liquid chromatographic system (3), equipped with a fixed-wavelength UV absorbance detector[5] at 280 nm, an on-line data system[6], and a column (30 cm × 3.9 mm) packed with cyano-bonded silica (10-μm)[7], was used. Sample injections were 50 μL. Mobile phase was prepared fresh daily by thoroughly mixing 150 mL of acetonitrile, 10 mL of glacial acetic acid, and 840 mL of sodium acetate trihydrate (0.068%, w/v) buffer which was filtered through a 0.5-μm filter[8] prior to use. A constant flow rate of 2 mL/min yielded a pressure of <2000 psi.

Standard concentrations of 500, 400, 300, 200, 100, and 0 μg/mL were prepared in quadruplicate. To 1.0 mL of each standard or sample was added 750 μL of the internal standard 2-(*p*-chlorophenyl)-2-methyl propanol (4 mg/mL) in methanol–water (50:50). Peak areas were measured, and the ratios for esmolol–internal standard were calculated with the data system, yielding a calibration curve. Samples were prepared in water at 500 μg/mL.

Specificity of the Method—Esmolol hydrochloride (50 mg) was placed in each of four 100-mL volumetric flasks. Into each flask was added 75 mL of either water, 1 M HCl, 1 M NaOH, or 30% hydrogen peroxide. The flasks were gently boiled for 1 h. After cooling, the pH was adjusted to 4 with concentrated

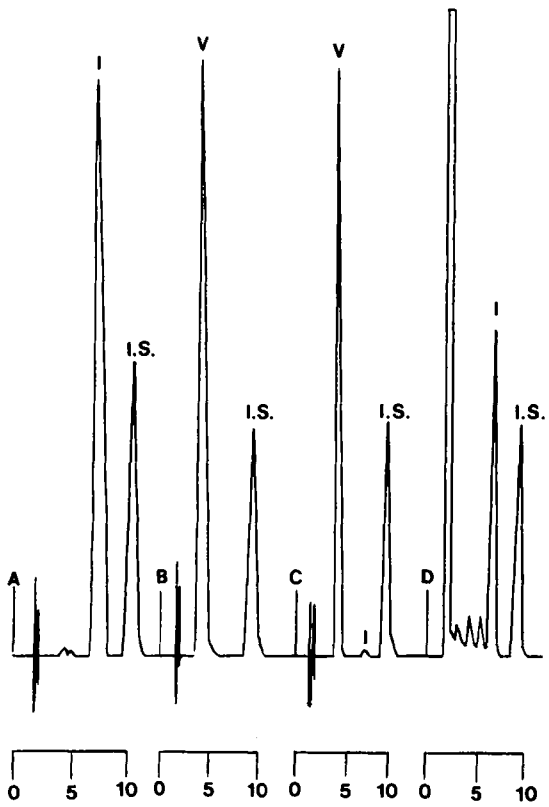

Figure 2—*Chromatogram of esmolol hydrochloride solutions boiled for 1 h. Key: (A) water, pH 5.5; (B) 1 M NaOH; (C) 1 M HCl; (D) 30% H_2O_2.*

HCl or 10 M NaOH. All flasks were brought to volume with water and analyzed.

RESULTS AND DISCUSSION

The direct measurement of the raw drug for esmolol hydrochloride content in the presence of the anticipated synthetic intermediates, the synthetic starting material, and the anticipated breakdown product is shown in Fig. 1. The detector wavelength (280 nm) was chosen to enhance visualization of all potential synthetic intermediates and not for maximum sensitivity for esmolol. The limit of quantitation for esmolol hydrochloride was ~10 μg/mL under the reported operating conditions.

Table I—Analysis of Four Experimental Lots of Esmolol Hydrochloride

Lot	Mean, %	RSD, %	Number of Determinations	Time
A	97.8	1.15	24	2 years
B	97.4	1.23	24	2 years
C	98.6	1.95	21	1 year
D	97.5	0.81	18	9 months

Applicability—The specificity of the HPLC system was tested with degraded esmolol samples. No changes in I concentration were seen in the boiled aqueous solution. After 1 h in boiling acid (1 M HCl) or base (1 M NaOH), I was almost completely converted to V, as might be expected under these conditions. Finally, boiling for 1 h in 33% hydrogen peroxide yielded several additional unidentified products (Fig. 2). In each chromatogram, it can be seen that the size of the I peak decreases with degradation. The practicality of the method was demonstrated by the analysis of four synthetic lots (Table I). The percent *RSD* values for the analysis over a 2-year period and with several analysts were consistently <2%.

Accuracy and Precision—In spite of consistently high correlation coefficients (>0.996), the peak height ratio method was not employed, as erroneous results were obtained due to tailing at higher concentrations. Curvature or tailing did not influence the peak area ratio calculations which were employed for all studies. Data generated by three separate analysts on each of 3 d yielded an accuracy >98.6%, percent *RSD* of <1.64%, and correlation coefficients >0.9996 for the calibration curves. The percent *RSD* values for a single sample were <2% (Table I).

Effect of Ethanol, Glycerol, and Propylene Glycol on the Stability of Phenobarbital Sodium

V. DAS GUPTA

Received October 18, 1983, from the *Department of Pharmaceutics, University of Houston, Houston, TX 77030.* Accepted for publication January 19, 1984.

Abstract □ The effects of ethanol, glycerol, propylene glycol, phosphate buffer, and ionic strength on the stability of phenobarbital sodium have been studied. Ethanol had the maximum stabilization effect followed by propylene glycol and glycerol when compared with the stability in water. The estimated half-lives at 50°C (pH ~ 8) were 78, 95, 109, and 127 d in water and 20% aqueous solutions of glycerol, propylene glycol, and ethanol, respectively. The effects of phosphate buffer and ionic strength were negligible.

Keyphrases □ Phenobarbital sodium—stability, effects of ethanol, glycerol, and propylene glycol □ Stability—phenobarbital, effect of solvents

It is well known that the stability of phenobarbital in liquid dosage forms depends on the pH and the vehicle. A common method to minimize degradation (1) is to use a mixed solvent of water and an organic solvent such as ethanol, glycerol, or propylene glycol. The stabilization effect of ethanol is thought to be due to a decreased dielectric constant (2), which slows down the reaction between ions of like charges, *i.e.*, the ionized form of phenobarbital and the hydroxyl ions.

An earlier report (1) indicated that it was difficult to select a stability-indicating method for the quantitation of phenobarbital. Recently, a stability-indicating assay method (3) based on HPLC has been reported which is applicable to liquid

dosage forms such as phenobarbital elixir. The purpose of these investigations was to study the effect of ethanol, glycerol, propylene glycol, phosphate buffer concentration, and ionic strength on the stability of phenobarbital sodium using the recently developed (3) HPLC method.

EXPERIMENTAL SECTION

Chemicals, Reagents, and Apparatus—All chemicals and reagents were either USP, NF, or ACS quality. Phenobarbital sodium[1] (1) was used as received.

The chromatograph[2] was equipped with a multiple-wavelength detector[3] and a recorder[4]. A semipolar column[5] (30 cm × 4 mm i.d.) was used. The mobile phase contained 35% methanol in 0.02 M aqueous ammonium acetate. The flow rate was 3.0 mL/min, and the temperature was ambient. The sensitivity was set at 0.1 (245 nm) and the chart speed was 30.5 cm/h.

Preparation of Phenobarbital Sodium Solutions—All solutions (Table I) contained 0.5 mg/mL of phenobarbital sodium and were prepared using a simple solution method. The standard solution of phenobarbital sodium in water (0.5 mg/mL) was prepared fresh daily.

After the initial assay and pH value determination[6] the solutions were stored at 50 ± 1°C in 60-mL amber bottles[7] in an electric oven. The data were recorded again at appropriate intervals. The solutions were assayed using HPLC (3) except that the flow rate was 3.0 mL/min. The other chromatographic conditions were the same, except that no internal standard could be added since the solutions were injected into the chromatograph without dilution. The results were calculated using a previously described equation (3) and are presented in Table I and Fig. 1.

RESULTS AND DISCUSSION

Effect of Vehicle—The results (Table I) indicate that ethanol had the maximum stabilizing effect on phenobarbital sodium followed by propylene glycol and glycerol. The apparent pH values of these solutions varied slightly, although they all contained 0.1 M phosphate buffer and the ionic strength was adjusted to 0.26 with KCl. The pH-rate profile curve of phenobarbital is less sensitive to pH changes from 7.5 to 9 (4), the range used in these experiments.

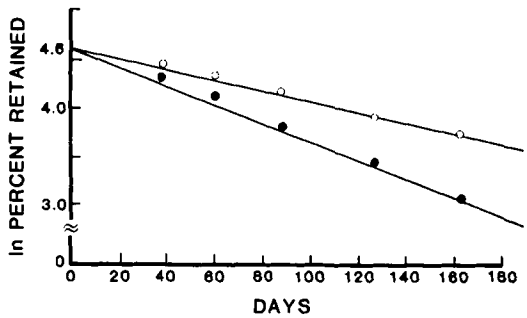

Figure 1—*First-order plots of solutions 1 and 5 (Table I). Key: (●) solution 1; (○) solution 5.*

Above pH 9, decomposition occurs readily (4). Considering this, it is obvious that the stabilizing effect of ethanol may be even better than the results indicate since the initial pH values of solutions containing ethanol (Table I) were higher than those containing propylene glycol or glycerol. Solutions containing glycerol had the lowest apparent pH values (Table I) and still had less stabilizing effect than propylene glycol and ethanol. Glycerol was better only when compared with water (Table I), which was expected. The estimated half-lives of solutions in water, 20% glycerol, 20% propylene glycol, and 20% ethanol were 78, 95, 109, and 127 d, respectively. Obviously, the stabilizing effect is inversely related to dielectric constant values of 80, 43, 32, and 25 for water, glycerol, propylene glycol, and ethanol, respectively, at 20°C. This is in agreement with earlier observations (2) that the stabilization effect is due to a decrease in the dielectric constant, which slows down the reaction between ions of like charges. Using the first-order equation (Fig. 1) and taking the activation energy value of 25 kcal/mol-deg (4), the t_{90} for solution 7 (Table I) at 25°C was determined to be ~1.8 years.

Effect of Phosphate Buffer and Ionic Strength—The phosphate buffer did not catalyze the reaction (solutions 8–10, Table I) and the effect of ionic strength was negligible (solutions 11–13). This was expected since the reaction between the un-ionized molecule of phenobarbital and the hydroxyl radical is ~250 times greater than that between the ionized form and OH^- (4).

Spectrophotometric Method for Quantitation of Peroxides in Sorbitan Monooleate and Monostearate

ADINA MAGILL and ALLYN R. BECKER ˣ

Received September 26, 1983, from the *Preformulation Department, Syntex Research, Palo Alto, CA 94304.* Accepted for publication February 9, 1984.

Abstract □ A rapid and sensitive spectrophotometric method has been developed to quantitate the peroxides present in sorbitan monooleate and monostearate. The method relies on the peroxide conversion of iodide to iodine. The method has also been found to work for polysorbate 60.

Keyphrases □ Peroxides—sorbitan monooleate and monostearate by spectrophotometry □ Sorbitan monooleate—spectrophotometric quantitation of peroxides □ Sorbitan monostearate—spectrophotometric quantitation of peroxides

Nonionic surfactants, used extensively as emulsifying agents, are integral components of semisolid dosage forms. However, surfactants tend to form peroxides, which have caused stability problems in numerous oxidizable drugs (1-3). The formation of peroxides can also lead to chemical modifications in the surfactants themselves (*e.g.*, chain shortening) that may unfavorably modify their physical properties (1, 4, 5). Titrimetric assay methods have been developed to determine the peroxide content in surfactants, but most of these are limited to the water soluble surfactants, *e.g.*, polyoxyethylene surfactants (6, 7). One titrimetric method, that has been used to quantitate the peroxides present in fats and oils, relies on the partitioning of the desired fat or oil between an organic and aqueous layer. The fat or oil is then transferred with "constant and vigorous shaking" from the organic layer to the aqueous layer where the actual titration occurs (8). Another limitation of titrimetric quantitation of peroxides can arise when methylene blue is used as an indicator. With the yellow surfactant sorbitan monooleate, for example, the color change at the end point, from green to aqua, is extremely difficult to detect.

In the course of our studies of the stability of steroids in surfactant systems, an analytical method was needed to quantitate the peroxides that were initially present in the surfactants. This method also had to be sensitive enough to ensure that the peroxide content had been significantly reduced in each of the surfactants following a purification procedure designed to eliminate peroxides from the surfactants.

To overcome the limitations of water insolubility and a difficult titrimetric assay, we have developed a rapid and sensitive spectrophotometric method to quantitate the peroxides present in sorbitan monostearate and monooleate, two poorly water soluble surfactants. This method was also shown to work for polysorbate 60.

EXPERIMENTAL SECTION

Materials and Instrumentation—Peroxides were removed from polysorbate 60[1], sorbitan monostearate[1], and sorbitan monooleate[1] according to the method of Segal *et al.* (9), with modifications. Hexane was substituted for methylene chloride to solubilize sorbitan monooleate, and hexane with ~5% methylene chloride was used to solubilize sorbitan monostearate.

The following reagents were used: resublimed iodine[2], potassium iodide[2], sodium thiosulfate[2], sodium metabisulfite[2], reagent grade isopropyl alcohol[2], methylene blue[3], and double-distilled water. UV spectral scans and absorbances were obtained on a rapid-scanning UV-VIS spectrophotometer[4].

Titrimetric Peroxide Number Determination of Polysorbate 60 and Sorbitan Monooleate—To 2.0 g of surfactant was added 3 mL of glacial acetic acid-methylene chloride (3:2). The mixture was stirred until a clear solution was obtained. After 50 μL of a KI-saturated aqueous solution was added, the mixture was stirred for exactly 2.0 min and 5 mL of isopropyl alcohol and 100 μL of an aqueous 0.025% methylene blue solution were added. The solution was titrated with standardized sodium thiosulfate to an aqua end point.

Iodine Standards for Spectrophotometry—A 0.010 M iodine standard was prepared by dissolving iodine in an aqueous 5% KI solution. This standard solution was further diluted with the 5% KI solution to give an iodine concentration of 10^{-4}-10^{-7} M. Iodine standards containing 2% purified surfactant were also prepared as described above at an iodine concentration range of 10^{-4} to 5×10^{-6} M.

Spectrophotometric Analyses of Polysorbate 60 and Sorbitan Monooleate—Aqueous saturated KI solution (50 μL) was added to 2 g of surfactant dissolved in 3 mL acetic acid-methylene chloride (3:2) and the solution was stirred under a blanket of nitrogen for 2 min. A 5.0-mL portion of isopropyl alcohol was added and immediately 200 μL of this solution was diluted to 2.0 mL with isopropyl alcohol. The absorbance at 360 nm was then measured within 2-3 min after mixing. Two blanks were determined under the same conditions, one without surfactant, and the other without KI.

Spectrophotometric Analysis of Sorbitan Monostearate—The procedure followed for analysis of sorbitan monostearate was exactly the same as for sorbitan monooleate with one exception: prior to the final addition of 2.0 mL of isopropyl alcohol, 100 μL of methylene chloride was added to maintain the solubilization of the monooleate.

RESULTS AND DISCUSSION

This spectrophotometric method takes advantage of the iodine generated from the reaction of peroxides on iodide (6). From the stoichiometry of the reaction, 1 mol of iodine is produced for each mole of hydroperoxide present. The quantitation of iodine formed is thus a direct measure of the peroxides present in the sample[5].

In the absence of surfactant, the absorbamce at 360 nm was obtained as a function of the concentration of iodine. Beer's law was obeyed over the 10^{-4}-10^{-7} M iodine concentration range. Beer's law was also followed in the presence of purified sorbitan monostearate at an iodine concentration range of 10^{-4}-10^{-6} M at 360 nm. The molar absorptivities in the absence of surfactant and in the presence of sorbitan monostearate were 24,000 M^{-1} cm^{-1} and 27,000 M^{-1} cm^{-1}, respectively, indicating that purified surfactant had little effect on the value of the molar absorptivity at 360 nm.

Two solutions prepared for peroxide quantitation by the spectrophotometric method, one without KI and the other without surfactant, showed no absorbance at 360 nm. Therefore, the absorbance determined in samples assayed by this method is due entirely to the generation of iodine by the peroxides present in the surfactant.

To eliminate iodine fading[6], one of the complications of iodimetric assays, part of the experimental procedure was conducted under a blanket of nitrogen. This nitrogen blanket provided several minutes to obtain the final absorbance reading after the dissolution of the surfactant. When the nitrogen blanket was not used, iodine fading was detected immediately after dilution with the final portion of isopropyl alcohol.

The quantitation of peroxides is frequently expressed in terms of the peroxide number (PN). By definition, the PN is the number of equivalents of peroxide contained in 1000 g of surfactant.

Table I—Peroxide Number (PN) of Sorbitan Monooleate, Sorbitan Monostearate, and Polysorbate 60 Using the Spectrophotometric Method

Surfactant	Peroxide Number Before Peroxide Removal	Peroxide Number After Peroxide Removal
Sorbitan Monooleate	0.24[a]	<0.10
Sorbitan Monostearate	1.3	<0.10
Polysorbate 60	9.8[b]	<0.10

[a] By titrimetric assay the PN was determined to be 0.39. [b] By titrimetric assay the PN was determined to be 5.8.

The PN of the three surfactants in this study were determined by the spectrophotometric method before and after peroxide removal (Table I). For comparison, the PN of polysorbate 60 and sorbitan monooleate were determined before peroxide removal by the titrimetric assay.

The lower limit of <0.10 for the PN by the spectrophotometric method (Table I) was chosen because it corresponded to the lowest iodine concentration in the presence of purified surfactant used in establishing the linearity of the method. This lower limit was sensitive enough to assure that the peroxide level had been significantly reduced after extraction with sodium metabisulfite[7].

From the results shown in Table I, the titrimetric and the spectrophotometric method for polysorbate 60 and sorbitan monooleate agreed fairly well. However, the color transition at the titrimetric end point for sorbitan monooleate, from green to aqua, was difficult to observe. No such problems were encountered using the spectrophotometric method; hence, this method may provide a more accurate measure of the peroxide content of sorbitan monooleate than the titrimetric assay.

While the titrimetric assay worked well for polysorbate 60 and fairly well for sorbitan monooleate, it did not work at all for sorbitan monostearate. It was not possible to keep the sorbitan monostearate solubilized during the titration with aqueous thiosulfate using the titrimetric method. Therefore, the PN of sorbitan monostearate could only be determined using the spectrophotometric method detailed in this report.

In summary, a sensitive spectrophotometric method has been developed to quantitate the peroxides present in sorbitan monostearate and monooleate, and polysorbate 60. This method should be easily extended to include other poorly water soluble as well as water soluble surfactants.

[7] These authors feel that the lower limit of peroxide quantitation by this spectrophotometric method can be extended by 10-fold, to PN values at levels <0.01. This is based on our findings that Beer's law is valid at a 50-fold lower iodine concentration in the absence of surfactant.

Gas Chromatographic Method for Solvent Residues in Drug Raw Materials

F. MATSUI ˣ, E. G. LOVERING, J. R. WATSON, D. B. BLACK, and R. W. SEARS

Received August 10, 1983, from the *Bureau of Drug Research, Health Protection Branch, Health and Welfare Canada, Ottawa, Ontario, Canada K1A 0L2.* Accepted for publication February 21, 1984.

Abstract □ A gas chromatographic (GC) method for screening drug raw materials, soluble in aqueous media, for volatile solvent residues has been developed. After dissolution, separate portions of the drug are each separately extracted with *n*-octane, toluene, and ether and injected into a chromatograph equipped with a porous polymer column and a flame ionization detector. The range of extractant polarities provides chromatograms which, taken together, are free of interfering peaks from 0 to ~20 min. Peaks due to solvent residues in the drug are identified by retention time with confirmation of identity by GC-MS.

Keyphrases □ GC—solvent residues in drug raw materials, comparison with MS □ Solvent residues—drug raw materials, GC, comparison with MS

Drug raw materials are manufactured in an increasing number of countries. Whether, for a given drug, the same synthetic route is used universally or whether different routes are used, the necessarily diverse sources of raw materials, technical experience, and manufacturing conditions can lead to differences in the amount and kind of drug-related impurities (1-4). Solvent residues may also be present (1). These may be revealed by modern techniques such as liquid chromatography but, due to their volatility, not by thin-layer chromatography (a method often used to assess drug impurities). Besides being undesirable contaminants, solvent residues may interfere with the determination of drug-related impurities. The problem of solvent residues is recognized by the USP (5) which includes monographs involving, for example, tests for chloroform and ethyl acetate in colchicine, pyridine in diethylstilbestrol diphosphate, and isopropyl alcohol in dihydroxyaluminum aminoacetate. Work in this laboratory, reported herein, has shown for example, that some sulfinpyrazone and flurazepam hydrochloride raw materials are contaminated with toluene and acetone, respectively. To maintain surveillance over this situation, a method for the detection and quantitation of solvent residues in drug raw materials has been developed.

Each of three portions of an aqueous solution of the drug to be examined is individually extracted with ether, toluene, and *n*-octane, and the extracts are tested for volatile organic solvents by gas chromatography (GC). The three solvents were chosen to provide a range of polarities. This enhances the probability that any solvent residue in the drug will be substantially extracted into at least one of them. In addition, each of the three provides a different retention time range free of

main peak or impurity interference so that impurities extracted from the drug can be easily detected. Any such peaks are tentatively identified by comparison of their retention times with the known retention times of common solvents, with confirmation of identity by MS comparison with known standards.

EXPERIMENTAL SECTION

Materials and Apparatus—Ether[1] (USP) and glass-distilled toluene[2] were used as received. *n*-Octane[3] (100 mL) was passed through three silica cartridges[4] prior to use. The drug raw materials were commercially available.

The gas chromatograph[5] was equipped with a flame ionization detector and a printer–plotter mechanism (attenuation 2↑5, corresponding to 32 pA/cm). The coiled glass column (0.91 m × 4 mm i.d.), packed with a porous polymer[6] (80/100 mesh), was adapted to the chromatograph with a short length of nickel tubing. The column, injector port, and detector temperatures were 210°C; gas flow rates were: nitrogen, 60 mL/min; hydrogen, 35 mL/min; air, 400 mL/min. Columns were conditioned for 72 h at 210°C with a nitrogen flow of 60 mL/min.

Drug Dissolution—Three solutions were prepared to contain ~200 mg of drug, accurately weighed in a minimum volume of aqueous solvent. The aqueous solvent, whether acidic, basic, or neutral, was chosen on the basis of a preliminary investigation to determine the conditions of maximum solubility. Thus, hydrochloric acid solution might be selected for a basic drug such as diazepam, whereas a sodium hydroxide solution would be selected for an acidic drug such as sulfinpyrazone.

Chromatographic profiles of the ether, toluene, and *n*-octane were obtained prior to use. Samples exhibiting significant impurity peaks were either purified or rejected. To each of the three drug solutions was added either toluene (1.0 mL), *n*-octane (1.0 mL), or ether (2.0 mL). Each tube was shaken vigorously for 2 min, centrifuged, and 2 μL of the organic phase was injected into the gas chromatograph.

Prior to beginning the actual examination of drug raw materials, the retention times of a number of possible volatile contaminants were determined (Table I). If an impurity peak was found in a drug extract, a tentative identification was made by reference to Table I and verified by injection of a solution of the suspected impurity in the appropriate solvent, either ether, toluene, or *n*-octane. Confirmation was by GC–MS[7] using GC conditions as described above with an electron ionization potential of 70 eV.

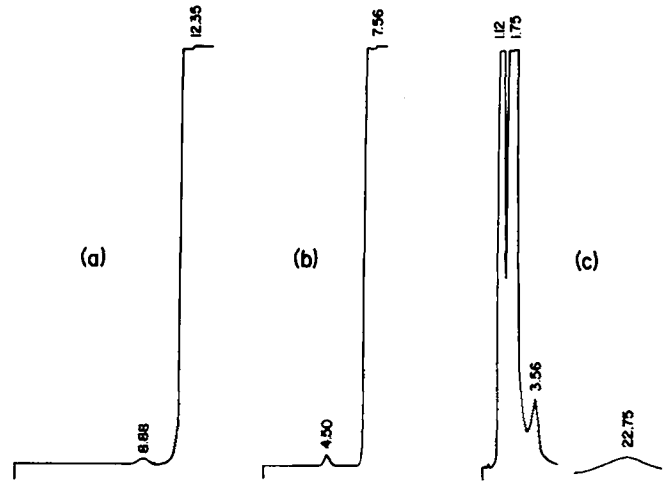

Figure 1—*Chromatograms of the extraction solvents. Key: (a) n-octane with an impurity at 8.88 min; (b) toluene with benzene at 4.5 min; (c) ether with several impurities.*

Quantitation—After identification, impurity levels were established by comparison to a three-point calibration curve. For example, for the quantitation of acetone, the calibration curve was prepared by shaking a 1-mL aliquot of each of three standard solutions of acetone in toluene (range, 1.58–0.0316 mg/mL) with the same volume of the aqueous solvent used for the dissolution of the drug raw material (Table II). Duplicate 2-μL aliquots of the organic phase representing an on-column range of 3.16–0.0632 μg acetone were chromatographed, and the response factor was calculated from the integrated area. For toluene, a three-point calibration curve was prepared in a similar manner using three standard solutions of toluene in *n*-octane (range, 0.866–0.0247 mg/mL) representing an on-column range of 1.732–0.0494 μg. Recovery of the impurity from the aqueous solution of the drug was determined by extracting a fresh sample of the drug with solvent containing a known amount of the impurity, usually one of the known solutions prepared for calibration purposes. This is equivalent to spiking the drug sample with a known amount of the impurity. Recovery, in percent, is given by: $(C_t - C_i/C_s) \times 100$, where C_t, C_i, and C_s are the area counts obtained for the spiked sample, the sample itself, and the standard solution used to spike the sample, respectively.

RESULTS AND DISCUSSION

The method was developed to screen drug raw materials for volatile organic solvent contaminants. Three portions of the material to be examined were

[a] Number of lots analyzed in parentheses. [b] Solvent residue levels are calculated on the basis of 400 μg of drug on-column. [c] Percent recovery in parentheses. [d] None detected.

extracted separately with *n*-octane, toluene, and ether. These extracts were chosen to provide a range of polarities to facilitate the extraction of impurities from aqueous drug solution and to leave open different retention time windows in the chromatograms (Fig. 1). Although good grades of these solvents were employed, they all contain minor impurities which are evident as peaks on the chromatograms.

The method described provides for minimum detectable levels of 0.002–0.005% (with respect to sampling technique equivalent to 400 μg of drug on column) volatile solvent in drug raw material, depending upon the solvent residue and its partition ratio between the organic and aqueous phases. If lower sensitivities can be tolerated, lesser amounts of drug raw material can be used.

Typical results are presented in Table II. Acetone was found in four of six lots of propranolol hydrochloride and in four of eight lots of flurazepam hydrochloride. For flurazepam, the acetone peak is clearly evident in the chromatograms of both the *n*-octane and toluene extracts (Fig. 2), but is, as expected, much larger in the latter. The acetone level, quantitated from the toluene extract, was ~0.5% in the sample illustrated; identity was confirmed by MS. The reproducibility of the acetone determination in these samples could not be established due to insufficient sample; however, the duplicate results for one of the flurazepam samples were 0.50 and 0.48%. Toluene was found in three of four samples of sulfinpyrazone. In this case, *n*-octane proved to be a better extract than ether and, of course, toluene could not be used. The level of toluene found in one of these samples was ~0.3% with reproducibility of 3% for five determinations; identity was confirmed by MS. In addition to the drugs listed in Table II, one or more lots of the following drug raw materials was examined, with the solvent given in parentheses: acetaminophen (1 mL 2.5 M NaOH), cimetidine (2 mL 1.0 M HCl), diazepam (0.5 mL 2.5 M HCl), phenytoin sodium (1 mL H_2O), metoprolol (0.5 mL 1 M HCl), pentobarbital sodium (0.5 mL H_2O), and triamterene (5 mL HCl). No solvent residues were detected in these lots.

Composite Pharmacokinetic Profiling

Keyphrases □ Pharmacokinetics—composite profiling, ceftriaxone, diazepam □ Composite profiling—pharmacokinetics, ceftriaxone, diazepam

To the Editor:

In certain patient populations, most notably neonates, it has been difficult to obtain an adequate number of blood samples to develop complete pharmacokinetic profiles of drugs due to sample-volume limitations. For this, as well as other ethical and medical reasons, the neonate has been termed a "therapeutic orphan" in that little pharmacokinetic information has been generated in this patient group. However, since the neonate represents the most physiologically dynamic patient population, it is important to understand the pharmacokinetics of drugs that are used to treat these patients. In an effort to minimize blood sampling and still develop meaningful pharmacokinetic profiles, a composite pharmacokinetic profiling approach (*e.g.*, combining blood concentrations from patients or subjects to produce a functional profile that is not possible to derive from the concentration–time data of one individual) has been investigated and will be developed in this report using simulation and curve-fitting techniques.

Crow and Gibaldi (1) have discussed the rationale for developing a composite pharmacokinetic profile by obtaining plasma concentration–time data at different times in the same patient during several dosing intervals at steady state. These authors stated that the accuracy of this composite method depends on assay variability, intrapatient pharmacokinetic variability, dosing interval reproducibility, and patient compliance. If one assumes that plasma concentration–time data among patients are normally distributed, one can apply this same rationale to developing a pharmacokinetic profile using plasma concentration–time data from several patients following single-dose administrations. This approach eliminates intrapatient pharmacokinetic variability, constancy of dosing interval, and patient compliance as variables, but adds interpatient pharmacokinetic variation. In addition, it may offer the only reasonable and perhaps the only ethical means of developing a single-dose pharmacokinetic profile of certain drugs in premature (≤2.0 kg) neonates in whom the total blood volume is ~75–80 mL/kg.

The composite profiling technique was tested by simulating blood concentration–time profiles for short and long half-life drugs that reflect both mono- and biexponential elimination characteristics following first-order absorption using complete sampling schedules. To reflect variability in real concentration–time profiles, data for 18 patients were simulated when three sampling groups were used, 20 patients were simulated when four sampling groups were used. Normally distributed error with a coefficient of variation (*CV*) of 10% was introduced into the pharmacokinetic parameters, and normally distributed error with a *CV* of 10% was introduced into the resulting concentration data. For the biexponential long half-life case, normally distributed error with a *CV* of 25% was introduced into the pharmacokinetic parameters followed by the same 10% error introduced into the resulting concentration data. These concentration–time data were then used to establish the impact of sampling times and the number of observations per time point on parameter estimations by employing the following three sampling schedules:

1. For the monoexponential short half-life drug, patients were divided into three groups of six patients each: group I was sampled at 0, 1, 4, and 12 h; group II was sampled at 0, 2, 6, and 18 h; group III was sampled at 0, 3, 8, and 24 h.
2. For the biexponential, short half-life drug, patients were divided into three groups of six patients each: group I was sampled at 0, 0.5, 3, 8, and 24 h; group II was sampled at 0, 1, 4, 12, and 24 h; group III was sampled at 0, 2, 6, 18, and 24 h.
3. For both the mono- and biexponential, long half-life drugs, patients were divided into four groups of five patients each: group I was sampled at 0, 1, 6, and 24 h; group II was sampled at 0, 2, 8, and 36 h; group III was sampled at 0, 3, 12, and 48 h; group IV was sampled at 0, 4, 18, and 72 h.

It was assumed that sampling would be limited to five or less samples per patient. These simulated data were then used as input for curve-fitting composite profiles using six, three, and one patients per group for three group sampling schedules or five, three, and one patients per group for the four group sampling schedules. Simulations and curve-fitting procedures were conducted using the nonlinear regression program, NONLIN (2).

The results of the composite curve-fits of these simulations are presented in Tables I (monoexponential elimination) and II (bioexponential elimination). If one compares the parameter values from the composite profiles to the ideal parameter values, it is clear that reasonable approximation of the "true" parameter values can be obtained by fitting the composite profile even if only one patient is included in each sampling group. The least-variable parameter is clearance (*e.g.*, the parameter of greatest interest), and good estimates of the elimination rate constants are obtained (Tables I and II). These observations are in good agreement with those of Crow and Gibaldi (1). The results of fitting the composite profiles containing normally distributed error with a *CV* of 25% in the parameter values as well as a *CV* of 10% in the resulting concentration data are presented in Table III. Good approximations of the "true" parameter values were obtained even with the introduction of normally distributed error with a *CV* of 25%, *i.e.*, two *SD* encompass 50–150% (threefold) of the mean. This observation indicates that the method is robust and can accommodate even large differences associated with interindividual variation.

Experimental data from two clinical pharmacokinetic studies were used as a final test of the proposed composite profiling technique. In the first study, 2 g of ceftriaxone was administered by intravenous infusion to 12 healthy male subjects over a 30-min interval. Blood samples were obtained during and following the infusion of drug. The subjects were divided into four groups of three subjects each: group I was sampled at 0, 10, and 40 min, 2 and 10 h; group II was sampled at 0, 20, and 50 min, 4 and 12 h; group III was sampled at 0 and 30 min, 1, 6, and 16 h; group IV was sampled at 0 and 35 min, 1.5, 8, and 24 h after starting the 30-min infusion. The *CV* for the analytical data in this study was 4.4%. In the second study 10 mg of diazepam was administered orally to 20 healthy

[a] Not applicable.

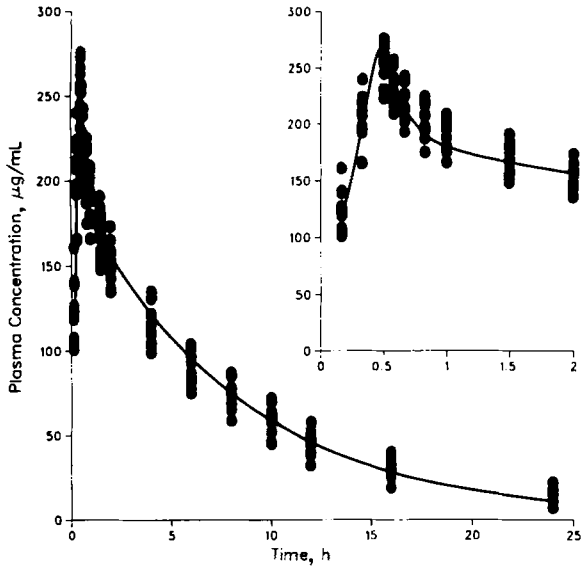

Figure 1—*All ceftriaxone plasma concentration–time data from 12 subjects together with the curve fitted using the composite pharmacokinetic profiling technique and three subjects in each of four sampling groups, as depicted in Table IV (inset).*

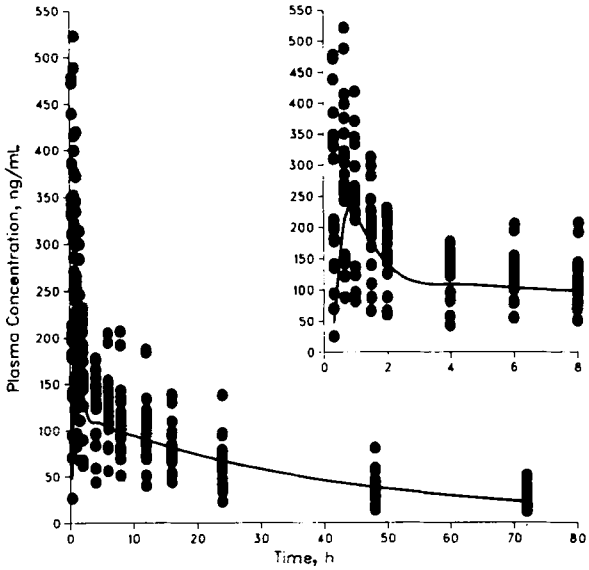

Figure 2—*All diazepam plasma concentration–time data from 20 subjects together with the curve fitted using the composite pharmacokinetic profiling technique and five subjects in each of four sampling groups, as depicted in Table IV (inset).*

subjects. Blood samples were obtained at specific times over the following 72 h. The subjects were divided into four groups of five subjects each: group I was sampled at 0, 0.33, 2, 12, and 72 h; group II was sampled at 0, 0.67, 4, 16, and 72 h; group III was sampled at 0, 1, 6, 24, and 72 h; group IV was sampled at 0, 1.5, 8, 48, and 72 h after the oral dose. The analytical *CV* for this study was 11.3%.

Four curve-fitting techniques were used to evaluate the data: (*a*) concentration–time data from the individual subjects were fitted and the mean parameters were calculated; (*b*) a single mean concentration–time profile from all subjects was fitted to determine parameter values; (*c*) all concentration–time data were fitted simultaneously to determine the parameter values; (*d*) a limited sample composite concentration–time profile was fitted to determine the parameter values. The results of these fitting procedures are presented in Table IV. In the first three of the methods, all of the concentration–time data were used in the sampling/fitting procedure, whereas in the final method, four groups of three or five patients, respectively, were used for ceftriaxone and diazepam. There was good general agreement of parameter estimates obtained by each of the four sampling/fitting techniques. The parameters A and α were variable among the four sampling/fitting procedures, and for the oral absorption of diazepam, k_a was variable as well. However, the remaining parameters for both diazepam and ceftriaxone were extremely consistent among the four methods. Again it should be noted that the clearances, volumes of distribution, and elimination rate constants show little variability. All ceftriaxone and diazepam concentration–time points, together with the composite profiling fits, are presented in Figs. 1 and 2, respectively, to show the randomness of scatter around the fitted curves.

The results of these simulations and curve-fitting procedures indicate that the composite pharmacokinetic profiling technique developed herein is a useful method that can be utilized to minimize the number of blood samples and, therefore, the total blood volume withdrawn. The application of this technique can allow for the development of pharmacokinetic profiles in patient populations, including neonates and certain disease states, in which little information has been generated due to sampling limitations. This technique has been used to develop a preliminary pharmacokinetic profile of vitamin E following an intramuscular injection to premature neonates (3).

products of this activating pathway are the 5-amino and cyano derivatives (6–8). Both of these metabolites have been found following anaerobic metabolism of nitrofurantoin by the 9000×*g* supernatant of rat liver and kidney homogenates (9). In addition, the cyano metabolite was detected in the perfusate and bile of isolated perfused rat livers (10), and the 5-amino derivative has been detected in the urine of male volunteers receiving an intravenous infusion or an oral tablet of nitrofurantoin (11). A third metabolite, the 4-hydroxy derivative, resulting from hydroxylation of the furan ring, has been identified (12) and detected in the urine of rats and the media of isolated perfused livers of rats induced with 3-methylcholanthrene (13–15). Unchanged nitrofurantoin in the urine accounted for 34–47% of the dose in humans (11) and 16–52% of the dose in rats (16–19).

Nitrofurazone, which is structurally similar to nitrofurantoin, is used topically as an antibacterial agent, but the frequency and severity of side effects preclude its systemic use. It is also reduced under anaerobic conditions to the analogous 5-amino and cyano derivatives (20). Furthermore, after subcutaneous injection, nitrofurazone produces kidney and liver lesions in the rat (21). Only 5–8% of a nitrofurazone dose was excreted unchanged in the urine of rats (16, 17, 22).

The available evidence suggests that, at least under *in vitro* anaerobic conditions, both nitrofurantoin and nitrofurazone are metabolized by kidney preparations. However, whole animal studies suggest that nitrofurazone is both more extensively metabolized and more toxic than nitrofurantoin.

We have studied the disposition of these two 5-nitrofurans in the isolated perfused kidney. We were particularly interested in studying the disposition of nitrofurantoin by the kidney because it controls the access of the drug to the urinary tract, and hence, the site of infection. The intact organ system allowed us to study the metabolism of nitrofurantoin by the kidney under well-oxygenated conditions without the potential confounding aspects of extrarenal, particularly hepatic, metabolism. Particular attention was directed to the known reduced metabolites of nitrofurantoin, since their presence would indicate that metabolic activation had occurred. Nitrofurazone was selected for comparison because it is structurally similar and metabolically activated to analogous derivatives; it is more toxic in general, and to the kidney in particular, than nitrofurantoin.

For each antibiotic, six rat kidneys were perfused with 6.5% bovine serum albumin dissolved in a Krebs–Henseleit buffer supplemented with glucose and eight amino acids (23). Inulin was added as a marker of the glomerular filtration rate. The 70 mL of recirculating perfusate was aerated with 95% O_2–5% CO_2, and the pH and temperature were maintained at 7.4 and 37°C, respectively. After a 20-min equilibration period, 0.1 mM nitrofurantoin or nitrofurazone dissolved in perfusate was added to the reservoir. Perfusate and urine were sampled with replacement at frequent intervals for 180 min. The pO_2 and pH were determined using a blood gas analyzer[1] and Na^+/K^+ levels were measured with a flame photometer[2]. Inulin was quantitated spectrophotometrically (24). Nitrofurantoin and nitrofurazone and their amino and cyano metabolites were quantitated by HPLC (25, 26). For nitrofurantoin the reabsorption of Na^+, fractional excretion of K^+, and the glomerular filtration rate were 90.0 ± 3.1%, 0.86 ± 0.28, and 0.39 ± 0.15 mL/min, respectively[3]. For nitrofurazone the corresponding values were 95.8 ± 1.4%, 0.49 ± 0.16, and 0.22 ± 0.07 mL/min. Although these glomerular filtration rates are low (27), suggesting a compromised preparation, subsequent studies in kidneys with improved physiological function handled both 5-nitrofurans similarly to the results reported here[4].

The concentration in the perfusate of both nitrofurantoin and nitrofurazone could be described by a one-compartment body model with first-order elimination kinetics. The total clearances[5], 0.64 ± 0.12 and 0.75 ± 0.18 mL/min for nitrofurantoin and nitrofurazone, respectively, were not significantly different. However, the fractions excreted unchanged in the urine[6] after 3 h, 0.19 ± 0.10 for nitrofurantoin and 0.02 ± 0.02 for nitrofurazone, were significantly different ($p < 0.005$). Known reduced metabolites of nitrofurantoin, the 5-amino and cyano derivatives, while not detectable in the perfusate, accounted for ~3% of the dose in the urine. Neither the 5-amino nor the cyano metabolite of nitrofurazone was detected in either the perfusate or urine. There was no evidence that the 4-hydroxy derivative of either 5-nitrofuran was formed. There appears to be net tubular reabsorption of both 5-nitrofurans since the ratios of their renal clearance to the glomerular filtration rate are <1.0 (0.39 ± 0.20 and 0.07 ± 0.06 for nitrofurantoin and nitrofurazone, respectively). These ratios could be <1.0 in the absence of tubular reabsorption if the 5-nitrofurans were highly bound to bovine serum albumin. However, only 60% of nitrofurantoin is bound to plasma proteins (11). Furthermore, nitrofurantoin, which has a pK_a of 7.2, is known to be secreted by the organic anion transport system and to be reabsorbed (28). Certainly at the pH of the urine (6.0–6.5), nitrofurantoin would be mostly un-ionized and could be reabsorbed by passive diffusion. Nitrofurazone is not ionized at the pH values encountered in this study.

At the conclusion of the 3-h experiment most of the dose of both these 5-nitrofurans is unaccounted for. Less than 15% remains in the perfusate as unchanged drug; 19% of the nitrofurantoin was excreted unchanged in the urine and ~3% as known metabolites. Thus, ~60% of the dose of nitrofurantoin is unaccounted for. For nitrofurazone, only 2% of the dose was detected in the urine. Hence, ~85% of the dose of nitrofurazone is unaccounted for. For both of these 5-nitrofurans, the fraction unaccounted for may be drug bound to tubing or chemically degraded, drug or metabolites trapped intracellularly, as yet unidentified metabolites, and/or drug covalently bound to tissue biomacromolecules after metabolic activation. The first possibility was dismissed, since identical 3-h experiments without the kidney in place resulted in no loss of either 5-nitrofuran. Some preliminary work with the 5-[2-^{14}C]nitrofurans has shown that nitrofurantoin, nitrofurazone, or their known metabolites were not detected after exhaustive extraction of homogenates of the perfused kidneys first with acetonitrile–water and then 5% trichloroacetic acid[4]. Thus, although the ^{14}C-label was found in the tissue, it would appear that neither the parent compound nor known metabolites were trapped intracellularly. Each of the remaining alternative hypotheses involve metabolism of the 5-nitrofurans. Since both the 5-amino and cyano derivatives of nitrofurantoin were detected in the urine, the drug must have been metabolically activated, and at least some of it could, therefore, have been

bound to biomacromolecules rather than have been further metabolized and eliminated as the end products of the activating pathway. Our preliminary work also indicates that ~5% of the ^{14}C-label is covalently bound to biomacromolecules at the end of the 3-h experiment[4]. Others have found carbon-14 bound to biomacromolecules after incubation of [2-^{14}C]nitrofurantoin with microsomal preparations from rat liver and lung (29). It is probable, therefore, that at least some portion of the dose of nitrofurantoin is covalently bound to the biomacromolecules in the perfused rat kidney with the remainder eliminated by as yet unidentified metabolic pathways. Since none of the nitrofurazone was excreted as the 5-amino or cyano metabolite, there is no direct evidence that any of the drug was reductively activated for binding to biomacromolecules. Other investigators have, however, found ^{14}C-label covalently bound to the proteins, DNA, and RNA, of the liver and kidney of rats fed [2-^{14}C]nitrofurazone (30), and our preliminary studies have found ~5% of the ^{14}C-label bound to biomacromolecules of the nitrofurazone perfused kidney[4]. The remaining 80% of the dose of nitrofurazone was accounted for by as yet unidentified metabolites in the perfusate and urine. These studies indicate that the perfused kidney does metabolize both nitrofurantoin and nitrofurazone. Furthermore, the more toxic nitrofurazone appears to be more extensively metabolized.

Pharmacokinetic Implications of Stereoselective Changes in Plasma-Protein Binding: Warfarin/Sulfinpyrazone

Keyphrases □ Warfarin—plasma-protein binding, stereoselective displacement, drug-drug interaction with sulfinpyrazone □ Sulfinpyrazone—plasma-protein binding, stereoselective displacement, drug-drug interaction with warfarin

To the Editor:

The intensity of the observed pharmacological response produced by any drug is invariably related, directly or indirectly, to its plasma concentration. In the systemic circulation most drugs are bound to plasma proteins, and thus an equilibrium is established between bound and free drug. Since free drug alone is the pharmacologically active agent, the drug-plasma protein interaction may not only influence overall drug disposition but also affect the magnitude and time-course of the pharmacological response. In theory, numerous models could describe the relationship between hepatic clearance and plasma protein binding. However, a widely accepted model which has been shown to explain the vast majority of empirical observations, and one which is consistent with the results to follow, is the so-called well-stirred model (1-4). For drugs exhibiting a low extraction ratio (ER <0.3), it may be shown that their observed total body clearance (CL) is directly related to their unbound fraction within plasma (f_u) (5, 6). Consequently, for low-extractration ratio drugs which are highly protein bound (>98%), a small change in the fraction of the drug bound to plasma protein will not only result in a relatively large change in f_u but also in a proportional change in CL and may thus have potentially important consequences in the in-

Pharmacokinetic Implications of Stereoselective Changes in Plasma-Protein Binding: Warfarin/Sulfinpyrazone

Keyphrases □ Warfarin—plasma-protein binding, stereoselective displacement, drug-drug interaction with sulfinpyrazone □ Sulfinpyrazone—plasma-protein binding, stereoselective displacement, drug-drug interaction with warfarin

To the Editor:

The intensity of the observed pharmacological response produced by any drug is invariably related, directly or indirectly, to its plasma concentration. In the systemic circulation most drugs are bound to plasma proteins, and thus an equilibrium is established between bound and free drug. Since free drug alone is the pharmacologically active agent, the drug-plasma protein interaction may not only influence overall drug disposition but also affect the magnitude and time-course of the pharmacological response. In theory, numerous models could describe the relationship between hepatic clearance and plasma protein binding. However, a widely accepted model which has been shown to explain the vast majority of empirical observations, and one which is consistent with the results to follow, is the so-called well-stirred model (1-4). For drugs exhibiting a low extraction ratio (ER <0.3), it may be shown that their observed total body clearance (CL) is directly related to their unbound fraction within plasma (f_u) (5, 6). Consequently, for low-extractration ratio drugs which are highly protein bound (>98%), a small change in the fraction of the drug bound to plasma protein will not only result in a relatively large change in f_u but also in a proportional change in CL and may thus have potentially important consequences in the in-

terpretation of the relationship between pharmacokinetic parameters and the observed pharmacological response.

Since albumin (the principal plasma binding protein for weakly acidic drugs) is chiral, its interaction with the enantiomers of racemic drugs might be expected to be different. Although stereoselective differences in protein binding have been previously noted (7–10), the implications of the phenomenon have not been generally recognized. The potential importance of stereoselective changes in plasma protein binding was demonstrated with the oral anticoagulant warfarin in its interaction with the uricosuric agent sulfinpyrazone[1]. Warfarin is administered as a racemic mixture despite the fact that the (*S*)-enantiomer is approximately five times as potent as the (*R*)-enantiomer. Moreover, the drug is highly bound (>98%) to plasma proteins.

The measurement of the free fraction of a highly bound drug such as warfarin is technically difficult due to the very low concentration of unbound drug (nanograms per milliliter at therapeutic levels). The problem is further compounded if the stereochemical composition of the free fraction is to be determined. One solution to the problem of measuring differences in enantiomeric binding is to use pseudoracemic drugs (a 1:1 mixture of (*R*)-[^{12}C]warfarin and (*S*)-[2-^{13}C]warfarin[2]) and then analyze the enatiomer concentrations by GS–MS, as previously reported (12). The advantage of this approach is that it allows an assessment of the drug in essentially the exact same form (racemate) as that which is used clinically. In addition, since MS allows differentiation of the two enantiomers within the same experiment, error can be significantly reduced. For example, the ratio, and changes in the ratio, between corresponding ions representing the (*R*)- and (*S*)-enantiomers can be measured directly without reference to internal standards or the requirement of mathematical treatment of any kind. The calculation of the degree of binding does, however, require the presence of a suitable internal standard and further data treatment.

Blood was drawn from healthy normal male volunteers and collected into flint-glass tubes containing 15% w/v potassium EDTA solution (0.1 mL), one of the few anticoagulants found to have little or no effect on drug–protein binding (13). Care was taken to avoid contact with materials that might modify the protein binding interaction in any way (14). Plasma was separated from the cellular components by centrifugation and all plasma samples were pooled. To a 12-mL plasma sample was added a methanolic solution (10 μL) of pseudoracemic warfarin to yield a final plasma concentration of 10 $\mu g \cdot mL^{-1}$. The spiked plasma samples (10 mL) were transferred into polycarbonate ultracentrifuge tubes and centrifuged at 50,000 rpm (300,000×*g*) for 20 h at 30°C. The clear supernatant (5 mL), containing unbound drug, was removed and to it was added a known amount of [phenyl-$^{2}H_5$]warfarin, the internal standard. The ultracentrifugation technique was chosen for its ability to handle relatively large plasma volumes. This feature is important as the low unbound concentration of warfarin necessitates the extraction of large volumes of plasma water to obtain sufficient amounts of the enantiomers for analysis. There are, however, practical concerns with this method. Contamination of the supernatant with albumin may result in erroneous estimates of the unbound fraction. For highly bound drugs such as warfarin, even minor contamination with albumin yields unnaturally high f_u values. Clearly, this is not the case in our investigations. Artifactual f_u values would also be readily apparent if there were any dissociation of the drug–protein complex during the centrifugation process. Although studies were undertaken to investigate the possibility, no evidence was found to suggest a concentration gradient of unbound warfarin (a result of sedimentation/layering) existed within the supernatant. Of the remaining 2 mL of spiked plasma, containing total (bound plus unbound) drug, a 1-mL sample was similarly spiked with the internal standard. The plasma and supernatant were extracted and derivatized as previously outlined for plasma samples[1]. Relative and absolute quantitation of (*R*)-[^{12}C]- and (*S*)-[2-^{13}C]warfarin was obtained by measurement of ion ratios with reference to the internal standard *via* GC–MS analysis (12).

The results of the study are shown in Table I. Although differences in the degree of binding of the two enantiomers was not significant, these differences are greatly magnified when considered in terms of the pharmacologically active free fractions. These data indicate that the (*S*)-enantiomer is more highly bound than the (*R*)-enantiomer, as previously reported (9). It is interesting to note the good agreement between our results and those reported previously, particularly in light of the different methodologies that were employed.

We have previously shown that (*R*)-warfarin has a greater distribution volume than the (*S*)-enantiomer[1]. As only free drug is available to distribute throughout the body, consideration of the present data provides an explanation for this observation: (*S*)-warfarin, being more highly bound to plasma proteins than the (*R*)-enantiomer, would be expected to have a smaller distribution volume, since it is more confined to the circulatory system. Interestingly, the ratio of the apparent volumes of distribution of the (*R*)- and (*S*)-enantiomers (V_R:V_S = 1.6) is almost identical to the unbound fraction ratio (Table I).

(*S*)-Warfarin has been shown to be about five times more potent an anticoagulant than its optical antipode. Determination of this difference, however, did not take into account the differential binding of the enantiomers (15) and thus does not reveal the true (intrinsic) difference in potency between the enantiomers. When protein binding is taken into account, the (*S*)-enantiomer has an inherent potency approximately eight times greater than that of the (*R*)-enantiomer. Clinically, it is sufficient to acknowledge the apparent differences in potency; however, the intrinsic difference in potency is important for the postulation of potential receptor sites and consideration of structure–activity relationships.

Changes in the plasma protein binding of a drug arising from multiple-drug therapy is well documented; probably, it is the most common explanation for any drug–drug interactions. Plasma is, however, an open compartment, and any drug that is displaced from plasma proteins will rapidly distribute into the tissue compartments. Consequently, the transient increase in f_u produced by the displacing drug is often of little pharmacological importance. Sulfinpyrazone is a widely used uricosuric agent, but more recently its effects on platelets has led to its use in the treatment of a variety of thromboembolic disorders. It is now well documented (16) that if warfarin and sulfinpyrazone are coadministered, the pharmacological response to warfarin is enhanced; the basis of the interaction appears to be metabolic in origin[1]. The important and poten-

[a] Calculated as the mean of the individual enantiomer binding data.

tially complicating role that stereoselective changes in protein binding play in the interaction is evident from a consideration of the equation for total body clearance which pertains to poorly extracted drugs (6):

$$CL = f_u \cdot CL'$$

Without acknowledging the stereoselective change in f_u between the two warfarin enantiomers brought about by concomitant sulfinpyrazone administration, one might incorrectly conclude that any inequivalent change in *CL* between (*R*)- and (*S*)-warfarin has its origins at the enzymatic level (as measured by the intrinsic clearance *CL'*), a result of metabolic induction or inhibition. In light of our present observations, it is apparent that stereoselective protein binding displacement of a poorly extracted drug may manifest itself as an inequivalent change in the *CL* of the two enantiomers in the absence of any dynamic change in metabolism. Sulfinpyrazone is metabolized in humans, and the plasma-protein binding of the parent drug and its metabolites have been investigated (17). Obviously, sulfapyrazone metabolites could complicate the protein binding interaction with warfarin *in vivo*; however, our evidence with volunteers who concomitantly receive warfarin and sulfinpyrazone (15) indicate this is not the case. Interestingly, sulfinpyrazone has been reported to induce the metabolism of (*R*)-warfarin while simultaneously inhibiting the metabolism of the (*S*)-enantiomer (18, 19). These conclusions were drawn from the sulfinpyrazone-induced changes in enantiomeric clearance.

Thermodynamic Studies of Tolbutamide Polymorphs

Keyphrases □ Tolbutamide—crystalline polymorphs, solubility as a function of temperature, polymorphic conversion, transition temperature

To the Editor:

Aqueous suspensions of tolbutamide were found to thicken to an unpourable state after several weeks of occasional shaking (prior to daily dosing). Samples of the same suspensions that were not shaken showed excellent stability after years of storage at ambient and elevated temperature. Microscopic examination revealed that the thickening was due to partial crystalline conversion of the original plate-like tolbutamide crystals to very fine needle-shaped crystals, which tend to form a highly flocculated structure. The crystals were identified as a polymorphic form rather than a solvate or change in habit. IR spectra and X-ray diffraction confirmed that the acicular form is identical with Burger's form III (1). The polymorphic conversion was unexpected since published solubility data suggest that form I is the more stable polymorph at room temperature (1, 2). However, a transition temperature, above which form III converts to form I, has been reported by several investigators to be somewhere between 98.5°C and 118°C (1, 3, 4). An inconsistency here is clearly apparent: form I cannot be the more stable polymorph at temperatures both above and below a transition temperature. Furthermore, the reported solubility data (1) indicating that form I is less soluble than form III at 37°C conflict with suspension stability data generated in this laboratory, which indicate that form I converts to form III at room temperature. To resolve the discrepancy between the published literature and recent observations in this laboratory, the aqueous solubilities of polymorphs I and III were determined as a function of temperature.

The form I tolbutamide used in this study was prepared for commercial use by a final recrystallization from methanol–water[1]. Form III was made by stirring an aqueous suspension

Table I—Enatiomeric Binding Data of Pseudoracemic Warfarin (10 μg·mL^{-1}) in the Absence and Presence of Sulfinpyrazone (15 μg·mL^{-1})

	Control	Sulfinpyrazone
(*R*):(*S*) Unbound fraction (f_u) ratio	1.58 (*SD* ± 0.15; *n* = 11)	2.25 (*SD* ± 0.26; *n* = 11)
t test		$p < 0.001$
Percentage bound[a]		
(*R*)	99.15 (*SD* ± 0.24) (f_u% = 0.85)	98.73 (*SD* ± 0.14) (f_u% = 1.27, increase of 49.41%)
(*S*)	99.47 (*SD* ± 0.16) (f_u% = 0.53)	99.42 (*SD* ± 0.10) (f_u% = 0.58, increase of 9.43%)
pesudoracemate	99.31 (f_u% = 0.69)	99.08 (f_u% = 0.92, increase of 34.06%)

[a] Calculated as the mean of the individual enantiomer binding data.

tially complicating role that stereoselective changes in protein binding play in the interaction is evident from a consideration of the equation for total body clearance which pertains to poorly extracted drugs (6):

$$CL = f_u \cdot CL'$$

Without acknowledging the stereoselective change in f_u between the two warfarin enantiomers brought about by concomitant sulfinpyrazone administration, one might incorrectly conclude that any inequivalent change in *CL* between (*R*)- and (*S*)-warfarin has its origins at the enzymatic level (as measured by the intrinsic clearance *CL'*), a result of metabolic induction or inhibition. In light of our present observations, it is apparent that stereoselective protein binding displacement of a poorly extracted drug may manifest itself as an inequivalent change in the *CL* of the two enantiomers in the absence of any dynamic change in metabolism. Sulfinpyrazone is metabolized in humans, and the plasma-protein binding of the parent drug and its metabolites have been investigated (17). Obviously, sulfapyrazone metabolites could complicate the protein binding interaction with warfarin *in vivo*; however, our evidence with volunteers who concomitantly receive warfarin and sulfinpyrazone (15) indicate this is not the case. Interestingly, sulfinpyrazone has been reported to induce the metabolism of (*R*)-warfarin while simultaneously inhibiting the metabolism of the (*S*)-enantiomer (18, 19). These conclusions were drawn from the sulfinpyrazone-induced changes in enantiomeric clearance.

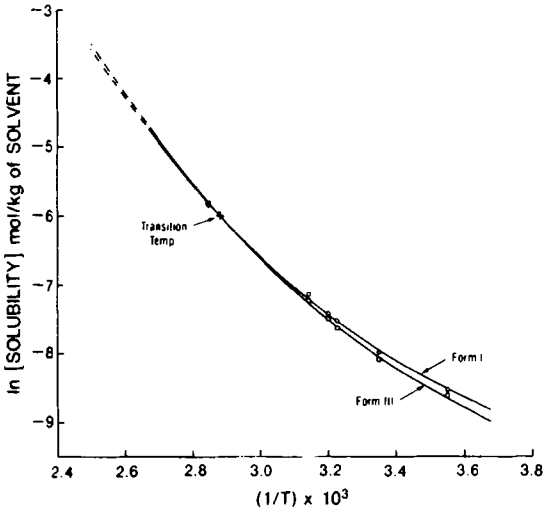

Figure 1—*Aqueous solubilities of tolbutamide forms I and III as a function of temperature.*

of form I tolbutamide (173 g in 20 L of water containing 10 g of polysorbate 80) for several days. The suspension was seeded initially with a small amount of the formulated suspension that contained some of the needle-like crystals of form III. Heating the suspension to ~40°C hastened the conversion of the plate-like form I crystals to the needle-shaped form III crystals. When conversion appeared complete by microscopic observation, the suspension was filtered on a coarse sintered glass filter, washed with deionized water, and dried at 40°C under reduced pressure. The converted crystal form was identified as form III and differentiated from form I by X-ray diffraction patterns and IR spectra which conformed with those published by Burger and others (1, 3, 4). Thermogravimetric analysis and melt solvate assays were negative for solvents. Melting points and differential scanning calorimetric thermograms corresponded to those published previously (1, 3, 4).

The aqueous solubilities of each of the two forms were obtained in the same way as reported by Burger (1). Samples of the stirred suspensions were taken periodically and assayed by UV spectrophotometry or reverse-phase HPLC at 229 nm until a constant value was obtained for several days. The solubility in octanol was determined in the same way, except that no HCl or polysorbate 80 was added. Samples were taken every hour until 4 or 5 h after apparent equilibrium.

The aqueous solubility at 37°C for form I was found to be 14.61 mg/100 mL, and that of form III was 13.03 mg/100 mL. These values are significantly different at the 95% confidence level. The aqueous solubility data in the molal units are plotted against $1/T$ in Fig. 1 (van't Hoff plot). The nonlinearity of the data is due to the wide temperature range covered, as pointed out by Grant (5). Using an iterative least-squares regression program, the solubility data for each of the forms was fit to a modified van't Hoff equation (6) as follows:

$$\ln m_{T_2} = \ln m_{T_1} + \frac{(\Delta\overline{H}_{T_1} - T_1\Delta\overline{C}p)(T_2 - T_1)}{RT_1T_2} + \frac{\Delta\overline{C}p}{R} \cdot \ln\frac{T_2}{T_1} \qquad \text{(Eq. 1)}$$

where T_2 is the temperature of interest and T_1 is an arbitrarily chosen reference temperature. In this study, T_1 was fixed at 128°C, the melting point of form I. $\Delta\overline{H}$ and $\Delta\overline{C}p$ are the differential heat of solution and the difference in heat capacity of dissolved and crystalline solute, respectively, for either form. $\Delta\overline{C}p$ is assumed constant with an arbitrary value of 84 cal/deg·mol, while the heat of solution is dependent on temperature as follows (6):

$$\Delta\overline{H}_{T_2} = \Delta\overline{H}_{T_1} + \Delta\overline{C}p(T_2 - T_1) \qquad \text{(Eq. 2)}$$

Table I—Thermodynamic Parameters Obtained from the Solubility *versus* Temperature Data (Eq. 1)

Polymorph	ln m(128°C)[a]	$\Delta\overline{H}$ (128°C), kcal/mol	$\Delta\overline{C}p$, cal/deg·mol
I	−3.52	15.0	84[b]
III	−3.44	15.4	84[b]

[a] Hypothetical value of the aqueous solubility at 128°C in units of molality. [b] Assumed to be equal in the least-squares fitting routine.

The two unknowns (heat of solution at 128°C and ln m at 128°C) are obtained from the iterative solution of Eq. 1 and are listed in Table I. The heat of solution of form I at 25°C is calculated to be 6.3 cal/deg·mol which is in good agreement with previously published data (2). The two polymorphs are enantiotropic since the solubility curves cross below the melting point. The transition temperature is estimated to be ~75°C. Below 75°C, form III has the lower solubility and is the most stable. Since the aqueous solubilities of the two forms are so close, form I may appear to be quite stable in suspensions at low temperatures, but given enough time, it will transform to the lower energy form. Above 75°C, form I has the lowest solubility and is the more stable of the two in that region.

A qualitative experiment was done to illustrate the transition point. A small quantity of form III crystals was mixed with mineral oil on a microscope slide. The mixture was heated to 100°C on a hot stage for several hours and periodically agitated by pressing and rotating the cover slip. When the temperature was reduced to 95°C and maintained, prismatic plate-like crystals, typical of form I, began to grow throughout the oil mixture while the form III clusters slowly dissolved. Then, the slide was removed from the hot stage and allowed to cool quickly to room temperature. The plates stopped growing, but fine needle-like crystals, typical to form III, began to grow. Obviously, there is a transition temperature between 25°C and 95°C.

The crystalline conversion was observed in 10 other solvents at room temperature: toluene, hexane, ethanol, chloroform, acetonitrile, methyl propyl ketone, isopropyl alcohol, tetrahydrofuran, dioxane, and octanol. The rate of conversion varied greatly with solubility, the better solvents promoting faster conversion. Since the conversion in octanol is relatively slow, it was chosen for accurate determination of polymorph solubilities. As might be expected, the solubility in octanol of form III at 30°C is significantly lower than that of form I: 19.33 mg/mL for form III and 23.54 mg/mL for form I. IR spectra were obtained on the solids remaining after the solubility study had been completed; the results confirmed the microscopic observation that no polymorphic conversion had taken place in either case during the solubility study.

The data given here present a rational explanation for the observed polymorphic change in suspensions at temperatures of <75°C. The small difference in free energy of the two polymorphic forms and the low solubilities at ambient temperature provide only a small driving force for the conversion.

This allows the preparation of apparently stable suspensions of either form. However, form I suspensions are metastable at ambient temperatures and eventually will change to form III. The conversion may be hastened by catalytic influences such as strong agitation.

OPEN FORUM

Safety and Efficacy of Dental Sealants in the Prevention of Tooth Decay

In a recent editorial ("Coming of Age" for Device Technology), Dr. Feldmann[1] appears to be unnecessarily harsh on the use of modern dental sealants in preventing caries. The designation of such procedure as "a hoax or even a well-intended but worthless effort by dentists to protect against the ravages of caries" may have had some validity 15 or so years ago, when the early sealant materials were in developmental stages and application techniques were not well understood. Today, however, new sealants have been developed and clinically proven by dental researchers as safe and effective in preventing caries[2]. The use of sealants by dentists in the United States[3] has increased dramatically since 1974 when 37.8% of those surveyed said they offered sealant therapy; in 1982, that figure increased to 57.7%.

The National Dental Caries Prevalence Survey (1979-1980) has shown that among 5- to 17-year-old children, only 16% of the caries incidence occurred in smooth surfaces, but 84% involved chewing surfaces with pits and fissures. It is known that the chewing surfaces of children's teeth are the most susceptible to decay and derive the least benefit from fluorides. The newly developed plastic films are applied to these chewing surfaces to seal the pits and grooves, which prevents food and cariogenic bacteria being trapped and thus offers a new approach to the prevention of dental caries.

The 1983 Consensus Development Conference on the use of dental sealants in the prevention of tooth decay, sponsored by the National Institutes of Health, made the following conclusions[4]:

"The placement of sealants is a highly effective means of preventing pit and fissure caries. It is safe. It is currently underused in both private and public dental health care delivery systems. The reasons for such underuse are complex, but intensive efforts should be taken to increase sealant use. Expanding the use of sealants would substantially reduce the occurrence of dental caries in the population beyond that already achieved by fluorides and other preventive measures. Because dental caries is still a disease common to most young people in the United States and in other countries of the world, such reductions would substantially improve the health of the public and reduce the expenditures for treatment of dental disease. Practitioners, dental health agency directors, and dental educators are urged to incorporate the appropriate use of sealants into their practice and programs."

The American Dental Association Council on Dental Materials, Instruments, and Equipment, which has an acceptance program to evaluate commercially available sealants for safety and efficacy, also considers[5] "pit and fissure sealants are safe and effective as a caries prevention procedure."

Author's Response:

Apparently, Dr. Rao misunderstood or misinterpreted the message of my June issue editorial. In his letter, Dr. Rao acknowledges that classifying dental sealants as being worthless 15 or so years ago may have had validity; however, he contends that today they are considered by experts in the field to be a highly beneficial technique in protecting against dental caries.

The entire thrust of the editorial, from its title ("Coming of Age" for Device Technology), through its entire text, to the very last paragraph (which stated that ". . . what we are witnessing is truly a medical revolution"), emphasized and reemphasized that many modern medical devices, procedures, and technology now constitute valuable health advances—although this was rarely the case a generation ago. As one dramatic example, we mentioned dental sealants and praised the FDA for keeping an open mind in judging positively the current products and their application. Yes, these modern products have indeed been proven to be a safe and effective caries prevention procedure.

Over twenty-five years ago, I personally was on the ADA staff as Director of the American Dental Association's drug testing laboratory. I well remember that the biggest challenge to ADA at that time was to reverse lay, professional, and scientific thinking regarding the value of fluoridation. Until then, only the toxicity and adverse effects were generally recognized and known. But, by carefully adjusting the daily intake of fluoride, remarkable benefits could be achieved while avoiding any adverse reactions. This was one of the earlier technical revolutions in the dental field—sealants are a more recent advance.

In conclusion, we would respectfully urge Dr. Rao to read again our June editorial. Then, it should be clear to him that we have no disagreement whatsoever as to the current value of dental sealants.

OPEN FORUM

Safety and Efficacy of Dental Sealants in the Prevention of Tooth Decay

In a recent editorial ("Coming of Age" for Device Technology), Dr. Feldmann[1] appears to be unnecessarily harsh on the use of modern dental sealants in preventing caries. The designation of such procedure as "a hoax or even a well-intended but worthless effort by dentists to protect against the ravages of caries" may have had some validity 15 or so years ago, when the early sealant materials were in developmental stages and application techniques were not well understood. Today, however, new sealants have been developed and clinically proven by dental researchers as safe and effective in preventing caries[2]. The use of sealants by dentists in the United States[3] has increased dramatically since 1974 when 37.8% of those surveyed said they offered sealant therapy; in 1982, that figure increased to 57.7%.

The National Dental Caries Prevalence Survey (1979-1980) has shown that among 5- to 17-year-old children, only 16% of the caries incidence occurred in smooth surfaces, but 84% involved chewing surfaces with pits and fissures. It is known that the chewing surfaces of children's teeth are the most susceptible to decay and derive the least benefit from fluorides. The newly developed plastic films are applied to these chewing surfaces to seal the pits and grooves, which prevents food and cariogenic bacteria being trapped and thus offers a new approach to the prevention of dental caries.

The 1983 Consensus Development Conference on the use of dental sealants in the prevention of tooth decay, sponsored by the National Institutes of Health, made the following conclusions[4]:

"The placement of sealants is a highly effective means of preventing pit and fissure caries. It is safe. It is currently underused in both private and public dental health care delivery systems. The reasons for such underuse are complex, but intensive efforts should be taken to increase sealant use. Expanding the use of sealants would substantially reduce the occurrence of dental caries in the population beyond that already achieved by fluorides and other preventive measures. Because dental caries is still a disease common to most young people in the United States and in other countries of the world, such reductions would substantially improve the health of the public and reduce the expenditures for treatment of dental disease. Practitioners, dental health agency directors, and dental educators are urged to incorporate the appropriate use of sealants into their practice and programs."

The American Dental Association Council on Dental Materials, Instruments, and Equipment, which has an acceptance program to evaluate commercially available sealants for safety and efficacy, also considers[5] "pit and fissure sealants are safe and effective as a caries prevention procedure."

Author's Response:

Apparently, Dr. Rao misunderstood or misinterpreted the message of my June issue editorial. In his letter, Dr. Rao acknowledges that classifying dental sealants as being worthless 15 or so years ago may have had validity; however, he contends that today they are considered by experts in the field to be a highly beneficial technique in protecting against dental caries.

The entire thrust of the editorial, from its title ("Coming of Age" for Device Technology), through its entire text, to the very last paragraph (which stated that ". . . what we are witnessing is truly a medical revolution"), emphasized and reemphasized that many modern medical devices, procedures, and technology now constitute valuable health advances—although this was rarely the case a generation ago. As one dramatic example, we mentioned dental sealants and praised the FDA for keeping an open mind in judging positively the current products and their application. Yes, these modern products have indeed been proven to be a safe and effective caries prevention procedure.

Over twenty-five years ago, I personally was on the ADA staff as Director of the American Dental Association's drug testing laboratory. I well remember that the biggest challenge to ADA at that time was to reverse lay, professional, and scientific thinking regarding the value of fluoridation. Until then, only the toxicity and adverse effects were generally recognized and known. But, by carefully adjusting the daily intake of fluoride, remarkable benefits could be achieved while avoiding any adverse reactions. This was one of the earlier technical revolutions in the dental field—sealants are a more recent advance.

In conclusion, we would respectfully urge Dr. Rao to read again our June editorial. Then, it should be clear to him that we have no disagreement whatsoever as to the current value of dental sealants.

Animal Models for Oral Drug Delivery in Man: In Situ and In Vivo Approaches. Edited by WILLIAM CROUTHAMEL and ALLEN C. SARAPU. American Pharmaceutical Association, Academy of Pharmaceutical Sciences, 2215 Constitution Ave. N.W. Washington, DC 20037. 1983. 179 pp. 15.5 × 23.5 cm. Price: $54.00.

This book is based on the symposium "Animal Models for Drug Absorption in Man" held in September 1980 at the APhA Academy of Pharmaceutical Sciences meeting in San Antonio, Texas. It contains texts from various recognized authorities in the field.

The book is divided into six chapters which discuss the mechanisms of drug absorption and techniques for studying them (Chapters 1 and 2), the use of the dog in new drug development, bioavailability testing and quality control (Chapters 3–5) and the regulatory viewpoint on the use of animals in NDA submissions (Chapter 6). In many respects, however, the most obvious division in the book is between the academic and industrial approaches to studying absorption—a distinction entirely appropriate in a subject that is of intense interest to both sides of pharmaceutical research. The text is well-argued and very readable and the rather unfortunate misspelling of 'gavage' as 'garbage' (Chapter 6) in no way reflects the general high quality of the contents.

The first two chapters (written by G. L. Amidon and N. F. H. Ho *et. al.*) are excellent and give a fairly comprehensive description of the theoretical and practical aspects of the subject. The analysis, in Chapter 2, of physiological factors controlling absorption is particularly effective.

The subsequent chapters are in some ways an anticlimax, although they do represent a useful account of industrial experiences with these models in new drug development. There are a number of examples or 'case studies' which readily illustrate the points being made, although the description of compounds in vague terms such as 'anxiolytic-type,' without structures, tends to be a little frustrating. The main criticism of this part of the book is in what it omits rather than what it includes; this may be a result of its origins as a symposium, where time is limited and a subject cannot be covered comprehensively. However, there does seem to be an overriding emphasis on the use of blood level studies in dogs when discussion of other species, such as rat and monkey, would have been of benefit. Other important considerations such as the correlation between *in situ* and *in vivo* absorption data and the crucial issue of interspecies variation in absorption also have not been given the coverage they deserve.

Nevertheless, an authoritative text on this subject is long overdue and this book is both welcome and useful. It will be of particular value to those in the pharmaceutical industry who are involved in drug design and product development. The more interested readers will be stimulated to look into the literature for some of the things the book omits and the excellent sets of references will be a useful guide for this.

Handbook of Powder Science and Technology. By M. E. FAYED and L. OTTEN, Van Nostrand Reinhold Company, Inc., 135 West 50th Street, New York, NY 10020. 1984. 650 pp. 18 × 26 cm. Price: $79.50.

This book is intended to be a guide for quick access to a wide range of information on powder science. Actually it is not a handbook, but is a comprehensive text to which 26 authors have contributed their expertise. For a multiauthored book it is very readable.

The book is divided into 19 chapters, which are entitled: "Particle Size Analysis: Theory and Statistical Methods"; "Particle Size Measurement: Experimental Techniques"; "Particulate Characterization: Future Approaches"; "Structural Properties of Packing Particles"; "Fundamental Properties of Powders"; "Vibration of Fine Powders and Its Application"; "Size Enlargement Methods and Equipment"; "Mixing of Powders; Storage of Particulate Solids"; "Fluidization Phenomena and Fluidized Bed Technology"; "Spouting of Particulate Solids"; "Transport of Solids in Pipelines"; "Size Reduction of Solids: Crushing and Grinding Equipment"; "Sedimentation"; "Filtration of Solids from Liquid Streams"; "Cyclones"; "Electrostatic Precipitator Applications and Concepts"; "Granular Bed Filters"; "Wet Scrubber Particulate Collection".

Statistical discussion is supported by sample problems, and the validity of the calculations are discussed. Analytical instruments and processing equipment are listed, and methods of selection for specific conditions are discussed in detail. The currentness of the book is exemplified by the modern chapter on morphology of a particle and powder signature. The book contains a wealth of information on the technology of handling, measurement, separation, and use of powders.

This excellent book has an abundance of information not only for those (graduate students) who have little experience in powder technology, but also for the pharmaceutical scientists in production, research and development, and academia.

Nucleosides, Nucleotides, and Their Biological Applications. Edited by JANET L. RIDEOUT, DAVID W. HENRY, AND LOWRIE M. BEACHAM III. Academic Press, 111 Fifth Avenue, New York, NY 10003. 1983. 327 pp. 16 × 24 cm. Price: $29.50.

The book presents the manuscripts of the 11 plenary lectures given at the Fifth International Round Table on Nucleosides, Nucleotides, and Their Biological Applications, held in Research Triangle Park, North Carolina, October 20–22, 1982. Each lecture is given its own chapter, a list of which includes "Nucleosides with Antiviral Activity", "The Chemistry and Biology of Nucleosides of Purines and Ring Analogs", "Experimental and Clinical Studies on 2′-Fluoroarabinosyl Pyrimidines and Purine-Like C-Nucleosides", "2′,5′-Oligoadenylates, Their Role in Interferon Action and Their Potential as Chemotherapeutic Agents", "Receptors for Adenosine and Adenine Nucleotides", "Analogs of 2′,5′-Oligoadenylates: Biological Probes for the Antiviral/Antitumor State of Mammalian Cells", "Synthesis of Pyrrolo[2,3-d]Pyrimidine Nucleosides by Phase Transfer Glycosylation and Their Function in Polynucleotides", "The Alkylsilyl Protecting Groups: in Particular, the *t*-Butyldimethylsilyl Group in Nucleoside and Nucleotide Chemistry", "Unusual Nucleoside Synthons and Oligonucleotide Synthesis", "Selective Modification and Deoxygenation at C-2′ of Nucleosides", and "Synthesis of Versitile C-Nucleoside Precursors and Certain C-Nucleosides".

While no attempt is made to exhaustively review all the literature in each chapter, general references are provided wherein additional reviews can be found. Each chapter is generally well written with very few typographical and/or structural errors, and all have substantial (albeit not extensive) bibliographies. The index at the end of the volume is quite detailed, including page references for specific compounds. Although the material is now almost two years old, and much new literature has been published, especially in the areas of adenosine receptors and antagonists, novel C-nucleosides, and 2′,5′-oligonucleotide synthesis, this reference is nevertheless a valuable source of information on methodology (both chemical and biological) and structural design of nucleoside/nucleotide analogues.

The Industry–University Interface

In terms of history, it was not so very long ago—less than a century—that scientists and inventors worked in virtual isolation in their laboratories. Along with a colleague or two at most, they conducted studies and experiments that led to some of mankind's greatest achievements and discoveries.

Thanks to the motion picture industry, many of us have had an opportunity to view top quality films with star performers who portrayed the lives and major accomplishments of Madame Curie, Paul Ehrlich, Thomas Edison, Wilbur and Orville Wright, Louis Pasteur, Alexander Graham Bell, and various other such notables.

But times have changed, and dramatically so.

Today, the overwhelming proportion of research is conducted by big scientific or technical teams, at big industrial firms, or at big universities, or at big government institutions. And as the complexity of contemporary research continues to grow, even those big operations apparently are not large enough to capably handle the kind of research job that sometimes needs to be done.

Antitrust legislation often presents a hurdle for companies that might otherwise contemplate banding together in joint efforts. However, joint efforts between industry and academia do not present these same legal difficulties. This is not to say that there are no legal problems. By no means. We are aware that there are many legal considerations involved in academia–industry joint ventures that often require significant paperwork, much justification, and what usually seems to be an inordinate amount of time. But as severe as these constraints may be, they are not as severe as those presented by the antitrust laws.

Early this year, in the February issue, we already commented on this overall subject under the heading "Universities for Hire." At that time, we termed the issue of jointly sponsored Academe/Industry Research as the current "great debate" within university and some industry circles. Our conclusion then was that if all involved exercised good will, pragmatic approaches, and honest attitudes, the big concern regarding erosion of ethics and academic freedom could be averted.

Nothing dramatically new has happened since then by way of a solution to the issues and concerns that were then prevalent. However, there is growing interest in the subject as research—especially in the fields of bioengineering and biotechnology—has become increasingly complex and expensive.

Indeed, in late August of this year, the National Science Foundation released a study that it had commissioned the consulting firm of Arthur D. Little, Inc., to conduct on its behalf. The resulting report, entitled "Study of Federal Biotechnology Policy Issues," identified two top biotechnology issues meriting federal attention. One of these was the subject of university-industry relationships.

Just a few weeks earlier, the incoming President of the American Association of Colleges of Pharmacy, Robert D. Gibson of the University of California School of Pharmacy, concluded his presidential address by calling attention to the issue as one that is emerging for schools of pharmacy. He correctly noted that, for some time, it has already been a concern for other disciplines and particularly bioengineering. Now, he stated, it is developing as an issue in pharmacy schools, and he urged giving it appropriate attention *before* it became a problem, rather than *after*.

In considering the subject, Dr. Gibson listed four areas in which industry/academia joint research ventures or partnerships might impinge:

- *Suppress the free transfer of information, thereby inhibiting the advancement of the science related to pharmacy.*
- *Undermine the development of the basic sciences by diverting faculty interests to problems of immediate commercial interest.*
- *Negatively affect the quality of instruction in our schools.*
- *Distort traditional academic values and goals.*

He plans to take certain positive steps during his presidential term to face these issues and, hopefully, to develop some guidelines that might provide helpful direction to schools of pharmacy.

In the meantime, the need to work out some suitable, mutually acceptable arrangement is definitely there. Just this past March, an editorial in *Science* was entitled "Graduate Education: Signs of Trouble." The author, John Brademas, called attention to the growing problems of financing graduate education and suggested industry support as a key solution. In turn, industry has a vested interest because its future research and technical talent will come from today's graduate schools.

Finally, a group of five clinical pharmacologists from Pfizer Pharmaceuticals coauthored a "commentary" article that was published in the April 1984 issue of *Clinical Pharmacology and Therapeutics*. Appropriately, their article was titled "University and Pharmaceutical Industry Cooperation: The Need to Plan for the Future."

Their article was refreshingly candid. In the opening paragraph, they began by noting the "history of mutual mistrust" and went on to state that: "It has been said by way of hyperbole that industry wants only to pick academia's brains, whereas universities are mostly interested in picking industry's pockets. Yet the potential for gains by both sides encourages the bridging of what once seemed a wide psychologic and programmatic gap."

Proceeding then with a very balanced view of the issue, they analyzed in significant depth the specific area of joint or cooperative research projects in the area of clinical pharmacology relating to drug development. Although their emphasis was particularly directed at pharmaceutical industry relations with medical schools, their ideas and views all apply equally to pharmacy schools.

After noting a series of specific benefits deriving from collaboration—some to the university, others to industry—they concluded that, although the idea of cooperatively conducted research is far from being a new development, the need for such arrangements has recently become far more important to both "camps." Moreover, going beyond the need for such arrangements merely for survival, they see these carefully developed relationships as presenting a potentially significant new benefit for the entire health care community.

This is a view in which we fully share!

General Treatment of pH–Solubility Profiles of Weak Acids and Bases and the Effects of Different Acids on the Solubility of a Weak Base

WILLIAM H. STRENG ˣ, SWEE K. HSI, PAUL E. HELMS, and HETTY G. H. TAN

Received August 15, 1983, from the *Merrell Dow Research Institute, Merrell Dow Pharmaceuticals, Cincinnati, OH 45215.* Accepted for publication January 19, 1984.

Abstract □ The pH–solubility profile of a weak acid or base is shown to be a function of its pK_{sp}, pK_a, and uncharged species solubility. Equations are presented that can be used to calculate the solubility as a function of pH. These equations can also be used when there is added salt present. Experimental data was obtained in three cosolvent systems consisting of methanol–water and ethanol–water. Also, the effect of different acids on the solubility of a weak base is reported. A pronounced effect on the solubility by the addition of salt is explained in terms of the K_{sp}.

Keyphrases □ pH—profiles *versus* solubility, weak acids, weak bases □ Solubility—profiles *versus* pH, weak acids, weak bases

It is well known that the solubility of an acid or base is dependent on its ionization constants and the maximum solubility of the various species of the compound (1–12). In these reports, equations were presented that can be used to calculate the solubility profile as a function of pH. The pH range over which these equations are applicable are, however, limited as some only consider the pH region where the uncharged species is saturated and none consider the effects of additional salt added to the system. Introduction of salts to a saturated solution will frequently alter the solubility of the compound. This change in solubility is related to solubility product (K_{sp}) effects as well as changes in the activity coefficients. It will be shown that by combining the known expressions for solubility as a function of pH with the appropriate solubility product expression, equations can be obtained which, over a wide pH range, correlate the measured solubility data with calculated values. To perform the calculations, the ionization constant(s), uncharged species solubility, and solubility product(s) for the compound need to be known. Although these expressions are typically used for pure aqueous solvent systems, some of the experimental data reported utilized methanol–water and ethanol–water cosolvent systems and show the applicability of these equations to cosolvent systems. The effect of different pH-adjusting acids on the solubility of a weak base in water is also reported.

THEORETICAL SECTION

Expressions have been reported for the solubility of weak acids and bases as a function of pH (1–12). The number of equations required to describe the solubility over the entire pH range is dependent on the number of equilibrium constants that the compound has. Each equation, representing a different region in the solubility profile, contains a different species saturating the region[1]. For monoprotic compounds these equations are:

$$S_{1,0} = \left(\frac{1}{Y_0} + \frac{K}{Y_1\{H\}}\right)\{HD\} \qquad \text{(Eq. 1)}$$

$$S_{1,1} = \left(\frac{1}{Y_1} + \frac{\{H\}}{KY_0}\right)\{D\} \qquad \text{(Eq. 2)}$$

where $S_{m,j}$ is the total concentration of all species of compound D in solution, *i.e.*:

$$S_{m,j} = \sum_{p=0}^{m} [H_{m-p}D] \qquad \text{(Eq. 3)}$$

where m is the number of equilibrium constants, j is the region, $[H_{m-p}D]$ is the concentration of species $H_{m-p}D$, $\{H_{m-j}D\}$ is the activity (maximum solubility) of species $H_{m-j}D$, K is the equilibrium constant, $\{H\}$ is the hydrogen ion activity, and Y_i is the activity coefficient for species i (Y_0 is that of the most protonated species).

When the species which is saturated in a region is charged, the species activity in Eqs. 1 and 2 can be replaced by the corresponding solubility product which for monoprotic compounds in the presence of 1:1 electrolytes are:

$$K_{sp} = \{M\}\{D\} \quad \text{weak acid} \qquad \text{(Eq. 4)}$$

$$K_{sp} = \{HD\}\{X\} \quad \text{weak base} \qquad \text{(Eq. 5)}$$

If the compound is a weak acid, the quantity $K_{sp}/\{M\}$ would be substituted

[1] See Appendix I.

0022-3549/84/1200-1679$01.00/0
© 1984, American Pharmaceutical Association

for {D} in Eq. 2, while $K_{sp}/\{X\}$ would be substituted for {HD} in Eq. 1 for a weak base. The terms {M} and {X} are the corresponding cation and anion activities for the salt MX.

Since the solubility is dependent on species other than those of the weak acid or weak base, the addition of salts to the solution will alter the solubility. If the salt concentration is sufficiently large that the solubility product in Eqs. 4 or 5 is exceeded, there will be a decrease in the solubility. There will also be an effect on the activity coefficients since the total ionic strength will increase with the addition of a salt. This change in the activity coefficients can result in either an increase or decrease in the solubility depending on the salt concentration. When the salt concentration is not sufficiently large that the solubility product is exceeded, only the effect on the activity coefficients will be present.

An equation can be derived which can be used to determine the pH at which the solubility expression changes from one region to a second region. The derivation takes into consideration the fact that at the pH where the saturated species changes, the solution will be saturated in two species, and the resulting equation is obtained by combining the equilibrium expressions for K_a and K_{sp} with the charge balance equation[2].

The equation obtained will depend on whether the compound is a weak acid or a weak base. For a weak acid, the hydrogen ion concentration is given by:

$$\{H\} = \frac{[X] + \left[[X]^2 + 4\left(\frac{K_{sp}}{K\{HD\}Y_M} + \frac{1}{Y_H}\right)\left(\frac{K\{HD\}}{Y_D} + \frac{K_w}{Y_{OH}}\right)\right]^{1/2}}{2\left(\frac{K_{sp}}{K\{HD\}Y_M} + \frac{1}{Y_H}\right)} \quad \text{(Eq. 6)}$$

For a weak base it is:

$$\{H\} = \frac{-[M] + \left[[M]^2 + 4\left(\frac{\{D\}}{KY_{HD}} + \frac{1}{Y_H}\right)\left(\frac{KK_{sp}}{\{D\}Y_X} + \frac{K_w}{Y_{OH}}\right)\right]^{1/2}}{2\left(\frac{\{D\}}{KY_{HD}} + \frac{1}{Y_H}\right)} \quad \text{(Eq. 7)}$$

For monoprotic compounds, the total solubility given by Eqs. 1 and 2 can be rewritten to include the K_{sp} and addition of salt[3]. For a weak acid, Eq. 1 will remain the same, but Eq. 2 will become:

$$S_{1,1} = \frac{-\left([X] - \frac{\{H\}}{Y_H} + \frac{K_w}{\{H\}Y_{OH}}\right) + \left[\left([X] - \frac{\{H\}}{Y_H} + \frac{K_w}{\{H\}Y_{OH}}\right)^2 + 4\frac{K_{sp}}{Y_M Y_D}\right]^{1/2}}{2\left(\frac{KY_{HD}}{\{H\}Y_D + KY_{HD}}\right)} \quad \text{(Eq. 8)}$$

In the case of a weak base Eq. 2 remains the same while Eq. 1 becomes:

$$S_{1,0} = \frac{-\left([M] + \frac{\{H\}}{Y_H} - \frac{K_w}{\{H\}Y_{OH}}\right) + \left[\left([M] + \frac{\{H\}}{Y_H} - \frac{K_w}{\{H\}Y_{OH}}\right)^2 + 4\frac{K_{sp}}{Y_{HD}Y_X}\right]^{1/2}}{2\left(\frac{\{H\}Y_D}{KY_{HD} + \{H\}Y_D}\right)} \quad \text{(Eq. 9)}$$

A number of methods have been reported (1, 2, 4, 13–15) for determining the pK_a, pK_{sp}, and uncharged species maximum concentration. Any of these could be applied to Eqs. 1 and 8 or 2 and 9 with slight modification. It was found that when the uncharged species solubility is established, values for pK_a and pK_{sp} can be obtained by fitting calculated solubility curves to the experimental data. The calculated curves were sensitive to the values of pK_a and pK_{sp} used and could be estimated to within ± 0.01 units by this approach. In performing these calculations, it is important to realize that, whenever possible, estimations of the activity coefficients should be made. This is because typical values for the activity coefficient of a singly charged species in a solution having a total ionic strength of 0.05 M is ~0.75. Factors this large entering into the above equations will have significant effects.

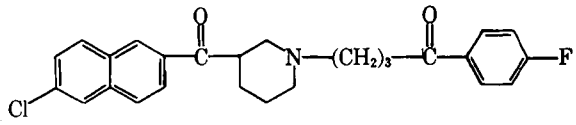
EXPERIMENTAL SECTION

Solubility In Cosolvent Systems—The solubility of 4-[4-[(6-chloro-2-naphthalenyl)carbonyl]-1-piperidinyl]-1-(4-fluorophenyl)-1-butanone (I)[4] was determined in several solvent systems as a function of pH. Additional sodium chloride was added into several of the systems to see the effect of an added salt and determine how accurately the computer program used to calculate the solubility profiles could match the experimental data.



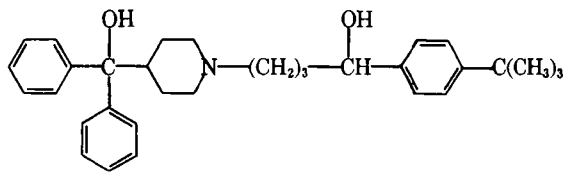
I

Solution Preparation—*85% Methanol*—Ampules were prepared containing 8.5 mL of methanol, 1.5 mL of water with 0–1.2 equivalents of HCl per equivalent of I, and 100 mg of I. In selected ampules, sodium chloride was present at concentrations of 0.01, 0.025, and 0.05 M. The ampules were sealed and placed into a 25.0°C constant-temperature bath, attached to a vibrating device, and allowed to equilibrate for 4 d. Following equilibration, the ampules were removed, and the contents were assayed.

50% Ethanol—Ampules were prepared containing 5 mL of ethanol, 5 mL of water with 0–1.2 equivalents of HCl per equivalent of I, and 100 mg of I. In selected ampules, sodium chloride was present at 0.01 and 0.05 M. The ampules were treated in the same manner as the methanol samples except they were allowed to equilibrate for 3 d.

25% Ethanol—Ampules were prepared containing 2.5 mL of ethanol, 7.5 mL of water with 0–1.2 equivalents of HCl per equivalent of I, and 100 mg of I. In selected ampules, sodium chloride was present at 0.01 and 0.05 M. The ampules were sealed and treated in the same manner as the methanol samples.

Assay Procedure—The contents of the ampules were filtered through a 0.2-μm membrane filter[5]. An appropriate aliquot was removed, and the pH of the remaining sample was measured[6]. The aliquot removed was placed in a volumetric flask and diluted with the mobile phase used in the HPLC assay. The following conditions were used in the HPLC assay: column, Partisil 10 ODS-3 (25 cm × 4.6 mm)[7]; mobile phase, acetonitrile–water (50:50) containing 0.005 M octanesulfonic acid and 0.2% acetic acid; flow rate, 120 mL/h; sample size, 10 μL (0.3–1.4 μg of I); wavelength, 246 nm[8]. The saturated concentrations were determined from the areas under the peaks, calculated with a centralized computer system[9].



II

Effect of Different Acids on the Solubility of a Weak Base—The solubility of terfenadine, α-[4-(1,1-dimethylethyl)phenyl]-4-(hydroxydiphenylmethyl)-1-piperidinebutanol (II), was determined in water as a function of pH using lactic acid, methanesulfonic acid, hydrochloric acid, and phosphoric acid. Samples were prepared by placing 200 mg of terfenadine into washed 30-mL vials and adding 25 mL of aqueous solution containing various amounts of the selected acids. The vials were capped with a polytef-laminated rubber stopper (previously autoclaved in water to remove any extractable materials) and sealed with aluminum ferrules. The samples were placed in a sonic water bath maintained at 25°C and allowed to equilibrate for 4 d.

After equilibration, the lactic acid and phosphoric acid samples were prefiltered through filter paper[10], followed by filtration through a disposable 0.45-μm membrane filter[11]. This was necessary due to a gel formation with these acids at high concentrations. The hydrochloric acid and methanesulfonic acid solutions were filtered through disposable 0.45-μm membrane filters[11].

After filtering, the pH of the solutions was measured[12], and the solutions were assayed. To obtain peaks of reasonable area, some samples were injected directly and others were diluted with 1% aqueous acetic acid solution. The conditions were: column, μ-Bondapak C-18[13]; mobile phase, acetonitrile–water containing 20% 1 M phosphate buffer (pH 7) and 1.2% diethylamine (50:50, v/v); flow rate, 2 mL/min[14]; injection volume, 50 μL[15]; wavelength, 235 nm[8]. The saturated concentrations were determined from areas under the peaks using a centralized computer system[9].

RESULTS AND DISCUSSION

The results of the cosolvent solubilities are shown in Figs. 1–3. Adjustments to the measured pH were needed due to changes in the standard state with the cosolvent systems used (16). These corrections were 0.13 in 85% methanol, −0.17 in 50% ethanol, and −0.02 in 25% ethanol.

Using Eqs. 2 and 9, the pH–solubility profiles were calculated (lines in Figs. 1–3). The calculations were made using the Davies equation (17) for the activity coefficients:

$$-\log Y_i = AZ_i^2\left(\frac{\sqrt{I}}{1+\sqrt{I}} - 0.2I\right) \qquad \text{(Eq. 10)}$$

where A is a constant for a given temperature and solvent system, Z_i is the charge on the ion, and I is the total ionic strength. Since the calculations are complex and would require a significant amount of time to hand calculate, a computer program was written to solve the equations[16].

In Table I, the values for pK_a, pK_{sp}, and the uncharged species solubility for each solvent system are given. There is good correlation between the calculated curves (Figs. 1–3) and the observed solubility. Also shown in these figures is the dependence of the solubility of I on chloride ion. In 85% methanol at pH 5, the solubility decreases by 26, 46, and 61% in the presence of 0.01, 0.025, and 0.05 M chloride ion, respectively. A 0.05 M sodium chloride solution is about one-third the concentration of an isotonic saline solution (0.154 M). Calculations at pH 5 indicate a solubility of ~1.2 mg/mL in a 0.15 M sodium chloride solution, which would be a decrease of 80% in the solubility compared with no added sodium chloride. Similar decreases in solubility were calculated for the 50 and 25% ethanol solutions at pH 5; however, the percentage decrease is greater in these solutions, ~90 and 98% in 50 and 25% ethanol, respectively (Table II).

Inspection of the curves in Figs. 1–3 reveals the following about the solubility profile of a weak base. As the solution pH increases there is initially an increase in the solubility followed by a region in which there is little change. With a further increase in pH, there is again an increase in the solubility until a maximum is obtained. Finally, after reaching the maximum, there is a rapid decrease in the solubility.

This behavior in the profile can be explained by considering the various equilibria and species which are present in solution. Initially, the increase in solubility is due to a decrease in the anion concentration (Cl^-). This effect is subject to the solubility product (Eq. 5), where the solubility is given by Eq. 9. The total anion concentration is approximately equal to the sum of the concentrations of the weak-base protonated species and the hydrogen ion. As the pH increases, the hydrogen-ion concentration becomes very small compared with the weak-base protonated species. When this occurs, there will be little change in the solubility with pH. The maximum shown in these curves is due to the presence of both the charged and uncharged species of the weak base. The increase in solubility up to the maximum is due to an increase in the weak base uncharged species concentration up to its maximum. The rapid decrease in solubility after the maximum is due to a decrease in the weak base charged species concentration. These concentrations are controlled by the equilibrium constant. The total solubility at pH values greater than the maximum is given by Eq. 2. As the maximum solubility of the weak base uncharged species decreases, the height of the maximum will decrease (see Figs. 1 and 3). This is because at the maximum, the solution is saturated in both the weak base charged and uncharged species. Finally, the differences shown between the curves for a specific solvent system at pH values greater than the maxima are due to activity coefficient effects. If all activity coefficients were equal to one, the curves after the maxima would be superimposable.

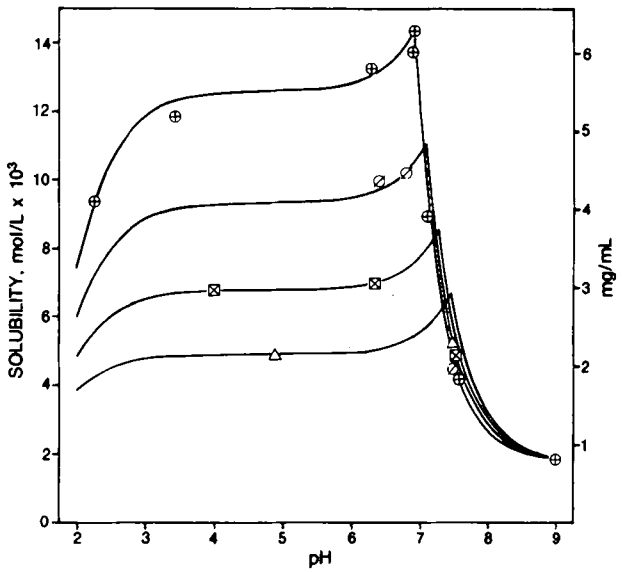

Figure 1—*pH–solubility profile of I with hydrochloric acid (solvent system, 85% methanol–water). Effect of salt on the solubility of I. Key: (⊕) no NaCl added; (Ø) 0.01 M NaCl; (□) 0.025 M NaCl; (△) 0.05 M NaCl.*

It is not possible to make direct comparisons of the pK_a value with those reported in the literature for similar compounds because of the solvent systems used. Decreases of >1 in the pK_a values compared with pure water for weak bases have been reported with 80% ethanol (18). Literature pK_a values for *N*-substituted piperidine compounds are typically 9–10 in pure water (19). This indicates that the values reported here are not unreasonable.

The pK_{sp} values used for the solubility of terfenadine with phosphoric, hydrochloric, methanesulfonic, and lactic acids are 5.6, 4.8, 4.6, and 4.05, respectively. The pK_{sp} value is largest for phosphoric acid and smallest for lactic acid. The higher the value of pK_{sp}, the lower the solubility of that salt; therefore, the solubility of terfenadine will be lowest in solutions pH-adjusted with phosphoric acid and will be highest in those solutions adjusted with lactic acid. The solubility profiles of terfenadine using these four acids are shown in Fig. 4. There is a maximum solubility between pH 4.5 and pH 5.5. The

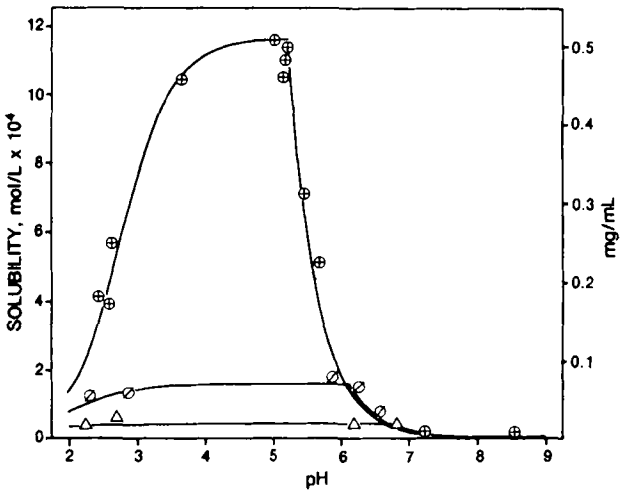

Figure 3—*pH-solubility profile of I with hydrochloric acid (solvent system, 25% ethanol-water). Effect of salt on the solubility of I. Key: (⊕) no NaCl added; (Φ) 0.01 M NaCl; (△) 0.05 M NaCl.*

decrease in solubility at higher pH is due to the solutions being saturated with respect to the uncharged form of terfenadine. At low pH, the terfenadine is forced out of solution due to the presence of additional anion from the pH adjustment.

Utilizing these pK_{sp} values, calculations were made to show the effects of the addition of sodium chloride to hydrochloric acid–terfenadine solutions and monobasic sodium phosphate to phosphoric acid–terfenadine solutions (Figs. 5 and 6). There is a pronounced effect on the solubility with the addition of even low concentrations of salts to these solutions.

These studies show the dependence of the solubility of a weak base on the pK_{sp}, pK_a, and maximum solubility of the uncharged species. Equations were presented which permit the calculation of pH-solubility profiles knowing the above constants. The effect of added salt is also shown where the solubility was significantly reduced on the addition of sodium chloride.

APPENDIX I

The derivation of Eqs. 1 and 2 and those for polyprotic compounds have been reported in detail elsewhere (1-12). They can be obtained by considering Eq. 3, the standard proton dissociation expressions, and individual species. For a monoprotic compound, Eq. 3 becomes:

$$S_{1,j} = [HD] + [D] \qquad \text{(Eq. 3a)}$$

In region $j = 0$ the HD species is saturated and, therefore, substitution of the equilibrium expression Eq. 3b into Eq. 3a for [D] will result in Eq. 3c:

$$K = \frac{\{H\}[D]}{\{HD\}} = \frac{\{H\}[D]Y_1}{\{HD\}} \qquad \text{(Eq. 3b)}$$

$$S_{1,0} = [HD] + \frac{K\{HD\}}{Y_1\{H\}} \qquad \text{(Eq. 3c)}$$

It is actually the activity of the species which is constant and not the concentration. Therefore, Eq. 3c should be expressed as Eq. 1:

Table I—Equilibrium and Solubility Constants of I

Solvent	pK_{sp}	pK_a	[A], mol/L	[A], μg/mL
85% Methanol	4.08	7.65	1.76×10^{-3}	771
50% Ethanol	4.51	7.81	7.5×10^{-5}	32.8
25% Ethanol	5.91	8.27	1×10^{-6}	0.44

Table II—Effect of Sodium Chloride On the Solubility of I at pH 5

Solvent	Solubility Without NaCl, μg/mL[a]	Solubility With NaCl, μg/mL[a]
85% Methanol	5520	1200
50% Ethanol	2870	272
25% Ethanol	509	7.8

[a] Concentration of NaCl is 0.15 M, approximately isotonic saline.

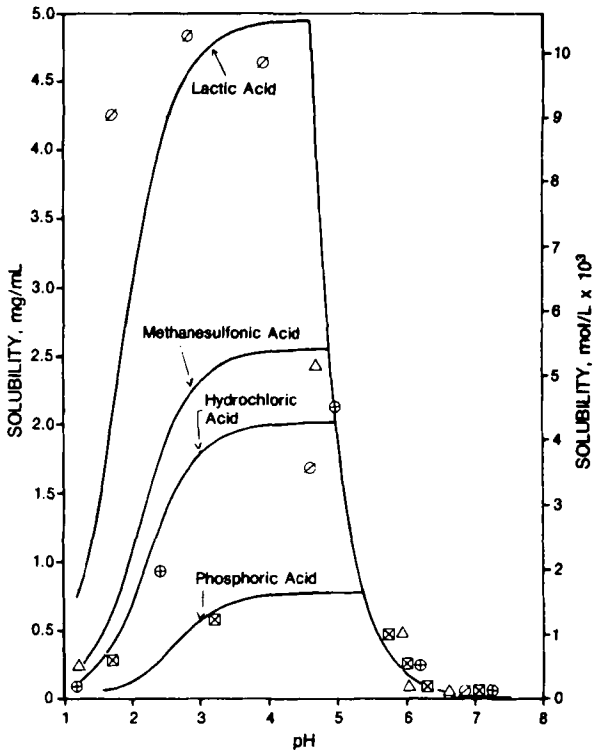

Figure 4—*pH-solubility profile of terfenadine with different acids. Effect of different acids on the solubility of terfenadine. Key: (Φ) lactic acid; (△) methanesulfonic acid; (⊕) hydrochloric acid; (□) phosphoric acid.*

$$S_{1,0} = \left(\frac{1}{Y_0} + \frac{K}{Y_1\{H\}}\right)\{HD\} \qquad \text{(Eq. 1)}$$

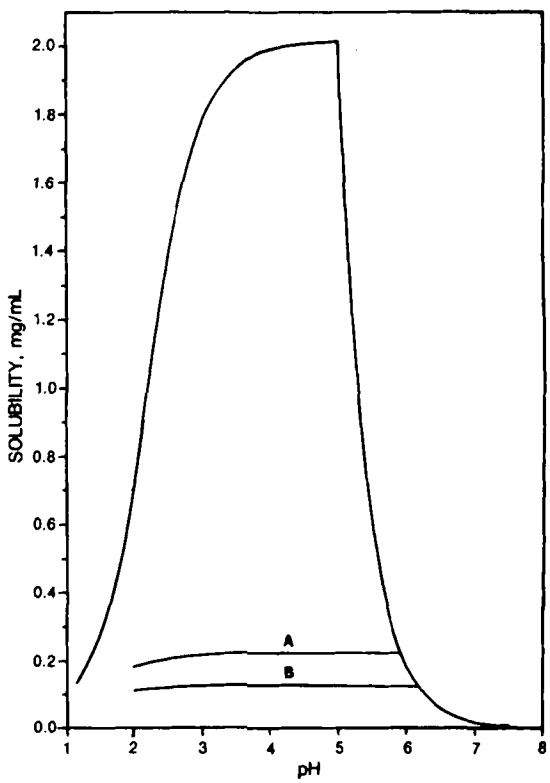

Figure 5—*pH-solubility profile of terfenadine with hydrochloric acid and salt. Calculated solubility profiles of terfenadine in solution with 0.05 M NaCl (A) and 0.1 M NaCl (B).*

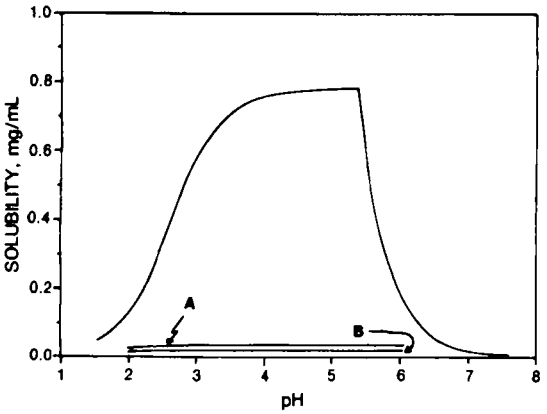

Figure 6—*pH-solubility profile of terfenadine with phosphoric acid and salt. Calculated solubility profiles of terfenadine in solution with 0.05 M NaH_2PO_4 (A) and 0.1 M NaH_2PO_4 (B).*

Similarly, Eq. 2 can be obtained by substituting the equilibrium expression into Eq. 3a for [HD], where in this case the region corresponds to $j = 1$.

Equations 1 and 2 can be generalized into the equation:

$$S_{m,j} = \sum_{j=0}^{m} \frac{\{H\}^j}{Y_0}\left[\left(\prod_{\alpha=0}^{j}\frac{1}{K_\alpha}\right)\left(1 + Y_0\sum_{i=1}^{m}\frac{1}{\{H\}^i Y_i}\prod_{t=1}^{i}K_t\right)\right]\{H_{m-j}D\} \quad \text{(Eq. 11)}$$

where $K_0 = 1$, and the other symbols are defined as above. This expression allows the determination of all equations necessary to describe the pH-solubility profile of any compound with protons that dissociate. For example, with a diacidic compound in which $m = 2$, the following equations are obtained:

$$S_{2,0} = \left(\frac{1}{Y_0} + \frac{K_1}{\{H\}Y_1} + \frac{K_1K_2}{\{H\}^2Y_2}\right)\{H_2D\} \quad \text{(Eq. 12)}$$

$$S_{2,1} = \left(\frac{1}{Y_1} + \frac{\{H\}}{K_1Y_0} + \frac{K_2}{\{H\}Y_2}\right)\{HD\} \quad \text{(Eq. 13)}$$

$$S_{2,2} = \left(\frac{1}{Y_2} + \frac{\{H\}^2}{K_1K_2Y_0} + \frac{\{H\}}{K_2Y_1}\right)\{D\} \quad \text{(Eq. 14)}$$

These equations are applicable to both weak acids and weak bases with appropriate charge assignments made to the activity coefficients and species.

APPENDIX II

The pH of maximum solubility for a monoprotic weak acid in the presence of added salt can be determined as follows[17]. For the equilibria:

$$HD \rightleftharpoons H + D \quad \text{(Eq. 6a)}$$

the equilibrium expression is given by Eq. 3b, and the solubility product is given by:

$$K_{sp} = \{M\}\{D\} \quad \text{(Eq. 4)}$$

where the added salt is MX. The charge balance equation is:

$$[M] + [H] = [OH] + [D] + [X] \quad \text{(Eq. 6b)}$$

Rearranging Eq. 3b yields:

$$\{H\} = \frac{K\{HD\}}{\{D\}} \quad \text{(Eq. 6c)}$$

Substituting for {D} from Eq. 4 into Eq. 6c gives:

$$\{H\} = \frac{K\{HD\}\{M\}}{K_{sp}} \quad \text{(Eq. 6d)}$$

Substituting for {M} from the charge balance equation (Eq. 6b) into Eq. 6d:

$$\{H\} = \frac{K\{HD\}}{K_{sp}}([D] + [X] + [OH] - [H])\,Y_M \quad \text{(Eq. 6e)}$$

Further substitution into Eq. 6e for [D] (from the equilibrium expression) and for [OH] from:

$$K_w = \{H\}\{OH\} \quad \text{(Eq. 6f)}$$

(the ionization constant product of water) results in:

$$\{H\} = \frac{K\{HD\}}{K_{sp}}\left(\frac{K\{HD\}}{HY_1} + [X] + \frac{K_w}{\{H\}Y_{OH}} - \frac{\{H\}}{Y_H}\right)Y_M \quad \text{(Eq. 6g)}$$

Rearranging Eq. 6g results in the quadratic equation:

$$\{H\}^2\left(\frac{K_{sp}}{K\{HD\}Y_m} + \frac{1}{Y_H}\right) - \{H\}[X] - \left(\frac{K\{HD\}}{Y_D} + \frac{K_w}{Y_{OH}}\right) = 0 \quad \text{(Eq. 6h)}$$

Solving Eq. 6h for {H} results in the desired equation for a monoprotic weak acid:

$$\{H\} = \frac{[X] + \left[[X]^2 + 4\left(\frac{K_{sp}}{K\{HD\}Y_M} + \frac{1}{Y_H}\right)\left(\frac{K\{HD\}}{Y_D} + \frac{K_w}{Y_{OH}}\right)\right]^{1/2}}{2\left(\frac{K_{sp}}{K\{HD\}Y_M} + \frac{1}{Y_H}\right)} \quad \text{(Eq. 6)}$$

A similar procedure is followed for a monoprotic weak base, but the solubility product is given by Eq. 5 and the charge balance is given by:

$$[M] + [H] + [HD] = [OH] + [X] \quad \text{(Eq. 7a)}$$

Substitution for {HD} from Eq. 5 is made into Eq. 6c and into the resulting equation for {X}. On rearranging and solving the resulting quadratic expression, Eq. 7 is obtained.

APPENDIX III

The equation for the total solubility of a monoprotic weak acid (Eq. 8) in the region saturated by the charged species D can be derived as follows[17]. Starting with Eq. 2 and substituting for {D} from Eq. 4 gives:

$$S_{1,1} = \left(\frac{1}{Y_D} + \frac{\{H\}}{KY_{HD}}\right)\frac{K_{sp}}{\{M\}} \quad \text{(Eq. 8a)}$$

Substituting into Eq. 8a for {M} from the charge balance equation 6b) results in:

$$S_{1,1} = \left(\frac{1}{Y_D} + \frac{\{H\}}{KY_{HD}}\right)K_{sp}/([D] + [X] + [OH] - [H])Y_M \quad \text{(Eq. 8b)}$$

Substituting Eq. 2 into Eq. 8b for [D], the ionization product constant of water (Eq. 6f) for [OH], and the hydrogen ion activity for [H] gives:

$$S_{1,1} = \left(\frac{1}{Y_D} + \frac{\{H\}}{KY_{HD}}\right)K_{sp}\Bigg/\Bigg(\frac{S_{1,1}}{\left(\frac{1}{Y_D} + \frac{\{H\}}{KY_{HD}}\right)Y_{HD}} + [X] + \frac{K_w}{\{H\}Y_{OH}} - \frac{\{H\}}{Y_H}\Bigg)Y_M \quad \text{(Eq. 8c)}$$

Equation 8c can be rearranged to the quadratic equation:

$$S_{1,1}^2\left[\frac{1}{\left(\frac{1}{Y_D} + \frac{\{H\}}{KY_{HD}}\right)Y_{HD}}\right] + S_{1,1}\left([X] + \frac{K_w}{\{H\}Y_{OH}} - \frac{\{H\}}{Y_H}\right) - \frac{K_{sp}}{Y_M}\left(\frac{1}{Y_D} + \frac{\{H\}}{KY_{HD}}\right) = 0 \quad \text{(Eq. 8d)}$$

Solving Eq. 8d for $S_{1,1}$ results in:

$$S_{1,1} = \frac{-\left([X] - \frac{\{H\}}{Y_H} + \frac{K_w}{\{H\}Y_{OH}}\right) + \left[\left([X] - \frac{\{H\}}{Y_H} + \frac{K_w}{\{H\}Y_{OH}}\right)^2 + 4\frac{K_{sp}}{Y_MY_D}\right]^{1/2}}{2\left(\frac{KY_{HD}}{\{H\}Y_D + KY_{HD}}\right)} \quad \text{(Eq. 8)}$$

A similar procedure is followed for a monoprotic weak base to arrive at Eq. 9. Substitutions are made in Eq. 1 for {HD} (from Eq. 5) and for [X] (from

[17] The charges on the ions have not been included in these equations: H and M are +1; OH, D, and X are −1.

the charge balance equation, Eq. 7a). On solving the quadratic equation, Eq. 9 is obtained.

Pharmacokinetics of Gliclazide in Healthy and Diabetic Subjects

KUNIO KOBAYASHI *x, MASAKO KIMURA *, TAKAFUMI SAKOGUCHI *, AYUMI HASE *, AKIRA MATSUOKA *, and SHIGEO KANEKO ‡

Received May 2, 1983, from the **Department of Clinical Pathology and Clinical Laboratory, Hyogo College of Medicine, Nishinomiya 663, Japan* and ‡*Shinko Hospital, Kobe 651, Japan.* Accepted for publication December 2, 1983.

Abstract □ The pharmacokinetics of total and free gliclazide, 1-(3-azabicyclo[3,3,0]oct-3-yl)-3-(*p*-tolylsulfonyl)urea, a potential hypoglycemic drug, was studied in healthy (n = 12) and diabetic (n = 12) subjects. The serum level of gliclazide was determined by a high-performance liquid chromatographic method (HPLC). The free fraction of gliclazide was obtained from serum by an ultrafiltration technique using a collodion membrane. The mean adsorption of gliclazide to the membrane was ~50% when the membrane was used more than twice. Therefore, the gliclazide level in the filtrate was corrected by doubling the apparent value. The ratio of gliclazide-protein binding remained constant at ~92% in serum after administration to healthy and diabetic subjects. The mean pharmacokinetic parameters of elimination rate (k_e), time to reach the peak level (t_{max}), elimination half-life ($t_{1/2}$), and volume of distribution (Vd) were 0.07 h^{-1}, 2.8 h, 12.3 h, and 17.4 L, respectively. The parameters did not differ significantly between healthy and diabetic subjects or between single and successive administrations; moreover, they did not differ between the free and total drug level. Although there were intersubject variations, the therapeutic effects of oral administration of gliclazide on serum glucose and insulin levels were found in four diabetic patients. The results of this study show that the pharmacokinetics of the total gliclazide level reflect those of the free gliclazide in serum.

Keyphrases □ Gliclazide—protein binding in healthy and diabetic human serum □ Pharmacokinetics—serum gliclazide level after administration in healthy and diabetic subjects □ Ultrafiltration—protein binding of gliclazide in healthy and diabetic human serum

The pharmacokinetic study of serum drug levels is important in the assessment of intrinsic properties of a drug (*e.g.*, absorption, distribution, metabolism, and excretion) to plan effective drug administration. Sulfonylureas, such as tolbutamide and chlorpropamide, bind to several circulating serum proteins (1). In particular, serum albumin strongly interacts with many sulfonylureas (2–4) and other drugs (5). Moreover, free sulfonylureas are the forms that exert the pharmacological effect of hypoglycemic activity (6–8). Therefore, the pharmacokinetics of the free sulfonylurea level in blood may be useful in programming drug administration.

The drug level in a protein-free solution must be measured to determine the free drug level in blood. Ultrafiltration (9), equilibrium dialysis (2, 3, 10), and gel filtration (11) techniques have been used to measure free drug level. Equilibrium dialysis has been commonly used to study the binding of drugs and proteins, but the time required to reach equilibration (8–24 h) is a major disadvantage. Due to simplicity, convenience, and speed, an ultrafiltration technique was used to separate the protein-free phase from serum in the present study.

In this study, a sensitive high-performance liquid chromatographic (HPLC) method (12) was used to determine the total and free levels of gliclazide (13), during a pharmacokinetic study.

EXPERIMENTAL SECTION

Subjects—Twelve male volunteers (age, 32–42 years; weight, 54–72 kg) served as test subjects. All were healthy according to clinical examinations and routine tests. Twelve patients (seven males, five females; age, 35–76 years; weight, 45–80 kg) were patients with maturity-onset diabetes mellitus (FBS: 121–302 mg/100 mL). They did not have impaired renal function, nor hepatic or endocrine disease.

Methods of Drug Administration—One tablet containing 40 mg of gliclazide[1] was administered orally before breakfast to the healthy subjects who had fasted overnight. Blood samples were obtained without an anticoagulant before and at 1, 2, 3, 4, 6, 10, and 24 h after drug administration. After the blood had clotted, the tube was centrifuged at 2500 rpm for 10 min and the supernatant serum was separated. All serum samples were stored at −20°C until use. The volunteers had regular mealtimes throughout the experiment. Twelve diabetic patients were orally administered two tablets containing 40 mg of gliclazide (therapeutic dose) in the morning; eight of them continued to take the drug (40 mg × 2) daily for 7 d. Blood samples were obtained as

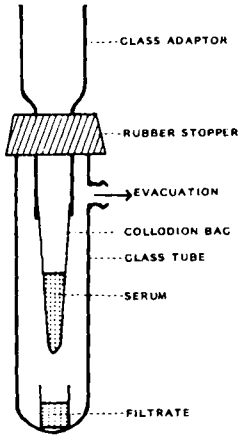

Figure 1—*Ultrafiltration assembly.*

described for the healthy subjects before drug administration and at 1, 2, 4, 6, 8, 12, and 24 h or 2, 6, and 24 h after administration.

Ultrafiltration—Ultrafiltration was performed using the apparatus shown in Fig. 1. A collodion bag[2] with an M_r cutoff of 13,200 was soaked in distilled water overnight before use. The serum samples (3 mL) were ultrafiltrated under reduced pressure (40 mm Hg) at room temperature (25–27°C). The extent of drug–membrane binding was assessed with the same apparatus by substituting 0.066 M phosphate buffer (pH 7.4) containing various concentrations of gliclazide (3–20 μg/mL) for serum. The concentration of free gliclazide in the filtrate (1–2 mL) was determined by HPLC (12). The same collodion bag was used repeatedly by washing with distilled water. Gliclazide level in the filtrate was corrected by doubling the apparent concentration based on the results of a drug-absorption experiment.

Measurements of Serum Gliclazide and Blood Glucose and Insulin Levels—The serum gliclazide level was determined by HPLC[3] (12). The free gliclazide level in the serum was found by determining the level in the filtrate that had passed through a collodion membrane filter at room temperature (25–27°C). Blood glucose and insulin (immunoreactive insulin) levels were measured with an autoanalyzer[4] and a single-antibody RIA (polyethylene glycol method) (14), respectively.

Calculations—Several pharmacokinetic parameters including the elimination rate (k_e, h^{-1}), the elimination half-life ($t_{1/2}$, h), and the area under the serum drug concentration curve (AUC_{0-24}, $\mu g \cdot h \cdot mL^{-1}$) from 0 to 24 h were calculated by conventional methods, and the peak level (C_{max}, μg/mL) and the time to reach the peak level (t_{max}, h) were graphically estimated from the decay curve. The volume of distribution (Vd) was calculated from the following equation proposed by Gibaldi *et al.*: $Vd = \text{dose}/\int_0^\infty C_p dt \cdot k_e^{-1}$, where dose, C_p, $\int_0^\infty C_p dt$, and k_e are the dose of administered drug, the serum level of drug, the area under the serum concentration curve ($AUC_{0-\infty}$), and the elimination rate, respectively. The Student's t test was used for statistical comparisons.

RESULTS AND DISCUSSION

The ultrafiltration techniques using a membrane filter[5] and a collodion membrane were tested for the measurement of free drug level. We chose a collodion membrane for the ultrafiltration because it was more convenient for multisample measurements and was more mechanically stable than other membranes. Many drugs, including sulfonylureas, are adsorbed on the membrane filter during ultrafiltration. We found that the degree of drug adsorption varies with use. We examined the recovery of gliclazide that had filtered through the collodion membrane (Table I). When a fresh membrane was used for the ultrafiltration, the mean recovery of gliclazide in the filtrate was ~27% of the original concentration (3–20 μg/mL). The recovery of gliclazide remained at ~50% when the membrane was used more than twice. If a constant amount of gliclazide was adsorbed in the membrane, the recovery would decrease with low concentrations, but this was not observed; thus, even when the gliclazide concentration was low, the binding constant between the drug and membrane filter remained the same. Based on the result from the drug-absorption experiment, the free gliclazide level in serum was measured by ultrafiltrating the serum sample (using the collodion membrane one time). The gliclazide level in the filtrate was corrected by doubling the apparent concentration.

Table I—Effect of Reuse of Collodion Membrane on Recovery of Gliclazide

	Recovery of Drug in Filtrate, %[b]				
	Original Conc. of Gliclazide, μg/mL				
n[a]	3	5	10	20	Mean ± *SD*
1	31.1	24.5	24.3	28.3	27.1 ± 3.3
2	51.1	45.6	51.4	49.8	49.5 ± 2.7
3	53.7	47.9	50.3	48.5	50.1 ± 2.6

5	50.0	30.7	–	55.8	45.5 ± 13.1

[a] Number of times membrane was used for ultrafiltration. [b] Each value represents the mean of 2–4 experiments. The ultrafiltration was carried out at room temperature (25–27°C).

Although it is known that the pharmacological activity of a sulfonylurea is exerted by free drug in the blood (6), to our knowledge no information on the pharmacokinetics of free sulfonylurea level in the serum has been reported. The decay curve and the pharmacokinetic data for the free gliclazide levels in healthy and diabetic subjects are demonstrated in the present paper. The decay curves of total and free gliclazide levels in the healthy volunteers orally administered the drug (40 mg of gliclazide) are shown in Fig. 2. Individual variation in serum gliclazide level and the time to reach the peak level (t_{max}) was large. The mean values of t_{max} for the total and free gliclazide levels in the healthy subjects were 2.8 and 2.7 h, respectively (Table II). The C_{max} and AUC_{0-24} for the total gliclazide level in the healthy subjects were 2.8 μg/mL and 37.2 $\mu g \cdot h \cdot mL^{-1}$ (40 mg of gliclazide). The mean ratio of free drug level (D_f) to total drug level (D_t) was ~8% during the 24-h period after gliclazide administration. We have reported that the value of C_{max} for the free gliclazide level was 0.11 μg/mL (4) which was half the amount in the present study (0.22 μg/mL). The apparent gliclazide concentration in the filtrate was not corrected, in the former study, for the amount adsorbed to the collodion membrane during ultrafiltration.

Decay curves of blood gliclazide level in diabetic patients who took single and successive administrations of the drug (80 mg/d) are shown in Fig. 3. The decay curve in the single administration had a profile similar to that of the healthy subjects, except for the C_{max} and the drug level 24 h after drug administration. In the case of successive oral administrations of the drug for 7

Method of Administration	Parameters						
	k_e, h^{-1}	C_{max}, μg/mL	t_{max}, h	$t_{1/2}$, h	AUC_{0-24}, μg·h·mL^{-1}	Vd_β, L	n
			Healthy Subject				
Single Dose							
D_t	0.07 ± 0.03	2.8 ± 0.8	2.8 ± 0.9	12.3 ± 6.0	37.2 ± 13.1	17.4 ± 6.7	12
D_f	0.07 ± 0.04	0.22 ± 0.06	2.7 ± 0.8	12.0 ± 0.8	2.8 ± 1.16		6
			Diabetic Subject				
Single Dose							
D_t	0.07 ± 0.02	4.5 ± 2.2	3.0 ± 1.9	11.6 ± 5.2	71.8 ± 6.8	17.9 ± 8.3	12
Successive Dose							
D_t	0.07 ± 0.01 [b]	7.7 ± 2.0 [c]	3.3 ± 1.5 [b]	11.4 ± 2.7 [b]	92.5 ± 19.5 [d]	14.2 ± 7.9	8

[a] Values are mean ± *SD*. [b] Not significantly different from single dose. [c] Significantly different from single dose ($p < 0.1$). [d] Significantly different from single dose ($p < 0.01$).

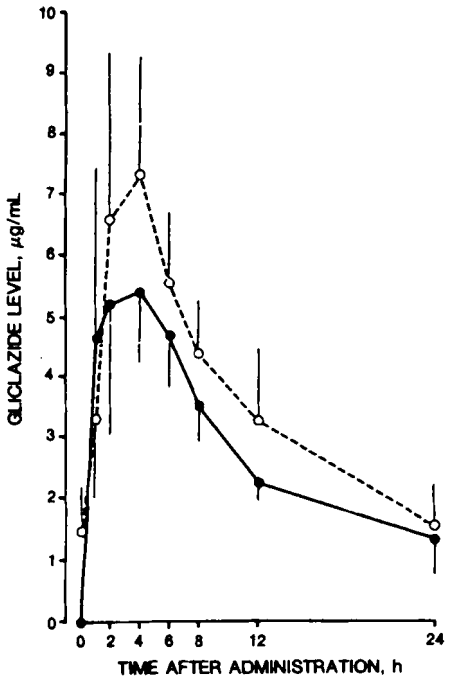

Figure 3—*Decay curves of total gliclazide level in diabetic patients. Each point represents the mean* ± SD *in seven patients who were administered a single dose of gliclazide (80 mg) (●), and four patients who took successive administration of gliclazide (80 mg/d) for 7 d (○).*

d, t_{max} = 3.3 h, was longer compared with 3.0 h for the single administration. The subjects also had higher levels of C_{max} (7.7 μg/mL) and AUC_{0-24} (92.5 μg·h·mL^{-1}) (Table II).

The decay curves of total and free serum gliclazide levels were examined in diabetic patients (Figs. 4A and B). A perfect decay curve for the free gliclazide level in the diabetic patients was not obtained because the amount of serum sample required for the ultrafiltration could not be repeatedly taken. Thus, the pharmacokinetic parameters could not be obtained by computer calculation (Table II). From the available data, the value of t_{max} for total drug level in the diabetic patients was almost equal to that in the healthy volunteers.

The total gliclazide levels reached a maximum (~7.7 μg/mL) 2 h after successive administration, which was higher than that obtained by single administration (4.5 μg/mL at 6 h). The values of C_{max} for free gliclazide levels were nearly equal for the different administration methods (0.47–0.55 μg/mL). The ratio of free drug level (D_f) to total drug level (D_t) in the diabetic subjects administered a single dose was ~8–9%, but the ratio in the diabetic subjects administered successive doses was lower (~7%).

The apparent volume of distribution (Vd) is important in the pharmacokinetic characterization of drugs. However, the calculation of volume of distribution is based on many assumptions and cannot, therefore, be estimated with a high degree of accuracy. Gibaldi *et al.* demonstrated that the volume of distribution was identical to the apparent volume of distribution obtained from the area under the serum concentration curve (AUC) determined by the equation for a two-compartment (α and β) open system (15). The volume of distribution (Vd_β) of gliclazide in healthy and diabetic subjects was 14.2–17.9 L (Table II). There was large intersubject variation in Vd but this could be due to variations in total adsorption that is known to occur with sulfonylureas. The distribution of gliclazide with high protein binding was expected to be confined more to the serum or extracellular fluid volume, as is the case of tolbutamide and chlorpropamide (16).

Effects of oral administration of gliclazide on blood glucose and insulin levels in four diabetic patients (A, B, C, and D) are summarized in Table III. The range of fasting blood glucose levels for the patient was 100–302 mg/100 mL. Although there are intersubject variations, the values of 24-h cumulative blood glucose levels were lowered by the administration of gliclazide (Δ, −177 to −1081 mg/100 mL, determined eight times in 24 h). On the other hand,

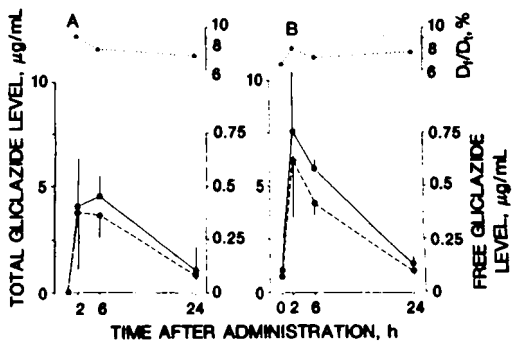

Figure 4—*Decay curves of total (—) and free gliclazide levels (- - -) in diabetic patients, who took single (A) and successive administrations (B) of gliclazide. Each point represents the mean* ± SD *in 3–4 diabetic patients.*

Table III—Effect of Oral Administration of Gliclazide on Blood Glucose and Insulin Levels in Diabetic Patients

Subject	FBS, mg/100 mL [a]	ΣBS, mg/100 mL [a]			ΣIRI, μU/mL [a]			ΣDrug, μg/mL [a]
		Predose	Postdose	Δ	Predose	Postdose	Δ

[a] FBS shows the fasting blood glucose level. ΣBS, ΣIRI, and ΣDrug, respectively, shows the sum level of blood glucose, immunoreactive insulin, and serum gliclazide determined eight times through 24 h. [b] C* is a diabetic patient administered gliclazide successively for 7 d.

the values of 24-h cumulative blood insulin levels were increased by the administration of the drug (Δ, 30-93 μU/mL), resulting in the stimulation of insulin release from pancreatic B cells in all cases. The difference between single and successive administration on cumulative blood glucose levels and cumulative blood insulin levels was not significant in patient C (Table III, footnote *b*).

Secondary Antithyroid Action of Drugs in Relation to Structure

J. BUXERAUD ˣ, A. C. ABSIL, and C. RABY

Received July 13, 1982, from the *Department of Chimica Therapeutica, Faculty of Medicine and Pharmacy, 87032 Limoges Cedex, France.* Accepted for publication November 29, 1983.

Abstract □ Molecular interactions between iodine and disulfiram, clomethiazole, and tolnaftate were investigated by electron spectroscopy. Iodine forms charge transfer complexes with these molecules, with 1:1 stoichiometry and of the n-σ type. The formation constants were compared with those obtained with antithyroid molecules. Only disulfiram appears to have any effect on the intrathyroid cycle of iodine.

Keyphrases □ Charge transfer complexes—iodine and disulfiram, clomethiazole, tolnaftate □ Disulfiram—charge transfer complexes with iodine □ Clomethiazole—charge transfer complexes, iodine □ Tolnaftate—charge transfer complexes, iodine

It has been shown that molecules possessing an NCS moiety can form charge transfer complexes with iodine (1, 2). Both qualitative and quantitative studies have shown that certain antithyroid drugs (those possessing the NCS function) form charge transfer complexes involving the transfer of charge from the pair of free electrons on the nitrogen and/or the sulfur atoms to the antibonding orbital of the iodine (3, 4). The intensity of this action can be determined from the complex formation constant and the thermodynamic parameters. A correlation has been demonstrated between the constant (K_c) and antithyroid activity (5). A structure-activity relationship has been developed to classify all known antithyroid molecules (6). Iodine fixation by complex formation is one action mechanism of synthetic antithyroid agents.

Synthetic antithyroid drugs can also inhibit peroxidase (7). This enzyme is necessary for the oxidation of circulating iodine, for its integration into thyroglobulin, and for coupling monoiodotyrosines and diiodotyrosines to form triiodotyronines (T_3) and tetraiodothyronines (T_4). While antithyroid agents display variable activity towards peroxidase, they can all complex iodine, so that the latter is unavailable for thyroid hormone synthesis.

This NCS function is found in many drugs belonging to other therapeutic classes. Hence, if we hope to understand biological activity it is important to investigate the possible formation of complexes between these molecules (tolnaftate, disulfiram, and clomethiazole) and iodine. This can help determine whether these molecules possess secondary antithyroid activity.

EXPERIMENTAL SECTION

Materials—An ultrapure iodine was prepared by sublimation and stored in a desiccator containing P_2O_5. Disulfiram[1] [tetraethylthioperoxydicarbonic diamide (I)], tolnaftate[2] [*O*-2-napthyl-*m*,*N*-dimethylthiocarbanilate (II)], and clomethiazole[3] [5-(2-chloroethyl)-4-methylthiazole (III)] were pharmaceutical grade; purity was determined by HPLC[4]. UV-grade carbon tetrachloride[5] was used.

UV and visible spectra were recorded on a double-beam spectrophotometer[6] equipped with a Peltier effect thermoelectric cell holder. Hellma quartz cells with a path length of 1 cm were employed.

Methods—The glassware was thoroughly dried with dry nitrogen to eliminate any effects due to hydration of the complex solutions. Volumetric solutions were prepared from initial solutions obtained by weighing. The spectra were recorded immediately after solution preparation.

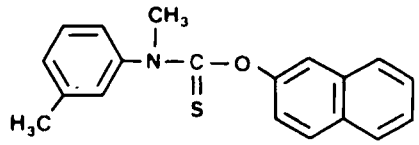
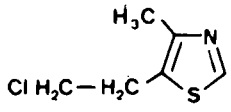
I



II



III

For all equilibrium constant calculations, a series of complex solutions were used with a constant iodine concentration and a variable donor concentration. The solutions were dilute ($\sim 10^{-4}$ M for iodine, $< 5 \times 10^{-2}$ M for tolnaftate and clomethiazole, and $< 4 \times 10^{-3}$ M for disulfiram). Optical densities were determined at three temperatures, 10°C, 20°C, and 30°C (± 0.1°C).

RESULTS

Visible Region— Iodine in solutions of carbon tetrachloride displayed an absorption peak at 515 nm. The donors displayed negligible absorption in the 350–700-nm region. All the complex solution spectra showed a disturbance of the visible band of the halogen consisting of a hypsochromic displacement ($\Delta\lambda$) of the $\pi g \rightarrow \tau_0$ transition of iodine (Fig. 1).

The stability of the complexes was examined by making new recordings after 24 h. Each of the three systems exhibited new absorption bands at 290 and 360 nm, characterizing the presence of I_3^- ions. The changes were greater with higher donor concentrations.

The 1:1 stoichiometry of the complexes was confirmed by analysis of the absorption bands, the accuracy of measurements, and the isosbestic points observed. However, this stoichiometry was checked experimentally by Job's method of continuous variations (8). To do this, the optical densities of the series of complex solutions with constant donor and iodine concentrations were recorded. A correction was made by subtracting from the optical densities recorded, the optical densities of donor and iodine solutions of the same concentration as in the complex solution:

$$A_{corr} = A_{obs} - \epsilon_D \cdot [D] - \epsilon_{I_2} \cdot [I_2] \qquad \text{(Eq. 1)}$$

where A_{corr} is the corrected optical density of the complex, A_{obs} is the optical density of the donor–iodine mixture, ϵ_D and ϵ_{I_2} are the molar absorption coefficients of the donor and iodine, and [D] and [I_2] are the donor and acceptor concentrations, respectively.

The curve obtained by plotting these optical densities for each complex solution against the iodine molar fractions displays a maximum for equal donor and iodine concentrations. The position of the maximum and the perfect symmetry of the curve confirms the presence of a complex with 1:1 stoichiometry and excludes the presence of higher-order complexes (Fig. 2).

The formation constants (K_c) and the absorption coefficients (ϵ_c) of the three donor–iodine systems investigated are given in Table I. These values were determined by using:

$$K_c = \frac{[C]}{([A_0] - [C])([D_0] - [C])} \qquad \text{(Eq. 2)}$$

where [C] is the complex concentration, [A_0] the initial iodine concentration, and [D_0] is the initial donor concentration. [C] can be replaced by the term d_c/ϵ_c leading to:

$$\frac{[A_0][D_0]}{d_c} = \left([A_0] + [D_0] - \frac{d_c}{\epsilon_c}\right) \cdot \frac{1}{\epsilon_c} + \frac{1}{K_c \epsilon_c} \qquad \text{(Eq. 3)}$$

where, at the wavelength investigated, d_c is the absorption of the complex only, ϵ_c is the molar absorption coefficient of the complex, and K_c is the complex formation constant. Equation (3) was resolved by computer using the least-squares method. Graphic representation of the term $[A_0][D_0]/d_c$ as a function of $[A_0] + [D_0] - (d_c/\epsilon_c)$ produces a line with a slope of $1/\epsilon_c$ and an intercept of $1/K_c$ (Fig. 3).

Graphic representation of $R \log K_c$ *versus* $1/T$ yields a line whose slope provides the value of $\Delta H°$, and the intercept determines the value of $\Delta S°$ (Fig.

[c] Six different disulfiram-I_2 solutions; $[I_2]$ 4.242 × 10^{-4} M; [disulfiram] varied from 0.434 × 10^{-3} M to 3.473 × 10^{-4} M. [d] Five different clomethiazole-I_2 solutions; $[I_2]$ 4.580 × 10^{-4} M; [clomethiazole] varied from 1.093 × 10^{-2} M to 5.467 × 10^{-2} M. [e] Values were calculated from absorption data in the visible region.

4). The thermodynamic parameters related to the formation of the complex are given in Table II.

Ultraviolet Region—The donors displayed strong absorption in the UV region (Table III), whereas iodine exhibited weak absorption. The high values of the molar extinction coefficients of the complexes in this spectral region permit the use of much lower donor concentrations than those required for the visible spectra.

The absorption bands due to the intermolecular charge transfer around 300 nm are superimposed on iodine and especially for donor absorption (Fig. 5). Analysis of these bands is therefore inaccurate and is limited only to qualitative results. Charge transfer bands, calculated graphically, are located at ~338 nm for the tolnaftate-iodine complex, at 310 nm for the disulfiram-iodine complex, and at 276 nm for the clomethiazole-iodine complex. The absorption intensity of the charge transfer bands increases with donor concentration and declines sharply with increasing temperature (Fig. 6). After 24 h the spectra

three absorption bands located at 290 and 360 nm (I_3^- ions) and 310 nm (charge transfer band).

DISCUSSION

Spectroscopic observations in the visible and UV regions confirm the n-σ character of the charge transfer complexes formed by iodine with disulfiram, tolnaftate, and clomethiazole. The 1:1 stoichiometry of these complexes is confirmed by analysis of the absorption bands, measurement accuracy, isosbestic points observed, and Job's method of continuous variations.

In agreement with Mulliken (9) and Popov and Deskin (10), the formation of I_3^- ions is caused by the conversion of an outer complex into an inner complex, releasing I^- ions which act on the free molecular iodine:

1. Disulfiram + I_2 ⇄ disulfiram-I_2 (outer complex)
2. Disulfiram-I_2 ⇄ disulfiram-I^+I^-
3. Disulfiram-I^+I^- ⇄ (disulfiram-I)$^+$ + I^- (inner complex)
4. I^- + I_2 ⇄ I_3^-

Reaction 2 occurs slowly, while the other three reactions display rapid kinetics.

Table IV—Comparison of Formation Constants of Iodine Complexes Obtained with Antithyroid Drugs and with Clomethiazole, Tolnaftate, and Disulfiram

	K_c at 20°C, L · mol^{-1}	Solvent
Potassium thiocyanate	94 (at 22°C)[a]	H_2O
2-Thiazoline-2-thiol	2527 ± 118[a]	CCl_4
Thiourea	8825 ± 505[a]	CH_2Cl_2
Tetramethylthiourea	13215 ± 1150[a]	*n*-Heptane
2-Mercapto-1-methylimidazole	23194 ± 667[a]	CCl_4
Clomethiazole	25.00 ± 0.19	CCl_4
Tolnaftate	56.65 ± 0.96	CCl_4
Disulfiram	296.78 ± 4.44	CCl_4

[a] From Ref. 5.

The formation constants K_c of the iodine complexes of tolnaftate, disulfiram, and clomethiazole were compared with those obtained for antithyroid molecules (Table IV).

Antithyroid compounds are stronger donors for iodine than tolnaftate, disulfiram, and clomethiazole. Only disulfiram displayed a constant higher than that of potassium thiocyanate, whose antithyroid action is well known. Without totally inhibiting the synthesis of thyroid hormones, disulfiram appears to diminish this formation and interferes with it, causing the formation of a goiter. This property has been reported in a clinical study (11).

Kinetic Study of the Hydrolysis of 1-(4-Nitrophenyl)-3-methyltriazene in Aqueous Solution and in the Presence of Surfactants

CYNTHIA EBERT, LUCIA LASSIANI, PAOLO LINDA *x, MARA LOVRECICH, CARLO NISI, and FULVIO RUBESSA

Received June 3, 1983, from the *Istituto di Chimica Farmaceutica*, and the **Istituto di Chimica, Università di Trieste, Italy.* Accepted for publication February 16, 1984.

Abstract □ The hydrolysis of 1-(4-nitrophenyl)-3-methyltriazene in aqueous solution has been studied over a pH range of 3–14. The effect of the anionic and cationic surfactants (sodium lauryl sulfate and hexadecyltrimethylammonium bromide) on the rate of hydrolysis was investigated. The quaternary ammonium bromide causes a rate decrease at all pH values studied, while sodium lauryl sulfate enhances the acid-catalyzed hydrolysis and decreases the observed rate constants in the pH-independent region. The results are discussed in terms of the current theory of micellar effects.

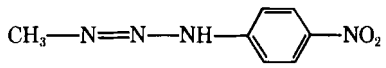
Keyphrases □ 1-(4-Nitrophenyl)-3-methyltriazene—kinetic study of the hydrolysis, effects of sodium lauryl sulfate and hexadecyltrimethylammonium bromide

The hydrolysis of arylmonoalkyltriazenes has been studied extensively (1–3). These substances are important as *in vivo* metabolites of the corresponding aryldialkyltriazenes, a class of compounds possessing antitumor (4–6), carcinogenic (7–9), and mutagenic (10–12) activity.

The pH-rate profiles in aqueous solution of various 1-aryl-3-methyltriazenes (1) and 1-phenyl-3-propyltriazenes (3) show two different regions; the rate of hydrolysis decreases sharply with increasing pH and then becomes almost constant. The plateau region is shifted to lower pH values by electron-withdrawing substituents in the aryl moiety. It has been postulated that the acid-catalyzed reaction involves an alkanediazonium ion as an intermediate or a protonated triazene as a discrete intermediate whose formation is rate determining. In the pH-independent region, a mechanism consisting of a simple unimolecular heterolysis of a nitrogen–nitrogen bond with anilide ion departing from an alkanediazonium ion was formulated (3).

Furthermore, the influence of serum albumins on the rates of some arylmonomethyltriazenes in buffered aqueous solution was also investigated (13). It was shown that the presence of these proteins in solution caused a marked reduction in the decomposition rates of the triazenes. The experimental results were interpreted by assuming that the substrates interact rapidly and reversibly with a binding site on the protein and that they cannot decompose when bound to this site.

The aim of the present work was to complete the pH–rate profile for a representative triazene, 1-(4-nitrophenyl)-3-methyltriazene (I), above pH 10 since systematic data of kinetic runs in this pH region were lacking. Furthermore, we studied the influence of the addition of cationic and anionic surfactants, above their critical micelle concentration (CMC), on the decomposition rate. During the past decade studies of this phenomenon have been stimulated by the hope that a micellar-catalyzed reaction might provide a basic model for interpretation of some aspects of enzymatic catalysis since micelles can be regarded as a model for enzymes and biomembranes (14–16). The effect of the micelles on drug stability has been recently reviewed (17).



EXPERIMENTAL SECTION

Materials—1-(4-Nitrophenyl)-3-methyltriazene (I) was prepared as described previously (18), mp 112–113°C [lit. (18) mp 111–113°C]. Hexadecyltrimethylammonium bromide and sodium lauryl sulfate were purified by methods described previously (19). The buffers used were: formate (pH 3.0–4.2), succinate (pH 4.5–6.0), phosphate (pH 6.5–8.0), borate (pH 9.0), carbonate (pH 10.0–11.0), and phosphate (pH 11.0–12.0).

Kinetic Methods—The triazene was dissolved in acetonitrile to give a 2×10^{-2} M stock solution which was stored in the refrigerator. This solution (10 μL) was added to a volume of the buffer in a quartz cell thermostated at 25 ± 0.1°C to obtain a concentration of the substrate on the order of 10^{-5} M. The ionic strength was kept constant at 0.01. The pH values were determined with a digital pH-meter[1] at the temperature of the kinetic run for reactions in water. The analytical pH was used for reactions in the presence of surface-active agents—as the apparent pH in micelles. The decomposition reactions were followed spectrophotometrically[2] at 350 nm when the disappearance of protonated or neutral triazene was followed, or at 470 nm when anionic triazene was present. These wavelengths were chosen to permit maximum variation and minimum interference with the spectrum of the decomposition product. The spectrum at the end of the reaction was coincident with that of *p*-nitroaniline. Absorbances were recorded as a function of time. Pseudo-first-order rate constants were calculated using a least-squares method. Correlation coefficients were between 0.994 and 0.999.

RESULTS AND DISCUSSION

Hydrolysis in Aqueous Solution—Figure 1 shows the dependence on pH of the first-order rate constant for the decomposition of I which is consistent with that obtained for 1-(4-nitrophenyl)-3-propyltriazene by Sinnot *et al.* (3). Two routes for the triazene decomposition were confirmed: a pH-independent pathway and an acid-catalyzed reaction with a negative slope (~1, Table I). The acid-catalyzed reaction pathway was interpreted as an $A\text{-}S_E2(N)$ reaction involving a transition state in which the proton is almost completely transferred and little N—N bond-breaking has occurred, whereas the pH-independent reaction was considered as an S_N1 reaction on nitrogen without participation of water (3).

Above pH 12.5, a third region was observed with a negative slope (~1); in this case the formation of the anionic triazene was shown by a change in the visible spectrum (Fig. 2). We suggest that the decrease in log k_{obs} in this pH region is essentially due to the diminution of the reactive neutral triazene involved in the acid–base equilibrium.

The suggested overall mechanism of the reaction is described in Scheme I, where T is the unprotonated, TH^+ the protonated, and T^- the deprotonated, triazene.

$$T^- + H^+ \underset{K_2}{\rightleftharpoons} T + H^+ \underset{K_1}{\rightleftharpoons} TH^+ \xrightarrow{k_1} \text{products}$$

$$\downarrow k_2$$

$$\text{products}$$

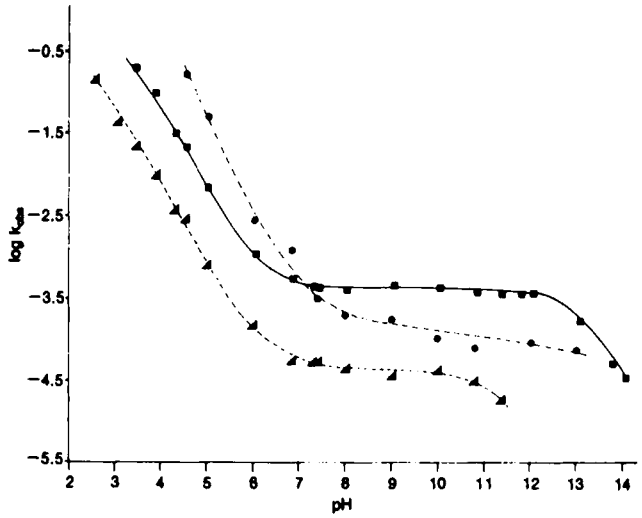

Figure 1—*Log k_{obs}-pH profile of I. Key: (■) in buffered aqueous solution at 25°C and μ = 0.01, calculated according to Eq. 1; (▲) in presence of 2 × 10^{-2} M hexadecyltrimethylammonium bromide; (●) in presence of 2 × 10^{-2} M sodium lauryl sulfate.*

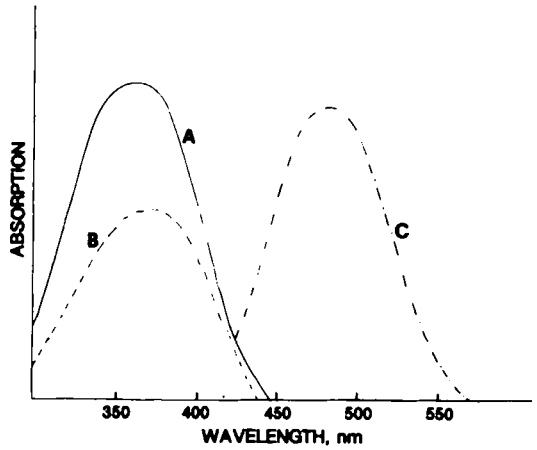

Figure 2—*Changes in visible absorption spectra in buffered aqueous solution. Key: (A) neutral triazene, pH 8.45 (I); (B) p-nitroaniline, pH 8.45; (C) the anionic form of triazene, 1M NaOH (I).*

Equation 1 represents the rate law for the mechanistic scheme:

$$k_{obs} = \frac{k_1[H^+]^2 + k_2K_1[H^+]}{[H^+]^2 + K_1[H^+] + K_1K_2} \qquad \text{(Eq. 1)}$$

The curve fitting of this equation is reported in Fig. 1 according to the following parameters: $k_1 = 0.5\ s^{-1}$; $k_2 = 3.5 \times 10^{-4}\ s^{-1}$; $K_1 = 7.9 \times 10^{-4}$ M; $K_2 = 1.0 \times 10^{-13}$ M. The estimated value of $pK_2 = 13.0$ is reasonable as compared, for example, with the $pK_a = 12.31$ measured for the deprotonation of *p*-nitroformanilide (20).

Inhibition of Hydrolysis by Hexadecyltrimethylammonium Bromide—Cationic micelles of hexadecyltrimethylammonium bromide inhibit the hydrolysis rate at any pH value considered (Table II). As expected, cationic micelles of hexadecyltrimethylammonium bromide inhibit the acid hydrolysis of I. The variation of rate constant with surfactant concentration is generally based on the assumption that substrate, in this case triazene (T), is distributed between the aqueous and micellar pseudophases, with the first-order rate constants designated as $k_{w'}$ and $k_{m'}$. The micellar surfactant concentration, $[D_n]$, is assumed to be the total surfactant concentration [D] less that of monomeric surfactant which is assumed to be given by critical micelle concentration (CMC), so that $[D_n] = [D] - CMC$; K_s is the equilibrium constant for substrate binding.

$$T + D_n \underset{}{\overset{K_s}{\rightleftharpoons}} TD_n$$

$$\downarrow k_{w'} \qquad \downarrow k_{m'}$$

products products

$$K_s = \frac{[TD_n]}{[T][D_n]}$$

Scheme II

Following Scheme II the relation between k_{obs} and $[D_n]$ is shown by:

$$k_{obs} = \frac{k_{w'} + k_{m'}K_s[D_n]}{1 + K_s[D_n]} \qquad \text{(Eq. 2)}$$

and its rearrangement gives:

$$\frac{1}{k_{w'} - k_{obs}} = \frac{1}{k_{w'} - k_{m'}} + \frac{1}{(k_{w'} - k_{m'})K_s([D] - CMC)} \qquad \text{(Eq. 3)}$$

By plotting $1/(k_{w'} - k_{obs})$ against $1/([D] - CMC)$ it is possible to calculate

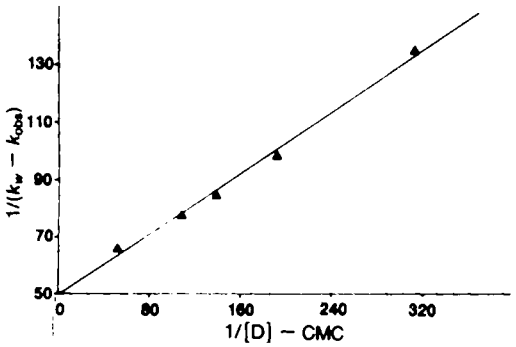

Figure 3—*The effect of hexadecyltrimethylammonium bromide on* k_{obs} *at pH 4.50 according to Eq. 2.*

$k_{w'}$, $k_{m'}$, and K_s. However, this plot is sensitive to CMC values and, as previously shown, this problem can be solved by assuming CMC as an adjustable parameter (21); a representative plot is shown in Fig. 3.

At pH 4.50 the best fit is obtained by taking CMC = 8 × 10^{-4} M, which is identical to the value determined by the surface tension method (22); then K_s = 180 M^{-1}. Similar treatment with data obtained at pH 7.30, 8.45, and 12.02 gives the results listed in Table III. Under these conditions $k_{m'}$ is very small relative to $k_{w'}$. From the estimated binding constants and pH-rate profile in micelles, it can be observed that the substrate in its neutral form is moderately bound to hexadecyltrimethylammonium bromide micelles while the anionic form, which is present at pH 12.02, is strongly bound (K_s = 35,000 M^{-1}). Also, the equilibrium between neutral triazene and its anionic form is strongly shifted by hexadecyltrimethylammonium bromide toward the anionic form, *i.e.*, the apparent pK_a value of triazene is changed by stabilization of the anionic form by cationic micelles. These effects of micelles on equilibria have been previously reported by Bunton *et al.* (23).

Hydrolysis in Presence of Sodium Lauryl Sulfate—The anionic sodium lauryl sulfate micelles enhance the rate of acid-catalyzed hydrolysis by a factor of ~10 at pH 4.5–6.0, as shown in Table I. Otherwise, sodium lauryl sulfate inhibits the uncatalyzed reaction by a smaller factor (~2).

For a given hydrogen ion concentration, the rate constants go through a maximum with increasing concentration of the anionic surfactant (Table IV). At pH 4.50 the largest enhancement occurs at 2 × 10^{-2} M sodium lauryl sulfate and the rate constant is approximately 10-fold higher than that determined in water.

The kinetic micellar effect could be interpreted by separation of the contributions of the reaction in the aqueous and micellar pseudophases, as reported (21). The quantitative treatment requires knowledge of the binding constant of triazene with micellar sodium lauryl sulfate. Unfortunately, we cannot measure or estimate K_s. However, the results in the acid-catalyzed region confirm the importance of the stabilization of the protonated form of the triazene in anionic micelles causing a change in its pK_a value.

The "Uncatalyzed" Reaction in Presence of Sodium Lauryl Sulfate and Hexadecyltrimethylammonium Bromide—The inhibition caused by both anionic and cationic micelles is not surprising since the transition state for the S_N1 decomposition of the triazene should have a strong zwitterionic character and, therefore, should be destabilized in the less polar micellar medium, whereas the initial state should be stabilized. Inhibitory effects by hexadecyltrimethylammonium bromide micelles have been previously found in the S_N1 reaction of 1-bromo-2-phenylpropane (24) and of 3-bromo-3-phenyl propionate ion (25) and by both hexadecyltrimethylammonium bromide and sodium lauryl sulfate on the S_N1 reaction of α-phenylallyl butanoate (26). These effects are comparable to the well-known effects of solvent on S_N1 reactions (27, 28).

Kinetics and Mechanism of Enzymatic Hydrolysis of Pivampicillin Monolayers

O. VALLS, M. ALVAREZ, A. ALSINA, and S. GARCÍA FERNANDEZ ˣ

Received May 19, 1982, from the *Department of Physical-Chemistry, Faculty of Pharmacy, University of Barcelona, Spain.* Accepted for publication October 17, 1983.

Abstract □ A study of the enzymatic hydrolysis of pivampicillin (an insoluble penicillin) extended as a monolayer on the aqueous interface at a constant surface pressure has been performed. Penicillinase promotes intensive hydrolysis of the pivampicillin monolayers, inducing their solubility. However, no action was observed with dog liver esterase. The hydrolytic process, which was dependent on the film surface pressure and on the quantity of the injected enzyme, is of the Michaelis-Menten type in two dimensions.

Keyphrases □ Pivampicillin—enzymatic kinetics, surface monolayers, penicillinase, esterases □ Kinetics—enzymatic, pivampicillin, surface monolayers, Michaelis-Menten

The catalytic action of an enzyme can generally be measured by the quantity of transformed substance or by the product generated per unit of time. The processes of enzymatic kinetics in bulk materials are usually Michaelis-Menten in character (1). Under these conditions, both soluble substrates and enzyme-substrate complexes are in a homogeneous system. However, insoluble substrates are normally in the form of micellar aggregates, which act as the real substrate. In such cases, study of the kinetics is complicated by the difficulty of knowing the concentration of substrate in contact with the enzyme.

This difficulty can be overcome by extending the insoluble substrate as a monolayer film over an aqueous mass which contains the soluble enzyme. Under these conditions, all the molecules of substrate are equally exposed to the action of the enzyme. Thus, it is possible to quantitate the amount of substrate in contact with the enzyme (by controlling its surface concentration in the film) and the amount of enzyme reacting with the surface (by controlling its concentration in the subphase). This system makes it possible to obtain information about action of the enzyme sites in the substrate molecules.

The first studies of enzymatic kinetics using the surface monolayer technique were performed by Hughes (2) in 1935. Measuring the decrease in surface potential during the hydrolysis process, Hughes observed that the hydrolysis rate of lecithin in monomolecular films catalyzed by phospholipase A_2 decreased when the surface concentration of the lecithin molecules in the interface increased. This method is, however, subject to significant errors in interpretation.

Since that time, several authors have used the monolayer technique to measure the activity of lipolytic processes catalyzed by lipases and phospholipases. Short-chain phospholipids and triglycerides were used as substrates so that the reaction products would be soluble and, therefore, diffuse into the aqueous subphase, leaving the monolayer. Garner and Smith (3) performed these determinations in a constant area, measuring the decrease of the monolayer surface pressure as the substrate was dissolved by the lipolytic effect of the enzyme. An inherent difficulty of this method is that the surface concentration of the film molecules vary continually during the process; therefore, the decrease of the surface pressure is linear with respect to time only in the first moment. Lagocki *et al.* (4), Dervichian (5), and Verger and de Haas (6) used methods with constant pressure, measuring the kinetic rate by the decrease of the area covered by the film (directly connected with the number of substrate molecules which escape from the surface).

The method of "zero-order trough" or "two-compartment trough" proposed by Verger and de Haas (6) is particularly interesting. In this method the enzymatic reaction takes place in a different compartment than the one which acts as a substrate reservoir. In this way, the number of the substrate molecules in the reaction compartment can be kept constant during the entire process. The process develops in a pseudo-zero-order manner, *i.e.*, the decrease of the monolayer area is proportional to time, yielding a straight line, the course and slope of which give the rate of the kinetic process.

Kinetic studies have been performed on monolayers of insoluble penicillins (7). The penicillin molecules are transformed by hydrolysis into soluble products that leave the monolayer and dissolve in the aqueous subphase. The number of hydrolyzed molecules can be determined by the monolayer surface decrease, maintaining a constant surface pressure at all times (Fig. 1).

For this type of study, pivampicillin is a particularly interesting test drug. It is a penicillin which is insoluble in neutral solutions and soluble in acidic media. Pivampicillin is activated by esterases, which transform it into ampicillin (8), and it is

The catalytic action of an enzyme can generally be measured by the quantity of transformed substance or by the product generated per unit of time. The processes of enzymatic kinetics in bulk materials are usually Michaelis-Menten in character (1). Under these conditions, both soluble substrates and enzyme-substrate complexes are in a homogeneous system. However, insoluble substrates are normally in the form of micellar aggregates, which act as the real substrate. In such cases, study of the kinetics is complicated by the difficulty of knowing the concentration of substrate in contact with the enzyme.

This difficulty can be overcome by extending the insoluble substrate as a monolayer film over an aqueous mass which contains the soluble enzyme. Under these conditions, all the molecules of substrate are equally exposed to the action of the enzyme. Thus, it is possible to quantitate the amount of substrate in contact with the enzyme (by controlling its surface concentration in the film) and the amount of enzyme reacting with the surface (by controlling its concentration in the subphase). This system makes it possible to obtain information about action of the enzyme sites in the substrate molecules.

The first studies of enzymatic kinetics using the surface monolayer technique were performed by Hughes (2) in 1935. Measuring the decrease in surface potential during the hydrolysis process, Hughes observed that the hydrolysis rate of lecithin in monomolecular films catalyzed by phospholipase A_2 decreased when the surface concentration of the lecithin molecules in the interface increased. This method is, however, subject to significant errors in interpretation.

Since that time, several authors have used the monolayer technique to measure the activity of lipolytic processes catalyzed by lipases and phospholipases. Short-chain phospholipids and triglycerides were used as substrates so that the reaction products would be soluble and, therefore, diffuse into the aqueous subphase, leaving the monolayer. Garner and Smith (3) performed these determinations in a constant area, measuring the decrease of the monolayer surface pressure as the substrate was dissolved by the lipolytic effect of the enzyme. An inherent difficulty of this method is that the surface concentration of the film molecules vary continually during the process; therefore, the decrease of the surface pressure is linear with respect to time only in the first moment. Lagocki *et al.* (4), Dervichian (5), and Verger and de Haas (6) used methods with constant pressure, measuring the kinetic rate by the decrease of the area covered by the film (directly connected with the number of substrate molecules which escape from the surface).

The method of "zero-order trough" or "two-compartment trough" proposed by Verger and de Haas (6) is particularly interesting. In this method the enzymatic reaction takes place in a different compartment than the one which acts as a substrate reservoir. In this way, the number of the substrate molecules in the reaction compartment can be kept constant during the entire process. The process develops in a pseudo-zero-order manner, *i.e.*, the decrease of the monolayer area is proportional to time, yielding a straight line, the course and slope of which give the rate of the kinetic process.

Kinetic studies have been performed on monolayers of insoluble penicillins (7). The penicillin molecules are transformed by hydrolysis into soluble products that leave the monolayer and dissolve in the aqueous subphase. The number of hydrolyzed molecules can be determined by the monolayer surface decrease, maintaining a constant surface pressure at all times (Fig. 1).

For this type of study, pivampicillin is a particularly interesting test drug. It is a penicillin which is insoluble in neutral solutions and soluble in acidic media. Pivampicillin is activated by esterases, which transform it into ampicillin (8), and it is

quickly inactivated by the action of β-lactamase enzymes secreted by penicillin-resistant microorganisms, *i.e.*, penicillinase (9). A previous study (7) with this antibiotic verified that stable monolayers can be obtained which, through the activity of hydrolytic agents, become soluble and pass into the aqueous subphase. It is possible, therefore, to perform kinetic studies on a monolayer of pivampicillin.

The results of the acid and alkaline hydrolysis of monomolecular films of pivampicillin and the first results of hydrolysis by β-lactamases have been presented previously (7). In the present study the kinetic processes of hydrolysis by an esterase and β-lactamase on monomolecular films of pivampicillin are amplified and debated.

EXPERIMENTAL SECTION

For this study a surface manometer, designed and built in our laboratory based on the pseudo-zero-order system proposed by Verger *et al.* (6), was used; this manometer was described in detail in a previous work (10). It has a barostatic system, allowing the maintenance of constant pressure and the direct registration of the variation of the monolayer area through time. Sörensen buffer (pH 7) was used as the base liquid of the film, filling both sections of the trough (11). The buffer was prepared with twice-distilled water, potassium phosphate[1], and disodium phosphate[1].

Purified technical-quality pivampicillin[2] was used for preparation of the substrate monolayer; a 10^{-5} M solution of this substance in 20% absolute ethanol–80% petroleum ether (bp 40–60°C) was used. The solvent evaporated spontaneously within ~60 s after extension, leaving a monomolecular film of the antibiotic over the aqueous surface. In each case, a variable volume of solution was spread; the resulting film was compressed, reducing its surface until the desired surface pressure for the kinetic studies was obtained. The initial surface concentration (C) of the substrate molecules in the film was calculated from the amount of penicillin extended and the total area (in cm^2) occupied initially by the film in both compartments.

While under constant agitation, 10–100 μL of enzyme solution was injected under the monolayer in the reaction compartment. The injected enzymes were an esterase and a penicillinase. The esterase used (type I from dog liver) is a carboxyesterase (E.C. 3.1.1.1)[3]. One unit of this enzyme hydrolyses 1.0 μmol of ethyl butyrate/min at pH 8 and 25°C. The enzyme (100 U/mg of protein) was used in a buffered phosphate solution at pH 8, at a concentration of 1000 IU/mL. The penicillinase, from *Bacillus cereus* (40,000 IU/mg), is a penicillinamide β-lactamhydrolase (E.C. 3.5.2.6)[4]. One international unit inactivates 1 U of penicillin/min at pH 7 and 25°C. It was used in a buffered phosphate solution at pH 7, at a concentration of 400,000 IU/cm^3.

The recording of the kinetic process (variation of the film area against time) started immediately after enzyme addition and continued for 60–120 min. The number of hydrolyzed molecules was calculated from the displacement of the mobile barrier, taking into account that a 1-cm displacement corresponds to a surface decrease of 17.5 cm^2 and to a number of hydrolyzed molecules equal to 17.5C (molecules/cm^2). A linear representation was obtained in the zero-order trough by plotting the number of hydrolyzed molecules against time. The type of slope allowed us to calculate the velocity of the hydrolytic process (molecules·cm^{-2}·min^{-1}).

RESULTS

The injection of dog liver esterase under the monolayer of pivampicillin, at final concentrations from 100 to 10,000 IU/100 mL of subphase and at starting film pressures from 1×10^{-3} to 2×10^{-2} N·m^{-1}, produced neither solubilization of the monolayer nor a real decrease of the starting pressure of the film over a 2-h period. After the injection of the enzyme, however, the surface pressure of the monolayer increased. This demonstrates penetration of the esterase in the penicillin film, but without a hydrolytic effect on pivampicillin.

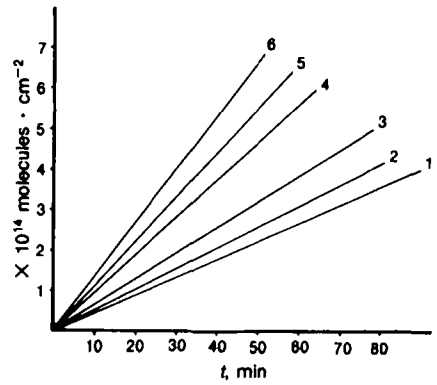

Figure 2—*Activity of the hydrolysis of pivampicillin films by penicillinase (4000 IU) at different film surface pressures. Key: (1) 4.2 × 10^{-3} N·m^{-1}; (2) 6.7 × 10^{-3} N·m^{-1}; (3) 8.4 × 10^{-3} N·m^{-1}; (4) 12.4 × 10^{-3} N·m^{-1}; (5) 13.9 × 10^{-3} N·m^{-1}; (6) 16.7 × 10^{-3} N·m^{-1}.*

The injection of penicillinase produced a rapid hydrolysis and solubilization of the pivampicillin, which manifested itself in a decrease in the monolayer area at constant surface pressure, after the short induction time (τ) necessary for the enzyme to penetrate the monolayer. The rate at which the substrate molecules leave the surface depends on the surface pressure of the film and the quantity of the enzyme injected.

In all cases, the activity of the process (hydrolyzed molecules by unit of surface), after the induction time (τ), was directly proportional to time, *i.e.*, it was a pseudo-zero-order process. As a result, the graphic representation of the activity against time was a straight line during the initial 60 min, after which the line curved slightly as the process decreased.

Figure 2 shows the hydrolytic activity (in hydrolyzed molecules per square centimeter of monolayer surface) in the reaction compartment *versus* time at different surface pressures after the injection of 4000 IU of penicillinase. After a short induction time (τ) the curve straightened until the final stage of the process. When the surface pressure of the film increases, the reaction rate also increases, tending to stabilize at high pressures (Fig. 3).

The activity of the hydrolytic process is strongly influenced by the amount of injected enzyme. This can be seen in Fig. 4, where the hydrolyzed substance is set against time, at a constant surface pressure of 4.2 × 10^{-3} N·m^{-1}, for different amounts of injected penicillin in the reaction compartment (4000–12,000 IU). As can be seen in Fig. 5, the reaction rate (hydrolyzed molecules per milliliter and per minute) increases with the amount of enzyme, giving a straight line.

The induction time (τ) decreases when the surface pressure of the film increases, stabilizing at high pressures (Fig. 6). The induction time also decreases when the amount of injected enzyme increases.

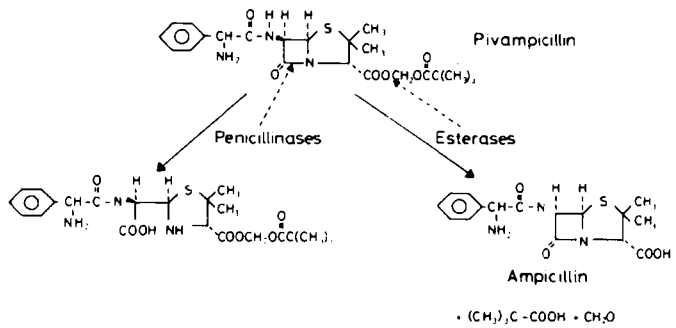
DISCUSSION

The pivampicillin molecule has two points especially sensitive to the hydrolytic process (Scheme I): the ester bond which forms the nucleus of 6-aminopenicillanic acid with the pivaloyl alcohol, and the β-lactamic bond of the 6-aminopenicillanic acid. Hydrolysis of the ester bond is produced through the effect of the blood esterases once the antibiotic has been absorbed, converting the antibiotic into active ampicillin, while the nonactive pivaloic ester (pivampicillin) is better absorbed through the digestive tract than the ampicillin itself (8).



Scheme I—Hydrolysis process of the pivampicillin by esterases and penicillinases.

The *in vitro* studies with bulk material performed by Yokota *et al.* (12) seem to indicate that the enzyme responsible for this hydrolytic process is a carboxyesterase (E.C. 3.1.1.1). But the results reported in the present study indicate that this enzyme is inactive, even when tested at very high concentrations. This fact can be interpreted in different ways: (*a*) lack of specificity of the enzyme with the substrate, which would contradict the results obtained by Yokota; (*b*) liberation of insoluble products, which is not very likely because the pivaloic alcohol and the ampicillin are extraordinarily soluble under the current experimental conditions; or (*c*) inactivation of the esterase enzyme in the interface (the more probable of the three interpretations). The latter would be in agreement with the results obtained in 1958 by Sarda and Desnuelle (13), who, using triacetin as a substrate in the monolayer, found very low hydrolytic activity for the esterase compared with that of the pancreatic lipase normally used in kinetic studies of lipolysis. Finally, the possibility exists that the ester group, due to the relatively large size of the molecule of pivampicillin, must be situated in the air–water interface in order to be reached by the enzyme molecules penetrating the monolayer from the aqueous subphase.

Compared with this poor hydrolytic esterase effect, the penicillinase produced a quick hydrolysis of the pivampicillin, with a rupture of the β-lactamic bond and solubilization of the penicillin, which let the monolayer pass into the aqueous subphase. Pivampicillin is normally considered more resistant than ampicillin to the action of β-lactamase enzymes, but more sensitive than other "resistant" penicillins. The resistance of pivampicillin to the penicillinase is due to the steric effect that results from the esterification of the ampicillin carboxyl group. This chemical modification makes access of the enzyme to the active site in the β-lactamic nucleus more difficult (9). In spite of this, β-lactamase has been shown in this report to be very active in the monolayer, producing hydrolysis of all the molecules in a few minutes.

The process for enzymatic reactions in monolayers, according to a general scheme proposed by Verger *et al.*, (14), takes place in three stages. In the first stage, the enzyme penetrates the monolayer in a reversible process, with a penetration constant K_p and a desorption constant K_d; with time an equilibrium is reached, so that the amount of the enzyme penetrated is equal to that desorbed. In the second stage, also reversible, an enzyme–substrate complex (of the Michaelis–Menten type) is made, with a formation constant K_m. Finally, the enzyme–substrate complex is broken, freeing the enzyme (which remains in the monolayer) and the soluble reaction product(s) (which dissolves in the aqueous subphase), with a velocity regulated by a catalytic constant K_{cat}.

This model has been discussed based on the results obtained by Dervichian (15). However, it adapts well to the results obtained in studying the enzyme kinetics of penicillin hydrolysis in monolayers by penicillinases.

At the beginning of this process, the penicillinase has to penetrate the monolayer, improving the velocity of reaction until it reaches an equilibrium between the adsorption and desorption of enzyme molecules, and the number of molecules which exist in the monolayer remains constant. This requires an induction time (τ), after which the reaction rate is constant (a pseudo-zero-order process).

The results obtained fit also with the equation proposed by Verger *et al.* (14):

$$V_m = \frac{K_{cat} E_0 S}{K_d / K_p \cdot K_m}$$

where V_m is the velocity of the process under steady-state conditions, *i.e.*, when the concentration of the intermediate products remains constant and, thus, the velocities of formation and decomposition of the enzyme-substrate complex are equal; E_0 is the enzyme concentration in the subphase; S is the surface concentration of substrate in the monolayer; K_m is the Michaelis-Menten interfacial constant ($K_{cat} + K_d/K_p$); and K_p and K_d are the penetration and desorption constants of the enzyme. As can be seen in this equation, the hydrolysis rate of the pivampicillin must increase proportionately with the increase of the enzyme concentration, which agrees with the results shown in Fig. 5.

The increase of the reaction rate with increasing surface pressure in the monolayer can be interpreted only when the increase in the pressure causes a higher surface concentration. One must remember, however, that the increase of surface pressure reduces the penetration capacity of the enzyme in the monolayer, as shown by Verger *et al.* (16) using radioactive enzymes. These two phenomena are the reason that a pressure of maximum activity can normally be reached, varying according to the enzyme and substrate used, after which the velocity of reaction decreases. In the process of the hydrolysis of pivampicillin by penicillinase, it has been impossible to reach this maximum value. However, using Fig. 4, one can assume that this maximum is found at $1.7\text{-}1.8 \times 10^{-2}$ N·m^{-1}.

Finally, one fact in this study that might be considered paradoxical is the decrease of the induction time (τ) when the surface pressure of the monolayer is increased (Fig. 6). That is, the enzyme penetrates more quickly in monolayers which are tightly compacted than in the monolayers in which the molecules of penicillin are free, leaving large intermolecular spaces. This effect can be interpreted as a result of the improvement of the "quality of the interface," especially as to the packing of the substrate molecules, which [as was demonstrated by Slotboom *et al.* (17)] influence the kinetic parameters of the enzyme, especially increasing the value of the penetration constant K_p.

Time-Dependent Elimination of Cinoxacin in Rats

MASAHIRO KOIKE ˣ, RYO NORIKURA, KENJI MIZOJIRI, and KOICHI SUGENO

Received May 19, 1983, from *Shionogi Research Laboratories, Shionogi & Co., Ltd., Osaka, Japan.* Accepted for publication March 8, 1984.

Abstract □ The effect of the variation of urinary pH on the pharmacokinetics of the acidic antibacterial agent, cinoxacin (pK_a 4.60), was examined. Urinary pH of 24-h fasted rats remained at about pH 6 during the daytime, while that of nonfasted rats was high (about pH 7.5) in the morning and gradually decreased to a pH similar to that of the fasted rat in the afternoon. The free fraction of cinoxacin in fasted rat sera in the morning was similar to that in nonfasted rats despite the longer half-life of cinoxacin in fasted rats. In the afternoon the free fraction was slightly different despite similar cinoxacin elimination in fasted and nonfasted rats. These findings seemed to exclude the contribution of protein binding from the causes of increased cinoxacin elimination in nonfasted rats in the morning. Elimination rate constants of cinoxacin obtained with a one-compartment open model correlated well with urinary pH 30 min after injection, suggesting that the urinary pH plays a more important role in cinoxacin elimination. When cinoxacin was orally administered to fasted rats at 11:00, the area under the plasma concentration-time curve was threefold larger than in nonfasted rats. As found with the intravenous administration, this difference may be explained by the prolonged half-life caused by decreased urinary pH after fasting. This study revealed the time-dependent elimination of cinoxacin in nonfasted rats, which is related to physiological change of urinary pH caused by food intake.

Keyphrases □ Cinoxacin—time-dependent elimination, effect of fasting, urinary pH, rats □ Urinary pH—effect of fasting on cinoxacin elimination, diurnal alteration, rats

The chronopharmacological aspects of drugs have been discussed in many review articles (1-3). Some attribute these phenomena to the diurnal oscillation of pharmacological sensitivity to drugs (4) and others to the diurnal variance of plasma levels (or levels at the receptor site) without alteration of the sensitivity to the drugs. Alteration of plasma levels can be expressed by pharmacokinetic parameters such as absorption, distribution, metabolism, and excretion (5-9). Circadian rhythms of hepatic drug-metabolizing ability have been especially well investigated (10-13), but the causes of the rhythmicity in absorption, distribution, and excretion have not been thoroughly investigated in spite of being frequently described (9).

We noticed a diurnal rhythm of urinary pH in normally fed rats and found that the rhythm disappeared with fasting. We tried to clarify the effect of such diurnal alteration of urinary pH and fasting on the pharmacokinetics of drugs in the rat. The model compound was cinoxacin (1-ethyl-1,4-dihydro-4-oxo[1,3]dioxolo[4,5-*g*]cinnoline-3-carboxylic acid). Cinoxacin is an acidic (pK_a 4.60), antibacterial agent, which is excreted almost completely unchanged in rat urine (14, 15).

EXPERIMENTAL SECTION

Materials—Male Sprague-Dawley rats, weighing 240–270 g, were purchased commercially[1] and were housed in group cages with wooden chips on the floor in a room with constant temperature (24 ± 1°C) and humidity (55

where V_m is the velocity of the process under steady-state conditions, *i.e.*, when the concentration of the intermediate products remains constant and, thus, the velocities of formation and decomposition of the enzyme-substrate complex are equal; E_0 is the enzyme concentration in the subphase; S is the surface concentration of substrate in the monolayer; K_m is the Michaelis-Menten interfacial constant ($K_{cat} + K_d/K_p$); and K_p and K_d are the penetration and desorption constants of the enzyme. As can be seen in this equation, the hydrolysis rate of the pivampicillin must increase proportionately with the increase of the enzyme concentration, which agrees with the results shown in Fig. 5.

The increase of the reaction rate with increasing surface pressure in the monolayer can be interpreted only when the increase in the pressure causes a higher surface concentration. One must remember, however, that the increase of surface pressure reduces the penetration capacity of the enzyme in the monolayer, as shown by Verger *et al.* (16) using radioactive enzymes. These two phenomena are the reason that a pressure of maximum activity can normally be reached, varying according to the enzyme and substrate used, after which the velocity of reaction decreases. In the process of the hydrolysis of pivampicillin by penicillinase, it has been impossible to reach this maximum value. However, using Fig. 4, one can assume that this maximum is found at $1.7\text{-}1.8 \times 10^{-2}$ N·m^{-1}.

Finally, one fact in this study that might be considered paradoxical is the decrease of the induction time (τ) when the surface pressure of the monolayer is increased (Fig. 6). That is, the enzyme penetrates more quickly in monolayers which are tightly compacted than in the monolayers in which the molecules of penicillin are free, leaving large intermolecular spaces. This effect can be interpreted as a result of the improvement of the "quality of the interface," especially as to the packing of the substrate molecules, which [as was demonstrated by Slotboom *et al.* (17)] influence the kinetic parameters of the enzyme, especially increasing the value of the penetration constant K_p.

Table I—Biochemical Examination of Rat Sera [a]

Examination	Sera at 09:30		Sera at 15:30	
	Fasted, $n = 5$	Nonfasted, $n = 6$	Fasted, $n = 6$	Nonfasted, $n = 4$
Total bilirubin, mg/dL	0.34 ± 0.06[b]	0.17 ± 0.05	0.32 ± 0.04[b]	0.18 ± 0.05
Albumin, g/dL	3.12 ± 0.11[c]	3.22 ± 0.07[d]	3.35 ± 0.15	3.40 ± 0.08
Total protein, g/dL	5.38 ± 0.15[d]	5.60 ± 0.21[c]	5.92 ± 0.27	5.90 ± 0.12
Non-esterified fatty acid[e], mEq/L	0.52 ± 0.08[b,c]	0.15 ± 0.05[d]	0.58 ± 0.11[b]	0.26 ± 0.10

[a] Mean ± *SD*. [b] Significant difference at $p < 0.01$ compared with nonfasted rats. [c] Significant difference at $p < 0.05$ compared with sera at 15:30. [d] Significant difference at $p < 0.01$ compared with sera at 15:30. [e] Calculated as oleic acid.

± 5%). Under a 12-h light-dark cycle, rats were given free access to solid animal chow[2] and water. One-half of the rats were transferred to a cage with a stainless steel net floor (mesh size: 1.5 × 1.5 cm) 24 h prior to drug administration to prevent coprophagy (± 1) and deprived of chow but not water. Cinoxacin was obtained commercially[3]. ^{14}C-Labeled cinoxacin was synthesized by the method of Nagasaki *et al.* (16). Its specific activity was 37.2 μCi/mg and radiochemical purity was >98%. All other chemicals were of reagent grade.

Animal Experiments—Fasted and nonfasted rats, under light ether anesthesia, were catheterized in the right external jugular vein by Upton's method (17) and urine-collecting adapters were attached to their penises. The animals were then placed in individual cages[4] and left for >2 h to eliminate the effect of ether. Next, 20 mg/kg of ^{14}C-labeled or unlabeled cinoxacin (10 mg/mL of aqueous solution with an equivalent amount of sodium hydroxide) was intravenously administered *via* the caudal vein. At 12:00, [^{14}C]cinoxacin was used and at 15:00, unlabeled cinoxacin was used. The rats were periodically forced to void urine by using ether. Blood was taken *via* the catheter and immediately centrifuged to obtain the plasma. In the case of oral administration, [^{14}C]cinoxacin was used and blood sampling was done nonserially. Twenty mg/kg of [^{14}C]cinoxacin (10 mg/mL of aqueous solution prepared similarly to the intravenous injection) was orally administered and blood samples were taken *via* the aorta after abdominal incision under light ether anesthesia. Cinoxacin in plasma was determined by fluorometry (15) and the urinary pH was measured. When ^{14}C-labeled cinoxacin was administered, radioactivity was measured with a liquid scintillation counter[5]. Diurnal changes of urinary pH in noncatheterized rats were measured as described above without cinoxacin administration.

Biochemical Examination of Serum and Protein Binding—At 09:30 and 15:30, fasted and nonfasted rats were lightly anesthetized with ether and blood was withdrawn *via* the aorta after an abdominal incision. Serum was obtained by centrifugation using a serum separation aid[6]. Total bilirubin, albumin, and total protein in the serum were determined with an autoanalyzer[7] and nonesterified fatty acids were determined with a kit[8]. Free cinoxacin in the serum was measured with an ultrafiltration method *in vitro*. Five microliters of cinoxacin (6.0 mg/mL, pH 7.4 phosphate buffer solution) was added to 2 mL of the serum to make a final concentration of 15 μg/mL. After this mixture had been left for 1 h at 25°C, the serum was centrifuged in a membrane cone[9]. The free cinoxacin in the filtrate was determined by fluorometry.

Calculation of Pharmacokinetic Parameters and Statistical Analysis—The cinoxacin elimination rate constant in plasma was calculated using MULTI (18), a nonlinear least-squares program, based on a one-compartment open model. For statistical analyses, the paired *t* test and regression analysis were used.

RESULTS AND DISCUSSION

The rat which we usually use as an experimental animal takes food exclusively at night and rarely during the daytime. Biological rhythmicity probably exists based on the food intake rhythm. The effect of food and diet on pharmacokinetic parameters, *e.g.*, absorption, distribution, metabolism, and excretion, have been reviewed (19-21). Therefore, time-dependent pharmacokinetics may be considered in relation to the rhythmicity of food intake. We examined the alteration of cinoxacin pharmacokinetics as a function of time and feeding.

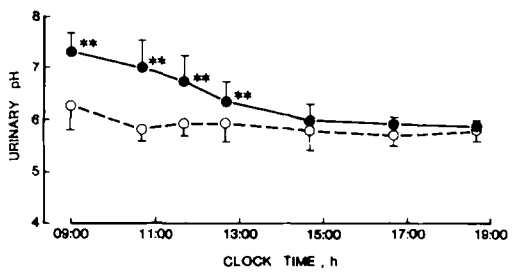

Figure 1—*Diurnal variance of urinary pH in fasted and nonfasted rats. The means and* SD *values from 15 rats are shown. Key: (●) nonfasted rats; (○) fasted rats; (**) significantly different from fasted rats at* $p < 0.01$.

In fasted and nonfasted rats, at either 09:30 or 15:30, serum was examined for factors affecting the protein binding of drugs (22-24). As shown in Table I, total bilirubin and nonesterified fatty acids increased markedly with fasting both in the morning and afternoon. Furthermore, a slight increase was observed in the afternoon in albumin, total protein, and nonesterified fatty acids in fasted and nonfasted rats. These results alerted us to the possibility that protein binding might be changed by time and feeding.

Next, we examined the diurnal rhythm of urinary pH and the effect of feeding. As shown in Fig. 1, urinary pH in fasted rats was constant during the daytime, whereas in nonfasted rats it was high in the morning and decreased slightly in the afternoon to the level of the fasted rats. This variance of urinary pH is likely to affect the renal excretion rate for drugs with pK_a values similar to urinary pH (25).

We selected cinoxacin as a model compound to investigate the effect of this variance of physiological parameters on pharmacokinetics. Renal excretion of cinoxacin is reported to be dependent on urinary pH because of renal reabsorption (26-29).

Table II shows serum protein binding of cinoxacin *in vitro*. Significant differences were detected between the serum of fasted and nonfasted rats at 15:30 but not at 09:30. Though the extent of the difference was small, it could affect the cinoxacin pharmacokinetics. Therefore, we investigated the cinoxacin elimination from plasma after intravenous administration in fasted and nonfasted rats in the morning and afternoon. Figure 2 shows the time course of plasma levels of cinoxacin after intravenous administration at 12:00 to fasted and nonfasted rats having different urinary pH values. As expected, plasma elimination was slower in fasted rats than nonfasted rats, and urinary excretion during the initial 1 h in fasted and nonfasted rats was 45.8 and 73.7% and at 2 h, 62.6 and 83.8% of the dose, respectively (data not shown). These results suggest that cinoxacin elimination was rapid especially in nonfasted rats, and the elimination was affected by minor difference of urinary pH at the time of and for at least 1 h after drug administration. This can be easily explained by greater renal reabsorption due to lower urinary pH in fasted rats (26-29).

On the other hand, when cinoxacin was injected at 15:00, it was similarly eliminated from plasma in both rat groups (Fig. 3), in spite of different serum protein binding ratios between fasted and nonfasted rats (Table II). This

Table II—*In Vitro* Serum Protein Binding of Cinoxacin in Rats

Rat	Unbound fraction, %[a]	
	Sera at 09:30	Sera at 15:30
Fasted	6.36 ± 0.38[b]	6.65 ± 0.25[c,d]
Nonfasted	6.54 ± 0.45[c]	6.00 ± 0.47[b]

[a] Percent of total concentration (15 μg/mL) ± *SD*. [b] $n = 5$. [c] $n = 6$. [d] Significant difference at $p < 0.05$ compared with sera in nonfasted rats at 15:30.

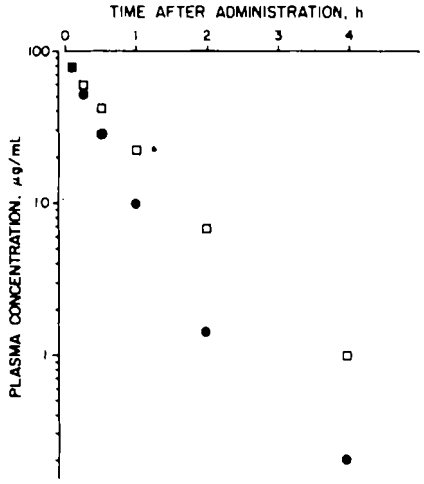

Figure 2—*Average plasma levels of cinoxacin after intravenous administration of 20 mg/kg of [^{14}C]cinoxacin to three fasted or nonfasted rats at 12:00. Key (□) fasted rats; (●) nonfasted rats.*

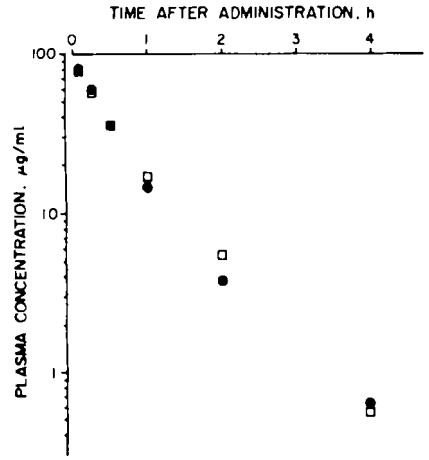

Figure 3—*Average plasma levels of cinoxacin after intravenous administration of 20 mg/kg of unlabeled cinoxacin to three fasted or nonfasted rats at 15:00. Key: (□) fasted rats; (●) nonfasted rats.*

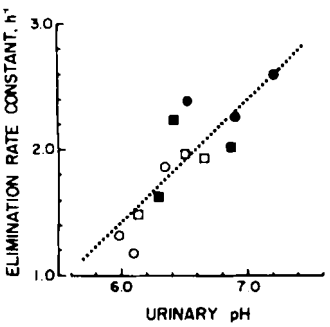

Figure 4—*Correlation between urinary pH 30 min after administration of 20 mg/kg of ^{14}C-labeled or unlabeled cinoxacin and elimination rate constant obtained from fasted or nonfasted rats at 12:00 or 15:30. Key: (●) nonfasted rats at 12:00; (○) fasted rats at 12:00; (■) nonfasted rats at 15:00; (□) fasted rats at 15:00.*

suggests that urinary pH plays a more important role than protein binding in cinoxacin elimination from the plasma. As previously described, cinoxacin elimination in nonfasted rats administered at 12:00 was rapid (Fig. 2) and >70% of the dose was excreted in urine until 13:00; furthermore, a higher pH

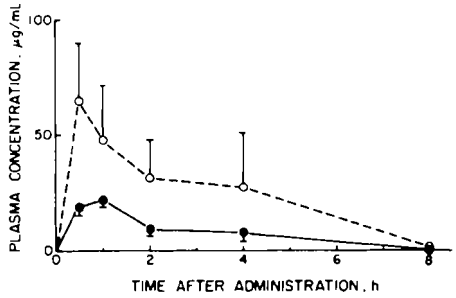

Figure 5—*Plasma levels of cinoxacin after oral administration of 20 mg/kg of [^{14}C]cinoxacin in fasted or nonfasted rats at 11:00. Means and* SD *values from three rats. Key: (○) fasted rats; (●) nonfasted rats.*

in urine was maintained at least until ~13:00 (Fig. 1). These results accounted for the faster elimination in nonfasted rats than fasted rats administered the drug at 12:00.

We investigated the correlation between urinary pH 30 min after intravenous administration and the elimination rate constant calculated from the values in Figs. 2 and 3. Figure 4 shows a significant correlation between the elimination rate constant obtained with the one-compartment open model and the urinary pH ($r = 0.8427$, $p < 0.01$). As the slope of the regression line is 1.033, if urinary pH decreases from 7 to 6, the elimination rate constant decreases from 2.43 to 1.40. Thus, diurnal variance of urinary pH in normally fed rats has an important effect on cinoxacin elimination, though in fasted rats changes in cinoxacin elimination do not arise because urinary pH remains constant during the daytime.

Figure 5 shows the plasma levels of cinoxacin orally administered to fasted and nonfasted rats at 11:00. As expected, higher plasma levels were observed in fasted rats. The area under the plasma concentration–time curve (AUC) calculated by the trapezoidal rule was 125.8 μg·h/mL in fasted rats and 40.9 μg·h/mL in nonfasted rats. The larger AUC in fasted rats is due to the lower urinary pH and in addition, a higher peak level may be partly attributable to a faster gastric emptying rate, as mentioned by Watanabe *et al.* (30).

Determination of Benzalkonium Chloride by Gas Chromatography

Z. R. CYBULSKI

Received November 25, 1983, from the *Physical Chemistry Department, Fisons plc, Pharmaceutical Division, Loughborough, LE11 ORH, UK.* Accepted March 7, 1984.

Abstract □ A new, simple, and useful approach for the analysis of benzalkonium chloride is presented. A gas chromatograph (GC) has been used to pyrolyze benzalkonium chloride in a specific and reproducible manner to yield two tertiary amines for each homologue of benzalkonium chloride present. These are separated by GC and are used to determine the homologue composition of the benzalkonium chloride. These determinations can be made with an analysis time of 25 min/sample.

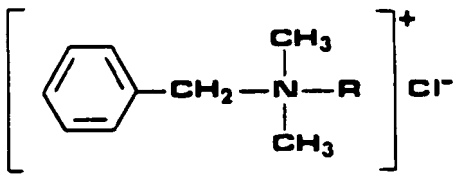
Keyphrases □ Benzalkonium chloride—determination by GC □ GC—determination of benzalkonium chloride

Benzalkonium chloride is used in pharmaceuticals as an antimicrobial preservative and is a mixture of homologous compounds (I), where the R group represents an *n*-alkyl chain which can vary from 10–18 carbon atoms. The relative amounts of the different *n*-alkyl species in benzalkonium chloride solutions greatly affect the antimicrobial spectrum and activity on the mixture (1). The current methods for analysis of benzalkonium chloride solutions according to the USP (2) rely upon titrimetric analysis of the total alkylbenzyldimethylammonium chloride based upon potassium iodate equivalents. Additionally, the ratio of *n*-alkyl components of benzalkonium chloride can be determined by microhydrogenation followed by solvent extraction and gas chromatography (GC). The ratio of alkyl components is then calculated and must meet specific USP requirements. These requirements state that the C_{12} homologue must comprise at least 40% of the total benzalkonium chloride content and that the C_{14} homologue must be at least 20%. Furthermore, these two homologues together must comprise not less than 70% of the total content.

Other methods have been reported for the determination of benzalkonium chloride, for example, ion-pairing techniques (3–5), direct titration involving tetraphenylboron sodium (6) and iodate (7). Later methods of analysis have included MS using laser ionization (8), chemical ionization (9), and HPLC (10).

GC methods include one based on a modified Hofmann degradation of benzalkonium chloride with subsequent analysis of the formed benzyldimethylamine and the corresponding alkene (11). Another method involves chemical derivatization of the benzalkonium chloride to introduce specific functional groups into the derivatives which are amenable to GC with enhanced detectability using electron capture and nitrogen-specific thermionic detecting systems (12).

The procedure presented here determines directly the alkyl chain-length ratios of benzalkonium chloride species in samples of benzalkonium chloride in an easy, sensitive, and reliable operation.



(I)

EXPERIMENTAL SECTION

Apparatus—Measurements were carried out using a GC[1] fitted with a flame ionization detector. The column used was a 0.9 m (2 mm i.d.) glass column packed with OV17 (3%) on Chromosorb W HP (80/100 mesh). A 10-μL syringe[2] was used to inject samples. The chromatograms were recorded on a potentiometric recorder[3] and peak area measurements were obtained using an integrator[4].

Mass spectrometric measurements for identification of the GC pyrolysis products were conducted using a spectrometer[5] operating in the electron impact ionization mode. The mass spectrometric data was handled by a data system[6].

Reagents, Solvents, and Standards—The carrier gas for the GC work was nitrogen; for MS work, the carrier gas was helium. The commercial samples of benzalkonium chloride were obtained from various manufacturers. Samples of benzalkonium chloride for analysis were prepared as solutions in methanol (0.5%). For confirmation, a benzalkonium chloride standard was obtained[7]. Individual pure benzalkonium chloride standards were examined with R = C_{14}, C_{16}, and C_{18}. The standards were also examined as solutions in methanol (0.5%).

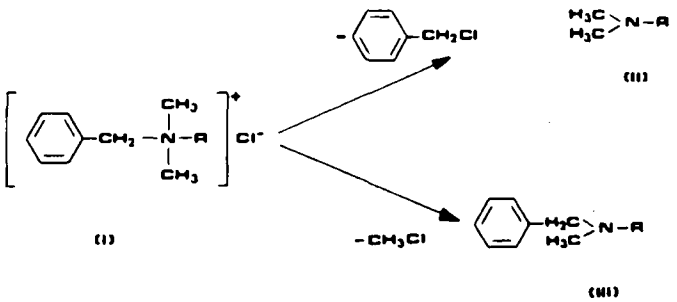

Scheme I—Gas chromatography pyrolysis products of benzalkonium chloride (I).

Assay—All benzalkonium chloride samples were dissolved in methanol to give 0.5% solutions which were used for the GC determinations. The optimum conditions for programmed GC were as follows: the oven start temperature was 100°C and this was programmed at 8.0°C/min up to 280°C; the flame ionization detector temperature was set at 350°C; the injection port temperature was 250°C; the carrier gas flow-rate was 40 mL/min. The injection size was 2 μL. The flame ionization detector sensitivity was 6.4×10^{-9} *A* full scale deflection.

Table I—MS Data on the GC Pyrolysis Products of Pure C_{14} Benzalkonium Chloride

GC Peak Retention time, min	Molecular Ion, *m/z*	Base Peak, *m/z*	Identity of Compound
0.8	126/128	91	Benzyl Chloride
5.2	241	58	Dimethylalkylamine (II) R = C_{14}
13.0	317	134	Benzylmethylalkylamine (III) R = C_{14}

Table II—Analysis of USP Benzalkonium Chloride Sample

Homologue	Label Claim, %	Found, %
C_{10}	0.8	0.0
C_{12}	41.5	41.3
C_{14}	49.1	50.5
C_{16}	8.7	8.2
C_{18}	0.0	0.0

RESULTS AND DISCUSSION

It has been shown previously (14) that when certain quaternary ammonium halides are pyrolyzed they yield tertiary amines. Benzalkonium chloride samples, when analyzed using the conditions described, yield two tertiary amines for each homologue of benzalkonium chloride present (Scheme I). The MS data supporting the structure of the pyrolysis products of the pure C_{14} benzalkonium chloride homologue are shown in Table I.

The method was applied to mixtures of benzalkonium chlorides. Using the retention times of the pyrolysis products of pure benzalkonium chloride homologues, the distribution of benzalkonium chloride was determined in a USP convention sample. The result is shown in Table II.

As there are two compounds formed for each homologue present, there are three possible methods available for calculating the percentage distribution of benzalkonium chloride homologues:

Method 1—Determination of the ratio of the responses for pyrolysis products (dimethylalkylamines) (II).

Method 2—Determination of the ratio of the responses for pyrolysis products (benzylmethylalkylamines) (III).

Method 3—Ratio of the sum of the responses determined for the corresponding pyrolysis products II and III.

Table III shows the reproducibility of the assay using the USP convention sample. The results of all three methods for calculating the homologue distribution are shown.

Since there is considerable variation in homologue composition between samples of benzalkonium chloride from different commercial sources, one commercial sample was analyzed by the new procedure. The chromatogram of the sample is shown in Fig. 1 and the homologue distribution and reproducibility data are presented in Table IV.

This assay was also conducted using nonpolar silicone phases such as SE-30, OV-1, and OV-101 (all 0.9 m columns with 3% loadings). The results obtained were reproducible for benzalkonium chloride samples which were composed predominantly of the C_{12}, C_{14}, and C_{16} homologues, although they proved to be unsuitable in cases where the C_{18} homologue was present as the C_{18} dimethylalkylamine could not be resolved from the C_{12} benzylmethylalkylamine. To demonstrate the ability of the described system to separate the pyrolysis products, a commercial sample was spiked with pure C_{18} benzalkonium chloride homologue. The resulting chromatogram is shown in Fig. 2.

Freshly packed OV-17 columns required considerable conditioning before they were suitable for use. New columns appeared to adsorb the dimethylalkylamine degradation products strongly resulting in poor peak shape (*i.e.*, considerable peak tailing). This was overcome by conditioning the columns by silylation and repeated injection with a benzalkonium chloride sample, such

Determination of Partition Coefficients of Glucocorticosteroids by High-Performance Liquid Chromatography

J. C. CARON ˣ and B. SHROOT

Received April 7, 1983, from the *Centre International de Recherches Dermatologiques, Sophia Antipolis, 06565 Valbonne, France.* Accepted for publication February 24, 1984.

Abstract □ Two high-performance liquid chromatographic (HPLC) techniques have been used for the determination of the lipophilicity of 50 glucocorticosteroids. For a log P range of 1 to 3, we used a persilylated octadecylsilane phase saturated with 1-octanol, which was eluted with 1-octanol saturated phosphate buffer (pH = 7). For log P values ≥3.00, the same phase was used without 1-octanol saturation and was eluted with different methanol-buffer mixtures. These two procedures allowed the determination of log P values ranging from 1.00 to >5.00. Good agreement was found between these procedures and others described in the literature. The effect of different structural changes in the glucocorticosteroid molecule on the lipophilicity is discussed.

Keyphrases □ Glucocorticosteroids--partition coefficients, determination by two HPLC methods □ HPLC--partition coefficients of glucocorticosteroids determination with and without 1-octanol □ Partition coefficients--1-octanol-water, glucocorticosteroids

The determination of 1-octanol-water partition coefficients is of particular interest in drug design for several reasons, but primarily because it governs absorption and transport to the site of action (1). Attempts have been made to calculate the partition coefficient of a given compound (2–4), but these theoretical approaches cannot take into account all the physicochemical properties of the molecule, especially the stereochemistry. It is thus advantageous to experimentally determine the lipophilicity of the compounds of interest. For this purpose, several methods have been proposed, of which the shake-flask technique (5) and the TLC method (6) are the most widely used. More recently, high-performance liquid chromatographic (HPLC) has been proposed for this purpose (7, 9) and we selected reverse-phase HPLC as a rapid and reliable method for the determination of log P. Log P is defined as the logarithm of the partition coefficient, $P = C_s/C_w$, where C_s and C_w are the equilibrium concentrations of a solute in the organic (usually 1-octanol) and aqueous (usually a buffer) phase, respectively.

EXPERIMENTAL SECTION

Materials - Hydrocortisone and its derivatives[1], triamcinolone acetonide[2], and other glucocorticosteroids[3] were used as received. Phenol, aniline, acetanilide, quinoline, anisole, benzene, *p*-chlorophenol, 4-methylquinoline, 3-bromoquinoline, phenazine, and acridine were analytical grade[4]. Pyridine, pyridine-*N*-oxide, 1-octanol, ethanol, trimethylchlorosilane, and hexamethyldisilazane were also analytical grade[5]. The HPLC columns used (stainless steel, 4.6 mm id) were of different lengths (5, 10, 15, 20, and 30 cm)[6], and packed with C_{18} Corasil[7] (particle size, 37–50 μm). The HPLC apparatus consisted of a pump[8], a valve injector[9], a UV-visible detector[10] fixed at 254 nm, and a strip chart recorder[11].

Methods—Two systems have been used for the determination of log P, depending on the lipophilicity of the compound studied.

Log P Range, 0.93 to 3.00 (a)--The method of Mirrless *et al.* (7) was used with minor modifications. The HPLC column was dry packed with a persilylated octadecylsilane phase and saturated with 1-octanol by successive injections of 250 μL of alcohol under pressure until droplets appeared at the outlet of the column. The column was then flushed with 1-octanol-saturated phosphate buffer (0.01 M, pH 7) until the eluate appeared clear. The column was then attached to the detector and elution was continued until a stable baseline was obtained (1–2 h).

Samples were dissolved in ethanol at a concentration of 0.2% (w/v) and 10 μL was injected *via* the valve injector. Pyridine-*N*-oxide was used as a nonretained solute for the determination of the void volume of the column, measured as the elution time on the recorder.

We determined the correlation between log P and log k' for 11 standards of known log P (9) (aniline, acetanilide, quinoline, benzene, anisole, *p*-chlorophenol, phenol, 4-methylquinoline, 3-bromoquinoline, phenazine, and acridine) for a given flow rate and length of column. The capacity factor, k', is defined as: $(t_r - t_0)/t_0$ where t_r is the retention time of the compound and t_0 is the retention time of a nonretained solute.

The calibration curve obtained by the HPLC 1-octanol saturation method, for a given column length and flow rate, is shown in Fig. 1. There is good linear correlation between log P obtained by the shake-flask method (7) and log k' ($r = 0.994$) which is expressed as: $\log P_{SF} = 1.024 \log k' + 0.775$. The slope is near unity and indicates that the HPLC elution process emulates a true 1-octanol-buffer partition.

To determine the log P of steroids, three standards appropriate to the log P range under investigation were run twice a day. The reproducibility between days appeared to be >2% in the k'. For each unknown compound, the average of three determinations of the elution time was used to determine k', and again the *SD* was >2%. The log P of steroids ≤3.00 log P units was determined in this way.

The use of a 5-cm column with a flow rate of 4 mL/min results in retention times of 1–30 min for a log P range of 1–3 using the octanol saturation method. Under these conditions, it is calculated that a compound with a log P = 4 would have a retention time of 280 min; if log P = 5, a retention time of 2670 min would be anticipated. Long retention times for log P values >3 under these experimental conditions lead to peak broadening with a resultant loss in resolution, accuracy, and sensitivity. In addition, high flow rates lead to a rapid

wash out of the 1-octanol coating of the column, the frequent replacement of which considerably reduces the convenience of the procedure. These points led us to the idea of the solvent mixture method for the determination of log P values >3.00 (9, 10).

Log P Values of 3.00 and Above (b)—For the measurement of these log P values, a 20-cm column, filled with the same persilylated octadecylsilane phase, was used but without the 1-octanol coating. Elution was performed with at least five different methanol–buffer mixtures, and the retention time for any given solvent composition was determined for each compound (standards and unknown). An extrapolation of the logarithm of the capacity factor to 0% of organic solvent gives an estimation of the lipophilicity of the molecules studied (Fig. 2).

The proportions of methanol for each compound were chosen to keep the log k' <1.5 so that retention times could be precisely determined ($t_r \leq 45$ min). These proportions were usually kept between 45 and 95% of methanol. For five different methanol buffer mixtures, the correlation between log k' and the proportion of methanol was linear; the correlation coefficient was always >0.98 (for the majority of the steroids, $r \approx 0.99$). Figure 2 shows examples of such correlations for prednisolone, triamcinolone acetonide, and hydrocortisone-21-butyrate, which cover two decades of log P.

RESULTS AND DISCUSSION

By the first procedure, we determined the log P of 12 steroids in the range 1.21–2.88 for which the log P was reported in the literature (11). A good correlation was obtained ($r = 0.951$): $\log P_{SF} = 1.011 \log P_{HPLC} + 0.072$.

Using the second procedure, extrapolation to 0% methanol gave a measure of the partition between the buffer and the octadecylsilane phase, which is

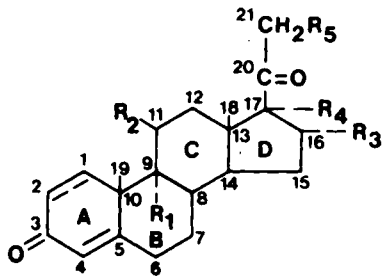
[a] These values are the means calculated from our experimental data and are not to be used to predict the lipophilicity changes induced by structure modification. [b] 1,2 refers to an olefinic bond between C_1 and C_2.

not, in fact, a true 1-octanol–buffer partition. When we compared these log k' 0% with the log P of the steroids determined by the saturation method, we obtained a linear relationship expressed as: log P (procedure *b*) = 0.939 log k' (procedure *a*) + 0.147 which validates the postulate that this procedure can be used for log P determinations >3 units, if closely related standards are used for the calibration. The main advantages of this method are the rapidity and ease of use, compared with the saturation method, but it also may allow us to determine log P values up to 6.

Listed in Table I are the log P values obtained by the 1-octanol saturation HPLC method, the shake-flask technique (11), the R_m values of Biaggi *et al.* (12), and hydrophobicity calculated by the Rekker method (3). R_m is defined as $R_m = \log (1/R_f - 1)$ and is related to the lipophilicity by log P = log K + R_m where K is a constant for the system. R_f is the usual measure of the migration of a compound in TLC.

Figure 3 shows the correlation between $HPLC_{1\text{-octanol}}$ and the 3 other methods for the 14 steroids of Table I. The agreement between $HPLC_{1\text{-octanol}}$ and shake flask and R_m methods is better than the correlation with the calculated hydrophobicity (Rekker). This is due to the fact that the Rekker method gives only an approximation and, like all results based upon calculations, it cannot take into account all the physicochemical properties of a molecule which are responsible for its lipophilicity (3).

We have used these 14 steroids as standards to determine, by the solvent mixture method, the log P of the glucocorticosteroids listed in Table II. The effect of the different structural changes on the lipophilicity of the steroids



A ring = $\Delta^{1,2}$
R_1 = H, F
R_2 = H, OH, =O
R_3 = H, OH, CH_3
R_4 = H, OH, ester
R_5 = H, OH, ester, Cl

can be determined by examining pairs of compounds differing by only one substituent.

The changes induced by the introduction of a double bond at C_1—C_2, the substitution of the hydrogen atom by a fluorine at C_9, or by changing from hydroxyl to carbonyl at C_{11} have only little effect on lipophilicity. However, changes at C_{16}, C_{17}, and C_{21} have a more significant effect on lipophilicity. The substitution of the C_{16} hydrogen atom by a methyl group induces a small increase in the lipophilicity (±0.50). At C_{17}, the substitution of H by OH only slightly modifies the lipophilicity, but the esterification of the hydroxyl group leads to an increase of the lipophilicity. Changing from OH to acetate increases the log P by 0.89 ± 0.15 (n = 4). A further increase in the chain length of the ester increases the log P with an increment of 0.46 ± 0.12 (n = 5) per carbon

atom. The C_{21} position shows the same tendency. Here the log P value changes by 0.42 ± 0.22 (n = 6) per carbon atom with increasing chain length. The introduction of a chlorine atom in place of OH causes only a slight increase in the log P value.

The two HPLC methods described for the determination of the lipophilicity of glucocorticosteroids are more rapid than the shake-flask method, and are more convenient than the TLC procedure.

Stability-Indicating Assay for Phenylbutazone: High-Performance Liquid Chromatographic Determination of Hydrazobenzene and Azobenzene in Degraded Aqueous Phenylbutazone Solutions

H. FABRE ˣ, N. HUSSAM-EDDINE, and B. MANDROU

Received December 30, 1982, from the *Laboratoire de Chimie Analytique, Faculté de Pharmacie, 34060 Montpellier Cedex, France.* Accepted for publication February 2, 1984.

Abstract □ A high-performance liquid chromatographic method was developed for the simultaneous determination of azobenzene, hydrazobenzene, and four other decomposition products in phenylbutazone injectable formulations. Separation was achieved on a C_{18} column, with 0.1 M Tris-citrate buffer (pH 5.25) and acetonitrile (52:48), at a flow rate of 2 mL/min and a detection wavelength of 237 nm. Diphenylamine was used as an internal standard. The limit of quantitation is 0.5% (with respect to phenylbutazone) of each degraded product. The detectability is 2.4×10^{-3} μg for azobenzene and 1.5×10^{-3} μg for hydrazobenzene. The limit of quantitation may be lowered to 0.1% (with respect to phenylbutazone) for azobenzene and hydrazobenzene in the presence of the two major decomposition products, which have been determined in commercially available injectable formulations. A higher sensitivity was obtained for azobenzene using the mobile phase 0.1 M Tris-citrate buffer (pH = 5.25) and acetonitrile (40:60) with detection at 314 nm. Under these conditions, 0.025% (with respect to phenylbutazone) of azobenzene is quantitated.

Keyphrases □ Phenylbutazone—HPLC, stability-indicating assay, degradation products □ Azobenzene—HPLC determination □ Hydrazobenzene—HPLC determination

The sodium salt of phenylbutazone (I) in aqueous solution undergoes hydrolysis and, to a small extent, oxidation and decarboxylation according to degradation Scheme I (1). Among these degradation products, some are of particular interest because of their deleterious effects: 4-butyl-4-hydroxy-1,2-diphenyl-3,5-pyrazolidinedione (II) may be involved in allergic reactions (2); hydrazobenzene (VIII) and azobenzene (IX) are suspected carcinogens (3). Despite their toxicity, no analytical method has been proposed for the identification and quantification of VIII and IX in phenylbutazone formulations. Only separation on chromatographic columns and identification by TLC have been reported as evidence for the presence of IX in commercial injections after prolonged storage (4). The present study was undertaken to complete preliminary work (5, 6); the conditions used previously in the high-performance liquid chromatographic (HPLC) procedure (6) did not allow the determination of VIII and IX within acceptable time. In this report, an improved, rapid, and sensitive HPLC procedure is presented that allows simultaneous determination of trace levels of II, III, IV, VI, VIII, and IX and a monitoring of the stability of I in injections.

EXPERIMENTAL SECTION

Materials and Reagents—Compounds I, II, III, IV, and VI were used as received[1]. Compounds VIII and IX, diphenylamine (DPA), Tris, and citric acid were analytical reagent grade. HPLC-grade acetonitrile, distilled-in-glass grade methanol, and water were also used. Injectable formulations were commercial formulations[2] (600 mg of the sodium salt of phenylbutazone, 6 mg of dibucaine, propylene glycol, and water per 3 mL of solution).

The HPLC[3] was equipped with a variable-wavelength UV detector[4]. The separation was carried out on a laboratory-made column (15 cm × 4.0 mm) containing microsilica particulate-bonded (5-μm) octadecylsilane[5]. The mobile phase A was 0.1 M Tris-citrate buffer (pH 5.25) and acetonitrile (52:48). The citrate buffer was filtered through a 0.45-μm filter[6], and the mixture was deaerated before use.

Standard Solutions—An initial mixed stock solution was prepared in the mobile phase using I (200 μg/mL) and II, III, IV, VI, VIII, and IX (100 μg of each/mL). This solution was suitably diluted in the mobile phase to give standard solutions. An internal standard solution (diphenylamine, 500 μg/mL in the mobile phase) was added to each diluted standard solution to give a 100-μg/mL concentration of diphenylamine. The final concentration range was from 5 to 160 μg/mL for I and from 2.5 to 80 μg/mL for II-IV, VI, VIII, and IX.

Test Solutions—Recovery studies were carried out on laboratory-prepared injections similar to commercial formulations with the following amounts

atom. The C_{21} position shows the same tendency. Here the log P value changes by 0.42 ± 0.22 (n = 6) per carbon atom with increasing chain length. The introduction of a chlorine atom in place of OH causes only a slight increase in the log P value.

The two HPLC methods described for the determination of the lipophilicity of glucocorticosteroids are more rapid than the shake-flask method, and are more convenient than the TLC procedure.

Stability-Indicating Assay for Phenylbutazone: High-Performance Liquid Chromatographic Determination of Hydrazobenzene and Azobenzene in Degraded Aqueous Phenylbutazone Solutions

H. FABRE ˣ, N. HUSSAM-EDDINE, and B. MANDROU

Received December 30, 1982, from the *Laboratoire de Chimie Analytique, Faculté de Pharmacie, 34060 Montpellier Cedex, France.* Accepted for publication February 2, 1984.

Abstract □ A high-performance liquid chromatographic method was developed for the simultaneous determination of azobenzene, hydrazobenzene, and four other decomposition products in phenylbutazone injectable formulations. Separation was achieved on a C_{18} column, with 0.1 M Tris-citrate buffer (pH 5.25) and acetonitrile (52:48), at a flow rate of 2 mL/min and a detection wavelength of 237 nm. Diphenylamine was used as an internal standard. The limit of quantitation is 0.5% (with respect to phenylbutazone) of each degraded product. The detectability is 2.4×10^{-3} μg for azobenzene and 1.5×10^{-3} μg for hydrazobenzene. The limit of quantitation may be lowered to 0.1% (with respect to phenylbutazone) for azobenzene and hydrazobenzene in the presence of the two major decomposition products, which have been determined in commercially available injectable formulations. A higher sensitivity was obtained for azobenzene using the mobile phase 0.1 M Tris-citrate buffer (pH = 5.25) and acetonitrile (40:60) with detection at 314 nm. Under these conditions, 0.025% (with respect to phenylbutazone) of azobenzene is quantitated.

Keyphrases □ Phenylbutazone—HPLC, stability-indicating assay, degradation products □ Azobenzene—HPLC determination □ Hydrazobenzene—HPLC determination

The sodium salt of phenylbutazone (I) in aqueous solution undergoes hydrolysis and, to a small extent, oxidation and decarboxylation according to degradation Scheme I (1). Among these degradation products, some are of particular interest because of their deleterious effects: 4-butyl-4-hydroxy-1,2-diphenyl-3,5-pyrazolidinedione (II) may be involved in allergic reactions (2); hydrazobenzene (VIII) and azobenzene (IX) are suspected carcinogens (3). Despite their toxicity, no analytical method has been proposed for the identification and quantification of VIII and IX in phenylbutazone formulations. Only separation on chromatographic columns and identification by TLC have been reported as evidence for the presence of IX in commercial injections after prolonged storage (4). The present study was undertaken to complete preliminary work (5, 6); the conditions used previously in the high-performance liquid chromatographic (HPLC) procedure (6) did not allow the determination of VIII and IX within acceptable time. In this report, an improved, rapid, and sensitive HPLC procedure is presented that allows simultaneous determination of trace levels of II, III, IV, VI, VIII, and IX and a monitoring of the stability of I in injections.

EXPERIMENTAL SECTION

Materials and Reagents—Compounds I, II, III, IV, and VI were used as received[1]. Compounds VIII and IX, diphenylamine (DPA), Tris, and citric acid were analytical reagent grade. HPLC-grade acetonitrile, distilled-in-glass grade methanol, and water were also used. Injectable formulations were commercial formulations[2] (600 mg of the sodium salt of phenylbutazone, 6 mg of dibucaine, propylene glycol, and water per 3 mL of solution).

The HPLC[3] was equipped with a variable-wavelength UV detector[4]. Scheme I—Degradation pathways of phenylbutazone according to Ref. 1. Key: (I) phenylbutazone; (II) 4-butyl-4-hydroxy-1,2-diphenyl-3,5-pyrazolidinedione; (III) 3-hydroxy-2-oxohexanoic acid 1,2-diphenylhydrazide; (IV) 3-carboxy-2-oxohexanoic acid 1,2-diphenylhydrazide; (V) 2-hydroxyhexanoic acid 1,2-diphenylhydrazide; (VI) hexanoic acid 1,2-diphenylhydrazide; (VII) 2-oxohexanoic acid 1,2-diphenyl hydrazide; (VIII) hydrazobenzene; (IX) azobenzene.

added: 1% (with respect to I) of II–IV, VI, VIII, and IX; 0.5% (with respect to I) of II–IV, VI, VIII, and IX; 0.2% (with respect to I) of VIII and IX in the presence of 3% (with respect to I) of III and IV; 0.1% (with respect to I) of VIII and IX in the presence of 3% (with respect to I) of III and IV. These prepared solutions and the commercial injections were diluted in the mobile phase and internal standard solution was added to match the calibration graph.

A 10-μL aliquot of each standard solution and 10 μL of test solution were injected in duplicate onto the chromatograph. The apparatus was operated at ambient temperature. The flow rate was 2 mL/min, the pressure was 140 ± 2 bars, and the detector was set at 237 nm or 314 nm, with a sensitivity of 0.1 AUFS.

RESULTS AND DISCUSSION

Specimen chromatograms of a standard solution recorded at 237 nm (suitable wavelength for simultaneous determination of I–IV, VI, VIII, and IX) and 314 nm (maximum absorbance wavelength for IX in the mobile phase) are shown in Figs. 1 and 2, respectively. A better sensitivity for IX and a negligible absorbance of I–IV, VI, and VIII is observed at 314 nm. Diphenylamine may be used as an internal standard at 237 and 314 nm. An excipient blank was injected. No interference was observed at these wavelengths.

Chromatographic Parameters—Table I lists the chromatographic data for phenylbutazone and its main decomposition products, expressed as the capacity factor k', the theoretical plate height H, the asymmetry factor A_s (7) under the conditions used in the present study (mobile phase A). To check the efficiency of acetonitrile on the selectivity, a modified mobile phase 0.1 M Tris-citrate buffer (pH 5.25)–acetonitrile–methanol (52:30:18) was used. No separation efficiency was obtained and a dramatic increase in the capacity factors and increased pressure (p = 218 bars) were observed.

Comparative data using mobile phase B, 0.1 M Tris-citrate buffer (pH 5.25) and acetonitrile (60:40) and the conditions used in a previous paper (flow rate,

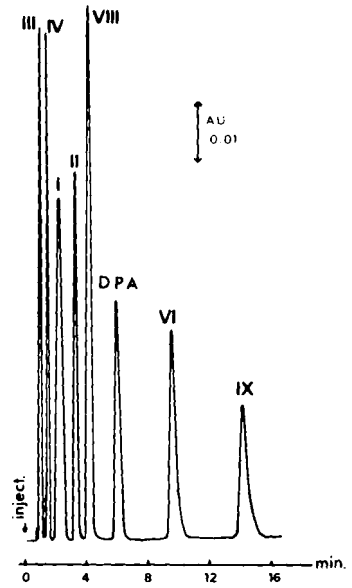

Figure 1—*Chromatogram of a standard solution of I (97.0 μg/mL), II (44.0 μg/mL), III (36.0 μg/mL), IV (40.0 μg/mL), VI (54.4 μg/mL), VIII (56.0 μg/mL), IX (48.0 μg/mL), and DPA (82.5 μg/mL). The mobile phase was 0.1 M Tris-citrate buffer (pH 5.25)–acetonitrile (52:48); flow rate was 2 mL/min, and pressure was 140 bars. Detector sensitivity was 0.1 AUFS, chart recorder speed was 0.5 cm/min, and λ was 237 nm.*

2.0 mL/min) (6), are given in Table I. Mobile phase B could not achieve the separation within an acceptable time. Accordingly, mobile phase A was chosen for the simultaneous determination of the degradation compounds.

Stability Studies—Hydrazobenzene (VIII) has been reported (1) to undergo easy oxidation into azobenzene and *trans*-azobenzene (IX) is susceptible to isomerization into *cis*-azobenzene under photolytic conditions (8). The stability of I–IV, VI, VIII, and IX was tested by separately injecting onto the chromatograph, at different time intervals, a solution of each compound (0.12

Table I—Chromatographic Data of Phenylbutazone and Its Main Decomposition Products

Compound	Mobile Phase A			Mobile Phase B
	k'	H, mm	A_s	k'
I	1.914	0.616	1.10	4.700

VI	11.948	0.028	1.21	38.820
VIII	4.603	0.032	1.33	12.380
IX	19.983	0.024	1.37	55.040
DPA	7.138	0.027	1.37	—

Table II—Minimum Detectable Amount and Sensitivity for Phenylbutazone and Its Main Decomposition Products

Compound	Minimum Detectable Amount, μg[a]		Sensitivity	
	λ = 237 nm	λ = 314 nm	λ = 237 nm	λ = 314 nm
I	4.8×10^{-3}	—	11.377	—
II	1.8×10^{-3}	—	14.740	—
III	1.1×10^{-3}	—	14.296	—
IV	1.2×10^{-3}	—	14.385	—
VI	4.5×10^{-3}	—	16.387	—
VIII	1.5×10^{-3}	—	19.214	—
IX	6.0×10^{-3}	2.40×10^{-3}	14.739	37.305

[a] Determined in the presence of I (20 μg).

mg·mL^{-1}) in the mobile phase. After 3 h at ambient temperature, under diffused light, no decomposition was observed for I–IV and VI. Only 1.37% of VIII was oxidized and no isomerization of IX was observed. Under chromatographic conditions used in this study, the retention time of *cis*-azobenzene relative to *trans*-azobenzene was 0.25 min.

Linearity of response was demonstrated for each solute by plotting the peak area ratio of solute to the internal standard against the solute concentration, from mixed standard solutions with equivalent concentration of degradation compound. The calibration graphs were linear for each compound with a correlation coefficient >0.998 in all instances. Each calibration graph intersected the origin. A similar correlation was obtained using the peak heights instead of the peak area.

Repeatability was assessed by five replicate determinations of a standard solution (80 μg/mL for I and 40 μg/mL for each degradation product) and a laboratory prepared injection with 3% of each degradation compound (with respect to I). For the standard solutions the data, expressed as the *CV*, were 1.57% (I), 2.86% (II), 1.88% (III), 3.85% (IV), 5.54% (VI), 2.22% (VIII), and 2.86% (IX). For the laboratory-prepared injection, the data were 0.59% (I), 1.66% (II), 1.00% (III), 0.67% (IV), 0.67% (VI), 1.75% (VIII), and 1.35% (IX).

The detectability [amount (μg) that gives a peak height equal to twice the background for the maximum on-column level tolerable for I] and the sensitivity (change in the area value, measured at the maximum detector sensitivity, resulting from a concentration change of one unit in μg/mL) were evaluated at 237 and 314 nm (Table II). The best wavelength for the detection of azobenzene is 314 nm.

The recovery studies on laboratory prepared injectable formulations with and without added amounts of degradation products are given in Table III. To determine trace amounts of decomposition products, a high concentration of phenylbutazone (2 mg/mL) had to be injected and a blank determination

Table III—Recovery Data from Laboratory Prepared Injectable Formulation

		Amount Added, mg	Amount Found, mg	Relative Error, %
Placebo +	I	600.00	588.06	−1.99
	I	600.00	591.14	−1.48

	IX	0.6[a]	0.588	−2.00

[a] Determined at 314 nm.

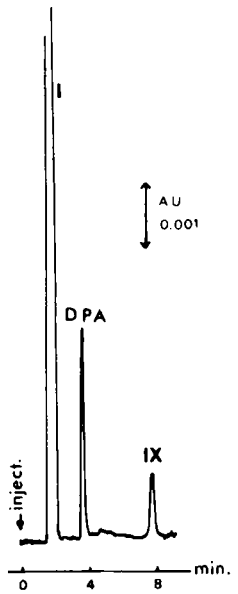

Figure 3—*Chromatogram of a laboratory-prepared injectable formulation of I (2.180 mg/mL), IX (0.525 μg/mL), and spiked with DPA (4.975 μg/mL). The mobile phase was 0.1 M Tris-citrate buffer (pH 5.25) and acetonitrile (40:60). Flow rate was 2.0 mL/min and pressure was 127 bars. Detector sensitivity was 0.01 AUFS, chart recorder speed was 0.5 cm/min, and λ was 314 nm.*

corresponding to an equal concentration of phenylbutazone had to be carried out. Recovery data presented in Table III are corrected from the blank determination. It must be noted that 0.5% (with respect to I) is the limit of quantitation for II because of the resolution between I and II in the presence of a large amount of I. The recovery studies for the two carcinogenic compounds (VIII and IX) were carried out at lower limits in the presence of the main degradation products (III and IV) determined in commercially available injectable formulations (5, 6) within the limit of validity. From Table III, 0.1% (with respect to I) may be estimated as the lowest limit of quantitation for VIII at 237 nm with acceptable accuracy. At 314 nm, where I, III, and IV are not interfering, the limit of quantitation of IX could be lowered to 0.05% (with respect to I).

To increase the detectability and the sensitivity for azobenzene, a more eluting mobile phase C [0.1 M Tris-citrate buffer–acetonitrile (40:60)] was used. Standard solutions of IX were prepared using mobile phase C as follows: 100 μg/mL of DPA was added to make an internal standard of 5 μg/mL. The concentration of IX ranged from 0.3 to 2.0 μg/mL. Good linearity was observed for the calibration graph ($r > 0.999$). The chromatogram of a laboratory-prepared injection with added amount 0.025% (with respect to I) of IX is given in Fig. 3. The recovery was 107.04% by peak area and 94.53% by peak height measurements. The detectability was 1.3×10^{-3} μg.

Commercial Injectable Formulation Analysis—Commercial injection samples issued from two different batches, within the limit of validity, were analyzed with the mobile phases A and C. For one sample, I was 99.73% of the declared value, III was 0.92% (with respect to I), and IV was 5.32% (with respect to I). For the second sample, I was 100.00%, III was 0.8% (with respect to I), and IV was 3.77%. Neither hydrazobenzene nor azobenzene were detected in these two batches.

CONCLUSIONS

The proposed method allows the detection of hydrazobenzene and azobenzene at trace levels: 1.5×10^{-3} μg for VIII, 2.4×10^{-3} μg for IX with mobile phase A, and 1.3×10^{-3} μg for IX with mobile phase C. The resolution obtained for these two carcinogenic substances from phenylbutazone and its two major decomposition products usually found in injections, allows the simultaneous determination of 0.1% of each with satisfactory accuracy. Due to the high toxicity of hydrazobenzene and azobenzene, such an assay should be carried out as a stability-indicating assay for the phenylbutazone injectable formulations susceptible to hydrolysis.

Autoxidation and Hydrolysis Kinetics of the Sodium Salt of Phenylbutazone in Aqueous Solution

H. FABRE ˣ, N. HUSSAM-EDDINE, D. LERNER *, and B. MANDROU

Received June 8, 1983, from the *Laboratoire de Chimie Analytique, Faculté de Pharmacie* and the **Laboratoire de Chimie Physique Appliquée, Ecole Nationale Supérieure de Chimie, 34060 Montpellier Cedex, France.* Accepted for publication February 16, 1984.

Abstract □ The present investigation offers experimental results concerning the degradation kinetics of the sodium salt of phenylbutazone based on a reliable HPLC procedure. The method allows the simultaneous determination of the parent compound and its main decomposition products. The degradation kinetics at 37°C were compared at pH 7.9 and 10.0 and under oxygen and nitrogen atmospheres. Parallel tests were carried out in the dark and under photolytic conditions for the aforementioned conditions. The influence of traces of iron and a chelating agent of iron on the degradation was studied. At pH 7.9 and pH 10.0 the main degradation products are 3-hydroxy-2-oxohexanoic acid 1,2-diphenylhydrazide and 3-carboxy-2-oxohexanoic acid 1,2-diphenylhydrazide. Azobenzene is formed only at pH 10.0. At pH 7.9, in the dark, the degradation proceeds with a lag phase. In contrast, no lag phase is observed under photolytic conditions. The process of autoxidation and hydrolysis is catalyzed by traces of iron both in the dark and under irradiation conditions. An unexpected increase in the degradation is observed in the presence of iron(III) and EDTA in aerobic conditions and under irradiation.

Keyphrases □ Phenylbutazone—autoxidation, hydrolysis, degradation, degradation products, effects of light and pH

Numerous accounts on the stability of phenylbutazone (I) in drugs have been reported (1–7). A degradation pathway has been suggested which involves oxidation and hydrolysis (4). Furthermore, Schmid (8) has shown that the hydrolysis of I to IV is reversible.

Kinetics of the degradation of the sodium salt of phenylbutazone in aqueous solution have been previously investigated (9, 10) using UV spectrophotometry. The procedure was only valid for the determination of the parent compound; the kinetics of formation of the degradation products were not evaluated.

Since II, VIII, and IX (see *Scheme I* of the immediately preceding paper for the structures of the degradation products) have been suspected to have noxious properties (11, 12) it is useful to investigate, under different conditions, the degradation kinetics of I together with the formation of all its decomposition products. In the present work, a reliable HPLC procedure (13) has been used to follow simultaneously the kinetics of the breakdown of the parent compound and the formation of six main degradation compounds, using experimental conditions which complement previous work (9, 10).

EXPERIMENTAL SECTION

Materials, Reagents, and Solutions—Phenylbutazone and its decomposition products (II[1], III[1], IV[1], VI[1], VIII, and IX) were used as received (see *Scheme I* of the immediately preceding paper for the structures of the degradation products). All chemicals were analytical reagent grade and water was glass distilled.

The study was conducted at pH 7.9 or 10.0 using a 3.24×10^{-3} M concentration of I and an ionic strength of $\mu = 0.5$. The solutions were prepared in 0.2 M ammonium acetate buffer (when a buffer effect was studied at pH 7.9 the buffer concentrations were 0.1, 0.2, and 0.3 M). The experiments were carried out at pH 7.9 and 10.0 without additives, and at pH 7.9 in the presence of iron and iron and EDTA.

For each set of experiments, the sodium salt of phenylbutazone solution (solution A) was prepared in a volumetric flask (100 mL) by dissolving phenylbutazone (100 mg) in a minimum amount of concentrated NaOH (~4 M). Solution A was then added to a volume of 100 mL as described below.

For experiments at pH 7.9 and 10.0, without additives, an acetic acid solution was added to solution A to get a 0.2 M (or 0.1 M, or 0.3 M) final acetate concentration. The pH was adjusted[2] to 7.9 or 10.0 with ammonium hydroxide. Potassium chloride and water were added to a volume of 100 mL to have an ionic strength of $\mu = 0.5$.

For experiments in the presence of iron, a saturated solution of iron(III) chloride in the buffer was prepared by shaking (in a water bath at 40°C) iron(III) chloride in the buffer for 48 h. The filtered solution was added to solution A to make 100 mL. The iron concentration was determined in the filtrate by atomic absorption spectrophotometry[3] using a graphite furnace. The concentrations of the solution was 0.008×10^{-3} M iron(III).

For experiments in the presence of iron and EDTA, an appropriate amount of EDTA was added to an aliquot of the solution described above. The concentrations of the solutions were 0.008×10^{-3} M and 10.52×10^{-3} M with respect to iron(III) and EDTA.

Sample Processing—For each experiment, 3-mL aliquots of the solution were transferred to 10-mL standard antibiotic vials. The vials were closed with a rubber seal. The solutions were bubbled for 3 min with either oxygen or nitrogen through the rubber cap using inlet and outlet syringe needles.

Sets of vials corresponding to the different experiments were placed in the same incubator at 37 ± 1°C. The ceiling of the incubator was fitted with a distributed light source delivering a radiative power ~1% of that emitted by the sun on a bright day. The amount of near UV and visible radiation received by the solutions was estimated using actinometry[4] and was found to be 800 $\mu W/cm^2$. The set of vials to be studied in the dark was enclosed in a light-tight

[4] In a first step, the spectral power distribution of a lamp was measured by means of a calibrated spectroradiometer. Then, a graph of the yield in Fe^{2+} ions *versus* lamp power was obtained using potassium ferrioxalate actinometry. Actinometer preparation and final titration followed the Parker and Hatchard procedure (C. A. Parker and C. G. Hatchard, *J. Phys. Chem.*, **63**, 22 (1959); see also C. A. Parker in "Photoluminescence of Solutions," American Elsevier, New York, N.Y. 1968, p. 210). The irradiation step only was different, since we used the full spectrum of the lamp. The last step was the measurement of the actual sample in the incubator. Once the absorbed power was measured, yield was obtained following standard procedures using the power distribution of the lamp, the yield *versus* wavelength quantum yield change of the actinometer, and the absorption curve of the sample.

Autoxidation and Hydrolysis Kinetics of the Sodium Salt of Phenylbutazone in Aqueous Solution

H. FABRE ˣ, N. HUSSAM-EDDINE, D. LERNER *, and B. MANDROU

Received June 8, 1983, from the *Laboratoire de Chimie Analytique, Faculté de Pharmacie* and the **Laboratoire de Chimie Physique Appliquée, Ecole Nationale Supérieure de Chimie, 34060 Montpellier Cedex, France.* Accepted for publication February 16, 1984.

Abstract □ The present investigation offers experimental results concerning the degradation kinetics of the sodium salt of phenylbutazone based on a reliable HPLC procedure. The method allows the simultaneous determination of the parent compound and its main decomposition products. The degradation kinetics at 37°C were compared at pH 7.9 and 10.0 and under oxygen and nitrogen atmospheres. Parallel tests were carried out in the dark and under photolytic conditions for the aforementioned conditions. The influence of traces of iron and a chelating agent of iron on the degradation was studied. At pH 7.9 and pH 10.0 the main degradation products are 3-hydroxy-2-oxohexanoic acid 1,2-diphenylhydrazide and 3-carboxy-2-oxohexanoic acid 1,2-diphenylhydrazide. Azobenzene is formed only at pH 10.0. At pH 7.9, in the dark, the degradation proceeds with a lag phase. In contrast, no lag phase is observed under photolytic conditions. The process of autoxidation and hydrolysis is catalyzed by traces of iron both in the dark and under irradiation conditions. An unexpected increase in the degradation is observed in the presence of iron(III) and EDTA in aerobic conditions and under irradiation.

Keyphrases □ Phenylbutazone—autoxidation, hydrolysis, degradation, degradation products, effects of light and pH

Numerous accounts on the stability of phenylbutazone (I) in drugs have been reported (1–7). A degradation pathway has been suggested which involves oxidation and hydrolysis (4). Furthermore, Schmid (8) has shown that the hydrolysis of I to IV is reversible.

Kinetics of the degradation of the sodium salt of phenylbutazone in aqueous solution have been previously investigated (9, 10) using UV spectrophotometry. The procedure was only valid for the determination of the parent compound; the kinetics of formation of the degradation products were not evaluated.

Since II, VIII, and IX (see *Scheme I* of the immediately preceding paper for the structures of the degradation products) have been suspected to have noxious properties (11, 12) it is useful to investigate, under different conditions, the degradation kinetics of I together with the formation of all its decomposition products. In the present work, a reliable HPLC procedure (13) has been used to follow simultaneously the kinetics of the breakdown of the parent compound and the formation of six main degradation compounds, using experimental conditions which complement previous work (9, 10).

EXPERIMENTAL SECTION

Materials, Reagents, and Solutions—Phenylbutazone and its decomposition products (II[1], III[1], IV[1], VI[1], VIII, and IX) were used as received (see *Scheme I* of the immediately preceding paper for the structures of the degradation products). All chemicals were analytical reagent grade and water was glass distilled.

The study was conducted at pH 7.9 or 10.0 using a 3.24×10^{-3} M concentration of I and an ionic strength of $\mu = 0.5$. The solutions were prepared in 0.2 M ammonium acetate buffer (when a buffer effect was studied at pH 7.9 the buffer concentrations were 0.1, 0.2, and 0.3 M). The experiments were carried out at pH 7.9 and 10.0 without additives, and at pH 7.9 in the presence of iron and iron and EDTA.

For each set of experiments, the sodium salt of phenylbutazone solution (solution A) was prepared in a volumetric flask (100 mL) by dissolving phenylbutazone (100 mg) in a minimum amount of concentrated NaOH (~4 M). Solution A was then added to a volume of 100 mL as described below.

For experiments at pH 7.9 and 10.0, without additives, an acetic acid solution was added to solution A to get a 0.2 M (or 0.1 M, or 0.3 M) final acetate concentration. The pH was adjusted[2] to 7.9 or 10.0 with ammonium hydroxide. Potassium chloride and water were added to a volume of 100 mL to have an ionic strength of $\mu = 0.5$.

For experiments in the presence of iron, a saturated solution of iron(III) chloride in the buffer was prepared by shaking (in a water bath at 40°C) iron(III) chloride in the buffer for 48 h. The filtered solution was added to solution A to make 100 mL. The iron concentration was determined in the filtrate by atomic absorption spectrophotometry[3] using a graphite furnace. The concentrations of the solution was 0.008×10^{-3} M iron(III).

For experiments in the presence of iron and EDTA, an appropriate amount of EDTA was added to an aliquot of the solution described above. The concentrations of the solutions were 0.008×10^{-3} M and 10.52×10^{-3} M with respect to iron(III) and EDTA.

Sample Processing—For each experiment, 3-mL aliquots of the solution were transferred to 10-mL standard antibiotic vials. The vials were closed with a rubber seal. The solutions were bubbled for 3 min with either oxygen or nitrogen through the rubber cap using inlet and outlet syringe needles.

Sets of vials corresponding to the different experiments were placed in the same incubator at 37 ± 1°C. The ceiling of the incubator was fitted with a distributed light source delivering a radiative power ~1% of that emitted by the sun on a bright day. The amount of near UV and visible radiation received by the solutions was estimated using actinometry[4] and was found to be 800 $\mu W/cm^2$. The set of vials to be studied in the dark was enclosed in a light-tight

box. The contents of the vials were mixed by a gentle motion once a day.

Analytical Procedure—The samples were analyzed by HPLC on a home-made Lichrosorb RP 18 column (5 μm, 15 cm × 0.4 cm) under the chromatographic conditions previously described[5,6] (13). A wavelength of 237 nm was selected for the detection of I–IV, VI, and VIII; 314 nm was used for IX. Determinations were carried out in duplicate on two separate vials withdrawn at suitable time intervals. The samples were assayed immediately after dilution with the mobile phase. The reaction was stopped at 50% completion. At this point, 0.315 mL of oxygen was consumed of the 7 mL present in the vial (on the average) since the total oxidation of 3.0 mg of I requires 0.63 mL of oxygen. The observed differences between the values measured for a duplicate pair of vials were ~3% for I for 95% of the samples. For the remaining 5%, differences as high as 5%, and rarely 10%, were noted. We tentatively attribute the latter to defective sealing and/or degradation of the stopper which permitted entry of oxygen. At the end of each experiment pH values were measured: no significant variation was observed.

RESULTS AND DISCUSSION

All experiments relate to 3.24×10^{-3} M solutions of I in a 0.2 M acetate buffer at an ionic strength of 0.5 μ and a temperature of 37°C, except where otherwise stated.

Aerobic Conditions—*Qualitative Results*—Typical chromatograms of phenylbutazone solutions withdrawn at ~30–40% decomposition level (at pH 7.9) under photolytic conditions are given in Figs. 1a and b. The chromatogram obtained at pH 10.0 is similar with one exception: product U_2 is not present in the latter. The same decomposition pattern for the identified products was obtained in the dark.

At pH 7.9, the main decomposition product is III; IV is formed in a smaller amount. Compound II is detected but is not quantifiable because it is readily hydrolyzed to III which is the major degradation product in aerobic conditions. Compound VI was not detected because it probably is not formed in our working temperature range (8, 14). No authentic samples of V and VII were available to identify on the chromatogram, but under our experimental conditions, the decarboxylation of III leading to V and VII seems improbable.

Two unknown degradation products (U_1 and U_2) are found at a low and nearly constant level. Product U_1 is detectable after 15% decomposition of I under illumination; U_2 is detectable after 20 and 25% decomposition of I under illumination and in the dark, respectively. Based on starting product I, the percent yields of U_1 and U_2 are supposed to have the same molecular absorption coefficient as I, and are, respectively, 0.7% (pH 7.9) or 1.15% (pH 10) and 0.56% (pH 7.9). Products VIII and IX are not involved in the pH range near neutrality (4) and are not formed.

At pH 10.0, the main decomposition product is III; IV is formed in a smaller amount and, as expected at this pH value, IX appears but at trace levels after 25% decomposition of I (Fig. 2). Both in the dark and under photolytic conditions, IX is present as *trans*-azobenzene (relative retention time of *trans*- to *cis*-azobenzene is 2.9 min with the mobile phase described in footnote 6). Although a photostationary mixture of *cis*- and *trans*-azobenzene should be formed under illumination, the competing thermal isomerization efficiency (*cis* to *trans*) at 37°C and the low incident light flux result in undetectable amounts of the *cis* isomer (15). These observations for experiments at pH 7.9 and 10.0 are in good agreement with degradation Scheme I of the immediately preceding paper.

Quantitative Results—Kinetics of decomposition of phenylbutazone were studied at two different pH values (7.9 and 10.0). The influence of pH on the degradation is shown in Figs. 3a (in the dark) and b (under irradiation). The degradation pattern under irradiation at both pH values, and in the dark at pH 10.0, results in a single straight line. In contrast, at pH 7.9 in the dark, two linear relationships are observed; the effect is more evident with product III. In the dark and under irradiation, the degradation of I is faster at pH 7.9 than at 10.0. The formation of III is a sensitive function of pH, in contrast to IV. This means that only degradation pathway 1 is dependent on pH.

In the dark, attempts to determine the reaction order at pH 7.9, by a graphical method, show that the degradation process does not follow a simple order and that a complex reaction is involved. A fractional order probably occurs in the dark at pH 7.9. The half-lives (Table I) show an acceleration of the degradation at pH 7.9 compared with pH 10.0. At pH 10.0, zero-order kinetics are observed ($r = 0.994$).

Under photolytic conditions, the degradation process follows zero-order kinetics at pH 7.9 ($r = 0.994$) and at pH 10.0 ($r = 0.999$). The rate constants

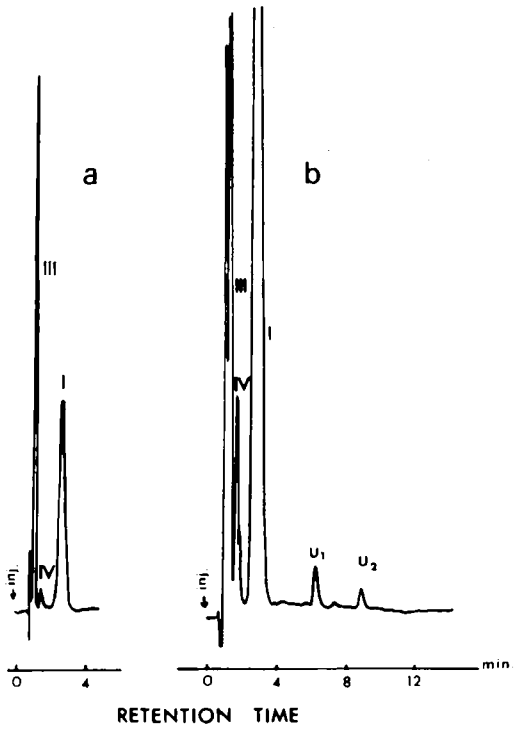

Figure 1—*Chromatograms of a 2.34 × 10^{-3} M phenylbutazone solution diluted 1 to 20 (a) and diluted 1 to 2 (b), withdrawn at ~30–40% degradation at pH 7.9. Kinetic determinations were made in aerobic conditions and under irradiation, determined at 237 nm.*

calculated from the slopes and the half-lives given in Table I clearly show an increase of the degradation at pH 7.9 compared with pH 10.0.

In contrast to pH 7.9, where the sum of I and its decomposition products is always ~100% (with respect to the initial concentration of I), this sum is lowered to 90% at pH 10.0. This apparent loss under photolytic conditions can be explained by the formation of non-UV-absorbing species.

The influence of the buffer concentration on the decomposition was carried out at pH 7.9 in the dark and under irradiation. No significant differences were found between the slopes obtained for each concentration. The influence of a buffer concentration change which could be expected to appear in the hydrolysis step is negligible.

The influence of light on the kinetic behavior of phenylbutazone solution without additives at pH 7.9 and 10.0 is shown in Figs. 4a and b, respectively.

Figure 2—*Chromatogram of a undiluted 2.34 × 10^{-3} M phenylbutazone solution withdrawn at ~30–40% degradation at pH 10.0. Kinetic conditions are the same as Fig. 1. Detection wavelength was at 314 nm.*

7.9	Iron	300	220	0.234
7.9	Iron + EDTA	450	170	0.281

Exposure to light increases the decomposition of I. (Compare half-lives in the dark and under irradiation at both pH values in Table I.)

For decomposition in the dark at pH 7.9 (Fig. 4a), the process shows a lag phase which is not observed under photolytic conditions. This induction phase suggests that radical formation is even taking place in the dark. At pH 7.9, 1 in 10^3 phenylbutazone sodium salt molecules [p$K \sim 4.6$ (16)] is in its acid form. In this form, the proton available next to the carbonyl group could be the site of the homolytic process. As the presence of oxygen is necessary to observe a photochemical degradation, it seems likely that some activated form of molecular oxygen is involved. The primary species would be either singlet $^1O_2$ or superoxide $O_2^{\cdot}$. The latter, in aqueous solution, would first react to give $^{\cdot}OOH$ radicals. These could be identical to the species generated in the thermal activation and explain why the observed decomposition products distribution is the same (10). The activation of molecular oxygen could be sensitized by I since the latter absorbs part of the exciting light.

At pH 10.0 no lag time is observed in the dark in the decomposition process, but the same pattern as for pH 7.9 for the evolution of III and IV is observed (Figs. 4a and b).

In the course of our kinetic run, we observed that the rate of formation of IV is not affected by irradiation at both pH values studied (Figs. 4a and b) whereas that of III is increased. In the presence of oxygen, the effect of light is to cause the reaction to proceed faster along path 1.

The influence of the additives iron and EDTA was investigated at pH 7.9. Figures 5a (in the dark) and b (under photolytic conditions) show the influence of traces of iron(III) alone and in the presence of EDTA, compared with the kinetics without iron. These graphs and the calculated values of rate constants and half-lives (Table I) show the catalytic role of iron(III) on the decomposition.

EDTA is a strong complexing agent for iron at pH 7.9. As can be seen, a large increase in the degradation is observed in the presence of iron(III) and EDTA, under irradiation (Figs. 5a and b, Table I). This result is unexpected since EDTA is used in commercial formulations for its "stabilization properties." Similar accelerating effects on the degradation rates have been previously observed with another chelating agent in the oxidation kinetics of epinephrine, carried out in the dark (17). The effect of EDTA in our system cannot be elucidated at present. Recent studies (18) have shown that the well-known decomposition of peroxides by iron(III) EDTA involves formation of active $^{\cdot}OH$ radicals.

Anaerobic Conditions—Determinations were carried out with nitrogen bubbled samples to compare with the oxygen-flushed samples. The results given in Table II show that in the presence of nitrogen, the degradation is largely decreased compared with the degradation in aerobic conditions, at

both pH values. In these samples, the main degradation route is 2 which, through hydrolysis, leads to IV. Compound III is also formed in small amounts. (The formation of III might be due to the fact that the deaerating procedure is not totally effective.) The removal of oxygen shows up clearly in the variation of the ratio IV:III in the dark as well as under irradiation (Table II).

The effect of additives (Table III) can be analyzed as follows: iron(III) alone induces some degradation whereas the addition of iron(III) and EDTA has no clear stabilizing effect in the dark. The effect of light is only to increase decomposition when it exists in the dark.

Table III—Effect of Additives on the Decomposition of Phenylbutazone under Anaerobic Conditions

	None	98.22	93.72
530	Iron	83.00	78.52
	Iron + EDTA	92.30	90.76

CONCLUSIONS

The results we obtained at pH 7.9 and pH 10.0 are in good agreement with the general degradation scheme proposed by Awang *et al.* (4): evidence for two main degradation paths corresponding to hydrolysis (path 2) and autoxidation followed by hydrolysis (path 1) have been disclosed by HPLC analysis.

Kinetic results in aerobic conditions showed that only the oxidation path is affected by pH. This agrees with the findings of Pawelczyk and Wachowiak (2). In the dark at pH 7.9, a lag phase is observed. This was not found by Pawelczyk and Wachowiak who worked at a higher temperature which offset the induction time. This means that one cannot use data obtained between 60°C and 100°C to predict the shelf life of phenylbutazone samples.

The influence of light as well as the catalytic effect of iron traces have been shown to increase the rate of degradation of I through the oxidation pathway. HPLC analysis permitted the determination of trace amount of IX. We have found that it would only be formed at pH 10.0 and after ~25% decomposition of I. Compound IX, a potential carcinogen, could be formed in pharmaceutical formulations where autoxidation and hydrolysis are found at such pH conditions; the problem could arise for injections. In fact, Pawelczyk and Wachowiak report the formation of IX in injectable formulations, but only beyond their storage limit (3). In tablet and capsules, hydrolysis would be so impeded that formation of IX is highly improbable. Compound IX has been detected

in solid formulations only after sustained heating at 60°C after a prolonged storage time (5).

Controlled Long-Term Release of Small Peptide Hormones Using a New Microporous Polypropylene Polymer: Its Application for Vasopressin in the Brattleboro Rat and Potential Perinatal Use

JENNEKE KRUISBRINK and GERARD J. BOER ˣ

Received June 13, 1983, from the *Netherlands Institute for Brain Research, Meibergdreef 33, 1105 AZ Amsterdam, The Netherlands.* Accepted for publication January 25, 1984.

Abstract □ Based on drug release by microporous hollow fibers and the recent introduction of microporous polymers, a new technique was developed for controlled delivery of peptides. Small-diameter microporous polypropylene tubing, lumen-loaded with microgram quantities of vasopressin, and coated with collodion, releases vasopressin after *in vitro* immersion slowly (1–100 ng/d) and constantly for months. The mechanism of pseudo-zero-order delivery is based on high adsorption of vasopressin, keeping the void volume concentration of dissolved vasopressin constant, which is consequently a constant driving force of outward diffusion. The collodion coating prevents the entry of proteinaceous compounds which would result in rapid desorption of vasopressin. The present delivery module provides a lasting release for other peptides as well (lysine-vasopressin, oxytocin, α-melanocyte-stimulating hormone and, to a lesser extent, Met-enkephalin). The microporous polymer-collodion device is biocompatible and, loaded with vasopressin, successfully alleviates the diabetes insipidus of Brattleboro rats deficient for vasopressin. Subcutaneous implantation normalized diuresis for a period of 60 d and constant urine vasopressin excretion is observed. When the commercially available osmotic minipump is too large for implantation, the small size of the present controlled-delivery system allows peptide treatment of young and immature laboratory rats, even if located *in utero*.

Keyphrases □ Controlled drug delivery—vasopressin, microporous polymers, Brattleboro rat □ Vasopressin—controlled drug delivery, microporous polymers, Brattleboro rat □ Brattleboro rat—vasopressin, controlled delivery, microporous polymers

Peptide hormones and many other substances must be administered in a long-term continuous fashion and within a specified range of concentrations in order to bring about physiological changes. Effective dosages can be given by injections, but because of the short half-life of hormone peptides, high doses often have to be administered, resulting in a sawtooth pattern of peptide levels. As a consequence, side effects frequently occur. Several controlled-release techniques have been developed, ensuring a continuous and constant application for a variety of substances (1–5). Most of these techniques are based either on the principle of: (*a*) constant diffusion of substances (mostly hydrophobic steroids and drugs) through polymer matrices (6) or (*b*) constant delivery of a liquid volume containing the physiologically active agents from an osmotically active core (3). A widely used osmotic minipump—an example of the second approach—has the advantage that it is suitable for all types of compounds (including peptide hormones). However, because of its size, implantation cannot be performed in small laboratory animals or fetuses.

Recently we encountered problems when vasopressin supplementation had to be given to vasopressin-deficient newborn Brattleboro rats (7). Based on the possibilities of drug release by the use of hollow fibers (6) and the recent introduction of a new microporous polymer matrix[1] (8, 9), a technique has now been developed through which controlled delivery of peptides can be obtained. It is small enough to allow the use in immature rats. Preliminary results both on the development and on the applications of the present technique have been partially in-

Controlled Long-Term Release of Small Peptide Hormones Using a New Microporous Polypropylene Polymer: Its Application for Vasopressin in the Brattleboro Rat and Potential Perinatal Use

JENNEKE KRUISBRINK and GERARD J. BOER ˣ

Received June 13, 1983, from the *Netherlands Institute for Brain Research, Meibergdreef 33, 1105 AZ Amsterdam, The Netherlands.* Accepted for publication January 25, 1984.

Abstract □ Based on drug release by microporous hollow fibers and the recent introduction of microporous polymers, a new technique was developed for controlled delivery of peptides. Small-diameter microporous polypropylene tubing, lumen-loaded with microgram quantities of vasopressin, and coated with collodion, releases vasopressin after *in vitro* immersion slowly (1–100 ng/d) and constantly for months. The mechanism of pseudo-zero-order delivery is based on high adsorption of vasopressin, keeping the void volume concentration of dissolved vasopressin constant, which is consequently a constant driving force of outward diffusion. The collodion coating prevents the entry of proteinaceous compounds which would result in rapid desorption of vasopressin. The present delivery module provides a lasting release for other peptides as well (lysine-vasopressin, oxytocin, α-melanocyte-stimulating hormone and, to a lesser extent, Met-enkephalin). The microporous polymer-collodion device is biocompatible and, loaded with vasopressin, successfully alleviates the diabetes insipidus of Brattleboro rats deficient for vasopressin. Subcutaneous implantation normalized diuresis for a period of 60 d and constant urine vasopressin excretion is observed. When the commercially available osmotic minipump is too large for implantation, the small size of the present controlled-delivery system allows peptide treatment of young and immature laboratory rats, even if located *in utero*.

Keyphrases □ Controlled drug delivery—vasopressin, microporous polymers, Brattleboro rat □ Vasopressin—controlled drug delivery, microporous polymers, Brattleboro rat □ Brattleboro rat—vasopressin, controlled delivery, microporous polymers

Peptide hormones and many other substances must be administered in a long-term continuous fashion and within a specified range of concentrations in order to bring about physiological changes. Effective dosages can be given by injections, but because of the short half-life of hormone peptides, high doses often have to be administered, resulting in a sawtooth pattern of peptide levels. As a consequence, side effects frequently occur. Several controlled-release techniques have been developed, ensuring a continuous and constant application for a variety of substances (1–5). Most of these techniques are based either on the principle of: (*a*) constant diffusion of substances (mostly hydrophobic steroids and drugs) through polymer matrices (6) or (*b*) constant delivery of a liquid volume containing the physiologically active agents from an osmotically active core (3). A widely used osmotic minipump—an example of the second approach—has the advantage that it is suitable for all types of compounds (including peptide hormones). However, because of its size, implantation cannot be performed in small laboratory animals or fetuses.

Recently we encountered problems when vasopressin supplementation had to be given to vasopressin-deficient newborn Brattleboro rats (7). Based on the possibilities of drug release by the use of hollow fibers (6) and the recent introduction of a new microporous polymer matrix[1] (8, 9), a technique has now been developed through which controlled delivery of peptides can be obtained. It is small enough to allow the use in immature rats. Preliminary results both on the development and on the applications of the present technique have been partially in-

corporated in other publications (10–12); this paper describes the method in full detail.

EXPERIMENTAL SECTION

Materials—The new microporous polymer matrix[1] has a large void volume, consisting of cells interconnected by small pores (8, 9, 12). In the present study, polymer matrix polypropylene tubing[2] (P 78/15/2; wall void volume 71%, cell and pore size of ~5 and 0.5 μm, and an o.d. and i.d. of 1.6 and 0.9 mm, respectively) was used. Vasopressin[3] (465 U/mg), lysine-vasopressin, Met-enkephalin[5], oxytocin[6], α-melanocyte-stimulating hormone[6], and [^{3}H]-Met-enkephalin[7] (50 Ci/mmol) were obtained commercially. [^{125}I-Tyr]-vasopressin was prepared (13) with a specific activity of 0.5–1.0 Ci/mmol.

Test Tube Experiments—Microporous polymer tubing (2 cm; one end heat-sealed with a mini-soldering iron) filled with ethanol (a few minutes under reduced pressure) was either immersed in an aqueous vasopressin solution for wall-loading (1 mg/mL, 24 h) or in water (1 h) for lumen-loading using a syringe (7 or 22 μg of vasopressin in 7.5 μL). The tubing was then mounted on a serum filter tube so that 1.5 cm of the closed end was immersed or, after heat-sealing the other end, was completely immersed. In the final stage a lumen-loaded double-closed preparation was enfilmed with collodion[8]: the tubing was dipped three times in the collodion solution [0.05 g/mL ether–ethanol, 3:1 (v/v)] and air dried between dippings (12). As a control for this final procedure, vasopressin was made in 2% agar and sucked into silicon tubing containing a strand of suture silk running through its lumen. A 1.5-cm rod was prepared with the outer dimensions of the microporous polymer tubing which could also be coated with collodion (6 dips).

Release of vasopressin was followed at 37°C in 1 mL of distilled water 10% swine serum containing 0.01% sodium azide or 0.5% bovine serum albumin. The volume was replaced daily. When release during 1 d was followed, 25-μL samples were drawn. Samples were stored at −20°C until an RIA for vasopressin was carried out (14, 15). Degradation of the vasopressin immunoreaction in water, serum, and albumin media (water, 0.5 ng–0.5 mg/mL; albumin and serum, 7 ng/mL) was determined during 24-h incubation at 37°C.

Microporous polymer-collodion devices were prepared (containing 7 μg of lysine-vasopressin, oxytocin, and α-melanocyte-stimulating hormone) and daily release was followed radioimmunologically in 10% serum (14–16). The tritiated form of Met-enkephalin (7 μg; final specific activity, 1.2 μCi/mmol) was applied and the release was followed by counting radioactivity.

Animal Experiments—Homozygous (HOM) Brattleboro rats (~140 g), congenitally deficient for vasopressin[9] (17), were kept under standard conditions in metabolism cages (18). After a control period of 3 d, in which the rats showed diabetes insipidus, the animals received subcutaneously, under light ether anaesthesia, microporous polymer-collodion tubing loaded with 7.5, 22, or 220 μg of vasopressin. Vasopressin release was followed in duplicate animals by measuring daily urine production and osmolality and by the assay of urine-excreted vasopressin (see above).

For comparison, single HOM Brattleboro male rats received: a 22-μg vasopressin-loaded microporous polymer without collodion enfilming; a 22-μg vasopressin-agar-collodion preparation; a minipump[10] filled with 22 μg of vasopressin in saline (pumping rate was 0.4 μL/h, *i.e.*, 1000 ng/d); or daily subcutaneous injections of vasopressin tannate[11] (0.5 U/100 g). Finally, a male Wistar rat received a microporous polymer-collodion implant containing 22 μg ^{125}I]-vasopressin (1 mCi/mmol), to follow urine excretion of iodine-125 (drinking water contained 0.1% KI).

Perinatal Implantations—HOM Brattleboro pups (age, 5 d) (7) received subcutaneously a water-filled microporous polymer-collodion tubing (1.5 cm) with a 0.7-mm diameter (P 17/80/2) or the dimensions used above. The largest tubing, placed longitudinally to the animal's spine, was checked daily by palpation, and, at 1 month of age, all pups were sacrificed and an attempt was made to locate the tubing.

The uterus of pregnant (18th day of gestation) Wistar rats was exposed for fetal operation according to Swaab and Honnebier (19). A small diameter microporous polymer-collodion preparation, 0.5- or 1-cm in length inserted into a 19-gauge needle, was placed through the uterine wall underneath the skin of the back of the fetus. Implants were performed on several fetuses within the exposed uterus. Ten days after birth the offspring were sacrificed and the location of the microporous polymer implant was examined.

RESULTS

Test Tube Experiments with Vasopressin—From the different loading procedures of the microporous polymer polypropylene tubing, the most continuous and constant release of vasopressin on water immersion was reached after lumen loading with double-end-closed tubing (Fig. 1). On wall filling, vasopressin ran out almost asymptotically whereas the lumen-filled open

tubing had a 5-d delay before a period of rather constant release. The enveloped vasopressin preparation total release was small: ~1% of the original vasopressin load after 2 weeks. Since aqueous vasopressin loses only 20% of its activity during the same period, a strong adsorption of vasopressin onto the large internal polypropylene surface (~100 m^2/g) (9) was presumed. This contention was supported by the 300% accumulation of radioactivity of the microporous polymer polypropylene after immersion for 1 h in a ^{125}I-vasopressin solution, and the enhancement of total release (≤70%) asymptotically when surface active (0.05% Triton X-100) and/or absorption-competitive proteinaceous compounds (concentration dependent from 0.025 to 1.0% gelatin) were coloaded with vasopressin (not shown). Since incubation in 10% serum (*i.e.*, entry of externally present proteinaceous compounds) showed the rapid depletion of vasopressin as well (Fig. 2), it was therefore necessary for *in vivo* application to abolish or suppress the effect of external agents. Enveloping the vasopressin-microporous polymer preparation with cellulose dialysis membrane or an exclusion filter[12] (both permeable to vasopressin) did not prevent the asymptotic release peak (data not shown). However, after coating with nitrocellulose (collodion), the constant release of vasopressin reappeared in serum solution (Fig. 2). This enfilming was therefore applied in all subsequent studies. With a 7-μg load, daily released amounts of 2–10 ng of vasopressin were found for at least 50 d. Higher loads increased the release rate, but the relation between loading and average first month daily release shows a progressive enhancement for the heterologous oxytocin (Fig. 3). For the highest load (200 μg), constancy of release was lost; instead, a slowly asymptotically decreasing release was seen over the 30-d period.

Concentration of vasopressin in the release medium as a function of time during the first 3 d of immersion and on day 15 showed similar daily logarithmic curves (maximum reached by 6 h in serum, Fig. 4). Incubations in 0.5% albumin, started in the presence of external vasopressin (≤200 ng/mL) showed that with external concentrations <50 ng/mL, a release of vasopressin

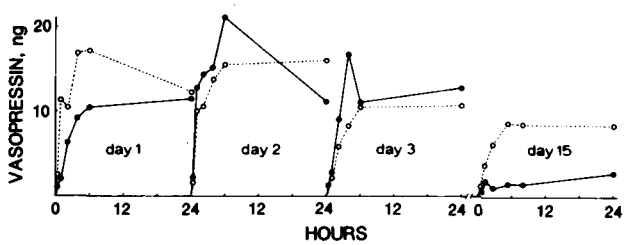

Figure 4—*Daily time course of vasopressin content in 1 mL of 10% serum on immersion of a vasopressin-microporous polymer-collodion device (7 μg) during the first 3 d and on day 15 (duplicate incubations).*

	200	187 ± 16	66 ± 13
	100	93 ± 9	59 ± 9
	50	40 ± 7	31 ± 7
	10	6.1 ± 0.5	34 ± 7
	0	0	30 ± 5
Medium [b]	200	197	164
	50	42	37

[a] Tubing loaded with vasopressin (7 μg) in a 0.5% albumin medium at 37°C. Data ± *SEM* are averages of duplicate findings assayed on 3 subsequent days ($n = 6$). [b] Duplicate assays were performed on a single day for the medium, showing no marked degradation of vasopressin.

is seen; with external concentrations >50 ng/mL, vasopressin is taken up from the medium by the microporous polymer device (Table I).

The mean thickness of the collodion layer around the tubing was 45 μm (*SEM*, 2) as measured under a microscope in random 30-μm cryostat cross sections of eight preparations. A collodion bag of similar shape and thickness (42 μm, *SEM*, 2; measured in three preparations) around vasopressin in agar shows a total wash-out of vasopressin in 10% serum within a few days, while without collodion this occurs even more rapidly (data not shown).

Test Tube Experiments With other Peptides—The *in vitro* results with vasopressin were similarly obtained with lysine-vasopressin- and oxytocin-loaded microporous polymer-collodion devices, while the release pattern of α-melanocyte-stimulating hormone showed an initial lag-phase of 5 d (Fig. 5). Met-enkephalin was not adsorbed to the polypropylene (in a water medium, 70% of the load released asymptotically within 4 d) but when microporous polymer tubing was covered with collodion, the release rate was considerably retarded.

Application in the Brattleboro Rat—Immediately after implantation of the vasopressin-microporous polymer-collodion preparation, diuresis decreased from 60–70 mL of urine/100 g of body weight/d to normal (heterozygous) levels of 5–15 mL. Urine osmolality concomitantly increased from 200 to >1000 mOsm/kg H_2O (Fig. 6 A–C; Table II). A load of 7.5 μg of vasopressin reduced diuresis for 30 d, after which it slowly reached pre-implantation diabetes insipidus values at day 60. The period of low urine production increased to 35–45 and 50–80 d for the 22- and 220-μg vasopressin-filled microporous polymer tubing, respectively, with urine osmolalities of ~1500 mOsm/kg of H_2O (Table II). Return to preimplantation values became immediate after surgical removal of the implants (Fig. 6B, C). The removal was carried out under ether anesthesia. The connective tissue enveloping the implant was not attached and no signs of infection or growth abnormalities were seen.

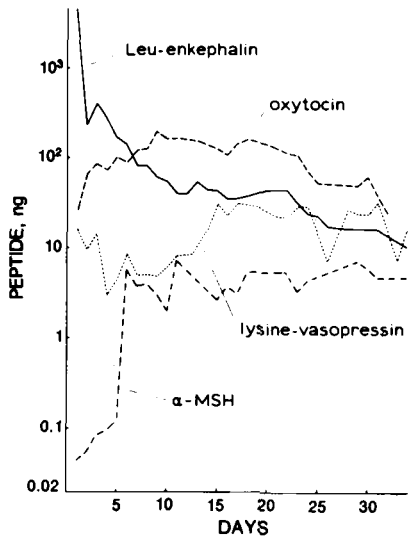

Figure 5—*Daily* in vitro *release in 10% serum medium of several neuropeptides from the microporous polymer-collodion delivery module filled with 7 μg/7.5 μL solutions.*

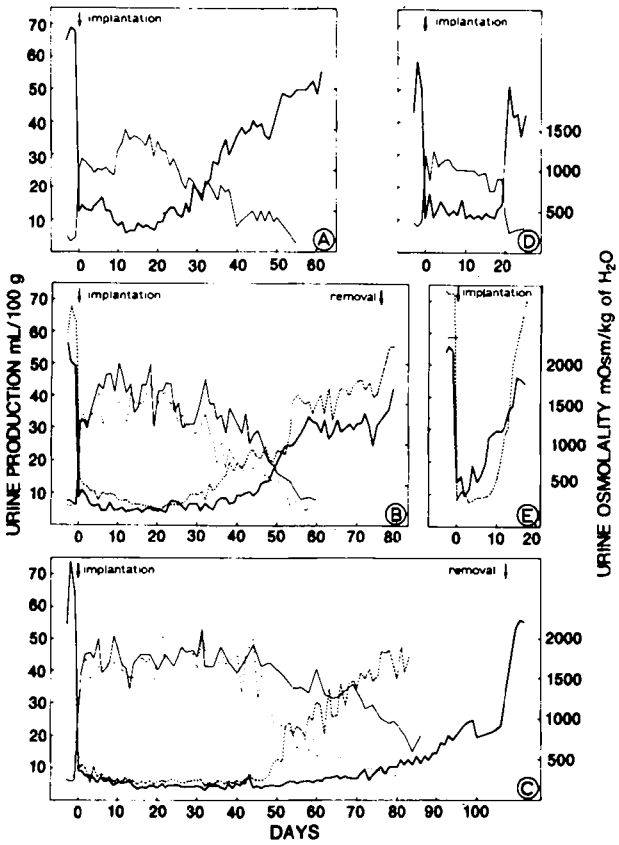

Figure 6—*Urine production (thick lines) and osmolality (thin lines) in male Brattleboro rats after implantation of different vasopressin-releasing preparations. Key: (A–C), duplicate subcutaneous implants of a microporous polymer-collodion device loaded with 7, 22, and 220 μg of vasopressin respectively (removal of the implant is indicated in B and C); (D) subcutaneous implanted osmotic minipump loaded with 22 μg of vasopressin (release rate, 1 μg/d); (E) implantation of a microporous polymer device without collodion enfilming (——) or of an agar cylinder with collodion ensheathment (·····) containing 22 μg of vasopressin.*

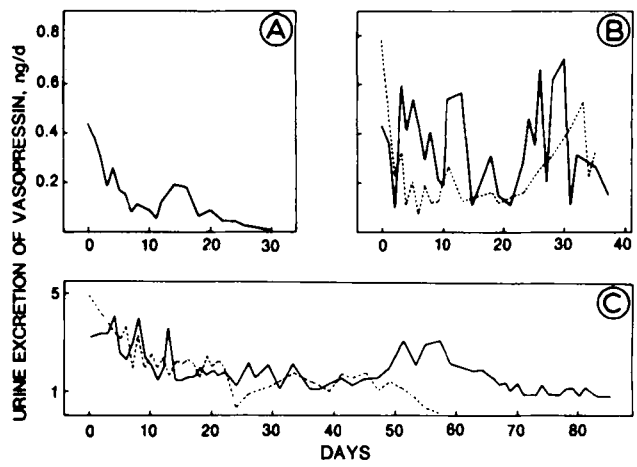

Figure 7—*Vasopressin excretion in the daily urine of Brattleboro rats after implantation of vasopressin-microporous polymer-collodion preparations containing 7 (A), 22 (B), and 220 μg of vasopressin (C) (Figs. 6A–C).*

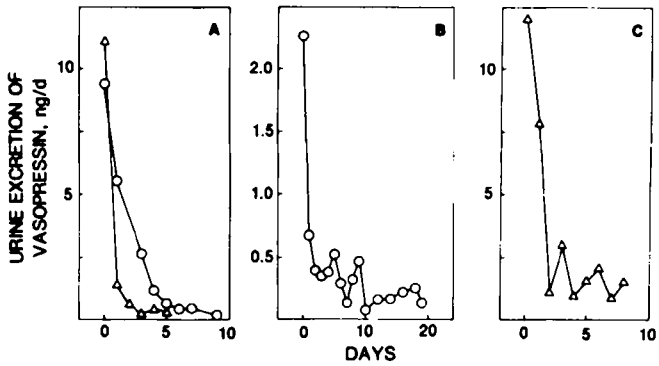

Figure 8—*Vasopressin excretion in the daily urine of Brattleboro rats after implantation of (A) a vasopressin-microporous polymer device with no collodion (△) and a vasopressin-agar-collodion preparation (○) (both with a 22-μg load; cf. Fig. 6E) and (B) an osmotic minipump (1 μg/d; cf. Fig. 6D), and after (C) daily vasopressin tannate injections (0.5 U/100 g of body weight).*

The implantation of an agar-collodion preparation and a microporous polymer tubing without collodion, both containing 22 μg of vasopressin, gave only short periods of low urine production (Fig. 6E). An osmotic minipump filled with 22 μg of vasopressin alleviated the diabetes insipidus for 20 d but not to control levels. (Fig. 6B, D; Table II).

The use of the microporous polymer technique gave reasonably constant amounts of vasopressin in daily urine during the periods of constant low diuresis (Fig. 7). Daily excreted quantities increased with the load of vasopressin, but not proportionally (Table II). Vasopressin excretion using microporous polymer without collodion or an agar-collodion preparation showed rapidly decreasing curves toward undetectable levels (Fig. 8A). Excretion of vasopressin in the first few days appeared to be somewhat higher (Fig. 7), which was also observed when the osmotic minipump or daily injections of vasopressin tannate were used (Fig. 8B, C).

To quantify the actual *in vivo* release, microporous polymer-collodion tubing filled with ^{125}I-vasopressin (22 μg) was used. Daily excretion of radioactivity with the urine was ~1% for 40 d (compare with Fig. 7B). After removal of the implant, 47% of its radioactivity was still present, giving an almost complete recovery of the label.

Perinatal Implantation Trials—Five-day-old pups always survived the implantation well, but the 1.5-cm microporous polymer preparation did not allow the sutured incision to heal if the tubing was not placed at a safe distance

Table II—Diuretic Changes and Urine Vasopressin Excretion of Homozygous Brattleboro Rats After Subcutaneous Implantation of Vasopressin Delivery Devices

	Load, μg	Period, d[a]	Diuresis, mL/100 g/d	Urine Osmolality, mOsm/kg	Vasopressin Urine Excretion, ng/d
Microporous polymer	7.5	30	10.8 ± 0.6[e]	1140 ± 40[e]	0.16 ± 0.03[e]
	22	35–46	7.3 ± 0.3[e]	1430 ± 30	0.30 ± 0.04

Heterozygous controls[d]			5.8 ± 0.7	1440 ± 60	0.44 ± 0.09

[a] Period of the drug-polymer-implanted animals taken as the period of urine output <12 mL/100 g/d and urine osmolality >800 mOsm/kg (Fig. 6). The first day peak values were not taken for the calculation of average values (see text and Fig. 6). [b] Injections (0.5 U/100 g) for 10 d. [c] Mean of all Brattleboro rats used (n = 10), measured 3 d prior to vasopressin treatment. [d] Nineteen animals taken from a prior study (7). [e] Significantly different from heterozygous rat control data, using Student's t test ($p < 0.05$). [f] Not detectable.

from the incision. Consequently, the implant was lost. Occasionally, skin tension at the site of the rough and hard ends of the implant caused injuries, and the implant was lost. However, when still present after 6 d, it remained *in situ* without further problems. These problems were not encountered when we used small-diameter (0.7 mm) microporous polymer tubing.

The subcutaneous deposition of a small implant into rat fetuses (18th day of gestation) by needle penetration through the uterus, chorion, and amnion appeared to be possible, since delivery normally took place 4 d later. The pups were sacrificed 10 d after birth and of 10 implants, 4 were localized subcutaneously, 3 were found between the rib muscles, and 3 were lost.

DISCUSSION

Mechanism of the Microporous Polymer–Collodion Delivery Module—In this study a long-lasting and rather constant release of vasopressin from microporous polymer polypropylene-collodion preparation was realized. Apparently the vasopressin, adsorbed on the large internal surface of the microporous polymer polypropylene, forms a stock from which it is gradually freed on immersion. The constant release period might be explained by a small change in the adsorption equilibrium-determined concentration of vasopressin in the void volume of the tubing, since only small amounts of vasopressin are released. This constant concentration consequently will be a constant drive for outward diffusion causing the pseudo-zero-order release rate. Such a mechanism is reinforced by: the logarithmic time release in a constant volume (the release stops when inside and outside aqueous concentrations are the same, Fig. 4); and the increase and decrease of external vasopressin concentration to a fixed level on immersion of a (high) vasopressin-loaded device in solutions of, respectively, lower and higher vasopressin (release or uptake until equilibrium is reached, Table I). It should be emphasized that such a state of equilibrium is maintained even in 10% serum (Fig. 4), in which considerable degradation of vasopressin occurs. The proposed mechanism also explains that a slowly declining release replaces the constancy of liberation of vasopressin when either the release rate is enhanced by coloading with gelatin (12) or the load is in excess of the adsorption capacity of the polypropylene surface (200 μg of oxytocin, Fig. 3). In both cases, according to Langmuir absorption kinetics, the concentration of vasopressin in the void volume of the microporous polymer polypropylene will be relatively high and on release not replenished from the adsorbed stock. Consequently, the device empties itself quickly, which diminishes release rate more noticeably with time. A period of pseudo-zero-order release is finally reached regardless, *i.e.*, when the adsorbed stock is below the maximum capacity[13].

The collodion layer apparently prevents the rapid entry of many proteinaceous surfactants that could otherwise desorb vasopressin. Like vasopressin, oligopeptides from a medium will pass this membrane but in the opposite direction and will possibly enhance desorption. Comparing the curves in Figs. 1 and 2, this is not noticeable for 10% serum immersion, but *in vivo* (a wider variety of tissue compounds) this might be different (see below). The necessity of both microporous polymer and collodion for long-lasting release is shown when vasopressin preparations are implanted in Brattleboro rats in the absence of one or the other (Figs. 6B and E). Collodion itself, therefore, does not stipulate the constant hormone delivery, although it will undoubtedly influence release rate because of its thickness (6, 20, 21).

On the basis of this mechanism, the microporous polymer polypropylene–collodion preparation should prove applicable to any peptide, provided it sufficiently adsorbs to the polypropylene. This was true for oxytocin, lysine-vasopressin, and α-melanocyte-stimulating hormone, although constant release was not achieved for Met-enkephalin. The extent to which polypropylene adsorbs a peptide will depend on the hydrophobicity of the peptide (*i.e.*, its constituent amino acids). If polypropylene does not act properly for less hydrophobic peptides, perhaps appropriate internal surface coating or the use of other microporous polymers might give the required surface interaction.

Determination of Release Rate—Because dynamic equilibrium is reached in constant-volume incubations *in vitro*, the actual *in vivo* release should be higher. Assuming the body to be an infinite medium (outside vasopressin concentration is always zero), the release rate measured directly after the onset of *in vitro* incubation might be extrapolated and considered to be the release rate present *in vivo*. Such a calculation, on the basis of several curves as presented in Fig. 4, gives a release of 1–2% of the vasopressin load each day. This fits the radioactivity data on daily *in vivo* urine excretion (~1%) of iodinated vasopressin for 40 d. However, in general, *in vivo* rates cannot be derived easily from the release patterns *in vitro* and should be determined *in vivo*, *e.g.*, by implants with [^{3}H]vasopressin.

Vasopressin Release in the Brattleboro Rat—Long-term reduction of diabetes insipidus and reasonably constant excretion of vasopressin for several weeks were achieved by vasopressin implants (Fig. 7; note that compared with Fig. 2, vasopressin data are not expressed on a logarithmic scale). The higher excretion in the first few days was due to adaptation, probably at the level of the kidney (22, 23), since it was also seen with injected or minipump-driven vasopressin treatment (Fig. 8B, C). Assuming that ~1% vasopressin was extruded daily from the implant for 40 d, the 67% remaining in the stock should have a lower release rate. Since vasopressin urine excretion in rats is independent of infusion rate (24), the vasopressin excretion in Brattleboro rats should decline over time. The present data do not show such an effect. Only a twofold decrease occurs during the first 40 d for the 220-μg loaded implant and no decrease is observed for the 22-μg load (Fig. 7B, C). For high loads, *i.e.*, high release rates, the expected 1–2% of release per day is therefore an overestimation, probably due to the assumption of a zero subcutaneous concentration. In fact, a concentration gradient is to be expected around the vasopressin implant, which inhibits release (21) (it also could not account for the preparation acting over 100 d; Fig. 7C). In contrast to *in vitro* release (Fig. 4), the *in vivo* release indicated by daily urine vasopressin excretion appeared to be lowered with vasopressin tubing load (Table II). This additionally points to a protracted subcutaneous release of vasopressin. The rapidly decreasing release rate with the use of low-vasopressin contents of the microporous polymer tubing (Fig. 7A) is less easy to explain. Inactivation of the lower vasopressin stock may have a relatively higher threshold, or a tight encirclement of the tubing by connective tissue may be more effective in reducing the escape of vasopressin into the blood (25).

Daily injection of 100 mU of vasopressin tannate (*i.e.*, ~200 ng of vasopressin as a long-acting preparation) is shown to be the substitution dose of the Brattleboro rats (22). Normalization of diuresis ≥40 d, was brought about by implantation of a 22-μg vasopressin-loaded microporous polymer–collodion device (Table II) from which <220 ng/d is extruded. An approximately fivefold higher treatment (but supplied by an osmotic minipump) decreased urine production to near normal levels (Table II) (26). The present device, therefore, not only yielded a better alleviation of the diabetes insipidus (Table II), but also considerably prolonged the period with a more efficient use of vasopressin. Perhaps differences in release surface (entire surface of tubing *versus* small orifice of minipump) cause this effect, which could result in a different rate of uptake.

Concluding Remarks—The microporous polymer–collodion delivery module appears to be biocompatible and can be used as an implant in adult rats. Its use requires a simple operation and treatment is easily terminated. When the commercially available osmotic minipump is too large for implantation, the size of the microporous polymer delivery system allows peptide treatment of young and immature laboratory rats. The potential of the present device, moreover, is underlined by the possibility of prenatal application with smaller-sized microporous polymer tubing. The release properties of this 0.7-mm diameter tubing have been examined only in pilot studies, but did give a lasting release for vasopressin *in vitro* as well[14].

The adsorption-based mechanism of the constant delivery makes the microporous polymer technique a novice in the field of polymer monolith or membrane-controlled drug delivery systems (5, 6, 21). Whenever adsorption can be introduced on the typical microporous structure of microporous polymer and protection against the rapid desorption from outside compounds is possible, the device will provide a constant and lasting release for other peptides and possibly for other physiological compounds and pharmaceuticals as well.

Sustained-Release Characteristics of a New Implantable Formulation of Disulfiram

MICHAEL PHILLIPS *§x **and JOSEPH D. GRESSER** ‡¶

Received November 7, 1983, from the **Division of Internal Medicine, Georgetown University Hospital, Washington, DC 20007* and *‡Dynatech Research and Development Company, Cambridge, MA 02139.* Accepted for publication March 1, 1984. Present addresses: §Division of General Medicine and Clinical Pharmacology, The Chicago Medical School, North Chicago, IL 60064 and ¶Key Pharmaceuticals, Inc., Miami Beach, FL 33169.

Abstract □ The object of this study was to evaluate the sustained-release characteristics of a new formulation of disulfiram. Solid rods (500 mg) made of a composite of 80% poly(glycolic-co-L-lactic acid) and 20% ^{14}C-labeled disulfiram were implanted subcutaneously in five Wistar CD-1 rats; a control group received 100 mg of ^{14}C-labeled disulfiram subcutaneously. Excretion of radiolabeled material in the urine and feces was monitored for 88 d. Sustained mobilization of drug was observed in the copolymer–disulfiram implant group, reaching a peak value 30 d after implantation. The control group exhibited first-order kinetics of drug mobilization. At necropsy, there was no encapsulation of the residual rods. The copolymer–disulfiram composite performed as a true sustained-release system, and improved formulations may have clinical applications in the treatment of alcoholic humans.

Keyphrases □ Disulfiram—sustained-release implantable formulation, rats, poly(glycolic-co-L-lactic acid) □ Sustained-release formulations—implantable disulfiram, poly(glycolic-co-L-lactic acid), rats

Disulfiram is widely prescribed to discourage alcoholics from drinking alcohol, since the two drugs interact to produce a subjectively unpleasant experience characterized by facial flushing, nausea, tachycardia, and hypotension (1–4). The effectiveness of disulfiram as a treatment for alcoholism is severely limited by the willingness of patients to take the drug every day; many stop taking their tablets so that they might resume drinking alcohol as soon as the effects have worn off (5). Frequent failures of treatment with the orally administered drug have stimulated interest in parenteral therapy with subcutaneously implanted disulfiram tablets, but numerous studies during the past 25 years have demonstrated that these implants have miniscule pharmacological effects, possibly due to their poor bioavailability (6–8).

However, animal studies have demonstrated that disulfiram can be rapidly mobilized from a subcutaneous site, provided that the drug is injected in an appropriate vehicle, *e.g.*, suspended in arachis oil (9) or dissolved in polyethylene glycol (10). These findings suggest that it might be possible to prepare a sustained-release disulfiram implant with a true pharmacological effect. Ideally, such a formulation would combine disulfiram with a vehicle which would deliver the drug into the circulatory system at a steady rate for several weeks or months at a time and be free of any significant local or systemic toxicity. A vehicle which appears to offer these features is a new biodegradable polymer, poly(glycolic-co-L-lactic acid) (PLGA). When implanted subcutaneously, the copolymer appears to degrade slowly into its parent monomers, lactic acid and glycolic acid, while continuously releasing any bound drug at a steady rate. *In vivo* studies of PLGA combined with contraceptives, narcotic antagonists, and antimalarials have shown that these implants can deliver the drug continuously into the circulatory system for several months at a time (11). We describe a study of the sustained-release characteristics of a new formulation of disulfiram combined with the copolymer, which was undertaken to investigate the feasibility of using such a preparation in the treatment of alcoholic humans.

EXPERIMENTAL SECTION

Polymer Synthesis—The general principles of poly(glycolic-co-L-lactic acid) synthesis have been described (11). It was synthesized in bulk in an evacuated glass vessel from a mixture of 90 g of L-lactide and 10 g of glycolide with 1 g of *p*-toluenesulfonic acid monohydrate as a catalyst. After deacrating the mixture to <0.05 mm Hg for 45 min, the vessel was sealed, rotated to mix the ingredients, heated at 118°C for 2 h, mixed again, then heated for 10 d at 118 ± 2°C. The resulting polymer was dissolved in tetrahydrofuran, filtered through glass wool, precipitated in distilled water, and vacuum dried. The mean molecular weight of the copolymer (34,428 ± 877) was determined by dissolving the polymer in tetrahydrofuran (5 mg/mL) and assaying by gel-permeation chromatography using an HPLC system[1] equipped with μ-Styragel columns and a differential refractive index detector.

Dilution of Radiolabeled Disulfiram—Radiolabeled (5.0 mCi) disulfiram, [1-^{14}C]bis(diethylthiocarbamoyl)disulfide[2], was diluted with 14.9991 g of unlabeled disulfiram[3] by stirring for 2 h at room temperature in 650 mL of reagent-grade ethanol[4]; 14.9860 g of diluted disulfiram was recovered after vacuum drying at 60°C for 10 d. Two samples of the diluted radiolabeled drug were assayed in triplicate for specific activity on a liquid scintillation counter[5]; the mean specific activity was 336 μCi/g.

Composite Preparation—A cosolution of ^{14}C-labeled disulfiram and PLGA (1:4, w/w) was prepared in dichlormethane and cast as a thin film on a clean glass surface. The film was adjusted to 0.06 cm (0.025 in.) in thickness with a film spreader[6], air dried, then vacuum dried at 45°C. The final dosage form was prepared by extruding rods of this composite through a 0.3175-cm die, at a temperature between 70–80°C and pressures up to 140 psi. These disulfiram–copolymer composite rods (20:80) had a mean specific activity of 62.92 ± 8.11 μCi/g.

Implantation—Two groups of animals were studied: a test group receiving the subcutaneous ^{14}C-labeled disulfiram–copolymer implant, and a control group receiving subcutaneous uncompounded ^{14}C-labeled disulfiram. Each group was comprised of five Wistar CD-1 male rats (100–200 g). After anesthesia[7] was administered a slit was cut in the skin of the interscapular region and a small subcutaneous pocket was dissected (large enough for the introduction of the 0.3175-cm diameter rods). Each rat received 500 mg of the compounded 20% rods (containing 100 mg of ^{14}C-labeled disulfiram and 400 mg of the copolymer) and the wound was closed with clips. The second group of rats served as controls and similarly received 100 mg of uncompounded powdered ^{14}C-labeled disulfiram. No attempt was made to preserve strict asepsis during these procedures.

Sample Collection and Analysis—All rats were individually housed in metabolism cages to facilitate the separate collection of urine and feces. Prior to implantation, three fecal and urine samples were collected to determine background counts. Subsequent samples of all excreted urine and feces were collected 1, 3, 7, 9, 11, 15, 18, 22, 25, 29, 32, 39, 46, 53, 60, 67, 74, 81, and 88 d after implantation. Urine samples were assayed for ^{14}C-labeled material in a liquid scintillation counter[8], and the extraction was calculated as the mass of implanted disulfiram which contained an equivalent amount of radiolabel. Feces were combusted to $^{14}CO_2$ with an oxidizer[9] and adsorbed in oxyfluor-CO_2[10] for counting. At the conclusion of the study, the rats were sacrificed and the excised rods from the experimental animals were assayed for residual drug. Pathological studies were performed on the injection sites of two animals from each group: the sites were inspected for gross changes and tissue sections were prepared (thickness, 7–10 μm), stained with hematoxylin and eosin, and examined microscopically.

Data Analysis—All data were stored on diskettes using a microcomputer[11] and software[12] to calculate the mean and standard deviation of total disulfiram excretion during each collection interval in the test and control groups. The line of best fit for the control group was calculated by the least-squares method.

RESULTS

Drug Excretion—The average daily excretion of radiolabeled material is shown for the test and control groups in Figs. 1 and 2. The combined excretion

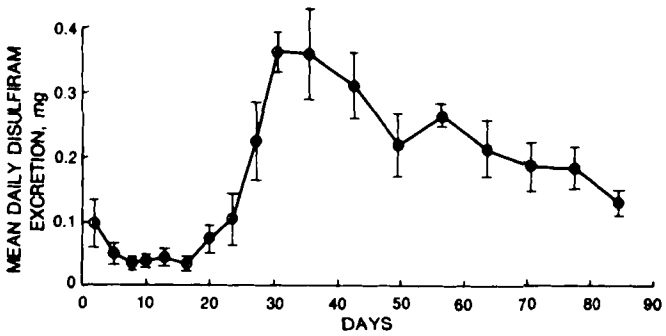

Figure 1—*Disulfiram–copolymer composite group mean daily excretion of radiolabeled metabolites in urine and feces following subcutaneous implantation. Bars indicate 1 SD.*

in urine and feces is expressed as the mass of implanted disulfiram which originally contained an equivalent amount of radiolabel. In all collection periods, the quantity of radiolabeled material in the urine was approximately 10 times greater than the amount detected in the feces. This was true for both groups of animals throughout the study. The cumulative recovery of radiolabeled material in urine and feces (expressed as a percentage of the total administered dose ±1 *SD*) was 17.41 ± 2.27% for the group receiving the disulfiram–copolymer composite and 80.54 ± 9.56% for the control group.

Residual Drug in Implanted Composite—The residual radiolabeled material in the excised composite rods accounted for an additional 55.53% (*SD* = 14.83%) of the administered dose of disulfiram. Hence, the total recovery of radiolabel from the rats receiving the disulfiram–copolymer composite accounted for 72.94% (*SD* = 14.49%) of the implanted dose. The mean weight of the rods recovered from the implantation sites was 55.53 mg (*SD* = 12.84). No residual drug was observed at the injection site in the control group.

Pathological Findings—One rat in the control group died on day 63 of the study; the cause of death was unknown. Excretion data from this animal did not deviate statistically from the others in the group and were included in the study. In the remaining animals, tissues from the injections sites were grossly and microscopically normal, with no evidence of residual drug, necrosis, or inflammatory reaction.

One rat in the test group excreted aberrantly large quantities of radiolabel during the early days of the study; at autopsy, a large abscess was found at the implantation site with no remaining rods. Data from this animal was not included in the findings reported above. The implantation sites of the remaining animals were grossly and microscopically normal, with no evidence of necrosis, inflammatory reaction, or encapsulation of the rods.

DISCUSSION

All excretion of radiolabeled material in this study was expressed in terms of the equivalent quantity of implanted disulfiram. This was not meant to imply that unchanged disulfiram was measured in the urine and feces; to the contrary, there is strong evidence that disulfiram is very rapidly metabolized in the blood and liver, and the breakdown products are promptly excreted (10, 12, 13). At least one of the metabolites, carbon disulfide, is a volatile compound excreted in the breath, which might account for some part of the discrepancy between the implanted dose and the total amount of drug recovered. The real utility of expressing excretion of radiolabel in terms of quantity of the parent drug lies in the insight it provides into the rate of mobilization of the disulfiram from the injection site.

The mobilization of drug from the disulfiram–copolymer composite (Fig. 1) demonstrates that the major objective of the study was achieved: sustained systemic delivery of disulfiram for a 3-month period. During that time, the drug was delivered continuously, although fluctuations were observed in the rate of delivery. An ideal implantable drug delivery system would achieve zero-order kinetics, *i.e.*, the rate of delivery would rapidly reach its maximal value and remain there until the supply of drug was exhausted. However, in clinical practice, even a nonideal delivery system may achieve a near-ideal pharmacological effect, provided that the rate of delivery oscillates within a defined "therapeutic window" (with upper and lower limits defined as the rates of delivery at which either toxic effects or inadequate clinical responses are observed). Consequently, even though fluctuations were observed in the rate of delivery of disulfiram from the composite implant, it could provide an acceptable therapeutic effect for a period of 3 months or longer.

The mobilization of injected powdered disulfiram in the control group provided an unexpected finding (Fig. 2), in view of the known poor bioavailability of disulfiram in subcutaneously implanted tablets. The first-order

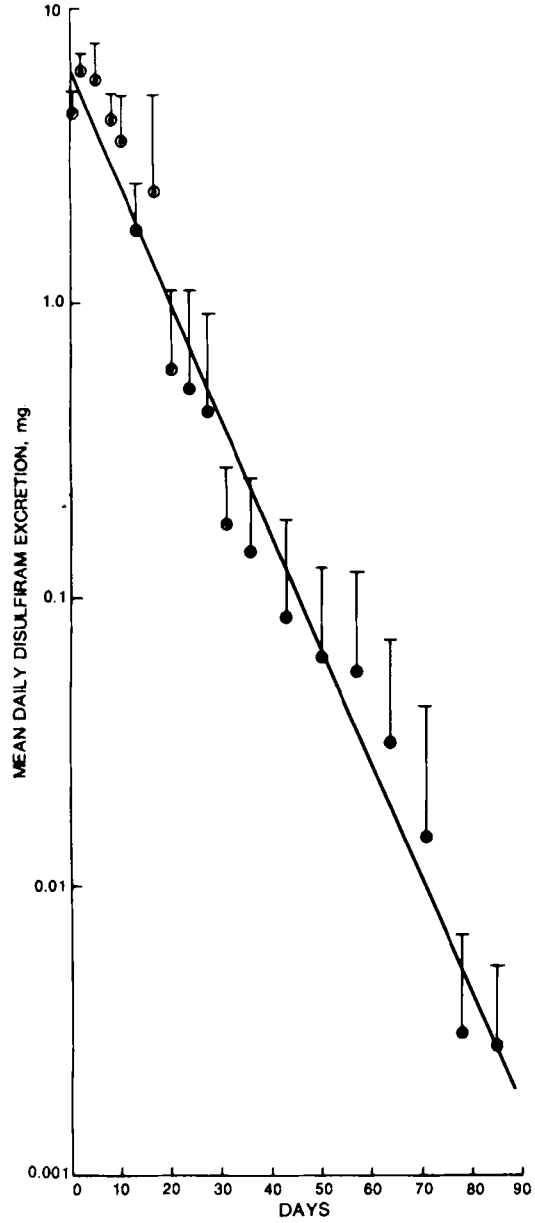

Figure 2—*Control group mean daily excretion of radiolabeled metabolites in urine and feces following subcutaneous injection of powdered disulfiram* $t_{1/2}$ = *7.53 d. Bars indicate 1* SD. (*Log* y = −0.04 x + 0.80; r^2 = 0.97; $p < 0.0001$.)

mobilization kinetics are consistent with the commonly observed kinetics of other parenterally administered drugs (14). It is possible that the bioavailability of the disulfiram was enhanced by administering it in powder form, thus greatly increasing the surface area available for the dissolution of the drug in the interstitial fluid. The long half-life of the powdered disulfiram (7.53 d) may be a function of its poor solubility in water, and raises the possibility that this preparation may also have potential clinical application.

These data demonstrate that the disulfiram–copolymer composite has the properties of a sustained-release formulation when implanted subcutaneously in rats, with no evidence of local or systemic toxicity. However, a number of factors must be taken into account before any trial of a similar material is contemplated in human subjects. First, the ratio of disulfiram to the copolymer is low, so that prohibitively large volumes of composite might be required for a prolonged period of treatment. For use in human subjects, an improved composite with a higher ratio of drug to vehicle would probably be desirable. Second, the daily dosage requirement for parenteral disulfiram is not yet known. Although patients generally require 250–500 mg of the oral drug each day to achieve a clinical effect, more research is required to determine whether or not parenteral disulfiram needs to be administered in similar quantities. Pending these advances in technology and basic knowledge, we suggest that sustained-release disulfiram implants may eventually achieve a clinical application in the treatment of alcoholic humans.

Characterization of Drug-Loaded Poly(*d*,*l*-lactide) Microspheres

S. BENITA *x, J. P. BENOIT ‡, F. PUISIEUX ‡, and C. THIES §

Received July 11, 1983, from the *Pharmacy Department, School of Pharmacy, Hebrew University of Jerusalem, Israel, the ‡Laboratoire de Pharmacie Galenique, Faculte de Pharmacie de l'Universite Paris-Sud, Chatenay-Malabry, France, and the §Biological Transport Lab., Washington University, St. Louis, MO 63130. Accepted for publication February 23, 1984.

Abstract □ Lomustine and progesterone have been incorporated in biodegradable poly(*d*,*l*-lactide) microspheres by evaporating dichloromethane from stirred dichloromethane-in-water emulsions. Spherical microspheres with lomustine or progesterone payloads ≤23% were obtained. Higher lomustine payloads gave irregularly shaped particles. Microspheres with ≤68% progesterone were obtained, but free drug crystals formed on the surface of such microspheres. Increased agitation rates decreased mean microsphere size. Addition of drug to the dichloromethane phase increased average particle size relative to that obtained with drug-free microspheres prepared under the same experimental conditions. Complete evaporation of the dichloromethane, while the medium was continuously stirred, promoted formation of free drug crystals in the aqueous phase. Increased emulsifier concentrations did not significantly enhance drug incorporation efficiency within the microspheres. Shelf-life stability of lomustine and progesterone was reduced by incorporation in the microspheres, presumably due to their molecular dispersion in the poly(*d*,*l*-lactide).

Keyphrases □ Poly(*d*,*l*-lactide) microspheres—loaded with lomustine, progesterone, effect of emulsifier concentrations, agitation rates on formation, stability □ Microspheres—poly(*d*,*l*-lactide), progesterone, effect of emulsifier concentration, stability

Parenteral controlled-release systems which are capable of being targeted to tissue sites and to deliver their active ingredient over a long period of time are of considerable interest (1). These potential sustained-release drug-targeting dosage forms require the use of biodegradable polymers as drug carriers. Candidate biodegradable materials include gelatin (2), albumin (3, 4), poly(lactide-glycolide) copolymers (5), and polylactide (6–9). Progesterone has been incorporated in poly(*d*,*l*-lactide) microspheres in order to design an injectable long-acting delivery system. Such a dosage form administered *in vivo* yielded promising pharmacological action (10). Since little has been reported about the physical properties of such microspheres, a study of their properties as a function of the preparative conditions was carried out. Poly(*d*,*l*-lactide) microspheres containing either progesterone or lomustine were prepared. The ultimate objective is to use the latter to produce tumor embolism by intra-arterial infusion. This therapeutic method has been shown by Kato *et al.* (11), using mitomycin C microcapsules, to be an effective means of combining vascular mechanical obstruction and slow release of active mitomycin C within tumors.

EXPERIMENTAL SECTION

Materials—Poly(*d*,*l*-lactide) was supplied by D. N. Mason[1] and had a mean mol. wt. of 61,000. Two polymeric emulsifiers were used: 88% hydrolyzed polyvinyl alcohol[2] and methylcellulose (10 and 400 cps grades)[3]. Progesterone[4] and lomustine[5] [*N*-(2-chloroethyl)-*N'*-cyclohexyl-*N*-nitrosourea] were used as supplied. Dichloromethane[6], Analar grade, was employed without further purification.

Methods—Microspheres were formed at atmospheric pressure by a process similar to that described by Beck *et al.* (10). The procedure involved placing, in a 400-mL glass beaker, 250 mL of water that contained polyvinyl alcohol or methylcellulose. A solution that contained 20 mL of CH_2Cl_2, 927 mg of poly(*d*,*l*-lactide), and a known weight of drug (280–2,000 mg), was poured rapidly into the aqueous phase as it was stirred at a constant rate by a stirrer fitted with a digital revolution counter[7]. The resulting emulsion was agitated at 22° C for a known period of time during which the CH_2Cl_2 evaporated. In a few cases, the system was agitated continuously until CH_2Cl_2 evaporation was complete. This is the continuous evaporation process. For most runs, the interrupted evaporation process was used; agitation was stopped before CH_2Cl_2 evaporation was complete, the partially dried microspheres were allowed to settle, and the aqueous phase that contained the polymeric dispersing agent was replaced with deionized water by three washing and decantation steps. Once the microspheres were resuspended in emulsifier-free water, they were agitated 7–17 h so that CH_2Cl_2 evaporation could proceed to completion. Removal of the polymeric emulsifier from the aqueous phase before completion of CH_2Cl_2 evaporation minimizes formation of free drug crystals in the aqueous phase or on the surface of the microspheres (12).

On completion of CH_2Cl_2 evaporation, the microspheres were isolated by filtration, washed, and dried under reduced pressure at 22° C for 20 h. The dried microspheres were sieved and stored in a desiccator until used. The preparative parameters varied in this study include: polymeric emulsifier and emulsifier concentration, amount and type of drug incorporated in the microspheres, rate of agitation, and length of agitation. Theoretical microsphere drug contents (or payloads) specified in this paper represent the percent by weight drug carried by a microsphere if all the drug and all the poly(*d*,*l*-lactide) added to an encapsulation system were incorporated in the microspheres. Actual or measured drug contents were usually lower than the theoretical values due to drug loss to the aqueous phase during CH_2Cl_2 evaporation.

Microsphere Evaluation—*Progesterone Content*—Progesterone-loaded microspheres (30 mg) were dissolved in 2 mL of CH_2Cl_2. Ethanol (23 mL) was added to precipitate the poly(*d*,*l*-lactide). The resulting suspension was centrifuged at 20,000 rpm for 10 min. The clear supernatant was diluted with ethanol and 10 μL of the resulting solution was injected into an HPLC[8]. The chromatograph operating conditions were: C_8 reverse-phase column (10-μm spheres); methanol eluant; eluant flow rate 2 mL/min; 254 nm detector. Under these conditions, progesterone had a retention time of 97 s. The progesterone content of sample solutions was obtained from a progesterone calibration curve constructed from standard progesterone solutions.

Lomustine Content—Lomustine-loaded microspheres (30 mg) were dissolved in 2 mL of CH_2Cl_2. Ethanol (23 mL) was added to precipitate the poly(*d*,*l*-lactide). After centrifugation at 20,000 rpm for 10 min, the clear supernatant (10 μL) was subjected to HPLC analysis. The HPLC operating conditions were the same as those used for progesterone assays, except that the eluant was an acetonitrile-water mixture (75:25, v/v). The lomustine retention time was 143 s. Control experiments with cyclohexylamine and 2-chloroethanol, two known lomustine degradation products, established that neither compound gave an interfering peak within 240 s of elution. Lomustine contents of all samples were obtained from a calibration curve constructed from standard lomustine solutions.

Microscopy Studies—Optical and scanning electron microscopy were used to evaluate the drug incorporation and surface characteristics of the microspheres prepared under the various conditions used. The optical microscope[9] and the electron microscope[10] were equipped with cameras.

RESULTS AND DISCUSSION

Characterization of the Microspheres Formed—The presence of an emulsifying agent is vital to the successful formation of individual spherical microspheres by the solvent evaporation process. The emulsifiers used in this

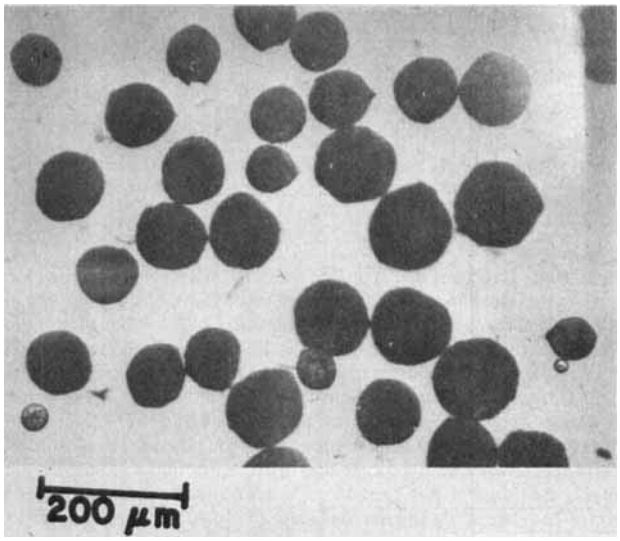

Figure 1—*Photomicrograph of lomustine-loaded microspheres prepared by the continuous evaporation process at 250 rpm with 0.05% (w/w) methylcellulose as emulsifier. Theoretical lomustine content: 35% (w/w). Magnification: 100×.*

study, partially hydrolyzed polyvinyl alcohol and methycellulose, gave suitable microspheres, although there was some difference in their performance. When lomustine was dissolved in the CH_2Cl_2 phase, along with poly(*d,l*-lactide), both emulsifiers gave spherical microspheres as long as the initial lomustine concentration was not >280 mg/20 mL of CH_2Cl_2. Higher lomustine concentrations gave irregularly shaped particles (Fig. 1).

Dichloromethane-poly(*d,l*-lactide) solutions that contained ≤2000 mg of progesterone/20 mL of CH_2Cl_2 formed stable emulsions in water when methylcellulose was the emulsifier. Higher progesterone concentrations gave misshapen particles or unstable emulsions. For this reason, poly(*d,l*-lactide) microspheres with a >68.3% (w/w) progesterone payload were not prepared. When polyvinyl alcohol was the emulsifier, solutions containing >0.5 g of progesterone/20 mL of CH_2Cl_2 consistently formed unstable emulsions. Accordingly, poly(*d,l*-lactide) microspheres with progesterone payloads >35% (w/w) were not prepared with this emulsifier.

Although polyvinyl alcohol and methylcellulose formed suitable CH_2Cl_2-in-water emulsions for a range of initial lomustine and progesterone solutions, spontaneous crystallization of these drugs occurred either in the aqueous phase or on the surface of the microspheres when either emulsifier was left in the aqueous phase until CH_2Cl_2 evaporation was complete. With lomustine, the free crystals usually appear as well-defined rods in the aqueous phase (Fig. 1). With progesterone, the free crystals also appear in the aqueous phase, but as very fine particles.

Crystal formation is eliminated or greatly reduced for 50–600-μm microspheres that have drug payloads ≤25% (w/w) if agitation is stopped well before solvent evaporation is complete and the emulsifier is removed from the aqueous phase. Solvent evaporation is then taken to completion in emulsifier-free water. If the emulsifier is removed too soon, the microspheres agglomerate because they contain too much CH_2Cl_2. If the emulsifier is removed too late, free crystals appear. Thus, there is an optimal time interval during which emulsifier removal can occur without microsphere agglomeration or free crystal formation (12). This time interval (or window) is defined experimentally for each formulation. For microspheres prepared at an agitation rate of 150 rpm, the time interval typically varied from 200 to 240 min.

Microspheres that contain ≤25% (w/w) progesterone or lomustine are spherical and have very smooth surfaces, if free crystals do not form. Figure

Table II—Effect of Stirring Rate on Lomustine Microsphere Content and Size [a]

Stirring Rate, rpm	Measured Drug Content, %[b]	Drug Loss, %[c]	Mean Particle Size, μm ± *SD*
150	20.2	12.9	289.9 ± 88.3
250	19.8	14.7	102.5 ± 25.1
350	19.7	15.1	71.0 ± 16.6
450	19.9	14.2	58.2 ± 15.6

[a] All microspheres had a theoretical content of 23.2% (w/w) lomustine and were made by the continuous evaporation process with 0.27% polyvinyl alcohol as the emulsifier. [b] Mean of three determinations. [c] [(Theoretical drug content − measured drug content)/(theoretical drug content)] × 100.

2 illustrates the type of smooth surface obtained. There is no evidence of macroscopic pores. Formation of free progesterone crystals seems to have no effect on the surface structure of poly(*d,l*-lactide) microspheres when the theoretical progesterone payload is ≤31% (w/w). This is not the case for lomustine-loaded microspheres. Figure 3 is a scanning electron micrograph of such microspheres that had a theoretical lomustine payload of 23% (w/w) and were made under conditions that allowed free lomustine crystals to form. The surface is rippled and rough. In most cases, free lomustine crystals are not visible on the surface of the microspheres.

As long as drug payloads are kept below ~25% (w/w) for lomustine and 32% (w/w) for progesterone, most free drug crystals that form either float in the water phase or are so loosely attached to the microsphere surface that they wash off during the isolation step. The loss of free drug crystals reduces the amount of lomustine or progesterone incorporated in the microspheres. Measured lomustine and progesterone losses in such cases range from 7.6 to 23.2% (Table I). Drug losses are reduced when microspheres are prepared by the interrupted evaporation process and free drug crystals do not form. However, efficiency of drug incorporation always is relatively high whether or not free crystals form. Large amounts of progesterone and lomustine are not partitioned from the CH_2Cl_2 phase into the aqueous phase during the multihour fabrication process. Since lomustine is sensitive to water, it is significant that extensive degradation did not occur during fabrication of the microspheres.

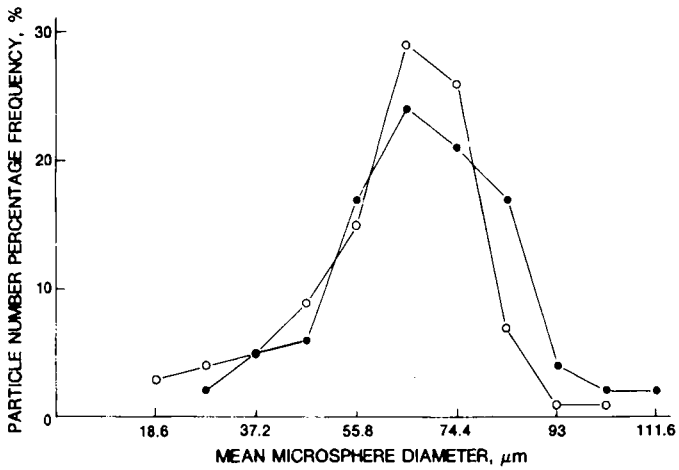

Figure 5—*Size distribution of drug-free and progesterone-loaded (23.2%, w/w) microspheres prepared at 350 rpm by the continuous evaporation process with 0.27% (w/w) polyvinyl alcohol as emulsifier. Key: (○) empty microspheres; (●) progesterone-loaded microspheres.*

Effect of Stirring Rate—Increasing the stirring rate decreases the mean diameter of the microspheres and reduces the width of the size distribution (Fig. 4, Table II). Incorporation of progesterone (23%, w/w) within the microspheres gives larger microspheres than drug-free microspheres prepared under identical conditions. However, the mean size and size distribution of drug-free and progesterone-loaded microspheres converge as the agitation rate is increased to 350 rpm (Fig. 5). The larger size of progesterone-loaded microspheres formed at lower agitation rates may reflect an increase in viscosity of the poly(*d,l*-lactide)–CH_2Cl_2 solution caused by the progesterone. Stirring rate had no detectable influence on drug content of the microspheres.

Effect of Initial Emulsifying Agent Concentration—Table III contains comments about initial polyvinyl alcohol concentration effects on microsphere properties. For a constant rate of agitation, microsphere size increased as the polyvinyl alcohol concentration increased due to an increase in viscosity of the aqueous phase. The high viscosity of the 5% (w/w) polyvinyl alcohol so-

0.27	31.7	21.5	47.4
0.27	31.7	24.8	27.8
2.5	23.6	19.0	24.2
5.0	23.2	17.8	30.3

[a] In a desiccator at 25° C for a period of 16 months. [b] Mean of three different experimental determinations.

lution hampered the washing process by prolonging microsphere sedimentation time. This led to increased microsphere aggregation.

Yields of isolated microspheres were related to final particle diameter. Microsphere batches composed of large particles were almost completely recovered. Yields of smaller particles (<100 μm) were reduced, since many small microspheres were lost during successive decantation washings.

Effect of Initial Drug Concentration—In an attempt to increase the progesterone content of the microspheres, a number of experiments were performed in which increasing amounts of progesterone were added to a fixed weight (927 mg) of poly(*d,l*-lactide). The comments in Table IV indicate that microspheres containing ≤31.7% progesterone could be prepared without appearance of free drug crystals in the aqueous phase, provided the emulsifier was removed from the system before CH_2Cl_2 evaporation was complete. Above 31.7%, free progesterone crystals appeared in the aqueous phase whether or not the emulsifier was removed. Moreover, crystals embedded in the microsphere surfaces could be distinguished. When the progesterone payload was raised to 68.3%, the microspheres remained basically spherical, but surface defects were visible (Fig. 6).

Stability Studies—Four progesterone-loaded microsphere samples were stored in a desiccator at room temperature for 16 months. They were prepared while avoiding formation of free progesterone crystals in the aqueous phase. The microspheres containing 31.7% progesterone became yellowish whereas the color of the 23.2% progesterone microspheres remained unchanged after a storage period of 16 months, even though progesterone experienced significant degradation during this period (Table V).

Lomustine microspheres, prepared by the standard procedure avoiding crystallization in the aqueous phase, were stored under different temperatures, in desiccators, and protected from light. The stability experiment results are

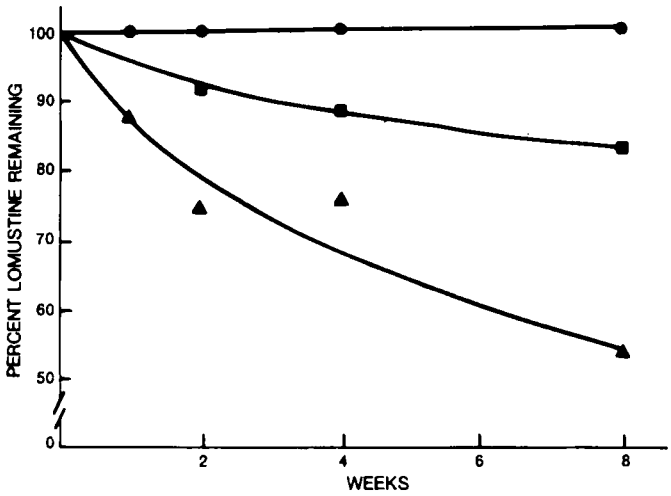

Figure 7—*Influence of storage temperature on desiccated shelf-life stability of lomustine-loaded (22.0%, w/w initially) poly(d,l-lactide) microspheres prepared by the interrupted evaporation process at 250 rpm with 0.27% (w/w) polyvinyl alcohol as emulsifier. Key, microsphere storage conditions: (●) 3° C; (■) 22° C; (▲) 37° C.*

shown in Fig. 7. At 3°C, lomustine incorporated into the microspheres remained stable for at least 8 weeks. However, degradation occurred within 8 weeks upon storage at 25° C and 37°C. The decomposition rate increased with increasing temperature. Lomustine crystals were stable over a period of 8 months at room temperature in a desiccator protected from light. Dispersing the drugs in the microspheres accelerated the degradation, probably as a result of their internal dilution within the coating polymer and chemical exposure to the polymer molecules.

Quantum Chemical Approach to the Relationship Between Molecular Structure and Serotonin Receptor Binding Affinity

J. S. GÓMEZ-JERIA ˣ and D. R. MORALES-LAGOS

Received December 1, 1982, from the *Departamento de Química, Facultad de Ciencias Básicas y Farmacéuticas, Universidad de Chile, Casilla 653, Santiago, Chile.* Accepted for publication September 13, 1983.

Abstract □ We have analyzed the dependence of the serotonin receptor binding affinity on the atomic net charges, superdelocalizabilities, mass, and moment of inertia in a group of indole derivatives. The approaches employed are a new nonempirical quantitative structure-activity relationship (QSAR) method and multiple regression analyses. The results suggest that the indole derivatives interact with the receptor through a charge transfer between the phenyl ring and a counterpart in the receptor, plus some localized electrostatic interactions. Also, the fit of the equation obtained suggests that the indole derivatives have the aromatic ring placed in the same relative position during the interaction with the receptor.

Keyphrases □ Quantitative structure-activity relationships—perturbation theory, serotonin receptor binding affinity, quantum chemistry □ Serotonin—receptor binding affinity, perturbation theory, quantitative structure-activity relationship (QSAR) quantum chemistry

In recent years, there have been important advances toward a greater understanding of the activity of indole derivatives in terms of how their molecular structures might influence biological activity (1–16). It has been observed that there is a linear correlation between the potencies of tryptamine derivatives on the rat fundus and their ability to inhibit LSD (lysergide) binding to brain membranes (1, 2). This fact strongly supports the hypothesis that the conclusions based on the rat fundus receptor may hold also for the receptor in the brain.

A good correlation has been found between frontier orbital electron densities (FOED) and the ability of tryptamine derivatives to contract the rat fundus strip (3, 7). Also, it was observed (8, 9) that the position at which a high FOED was correlated with high biological potency corresponded to the sites at which the density of the highest occupied molecular orbital (HOMO) is localized in 5-hydroxytryptamine (serotonin, 5-HT), a fact that might explain the negative correlation between potency and FOED at certain atoms (1, 4). Also, the localization pattern of electron density for the HOMO and the next HOMO (NHOMO) of LSD is similar to that of 5-HT (10). These facts suggest that these molecules may interact with the receptor through a complex involving charge transfer from certain sites of the drug toward the receptor.

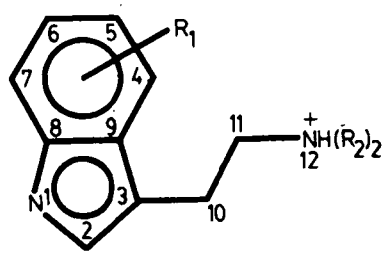
The patterns of the electrostatic potential maps of LSD and 5-HT show great similarities (10). The HOMO has a high influence on the electrostatic potential on the vicinities of the aromatic portion of the tryptamine derivatives (11).

Weinstein and co-workers (10, 12, 13) have suggested that a tryptamine congener attains a 5-HT-like recognition at the receptor by anchoring its side chain at the same place as 5-HT with its electrostatic vector (the vector connecting the minima through the area of the steepest change in the electrostatic potential) oriented parallel to the electrostatic vector in 5-HT. This matching is achieved by a conformational change in the side chain. For example, in the model of Weinstein and coworkers the aromatic rings of 5-HT and 6-HT are not in the same position during the interaction with the receptor (13). Also, on the basis of model complex calculations, these authors suggested that the interaction is mainly electrostatic (12), the transfer of charge being negligible.

The analysis of the photoelectron ionization potentials of LSD, some phenethylamines, and tryptamine derivatives (14, 15) has shown that not only the first ionization potential, but also the second ionization potential must be considered in order to correlate biological activity with the ionization potentials. This is consistent with the participation of the aromatic ring as an electron donor in the drug-receptor interaction, the ability of the stronger donor generally correlating with a greater activity. This study confirms the importance of the frontier orbitals, coinciding with the above points.

Glennon and Gessner (16) obtained a correlation between the binding affinities (pA_2) of some tryptamine derivatives in the 5-HT receptor of the rat stomach fundus and the ability to donate electrons in a localized charge transfer manner from the 4-position of the indole nucleus. Considering that the rat stomach fundus is an *in vitro* preparation (17, 18), the measured binding affinities will reflect only the binding energy between the drugs and the receptor. Also, as it seems that there is a certain similarity between the ability to interact with the rat fundus 5-HT receptor and 5-HT binding sites in the brain (1, 2), the study and analysis of the relations between pA_2 and the molecular electronic structure would be of a great help in a rational design of new tryptamine derivatives.

We report here the application of a new quantum-statistical approach, searching for a relationship between pA_2 and some reactivity indices.



EXPERIMENTAL SECTION

Consider the weak interaction of a drug, D_i, and a macromolecular receptor, R. The model is based on the following reasonable hypotheses (19):

1. The conformation of the receptor is so strongly preferred that the binding energy is accounted for entirely in terms of local atomic interactions.
2. The total molecular partition functions can be factorized in terms of independent and uncoupled translational, rotational, vibrational, and electronic partition functions.
3. Only the electronic ground state is important in the electronic partition function.

With this model, it is possible to show formally that the drug-receptor equilibrium constant, K_i may be expressed as (19):

$$\log K_i = q + b \cdot \log M_i + c \cdot \log \sigma_i/(\mathrm{ABC})_i^{3/2}) + d\Delta E_i \quad \text{(Eq. 1)}$$

[a] See Fig. 1 for the substituent position. [b] Calculated using Eq. 5. [c] Taken from Ref. 26. [d] With a methyl group in position 2. [e] With S instead of N in position 1. [f] With a methyl group in position 1.

where a, b, c, and d are constants; M, σ, and (ABC) are, respectively, the mass, the symmetry number, and the product of the three moments of inertia about the three principal axes of rotation of the ith drug molecule; and ΔE_i is the difference between the ground state energy of the complex and the energies of D_i and R, *i.e.*:

$$\Delta E_i = E_{D_iR} - (E_{D_i} + E_R) \qquad \text{(Eq. 2)}$$

In a first approach, we shall accept that, among all the components of ΔE_i the most important is the change in the electronic energy ΔE_i^e (20). Considering the interaction of the indole derivatives with the receptor as weak (*i.e.*, without the formation of covalent bonds), a perturbation treatment (21) may be performed for the evaluation of ΔE_i^e. In this way, after some approximations as the molecular structure of the receptor is unknown (22, 23), ΔE_i^e can be expressed as:

$$E_i^e = q + \sum_p (f_p Q_p^i + g_p S_p^{E,i} + h_p S_p^{N,i}) \qquad \text{(Eq. 3)}$$

where q, f_p, g_p, and h_p are constants; and Q_p^i, $S_p^{E,i}$, and $S_p^{N,i}$ are, respectively, the net charge, the electrophilic superdelocalizability, and the nucleophilic superdelocalizability of atom p in molecule i (24).

Inserting Eq. 3 into Eq. 1, we get (19):

$$\log K_i = q' + b \cdot \log M_i + c \cdot \log [\sigma_i (\mathrm{ABC})_i^{-3/2}] + \sum_p (f_q Q_p^i + g_p S_p^{E,i} + h_p S_p^{N,i}) \qquad \text{(Eq. 4)}$$

The summation on p is over a set of atoms common to all the drugs that interact with the receptor. If Eq. 4 is to be satisfied, there must exist a common set of atomic reactivity indices in all the drugs interacting with the same receptor.

We have taken the pA_2 value as a good approximation to the affinity constant of the drug-receptor complex (25). These values were selected from the literature (26) (Table I).

We employed statistical analysis to determine the set of atomic properties in an attempt to find a group of variables whose variation better explains the variation of the pA_2 values in a series of molecules. A special case of Eq. 4 has been applied with success to very different kinds of drugs (22, 27–29).

The ring geometry is displayed in Fig. 1; this geometry is similar to the one used by Inoue *et al.* (30). The bond distances for the ring substituents were taken from the literature (31).

Considering that the structure of LSD possesses both the phenylalkylamine and the indolealkylamine molecular subfragments (32), we accepted as a working hypothesis that the phenethylamine and tryptamine derivatives mimic partially or totally the LSD structure during interaction with the receptor. With this consideration, and for the sake of simplicity, we placed the amine

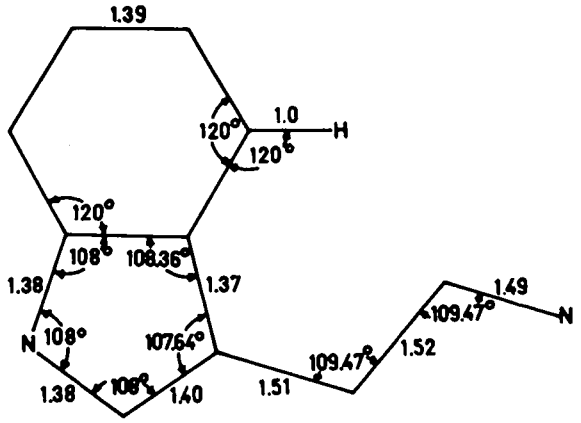

Figure 1—*Geometric parameters for the ring and the side chain.*

chain in the same plane as the phenyl ring. The net charges and the superdelocalizabilities were calculated from a CNDO/2 wave function (33).

RESULTS AND DISCUSSION

The statistical fitting of Eq. 4 was performed by means of a stepwise regression technique with pA_2 as the dependent variable. The net charges and the electrophilic superdelocalizabilities of the aromatic ring, plus the net charges and the nucleophilic superdelocalizabilities of the side-chain atoms, plus the mass and moment of inertia factors were used as independent variables (20 in all) (Table II). More than 500 combinations of variables were analyzed. The best expression found is:

$$pA_2 = 8.2812 + 3.1383Q_4 + 2.0529Q_7 + 4.8660S_5^E - 3.1825S_7^E - 2.2494S_8^E + 1.1416I \qquad \text{(Eq. 5)}$$

where $I = \log [\sigma_i/(\mathrm{ABC})_i^{3/2}]$.

This equation has a multiple correlation coefficient (r^2) of 0.97, which represents a significance of >94.1%, and a mean SD of 0.20. The analysis of variance (34) of Eq. 5 gives $F_{6,17} = 42.22$, showing the very high significance of this equation ($p < 0.0005$).

The results of the Student's t test for the significance of the coefficients are shown in Table III; the pA_2 values calculated with Eq. 5 are shown in Table I. The squared correlation matrix for the independent variables is presented in Table IV. The variables Q_4 and S_5^E appear with a relatively high r^2 value (Q_4 explaining the 62% of S_5^E). Nevertheless, considering that a certain degree of correlation between variables belonging to an aromatic system must be expected, and that these two variables have different physical meanings (the net charges representing electrostatic interactions and the electrophilic superdelocalizabilities being related to charge transfer), we think that they represent different physical processes.

Also, from the work of Topliss and Edwards (35), we can see that the relationship between the number of observations required to screen 18 variables, while keeping the probability of encountering a chance correlation with $r^2 \geq 0.9$ at the ≤1% level, is ~19. Therefore, the risk of chance correlation is very low.

The binding affinity is, therefore, related to a definite set of electronic indices. Considering the high significance of Eq. 5, we accepted that, within the accuracy of the approximations used for the determination of ΔE_i and pA_2, the results obtained suggest the existence of a direct dependence between the variation of pA_2 and those of the reactivity indices of Eq. 5.

The appearance of the total atomic electrophilic superdelocalizabilities in Eq. 5 indicates that the variation of pA_2 will depend on the relative reactivity of atoms 5, 7, and 9 toward the electrophilic components of the receptor. Also, their appearance suggests that the drug–receptor interaction has a strong orbital-controlled character (21). This is in perfect accord with the idea of a localized charge transfer from the drug to the receptor.

Remembering that S_5^E contains the contribution of the HOMO, the appearance of S_5^E is similar to that of the FOED at the 5-position. We cannot ensure that the frontier orbitals play a high significant role, because S^E, by including the other molecular orbitals, will obscure the contribution of the HOMO and NHOMO. The dependence of the variation of pA_2 on a variation of Q_4 and Q_7 indicates an electrostatic interaction between these atoms and one or more centers in the receptor.

The other index which contributes significantly is related to the molecular moment of inertia, and is defined as:

$$I = \log \sigma_i - (3/2)(\log A + \log B + \log C) \qquad \text{(Eq. 6)}$$

For explanatory purposes we shall examine the case where $A = Ixx$. In this case we have:

$$\log A = \log Ixx = \log \sum_i m_i(y_i^2 + z_i^2) \qquad \text{(Eq. 7)}$$

where m_i is the mass of atom i, whose coordinates are x_i, y_i, z_i. Inspection of Eq. 7 shows that these kinds of terms will appear in three cases: (*a*) when molecules differ in the nature of an atom at a certain position (m_i will be different); (*b*) when molecules differ in the position of an atom ($m_i y_i^2$ or $m_i z_i^2$ will be different); (*c*) a mixture of cases *a* and *b*. Therefore, this index can be associated with a purely positional effect and, in the case where all the molecules have a different substituent attached to the same place, with a steric effect.

Also, it is interesting to note that Eq. 5 does not include terms belonging to the side-chain atoms. There are two hypotheses explaining this fact:

1. The side chains used throughout this study are relatively constant, with the terminal amine position being primary or possessing a dimethyl group. In this case the contribution of the side chain will be almost constant, and it will be included in the constant term of Eq. 5.
2. The side chain, especially the charged nitrogen atom, only participates in the orientation and long-range recognition of these molecules by the receptor (36).

Table III—Student's *t* Test Values for Variables of Eq. 5

Variable	*t* Value	*p*
Q_4	3.20	<0.005
Q_7	3.11	<0.005
S_5^E	10.74	<0.0005
S_7^E	−9.06	<0.0005
S_9^E	−2.36	<0.025
I	4.73	<0.0005

Table IV—Squared Correlation Matrix for Varibles in Eq. 5

	Q_4	Q_7	S_5^E	S_7^E	S_9^E	I
Q_4	1.00					
Q_7	0.01	1.00				
S_5^E	0.62	0.0009	1.00			
S_7^E	0.12	0.18	0.07	1.00		
S_9^E	0.19	0.07	0.13	0.43	1.00	
I	0.19	0.0004	0.34	0.0004	0.02	1.00

Given that we are interested in the relative variation of the net charges, of the superdelocalizabilities, and of the inertia moment term, the position of the side chain will not be important if we place it in the same relative position in all the molecules considered. Also, as the pyrrole portion of the indole nucleus is relatively homogeneous in the molecules of Table I, it is not possible to determine its true importance in the regulation of the drug-receptor interaction.

Remembering that S^E is always negative, and considering only its absolute value, we may conclude that a high pA_2 is associated with: positive net charges for atoms 4 and 7; a low value of log $[\sigma/(ABC)^{3/2}]$ (which suggests a limit value for the size of the substituents); high S^E values for atoms 7 and 9, and a low S^E value for atom 5. This indicates that for atom 7 there must be an equilibrium between a positive (or slightly negative) net charge and an electronic density that participates in the interaction.

As an example of the predictive capacity of Eq. 5, we have considered the case of the 7-bromo-*N*,*N*-dimethyltryptamine. The experimental pA_2 for this compound is 6.51 (26), and Eq. 5 gives a pA_2 of 6.93.

Another problem is the solvation. It is clear that the charged groups of the drugs (*i.e.*, —$COCH_3$, —OH, *etc.*) are solvated. As we have shown[1], part of the solvation energy change calculated with the Born equation (37) is implicitly considered in the electrostatic terms of Eq. 5.

In conclusion, it seems well established that the 5-position in indole derivatives has a first-order importance in regulating pA_2, and that this regulation is associated with the availability of an electron density at this position. Our results agree with those of Weinstein and co-workers (8–10). Also, Eq. 5 shows that the ability of the ring to donate electrons is of great importance in the variation of pA_2; this agrees well with experimental (14, 15) and theoretical (10, 16) results. However, our results do not support suggestions that the charge transfer is negligible (12).

The derivation of Eq. 5 suggests very strongly that these molecules interact with the serotonergic receptor in a way such that their aromatic rings are in the same relative positions. This conclusion is in contrast with the previous suggestion that the main process in this drug-receptor interaction is the orientation of the electrostatic vector (10, 12, 13).

A question raised by this and other similar studies is why is it not possible to obtain equations with still higher multiple correlation coefficients without adding highly correlated variables. It seems that, experimental errors apart, the factors responsible are: (*a*) the method employed to obtain the reactivity indexes, especially the nucleophilic superdelocalizability (38) and (*b*) the quality of the approximations made to simplify the expression for ΔE_i^e given by perturbation theory[1].

Electrical Conductivity of a Docusate Sodium Coacervate System

CHRISTOPHER HUGHES *§ **and BERNARD ECANOW** ‡x

Received February 17, 1983, from * *Stanford University, Dept. of Biological Sciences, Stanford 94305* and the ‡ *College of Pharmacy, University of Illinois, Chicago IL 60612.* Accepted for publication August 16, 1983. § Present address: College of Medicine, University of Illinois, Chicago IL 60612.

Abstract □ The conductivity of three xanthines (caffeine, theobromine, and theophylline) and three sugars (glucose, sucrose, and glucose-6-phosphate) was measured as part of a docusate coacervate system. The conductivity of the coacervate phase was always lower than the equilibrium phase. Conductivity of xanthines showed that caffeine had the highest conductivity, followed by theobromine and theophylline. At high concentrations, these values fell and the highest conductivity was seen in samples containing theobromine, caffeine, and theophylline. For sugars at high concentrations, the lowest values of conductivity were seen in sucrose samples. Saturated theophylline samples exhibited an increased volume in the coacervate phase while the saturated sugar systems displayed a decreased coacervate phase volume. These findings are discussed with reference to various clinical parallels and thus supply evidence that coacervates can provide a useful model for human cytoplasm.

Keyphrases □ Conductivity—docusate sodium coacervate, caffeine, theobromine, theophylline, glucose, sucrose, concentration effects □ Docusate sodium—coacervate system, partition coefficients, caffeine, theobromine, theophylline, glucose, sucrose, concentration effects

Coacervates have been suggested as a model for human cytoplasm since cytoplasm is also essentially an aqueous phase of water–macromolecule colloid complexes (1, 2). Ecanow (3) has shown that coacervate systems react with more similarity to cytoplasm than do presently accepted organic solvent–water models when subjected to pH change or polar–nonpolar molecule partitioning. This report will deal with the electrical conductivity of a sodium dioctyl sulfosuccinate (docusate sodium) coacervate system as a function of pharmaceutical drug and sugar concentration. The drugs (theophylline, theobromine, and caffeine) were chosen because of their known clinical effects. The sugars (sucrose, glucose, and glucose-6-phosphate) were chosen to investigate the known phenomenon of sugar acting as a depressant at high concentrations (4).

EXPERIMENTAL SECTION

Materials and Instrumentation—All chemicals used for the HPLC analysis were used as supplied[1] and the docusate used for the preparation of the coacervate system was analytical reagent grade[2]. The sugars and xanthines were purchased from commercial sources. The liquid chromatographic apparatus used for these investigations consisted of a solvent delivery system[3], a variable-wavelength detector set at 254 nm[4], and a variable-volume injector[5]. The column used was a reverse-phase C_{18}[6] and the mobile phase consisted of acetonitrile–water (6:94, v/v). The conductivities of the samples were determined by the use of a conductivity bridge[7] and a glass dip conductivity cell[8].

Preparation of Coacervate—The docusate coacervate system was produced using the technique outlined by Acharya *et al.* (5). Solid docusate (10%, w/v) was added to distilled H_2O and mixed thoroughly. Sodium chloride was then added (2.5%) until oil-like droplets began to separate out of solution. Within a few minutes the biphasic system was obtained.

Procedure—Nine docusate sodium coacervate samples were made for each of the three drugs and eight samples were made for each of the three sugars. Each sample contained 5 mL of the coacervate plus 5 mL of the equilibrium solution. Solutions of each additive were made (100 μL) and added to the coacervate system in amounts ranging from 2.44 to 21.96 mg of chemical. Previous studies have been done to determine the partition coefficients of theophylline and theobromine in coacervate systems (6). In this study, the concentration of the drug in each phase was accurately measured by HPLC and the partition coefficients were thereby obtained for this docusate system.

Chromatographic conditions for the HPLC analysis were as follows: the flow rate was set to 3.0 mL/min with a chart speed of 10 cm/h and sensitivity set at 0.02 AUFS for the theophylline and theobromine systems. Due to the wide peaks for caffeine, the chart speed was set at 5 cm/h with a sensitivity setting of 0.005 for the detection of this compound. A 100-μL aliquot from each layer of every sample was diluted with water due to the high concentrations of the drugs in the samples and the high sensitivity of this method of analysis.

Each layer in the control sample was diluted 1:10 and run with the other samples. No concentration of any of the drugs was found in this control sample. The conductivity of each phase of this control sample was measured; these were used as control values. From the dilution of each layer, a 10-μL sample was injected into the column and chromatographed.

Standards—Standard solutions were prepared for theophylline, theobromine, and caffeine at concentrations of 10, 20, and 40 μg/mL and also injected into the column. Peak heights on the chromatogram were measured for each specimen and the concentration was determined from the respective standard curve using peak height *versus* concentration. Retention times for each of the drugs were: theophylline, 6.0 min; theobromine, 3.9 min; caffeine, 12 min.

Conductivity—The conductivity of each phase of every sample was measured 10 times and an average value for each was obtained. To ensure no contamination, the conductivity cell was rinsed completely between each measurement.

RESULTS

Partition Coefficient—The partition coefficient for each drug was obtained by plotting the concentration of the drug in the coacervate phase *versus* the concentration in the equilibrium phase (Fig. 1). The slopes of the resulting curves (in these cases, straight lines) are equal to the partition coefficients (P). For this coacervate system, the P values for these drugs are: theophylline = 1.600; caffeine = 1.522; theobromine = 1.260.

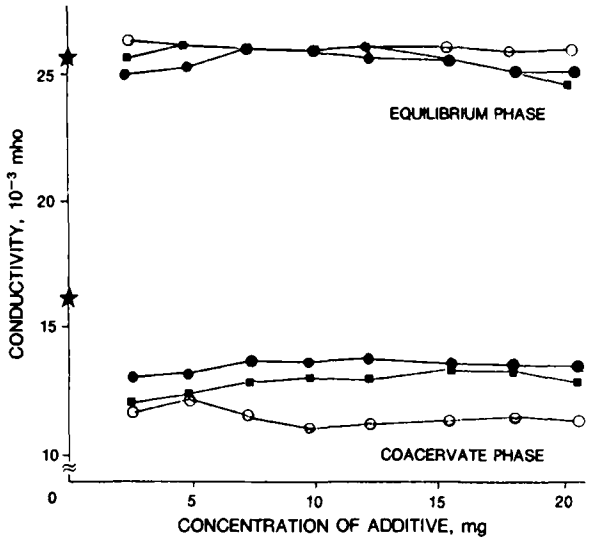

Figure 3—*Sugar conductivity as a function of total concentration. Key: (●) glucose-6-phosphate; (■) sucrose; (○) glucose; (★) control.*

Theobromine, having a low solubility constant in water, reached its saturation level in the sample containing 4.88 mg theobromine; therefore, precipitation was noted in the samples with a higher concentration of this drug. This saturation and precipitation account for the abbreviated partition coefficient graph for this drug.

Conductivity—Figures 2 (drug series) and 3 (sugar series) were obtained by plotting the electrical conductivity, measured in 10^{-3} mho, of each phase of the samples as a function of the total concentration of the additive in the system. Note that control values are indicated at the zero concentration points. In the concentration range of the drug series, the conductivity of theophylline was lowest, followed by theobromine and caffeine; for the sugar series, the lowest was glucose, then sucrose and glucose-6-phosphate. However, the conductivity did not vary significantly as a function of the concentration of the additive in the system. Therefore, samples containing additives at 2–4 times the original concentration were prepared to investigate the behavior of the coacervate system under increased concentrations.

Figures 4 and 5 are plots of conductivity *versus* total concentration of additive, but these graphs have a larger concentration scale to include the additional data mentioned above. These figures show that the high concentrations of the additives in some cases greatly affected the conductivity of the coacervate system. In the drug series, the conductivity decreased in both the coacervate and equilibrium phases and were usually lowest in theophylline and highest in theobromine, especially in the coacervate phase. A similar decrease was noted in the sugar series, with a marked change in the sucrose values. Glucose demonstrated a reversal or increase in conductivity before a later decrease with highest concentrations. These high concentrations also affected the coacervate system in other ways, as seen in the sugar samples containing 30–80 mg of additive; in these samples a clear, viscous, gel-like layer formed at the bottom of the tube. Because of the formation of this third layer, the volume of the coacervate layer decreased ~2 mL in these samples.

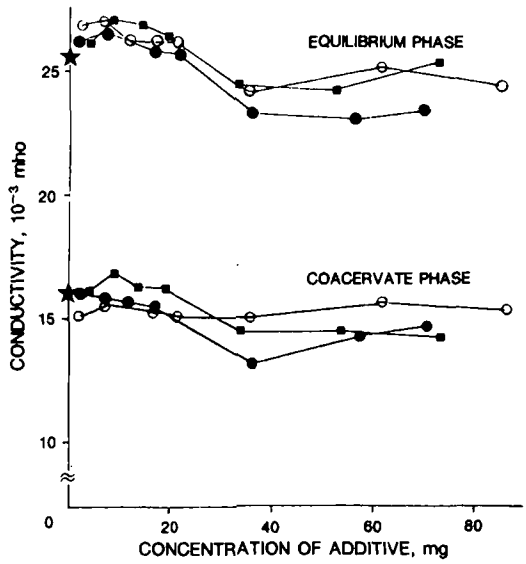

Figure 4—*Drug conductivity at increased concentrations. Key: (●) theophylline; (■) caffeine; (○) theobromine; (★) control.*

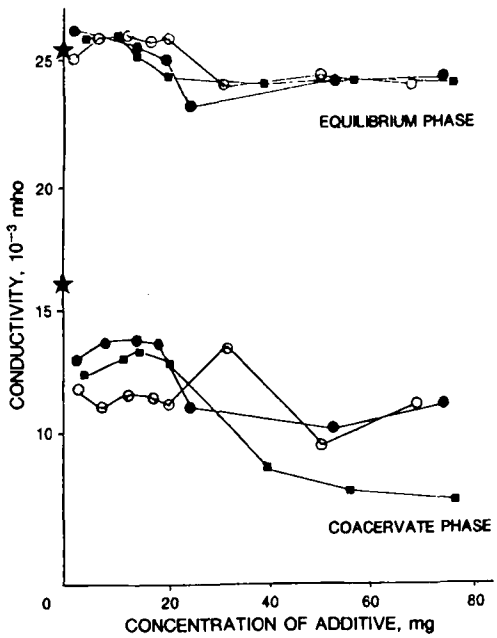

Figure 5—*Sugar conductivity at increased concentrations. Key: (●) glucose-6-phosphate; (■) sucrose; (○) glucose; (★) control.*

Table I—Coacervate Layer Volume Increases in Theophylline Samples

Sample	Theophylline Conc., mg	Coacervate Volume, mL	
		Total	Increase
1	36.41	5.6	0.6
2	57.64	6.5	1.5
3	71.03	6.8	1.8

The high-concentration theophylline series (30–80 mg) exhibited an increase in the coacervate layer volume as shown in Table I. Furthermore, the sample containing the highest concentration (71.03 mg) also had a white precipitate, indicating that the sample had reached the saturation point.

DISCUSSION

At high concentrations beyond the solubility point, sugars, like most compounds, will precipitate out of solution. However, because of the high solubility of the sugar and a strong physicochemical attraction to water, the sugar and bound water that separates as an additional phase from the rest of the system

is not a white, chalk-like powder, but rather a clear, viscous, sugar-water gel. This characteristic explains the formation of the third layer in the high-concentration sugar samples.

The increase in volume of the coacervate phase in the high-concentration theophylline samples (Table I) indicates a general increase in the structuring of this phase. In this case, the additives also act as general structure makers causing an increased nonpolarity of the equilibrium phase. This hypothesis is consistent with the decrease in electrical conductivity of these samples (Fig. 4), indicating a more structured system.

If the coacervate state is a model for human cytoplasm, then clinical parallels should be found in man. The decrease in the volume of the coacervate layer in the high-concentration sugar samples may be related to the known delayed healing of wounds in diabetics with low insulin and therefore high blood sugar levels. Ecanow *et al.* (7) have hypothesized that this delay in healing is partially caused by a rupturing of the cells in the wounded area from the high sugar concentrations acting as a structure breaker of these cells. This hypothesis is consistent with the decrease in the volume of the coacervate in the high-concentration sugar samples (acting as a structure breaker in the highly structured coacervate phase) without noticeable effect on the loosely bound equilibrium phase.

For each additive, the conductivity of the coacervate phase is reduced compared with the equilibrium phase (Figs. 2–5). This decreased conductivity of coacervates is consistent with both the hypothesis of Ecanow *et al.* (7) that conditions like malignancy occur in a nonpolar aqueous matrix (coacervate) and the findings of Lowenstein and Kanno (8) that malignant cells have a reduced action potential. Also, a low conductivity of the sugars is shown which may be related to the known depressant effect of sugars on the central nervous system, culminating in diabetic coma with high glucose concentrations (4). The effect of high concentrations of sucrose on membrane interface disorientation (structure breaking) can account for the known low absorption rate of sucrose in the intestine, compared to glucose (9).

The conductivity of caffeine was highest, followed by theobromine and theophylline (Fig. 2). These data may have a relationship to the decurarizing effects of these three drugs with caffeine showing the greatest effect, followed by theobromine and theophylline (10). With higher concentrations (Fig. 4) the conductivity was generally highest in theobromine, then caffeine and theophylline. These data may then be related to the effects of these drugs on urine production with theobromine showing the greatest effect followed by caffeine and theophylline, as reported by Scott *et al.* (11).

The increase over control values of the caffeine (Figs. 2, 4) followed by a reversal of a decrease with high concentrations (Fig. 4) finds a clinical parallel in the known increased cardiac contraction effect of caffeine at concentrations of 0.25–1.50 mM and a decreased contraction effect with concentrations >2.0 mM as reported by Guboreff and Sleator (12).

This discussion has shown a number of clinical parallels in the conductivity changes from the drug and sugar series and provides evidence in favor of the usefulness of a coacervate system as a model for human cytoplasm.

Received June 15, 1983, from *Merck Sharp & Dohme Research Laboratories, Rahway, NJ 07065.* Accepted for publication February 2, 1984.

Abstract □ ^{1}H-NMR and MS were employed to identify 13 rat urinary metabolites of ^{14}C-labeled *cis*-3a,4,5,6,7,7a-hexahydro-3-(1-methyl-5-nitro-1*H*-imidazol-2-yl)-1,2-benzisoxazole (MK-0436). The major free (unconjugated) metabolite was *cis*-3a,4,5,6,7,7a-hexahydro-3-carboxamido-1,2-benzisoxazole; it was also the second most abundant metabolite released during hydrolysis of the conjugated fraction. All other identified metabolites were hydroxylated analogues substituted at C(4)—C(7a) of the cyclohexane ring. The 4-equatorial,5-axial,7a-triol was the second most abundant metabolite excreted in an unconjugated form. Four monohydroxy (5-axial, 6-axial, 6-equatorial, 7-equatorial) metabolites of the drug were identified; they were found in the conjugated fraction only and were released by hydrolysis. The 5-axial hydroxy compound is the major conjugated metabolite and is overall the most abundant of all the metabolites. Six dihydroxy metabolites were identified: one was found exclusively in the free state, three as conjugates only (including the 7-axial,7a-diol, which is the major dihydroxy species), and two both free and conjugated. A second triol was found both free and conjugated.

Keyphrases □ *cis*-3a,4,5,6,7,7a-Hexahydro-3-(1-methyl-5-nitro-1*H*-imidazol-2-yl)-1,2-benzisoxazole—urinary metabolites, rat, NMR, MS □ Hydroxylation—conjugation, *cis*-3a,4,5,6,7,7a-hexahydro-3-(1-methyl-5-nitro-1*H*-imidazol-2-yl)-1,2-benzisoxazole, NMR, MS

Elliott and co-workers (1) reported that in the rabbit, the urinary metabolites of cyclohexane were cyclohexanol and cyclohexane-*trans*-1,2-diol (as conjugates); Renwick and Williams (2) showed that cyclohexylamine was converted to mono- and dihydroxy metabolites (free and conjugates). Testa and Jenner (3) also discussed the metabolic hydroxylation of cyclohexyl ring systems. Substituted nitroimidazoles are known to undergo hydroxylation on their hydrocarbon moieties: metronidazole is hydroxylated on the 2-methyl group (4), ipronidazole on the 2-isopropyl group (5). The antipro-

Four monohydroxy (5-axial, 6-axial, 6-equatorial, 7-equatorial) metabolites of the drug were identified; they were found in the conjugated fraction only and were released by hydrolysis. The 5-axial hydroxy compound is the major conjugated metabolite and is overall the most abundant of all the metabolites. Six dihydroxy metabolites were identified: one was found exclusively in the free state, three as conjugates only (including the 7-axial,7a-diol, which is the major dihydroxy species), and two both free and conjugated. A second triol was found both free and conjugated.

Keyphrases □ *cis*-3a,4,5,6,7,7a-Hexahydro-3-(1-methyl-5-nitro-1*H*-imidazol-2-yl)-1,2-benzisoxazole—urinary metabolites, rat, NMR, MS □ Hydroxylation—conjugation, *cis*-3a,4,5,6,7,7a-hexahydro-3-(1-methyl-5-nitro-1*H*-imidazol-2-yl)-1,2-benzisoxazole, NMR, MS

Elliott and co-workers (1) reported that in the rabbit, the urinary metabolites of cyclohexane were cyclohexanol and cyclohexane-*trans*-1,2-diol (as conjugates); Renwick and Williams (2) showed that cyclohexylamine was converted to mono- and dihydroxy metabolites (free and conjugates). Testa and Jenner (3) also discussed the metabolic hydroxylation of cyclohexyl ring systems. Substituted nitroimidazoles are known to undergo hydroxylation on their hydrocarbon moieties: metronidazole is hydroxylated on the 2-methyl group (4), ipronidazole on the 2-isopropyl group (5). The antipro-

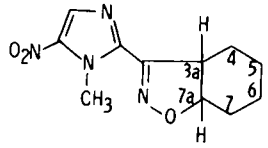
tozoal agent *cis*-3a,4,5,6,7,7a-hexahydro-3-(1-methyl-5-nitro-1*H*-imidazol-2-yl)-1,2-benzisoxazole (MK-0436, I) is metabolized by the dog to a series of alicyclic ring hydroxylation products (6, 7). The *in vitro* [rat liver post mitochondrial fraction (S9)] metabolism of I was reported recently (8). As in the dog study, metabolite formation in all cases involved biotransformations on C(4)—C(7a) of the cyclohexane ring. Two dihydroxy and seven monohydroxy metabolites were identified; the major *in vitro* metabolite is the 5-axial hydroxy analogue. The rat urinary metabolite study reported herein was executed to allow a direct comparison of the *in vitro* and *in vivo* metabolism of I, which possesses trypanocidal activity (1, 9-12) and is reported (6)[1,2] to be converted to bioactive metabolites.



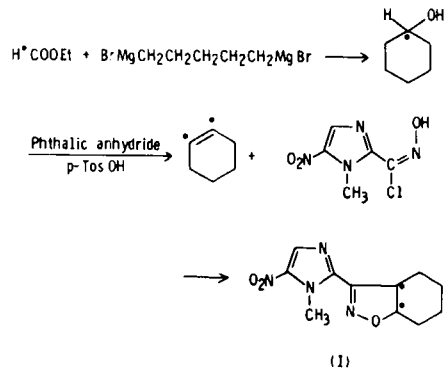
I

EXPERIMENTAL SECTION

Two Sprague-Dawley CD rats were pretreated with phenobarbital (0.1% in their drinking water) for 8 consecutive days. The animals were then dosed twice (16 h apart) at 500 mg/kg ip with I labeled with carbon-14 in the 3a- and 7a-positions (*vide infra*). Urine, collected until 24 h following the second dose of labeled I, was extracted with dichloromethane. The spent urine was incubated for 5.5 h at 37°C with β-glucuronidase and sulfatase[3] and then extracted with dichloromethane. The solvent was removed under reduced pressure to give two fractions containing the "free" and "liberated" metabolites of I (fractions 1 and 2, respectively). These fractions were subjected to TLC[4] with solvent[5] system A (toluene–ethyl acetate, 3:1) to yield partially purified metabolite fractions. Further purification was achieved by repeated use of this system and by TLC with two other solvent systems (system B: dichloromethane–methanol, 10:1; system C: trimethylpentane–2-propanol, 4:1). Metabolite zones were scraped from the plates, and metabolite fractions were isolated as described previously (8). The latter were assayed for radioactivity by use of the liquid scintillation counting technique[6].

Electron-impact[7] mass spectra (low resolution) of metabolite fractions were obtained using a 3.5-kV accelerating potential, 60-μA trap current, 70-eV ionizing energy, and 250°C source temperature. High-resolution (exact-mass)[8] mass spectrometric data were obtained using an 8-kV accelerating potential, 100-eV ionizing potential, and 200°C source temperature. Chemical-ionization[9] mass spectrometric data were obtained using methane as the reagent gas (1 Torr) and a 150-eV ionizing potential, 0.8-mA emission current, 1.8-kV electron multiplier, and 130°C source temperature. ^{1}H-NMR spectra[10] were obtained in deuterochloroform using tetramethylsilane as the internal standard. The chemical shifts and coupling patterns of H_{3a} and H_{7a} together with any new signals in the δ 3.5–5.5 ppm region (*i.e.*, diagnostic of *H*COH) were used to assign the location and stereochemistry of the hydroxyl groups of the transformation products.

Labeled I was prepared as shown in Scheme I. Ethyl [^{14}C]formate was treated with Grignard reagent prepared from 1,5-dibromopentane and magnesium to give [1-^{14}C]cyclohexanol, following the procedure of Fields *et al.* (13). Treatment of the [1-^{14}C]cyclohexanol with phthalic anhydride and *p*-toluenesulfonic acid (catalyst) then gave [1,2-^{14}C]cyclohexene (14). Reaction of the labeled cyclohexene with 1-methyl-5-nitro-1*H*-imidazol-2-hydroxyamoyl chloride (15) gave [3a,7a-^{14}C]I.



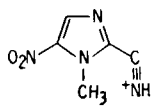
(I)

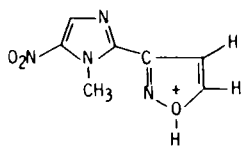
Scheme I—Synthesis outline; asterisks indicate position(s) of the ^{14}C-label.

RESULTS AND DISCUSSION

The pre- and posthydrolysis extractions resulted in the isolation of most (70%) of the total urinary radioactivity, with 70% of this associated with the posthydrolysis extraction fraction. Analytical TLC (solvent system A) of the pre- and posthydrolysis extraction fractions (1 and 2, respectively) demonstrated their multicomponent nature. The fractions were subjected to preparative-scale TLC with the same solvent system. Fraction 1 gave three major radioactive zones (R_f ~0.05, ~0.10, and ~0.27) with no evidence of more than a trace of the parent drug (R_f 0.70). The liberated metabolites (fraction 2) were subjected to preparative TLC as above; a broad, smeared zone (R_f ~0.05–0.10) and three more defined zones (R_f ~0.15, ~0.20, and ~0.28) were obtained, each of which contained drug-related species. These seven metabolite zones were further purified by TLC using solvent systems A–C to yield a total of 16 metabolites, 13 of which (accounting for >98% of the total of isolated metabolites) were identified (Table I). Five of the isolated, identified metabolites (or hydrolysis products thereof) were shown to be compounds previously identified as biotransformation products of I, and their designations (III and VI–IX, respectively) are as previously described (7, 8). The monohydroxy compounds (VI, VII, and IX) were found as rat *in vitro* metabolites (8), and III was found in dog urine (7). Compounds IX and VI were found to be the major and second most abundant rat *in vitro* metabolites, respectively. The dihydroxy metabolite VIII was found both as a rat *in vitro* metabolite (8) and a dog urinary metabolite (unconjugated) (7).

The electron-impact mass spectrometric behavior of I and several of its metabolites (those possessing hydroxyl groups on the cyclohexane ring) was discussed previously (6, 7). Not only do increases of 16 mass units in the molecular ions signify the number of oxygen atoms added to form hydroxyl groups, but the continuing presence of the fragment ions of *m/z* 153 and 195 appears to demonstrate that metabolism has occurred on the cyclohexane ring (6, 7). Thus for I and its mono-, di-, and trihydroxy metabolites, the molecular ions are *m/z* 250, 266, 282, and 298, respectively, and with these compounds the fragment ions *m/z* 153 and 195 are observed (see Table II for representative spectral data).





With respect to the identified rat urinary metabolites, two [the 5-equatorial,7a dihydroxy (XVI) and 4-equatorial,5-axial,7-axial trihydroxy (XVII) metabolites] were found only in the free form. Seven were found as conjugates only [the 5-axial hydroxy (IX), 6-axial hydroxy (III), 6-equatorial hydroxy (VII), 7-equatorial hydroxy (VI), 5-axial,6-equatorial dihydroxy (XVIII), 7-axial,7a dihydroxy (XIX), and 7-equatorial,7a dihydroxy (XX) metabolites]. Four of the metabolites [5-axial,7a dihydroxy (VIII), 5-axial,7-axial dihydroxy (XII), 4-equatorial,5-axial,7a trihydroxy (XXI), and the carboxamide (XXII) metabolites] were found in both free and conjugated forms. Identification of the eight newly recognized metabolites (XII and XVI–XXII; each isolated by TLC and homogeneous in three solvent systems) is discussed below (*cf.* Table I).

Metabolites XVI and XVII, under electron-impact mass spectrometry conditions, possess molecular ions of *m/z* 282 and 298, respectively, and thus these compounds are di- and trihydroxy analogues of I (for comparison, I yields

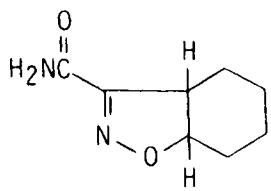
[a] Electron-impact low-resolution[7].

a molecular ion of *m/z* 250). The presence of fragment ions *m/z* 153 and 195 in the mass spectra of the metabolites strongly suggests (6) that hydroxylation occurred on the cyclohexane ring. Pertinent NMR data for the two metabolites are as follows: XVI: δ 3.86 (m, H_{6ax}) and 3.50 ppm (dd, 11.5, 7.2, H_{3a}); XVII: δ 4.99 (dd, 11.4, H_{7a}), 4.36 (m, H_{7eq}), 4.22 (br s, H_{4ax}), and 3.80 ppm (dd, 11, 9, H_{3a}).

The hydrolysis products of XVIII–XX each exhibit molecular ions of *m/z* 282 and fragmentation patterns indicative of hydroxylation of the alicyclic ring; these metabolites are thus dihydroxy analogues of I. NMR data critical for locating the hydroxy groups and defining their stereochemistry in these compounds include: XVIII: δ 4.69 (m, H_{7a}), 4.04 (br s, H_{5eq}), 3.57 (m, H_{6ax}), and 3.74 ppm (dt, H_{3a}); XIX: δ 4.22 (dd, 6.5, 4.5, H_{7eq}), and 3.70 ppm (dd, 11, 7, H_{3a}); XX: δ 4.02 (dd, 10, 6, H_{7ax}) and 3.66 ppm (t 8.5, H_{3a}). The NMR, MS, and TLC data of XVIII match those for the synthetic 5,6-*cis* (5-axial,6-equatorial) diol of I[11].

Two of the newly identified metabolites found both free and as conjugates were also shown to be hydroxy analogues of I. Metabolites XII and XXI exhibit molecular ions of *m/z* 282 and 298, demonstrating that they are di- and trihydroxy species, respectively. The mass spectrometric fragmentation patterns for the two compounds demonstrated the general sites of substitution [C(4)—C(7a)], but NMR spectrometry once again pinpointed the exact position and stereochemistry of the hydroxyl groups. Thus, for the 5-axial,7-axial-diol (XII), the NMR data include: δ 4.60 (br d, 7, H_{7a}), 4.32 (m, H_{7eq} + H_{5eq}), and 4.02 ppm (dt, 10, 7, 7, H_{3a}). For the 4-equatorial,5-axial,7a-triol, the NMR data include: δ 4.09 (br s, H_{5eq}), 3.44 (dd, 9.0, 3.0, H_{4ax}), and 3.40 ppm (d, 9.0, H_{3a}). Metabolite XII was actually noted previously as an *in vitro* biotransformation product of I but was not identified in the earlier work (8).

Metabolite XXII is the major drug-related species in the unconjugated fraction and the second most abundant of the metabolites released from the conjugated fraction during hydrolysis. Its relatively large R_f in solvent system A suggested that it was not a hydroxy analogue of I. The mass spectrometric (electron-impact) behavior of XXII (apparent molecular ion of *m/z* 168, with none of the normally encountered metabolite fragment ions) strengthened this assumption. Chemical-ionization MS of XXII yielded a pseudomolecular ion of *m/z* 169, confirming 168 as the molecular weight of the metabolite. An exact mass determination on the molecular ion (*m/z* 168) gave an empirical formula of $C_8H_{12}N_2O_2$ (calc., 168.0898; found, 168.0905). The metabolite did not possess the UV spectral features (λ_{max} at 240 and 320 nm) characteristic of I and its hydroxy metabolites. A structure which fits all these data is presented below. NMR data [δ 6.54 and 5.39 (2, $CONH_2$), 4.58 (qn, 3.7, H_{7a}), and 3.26 ppm (q, 8.0, H_{3a})] confirmed that the metabolite is indeed *cis*-3a,4,5,6,7,7a-hexahydro-3-carboxamido-1,2-benzisoxazole.



XXII

Three other rat urinary metabolites of I were partially characterized. Compound XXIII, found only in the nonconjugated form, is a dihydroxy analogue of I. Compounds XXIV and XXV, released from the conjugate fraction by hydrolysis, are both monohydroxy metabolites.

All the rat urinary metabolites of I identified (and the three isolated but only partially characterized), except one, are hydroxy analogues of the drug with substitution at C(4)—C(7a) of the cyclohexane ring. The lone exception is the carboxamide XXII which arises *via* degradation of the nitroimidazole ring. Another carboxamide, acetamide, has been found as a metabolite resulting from the *in vitro* reduction of metronidazole by xanthine oxidase (16) and the *in vivo* (turkey) metabolism of another nitroimidazole, ronidazole (17). As XXII was not found as an *in vitro* (rat liver S9) metabolite, it may arise *in vivo via* a nonhepatic metabolic route, such as reduction by gut flora.

Urinary monohydroxy metabolites of I were found only as conjugates. Compounds IX and VI (released by hydrolysis) are the two most abundant (in that order; see Table I) hydroxy metabolites of I, paralleling the rat *in vitro* situation (8). Of the two other monohydroxy metabolites, III and VII (both found as conjugates), the former was previously identified as a canine urinary metabolite (7) and the latter as a rat *in vitro* biotransformation product (8).

Although dihydroxy metabolites of I are produced by the rat both *in vitro* (free only) and *in vivo* (free and conjugated), trihydroxy metabolites XVII and XXI are found only as urinary metabolites. Compound XVII was found exclusively in the unconjugated form, whereas XXI was found both free and conjugated. The latter is the second most abundant of the metabolites excreted free.

It is clear that the alicyclic hydrocarbon moiety of I is very susceptible to hydroxylation by the rat, both *in vivo* and *in vitro*. Nine hydroxy analogues

[11] H. Mrozik and P. Eskola, unpublished data.

of I were identified as rat liver S9 *in vitro* metabolites, and this current paper reports the identification of a dozen metabolites of I in which hydroxylation occurred at C(4) - C(7a) of the cyclohexane ring. The intact animal produces not only a greater total number of and several more-extensively hydroxylated metabolites, but also effects an entirely different and quantitatively significant metabolic conversion, *i.e.*, degradation of the nitroimidazole ring. The most common metabolic transformation both *in vivo* and *in vitro*, however, is hydroxylation to form the 5-axial hydroxy metabolite. Axial hydroxyl groups at C-5 are also found in three of the dihydroxy metabolites and both of the urinary trihydroxy metabolites.

Acyloxyamines as Prodrugs of Anti-inflammatory Carboxylic Acids for Improved Delivery Through Skin

K. B. SLOAN*[x], S. SELK, J. HASLAM, L. CALDWELL, and R. SHAFFER

Received April 18, 1983, from the *INTER$_x$ Research Corporation, Merck Sharp and Dohme Research Laboratories, Lawrence, KS 66044.* Accepted for publication, March 21, 1984.

* Present address: Department of Medicinal Chemistry, College of Pharmacy, University of Florida, Gainesville, FL 32610.

Abstract □ An *N,N*-dialkylhydroxylamine derivative of indomethacin has been synthesized. It has been shown to improve the delivery of indomethacin through mouse skin (compared to indomethacin itself) by a factor of two, to be more effective than indomethacin in inhibiting thermal inflammation (two to three times) in animal models, but to be only as effective as indomethacin in inhibiting UV-B radiation erythema in human volunteers.

Keyphrases ■ Indomethacin—derivatives, erythema inhibition in humans, inflammation inhibition in rats, delivery vehicle comparison □ Erythema—inhibition by indomethacin derivatives in humans, inflammation inhibition in rats, delivery vehicle

It is well known that UV radiation on skin produces intense erythema, pain, and blistering (1). However, the proximal cause or causes of the response of skin to UV radiation is less than well understood. UV radiation is usually divided into three arbitrary regions: UV-A, 320–400 nm; UV-B, 320–290 nm, which is also known as sunburn UV radiation; UV-C, 290–200 nm. Regardless of the wavelength, there is a delay of onset of redness that is inversely proportional to the intensity of the radiation. Furthermore, the erythema will persist for hours or days depending directly on the intensity of the radiation. The intensity of the effect of the UV-B radiation has been shown to be particularly sensitive to treatment with nonsteroidal anti-inflammatory agents while UV-C radiation is less sensitive (2) and UV-A radiation is insensitive to nonsteroidal anti-inflammatory agents (3). For instance, topically administered indomethacin has been shown to decrease the redness, as determined visually, and the temperature, as determined by telethermometer readings, of sunburned or UV-B treated skin compared with controls (4).

Since the nonsteroidal anti-inflammatory agents are known to prevent inflammation by inhibiting prostaglandin synthesis, it was logical to suspect that prostaglandins (5) were the proximal cause of at least some of the effects of UV-B radiation because UV-B radiation was susceptible to treatment with nonsteroidal anti-inflammatory agents. Indeed, increased levels of arachidonic acid and prostaglandins E_2 and $F_{2\alpha}$ were found in human skin after treatment with UV-B (6) and UV-C radiation (7); the levels of prostaglandin E increased in a parallel manner with increased erythema over the first 4 h after exposure of guinea pig skin to UV-B radiation (8). However, after 4 h erythema scores stayed high but prostaglandin levels fell back to normal (8). Thus, oral or topical administration of indomethacin completely suppressed the elevation of the levels of the prostaglandins (9) but the erythema associated with the radiation damage was only partially suppressed compared with controls and then for only ~24 h, and the acute

Acyloxyamines as Prodrugs of Anti-inflammatory Carboxylic Acids for Improved Delivery Through Skin

K. B. SLOAN*[x], S. SELK, J. HASLAM, L. CALDWELL, and R. SHAFFER

Received April 18, 1983, from the *INTER$_x$ Research Corporation, Merck Sharp and Dohme Research Laboratories, Lawrence, KS 66044.* Accepted for publication, March 21, 1984.

* Present address: Department of Medicinal Chemistry, College of Pharmacy, University of Florida, Gainesville, FL 32610.

Abstract □ An *N,N*-dialkylhydroxylamine derivative of indomethacin has been synthesized. It has been shown to improve the delivery of indomethacin through mouse skin (compared to indomethacin itself) by a factor of two, to be more effective than indomethacin in inhibiting thermal inflammation (two to three times) in animal models, but to be only as effective as indomethacin in inhibiting UV-B radiation erythema in human volunteers.

Keyphrases ■ Indomethacin—derivatives, erythema inhibition in humans, inflammation inhibition in rats, delivery vehicle comparison □ Erythema—inhibition by indomethacin derivatives in humans, inflammation inhibition in rats, delivery vehicle

It is well known that UV radiation on skin produces intense erythema, pain, and blistering (1). However, the proximal cause or causes of the response of skin to UV radiation is less than well understood. UV radiation is usually divided into three arbitrary regions: UV-A, 320–400 nm; UV-B, 320–290 nm, which is also known as sunburn UV radiation; UV-C, 290–200 nm. Regardless of the wavelength, there is a delay of onset of redness that is inversely proportional to the intensity of the radiation. Furthermore, the erythema will persist for hours or days depending directly on the intensity of the radiation. The intensity of the effect of the UV-B radiation has been shown to be particularly sensitive to treatment with nonsteroidal anti-inflammatory agents while UV-C radiation is less sensitive (2) and UV-A radiation is insensitive to nonsteroidal anti-inflammatory agents (3). For instance, topically administered indomethacin has been shown to decrease the redness, as determined visually, and the temperature, as determined by telethermometer readings, of sunburned or UV-B treated skin compared with controls (4).

Since the nonsteroidal anti-inflammatory agents are known to prevent inflammation by inhibiting prostaglandin synthesis, it was logical to suspect that prostaglandins (5) were the proximal cause of at least some of the effects of UV-B radiation because UV-B radiation was susceptible to treatment with nonsteroidal anti-inflammatory agents. Indeed, increased levels of arachidonic acid and prostaglandins E_2 and $F_{2\alpha}$ were found in human skin after treatment with UV-B (6) and UV-C radiation (7); the levels of prostaglandin E increased in a parallel manner with increased erythema over the first 4 h after exposure of guinea pig skin to UV-B radiation (8). However, after 4 h erythema scores stayed high but prostaglandin levels fell back to normal (8). Thus, oral or topical administration of indomethacin completely suppressed the elevation of the levels of the prostaglandins (9) but the erythema associated with the radiation damage was only partially suppressed compared with controls and then for only ~24 h, and the acute

0022-3549/84/1200-1734$01.00/0

UV damage to epidermal cells was not affected (10). Moreover, the concentration of indomethacin used was fairly high (2.5%) and the vehicle used in all treatments contained a penetration enhancer (ethanol–propylene glycol–dimethylacetamide or dimethylformamide, 19:19:2 or 1:1:2).

Thus, although in general the treatment (oral) of sunburn with nonsteroidal anti-inflammatory agents appears promising from the point of view of increasing the minimal dose of light necessary to produce erythema (11), the lack of reports of topical activity by indomethacin without the use of penetration enhancers and its lack of effect on the long term effects of sunburn make it an unsatisfactory therapeutic agent at least from a topical delivery point of view. Therefore, in order to determine if increased delivery of indomethacin through skin would improve its therapeutic effectiveness, a number of prodrug derivatives have been prepared and evaluated (12). This paper describes the preparation and evaluation of an *N,N*-dialkylhydroxylamine derivative of indomethacin as one example of the prodrugs of anti-inflammatory carboxylic acids (13) designed to improve therapeutic effectiveness by increasing their delivery through skin.

Ib, R = Cl
Ic, R = $ON(C_2H_5)_2$

EXPERIMENTAL SECTION[1]

Preparation of 1-(4′-Chlorobenzoyl)-5-methoxy-2-methyl-3-indolylacetyl Chloride (Ib)—To a suspension of indomethacin (21.9 g, 0.061 mol) in 300 mL of benzene, 10.8 g (0.085 mol) of oxalyl chloride was added with stirring. The reaction was heated at reflux for 2 h. Then the solution was concentrated to give a residue which was triturated with 300 mL of ether. The suspension was filtered and the solid material dried to give the acid chloride as a yellow powder (18.9 g, 82% yield), mp 125–128°C. IR (KBr): 1790 and 1675 cm^{-1} (s, C=O);[1] H-NMR ($CDCl_3$): δ 7.60 (ABq, 4, J = 9 Hz, $\Delta_{\nu AB}$ = 11 Hz, ArH), 7.0–6.55 (m, 3, ArH), 4.17 (s, 2, CH_2COCl), 3.83 (s, 3, OCH_3), and 2.41 ppm (s, 3, CH_3–C=C).

Anal.—Calc. for $C_{19}H_{15}Cl_2NO_3$: C, 60.65; H, 4.02; N, 3.72. Found: C, 60.59; H, 4.08; N, 3.50.

Preparation of *N*-[1-(4′-Chlorobenzoyl)-5-methoxy-2-methyl-3-indolylacetyloxy]-*N,N*-diethylamine (Ic)—To a suspension of Ib (18.9 g, 0.048 mol) in 500 mL of ether was added *N,N*-diethylhydroxylamine (8.88 g, 0.1 mol). The mixture was stirred for 1 h at room temperature and then was filtered. The filtrate was concentrated to give solid material which was extracted with 200 mL of dichloromethane. The organic phase was washed successively with 100 mL of 0.5 M NaOH and 100 mL of water. The organic layer was separated, dried over Na_2SO_4, and concentrated to a viscous mass which was triturated with 100 mL of ether. The crystals were removed by filtration and then recrystallized from dichloromethane–ether to give 14.4 g (70% yield) of the desired product as transparent yellow prisms, mp 100–101°C. IR (KBr): 1747 cm^{-1} (s, O—C=O) and 1650 cm^{-1} (s, N—C=O); ^{1}H-NMR ($CDCl_3$): δ 7.8–7.3 (m, 4, ArH), 7.0–6.6 (m, 3, ArH), 3.83 (s, 3, OCH_3), 3.67 (s, 2, O=CCH_2), 2.89 (q, 4, J = 7 Hz, NCH_2), 2.39 (s, 3, CH_3C=C), and 1.06 ppm (t, 6, J = 7 Hz, NCH_2CH_3).

Anal.—Calc. for $C_{23}H_{25}ClN_2O_4$: C, 64.40; H, 5.88; N, 6.53. Found: C, 64.39; H, 5.86; N, 6.29.

Biological Tests—*Rat Ear Burn Test*—These results were obtained according to the method of Bronaugh *et al.* (14) where warm (51.7°C) metal cylinders were applied to the right ear of rats to cause the burn. After 1 min the burned ears were treated with 50 μL of a 0.03–0.003 M isopropyl myristate, propylene glycol solution, or a suspension of Ia or Ic. The animals were sacrificed after 10 h, circular sections of the ears were made with a leather punch, and the weights of both the right ear and the left ear pieces were determined immediately. Inflammation was determined as the increase in weight of the burned right ears compared with the weight of unburned left ears of the same animals. The percent increase in ear weight was calculated as: (weight of right ear − weight of left ear)/(weight of left ear) × 100. The percent increase in burned ear weight of animals receiving vehicle (%C) was compared with the percent weight increase in ear weight of animals receiving vehicle containing drug (%D) to give a percent inhibition of edema as follows: (%C − %D)/%C = percent inhibition of edema. The results for the comparison of indomethacin with the indomethacin hydroxylamine derivative are given in Table I.

Sunburn Test—This procedure is slightly modified from that described by Snyder (15). The differences in this procedure were the concentrations (1.1 *versus* 2.5% for Ia), amounts applied (50 *versus* 20 μL), number of applications (1 *versus* 4–19), period of observation (6 *versus* 48 h), and the fact that occlusion was used. Briefly, the test areas (4 cm^2) on the backs of human volunteers were irradiated using a bank of sunlamps. The minimum erythemal dose was determined for each subject; subsequent test exposures were 2–3 times this amount. Test formulations of Ia or Ic (0.03 M, 50 μL) or the vehicle alone were applied immediately after exposure and were partially occluded for 5 h with 2.54-cm adhesive bandages (9 spots per subject); three applications each of Ia, Ic, and vehicle in a randomized asymmetric array. Erythemal response was evaluated each hour for 6 h after exposure and graded on a scale of 0–4 (4 being a response of maximum redness). Indomethacin and Ic in the polyethylene ointment base[2] were each tested on two volunteers with the result that no difference between indomethacin and Ic could be seen (Table II). Similar results were obtained when Ia and Ic were compared in petrolatum.

Table I—Ear Burn Test: Effect of Indomethacin and Its Derivative on Inhibition of Inflammation[a]

Compound	Increase in Ear Weight, %	Inhibition of Edema	*n*
Isopropyl myristate (control)	24.1 ± 2.0	—	10
Indomethacin (0.03 M)	18.6 ± 2.0	22.8	10
Ic (0.03 M)	12.0 ± 1.6	50.2	10
Propylene glycol (control)	36.1 ± 1.8	—	18
Indomethacin			
0.03 M[b]	30.9 ± 2.3	21.6	21
0.01 M	31.9 ± 4.3	11.6	5
0.003 M	34.7 ± 3.6	3.9	16
Ic			
0.03 M[b]	28.3 ± 2.5	28.2	20

Table II—Sunburn Test: Comparison Between Indomethacin and Ic

After UV Exposure	Evaluation of Redness[a]		
	0.03 M Ic	0.03 M Indomethacin	Control
1	0	0	0
2	0.5 ± 0.8	0.8 ± 1.0	2.0 ± 1.3
3	0.7 ± 0.8	1.1 ± 0.8	2.6 ± 1.2
4	1.1 ± 0.5	1.3 ± 0.6	3.0 ± 1.1
5	1.8 ± 0.6	1.9 ± 0.8	3.5 ± 0.8
6	2.0 ± 0.6[b]	2.0 ± 0.6[b]	3.5 ± 0.8

[a] The vehicle was the polyethylene ointment base: given as 50 μL/4 cm^2 spot (n = 6). Score ± *SD*; maximum redness = 4. [b] $p < 0.005$ compared with control.

[1] TLC was run on Brinkman Polygram Sil G/UV 254. Melting points (uncorrected) were taken with a Thomas-Hoover capillary apparatus. NMR spectra were recorded on a Varian T-60 spectrometer. IR spectra were obtained on a Beckman Acculab 4 infrared spectrophotometer. Microanalyses were obtained from Midwest Microlab, Ltd., Indianapolis, Ind. The indomethacin was obtained from Sigma. The *N*-hydroxydiethylamine and the remaining reagents were obtained from Aldrich except for isopropyl myristate which was obtained from Eastman Kodak. The bulk solvents were obtained from Mallinckrodt. The mice used in the diffusion cell experiments were ICR white Swiss mice (22–25 g) from Sprague–Dawley and the diffusion cells were obtained from Kersco Engineering Consultants, Palo Alto, Calif. The HPLC system was a Waters Associates instrument using a μ-Bondapak C_{18} column. The sunlamp used was a Westinghouse FS-20.

[2] Plastibase; 5 g of polyethylene and 75 g of liquid paraffin.

Table III—Diffusion Cell Test: Comparison Between Indomethacin and Ic [a]

Hours after Application	Indomethacin Delivered, μg	
	From Indomethacin	From Ic
4	0.20 ± 0.19	0.40 ± 0.12
7	0.85 ± 0.48	1.78 ± 0.23
11	1.33 ± 0.73	2.87 ± 0.32
24	4.48 ± 1.86	8.81 ± 0.66

Petrolatum	10[c]	99.6

[a] After 7 d except for isopropyl myristate which was 5 d. [b] A solution of Ic. [c] A suspension of Ic.

Diffusion Cell Test—The plexiglass diffusion cells have been described previously (16) but essentially consist of a lower and an upper chamber with a side arm to allow sampling of the receptor phase (lower chamber). The mice were sacrificed by cervical dislocation. Their hair was carefully clipped and the dorsal skin removed and stretched over the receptor chamber using a rubber gasket to secure it. The receptor phase (40 mL) contained 0.9% NaCl and 0.01% thimerosal. The test formulations (0.25 mL, 0.03 M) were applied to the skin, then the entire cell was incubated at 32°C. Two-mL samples were withdrawn at the appropriate times and replaced with 2 mL of fresh receptor phase. The samples were analyzed immediately by HPLC using methanol–water with 1×10^{-3} M tetrabutylammonium perchlorate as the solvent (flow = 2.0 mL/min; absorbance at 280 nm). Samples of 500 μL were injected onto the HPLC column and eluted with a convex gradient using a commercial program[3]; 50% methanol–50% water (solvent A) and 75% methanol–25% water (solvent B) starting with 20% solvent system B and concluding with 60% solvent system B after 5 min. Under those conditions, Ia (indomethacin) had a retention time of 6.7 min while Ic had a retention time of 9.0 min. Peak heights for Ia were quantitated by comparison with standards of known concentration similarly chromatographed. In every case only Ia was observed in the receptor phase on analysis.

The comparison of the ability to deliver indomethacin from the polyethylene ointment base between indomethacin and Ic is shown in Table III. The amounts of indomethacin delivered from the application of Ic in isopropyl myristate (42.7 ± 5.4 μg of indomethacin) and petrolatum (7.9 ± 2.9 μg of indomethacin) were determined; the amounts delivered after 24 h are reported.

Physical Properties—The stability of Ic was determined by preparing solutions or suspensions of Ic in the solvents listed in Table IV. At the appropriate time samples were dissolved in or diluted with ethyl acetate and those solutions were analyzed by HPLC using the same conditions used in the diffusion cell experiments. Only Ia was observed as a decomposition product.

RESULTS AND DISCUSSION

The development of a prodrug derivative of a drug containing a specific functional group requires that the derivative of that functional group exhibit specific characteristics. The derivative should be stable enough to have a useful shelf life, yet revert quickly to the parent compound *in vivo;* the derivatizing agent should be nontoxic and impart the desired change in physicochemical properties to the parent compound. The last characteristic, in many cases, is the most difficult to predict.

N,N-Dialkylhydroxylamines appear to be attractive candidates as derivatizing agents for carboxylic acid based on the above criteria. Acyl-*N,N*-dialkylhydroxylamines are relatively stable derivatives of carboxylic acids yet are sufficiently labile to serve as activated esters in amination reactions when the reaction is catalyzed by a weak acid (17). Thus, they should be stable as long as they are kept out of contact with protic solvents, but, because they are chemically labile, they also should be labile *in vivo*. In addition, the derivatizing agents exhibit a low order of acute toxicity. *N,N*-Diethylhydroxylamine exhibits an oral LD_{LO}[4] of 1600 mg/kg in rats and a topical LD_{LO}[4] of 2000 mg/kg in rabbits (18), compared with diethylamine which exhibits an oral LD_{50} of 540 mg/kg in rats and a topical LD_{50} of 820 mg/kg in rabbits. Finally, although amines have previously been employed successfully as penetration enhancers in formulations (19, 20), derivatizing agents containing low pK_a amines [the pK_a of *N,N*-dimethylhydroxylamine is 5.2 (21) and the *O*-acylated hydroxylamine should be even less basic] have not been employed to prepare prodrugs of carboxylic acids for the purpose of improving the ability of the carboxylic acid to penetrate biological membranes. Such derivatizing agents containing a low pK_a amine group offer several potential advantages. First, the amine group generally confers to the molecule a greater ability to partition from an aqueous environment into lipids than does a carboxylic acid group (22); although it is not clear whether this tendency is due to a more favorable free energy of adsorption or dehydration contribution to the free energy of transfer, previous work (23) suggests that it is probably the latter. Second, the low pK_a amine is present in its unprotonated form (99% at pH 7.4) which is the form that undergoes partitioning (22), compared with other tertiary amines which are ~0.1% unprotonated at pH 7.4. Thus, it seemed likely that the conversion of the carboxylic acid group in nonsteroidal anti-inflammatory agents to low pK_a amine derivatives would impart the desired physical chemical properties to the derivatives.

The acylated hydroxylamine derivative (Ic) was synthesized from the reaction between Ib and two equivalents of hydroxylamine (17). Various other bases such as triethylamine or potassium carbonate were tried as substitutes for the second equivalent of hydroxylamine but the best yields were obtained with the second equivalent of hydroxylamine acting as the acid scavenger. A second route involving the use of a dehydrating agent (1,3-dicyclohexylcarbodiimide) to form the ester bond (17) has also been used to prepare these acylated hydroxylamine derivatives (13). The yields of product were generally lower using this last approach but such an approach should be more generally acceptable for carboxylic acids with sensitive functional groups.

To determine if the substitution of a carboxylic acid group by a low basicity amine group had an effect on the ability of the parent compound to penetrate biological membranes, the diethylhydroxylamine derivative of indomethacin (Ic) was compared with indomethacin in diffusion cell tests using the polyethylene ointment base as the vehicle. Almost twice as much indomethacin was delivered by the derivative Ic than by indomethacin itself (Table III, 0.03 M = ~1% Ia). In addition, only indomethacin was observed on the receptor side; no indole-chlorobenzoyl cleavage was observed. The effect of other vehicles on the delivery of indomethacin by Ic was also determined. A vehicle of petrolatum gave diffusion results that were comparable with the polyethylene ointment base (8 μg) while a vehicle of isopropyl myristate containing Ic delivered almost five times as much indomethacin as did Ic in the polyethylene ointment base. In separate experiments, ≤6% dimethylacetamide in petrolatum was used as a vehicle for the delivery of indomethacin from Ic. However, only ~25 μg of indomethacin was delivered to the receptor phase in 24 h under the best conditions using the vehicle containing the penetration enhancer compared with 42 μg of indomethacin delivered from Ic using isopropyl myristate[5]. These results show that Ic delivers indomethacin through skin better than does indomethacin.

A comparison of the stability properties of Ic in various solvents are given in Table IV. It is apparent that Ic is stable in aprotic vehicles. The relative instability of Ic in the polyethylene ointment base was attributed to acidic impurities in the ointment. The addition of an organic base such as 1-methylimidazole or inorganic bases such as magnesium oxide or zinc oxide resulted in little or no decomposition of Ic in the polyethylene ointment base being detected using the same experimental conditions[5]. In separate diffusion cell experiments zinc oxide was shown to have no effect on the delivery of indomethacin by Ic from the polyethylene ointment base vehicle[5].

The effects of Ic on inhibiting inflammation in animal models is shown in Table I. In the ear burn test, Ic was about three times as potent as indomethacin if the compounds were tested in a propylene glycol vehicle while Ic was twice as potent as indomethacin if the two compared in an isopropyl myristate vehicle. A croton oil irritation test was also used (24, 25). In that test, Ic was only marginally better than indomethacin[6], but this may have been due to the partial decomposition of Ic by the croton oil which contains an acidic component. The advantages of the ear burn model in these tests are that a comparison between vehicles can be obtained and that labile derivatives can be compared under conditions where their stability can be assured. Thus, Ic was clearly more active than indomethacin in inhibiting inflammation in animal models.

The effectiveness of Ic and indomethacin in inhibiting inflammation due

[3] The HPLC program was program 4 on a Waters Associates M660 programmer.

[4] Lowest dose at which toxic effects are observed.

[6] Kanebo Company, Japan, unpublished data.

to UV-B light is shown in Table II. There was no significant difference between the two compounds at 0.03 M in petrolatum or at 0.03 M in the polyethylene ointment base. Only the results from the latter experiment are shown but the petrolatum results were essentially identical including the lag time for development of redness, although the inhibitory effect of indomethacin and Ic was apparent after 2 h, using the polyethylene ointment base formulation, instead of 3 h for the petrolatum formulation. Thus, no difference between Ic and indomethacin was observed under conditions where the diffusion cell experiments had shown that Ic delivered twice as much indomethacin through the skin as indomethacin itself (see Table III). This effect may be the result of the delivery of a maximum effective dose of indomethacin from the application of indomethacin in the polyethylene ointment base so that there was no observable effect of the excess indomethacin delivered by Ic in the polyethylene ointment base.

The initial suppression of the redness score, then the gradual approach of the redness score for the indomethacin or Ic treated areas to the redness score for the control areas after 6 h, is similar to the observations of Snyder (8) in guinea pigs and of Eaglstein *et al.* (26) in human volunteers. Thus, although an *N,N*-dialkylhydroxylamine derivative of indomethacin exhibited improved delivery of indomethacin through skin and was more effective than indomethacin in inhibiting thermal and chemical inflammation, it was no more effective than indomethacin in inhibiting the long term erythema of UV-B radiation. However, these derivatives of nonsteroidal anti-inflammatory agents may be useful in treating other inflammatory skin reactions such as allergic eczematous contact dermatitis (27) where prostaglandins have also been implicated as causative factors and insufficient nonsteroidal anti-inflammatory agent is delivered using conventional formulations and the underivatized nonsteroidal anti-inflammatory agent.

Microstructure of Aluminum Hydroxides and the Formation of Aluminum Dye Lakes

LYNDON L-S. WOU * and B. A. MULLEY ˣ

Received May 11, 1983, from the *Postgraduate School of Studies in Pharmacy, University of Bradford, Bradford, BD7 1DP, United Kingdom.* Accepted for publication February 22, 1984. *Present address: Beecham Pharmaceuticals Research Division, Animal Health Research Centre, Walton Oaks, Dorking Road, Tadworth, Surrey, KT20 7NT, United Kingdom.

Abstract □ The effect of processing variables on the type of aluminum hydroxide and the dye content of the resultant lakes were investigated. The solid-state structure of aluminum lakes in conjunction with the associated aluminum hydroxide was studied by electron microscopy, X-ray diffraction, and IR spectroscopy. The conditions under which the aluminum hydroxide was prepared were shown to govern the amorphous/crystalline character of the product, which was reflected in changes in particle size and surface area. A hypothesis for the interaction of the dye and aluminum hydroxide is formulated in which the amount of dye adsorbed on the aluminum hydroxide is dependent on the surface area of the microstructures present.

Keyphrases □ Aluminum hydroxides—dye lake formation □ Dye lakes—aluminum hydroxide, processing variables

FD & C aluminum lakes are widely used in edible pharmaceutical inks and to color pharmaceutical tablets, but little has been published about their nature and coloring properties. The conditions of preparation of the aluminum hydroxide, which is the substrate on which the dye is adsorbed to form the lake, have a profound effect on lake formation. The degree of alkalinity, temperature, concentration of reagents, as well as the salts used are all factors affecting the type of aluminum hydroxide formed.

The purpose of this study was to demonstrate that aluminum hydroxide, produced by methods described in lake formation processes, has properties which can be related to products described in the literature outside the laking field. The lake forming qualities of aluminum hydroxides are then evaluated in the context of the extensive fundamental work on the nature of this complex and variable material, which changes so markedly with relatively minor variations in the preparative process.

EXPERIMENTAL SECTION

Materials—Commercial FD & C dyes[1] were used in the preparation of the lakes: FD & C Blue No. 2 dye (lot No. 27390) for lake preparation No. B2; FD & C Red No. 40 dye (lot No. AA7490) for lake preparation No. R40; FD & C Yellow No. 5 dye (lot No. Z9313) for lake preparation Nos. Y5 and 1–21. Commercial lakes[1] obtained for this study were FD & C Yellow No. 5 lake (lot No. 127) and FD & C Yellow No. 6 lake (lot No. 634). Commercial aluminum hydroxides[2] were obtained as standard samples of different hydrated forms of alumina: gibbsite (lot No. RD 58/78), bayerite (lot No. RD 57/78), boehmite (lot No. RD 59/78), and pseudoboehmite (lot No. RD 60/78). All other reagents were of Analar or laboratory reagent quality.

Standard Procedures—*Preparation of Aluminum Hydroxide (Preparation No. 1)*—This method was based on the Colorcon process, which is comparable with that of Harrison (1). Sodium carbonate solution (0.96 M, 1800 mL) was added in a dropwise manner at 25°C to aqueous aluminum sulfate solution (0.16 M, 1600 mL) at 10–12 mL/min with continuous vigorous stirring. At pH 6.9, addition was halted. The precipitate was stirred slowly for 30 min and kept at pH 6.9 by adding sodium carbonate solution as necessary. The precipitate was washed until sulfate-free (barium chloride test).

Preparation of FD & C Yellow No. 5 Lake (Preparation No. Y5)—FD & C Yellow No. 5 (71 g) was dissolved in distilled water (1400 mL) at 35°C. The dye solution was passed through a filter into the aluminum hydroxide slurry (prepared in the above process) and stirred for 15 min at 20–25°C. Aluminum chloride solution (5.25 M, 69 mL) was added to the slurry at a rate not exceeding 1 g/min; the final pH was 3.8–4.0. The slurry was stirred slowly overnight. The following morning a few drops of suspended lake were spotted on filter paper to test for bleeding of the dye from the lake. The lake was washed until a 10-mL sample of wash water was no more turbid than the original water by the silver nitrate test. The lake (yield 140 g) was air dried in an oven at 50°C overnight.

Preparation of FD & C Blue No. 2 Lake (Preparation No. B2)—The method was the same as for Yellow No. 5 lake except that FD & C Blue No. 2 (70 g) was dissolved in distilled water (4700 mL) at 55°C. The dye solution was passed through a filter into the slurry and stirred for 15 min at 45–50°C. Aluminum chloride solution (5.25 M, 69 mL) was rapidly added to the slurry; the pH at the end was 4.0–4.1. The yield was 152 g.

Preparation of FD & C Red No. 40 Lake (Preparation No. R40)—The method is the same as for Yellow No. 5 lake except that FD & C Red No. 40 (86 g) was dissolved in distilled water (1400 mL) at 35°C. The yield was 150 g.

Preparation of Aluminum Hydroxide Under Different Conditions—Variations in the processing parameters during aluminum hydroxide precipitation were made by altering the following factors: pH, temperature, aging time, concentration of reagents, presence of sulfate, and nature of aluminum salts and bases. FD & C Yellow No. 5 was the dye used for lake formation in these experiments.

Preparations From Aluminum Sulfate—Since aluminum sulfate is the salt normally used for preparing the aluminum hydroxide substrate for lake formation, this was taken as a starting point for variations in processing parameters to be made. For preparation Nos. 1–4, sodium carbonate solution (1 M or 2 M) was added in a dropwise manner (10 mL/min) into aluminum sulfate solution (0.2 M) varying pH, temperature, and aging time (Table I). Lakes were formed in each case from the sulfate-free precipitate by the standard procedure. For preparation Nos. 5 and 6, sodium carbonate solution (2 M) was added to the aluminum sulfate solution (0.33 M) at 5.5 mL/min until the pH was 10.8, with a large excess of base added to preparation 5. Lakes were formed from the sulfate-free precipitate. By using sodium hydroxide solution (2 M) as the base in preparation 7, the pH of the resulting precipitate was taken up to 12.3. The standard procedure for the preparation of aluminum hydroxide was followed for preparations 9 and 10 except that the sulfate was not removed before lake formation (No. 9) and the precipitation stopped at pH 4.5 (No. 10). For preparations 11–13, sodium carbonate (1 M) and/or sodium hydrogen carbonate solutions (1 M) were added in a dropwise manner into an aluminum sulfate solution (0.2 M) at 10 mL/min until pH 6.9 was reached (Table I).

Preparations From Aluminum Chloride and Nitrate (Nos. 14–20)—Sodium hydroxide (2 M or 4 M) or sodium carbonate solution (2 M) was added to the aluminum chloride solution (0.67 M or 0.5 M) or aluminum nitrate solution (0.67 M or 0.2 M) at 10 mL/min with pH of precipitation and aging conditions given in Table I.

Preparation From Commercial Gibbsite (No. 21)—An attempt was made to form lakes from gibbsite using the standard procedure. After the excess dye was washed off, a slightly yellow grainy material was left.

Lake Analysis—*Dye Content*—Spectrophotometric analysis was used to determine the dye content of the lakes (2). For all lakes, except FD & C Blue No. 2, a sample (200 mg) in distilled water (200 mL) was boiled (3 min) with sodium hydrogen tartrate (3 g). The solution was cooled and diluted suitably for spectrophotometric analysis by scanning the visible spectrum from 400 to 700 nm. A similar process was used for FD & C Blue No. 2, except that more tartrate (6 g) was required.

Moisture—The methods employed were the Karl Fischer method[3] (3) and

weight loss on drying, in which samples (0.5 g) were dried to constant weight in a hot air oven at 10°C intervals, up to 135°C (4).

Chloride—The procedure was adapted from a potentiometric titration method (5). The lake sample was dissolved in nitric acid prior to titration against silver nitrate.

Sulfate—A gravimetric method (6) was used. The lake sample was boiled with sodium hydrogen tartrate to form a solution before the addition of barium chloride solution. Chloride and sulfate analyses were done only on the standard lakes.

Physical Investigation of Lakes—*Scanning Electron Microscopy*[4]—Specimens were mounted on aluminum stubs and gold coated.

Transmission Electron Microscopy[5]—Specimens were prepared by dispersing (1 min) powdered samples in methanol using an ultrasonic bath. A drop of the dispersion was put on a copper specimen support grid which had previously been coated with a thin carbon film.

Infrared Spectroscopy[6]—Pressed disks of potassium bromide (150 mg) containing finely ground sample (1 mg) were used to record the IR spectra.

X-ray Diffraction—The X-ray powder diffraction patterns were taken on an automated diffractometer[7] equipped with a scintillation detector and pulse-amplitude discrimination, using monochromatic CuK_α radiation.

Nitrogen Gas Adsorption—Two methods were used for the determination

of the surface area of lakes: the static method[8] using a high-vacuum system and the dynamic method[9].

RESULTS

Aluminum Hydroxide Substrate—Electron microscopy clarifies the morphology of amorphous precipitated aluminum hydroxide, which was freshly prepared (preparation No. 1). With transmission electron microscopy, the agglomerated particulate material, visible at lower magnifications, are composed of 0.1–0.2-μm diameter aggregated entities, which are primary particles of 10 nm × 20–30 nm. Each primary particle is composed of finer units, spherules of 2.5–5-nm diameter and possibly even smaller (as shown in Fig. 1A). The precipitate is thus composed of extremely fine particles (spherules) which are fairly homogeneous. This evidence, by transmission electron microscopy, is a considerable help in dispelling speculation on the structure of the gel. Electron diffraction gave a diffuse halo indicating an amorphous material. With scanning electron microscopy (photographs not shown), the precipitate appears as agglomerated material (~1.6 μm), apparently composed of 0.15-μm particles; also present is particulate material (~60 nm). When the same precipitate was dispersed for 85 h on a paint conditioner[10] in an ethanolic shellac solution, the specimen gave the appearance of 0.3–0.7 μm clusters; the smaller clusters seemed to be composed of spherical particles (40–80 nm) in groups.

The morphology of the various known samples of aluminum hydroxides showed the following features in increasing order of crystallinity as indicated from the diffractograms. Pseudoboehmite (RD 60/78) appears as a more compact gel with a more definite form than amorphous aluminum hydroxide (preparation No. 1). Boehmite (RD 59/78) contains more agglomerated material than pseudoboehmite. Bayerite (57/78) consists of a more organized and substantial material with a more definite outline. Gibbsite (RD 58/78) has a crystalline morphology.

IR spectra were obtained for amorphous aluminum hydroxide, pseudoboehmite, boehmite, bayerite, gibbsite, and aluminum hydroxides Nos. 1–20. Good agreement between the spectra for the nonamorphous hydroxides and literature data (7) was observed. Amorphous aluminum hydroxide (Fig. 2) was almost featureless and many of the aluminum hydroxides (Nos. 1–20) were virtually identical. Others were crystalline forms or these mixed with the amorphous variety, and could be identified from the spectra (*e.g.*, gibbsite has strong bands at 3550, 3490, 1020 cm^{-1}; bayerite at 3580, 3450, 765 cm^{-1}; boehmite at 3320, 3100, 1080 cm^{-1}). Selected spectra in Fig. 2 show a standard prepared amorphous form, a standard boehmite and No. 4, a standard bayerite, and No. 7, and a standard gibbsite and No. 19.

X-ray powder diffraction patterns (Fig. 3) were obtained for the preparations and complement the IR spectra. Amorphous aluminum hydroxide was devoid of lines, while the crystalline forms had the lines at the appropriate angles from which the d-spacings could be related to literature data (8). Figure 3 shows a prepared amorphous form, a standard boehmite and No. 4, a standard bayerite and No. 7, and a standard gibbsite and No. 19.

Aluminum Lakes—Chemical analyses for the standard lakes are tabulated in Table II for dye, sulfate, chloride, and moisture content with an indication of hardness (on an arbitary scale, in which 0 represents a very soft lake and 10 is a very hard lake). For the FD & C Yellow No. 5 lakes made under dif-

ferent experimental conditions, the dye and moisture contents with an indication of hardness are shown in Table I. The importance of washing off the sulfate from the aluminum hydroxide substrate is apparent from lake preparation No. 9. The sulfate must compete with dye anions and reduce the dye content of the resulting lake. This has been noted by various patent holders (9).

Transmission electron microscopy shows that the morphology of the FD & C aluminum lakes have a definite similarity to the amorphous aluminum hydroxide (preparation No. 1) but with a denser appearance, presumably caused by a tightly packed layer of dye molecules. FD & C Blue No. 2 lake (B2) contains features of homogeneous "hydroxide" particles as well as cigar-shaped particles (Fig. 1B). FD & C Red No. 40 lake (R40) contains features of homogeneous "hydroxide" particles as well as some U- or oval-shaped particles. FD & C Yellow No. 5 lake (Y5) (Fig. 1C) and FD & C Yellow No. 6 lake (lot No. 634) both have the homogeneous "hydroxide" particles, reminiscent of amorphous aluminum hydroxide. Electron diffraction of the above four lakes gave a diffuse halo indicating the presence of amorphous material. FD & C Blue No. 2 dye (Z7390) appeared as cigar-shaped crystals (Fig. 1D). Electron diffraction gave an array of spots indicating a crystalline material.

Energy dispersive analysis gave a semiquantitative analysis of submicrometer features which conventional forms of analyses cannot do (Table III). Elements lighter than sodium were not detected. For the lakes, the "hydroxide" particles, which are morphologically similar to the amorphous aluminum hydroxide, have a fairly constant composition. The cigar-shaped particles associated with the Blue No. 2 lake and the U- or oval-shaped particles associated with the Red No. 40 lake have a higher sulfur-to-aluminum content. These particulate materials probably originate from the respective dyestuffs and not from the aluminum hydroxide. The composition of the lakes in terms of the ratio of sulfur to aluminum is in broad agreement with the dye content to aluminum hydroxide ratio (corrected for water content) from bulk chemical analysis.

IR spectra were obtained for FD & C Yellow No. 5 dye and lakes Nos. Y5 (preparations 1–21), FD & C Blue No. 2 dye and lake No. B2, FD & C Red No. 40 dye and lake No. R40, and FD & C Yellow No. 6 dye and lake No. 634. The corresponding lakes of amorphous aluminum hydroxide (Y5), boehmite No. 4, bayerite No. 7, and gibbsite No. 19 are depicted in Fig. 4. The composition of other preparations deduced from the spectra are shown in Table I. The spectra of the lakes show a weakening of the intensity for many of the bands compared with the corresponding dyes, indicating some immobilization of the groups. Frequencies with intensities attenuated after lake formation were found at 1415, 1130, 1040, 1010, 720, 695, and 650 cm^{-1} for FD & C Yellow No. 5 lake (No. Y5). There were also minor band shifts from 1190 and 1220 cm^{-1} to 1140 and 1180 cm^{-1}, respectively. These bands are attributable to sulfonate groups (10). There are, however, no new bands in the IR spectra of the lakes; the spectra are additives of those of the dye and aluminum hydroxide substrate.

All the dyes gave strong X-ray powder diffraction patterns. However, the same dyes "laked" on amorphous aluminum hydroxide gave patterns surprisingly devoid of crystalline structure, having only a "memory" of the derived dye. It was found that the crystal structure of the experimentally prepared lakes closely reflect the crystalline state of the substrate. The diffractograms of the corresponding lakes of amorphous aluminum hydroxide No. Y5, boehmite No. 4, bayerite No. 7, and gibbsite No. 19 are shown in Fig. 5. When the boehmite substrate was "laked" (*i.e.*, exposed to pH 3.8 and dye added) the resulting lakes are essentially amorphous forms such as Nos. 4, 5, 6, 14,

[a] Divided by atomic weight.

and 18. Under the acidic conditions of the lake formation process, the boehmitic structure is probably destroyed or modified to an amorphous form of aluminum hydroxide to which the dye is adsorbed. In contrast, the bayerite and gibbsite forms are resistant to phase changes during lake formation. A summary of the effect of preparation method on the type of aluminum hydroxide and the lake obtained is given in Table I.

Gas adsorption results were obtained for the surface areas of aluminum lakes and the substrate of amorphous aluminum hydroxides (Table IV). The Quantasorb gives a favorable comparison with the static method for the specific surface area of a Yellow No. 5 lake (lot No. 127).

DISCUSSION

The conditions of preparation have a profound effect on the type of aluminum hydroxide produced and this in turn influences the dye content and physical properties of the resulting lakes. By means of two complementary techniques, X-ray diffraction and IR spectroscopy, it is possible to decide the type of aluminum hydroxide present.

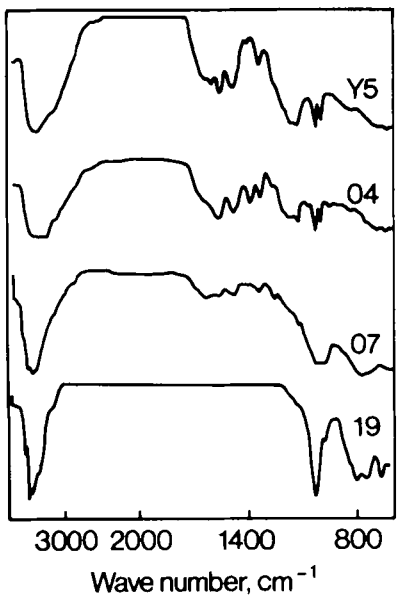

Figure 4—*IR spectra of experimentally prepared FD & C Yellow No. 5 dye and lakes Nos. Y5, 4, 7, and 19.*

An amorphous aluminum hydroxide gel was produced by the standard method of lake preparation (No. Y5) of aluminum hydroxide from aluminum sulfate and sodium carbonate at pH 6.9. An amorphous product was also obtained from the same reagents at pH 9 with 14 d aging at room temperature (No. 1) and at pH 4.5 (No. 10). When sodium bicarbonate was employed as a base (No. 12) or mixed with sodium carbonate (No. 11) an amorphous gel was prepared. The resulting lakes had a dye content of 36–39% dye (Table I). The preparation (No. 10) with the gel precipitated at pH 4.5 and had a slightly lower dye content of 32%; this may be because some of the aluminum ions were still in solution and the gel was not fully formed. The X-ray patterns for the gel and resultant lakes were featureless.

Petz (11) studied the structure of amorphous aluminum hydroxide gels by radial distribution functions computed from X-ray measurements. He found that the Al^{3+} ion is coordinated by an octahedral arrangement of oxygen sites and the relationship between the remaining oxygens is essentially the same as in water. An "icelike" quasi-lattice was postulated. Recently, Oka *et al.* (12) considered amorphous anodic alumina films to contain AlO_5 coordination polyhedra as well as AlO_4 tetrahedra and AlO_6 octahedra. These polyhedra are envisaged to be arranged in a mixture of two conformations, one of which is a crystalline modification of γ-Al_2O_3 within a short range of radial distance of <0.45 nm and the other is a conformation with randomly arranged coordination polyhedra.

Transmission electron microscopy of amorphous precipitated aluminum hydroxide gel shows "primary" particles of 10 nm × 20–30 nm existing as aggregated entities of 0.1–0.2-μm diameter, but each "primary" particle is apparently composed of still finer spherules of 2.5–5-nm diameter and possibly

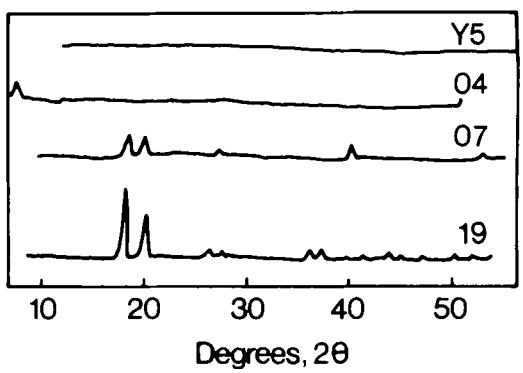

Figure 5—*X-ray diffraction patterns of experimentally prepared FD & C Yellow No. 5 dye and lakes Nos. Y5, 4, 7, and 19.*

Table IV—Surface Area Measurements of Aluminum Lakes and Their Aluminum Hydroxide Substrate

Sample	Surface Area, m^2/g
	Static Method
FD & C Yellow No. 5 Lake (Lot No. 127)	13.6
	Quantasorb
FD & C Yellow No. 5 Lake (Lot No. 127)	14.1
FD & C Yellow No. 5 Lake (Preparation No. Y5)	33.0
FD & C Yellow No. 6 Lake (Lot No. 634)	27.0

Amorphous Aluminum Hydroxide (Preparation No. 1)	114

even smaller (Fig. 1A). This is in accordance with Lippens and Steggerda (13), who are of the opinion that amorphous material consists of spherical particles 2–5 nm in diameter, loosely aggregated to bigger units.

From the nitrogen adsorption results, the standard lakes have specific surface areas less than one-third of that for the substrate amorphous aluminum hydroxide (Table IV). This may be interpreted as follows: the adsorbed layer of dye molecules on the surface of the aluminum hydroxide envelopes the micropores (pores with radii $< \sim 1.5$ nm) and probably some of the mesopores (intermediate pores with radii of 1.5–100 nm). Thus, in the lakes, nitrogen can only be adsorbed on the dye-enveloped aluminum hydroxide, which is "smoother" since the larger dye molecules are either blanketing the micropores so that there are fewer sites for adsorption or else steric hindrance repels the nitrogen molecules, resulting in a considerable reduction in the measured specific surface area.

X-ray diffraction of the FD & C dyes, *i.e.*, Blue No. 2, Red No. 40, and Yellow Nos. 5 and 6, all show a large number of sharp lines, indicating the dyes are highly crystalline. However, lake formation of the same dyes with amorphous aluminum hydroxide gives a rather diffuse X-ray pattern in the region of the sharp lines of the dyes. The lakes are thus amorphous. Electron diffraction, associated with transmission electron microscopy, also gives the same results. Electron diffraction enables small, identifiable regions of a few cubic micrometers to be examined, whereas X-ray diffraction needs several cubic millimeters of sample, although the information obtained by the latter is more accurate.

Kiel and Heertjes (14) found that the calcium–aluminum lake of alizarin shows four sharp lines on a powder X-ray diagram indicating that the substance is highly crystalline. Furthermore, its IR spectra had some new bands, which the alizarin did not exhibit.

The IR spectra of the FD & C dyes have a number of peaks of strong intensity while the corresponding lakes have attenuated absorption bands. Since the bands attributed to sulfonate groups are immobilized, the IR spectra indicate that in all the lakes used, the sulfonate group is involved in bonding the dye to the aluminum hydroxide. This conclusion is in agreement with Cummings *et al.* (15), who suggested that the adsorbed dye anions forming the monolayer could be composed of monodispersed anions, each orientated with all the sulfonate groups as close as possible to the surface. The adsorption mechanism is probably an exchange of chloride ions for the adsorbed anions, but there may also be some covalent bonding occurring. In the laking process, pretreatment of the substrate with an acid covers the surface with anions that may be either covalently bound or present as ions. The anion may be replaced by dye anion, and it is this reaction that is the basis of the alumina dyeing process (16, 17). Under the laking conditions (pH 3.8–4.0) the aluminum hydroxide particles are positively charged enabling interaction to take place with anionic dyes. The importance of the surface charge on aluminum hydroxide particles and its dependence on pH has been recently studied (18–21).

Boehmite was produced from aluminum sulfate and sodium carbonate under alkaline conditions, but the condition of pH 7.4 for 2 h at 70°C produced pseudoboehmite, which was boehmite in an excess of amorphous gel (No. 2). Preparations at pH 10 and aging under various conditions also produced boehmite (Nos. 3, 4, 5, and 6). Aluminum nitrate and aluminum chloride, precipitated with sodium carbonate under alkaline conditions (pH 10), also produced a boehmitic gel (Nos. 14 and 18, respectively). Some of the boehmites produced lakes with a higher dye content than with the amorphous gels, *e.g.*, No. 6 contains 51% and No. 18 47% dye content but these were both very hard (Table I).

There is controversy in the literature concerning the mechanism by which aluminum hydroxide gels change during the aging process. The term "aging" is used to connote all irreversible structural or textural changes in the colloidal system which may occur after flocculation or gelation (22). Aging is a complex phenomenon. Water plays a key role in all the aging mechanisms. The poorly organized flocculated hydroxide prepared from salts of hydrated cations usually contains large quantities of molecular water (22). Baker and Pearson (23) propose that it is not a large conceptual step from the hydrolytic polymers in aluminum salt solutions [the dimer, $Al_2(H_2O)_8(OH)_2^{4+}$, for example] to the small boehmite-like crystallites capable of giving an X-ray diffraction pattern. Thus, pseudoboehmite is nothing more than an aggregate of ultra small boehmite-like crystallites, and a boehmitic pattern in crystallites as small as ~2.5 nm can be detected. The end point of the hydrolytic polymerization may be either an infinite series of chains (*i.e.*, the boehmitic-like materials) or ring structures (*i.e.*, gibbsite or bayerite).

Serna *et al.* (24) have found that sulfate and carbonate anions both show evidence of coordination with the surface aluminum cations. The carbonate interaction appears to be the strongest and is believed to be responsible for the relatively high degree of stability of carbonate-containing aluminum hydroxide gel. This could explain why the gel from sodium carbonate did not age beyond boehmite at pH 10. Only Baker and Pearson's (23) chain structure could be formed and not the ring structure. It is interesting to see from the X-ray diffraction patterns that the boehmite degenerated to various amorphous forms after lake formation, although IR spectroscopy still detected the boehmite.

On aging of the precipitate at pH ~12, gibbsite is formed from sodium hydroxide with aluminum nitrate (No. 15), and similarly with aluminum chloride (No. 19). However, at 60°C with aging, some less well crystallized material is formed: sodium hydroxide with aluminum nitrate (No. 17) forms gibbsite with bayerite and boehmite, while sodium hydroxide with aluminum chloride (No. 20) forms gibbsite and bayerite. It is noteworthy that the aged product of aluminum sulfate precipitated with sodium hydroxide at pH 12 is in the form of bayerite (No. 7). The reason may be that the sulfate coordinates to the aluminum and inhibits crystallization to the gibbsite phase. The aluminum nitrate and chloride salts, precipitated with sodium hydroxide at pH 12 with aging, both crystallize to the same end product, gibbsite. This is in line with the hypothesis that the rate of aluminum hydroxide crystallization is inversely related to the tendency of anion inclusion in aluminum hydroxide precipitates (25). The precipitation at 60°C to produce a mixed product (gibbsite plus bayerite or boehmite) happens since at elevated temperature there is a "fast" transformation to a boehmitic structure which only slowly, with aging, crystallizes to the trihydroxides.

The lakes containing gibbsite or bayerite have a much lower dye content than the amorphous lakes [lake Nos. 7, 17, and 19 contain 8, 5, and 8%, respectively, while gibbsite crystals (No. 21) adsorb a negligible amount of dye (Table I)]. This may be explained from surface area considerations. Crystalline gibbsite evidently has the least surface area available for adsorption of dye since most of the aluminum atoms are incorporated in the crystal lattice and are unavailable for adsorption. The morphology of gibbsite from transmission electron microscopy consists of straight edges and hexagonal shapes. Lippens (26) prepared gibbsite crystals in the form of hexagonal platelets of diameter 0.3 μm, and rod-shaped crystals 10×3 μm^2. Hence the surface area was quite small. Bayerite particles range from ~50 to 100 nm upwards, forming larger aggregates. Lippens (26) found that the surface area of bayerite was 6–75 m^2/g and his micrographs showed bayerite particles, called somatoids, which had a variable size, with the width being mostly smaller than 0.5 μm with a length 3–10 times the width. In contrast, Lippens and Steggerda (13) found the surface area of gelatinous boehmite to be ~200–500 m^2/g. An amorphous gel of spherical particles of 2–5-nm diameter would be expected to give a surface area of ~1000 m^2/g, but Lippens and Steggerda (13) were unable to measure the surface area by the nitrogen Brunauer, Emmett, and Teller (BET) method, since it was found that the surface was not accessible to nitrogen.

Recently, Pyman and Posner (27) have questioned the meaning of the term "surface area," since amorphous materials generally have large surface areas of 50–1000 m^2/g, a considerable pore structure which is frequently microporous, and contain appreciable quantities of water, both adsorbed onto the surface and incorporated into the structure. They suggest that assignment of a specific surface area to amorphous materials should be related to the purpose for which the surface is to be used and that the value is dependent on the method. With lakes formed from the amorphous aluminum hydroxide gel, which are believed to be composed of spherules 2.5–5 nm in diameter from the transmission electron microscopy work, the envisaged surface area of 1000 m^2/g may be regarded as an effective surface area from the viewpoint of the dye anions. Such a surface is not accessible to nitrogen adsorption, which gives a lower surface area value of 114 m^2/g $Al(OH)_3$ (Table IV). It appears that nitrogen envelopes the 10–30 nm particles without being able to reach the spherules of 2.5–5 nm.

From these considerations the following picture of lake formation is proposed. In aluminum lakes, the amount of dye adsorbed on the aluminum hydroxide is dependent on its surface area. The dye molecules are envisaged to form a monolayer on the surface of amorphous aluminum hydroxide spherules of 2.5–5-nm diameter, which provides sufficient surface area to account for

the 30–40% dye content of aluminum lakes. Direct evidence for the existence of these spherules comes from the highest power transmission electron micrographs. This conclusion is supported by the work of Lippens and Steggerda (13) who have also described amorphous aluminum hydroxide gel as being composed of 2–5-nm diameter spherical particles, loosely aggregated to form larger units. Further it agrees with the results of Bye and Chigbo (28) where they found weakly bonded flocs of apparently isometric particles of ~5 nm.

The quantity of dye adsorbed in terms of mmol dye/g Al_2O_3 [notation after de Boer *et al.* (29)] is readily calculated from the lake dye content. Since aluminum hydroxide has a variable water content, the formula $2Al(OH)_3$ may be written as $Al_2O_3 \cdot 3H_2O$, and Al_2O_3 is expressed as that equivalent amount of aluminum hydroxide with no water content. For aluminum lakes, the quantity of dye adsorbed was found to be ~2 mmol/g Al_2O_3 for Blue No. 2 and Yellow No. 5 and ~3 mmol/g Al_2O_3 for Yellow No. 6 and Red No. 40. Giles *et al.* (16) have made studies of dye adsorption on anodic films and found that for disulfonated dyes there was a maximum adsorption of ~0.2 mmol/g corresponding to ~100 m^2/g, the adsorbed dye molecule generally being orientated "edge-on." Since aluminum lakes contain about 10 times more dye than the anodic films of Giles, this suggests that the surface area of substrate covered would be in the order of 1000 m^2/g and is consistent with the spherule size of 2.5–5-nm diameter. However, the nitrogen gas adsorption results give a surface of area of amorphous aluminum hydroxide gel compatible with a "primary" particle size of 10 nm × 20–30 nm. The surface of the 2.5–5-nm diameter spherules is presumably inaccessible to nitrogen and thus the smallest particle penetrable by nitrogen may contain many crystallites. Baker and Pearson (23) suggested that the packing of these crystallites reduces the accessible surface to nitrogen. It may be firmly concluded that the evidence points to the dye being surface adsorbed on very small particles, mainly <50 nm.

These experiments provide good evidence that the fully amorphous type of aluminum hydroxide is the best form for lake formation confirming what is empirically known within the industry. It is also evident that the gel should be washed free of sulfate ion before laking to avoid interference with dye adsorption. The conditions under which the aluminum hydroxide is prepared governs the degree of amorphous/crystalline character of the product, which is reflected in changes in particle size and surface area of the aluminum hydroxide. This then controls the amount of dye taken up. Although lakes can be formed from boehmite, the product is usually hard and glassy; thus the product is unsuitable for industrial use. The crystalline trihydroxides, bayerite and gibbsite, produced under aging conditions, take up considerably less dye. Gibbsite crystals take up a negligible amount of dye. To prevent lake formation failure, aging conditions, which are likely to produce the crystalline forms of aluminum hydroxide, should be avoided.

Determination of Trimipramine and Metabolites in Plasma by Liquid Chromatography with Electrochemical Detection

RAYMOND F. SUCKOW [x] **and THOMAS B. COOPER** *

Received November 28, 1983, from the *Analytical Psychopharmacology Laboratory, Nathan S. Kline Institute for Psychiatric Research, Orangeburg, NY 10962* and the **New York State Psychiatric Institute, 722 West 168th Street, New York, NY 10032.* Accepted for publication March 9, 1984.

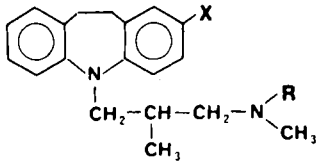
Abstract □ A procedure for the determination of trimipramine, the demethyl, 2-hydroxy, and 2-hydroxy demethyl metabolites in plasma by liquid chromatography with electrochemical detection is described. A 1-mL plasma sample is made alkaline with a carbonate buffer (pH 9.8) and extracted with 20% ethyl acetate in *n*-heptane. After back-extraction into an acid phosphate buffer, an aliquot is injected onto a reverse-phase trimethylsilyl-packed column and eluted with a phosphate buffer–acetonitrile mobile phase (65:35) containing *n*-butylamine. The peaks were detected at +1.1 V *versus* the silver–silver chloride reference electrode. The method provides absolute recoveries of 60–91% and a day-to-day precision of <9% for all compounds. The minimum quantifiable level for all compounds was 3 ng/mL. Steady-state plasma concentration data for 29 depressed patients receiving either 75 mg or 150 mg/d is reported.

Keyphrases □ Trimipramine—metabolite detection, HPLC, electrochemical detection, human plasma □ HPLC—electrochemical detection, trimipramine and its metabolites

Trimipramine (I) is a relatively recent addition to the structurally related dibenzazepine class of tricyclic antidepressants. It differs chemically from the prototype imipramine by a replacement of the *n*-propyl side chain with a 2-methyl propyl group. A review of its clinical use has been presented (1).

Trimipramine has been included in many tricyclic antidepressant methodologies either as an internal standard or for the purpose of demonstrating its chromatographic separation from other tricyclic antidepressants. Presently, there are two reports of its quantitation in plasma with respect to its therapeutic use. One method does not include its metabolites nor present any clinical data derived from its measurement (2). Another report (3) describes a GC procedure and its application to the pharmacokinetics of trimipramine only.

Since trimipramine is structurally very similar to imipramine one might expect its metabolic profile to be similar. We therefore developed an HPLC assay that will separate and quantitate I and its known major metabolites—the demethyl metabolite (II), the 2-hydroxy metabolite (III) and the 2-hydroxy demethyl metabolite (IV). Fixed-dose steady-state plasma concentration data for 29 patients are reported.



I: X = H, R = CH_3
II: X = H, R = H
III: X = OH, R = CH_3
IV: X = OH, R = H

EXPERIMENTAL SECTION

Apparatus and Reagents—Chromatography was performed using a dual piston solvent delivery pump[1] and an automatic sampler[2]. The column was 25 cm × 4.6 mm i.d. packed with 5-μm particle size trimethyl silyl material[3]. The detector system consisted of a thin-layer flow through electrochemical transducer[4]. The potential and current response were monitored by an amperometric controller[5] and recorder[6] and interfaced with a laboratory data acquisition system[7]. An aluminum column temperature control block was devised to fit the column and the temperature controlled by a circulating water bath[8]. Voltammograms were performed by a cyclic voltammetry instrument[9] and recorded on an X-Y recorder[10]. The potential was scanned from 0.0 to +1.3 V *versus* silver–silver chloride reference electrode at 180 mV/s. Glassy carbon was used as the working electrode.

Phosphoric acid[11], monobasic potassium phosphate[11], sodium carbonate[11], and potassium bicarbonate[11] were all analytical reagent grade. Acetonitrile-UV[12], *n*-heptane[11], *n*-butylamine[11], and β-glucuronidase[13] were used as received. Ethyl acetate[11] was purified through a silica-packed column prior to use. Distilled water was passed through a water purification system[14] before use.

Standards—One milligram (free base) per milliliter of stock solutions of trimipramine maleate (I)[15], the demethyl metabolite (maleate salt) (II)[15], the 2-hydroxy metabolite (fumarate salt) (III)[15], the 2-hydroxy demethyl metabolite (fumarate salt) (IV)[15], the didemethyl metabolite (maleate salt) (V)[15], and mianserin hydrochloride (VI)[16] were prepared in 0.01 M HCl. All stock solutions were further diluted with 0.01 M HCl to give working solutions of 1 μg/mL. Working standards of III and IV were prepared as 10 μg/mL for conjugate studies.

Standard curves were prepared containing five levels of spiked samples: 25, 50, 100, 200, and 400 ng/mL of I and II, and 12.5, 25, 50, 100, and 200 ng/mL of III and IV. For total III and IV, 100, 250, 500, 1000, and 2000 ng/mL spiked samples were prepared.

Extraction—The internal standard, mianserin (75 μL = 75 ng), and 0.5 mL of 0.6 M potassium bicarbonate–sodium carbonate buffer (pH 9.8) were added to 1.0 mL of plasma sample. Seven milliliters of 20% v/v ethyl acetate in *n*-heptane was added, the contents were mixed for 15 min and then centrifuged at 1500×*g* for 10 min. The organic layer was transferred to a 15-mL tapered centrifuge tube containing 0.25 mL of acidic phosphate buffer (0.025 M KH_2PO_4 adjusted to pH 2.5 with 85% H_3PO_4). After mixing for 10 min and centrifuging at 1500×*g* for 10 min, the organic layer was discarded and the aqueous portion was transferred to a small glass vial[17] and capped. Suitable aliquots were injected for chromatographic separation.

For the analysis of the 2-hydroxy and 2-hydroxy demethyl metabolites III and IV (total, free and conjugated), the pH of 0.5 mL of plasma was adjusted to 4.7 with the addition of 0.5 mL of 0.2 M KH_2PO_4. Then, 25 μL of β-glucuronidase solution was added to each tube and the mixture was incubated for 24 h at room temperature. Fifty microliters of 2 M NaOH, 50 μL (500 ng) of internal standard, mianserin, 0.5 mL of carbonate buffer, and 7 mL of 20% v/v ethyl acetate in *n*-heptane were added and the extraction was carried out as previously described. Standards containing III and IV were treated in the manner described above (including the incubation procedure).

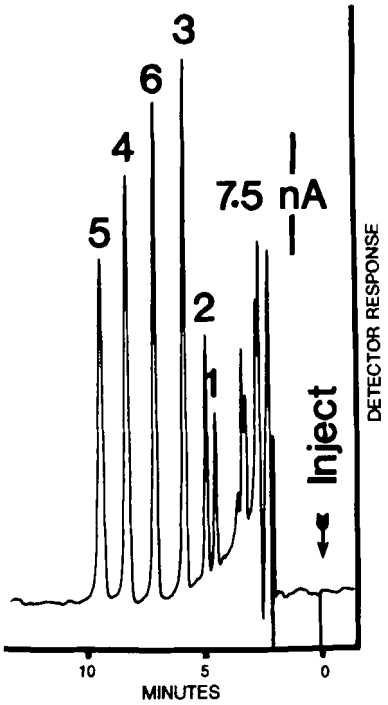

Figure 1—*A chromatogram of a spiked 1-mL plasma extract containing 25 ng each of III and IV (2 and 1) and 50 ng each of I, II, and V (5, 4, and 6). Actual patient samples showed little or no V (6). Mianserin (3) is the internal standard.*

Chromatographic Conditions—The mobile phase consisted of 0.05 M monobasic potassium phosphate-acetonitrile (65:35) with the addition of 1.2 mL/L of *n*-butylamine and 1.0 mL/L of phosphoric acid. The mixture was filtered and deaerated prior to use. The flow rate was 1.5 mL/min and the column temperature was set at 32°C. Detector potential was set at +1.10 V *versus* silver-silver chloride reference electrode.

Quantitation—All determinations were performed by calculating the peak height ratios of each compound to the internal standard. A linear regression analysis for each of the standard curves was performed by a computer program resulting in the calculations of slope, *x*-intercept, correlation coefficient, and standard error.

RESULTS AND DISCUSSION

Trimipramine (I) and its major metabolites (II, III, and IV) were separated in a single chromatogram in <10 min. Figure 1 illustrates a typical chromatogram of a spiked plasma sample. A blank plasma extract showed no endogenous interfering peaks.

The optimum oxidation potential of I–IV was determined by cyclic voltammetry. The presence of the 2-hydroxy groups on III and IV lowers the oxidation potential from that of the parent compound I. This profile, not surprisingly, resembles that of imipramine and its major analogous metabolites (4). Proposed mechanisms for the electrochemical oxidation of these compounds have been presented (5–7). The electrochemical oxidation profile for mianserin has been reported with the optimum being ~ +1.1 V *versus* the silver-silver chloride reference electrode (8).

The precision of this method was determined by spiking eight 1.0-mL aliquots of drug-free plasma with various levels of drug and metabolites. After the addition of 75 ng of internal standard, the samples were processed as described. The percent relative standard deviation for various levels are reported in Table I. Day-to-day accuracy was checked after runs over 7 consecutive days. The linear regression slopes as well as the quality control samples were assessed and are presented in Tables II and III.

Table I—Within-Run Variability of Trimipramine and Its Metabolites [a]

Concentration, ng/mL	*RSD*, %			
	I	II	III	IV
400	3.7	7.0		
200			2.1	4.4
100	1.6	3.7		
50			3.0	3.8
25	4.9	12.2		
20			3.7	5.2
5	5.1	9.6	10.4	12.1

Compound	Amount added, ng/mL	Amount found, ng/mL	*RSD*, %
I	100	101	4.4
II	100	98	9.3
III	50	52	8.0
IV	50	51	6.5

[a] Data computed from quality control samples analyzed on seven consecutive days.

Table IV—Recovery of Trimipramine and Its Metabolites [a]

Compound	200 ng		25 ng	
	Percent	*RSD*, %	Percent	*RSD*, %
I	74	6.0	71	7.5
II	79	6.5	72	9.9
III	91	7.0	83	6.6
IV	60	6.4	59	5.7

[a] From 1 mL of plasma; $n = 8$.

The absolute recovery was determined by preparing a solution of known concentrations of all compounds, I–IV. The internal standard was added to each solution and the sample injected into the chromatograph. The same standards were added to 1 mL of plasma and processed routinely except for the internal standard. To the final acid extract, 75 ng of internal standard was added, mixed, and injected. The difference between the ratios of the standards to internal standard in processed sample *versus* the direct injection samples gave a measure of overall recovery (Table IV).

The absolute sensitivity ($S/n = 3$) of this method was 0.5-ng injected for all compounds (I–IV). In practical terms, however, the lowest quantifiable levels were ~3 ng/mL of plasma. Linearity was checked up to 500 ng.

Interfering peaks occurred in samples from patients receiving imipramine, desipramine, chlorimipramine, chlorpromazine, amoxapine, loxapine, trazodone, and haloperidol. Other tricyclic and tetracyclic antidepressants such as amitriptyline, nortriptyline, protriptyline, doxepin, and maprotiline do not interfere since they are not electroactive under these conditions. Some commonly used benzodiazepines (flurazepam, diazepam, and chlordiazepoxide) also do not interfere because they do not respond electrochemically at these conditions. This selectivity is one advantage of the electrochemical detector over a UV detector at the frequently used wavelength of 254 or 214 nm.

The extraction procedure was developed specifically for the simultaneous recovery of I–IV as well as VI. The pH of the plasma must be between 9–10 for optimum recovery of III and IV. The use of 20% v/v ethyl acetate in *n*-heptane was sufficiently polar enough to extract III and IV and at the same time did not cause variability in recoveries of I, II, and VI as was frequently encountered when using a 5–10% v/v isoamyl alcohol in *n*-heptane mixture or when using methyl *tert*-butyl ether.

When hydrolyzing plasma for the preparation of samples for the measurement of the total (conjugated and unconjugated) III and IV, an attempt was made to prevent decomposition of these hydroxy metabolites by the addition of an antioxidant. A previous report (9) indicated that the addition of ascorbic acid to the plasma hydrolysis buffer prevented a rapid decomposition of 2-hydroxydesipramine. We found this to be true not only for 2-hydroxydesipramine but for 2-hydroxyimipramine. However, the two hydroxy metabolites of trimipramine did not appear to be susceptible to this decomposition. Thus, no ascorbic acid was added to the hydrolysis buffer.

To check the validity of this assay, 100 samples were randomly selected and analyzed for I by GC with a nitrogen detector using a modified procedure developed initially for imipramine (10). The correlation coefficient between the two methods was 0.980, with HPLC = 0.942 (GC) −1.6.

Plasma samples from 29 different patients receiving either 75 or 150 mg/d

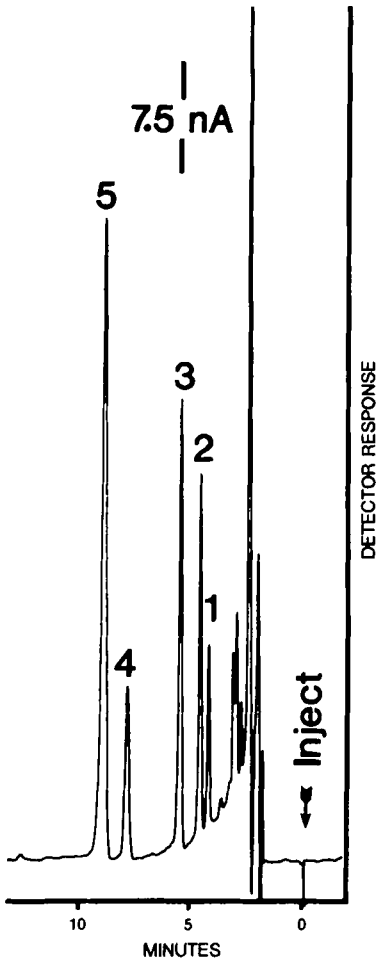

Figure 2—*A chromatogram of an extract of 1 mL of plasma from a patient receiving 150 mg/d of trimipramine. Concentrations were: I (5), 111 ng/mL; II (4), 25 ng/mL; III (2), 40 ng/mL; IV (1), 32 ng/mL.*

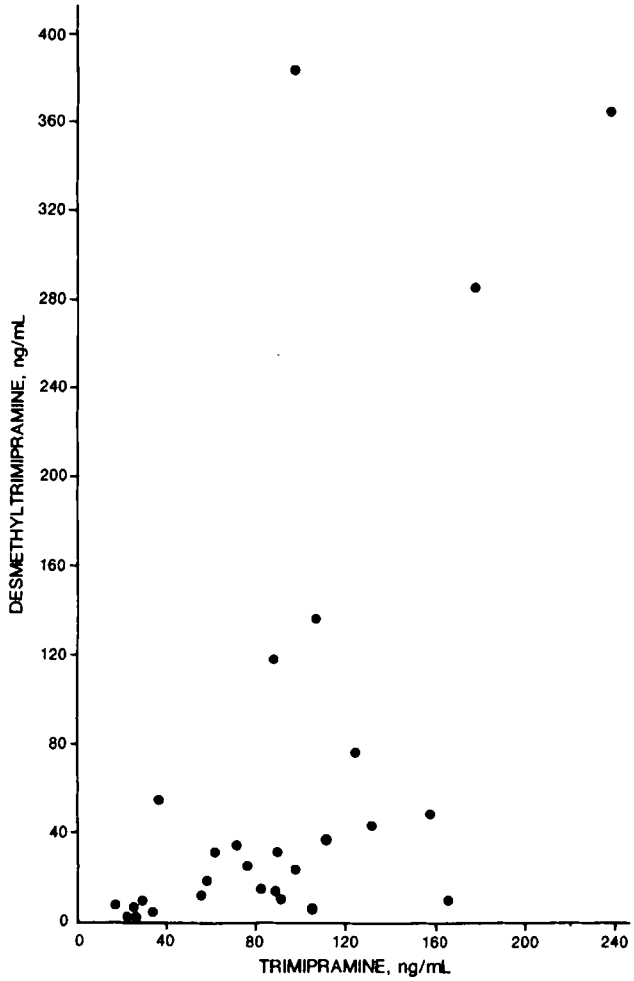

Figure 3—*Plasma concentrations of trimipramine I and the demethyl metabolite II in 28 patients. All patients were at steady state receiving either 75 or 150 mg of trimipramine (r = 0.62).*

were analyzed for trimipramine and its major metabolites (II, III, and IV). A typical chromatogram from one of these patients is shown in Fig. 2. In several patients who exhibited a relatively high level of II (>200 ng), another peak appeared at a retention time of ~7.0 min. This peak was identified as the didemethyl metabolite (V) by comparison with the retention time of a standard solution of V. A chromatogram of a spiked sample containing V as well as the other standards I–IV and VI is depicted in Fig. 1. Although never accurately quantitated, V was never found in any significant (>10 ng/mL) levels in over 120 samples tested.

To date, no clinical plasma concentrations for I and its major metabolites (II–IV) have been reported. From our preliminary data, we found that I undergoes the same metabolic pathway as imipramine: namely I is demethylated as well as hydroxylated in the 2-position, conjugated as the glucuronide, and excreted. Other minor pathways may exist for I such as *N*-oxidation, side-chain dealkylation, and others that again resemble the imipramine pathway. Metabolite II is also hydroxylated and, in a few instances, further demethylated to the primary amine (V).

Table V—Mean Data From 29 Patients Receiving 75 or 150 mg/d of Trimipramine [a]

Variables in Plasma	Mean, ng/mL	Range, ng/mL
I	86	11–241
II	65[b]	3–382
III (u)[d]	16	3–40
IV (u)	17[b]	3–49
III (T)[d]	379[b]	58–1126
IV (T)	317[b]	63–800
Ratios		
II/I	0.61[b]	0.07–3.71
III(u)/III(T)	0.04[b]	0.02–0.08
IV(u)/IV(T)	0.05[c]	0.01–0.10
III(u)/I	0.26	0.02–0.75
IV(u)/II	0.86	0.02–1.67

[a] n = 29; patient ages, 18–65. [b] n = 28. [c] n = 27. [d] Key: (u) unconjugated; (T) total.

Plasma concentrations of I and its metabolites (II–IV) varied widely among the 29 depressed patients (14 receiving 75 mg; 15 receiving 150 mg/d of I). This variability has been demonstrated for other tricyclic antidepressants such as imipramine, amitriptyline, *etc.* Table V lists the means, ranges, and various ratios for these 29 depressed patients. Demethylation of I does not appear to occur as readily as with imipramine or amitriptyline since it was reported that the ratios of the demethylated metabolites to the parent drug of both these compounds were 1.0–1.6 and 1.0 (11–13), respectively. The difference in the side chain probably accounts for this retardation in demethylation of I. A correlation between I and II is illustrated in Fig. 3.

The mean ratio of unconjugated III to I was 0.26, which is similar to the reported ratio of 2-hydroxyimipramine to imipramine (0.18–0.25) (12, 13). However, the ratio of unconjugated IV to II was 0.86 which is greater than that found for 2-hydroxydesipramine to desipramine (0.50) (12, 13). This increase in ratio of IV/II may occur because of the existence of an additional demethylation pathway from III to IV. Of the 29 patients, 3 were found to have a ratio of unconjugated III + IV/II + I ≤0.03 which could indicate the portion of the population that is considered deficient in the ability to hydroxylate (14). There was no correlation between either unconjugated III and I or unconjugated IV and II. This finding differs from the weak to moderate correlation between 2-hydroxyimipramine and imipramine and 2-hydroxydesipramine and desipramine reported by DeVane and Jusko (13) and Suckow and Cooper (4). Four to five percent of the total plasma hydroxy metabolites are unconjugated. Bock *et al.* (9) has reported 8% of the total plasma 2-hydroxydesipramine metabolite as unconjugated. This analytical procedure has sufficient sensitivity for single dose pharmacokinetic studies of trimipramine and its metabolites in plasma.

Gas Chromatographic Analysis of Cetiedil, a Candidate Antisickling Agent, in Human Plasma With Nitrogen-Sensitive Detection

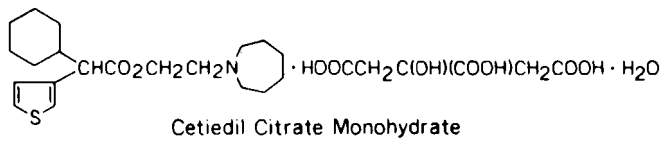
JAMES D. HENDERSON ˣ, VIPUL N. MANKAD, THOMAS M. GLENN, and YOUNG W. CHO

Received May 24, 1982, from the *Departments of Pharmacology and Pediatrics, University of South Alabama, College of Medicine, Mobile, AL 36688.* Accepted for publication August 24, 1983.

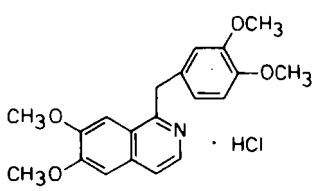
Abstract □ In this report a sensitive gas chromatographic assay for cetiedil, a candidate antisickling agent, in human plasma is described. After a triple extraction procedure, cetiedil was analyzed without derivatization with a nitrogen-phosphorus detector (with papaverine used as the internal standard.) Cetiedil was measured in plasma samples taken from human volunteers administered the drug intravenously.

Keyphrases □ Gas chromatography—cetiedil, human plasma, nitrogen-phosphorus detector □ Antisickling agents—cetiedil, GC analysis in human plasma, nitrogen-phosphorus detector □ Cetiedil—antisickling agent, GC analysis in human plasma, nitrogen-phosphorus detector

At present there is no pharmacological agent available to prevent or attenuate the sequelae of sickle cell crisis. For acute crisis, analgesics, hydration, and symptomatic care remain the standard therapy. In 1977, Cabannes reported on the clinical use of cetiedil citrate monohydrate for management of the painful thromboembolic crises characteristic of sickle cell disease (1).



Cetiedil Citrate Monohydrate



Papaverine Hydrochloride

Cetiedil[1] was first introduced for the treatment of peripheral and cerebral vascular disease (2). Subsequent studies have demonstrated that this vasoactive agent was also active in erythrocytes, in that it could prevent or reverse sickling by altering the permeability characteristics of the erythrocyte membrane (3–5). Several of its pharmacological properties (vasodilation, anticoagulation, analgesia, and inhibition of platelet aggregation) would be favorable for management of the thromboembolic episodes associated with sickle cell disease (6–8).

In this report, a reliable and sensitive gas chromatographic (GC) assay for cetiedil in human plasma, employing a triple extraction procedure and a nitrogen-phosphorus detector is described. The assay is similar to a previously reported method for analysis of papaverine in blood samples (9).

EXPERIMENTAL SECTION

Chemicals—Cetiedil citrate monohydrate[2] (white powder) and papaverine hydrochloride[3] were used without further purification. All solvents[4] were either nanograde or organic residue-analysis grade. All other reagents were certified ACS reagent grade.

Chromatographic Conditions—The gas chromatograph[5] was equipped with a nitrogen-phosphorus detector. A glass column (1.5 m × 2 mm i.d.) packed with 2% OV-101 on Chromosorb W HP 100–120-mesh support[6] was conditioned overnight (300°C). High-temperature septa[5] and graphite ferrules[6] were used. Air, helium, and hydrogen of the highest purity available[7]

were used. Operating conditions were as follows: isothermal column temperature, 252°C; injection port temperature, 300°C; detector temperature, 300°C; carrier gas (helium) flow, 20 mL/min; air flow, 54 mL/min; hydrogen flow, 1.5 mL/min; range 1; and attenuation, 2–8. Injections (0.5–2 μL[8]) were made directly on column, the chart[9] speed was 1.3 cm/min.

Glassware Preparation—All glassware was washed in phosphate-free detergent[10] and rinsed with glass-distilled acetone. Silanization was accomplished by treatment with a 5% solution of dimethyldichlorosilane[11] in toluene, followed by rinsing in methanol. (Due to the toxicity of the silanizing agent, it is best handled with gloves and safety glasses in a well-ventilated hood. Addition of methanol produces fumes of hydrogen chloride gas if excess silanizing agent is present.) The glassware was then sonicated[12] in dichloromethane.

Internal Standard—Papaverine hydrochloride (55 ± 1 mg) was accurately weighed and transferred to a 125-mL separatory funnel. Glass-distilled water (25 mL) was added to dissolve the powder; the free base was formed by the addition of 10 M KOH (2 mL) and extracted with dichloromethane (3 × 30 mL). The combined extracts were filtered through anhydrous sodium sulfate (1 kg washed with 6 × 200 mL of methylene chloride) and brought to 100.0 mL (stock solution I). A total of 1 mL of stock solution I was diluted to 100.0 mL with dichloromethane (stock solution II). A total of 5 mL of stock solution II was placed in a 1000-mL volumetric flask and evaporated under a nitrogen[7] stream. 2-Propanol (50 mL) was added to dissolve the residue, and the volume was brought to the mark with *n*-heptane (working internal standard solution).

Cetiedil Standard Solutions—Cetiedil citrate monohydrate (16.0 mg, equivalent to 10.0 mg of free base) was dissolved in water and diluted to 200.0 mL (50 μg/mL). Serial dilutions with water gave working standard solutions of 10, 20, 40, 80, and 160 ng/mL.

Buffer Solution—Boric acid (12.4 g) and potassium chloride (14.9 g) were dissolved in water and diluted to 1 L. Of this solution, 50 mL was adjusted to pH 7.0 with 0.2 M KOH and diluted to 200 mL with water.

Extraction Procedure[13]—*Standards for Calibration Curve*—Buffer solution (pH 7, 4 mL) and blank plasma[14] (2.0 mL) were added to each of six 35-mL centrifuge tubes[15]. To one tube was added 1.0 mL of water; to each of the remaining tubes was added a 1.0-mL aliquot of each of the cetiedil working standard solutions, respectively. After addition of working internal standard solution (20.0 mL) to each tube, the mixtures were shaken at highest speed[16] (30 min) and centrifuged (30 min at 2500 rpm)[17]. The top layer was transferred to another tube containing 1 M HCl (3 mL)[18]. The mixtures were vortexed at highest speed (1 min) and centrifuged, and the top layer was discarded. The acidic extract was washed with *n*-heptane (5 mL) by vortexing for 30 s, centrifuging, and discarding the top layer. To each tube was added 10 M KOH (0.5 mL); after cooling to room temperature, dichloromethane (4 mL) was added. The mixtures were vortexed (1 min) and centrifuged, and the top layer was discarded. The organic layer was transferred directly[19] to a 5-mL vial[6], and the solutions were evaporated[20] to dryness under a nitrogen stream at 40°C. After rinsing the vial walls with dichloromethane (100 μL) and evaporating, the residue was dissolved in 2-propanol (10 μL), and an aliquot was injected.

Subject Samples—The procedure described above was followed for subject samples, except that 2.0 mL of the plasma was used in place of the blank plasma, and 1.0 mL of water was used in place of the cetiedil standard solution.

Calculations—The ratio of peak height of cetiedil to peak height of papaverine was determined for each of the calibration standards; linear regression analysis of these ratios *versus* the known cetiedil concentrations gave a slope and intercept, from which the equation for a straight line was obtained. Cetiedil concentrations in subject samples were obtained by substitution of the experimentally determined peak height ratio into the equation for the standard curve prepared for analysis of every set of samples.

Plasma Level Studies—Three adult male volunteers were admitted[21] to the study after signing informed-consent releases[22]. The subjects received a 0.15-mg/kg dose of cetiedil citrate monohydrate injectable[2] as a 30-mm intravenous infusion[23], followed by a 72-h observation period. Blood samples were obtained through a catheter placed in the arm contralateral to the infusion drip at 0 (prior to infusion), 5, 10, 15, 30, and 45 min and 1, 1.5, 2, 4, and 6 h postinfusion; the catheter was kept patent with heparinized saline. Before each blood collection, dead-space volume heparin solution was removed. After each collection, the catheter was refilled with heparinized saline (33 U of heparin/mL). Samples were collected into heparinized tubes[24] and centrifuged; the plasma was separated and stored at −15°C until assayed.

RESULTS

Standard Curve—In Fig. 1 is shown a typical chromatogram obtained for the analysis of unchanged cetiedil, with papaverine as internal standard. There

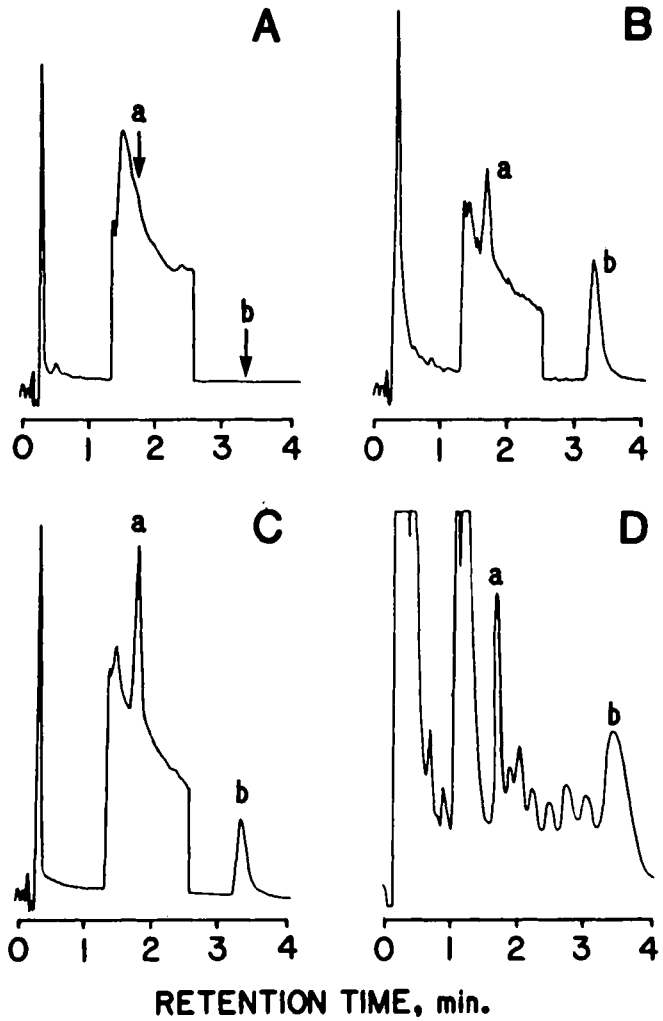

Figure 1—*Typical chromatograms of drug-free plasma carried through the procedure: (A) drug-free plasma to which 5 ng/mL of cetiedil (a) and papaverine (b) were added; (B) plasma from a subject receiving cetiedil; (C) with papaverine as the internal standard; (D) effects of filtration through sodium sulfate with possible contributions from contaminated solvents or glassware. The sudden jumps in the base line are due to programmed changes in recorder attenuation.*

Table I—Cetiedil Determination in Human Plasma [a]

Cetiedil Added, ng/mL	Cetiedil Determined, ng/mL	*SD*	*n*
5	4.99	0.43	4
10	4.87	0.84	8
	11.45	1.63	5
20	19.54	2.66	5
	22.60[b]	1.43	5
40	49.76	4.05	5
200	181.35	16.14	8

[a] Different concentrations of cetiedil were added to drug-free plasma, and samples were then analyzed by the procedure described in the text. [b] Using 4 mL of blank plasma.

were no interfering peaks at the retention times for cetiedil or papaverine. The retention times for cetiedil and papaverine were 1.7 and 3.3 min, respectively. There was a linear relationship between the ratios of the peak height of cetiedil to the peak height of papaverine and the corresponding concentrations of cetiedil. The resulting general equation for the standard curve as described above ($y = 0.119x - 0.0259$) was linear ($r = 0.984$; $n = 37$) over the concentration range of 5–80 ng/mL, where y was the peak height ratio, and x was cetiedil concentration.

Precision—The precision of the method was determined by adding different concentrations of cetiedil and analyzing samples of each concentration by the described procedure (Table I). The average coefficient of variation over the concentration range of 5–200 ng/mL was 11%.

Reproducibility—To determine the day-to-day reproducibility, five different cetiedil concentrations were added to drug-free plasma, and the samples were analyzed over a period of 3 months (Table II). The average day-to-day coefficient of variation over the concentration range of 5–80 ng/mL was 16.3%. These results also indicate that cetiedil in plasma samples was stable for at least 3 months when kept frozen.

Recovery—2-Propanol solutions of cetiedil citrate were prepared so that injection of 1 μL would give a peak representing complete recovery of cetiedil from extracted plasma samples. The ratio of cetiedil peak height from the extracted samples to the standard solutions gave an average cetiedil recovery of 67.5 ± 15.5% over a concentration range of 10–80 ng/mL. Papaverine recovery was determined similarly (57.4 ± 5.2%).

Sensitivity—At an added cetiedil concentration of 0.5 ng/mL, the cetiedil peak was not routinely detected under optimal conditions (chromatograph attenuation, 2; injection volume, 2.0 μL). At 1 ng/mL, cetiedil peaks were detectable; however, the determined value was 2.56 ± 0.09 ng/mL ($n = 5$). This unacceptably large value may reflect nonlinearity of the standard curve at <5 ng/mL. When 2.0 mL of plasma was used, 5.0 ng/mL (average *CV*, 12.9%; Table I) was the sensitivity limit. From the general standard curve equation ($y = 0.0119x - 0.0259$), the theoretical sensitivity limit of the procedure would be 2.18 ng/mL. This large value may indicate that the plasma background was producing a significant amount of signal. Alternatively, the tailing of the solvent peak under maximal detection conditions may contribute to the large amount of background signal.

Plasma Level Studies—In Fig. 2 is shown the decline of unchanged cetiedil in human plasma after a 30-min intravenous infusion at a dose of 0.15 mg/kg in three subjects. The disposition of cetiedil is described by a two-compartment model (10).

DISCUSSION

The described procedure is sensitive and reproducible over a 5–80 nanogram per milliliter range. Detector response was linear over a wide concentration range. When kept in the dark at −15°C, the samples remained stable for at least 3 months without any added preservative. Standard solutions were kept in the dark at room temperature and remained stable for at least 2 weeks. All glassware were silanized to minimize drug losses.

In summary, this report, along with many other recent studies, illustrates the utility of the nitrogen-phosphorus detector in measuring drug levels over a 5–80 nanogram per milliliter range. Although combined GC-MS may provide greater sensitivity and require less time for sample analysis, such instrumentation is not universally available. Application of the nitrogen-sensitive detection technique to measurement of the candidate antisickling agent cetiedil has provided preliminary information regarding its plasma levels in humans.

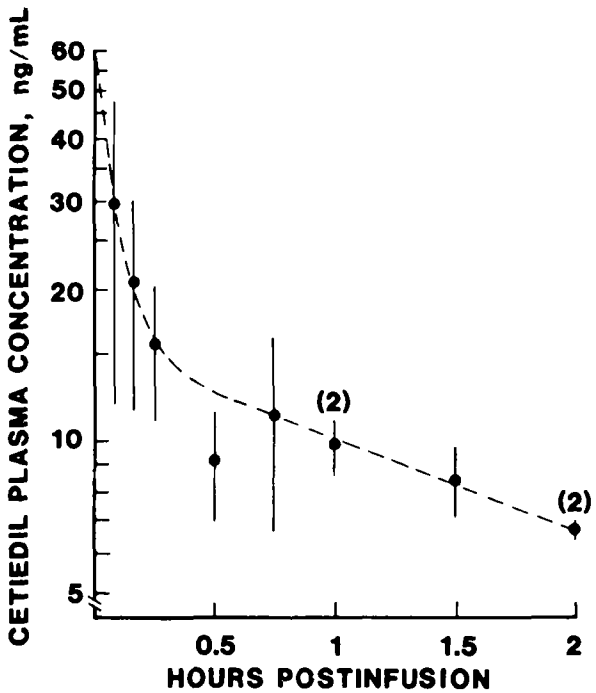

Figure 2—*Plasma level decline of unchanged cetiedil after an intravenous infusion of 0.15 mg/kg;* n = *3 unless otherwise indicated by numbers in parentheses.*

Table II—Reproducibility of Cetiedil Determination over Time [a]

Amount of Cetiedil Added, ng/mL	Concentration of Cetiedil Found, ng/mL						
	1 d	3 d	5 d	7 d	30 d	90 d	Mean ± *SD*[b]
5	7.1	5.7	5.4	5.4	5.6	5.2	5.64 ± 0.82
10	12.2	11.2	6.0	9.2	11.2	8.6	9.75 ± 2.25
20	22.3	20.6	18.4	28.4	24.8	22.8	22.86 ± 3.46
40	49.2	42.3	36.1	46.0	57.4	42.4	45.58 ± 7.26
80	96.6	84.9	80.7	111.4	100.0	84.1	92.93 ± 11.82

[a] Different concentrations of cetiedil were added to drug-free plasma and kept frozen in aliquots. Each aliquot was thawed on the day of analysis. [b] Reproducibility at 10 months could be demonstrated only at cetiedil concentrations of 5 ($n = 4$), 20 ($n = 3$), and 40 ($n = 3$) ng/mL; the respective determined mean ± *SD* values were 4.05 ± 0.46, 19.74 ± 2.15, and 32.76 ± 6.25 ng/mL. Determined values for 10 and 80 ng/mL were 71–75% of the theoretical added values.

Radiopaque Liposomes: Effect of Formulation Conditions on Encapsulation Efficiency

S. BENITA *[x], P. A. POLY [‡], F. PUISIEUX [‡], and J. DELATTRE [§]

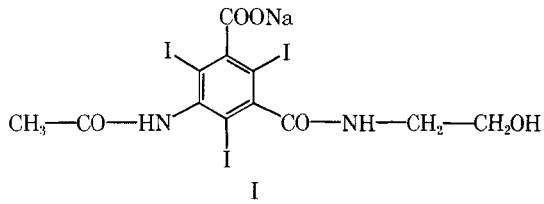
Received May 27, 1983, from the **Pharmacy Department, School of Pharmacy, Hebrew University of Jerusalem, Jerusalem 91120, Israel,* [‡]*Laboratoire de Pharmacie Galenique, Faculte de Pharmacie de Paris-Sud, 92290 Chatenay-Malabry, France,* and [§]*Laboratoire de Biochimie, Faculte de Pharmacie, 63100 Clermont Ferrant, France.* Accepted for publication, September 14, 1983.

Abstract □ Liposomes containing sodium ioxitalamate were prepared by sonication. Suitable amounts of purified soybean phosphatidylcholine and cholesterol were used at various molar ratios. Stearylamine or dicetylphosphate were added to this lipid composition when charged liposomes were required. After sonication and removal of unencapsulated solute, this manufacturing process yielded small multilamellar vesicles as confirmed by electron microscopy. These liposomes did not exhibit a narrow range of size distribution; the mean particle size varied from 135 to 145 nm. With respect to the efficiency of encapsulation, two parameters were distinguishable: the volume of encapsulated aqueous space per unit of lipid weight and the percentage of the contrast agent added that became encapsulated in the liposomes. Investigation of the preparative parameters revealed that increased molar ratios of cholesterol yielded higher aqueous volume and iodine contents in the liposomes, which were attributed to a reduction of the liposome permeability to the contrast agent. However, the inclusion of cholesterol into the bilayer liposomal membrane was limited, probably by solubility restrictions. Negatively and positively charged liposomes had higher rates of encapsulation than did neutral liposomes. This result was expected since efficient encapsulation of polar compounds requires formation of large aqueous spaces within the vesicles per mole of lipids. Increase of the lipid fractions at a constant ratio of phosphatidylcholine–cholesterol, with all the other factors kept constant, reduced the aqueous volume entrapped per millimole of lipid and, consequently, the iodine content in the liposomes. However, an increase in the initial sodium ioxitalamate concentration diminished the aqueous volume entrapped in the liposomes but increased the iodine content.

Keyphrases □ Liposomes—radiopaque, effect of formulation conditions on encapsulation efficiency □ Formulations—radiopaque liposomes, effect on encapsulation efficiency □ Encapsulation—radiopaque liposomes, effect of formulation conditions

The possibility of utilizing liposomes as vehicles for therapeutic agents had been widely considered over the last 16 years. The potential applications have been extensively reported and clearly summarized (1–3). The ultimate goal has been the targeting of drugs and other biologically active ingredients to specific cells within the body. However, this cannot be easily accomplished since it has been shown in numerous reports that intravenously injected liposomes localize predominantly in the liver, spleen, and other organs rich in cells of the reticuloendothelial system (4).

The specific hepatic uptake can be exploited to design a selective delivery system based on liposomes containing sodium ioxitalamate, which is a water-soluble iodinated contrast agent characterized by its high iodine content (57%). The radiopaque agent, sodium ioxitalamate (I), is primarily used for urography because of its pharmacokinetic properties, (5, 6); however, side



I

effects, allergic reactions, and intolerance have been reported. The preparation of liposomes containing the radiopaque agent is, therefore, also aimed at reducing or avoiding these adverse reactions since selective liver uptake enables administration of smaller amounts of radiopaque agent for a similar or even improved diagnostic result. The liposomal preparation will probably be able to produce a visible contrast enhancement of the liver, which will help improve the diagnostic accuracy of computerized tomography of this organ. Some attempts, including the preparation of brominated radiopaque liposomes (7) and the encapsulation of diatrizoic acid salts within liposomes (8), have already been performed, yielding preliminary results that are promising. However, this interesting approach is limited by the amount of contrast agent that can be entrapped in the aqueous phase of liposomes and the potential release of the opaque ingredient from the liposomes. The objective of this study, therefore, is to incorporate the contrast agent within liposomes and to investigate some of the physical and chemical factors which may control the efficiency of the encapsulation rate. The results of such an investigation offer the possibility of optimizing liposome formulation, enabling a high encapsulation rate and, consequently, an increase in the opacification of the liposomes caused by their high iodine content.

EXPERIMENTAL SECTION

Materials—Soybean phosphatidylcholine[1] was purified by the method of Singleton *et al.* (9), and the purity was ascertained by a TLC analytical method (10). Stearylamine and dicetylphosphate were obtained commercially[2]. Cholesterol[3] was purified by two recrystallizations. Sodium ioxitalamate was used as supplied[4].

Methods—*Preparation of Liposomes*—Suitable amounts of purified phosphatidylcholine and cholesterol in various molar ratios were dissolved in 20 mL of chloroform to which stearylamine or dicetylphosphate was added when charged liposomes were required. The lipid mixture was deposited as a thin film on the walls of a round-bottomed flask by rotary evaporation under reduced pressure at 30°C. Twenty-five milliliters of an aqueous solution of sodium ioxitalamate at a given concentration was poured into the flask, shaken by continuous rotation for 30 min at 30°C, and allowed to stand over a 2-h period. The liposomal dispersion obtained was then sonicated[5] for 3 min under a nitrogen atmosphere at 0°C for homogenization. Sonication promoted conversion of the large multilamellar vesicles (MLV) into smaller liposomes which were separated from the excess of free sodium ioxitalamate by gel filtration on a coarse Sephadex G-50 column. The liposomes were mainly collected from fractions three to six after the void volume was eluted; they were identified by the presence of turbidity in the different samples collected. The liposome size was then measured[6].

Drug Encapsulation Efficiency—After vesicle preparation and removal of the unencapsulated solute, the amount of encapsulated compound could be determined. With respect to the efficiency of encapsulation, two parameters can be distinguished: first, the volume of encapsulated aqueous space per millimole of lipid and, second, the percentage of the compound added which becomes encapsulated in the liposomes. The latter, when expressed in percent iodine content of the liposomes, in fact represents a measure of the probable opacification ability of the liposomal preparation. The first parameter, which is defined as the encapsulation capacity (EC), is a function of liposome size and number of lamellae per particle. EC represents the fraction of aqueous volume entrapped per millimole of lipids and is calculated by (11):

$$EC = \frac{C_e}{C_0} \cdot \frac{1}{C_l} \qquad \text{(Eq. 1)}$$

where C_0 is the initial sodium ioxitalamate concentration, C_e is the final concentration found, and C_l is the lipid concentration in the liposomes. In contrast, the molar fraction of drug entrapped per mole of lipid is calculated by the simple ratio of the molar concentration of sodium ioxitalamate to the molar concentration of lipids determined in the liposomes. Obviously, the second parameter, which is defined as the entrapment efficiency or drug content (DC), depends on EC, but in addition, it also depends on the lipid concentration in the vesicles. DC is expressed by (in percent):

$$DC = \frac{W_c}{W_c + W_l} 100 \qquad \text{(Eq. 2)}$$

where W_c is the amount of drug found in the liposomes, and W_l is the amount of lipids which form the bilayer membrane found experimentally in the liposomes. The sodium ioxitalamate amount entrapped was determined with a liquid chromatograph[7] consisting of a pump[7], an injector[7], and a UV detector[7] fixed at 254 nm. The stationary phase was C_{18}[8], and the eluant was methanol–water (70:30) containing 1% tetrabutylammonium phosphate, supplied at a flow rate of 1 mL/min. A portion of the liposomal preparation was diluted with water (1:100) before injection. The amount of contrast agent in the liposomal preparation was calculated by using a calibration curve based on standard solutions determined under identical experimental conditions. No interference of the phospholipid fragments by the HPLC method was observed. The phospholipids in the liposomal preparation were assayed by using a phospholipid B test[9] based on a colorimetric reaction (12). No disturbance of the colorimetric reaction was detected as a result of the presence of sodium ioxitalamate, proving that the concentrations of the phospholipid found were correct. For stearylamine-, dicetylphosphate-, and cholesterol-incorporated liposomes which were eluted through the gel column, the original molar ratio to lecithin on mixing was assumed to be maintained (11). All the calculations on drug encapsulation efficiency were carried out on the basis of this assumption. Each batch of liposomes was triplicated. The different values reported are the average of six experimental measurements since the property determinations of each liposome batch were duplicated.

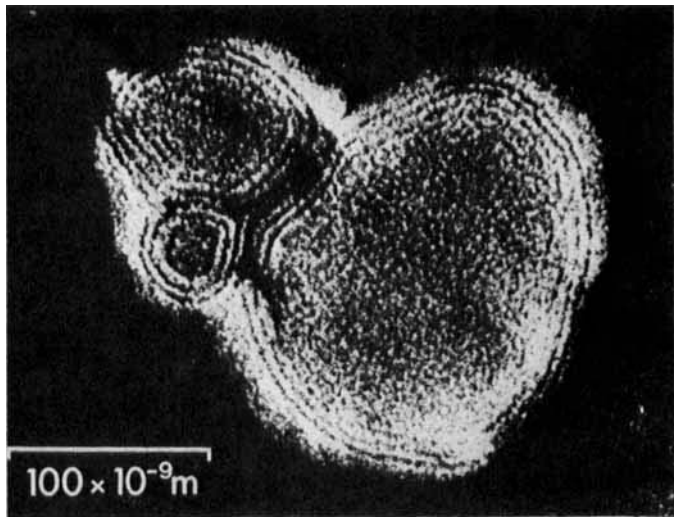

Figure 1—*Electron micrograph of multilamellar liposomes produced by the method described in the text (initial conditions: phosphatidylcholine, 500 mg; cholesterol, 70 mg in 20 mL of chloroform; 25 mL of sodium ioxitalamate aqueous solution equivalent to 100 mg of iodine/mL).*

RESULTS AND DISCUSSION

Water-soluble compounds entrapped within liposomes are found in the internal aqueous compartments of these particles (13) owing to their low affinity and solubility in the lipids which constitute the liposomal membrane. Thus, efficient encapsulation of polar compounds requires formation of large aqueous spaces within the MLV. The manufacturing process used in this study yielded, after sonication and removal of unencapsulated solute, small MLV, as confirmed by electron microscopic examinations (Fig. 1). These liposomes did not exhibit a narrow range of size distribution, and their mean particle size varied from 135 to 145 nm[6]. Polydispersity index values were obtained during routine liposome size measurements and ranged from 3 to 5, which indicated, according to the manufacturer's instructions, a distribution range, by diameter, of 2:1 in the liposome samples.

In preliminary studies, the influence of the phospholipid characteristics on liposome properties was investigated. The chemical purity of the phosphatidylcholine source, which might slightly affect the chemical composition, had little effect on solute retention or particle size of the liposomes formed. The entrapped volume of the total internal aqueous phase remained practically constant, irrespective of the phosphatidylcholine used. In spite of these results, purified soybean phosphatidylcholine, as compared with commercial soybean phosphatidylcholine, was preferred for liposomes production since fewer adverse toxic reactions would be expected after parenteral administration of such liposomes in future animal experiments.

Effect of Cholesterol Concentration—Increased initial molar ratios of cholesterol, with respect to the phosphatidylcholine concentration, yielded higher aqueous volumes and iodine contents in the liposomes (Table I). This was attributed to a reduction in the liposome permeability to the contrast agent

Table I—Influence of Initial Cholesterol Concentration on Liposome Properties [a]

Soybean Phosphatidylcholine–Cholesterol, Molar Ratio	Encapsulation Capacity, mL/mmol	Iodine Content, %[b]	Molar Fraction of Drug Entrapped/mol of Lipid, × 10^2 [c]
8:0	0.78	9.5	20.42
8:2	1.00	11.89	20.79
8:4	1.41	15.97	29.05
8:8	1.52	16.87	29.01

[a] Conditions: 500 mg of phosphatidylcholine, 4.325 g of sodium ioxitalamate, with various amounts of cholesterol. [b] Calculated according to Eq. 2 by using only the molar fraction weight of iodine contained in the sodium ioxitalamate molecule. [c] The ratio was calculated according to the experimental results by using the analytical methods described in the text.

Table II—Influence of a Positive Charge, Stearylamine, or Negative Charge, Dicetylphosphate, on the Liposome Properties[a]

Liposome Composition, Molar Ratio	Mean Particle Size, nm[b]	Encapsulation Capacity, mL/mmol	Iodine Content, %[c]	Molar Fraction of Drug Entrapped/mol of Lipid, $\times 10^2$ [d]
Soybean phosphatidylcholine-cholesterol, 8:2	140	1.00	11.89	20.79
Soybean phosphatidylcholine-cholesterol-stearylamine, 8:2:1	128	1.22	14.03	24.84
Soybean phosphatidylcholine-cholesterol-stearylamine, 8:2:2	145	1.33	15.25	29.87
Soybean phosphatidylcholine-cholesterol-dicetylphosphate, 8:2:1	138	1.19	13.87	25.29
Soybean phosphatidylcholine-cholesterol-dicetylphosphate, 8:2:2	144	1.43	16.25	27.76

[a] Conditions: 500 mg of phosphatidylcholine, 4.325 g of sodium, ioxitalamate, with various amounts of cholesterol. [b] The polydispersity index in all the measurements performed was 4. [c] Calculated according to Eq. 2 by using only the molar fraction weight of iodine contained in the sodium ioxitalamate molecule. [d] The ratio was calculated according to experimental results by using the analytical methods described in the text.

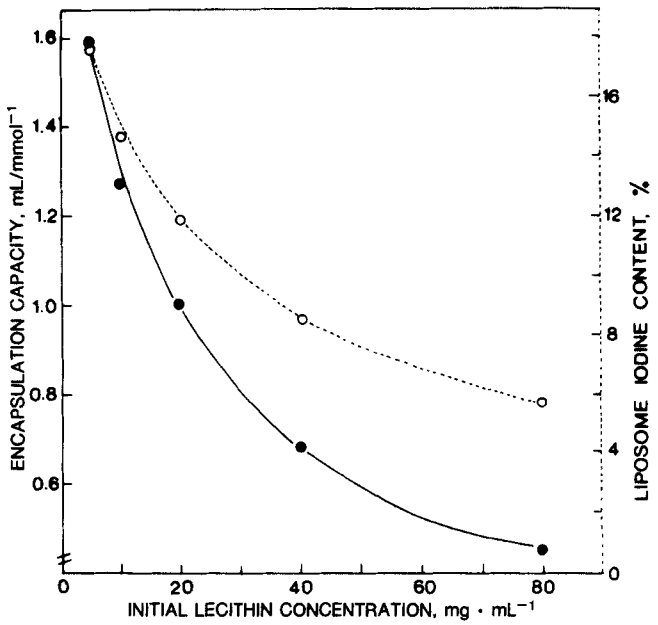

Figure 2—*Effect of initial phosphatidylcholine concentration on encapsulation capacity (●) and iodine content (○) of the liposomes prepared.*

(14). In addition to its barrier-controlling property, the incorporation of cholesterol was found to provide more physical stability against the ultrasonic vibration force as compared with that of the cholesterol-free liposomes (11). This effect might reduce precocious sodium ioxitalamate release during liposome size homogenization by sonication. However, the concentration of radiopaque agent entrapped in the liposome augmented and reached a maximum (*i.e.*, a plateau) with increasing cholesterol molar ratio (Table I). This phenomenon could be expected since the inclusion of cholesterol into the bilayer liposomal membrane is limited, probably as a result of solubility restrictions which were corroborated by the existence in the highest initial cholesterol concentration of a crystallization process, which is attributed to an excess of cholesterol after vesicle formation.

Effect of Electric Charge on the Surface of the Bilayer Membrane—Various concentrations of stearylamine (cationic substance) or dicetylphosphate (anionic substance) were included in the liposomal bilayer membranes, rendering the surface electrically charged. This resulted in a repulsion and, hence, an increase in the distance between the different bilayers, which appear to be very close to one another in neutral liposomes (Fig. 1); consequently, more hydrophilic solute can be trapped in the aqueous compartments than in neutral liposomes. Negatively and positively charged liposomes gave larger amounts of radiopaque agent and higher rates of aqueous volume encapsulation than did neutral liposomes, confirming the previous hypothesis (Table II). It should be noted that an increase in the charge membrane concentration (*i.e.*, the stearylamine or dicetylphosphate concentration) while all the other factors were kept constant enhanced the sequestration volume capacity and iodine content of the liposomes, indicating that the interlamellar spacing within the vesicles depended on the extent of bilayer ionization. No significant difference with respect to the various properties (Table II) could be detected between negatively or positively charged liposomes at an ionic compound concentration of ~10 mol%. However, a distinct increase in the encapsulation capacity was observed in negatively charged liposomes, as compared with positively charged liposomes (Table II), at an ionic compound concentration of ~20 mol%. This effect could be attributed to a minimization of the leakage during liposome production due to electrostatic repulsion between the similar negative charges of the lipid membranes and the entrapped ioxitalamate ion (15). This electrostatic repulsion reduced the diffusion of the contrast agent through the bilayer membrane. It is interesting to note that in contrast with previous reports (16), the addition of charged lipid in excess of 10 mol% of the total lipid mixture increased volume entrapment (Table II). Moreover, no marked particle size alteration (Table II) was observed among the various species of liposomes, and enlargement of the space between the lamellae did not contribute to an increase in the final liposome size.

Effect of Initial Phosphatidylcholine Concentration on Liposome Properties—It is a well-accepted fact that MLV possess a low encapsulation capacity as compared with LUV (17). The preparation method previously described yielded mainly liposomes of the MLV type, which were characterized by a large core lamella and adjacent bilayer membranes separated by small aqueous spaces. It could be considered that these resulting MLV have a similar encapsulation ability to LUV since the main part of the sequestered solution volume should be stored inside of the core space. Therefore, any variable experimental factor which could modify the physical characteristics of these MLV liposomes alters their encapsulation capacity. An increase in the phospholipid concentration at a constant ratio of cholesterol-phosphatidylcholine reduced the aqueous volume entrapped per millimole of lipid and, subsequently, the iodine content in the liposomes (Fig. 2). These results indicate that although all the other experimental factors were kept constant, larger phosphatidylcholine concentrations produced liposomes of the MLV type consisting of a larger number of lamellae per single vesicle, even if the sonication time was maintained constant during the preparation process in all the different liposome batches. It appeared that fewer liposomes were

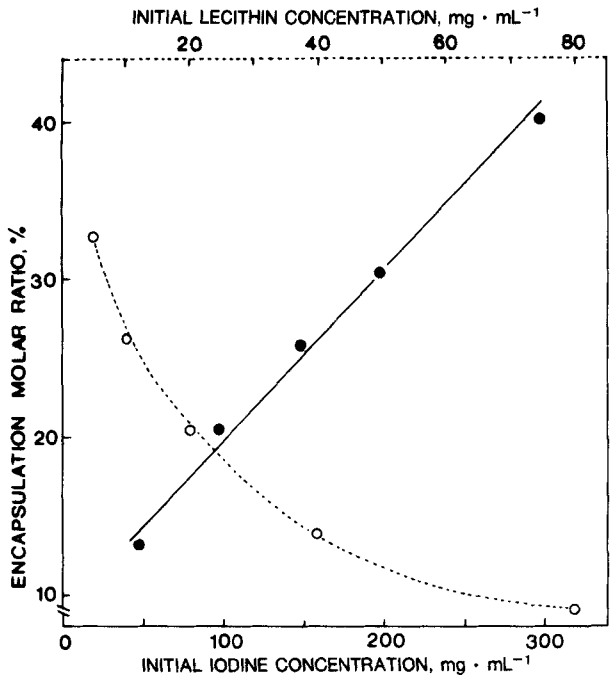

Figure 3—*Effect of initial iodine concentration (●) and initial phosphatidylcholine concentration (○) on the sodium ioxitalamate encapsulation molar ratio.*

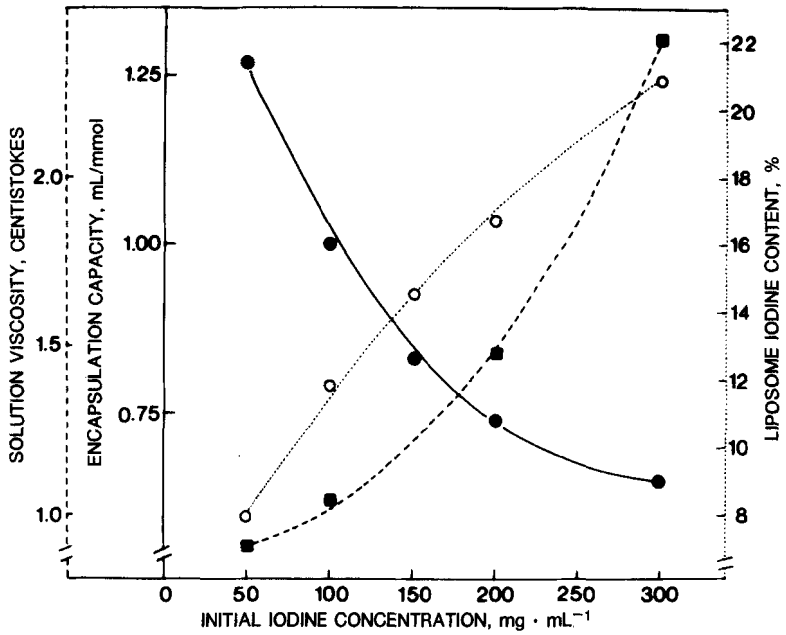

Figure 4—*Effect of initial iodine concentration on encapsulation capacity (●), iodine content of liposomes (○), and viscosity of the aqueous solution (■).*

formed in proportion to the initial amount used, but more membranes were produced per single particle by increasing the initial phosphatidylcholine concentration. Thus, the effective volume entrapped within these liposomes diminished, and since the radiopaque agent concentration remained unchanged, it resulted in a reduction in the iodine content, as seen in Fig. 2. It should be noted that an identical parallel decrease between the encapsulation volume capacity (Fig. 2) and the encapsulation molar ratio (Fig. 3) was observed. The plot obtained yielded a curved line that fell sharply at the beginning and moderately on approaching the highest phosphatidylcholine concentrations (Fig. 3), indicating probable formation of smaller interlamellar spaces within the liposomes and supporting the fact that the polar compound sodium ioxitalamate is found totally in the aqueous compartments of the MLV. No part of it was bound to the lipid membrane, as was reported for some other water-soluble drugs (13).

Effect of Initial Sodium Ioxitalamate (or Iodine Equivalent) Concentration—Dependence of the different liposome properties on the initial radiopaque agent concentration was examined. A plot of the volume encapsulation capacity against the initial iodine concentration yielded a curved line that fell almost linearly initially and curved off at the highest iodine concentration (Fig. 4). Obviously, the iodine content of these liposomes was enhanced, but the iodine encapsulation efficiency decreased with increasing initial contrast agent concentration (Fig. 4); no linear relationship was observed. Since fixed amounts of lipids were used, the decrease in EC was probably caused by other experimental factors which were affected by the initial sodium ioxitalamate concentration. Some of these factors, *e.g.*, the ionic strength or the viscosity of the dispersion medium, might alter the physical characteristics of the vesicles formed (*i.e.*, the size and the number of bilayers per particle). However, in a previous report, it has been shown that no variation in trapped volume within neutral liposomes was observed over a full range of salt concentrations corresponding to an increase in the ionic strength of the aqueous phase (15). Therefore, the explanation should be sought elsewhere. Apparently, the viscosity of the dispersion medium affected the encapsulation ability of the vesicles. Viscosity measurements of the different sodium ioxitalamate solutions were carried out with a viscometer[10] according to the British Pharmacopoeia (18). The relationship of the sodium ioxitalamate concentration effects on encapsulation capacity, iodine content, and viscosity of the aqueous phase are more clearly evident when seen graphically (Fig. 4). The encapsulation capacity function follows an inverse pattern to that of viscosity; it is clearly indicated that the sequestration ability falls off, whereas the viscosity increases drastically with increasing contrast agent concentration. It seems that the liposome entrapment process reflects fundamental changes arising from the viscosity variation of the dispersion medium. The reasons for this are not clear, but it might be due to any or all of the following factors. By raising the viscosity the shape of the vesicles formed is probably altered, thus increasing the proportion of spheroids (oblate or prolate) to spheres. If it is assumed that the surface area of these vesicles remains almost constant, then the volume of these spheroids diminishes as compared with that of the spheres. Consequently, a reduction in volume encapsulation ability should be expected, as was observed experimentally (Fig. 4). This solution is in reasonable agreement with the electron microscopic observations. Other factors which should be considered that account for an encapsulation capacity decrease are the formation of a vesicle structure that is not tightly closed at higher viscosities, enhancement of permeation (*i.e.*, loss) of the trapped ionic compound through the membrane, and a diminution in the hydration extent of the head groups which reduce the electrostatic interactions with increasing medium viscosity, leading to smaller distances between the lamellae within the liposomes. It is interesting to note that the sodium ioxitalamate encapsulation molar ratio increased linearly with the initial equivalent iodine concentration, whereas it declined nonlinearly with the initial phosphatidylcholine concentration (Fig. 3). These results indicate that the radiopaque agent incorporated within the liposomes was not influenced by the moderate lack of volume encapsulation efficiency on approaching the maximal contrast agent concentrations.

Finally, it can be concluded that any variable factor which can affect the vesicle volume encapsulation ability determines the properties of the radiopaque liposomes formed. However, by choice of suitable experimental parameters, full efficiency can be achieved without altering the fundamental characteristics of the liposomes.

Gastric and Intestinal Absorption of Captopril in Acutely and Chronically Treated Rats: Comparison with Salicylic Acid

PETER J. WORLAND ˣ, OLAF H. DRUMMER, and BEVYN JARROTT

Received December 12, 1983, from the *University of Melbourne, Department of Medicine, Clinical Pharmacology and Therapeutics Unit, Austin Hospital, Heidelberg, Victoria, 3084, Australia.* Accepted for publication April 4, 1984.

Abstract □ The gastric and intestinal absorption of captopril, an orally active angiotensin-converting enzyme inhibitor was determined using rat *in situ* gastric pouch and intestinal loop techniques and compared with the absorption of another acidic drug, salicylic acid, whose absorption has been well established from both gastric and intestinal sites. Captopril absorption was determined at two initial intraluminal concentrations in acute (untreated) rats and in rats that had been chronically treated with captopril. Salicylic acid absorption was determined at one concentration in acute rats. During the 40-min experimental period, captopril absorption at the 4.6 mM dose from the gastric pouch was 17.0 ± 1.8% and 17.9 ± 5.4% in acute and chronically treated rats, respectively, and 33.6 ± 9.2% and 23.7 ± 7.6%, respectively, from the intestinal loop. At the 11.5 mM dose the captopril absorption in 40 min was 13.7 ± 2.7% and 17.3 ± 4.2% from the gastric pouch of acutely and chronically treated rats, respectively, and 17.8 ± 4.2% and 22.9 ± 3.3%, respectively, from the intestinal loop. As similar fractions of the different administered doses were absorbed from the respective gastric and intestinal sites in both acutely and chronically treated rats, the absorption process of captopril appears to be principally by passive diffusion and unaffected by chronic administration of captopril. In comparison, salicylic acid was absorbed more rapidly and to a greater extent from both the gastric and intestinal preparations. The percent of salicylic acid absorbed into the plasma at the 11.5 mM dose was 44.8 ± 4.4% and 65.3 ± 5.3% from the gastric and intestinal preparations, respectively. It is concluded that gastric absorption of captopril does occur, but its relative importance to intestinal absorption is dependent on the transit time from the gastric to intestinal site.

Keyphrases □ Captopril—*in situ* absorption, comparison with salicylic acid, rats □ Salicylic acid—*in situ* absorption, comparison with captopril, rats

Captopril, 1-[(2*S*)-3-mercapto-2-methylpropionyl]-pyrrolidine-2-carboxylic acid is the first orally effective, antihypertensive drug in a new class of angiotensin-converting enzyme inhibitors. This drug contains a reactive thiol group postulated to be necessary for its binding to the Zn^{2+} of the angiotensin-converting enzyme (1). However, this functional group also reacts to form low molecular weight disulfide conjugates of captopril in tissues such as liver and kidney (2, 3). Captopril also forms covalent links with plasma proteins *via* disulfide linkages with thiol-containing residues (4) and this may explain the extensive tissue binding of captopril (3). Possible significant alterations in the pharmacokinetics of captopril, particularly following chronic treatment, could result from tissue uptake saturation and binding processes.

Several studies on the disposition of captopril in humans and laboratory animals (3, 5–8) have found an early appearance of captopril in the plasma following oral administration with peak drug levels usually occurring within 1 h. As captopril is a structural derivative of the amino acid proline, there exists the possibility that it could be a substrate for an amino acid transport process that rapidly transports captopril across the gut wall. Additionally, the acidic nature of the drug would, according to the pH partition hypothesis (9), allow passive absorption from the highly acidic gastric site prior to entry into the intestinal absorptive sites. Recently, a clinical study with captopril observed much higher blood levels of the drug following chronic treatment than acute captopril administration, suggesting an increase in the rate and extent of absorption and bioavailability (5). However, no studies to date have directly examined whether changes in the absorption rate occur during chronic therapy.

The definition of the sites and processes involved in the absorption of captopril into the systemic circulation has an important place in the description of the disposition of captopril. In this study, the recently described *in situ* gastric pouch and *in situ* intestinal loop preparations (10, 11) have been utilized to investigate captopril absorption at these sites using acute (untreated) rats and rats chronically treated with captopril over 40 d. These techniques offer the advantage of allowing direct determination of drug traversing the gut wall and also enable the quantitation of any metabolites that may be produced that contribute to a "first pass" effect from either the gastric or intestinal sites. For comparison, we have included in the study the acidic drug salicylic acid, which is known to be readily absorbed from both sites (12).

EXPERIMENTAL SECTION

Materials—Captopril[1], captopril disulfide dimer[1], and salicylic acid[2] were used in the experiments. For the measurement of captopril using a gas chromatographic-mass spectrometric (GC–MS) assay, 3-(3-mercapto-2-methyl-propionyl)-4-thiazolidine carboxylic acid[3] (YS-980) was used as an

internal standard (3). Other chemicals required for the GC–MS assay were obtained as described previously (3) and all other chemicals were analytical reagent grade.

***In Situ* Gut Preparations**—Male Wistar–Kyoto rats (215–300 g) that had access to food and water *ad libitum* were used for both gastric and intestinal absorption experiments. The gastric pouches were prepared as previously described (10). Briefly, following anesthetizing the animal with pentobarbital sodium (50 mg/kg ip), a jugular vein cannula was implanted for administering heparin (3000 IU/kg) and for whole blood replacement. A cannula for the collection of systemic blood samples was placed into the carotid artery. The esophagus, pylorus, pyloric blood vessels, and the branches of the gastroepiploic blood vessels were ligated. Gastric contents were removed *via* a small incision made in the rat forestomach and the pouch was rinsed clean with saline. Remaining fluid was removed with an absorbent tissue. After transposition of the stomach, and exposing the left gastric vein, a 21-gauge needle attached to a 15-cm length of polyethylene tubing (0.75-mm i.d., 1.45-mm o.d.) was inserted into the vein to allow collection of the venous blood draining the pouch. The drug was then administered *via* a syringe tied into the incision made earlier in the forestomach.

A slight modification of the method previously described by Worland and Ilett (11) was used for preparing the *in situ* intestinal loops. Slightly larger sections (length, 8–10 cm) of jejunum were selected and the same size needle (21 gauge) and cannula length (15 cm) employed for the gastric pouches were used to cannulate the vein leading away from the *in situ* loop. Blood samples were collected from the *in situ* gut preparation over 4-min intervals for a total of 40 min for all experiments.

To maintain blood flow through the *in situ* gut preparations, heparinized whole blood replacement was given *via* the jugular vein at 0.7 mL/min using a peristaltic pump[4]. The blood collected immediately prior to the experiment from donor rats was continually mixed during the replacement by a gently oscillating reservoir.

The stomach and intestine were able to adjust the pH of the administered drug in saline solutions to the physiological relevant values (~1.0 and 6.3, respectively) within a 5-min period.

Captopril was prepared at concentrations of 4.6 or 11.5 mM in normal saline (0.9% NaCl) within 2 min of being administered in a 0.5-mL volume to the isolated gut preparations. These concentrations of captopril were chosen as they approximate doses of 2 mg/kg and 5 mg/kg which are known to be pharmacologically active when given orally to rats (1). Salicylic acid was given in a 0.5-mL volume in normal saline only at a concentration of 11.5 mM.

Rat Treatment—Rats were treated with 1 mg/kg of captopril by gavage twice daily for 40 d prior to the absorption experiment; the last dose was given 14 h prior to the experiment. The male Wistar–Kyoto rats used in the study were 250–300 g at the time of the experiment.

Determination of Captopril and Salicylic Acid Levels—For the assay of free captopril using GC–MS, an aliquot of the blood sample (200 μL) was taken immediately after sample collection and added to glass extraction tubes containing 2 mg of *N*-ethylmaleimide (20 mg/mL solution in water). Internal standard (4 μg of 1-mg/mL solution in acetone) was included. The determination of total captopril (free captopril and disulfide conjugates) was obtained following reduction of disulfide bonds using the reducing agent dithiothreitol (3). Samples were also assayed for the *S*-methyl metabolite of captopril (3, 13). At the completion of the experiment, the gut tissue used for either the gastric pouch or the intestinal loop was rinsed with saline, blotted, and then finely minced in 5 volumes of phosphate buffer (0.05 M, pH 7.4). It was then homogenized with a homogenizer[5] for 45 s and an aliquot was taken to assay total captopril. Salicylic acid levels were determined from plasma collected from the *in situ* gut preparations using HPLC as described (10).

Data Analysis—The BMDP statistical software package (14) was used for the analysis of variance (ANOVA, one- and two-way). A significant difference was assumed at the $p < 0.05$ level in all statistical tests. The results are expressed as the mean ± *SEM* of four experiments.

RESULTS AND DISCUSSION

Captopril has previously been observed to be rapidly absorbed into the systemic circulation following oral administration (3, 5–8), and the gastric absorption of captopril, an acidic drug ($pK_a = 3.7$)[6] could be expected to contribute to its early appearance in systemic blood samples. In addition to passive absorption of captopril from either the gastric or intestinal regions, there is the possibility of an active absorption process in the small intestine principally intended for amino acids, but capable of transporting captopril as it is a structural derivative of the amino acid proline. The experiments reported herein have utilized *in situ* gastric pouch and intestinal loop preparations to directly determine the absorption of captopril from both the gastric and intestinal sites as represented by these *in situ* gut preparations. Although these preparations can only approximate the real situation, as the animal is anesthetized and the absorption site is necessarily restricted to either the stomach or a section of jejunum, they do allow a direct comparative measurement of drug absorption and drug metabolism across the gut wall from the respective regions.

Table I—Percent of Administered Captopril Dose in Effluent Venous Blood from *In Situ* Gut Preparations[a]

Initial Intraluminal Concentration, mM	Gastric Pouch		Intestinal Loop	
	Total Captopril	Disulfide Conjugates	Total Captopril	Disulfide Conjugates
4.6				
Acute	17.0 ± 1.8	5.4 ± 2.7	33.6 ± 9.2	3.1 ± 1.8
Chronic	17.9 ± 5.4	1.7 ± 1.4	23.7 ± 7.6	0.4 ± 0.2
11.5				
Acute	13.7 ± 2.7	1.5 ± 1.0	17.8 ± 4.2	1.9 ± 1.4
Chronic	17.3 ± 4.2	6.7 ± 4.9	22.9 ± 3.3	1.1 ± 1.0

[a] Taken over 40 min. Results presented as mean percent ± *SEM* ($n = 4$).

The percentages of captopril doses absorbed into the blood draining the *in situ* gut preparations are shown in Table I. No significant differences between the acutely and chronically treated rats were observed in either the gastric or intestinal preparations at either initial intraluminal concentrations of 4.6 or 11.5 mM. Also, the extent of disulfide conjugates appearing as metabolites from the gastric or intestinal sites at either initial concentration of captopril were not different. Captopril (detection limit, 1 ng) was not detected in systemic blood samples obtained at the completion of the experiment (40 min) indicating that the collected blood from the *in situ* gut preparation contained only absorbed drug and its metabolite produced during the absorption from the tissue or within the blood draining the tissue. A similar percentage of administered dose, to either the gastric or the intestinal preparation, was absorbed at the two concentrations; this suggests that the predominant absorption mechanism is a passive process at these doses. The significant absorption from the gastric preparation suggests that gastric absorption contributes to the early appearance of captopril in the plasma observed after oral administration of the drug (3, 5–8).

The extent of disulfide formation was small and variable. Earlier work on the biotransformation of captopril in blood by Wong *et al.* (15) has shown that, following the addition of captopril to whole rat blood and immediately attempting to stabilize the free drug with *N*-ethylmaleimide, ~17% of added captopril was covalently bound to whole blood components. Similar results were obtained by Park *et al.* (4). In our experiments the sample collection period from the gastric pouch and intestinal loop was 4 min and it would seem plausible that the extent of disulfide formation observed has occurred entirely

Results are mean ± SEM (n = 4); error bars are not shown if less than symbol size.*

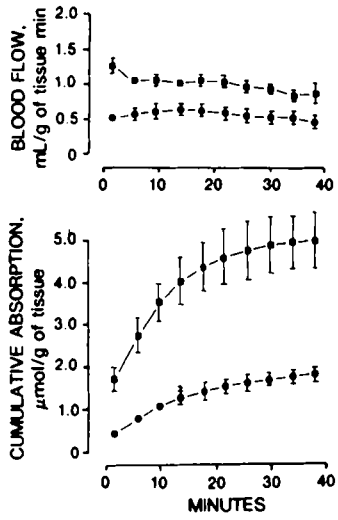

Figure 3—*Blood flow from the* in situ *gastric (●) and intestinal (■) preparations and the cumulative absorption of salicylic acid at 11.5 mM initial intraluminal concentration into the plasma. Results are mean ± SEM (n = 4); error bars are not shown if less than symbol size.*

within the blood and not the gut wall. The *S*-methyl metabolite of captopril was not detected in the blood draining from either the gastric or intestinal preparation. This metabolite has been detected in human and animal studies following oral administration of captopril (3, 13, 16), but does not appear to be produced from either the gastric or intestinal site during the absorption process.

Blood flow through the intestinal tissue has been demonstrated to be an important factor in the absorption of drugs (17-20) particularly when movement of the drug across lipoidal barriers is not the rate-limiting step. In order to eliminate possible changes in the absorption rate that may have resulted from variable blood flow, replacement blood was delivered at a constant rate throughout the experiment. The blood flow rates from the gastric pouch and intestinal loop preparations that had been given captopril are shown in the upper panels of Figs. 1 and 2. The blood flow rates did not vary significantly during the experiments and were not affected by either the dose of captopril or the chronic treatment with captopril. On the standardized basis of blood flow per gram of wet weight tissue, the blood flow from intestinal loops was two- to threefold greater than that of the gastric pouches. The weights of the intestinal segments used for the captopril (and salicylic acid) experiments were not significantly different between groups (overall mean weight, 0.74 g). Similarly, the weights of the gastric pouches (overall mean weight 1.59 g for the captopril and salicylic acid experiments) were not significantly different between groups as tested by an ANOVA (one-way).

The lower panels of Figs. 1 and 2 show the cumulative absorption of captopril during the experiments using the acutely and chronically treated rats at the two doses. The graphs are plotted on a standardized basis of per unit wet tissue weight to show differences in the capacity for absorption between the gastric and intestinal tissue. On this standardized basis, the intestinal tissue absorbed a significantly greater amount of captopril than the gastric tissue (ANOVA, two-way, $p < 0.001$) and the magnitude of the difference in the amount of captopril absorbed was similar to the difference observed in blood flow from the two sites. The back extrapolation of the terminal phase of the intestinal absorption plots from the acutely treated rats suggests a lag phase for absorption in the early period of the experiment. This phase was not as prominent in the corresponding gastric absorption and intestinal absorption plots obtained from the chronically treated rats.

Table II—Gut Tissue Concentrations of Total Captopril [a]

Initial Intraluminal Concentration, mM	Gastric Pouch	Intestinal Loop
4.6		
Acute	381.3 ± 78.0 (24.5%)[b]	1515.6 ± 199.6 (49.3%)
Chronic	278.5 ± 46.8 (23.3%)	1390.0 ± 278.6 (42.7%)
11.5		
Acute	389.2 ± 78.0 (10.9%)	1192.8 ± 238.4 (15.0%)
Chronic	597.0 ± 194.5 (16.7%)	1374.6 ± 382.4 (17.2%)

[a] In nmol/g of tissue wet weight, determined at the completion of the absorption experiments. Results presented as mean ± *SEM* ($n = 4$). [b] Values in parentheses represent the amount in the tissue as a percentage of the dose administered.

Gut tissue concentrations of total captopril were determined at the completion of the experiment. The total captopril concentrations in the gut walls from either the gastric or the intestinal tissue were not different after different doses. This suggests a saturation of tissue uptake of captopril and is perhaps more clearly shown as a percentage of administered dose. At the higher administered dose a lower percentage of the dose is found within the gut wall (Table II).

The results of this study demonstrate that in rats the rate of captopril absorption from both the gastric and intestinal sites is unchanged after chronic captopril treatment, supporting a previous report that indicated pretreatment of mice for a minimum of 14 d did not affect the extent of absorption or bioavailability of captopril as assessed by urinary excretion (21). However, these rodent studies do not conform with a report of captopril kinetics in hypertensive patients (5) in which greater plasma levels of the drug were achieved after chronic usage, suggesting a possible increase in the bioavailability of captopril.

As captopril is an acidic drug, it was of interest to compare the absorption characteristics as determined by these *in situ* gut preparations with salicylic acid, a drug whose absorption has been well studied (12, 17). The cumulative absorption of salicylic acid on the standardized basis of unit weight from the gastric and intestinal *in situ* preparations is shown in the lower panel of Fig. 3 with the respective blood flows shown in the upper panel. Significant, but small differences in blood flow were found by an ANOVA (two-way) when comparing blood flow from the intestinal loop after receiving either captopril at the two doses (acutely and chronically treated rats) or salicylic acid at the 11.5-mM dose. This was also true for blood flow from the gastric pouch. Blood flow through the intestine was less following salicylic acid administration relative to captopril ($p < 0.001$) but greater from the gastric pouch after salicylic acid than captopril ($p < 0.0001$). During the 40-min experimental period, 44.7 ± 4.4% and 65.3 ± 5.0% of the salicylic acid added to the lumen was absorbed into the plasma draining through the *in situ* stomach and intestinal preparations, respectively. The majority of this was absorbed in the first 12 min of the experiment and a lag phase for salicylic acid absorption was not evident from the absorption profiles with the collection times shown in Fig. 3. The salicylic acid absorption profiles differ markedly from those observed with captopril. This difference resulted from a greater absorption rate for salicylic acid from the gastric and intestinal loop. Twelve minutes after administration of salicylic acid ~25 and ~46% of the administered dose to the gastric and intestinal sites, respectively, had been absorbed into the plasma. In comparison, captopril absorption was only 3.3 and 2.3% of the same molar dose from the *in situ* gastric and intestinal loop preparations in 12 min. Thus for salicylic acid, the large changes in the amounts and the concentration within the gut lumen would result in a decrease in the driving force for absorption across the gut wall. For captopril, although the absorption process at the doses given suggests passive absorption, the absorption rate was not observed to decrease during the experiment. This can be expected as the intraluminal captopril concentrations would not be altering as rapidly nor to the same extent as salicylic acid within the time of the experiment.

In summary, our results have shown that the gastric absorption of captopril would contribute to the early appearance of captopril in the blood, but the intestine has a greater capacity than the stomach for the absorption of captopril and the relative magnitude of captopril absorption from the gastric site will depend on the transit rate through the stomach. Furthermore, it has been shown that chronic treatment of captopril in the rat does not increase the rate of captopril absorption from either the stomach or intestine. In comparison to salicylic acid, captopril is not as rapidly absorbed from either the stomach or intestine.

Pharmacokinetics of Probucol in Male Rats

JOEL F. HEEG ˣ, MICHAEL F. HISER, DARLENE K. SATONIN, and JAMES Q. ROSE

Received July 15, 1983, from the *Department of Pharmacokinetics and Drug Metabolism*, and the *Department of Bioanalytical Chemistry, Merrell Dow Research Institute-Indianapolis Center, Indianapolis, IN 46268-0470.* Accepted for publication April 5, 1984.

Abstract □ The bioavailability and pharmacokinetic behavior of 10 mg/kg of [^{14}C]probucol in an oil-water emulsion was determined after oral and intravenous administration to rats. The bioavailability of the oral formulation was ~6%. For the first 12-h interval after the intravenous bolus, plasma probucol concentrations increased after an initial decrease. This effect may be attributed to the formulation or precipitation of the drug in the vasculature. The terminal plasma half-life was 6 d. By 7 d, 45 and 4.65% of the labeled intravenous bolus was excreted in the feces and in the urine, respectively. Although most of the labeled dose was excreted in the bile, any enterohepatic recirculation that did occur did not contribute to the atypical plasma concentration *versus* time profile. The tissue distribution of the label and elimination rates in the bile differed between the two routes of administration. Either the total body burden, precipitation of the drug, or the emulsion vehicle may be responsible for the nonlinear distribution and clearance of the intravenous dose.

Keyphrases □ Bioavailability—oil-in-water emulsion, tissue distribution, probucol, biliary elimination, rats □ Probucol—bioavailability, oil-in-water emulsion, tissue distribution, biliary elimination

Probucol (I)[1], 4,4′-[(1-methylethylidene)bis(thio)]-bis[2,6-bis(1,1-dimethylethyl)]phenol, is an orally effective hypocholesterolemic drug. Its efficacy has been demonstrated in mice, rats, monkeys, and humans (1), and its chemical structure is unlike that of other hypocholesterolemic agents. There are no published pharmacokinetic studies of probucol in rats to characterize the dose-response of the drug (2) and only recently have aspects of the pharmacokinetic behavior of probucol in humans been presented (3).

The present pharmacokinetic studies were conducted in rats. Long-term toxicity and efficacy studies have been conducted in rats and other rodent and nonrodent species, and the identity of pharmacokinetic parameters that might assist interpretation of the outcome of the dose-response studies was sought.

EXPERIMENTAL SECTION

Probucol Formulations—[Ring(U)-^{14}C]probucol[2] with a specific activity of 7.58 or 34.1 μCi/mg was used for distribution and excretion studies. The compound is labeled with statistical uniformity in all positions of each ring. A radiochemical purity of >98% was determined with TLC, autoradiography, and liquid scintillation counting (LSC) techniques. Two TLC systems were used: hexane–benzene (80:20) and hexane–ether (95:5) on silica gel (0.25 mm) plates[3]. Uniformly ring-labeled [^{14}C]probucol with a specific activity of 34.1 μCi/mg and a radiochemical purity of 99.5% by HPLC and LSC techniques was used for the biliary excretion studies. Labeled probucol was mixed with nonlabeled probucol which had a chemical purity of >99.5% to provide the intended regimens of oral and intravenous probucol. The specific activities of the resultant mixtures ranged from 1.57 to 8.74 μCi/mg.

Both oral and intravenous formulations of probucol were prepared as oil-

In summary, our results have shown that the gastric absorption of captopril would contribute to the early appearance of captopril in the blood, but the intestine has a greater capacity than the stomach for the absorption of captopril and the relative magnitude of captopril absorption from the gastric site will depend on the transit rate through the stomach. Furthermore, it has been shown that chronic treatment of captopril in the rat does not increase the rate of captopril absorption from either the stomach or intestine. In comparison to salicylic acid, captopril is not as rapidly absorbed from either the stomach or intestine.

I

water emulsions. Probucol was dissolved in a saturated triglyceride from coconut oil[4]. The oil-water emulsion, like the physiologically compatible hyperalimentation emulsions, was then formulated to contain 4% glucose, 1.2% vegetable lecithin, 0.3% nonionic surfactant[5], and 15% of the saturated triglyceride containing the probucol. The mixture was sonicated[6] to form the emulsion. Because of the poor aqueous solubility of probucol, coconut oil or the above emulsion was used in previous pharmacological, toxicological, and clinical studies and in the studies reported here. All dose solutions were stored under nitrogen gas to prevent autoxidation.

Animal Maintenance and Posology—Adult male Sprague–Dawley rats were individually housed in modified, Roth-type glass metabolism chambers[7] for the separate collection of urine, feces, and expired air, or were housed in stainless-steel cages prior to sacrifice. Room air was drawn through the chambers (500–600 mL/min) and then scrubbed with a solution of ethanolamine–2-methoxyethanol (3:7) to trap any $^{14}CO_2$ as the carbamate. The rooms were temperature- and humidity-controlled and operated on a 12-h light/dark cycle. Water was provided *ad libitum* and food was withheld from the animals 4 h prior to and 4 h after dosage.

Two groups of four male rats were given a single 10-mg/kg dose of [^{14}C]probucol as an emulsion to determine the tissue distribution and the rates and routes of excretion. One group was given ~1.4 mL of the emulsion orally through stainless-steel feeding needles. The other group of rats was given ~0.3 mL iv of the emulsion over a 30-s period. The intravenous emulsion was injected into a jugular vein cannula implanted 48 h earlier. After the dose was injected, the cannula was flushed with 0.2 mL of saline.

The plasma distribution and clearance of 10 mg/kg of probucol or [^{14}C]-probucol was determined in two groups of male Sprague–Dawley rats. One group of 102 rats was given a 10-mg/kg iv dose of an 8.33-mg/mL emulsion (0.12 mL/100 g body weight) by way of a jugular cannula and a second group of 75 rats was given a single oral dose of a 1.67-mg/mL emulsion (0.6 mL/100 g body weight).

Biliary excretion studies were conducted with 11 adult male Sprague–Dawley rats. A cannula of polyethylene tubing[8] was inserted into the common bile duct, anterior to the pancreatic junction, passed subcutaneously, and exteriorized dorsally. Bile was allowed to flow continuously over a 3-d recovery period. On the second day after surgery, a jugular vein cannula was placed in six of the animals. On the third day a 10-mg/kg dose of [^{14}C]probucol emulsion was given by intravenous infusion, as described previously, to six of the rats and by oral gavage to the remaining five rats.

Sample Collection—To collect an adequate volume of blood for probucol analysis, rats were decapitated and exsanguinated at predetermined times. Following oral administration blood was collected at 0.25, 0.5, 0.75, 1, 2, 4, 6, 8, 12, 18, 24, 30, 36, 42, 48, 60, 72, 96, 120, 144, 192, 240, 288, 336, 384, 432, and 480 h postdose. Blood taken following intravenous dosing was similar except no samples were taken at 30 and 480 h and additional samples were taken at 168 h. Blood was taken from the jugular cannula or by decapitation for the biliary excretion studies. All samples were collected in heparinized containers, and the plasma fraction was stored frozen until analysis. Probucol had been shown to be stable for >16 months in frozen plasma. All analyses were completed within that time.

Urine was collected in dry ice traps, and both urine and feces were obtained every 6, 12, or 24 h and stored frozen until label analysis. The CO_2 trapping solution was changed frequently over the first 48-h test period. Tissues were harvested immediately after exsanguination and analyzed for concentrations of label activity or probucol. Bile was collected at 6-h intervals for 24 h after administration.

Sample Preparation for Probucol Analysis—*Plasma*—Plasma samples for the determination of probucol concentrations from 0.25 to 100 μg/mL were assayed by EC/GC or by HPLC and concentrations from 0.005 to 1.0 μg/mL were determined by GC/MS. All samples were fortified with aliquots of a methanolic solution containing the internal standard, 4,4′-[(1-methylbutylidene)bis(thio)]bis[2,6-bis(1,1-dimethylethyl)phenol], and the plasma protein was precipitated with methanol–acetone (3:2, v/v). After centrifugation, the liquid phase was extracted with hexane. Hexane extracts destined for HPLC were evaporated with nitrogen gas and reconstituted in methanol.

The hexane extracts destined for GC/MS were evaporated to dryness under nitrogen, reconstituted with benzene, and passed through a silica column[9]. The benzene eluant containing the probucol was evaporated to dryness under nitrogen, and the sample was reconstituted in methanol. Standard curves were prepared for all plasma samples by fortifying blank plasma with appropriate amounts of methanolic solutions of probucol prior to the above extraction schemes.

Tissue Samples—Tissues were homogenized[10] in ethanol–acetone (3:2, v/v) and diluted to 10 mL with ethanol–acetone. A 1-mL aliquot was transferred to a screw-cap test tube, and the internal standard was added along with 1 mL of hexane and 0.5 mL of water. After mixing and centrifugation, the hexane layer was evaporated to dryness with a nitrogen gas stream and the residue was reconstituted in methanol. Standard curves were prepared for tissue samples as described for plasma samples.

Instrumentation—*Electron-Capture Gas Chromatography*—The hexane extract of plasma destined for EC/GC[11] was injected directly onto a coiled glass GC column[12]. Operating conditions were as follows: carrier gas, 5% methane in argon; flow rate, 40 mL/min; injection port, 300°C; detector, 300°C; column, 270°C.

Gas Chromatography/Mass Spectrometry—The methanol extract of plasma destined for GC/MS[13] was injected onto a glass GC column[14]. Helium carrier gas at a flow rate of 20 mL/min was used. Temperatures were set as follows: injection port, 250°C; column, 280°C. The mass spectrometer was operated in the electron-impact mode. The fragment ions at *m/z* 278 (probucol) and *m/z* 306 (internal standard) were recorded by selective-ion monitoring.

Liquid Chromatography—A modular liquid chromatographic system was used in the analysis of probucol in plasma or tissue. The methanolic extracts were injected onto a reverse-phase column[15]. The HPLC system consisted of an autosampler[16], a high-pressure pump[17], and a fixed-wavelength UV (254 nm) detector[18]. The mobile phase consisted of acetonitrile, hexane, and 0.1 M ammonium acetate (900:35:65). The flow rate was 0.9 mL/min.

Analytical Recovery and Precision—The EC/GC procedure had a relative recovery of 98.4% and a relative precision at the 95% confidence level (C.L.) of 14.1%. The relative recovery of the HPLC assay was 97.2% and the relative precision was 9.6% (95% C.L.). For the lower concentrations of probucol determined by GC/MS, the relative recovery was 105.5% with a relative precision of 24% at the 95% C.L.

Sample Preparation for Radioactivity Analysis—The label activity in most of the samples was determined by direct LSC techniques. Plasma samples were prepared by the addition of 0.03–1.0 g of plasma to 0–1 mL of water; urine samples and cage washings were prepared by the addition of 0.5 mL of sample to 1 mL of water; and bile was prepared by the addition of 50 mg of bile to 1 mL of water. Ten milliliters of scintillation reagent[19,20] was then added to each sample. Exhaled $^{14}CO_2$ was trapped as the carbamate. Five milliliters of the trapping solution was then combined with 5 mL of a scintillation cocktail consisting of 120 mL of scintillation reagent[21], 220 mL of 2-methoxyethanol, and 660 mL of toluene.

Tissues were frozen in liquid nitrogen and pulverized by an electromagnetic, cryogenic impact grinding apparatus[22] (4). Samples (30–100 mg) of the pulverized tissues were added in triplicate to LSC vials containing 12 mL of scintillation fluid. A fine suspension was formed by the addition of 3 mL of water and shaking to form a sol–gel. The label activity in the samples was determined in the liquid scintillation counter[23]. External standardization was used to determine quench correction.

Aqueous fecal homogenates, equivalent to 150 mg of fecal solids, were oxidized by combustion[24] to CO_2 and trapped as the carbamate in 8 mL of a 30% solution of ethanolamine in 2-methoxyethanol. This solution was combined with 10 mL of the scintillation cocktail described earlier. Skin

samples (150 mg) were processed similarly without prior homogenization. The label activity from feces and skin was then counted with a liquid scintillation counter.

Pharmacokinetic Analysis—Since the choice of a definitive model was considered premature, model-independent techniques were used to describe the pharmacokinetic behavior of probucol. Over the sampling interval the area under the concentration-time curve (AUC) was determined by the trapezoidal rule (5). The first moment of the plasma concentration-time profile (AUMC) was determined similarly, after multiplying each concentration by its time (6). The AUC beyond the last plasma concentration value (AUC_t^∞) and the AUMC beyond that point ($AUMC_t^\infty$) were calculated by Eqs. 1 and 2, respectively. The terminal slope (β), the last plasma concentration (C_{pt}), and the time (t) when C_{pt} occurred were used in that calculation:

$$AUC_t^\infty = \frac{C_{pt}}{\beta} \quad \text{(Eq. 1)}$$

$$AUMC_t^\infty = \frac{C_{pt} \cdot t}{\beta} + \frac{C_{pt}}{\beta} \quad \text{(Eq. 2)}$$

The apparent oral (aCL_o) or systemic (CL_s) plasma clearance, the mean residence time of the drug in the plasma (MRT), and the apparent steady-state volume of distribution (Vd_{ss}) were calculated *via* Eqs. 3–6. After oral administration:

$$aCL_o = \frac{F \cdot \text{Dose}}{\text{AUC}} \quad \text{(Eq. 3)}$$

where F was the fraction of the dose absorbed and:

$$\text{MRT} = \frac{\text{AUMC}}{\text{AUC}} - \frac{1}{k_a}, \quad \text{(Eq. 4)}$$

where k_a was the absorption rate constant. After intravenous administration:

$$CL_s = \frac{\text{Dose}}{\text{AUC}} \quad \text{(Eq. 5)}$$

$$\text{MRT}_{iv} = \frac{\text{AUMC}}{\text{AUC}} \quad \text{(Eq. 6)}$$

The apparent steady-state volume of distribution (Vd_{ss}) was the product of CL_s and MRT_{iv}. The absorption was presumed to be a first-order rate phenomenon. An estimate of the absorption rate constant (k_a) was determined from a nonlinear least-squares parameter optimization computer program (NONLIN) (7) that assumed the plasma concentration-time profile of oral drug could be described by a first-order rate of absorption and biphasic first-order rates of elimination, such that $C_{p(oral)} = Ae^{-\alpha t} + Be^{-\beta t} + Me^{-k_a t}$. The half-life was calculated by dividing the ln 2 by the terminal slope (β).

A prediction of the mean plasma concentration at steady-state ($\overline{C}_p^{ss}$) was obtained from Eq. 7 which employs the accumulation ratio (8), MRT/τ, the dosage interval (τ), and the mean plasma concentration, $\overline{C}_p = (\text{AUC}/\text{MRT})$, after a single oral dose:

$$\overline{C}_p^{ss} = \frac{\text{MRT}}{\tau} \cdot \overline{C}_p \quad \text{(Eq. 7)}$$

RESULTS

The Pharmacokinetics of Probucol in Blood Plasma—After the 10-mg/kg intravenous dose, plasma probucol concentrations decreased over the first 20-min period and then increased fourfold such that concentrations of probucol over the next 12 h were greater than concentrations observed just after administration. In a separate group of rats the concentrations of label activity in plasma (expressed as microgram equivalents of probucol per milliliter) mimicked the decrease and subsequent increase in probucol concentrations (Fig. 1A). Peak concentrations of probucol were observed 8–12 h after the intravenous dose and a biexponential first-order rate of elimination of probucol from plasma then occurred. The half-life of the terminal elimination phase was 6.1 d, and the apparent systemic clearance of probucol was 21 mL/h/kg (Table I). Only 11–23% of the label concentration in plasma after the labeled intravenous dose was attributed to labeled metabolites of probucol.

After the 10-mg/kg oral dose of probucol, peak plasma concentrations of drug occurred within 2 h of administration (Fig. 1A). Initially, during the absorption phase, concentrations of probucol were greater than concentrations of label activity. This phenomenon was attributed to the fact that a different

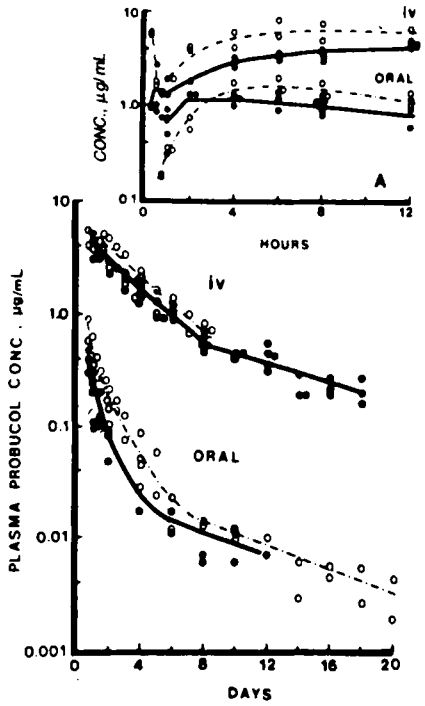

Figure 1—*Plasma concentrations of probucol (●) and [^{14}C]probucol equivalent(s) (○) after a single 10-mg/kg oil–water emulsion dose of probucol to male Sprague–Dawley rats. Inset A shows the initial 12 h of the graph in greater detail.*

group of rats was used to define the label and probucol plasma curves. The elimination of probucol from plasma consisted of two phases, and the half-life of the terminal phase was ~5.6 d. The mean residence time (MRT) of probucol was 2.36 d and the apparent oral plasma clearance was 25.0 mL/h/kg (Table I). The plasma concentration-time curve of probucol and the curve suggested by the corresponding plasma concentrations of label activity were parallel. The difference between the AUC values of the two profiles during the first 8 d indicated that 25–48% of the label activity in plasma was associated with metabolites of probucol.

Tissue Distribution—One hour after intravenous administration, 72% of the dose was found as probucol in the liver; the concentration in liver was 130–200 times the concentration in plasma (Fig. 2). After 7 d, the liver still contained more of the radioactivity (8.2%) than any other tissue studied (Table II). On day 8, 5.6% of the dose was found in the liver as unchanged drug. The half-life during the terminal phase of probucol elimination from liver was 5.5 d.

In contrast to the distribution of intravenous probucol, 7 d after the 10-mg/kg oral dose of [^{14}C]probucol, the highest concentrations of radioactivity were found in the adrenals and in brown and body fat (Table II). Concentrations in the liver after 7 d were <10% of those observed in brown fat. The largest fraction of the oral labeled dose was detected in muscle and body fat when the study was terminated (day 7). Based on reported values for body fat and muscle mass for the rat (9), these two tissues on day 7 contained 0.44 and 0.58% of the labeled dose, respectively.

Excretion—After intravenous administration, only 19% of the labeled dose was excreted in feces within the first 48 h, but after oral administration, 92% of the labeled dose was detected in feces within 48 h (Table III). By the seventh day, 94% of the labeled oral dose was recovered in the feces, in contrast to only 45% of the intravenous dose. Most of the remaining label activity from the intravenous dose was found in tissues (42.5%) (Table II). Less than 5% of the labeled intravenous dose was recovered in urine over the 7-d test period, and negligible amounts of the labeled dose were detected in CO_2.

To determine the degree to which the labeled dose was excreted in the bile, the bile duct was cannulated and animals were given [^{14}C]probucol 3 d after cannulation. After intravenous administration, 5% of the labeled dose was excreted in bile in the first 24 h, a value comparable to the 6% excreted in the feces of noncannulated rats given the intravenous dose (Table III). The rate of elimination of label in bile over the first 24-h interval after intravenous dosing appeared to be a zero-order process since ~1.3% of the labeled dose was excreted in bile during each of the 6-h collection intervals for the first 24 h (Fig. 3). Plasma drug concentrations of the bile duct-cannulated rats 12 and 24 h after intravenous dosing were comparable to the concentration of probucol in noncannulated rats (Table IV).

[a] Given a single oral or intravenous dose of 10 mg/kg of a probucol emulsion. Data expressed as mean ± *SD*. [b] Terminal slope (β) of intravenous probucol was employed to obtain these estimates.

For the first 24 h after oral administration ~0.8% of the labeled dose was recovered in the bile of bile duct-cannulated rats (Table III), and the apparent first-order label elimination half-life during the interval was ~6 h (Fig. 3). Approximately 93.6% of the labeled dose was recovered in the feces of orally dosed noncannulated rats by day 7, and 92% of the dose was fecally excreted in the first 48 h. In the 0–24-h bile collection, only 0.8% of the labeled dose was recovered. During the 24–48-h interval, bile was not collected but must have contained <0.8% recovered in the 0–24-h interval because biliary label excretion declined in a first-order fashion during the 0–24-h interval; only 0.7% of the labeled dose was excreted in the feces during the 48–72-h collection interval (Table III). Thus, the sum of the amount of labeled dose recovered in the 0–168-h urine samples (0.3%), the amount in tissues at 168 h (3.1%), the amount excreted in the 0–24-h bile (0.8%), the amount expected to be excreted in bile during the 24–48-h interval (0–0.7%), and the amount excreted in feces during the subsequent 48–168-h interval (1.5%), provided an approximation of the absorbed labeled dose (5.7–6.4%).

DISCUSSION

Probucol is highly lipophilic (10), and tablet dosage forms are made with micronized drug. Clinical pharmacokinetic studies in healthy volunteers and in hypercholesterolemic patients after single and repeated oral doses of probucol have demonstrated aspects of the steady-state distribution and clearance of probucol (3). Although extensive studies have been conducted in the rat and monkey to elucidate the pharmacodynamic features of probucol, little is known of the bioavailability and pharmacokinetic disposition of probucol and its metabolites in these test species.

In this rat study, ~6% of the administered [^{14}C]probucol was absorbed from the oil–water emulsion. As described earlier, this approximation was the sum of all the label excreted in urine (0–168 h), bile (0–24 h), the biliary excretion estimate (24–48 h), feces (48–168 h), and residual radioactivity in tissues and carcass 7 d after dosage. Another estimate of absorption (5.3%) was obtained from a comparison of the oral and intravenous AUC values, but the apparent nonlinear distribution and/or elimination of probucol over the 0–6-d interval make this estimate less reliable (Fig. 1). Comparisons of the radioactivity in the urine and in various tissues 7 d after the oral and intravenous regimens suggest that the bioavailability of this probucol formulation was poor. A recent study suggests that the drug is selectively absorbed into the lymph rather than the portal circulation and that some oleaginous vehicles enhance its absorption (11).

Although the terminal slopes of the plasma concentration–time curves after the oral and intravenous regimens were similar, a comparison of the preterminal phase of elimination after oral and intravenous administration of probucol suggests that the disposition of the intravenous probucol is nonlinear

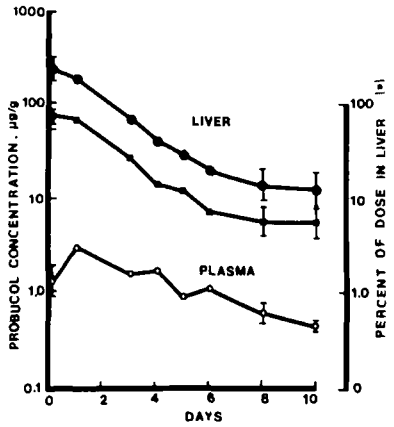

Figure 2—*Concentrations of probucol in plasma (○), liver tissue (●), or percent of dose in liver tissue (■) after a single intravenous dose of 10 mg/kg to male Sprague-Dawley rats.*

(Fig. 1). Also, the unusual decline and recurrence of probucol concentrations seen shortly after intravenous administration, but not after oral administration (Fig. 1A), suggest that the disposition of the intravenous dose may be nonlinear. Differences in the initial (0–24-h) elimination rates of radioactivity in bile and differences in the relative tissue distribution of the oral and intravenous regimens also indicate that the disposition of the intravenous [^{14}C]-probucol dose is concentration dependent.

The apparent zero-order rate of elimination of label activity in bile is seen only after intravenous administration. This may be a consequence of concentration-dependent elimination of the higher concentrations associated with the intravenous dose or the zero-order dissolution of microprecipitated drug. Since oral regimens of 100–1000 mg/kg/d in Sprague-Dawley rats did not elevate serum bilirubin (12), cholestasis is not responsible for this apparent zero-order elimination. Subsequent first-order rates of elimination of probucol and label activity from the plasma and liver tissue indicate that the zero-order rate of elimination is short-lived.

Both oral and intravenous studies indicate that an absorbed dose of probucol is excreted primarily in the feces; the elimination of label in bile duct-cannulated rats (Table III) suggests that most of the label body burden is secreted in the bile. Also, since the amount of radioactivity excreted into bile (0–24 h) is comparable to the amount of labeled dose excreted in feces after intravenous administration (0–24 h), little enterohepatic cycling may occur. The similar plasma concentrations 12 and 24 h after intravenous administration in bile duct-cannulated and noncannulated rats also indicate that enterohepatic cycling would have little effect on circulating plasma probucol concentrations.

The unusual pharmacokinetic behavior of probucol and radioactivity in plasma during the first 12 h after intravenous administration is difficult to explain (Fig. 1A). This effect (the valley in plasma concentration shortly after administration as well as concentrations of the drug from 4 to 12 h that superseded the concentration directly after injection) may be seen with drugs that undergo enterohepatic circulation; but in this study the effect may occur too fast (0–30 min) for such an explanation. Moreover, the radioactivity ex-

24	3.5 ± 0.9 (3)	3.7 ± 0.8 (4)

[a] Dose, 10 mg/kg. Expressed as mean (µg/mL) ± *SD*; numbers in parentheses indicate number of animals.

creted in bile is similar to that recovered in feces over a 24-h collection period, and plasma concentrations in bile duct-cannulated rats are comparable to those of noncannulated rats. Consequently, significant recycling is unlikely.

Alternatively, fat and fat-containing emulsions given intravenously tend to accumulate in hepatic tissue (13) and, subsequently, are cleared in a manner comparable to the clearance of chylomicrons. In the present study, the oil from the oil-water emulsion of probucol may accumulate in the hepatic tissue, create a partititoning depot in the liver (since in this study 72% of the intravenous dose was found in the liver at 1 h), and then govern the release of probucol into the systemic circulation. The unusual behavior of the plasma concentration-time curve of carbamazapine, another compound with low aqueous solubility, during intravenous infusion is similar (14). In that study, carbamazapine was solubilized in vehicles containing high concentrations of propylene glycol and given as an infusion. A precipitous fall in plasma concentrations of carbamazapine began shortly after the infusion was initiated. Although Levy *et al.* (14) conducted several experiments to characterize the effect, no definitive explanation was found. Precipitation of the drug in plasma and subsequent redissolution was proposed.

Since the mean residence time of probucol in plasma was 2.4 d after the 10-mg/kg oral dose, with a regimen of 10 mg/kg/d less than a twofold increase in the mean plasma concentration is expected before steady-state $\overline{C}_p^{ss}$ is achieved (nonlinear distribution and/or clearance is not operative in this concentration range). The pharmacokinetic behavior of larger oral doses or an increased number of doses per day, however, may become concentration dependent (indicated by the nonlinear distribution and clearance of the intravenous plasma probucol concentrations) and exhibit another steady-state profile. Dietary and/or formulation factors may also modify the bioavailability, and hence the anticipated effects, of long-term exposure to the drug.

Although the total body clearance is known, the metabolic clearance of probucol is not. Differences between the probucol concentrations and the radiolabeled microgram equivalent concentrations of probucol in plasma indicate the presence of labeled metabolites. Studies of the metabolites of probucol, however, are limited to the characterization of ^{13}C- and ^{14}C-labeled products in the liver and adipose tissue of the rhesus monkey. In both tissues most of the ^{14}C-labeled material was probucol. Six metabolites were also identified in the fat and liver of the monkey[25].

The pharmacokinetic behavior of this formulation of probucol demonstrates not only the poor availability of such a dosage form but also the nonlinear distribution that may be a consequence of the formulation and/or the dose of probucol. This study illustrates the fate of probucol in rats and the potential for accumulation associated with repeated oral regimens of probucol. The need for further investigation of oleaginous vehicles used in preclinical studies is apparent.

2-Acetylpyridine Thiosemicarbazones XI: 2-(α-Hydroxyacetyl)pyridine Thiosemicarbazones as Antimalarial and Antibacterial Agents

DANIEL L. KLAYMAN *x, AI J. LIN *, JAMES M. HOCH *, JOHN P. SCOVILL *, CHRIS LAMBROS *, and ARTHUR S. DOBEK ‡

Received December 21, 1983, from the **Division of Experimental Therapeutics, Walter Reed Army Institute of Research* and the ‡*Department of Clinical Investigation, Walter Reed Army Medical Center, Washington, DC 20307.* Accepted for publication February 24, 1984.

Abstract □ A series of 2-(α-hydroxyacetyl)pyridine thiosemicarbazones was synthesized as potential antimalarial and antibacterial agents. Their synthesis was achieved by the condensation of N^4-mono- or N^4,N^4-disubstituted thiosemicarbazides with 2-(α-hydroxyacetyl)pyridine. The latter was prepared by selective bromine oxidation of (2-pyridinyl)-1,2-ethanediol. The new compounds show potent inhibitory activity against penicillin-sensitive as well as penicillin-resistant *Neisseria gonorrhoeae* (MIC, 0.5–0.004 μg/mL), against *Neisseria meningitidis* (MIC, 0.5–0.032 μg/mL), and *Staphylococcus aureus* (MIC, 0.5–2 μg/mL). Good *in vitro* antimalarial effects against *Plasmodium falciparum* (Smith strain; ID_{50}, 6.7–38 ng/mL) were observed in most of these new agents, but only 3 of 12 compounds exhibit moderate *in vivo* activity against *Plasmodium berghei*. These new agents appear to be less toxic to the host and more water soluble than the corresponding 2-acetylpyridine thiosemicarbazones.

Keyphrases □ Thiosemicarbazone derivatives—2-(α-hydroxyacetyl)pyridine thiosemicarbazones, antimalarial and antibacterial activity □ Antimalarial agents—potential, 2-(α-hydroxyacetyl)pyridine thiosemicarbazones □ Antibacterial agents—potential, 2-(α-hydroxyacetyl)pyridine thiosemicarbazones

Members of a series of N^4-mono- and N^4,N^4-disubstituted 2-acetylpyridine thiosemicarbazones (I) have been reported by us to possess antimalarial (1, 2), antibacterial (3), and antiviral (4) properties. Based on these studies, the structure–activity relationship of this class of compounds has been defined. Thus, N^4,N^4-disubstitution of the thiosemicarbazone moiety appears to be essential for optimal activity against *Plasmodium berghei* in the mouse (2) and several bacterial genera (3). Replacement of the sulfur atom with oxygen leads to inactive compounds. Furthermore, biological activity is limited to those compounds in which the ethylidene group is attached to the 2-position, rather than the 3- or 4-position, of the pyridine ring. The effects resulting from placement of a functional group on the ethylidene function, however, have not been studied. N^4,N^4-Disubstituted 2-acetylpyridine thiosemicarbazones, in particular, exhibit potent antimalarial properties *in vitro* as well as *in vivo*. Against *P. berghei* in mice, the 4-(2-pyridinyl)piperazine and 3-azabicyclo[3.2.2]nonane analogues produced cures of all infected test animals at a dosage of 80 and 160 mg/kg, respectively (2). Although potent inhibitory activity against *Plasmodium falciparum* (Smith) *in vitro* (ID_{50} = 3.6 ng/mL) was observed, 2-acetylpyridine 4,4-dimethyl-3-thiosemicarbazone shows no significant *in vivo* activity against *P. berghei* in mice due to its high host toxicity.

As antibacterial agents, 2-acetylpyridine thiosemicarbazones show excellent activity against both penicillin-sensitive and -resistant strains of *Neisseria gonorrhoeae* with MIC (minimum inhibitory concentration) values in the range of 0.002–0.062 μg/mL. These agents were also found to inhibit the growth of *Neisseria meningitidis* as well as *Staphylococcus aureus*, with the MIC in the range of 0.016–0.062 μg/mL and 0.125–0.5 μg/mL, respectively. 2-Acetylpyridine 4,4-dimethyl-3-thiosemicarbazone [I, $R^2 = N(CH_3)_2$] is by far the most potent compound against *N. gonorrhoeae* among the analogues tested, with an MIC of 0.002–0.008 μg/mL. However, the substantial toxicity observed in mice (2) has limited its potential as a clinical agent.

In the search for agents with lower toxicity, increased water-solubility, and improved structure–activity relationship, the synthesis of a new series of 2-(α-hydroxyacetyl)pyridine thiosemicarbazones (II) was undertaken. These compounds were screened for their antimalarial properties as well as their antibacterial activity.

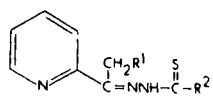
Although potent inhibitory activity against *Plasmodium falciparum* (Smith) *in vitro* (ID_{50} = 3.6 ng/mL) was observed, 2-acetylpyridine 4,4-dimethyl-3-thiosemicarbazone shows no significant *in vivo* activity against *P. berghei* in mice due to its high host toxicity.

As antibacterial agents, 2-acetylpyridine thiosemicarbazones show excellent activity against both penicillin-sensitive and -resistant strains of *Neisseria gonorrhoeae* with MIC (minimum inhibitory concentration) values in the range of 0.002–0.062 μg/mL. These agents were also found to inhibit the growth of *Neisseria meningitidis* as well as *Staphylococcus aureus*, with the MIC in the range of 0.016–0.062 μg/mL and 0.125–0.5 μg/mL, respectively. 2-Acetylpyridine 4,4-dimethyl-3-thiosemicarbazone [I, $R^2 = N(CH_3)_2$] is by far the most potent compound against *N. gonorrhoeae* among the analogues tested, with an MIC of 0.002–0.008 μg/mL. However, the substantial toxicity observed in mice (2) has limited its potential as a clinical agent.

In the search for agents with lower toxicity, increased water-solubility, and improved structure–activity relationship, the synthesis of a new series of 2-(α-hydroxyacetyl)pyridine thiosemicarbazones (II) was undertaken. These compounds were screened for their antimalarial properties as well as their antibacterial activity.



I, $R^1 = H$
II, $R^1 = OH$

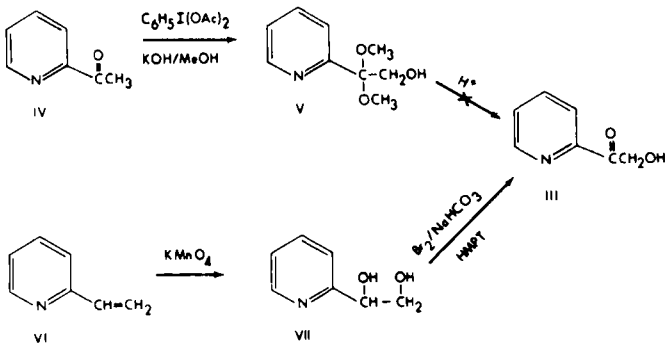
BACKGROUND

The preparation of the target compounds involved the synthesis of the unknown key intermediate, 2-(α-hydroxyacetyl)pyridine (III), followed by its condensation with an appropriately substituted thiosemicarbazide. The method used to convert 2,6-diacetylpyridine to 2,6-bis(α-hydroxyacetyl)-pyridine was applied to 2-acetylpyridine (IV) (Scheme I). In the procedure reported by Moriarty *et al.* (5), 2,6-diacetylpyridine was treated with iodosobenzene diacetate under KOH–MeOH catalysis to give a moderate yield of the corresponding dimethyl ketal. The latter was hydrolyzed to 2,6-bis(α-hydroxyacetyl)pyridine by the action of *p*-toluenesulfonic acid in acetone.



Scheme I

In our case, IV was readily converted to the corresponding ketal (V); however, the recommended technique for hydrolysis to III gave unchanged material. The use of acetic, hydrochloric, or hydriodic acids under a variety of conditions also gave either starting material or decomposition products.

An alternate avenue which was investigated involved the oxidation of 2-vinylpyridine (VI) to (2-pyridinyl)-1,2-ethanediol (VII) by potassium permanganate according to a procedure of Furuyama *et al.* (6). Further oxidation of VII to III was achieved in 35% yield using Br_2–$NaHCO_3$ with hexamethylphosphoramide serving as the coreactant. This method had been reported (7) to selectively oxidize secondary alcohols to their corresponding ketones in the presence of a primary hydroxy group. The product (III), a low-melting solid, was found to be best purified on a silica gel flash column.

Condensation of III with the appropriate thiosemicarbazides gave the desired thiosemicarbazones (IIa,d–k) in moderate yield (*cf.* Table I). Three of the thiosemicarbazides, precursors of IIe, f, and k, had not been reported previously and were prepared by a new procedure in which 4-methyl-4-phenyl-3-thiosemicarbazide [VIII (8)] is heated under reflux with a secondary amine (Scheme II). This transamination reaction gave better yields of N^4,N^4-disubstituted thiosemicarbazides (IX) than the older method involving an amine displacement reaction of methyl hydrazinecarbodithioate (9).

The hydrazone of III, *i.e.*, X, reacted with methyl and phenyl isothiocy-

XI II

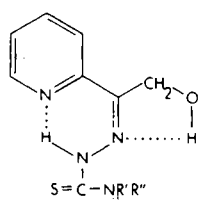
Scheme IV

anates to give the corresponding N^4-monosubstituted thiosemicarbazones (IIb,c) (Scheme III).

Another route for the preparation of II which was considered was the displacement of the $-SCH_3$ function of XI with either primary or secondary amines. Although this method (1, 2) proved to be useful for the synthesis of 2-acetylpyridine thiosemicarbazones, in the case of the α-hydroxy analogue, the reaction of carbodithioate (XI) with amines gave little or no product (Scheme IV).

A determination and comparison of the water solubility at 37°C of α-hydroxylated 2-acetylpyridine thiosemicarbazones with analogues lacking the hydroxy group revealed that appreciable hydrophilic enhancement occurred. For example, IId and f increased water solubility 1.3-fold and 7.5-fold, respectively, by having the α-hydroxy group present in the molecule.

It is of interest to note that while the N^4,N^4-disubstituted 2-acetylpyridine thiosemicarbazones exist in three tautomeric forms in $CDCl_3$, as indicated by NMR spectral data (10), only a single tautomer was observed for both N^4-mono- and N^4,N^4-disubstituted 2-(α-hydroxyacetyl)pyridine thiosemicarbazones. The C-methyl protons of 2-acetylpyridine N^4,N^4-dimethylthiosemicarbazone [I, $R^2 = N(CH_3)_2$] are seen as an unequal triplet centered at δ 2.5 ppm ($CDCl_3$) and the thiosemicarbazone NH proton appears as three peaks, *i.e.*, at δ 15, 14.5, and 8 ppm. These data suggest that the N^4, N^4-disubstituted 2-acetylpyridine thiosemicarbazones form three tautomers in $CDCl_3$. However,the N^4-monosubstituted 2-acetylpyridine thiosemicarbazones exist solely as a single *E*-isomer, with N^2 proton resonance at $\delta \sim 8$ ppm. The methylene protons of the N^4,N^4-disubstituted 2-(α-hydroxyacetyl)-pyridine thiosemicarbazones and those of the unsubstituted (IIa) and monosubstituted (IIb,c) analogues resonate as a singlet and as doublets, respectively, at $\delta \sim 4.7$ ppm. The NH proton on N^2 appears in all analogues as a singlet at $\delta \sim 15$ ppm. The NMR data suggest that the 2-(α-hydroxyacetyl)pyridine thiosemicarbazones exist primarily as the *Z*-isomer with NH forming an internal hydrogen bond with the pyridine ring nitrogen, as shown in XII. Furthermore, the lack of coupling between the methylene protons and



XII

the hydroxyl on the N^4,N^4-disubstituted thiosemicarbazones suggests that the hydroxyl function forms another internal hydrogen bond with the N^1 nitrogen atom of the thiosemicarbazone function. The fact that a coupling between methylene protons and the hydroxyl exists in IIa–c indicates that the hydroxyl function of unsubstituted and monosubstituted analogues is not involved in hydrogen bond formation as seen in the N^4,N^4-disubstituted thiosemicarbazones IId–k. A substantial downfield chemical shift of the proton on N^2 of thiosemicarbazones as a result of internal hydrogen bonding has been reported (11–13).

EXPERIMENTAL SECTION[1]

(2-Pyridinyl)-1,2-ethanediol (VII)—2-Vinylpyridine (VI, 75.6 g, 0.72 mol) was dissolved in 900 mL of acetone, and the solution was cooled in an ice bath to 0–5°C. A chilled solution of $KMnO_4$ (75.9 g, 0.48 mol) and $MgSO_4$ (28.8 g, 0.24 mol) in 1.5 L of H_2O was added slowly with agitation[2] to the 2-vinylpyridine solution at such a rate as to maintain the temperature of the mixture at ~5°C. After addition of all the $KMnO_4$ solution (1.5 h), the mixture was stirred at 5°C for 1 h and then at ambient temperature overnight.

A small amount of hydroquinone was added to the resulting thick, dark-brown slurry which was then filtered through diatomaceous earth[3]. The filtrate was concentrated to ~200 mL, and 750 mL of 95% EtOH was added. The filter cake was extracted with 500 mL of 95% EtOH, and the filtrate and extract were combined and stored overnight at 5°C. The mixture was filtered to remove K_2SO_4, and the filtrate was then concentrated under reduced pressure to a volume of 250 mL. The crude VII (37.1 g, 37% yield) was collected and recrystallized from MeOH–CH_3CN to give light-brown crystals, mp 93–96°C. Further recrystallization from EtOH–CH_3CN gave colorless crystals of (2-pyridinyl)-1,2-ethanediol, mp 94–96°C [lit. (14) mp 97°C].

2-(α-Hydroxyacetyl)pyridine (III)—(2-Pyridinyl)-1,2-ethanediol (10.8 g, 77.7 mmol) was suspended in 600 mL of CH_2Cl_2. To the suspension was added 3.8 g of hexamethylphosphoramide and 132 mL of 16% aqueous $NaHCO_3$ solution. The mixture was cooled to 0–5°C with an ice bath and to the mixture Br_2 (18 g, 112.5 mmol) in 60 mL of CH_2Cl_2 was added in a dropwise manner with vigorous stirring. The mixture was stirred at room temperature until the Br_2 was consumed (8–12 h). The organic layer was separated, and the aqueous layer was extracted twice with CH_2Cl_2. The organic layer and extracts were combined, dried over Na_2SO_4, and evaporated to dryness under reduced pressure. The oil was purified on a silica gel flash column, using CH_3CN as eluant to give 3.8 g (36% yield) of III. Recrystallization of III from benzene–cyclohexane gave colorless needles, mp 68–70°C, which gradually turned brown on standing. IR (KBr): 3280, 1710, 1585, 1438, 1222, 1005, 975, 776, and 625 cm^{-1}; ^{1}H-NMR ($CDCl_3$): δ 3.40 (br s, 1, OH), 5.09 (s, 2, CH_2), 7.45 and 8.12 (m, 3, ArH), and 8.68 ppm (d, 1, ArH).

Condensation of III with N^4,N^4-Disubstituted Thiosemicarbazides—2-(α-Hydroxyacetyl)pyridine (III) (2.2 g, 16 mmol) and 16 mmol of an N^4, N^4-disubstituted thiosemicarbazide were heated under reflux in 60 mL of MeOH, with two drops of glacial HOAc as catalyst, for 1.5 h. The solvent was evaporated to dryness under reduced pressure, and the crude product was recrystallized.

2-(α-Hydroxyacetyl)pyridine Hydrazone (X)—2-(α-Hydroxyacetyl)pyridine (2 g, 14.6 mmol) and 85% hydrazine hydrate (2 mL, 53.8 mmol) in 30 mL of MeOH were heated under reflux for 3.5 h. The solvent was evaporated to dryness under reduced pressure, and the resulting oil was extracted several times with hot C_6H_6. The C_6H_6 extracts were combined, dried over Na_2SO_4, and evaporated to a small volume. The crystals of X which formed were collected (1.2 g, 54% yield) and recrystallized from C_6H_6 to give light-straw needles, mp 113–115°C; ^{1}H-NMR ($CDCl_3$): δ 3.60 (br s, 1, OH), 4.57 (s, 2, CH_2O), 7.18–7.87 (m, 3, pyridinyl-H), 8.41 (br s, 2, NH_2), and 8.65 ppm (d, 1, pyridinyl H).

2-(α-Hydroxyacetyl)pyridine 4-Methylthiosemicarbazone (IIb)—2-(α-Hydroxyacetyl)pyridine hydrazone (X) (1.5 g, 10 mmol) and 0.75 g (10 mmol) of methyl isothiocyanate were heated in CH_3CN under reflux for 2 h. The solvent was evaporated to dryness under reduced pressure, and the residue was recrystallized. 2-(α-Hydroxyacetyl)pyridine 4-phenylthiosemicarbazone (IIc) was made in a similar manner using phenyl isothiocyanate.

3-Azabicyclo[3.2.2]nonane-3-thiocarboxylic Acid Hydrazide (IXf)—A solution of 5 g (27.6 mmol) of 4-methyl-4-phenylthiosemicarbazide (8) in 10 mL of EtOH was combined with 3.43 g (27.6 mmol) of 3-azabicyclo[3.2.2]-nonane, and the solution was heated under reflux for 5 h. The mixture was chilled; the crystals which separated were collected and recrystallized from EtOH. This afforded 3.36 g (61% yield) of colorless rods of 3-azabicyclo[3.2.2]nonane-3-thiocarboxylic acid hydrazide, mp 164–165°C dec.; IR (KBr): 3244, 2930, 2860, 1604, 1515, 1343, 1216, 1009, and 975 cm^{-1}.

1-(2-Pyridinyl)piperazine-4-thiocarboxylic acid hydrazide (IXc) was prepared by the method described above in 47% yield, mp 184–185°C (from EtOH). 1-Carbethoxypiperazine-4-thiocarboxylic acid hydrazide (IXk) was prepared by the method described above in 63% yield, mp 158–159°C (from EtOH).

Methyl 3-[1-(2-pyridinyl)-2-hydroxyethylidene]hydrazinecarbodithioate (XI)—Compound III (0.25 g, 1.8 mmol) and methyl hydrazinecarbodithioate (1) (0.23 g, 1.8 mmol) in 25 mL of MeOH containing one drop of HOAc was heated on a steam bath for 1.5 h. The solvent was evaporated under reduced pressure and the yellow solid obtained was recrystallized from C_6H_6 to give 0.36 g (85% yield) of XI as yellow needles, mp 122–124°C.

Solubility Determination—A saturated solution of the thiosemicarbazone,

[1] Melting points were taken on a Thomas-Hoover capillary melting point apparatus and are uncorrected. Microanalyses were performed by Spang Microanalytical Laboratory, Eagle Harbor, Mich. Analytical results were ±0.3% of the calculated values. IR spectra of solid samples were obtained in KBr disks on a Perkin-Elmer Model 283 spectrophotometer. ^{1}H-NMR spectra were run on a JEOL-FX90Q spectrometer using Me_4Si as an internal standard.

[2] A "Vibro-mixer" was found to be the most efficient.

[3] Celite.

prepared by suspending an excess quantity of the compound in distilled H_2O, was shaken in a constant-temperature bath at 37°C for 24 h, and then a 5-mL portion of the supernatant was lyophilized to constant weight. Solubilities were as follows: 2-acetylpyridine 4,4-dimethylthiosemicarbazone, 0.96 mg/mL; *N,N*-hexamethylene-2-[1-(2-pyridinyl)ethylidene]hydrazinecarbothioamide, 0.04 mg/mL; IId, 1.28 mg/mL; IIh, 0.30 mg/mL.

Antimalarial Studies—*In Vitro*—Antimalarial activity of the new compounds was evaluated *in vitro* against a chloroquine-resistant *P. falciparum* (Smith) by assessing the inhibition of uptake of [G-^{3}H]hypoxanthine by the parasites. A detailed procedure was given in a previous report from this laboratory (15).

In Vivo—The compounds described herein were tested[4] against a drug-sensitive strain of *P. berghei* (strain KBG 173) in mice. Five mice per dose level were infected by the intraperitoneal administration of parasitized erythrocytes. Untreated infected animals, which served as controls, died (on the average) after 6.2 d. A candidate drug was given 72 h after the mice were infected and was judged to be toxic if the infected mice died before day 6, inactive if they died between day 6 and day 12, active if the mean survival time of 6.2 d was at least doubled, and curative if the mice survived 60 d postinfection. Compounds which were active or curative at a dose of 40 mg/kg were retested at several lower dose levels, but results are not reported unless extension of mouse survival time was observed. Details of the test procedure were given in the first paper in this series and by Osdene *et al.* (16).

Antibacterial Studies—*Organisms*—Five clinical isolates of *S. aureus* were obtained from the Clinical Microbiology Laboratory, Walter Reed Army Medical Center. Five *N. meningitidis* and 25 *N. gonorrhoeae* isolates were obtained from the collections of the Department of Bacterial Diseases, Walter Reed Army Institute of Research, and the Centers for Disease Control, Atlanta, Georgia.

Testing Procedure—The standard agar plate dilution method using Mueller Hinton agar, as described by Washington and Sutter (17), was utilized to determine the MIC values of the test compounds against the *S. aureus* and *N. meningitidis* isolates tested. The *N. gonorrhoeae* isolates were similarly tested, but with GC agar plus 1% of a modified defined supplement (18). This supplement consisted of 81 mL of aqueous solution A (containing 40.5 g of dextrose and 0.002 g of cocarboxylase) which was mixed with 19 mL of aqueous solution B [83 mg of $Fe(NO_3)_3 \cdot 9H_2O$ and 1 g of L-glutamine]. It was then filter-sterilized and kept frozen until used.

The *S. aureus* inoculum was standardized after a 1–2-h incubation in Mueller Hinton broth by adjusting the turbidity to that of a 0.5 MacFarland standard (17) representing 10^7–10^8 colony-forming units (CFU)/mL, and then further diluted 20-fold in Mueller Hinton broth. The inocula of the two *Neisseria* species were standardized by suspending agar plate colonies of overnight growth in Mueller Hinton broth for *N. meningitidis* and GC broth plus 1% modified defined supplement for *N. gonorrhoeae* in order to approximate the turbidity of an overnight broth culture. The inocula were then further diluted 200-fold in the appropriate broth.

Because of the poor water solubility of the test compounds, it was necessary to dissolve them initially in dimethyl sulfoxide. The control plates also contained the highest concentration of Me_2SO present in each particular dilution series. Further dilutions were done with Mueller Hinton broth or, in the case of *N. gonorrhoeae* testing, with GC broth plus modified defined supplement (19). The concentrations of the test compounds were twofold dilutions from 32 to 0.25 μg/mL for *S. aureus* and from 1 to 0.002 μg/mL for the two *Neisseria* species.

The standardized bacterial inocula were applied to the thiosemicarbazone-containing agar plates and the controls using a Lidwell apparatus (20). Cultures were incubated under appropriate atmospheric conditions for 24 h at 37°C and read. The MIC for each compound was the lowest concentration of that compound which still inhibited all visible bacterial growth on the agar surface.

[4] Tests performed at the Dr. Leo Rane Laboratory, University of Miami, Miami, Fla.

RESULTS AND DISCUSSION

Antimalarial Activity—The *in vitro* antimalarial studies (Table II) of the 2-(α-hydroxyacetyl)pyridine thiosemicarbazones and the 2-acetylpyridine thiosemicarbazones indicated that, except for IIe, f, and j, the latter compounds had greater inhibitory properties against *P. falciparum*. The lower toxicity of the 2-(α-hydroxyacetyl)pyridine thiosemicarbazones to mice was evident in the *in vivo* antimalarial screen (Table II). Similarly, these compounds, in general, were less efficacious as antimalarials than their corresponding 2-acetylpyridine thiosemicarbazones. Compound IIj showed low levels of activity, whereas the best compound of the series was IIf, which showed two of five cures and no toxicity at a dose of 320 mg/kg. However, the corresponding compound with identical N^4,N^4-substitution showed three of five mouse cures at a dose of 40 mg/kg. It appears that α-hydroxylation

of the acetyl group had an overall negative effect on the antimalarial potency of this series of thiosemicarbazones.

Antibacterial Activity—In the assessment of the antibacterial activity of the 2-(α-hydroxyacetyl)pyridine thiosemicarbazones (Table III), the strong inhibitory effect of the 2-acetylpyridine thiosemicarbazones seen against *N. gonorrhoeae* and *N. meningitidis* (3) was also observed here. Most of the 2-(α-hydroxyacetyl)pyridine compounds had MIC values of <0.1 μg/mL against these bacterial species, and in a few instances the degree of inhibition was slightly superior to that observed with the 2-acetylpyridine thiosemicarbazones.

Against *S. aureus*, several of the 2-(α-hydroxyacetyl)pyridine thiosemicarbazones, *i.e.*, IIf, h, and j, had MIC values of 0.5–1 μg/mL. Again, there were several instances in which inhibitory activity superior to the 2-acetylpyridine thiosemicarbazones (*i.e.*, in IId, e, h, and k) was seen.

CONCLUSIONS

The biological data for the newly synthesized 2-(α-hydroxyacetyl)pyridine thiosemicarbazones indicates that N^4,N^4-disubstitution provides optimal *in vivo* and *in vitro* antimalarial and antibacterial activities. The introduction of a hydroxy function into the α-position of 2-acetylpyridine thiosemicarbazones results in compounds with increased solubility, decreased host toxicity, and in some instances, improvement of antimalarial and antibacterial activity *in vitro*. However, this is offset by the concomitant decrease in *in vivo* antimalarial effects. These results suggest that pharmacological parameters, such as tissue distribution and the rate of metabolism, play an essential role in determining the *in vivo* antimalarial activity, as well as host toxicity, of this series of compounds.

Kinetics and Mechanism of the Alkaline Hydrolysis of Maleimide

M. NIYAZ KHAN

Received August 23, 1983, from the *Department of Chemistry, Bayero University, Kano, Nigeria.* Accepted for publication March 21, 1984.

Abstract □ The kinetics of hydrolysis of maleimide was carried out within the $[OH^-]$ range of 2.46×10^{-6} to 2.0 M at 30°C. The observed pseudo-first-order rate constants, k_{obs}, follow the empirical equation: $k_{obs} = (A_1[OH^-] + A_2[OH^-]^2)/(1 + A_3[OH^-])$. Both ionized and un-ionized forms of maleimide have been suggested to be involved in hydrolysis. The nucleophilic attacks by hydroxide ion at the carbonyl carbon of both ionized and un-ionized maleimide and by water at the carbonyl carbon of ionized maleimide to form tetrahedral intermediates are considered to be the rate-determining steps. The observed results obtained at different 1,4-dioxane–water compositions have revealed an increase in k_{obs} with a decrease in 1,4-dioxane content which could be attributed to the higher polarity of the transition state compared with the reactant state.

Keyphrases □ Maleimide—kinetics, mechanism of hydrolysis □ Hydrolysis maleimide, effect of temperature

Many compounds containing an imide group act as drugs (1). *N*-Ethylmaleimide is of interest because of its rapid and Michael-type reaction with the sulfhydryl group of proteins (2, 3). Usually, the alkaline hydrolysis of amides and imides have been found to occur by a stepwise mechanism involving the tetrahedral intermediate (I) (4). Biechler and Taft (5) were the first to propose an additional oxydianionic tetrahedral intermediate (II) in the alkaline hydrolysis of trifluoroacetanilide. Later, II was found to exist in many acyl transfer reactions where the acyl substrates contained electron-withdrawing substituents and hydrolytic conditions covered a reasonable range of $[OH^-]$ (6). Recently, we have observed II in the alkaline hydrolysis of methyl-*o*-methoxybenzoate (7). In the continuation of our work on mechanistic studies on aqueous cleavage of amides (8) and imides (9) in a highly alkaline medium, we initiated this study to determine if an intermediate (II) exists and to study the nature of the rate-determining step.

of the acetyl group had an overall negative effect on the antimalarial potency of this series of thiosemicarbazones.

Antibacterial Activity—In the assessment of the antibacterial activity of the 2-(α-hydroxyacetyl)pyridine thiosemicarbazones (Table III), the strong inhibitory effect of the 2-acetylpyridine thiosemicarbazones seen against *N. gonorrhoeae* and *N. meningitidis* (3) was also observed here. Most of the 2-(α-hydroxyacetyl)pyridine compounds had MIC values of <0.1 μg/mL against these bacterial species, and in a few instances the degree of inhibition was slightly superior to that observed with the 2-acetylpyridine thiosemicarbazones.

Against *S. aureus*, several of the 2-(α-hydroxyacetyl)pyridine thiosemicarbazones, *i.e.*, IIf, h, and j, had MIC values of 0.5–1 μg/mL. Again, there were several instances in which inhibitory activity superior to the 2-acetylpyridine thiosemicarbazones (*i.e.*, in IId, e, h, and k) was seen.

CONCLUSIONS

The biological data for the newly synthesized 2-(α-hydroxyacetyl)pyridine thiosemicarbazones indicates that N^4,N^4-disubstitution provides optimal *in vivo* and *in vitro* antimalarial and antibacterial activities. The introduction of a hydroxy function into the α-position of 2-acetylpyridine thiosemicarbazones results in compounds with increased solubility, decreased host toxicity, and in some instances, improvement of antimalarial and antibacterial activity *in vitro*. However, this is offset by the concomitant decrease in *in vivo* antimalarial effects. These results suggest that pharmacological parameters, such as tissue distribution and the rate of metabolism, play an essential role in determining the *in vivo* antimalarial activity, as well as host toxicity, of this series of compounds.

EXPERIMENTAL SECTION

Materials—Reagent grade maleimide, 2-amino-2-methyl-1,3-propanediol and Tris were obtained commercially[1]. All other reagent grade chemicals were obtained commercially[2] and were used without further purification. Glass-distilled water was used throughout the studies. Buffer solutions were prepared by partial neutralization.

Kinetic Measurements—For a typical kinetic run, 47.5 mL of a mixture containing sodium hydroxide or buffer solutions of desired pH and potassium chloride to maintain the ionic strength was incubated at 30°C in a thermostatic water bath[3] for ~10–15 min. The reaction was started by adding 2.5 mL of 0.0125 M solution of maleimide prepared in 100% 1,4-dioxane. An aliquot (~2.5 mL) was withdrawn from the mixture and was quickly transferred to a 3-mL quartz cuvette kept preincubated (30°C) in the thermostatic cell holder of a spectrophotometer[4]. The temperature was maintained electronically by a temperature-control unit of the spectrophotometer[4]. The progress of the reaction was followed by monitoring the disappearance of maleimide spectrophotometrically[4] at 300 nm.

The observed pseudo-first-order rate constants, k_{obs}, were calculated from:

$$A_{obs} = E_{app}X_0 \exp(-k_{obs}t) + A_\infty \qquad \text{(Eq. 1)}$$

where X_0 is the initial concentration of substrate; A_{obs} and A_∞ are the absorbance values at any time t and $t = \infty$, respectively; and E_{app} represents the apparent molar extinction coefficient. The nonlinear least-squares technique[5] was used to calculate three unknown parameters (k_{obs}, E_{app}, and A_∞) from Eq. 1. The calculated values of A_∞ were compared with the corresponding A_{obs} obtained after ~10 half-lives of the reactions; they were almost the same. Most of the kinetic runs were carried out for more than 6 half-lives and fitting of the observed data to Eq. 1 was good for all runs. Maleamic acid and maleic acid are expected to have similar extinction coefficients at 300 nm and therefore, the hydrolysis of maleamic acid could not complicate the simple first-order kinetics. Furthermore, the bimolecular rate constant for alkaline hydrolysis was found to be 2.2×10^{-4} M^{-1} s^{-1} at 65°C (10). This indicates that the rate constant obtained at even the highest [OH^-] (2.0 M) and at 30°C, is nearly 70-fold larger than the corresponding rate constant for the hydrolysis of maleamic acid obtained at 65°C.

Because of the low aqueous solubility of maleimide, its pK_a was determined with a spectrophotometric technique (11). The value of the ionization constant, K_a, was 3.30 (±0.53) $\times 10^{-10}$ M at 30°C.

Product Characterization—A typical absorption wavelength for a cyclic imide group is 300 nm, while an amide group generally does not absorb here. Therefore a decrease in absorption peak at 300 nm should demonstrate the cleavage of the imide bond. We carried out experiments, described below, to determine the quantitative yield of the suspected product, maleamic acid.

One milliliter of 0.0125 M maleimide at 30°C was added to a mixture (total volume 19 mL) containing 0.03 M NaOH. The mixture (1 mL) was withdrawn at 25 min and was analyzed for ammonia by the nesslerizing technique (8, 12). The analysis revealed the absence of any detectable amount of ammonia formed within the 25-min period. After more than 12 half-lives of the first step of hydrolysis (25 min), 1.0 mL of 10.5 M HCl was added to the mixture. The mixture was made acidic because the acid-catalyzed hydrolysis of maleamic acid is substantially accelerated due to intramolecular carboxyl group participation (13). The recovery of ammonia was 95% at 300 min, 99% at ~21 h, and ~99% at ~41 h. Similar results were obtained for another reaction carried out at 0.2 M NaOH (other conditions similar to those described above). To substantiate the observation that no detectable ammonia formed within 25 min after the start of the reaction in basic medium, we performed a kinetic run at 30°C with a mixture containing 2.0 M NaOH and 6.25×10^{-4} M maleimide. The reaction was carried out for >72 h; the observed pseudo-first-order rate constant was 1.62 (±0.19) $\times 10^{-3}$ min^{-1} which could be compared with the literature value (25.8×10^{-3} min^{-1}) obtained at 65°C (10). To determine the rate constant for acid-catalyzed hydrolysis of the intermediate product maleamic acid, we carried out a kinetic run containing 5.952×10^{-4} M maleimide and 0.03 M NaOH at 30°C. After 24 min, 1.0 mL of 10.5 M HCl was added to the mixture. The reaction was followed for more than 10 half-lives; the observed pseudo-first-order rate constant was 5.34 (±0.04) $\times 10^{-3}$ min^{-1}. This result could be compared with the literature values 5.28×10^{-3} min^{-1} (14) and 3.16×10^{-3} min^{-1} (12).

We also carried out the hydrolysis of maleimide in the presence of 1.0 M HCl at 30°C. The observed result has shown the absence of any detectable amount of ammonia formed within 525 min after the start of the reaction and only ~14, ~37, and ~46% ammonia was recovered at 23, 73, and 97 h, respectively. This indicates that the acid-catalyzed hydrolysis of maleimide is much slower than the base-catalyzed hydrolysis.

RESULTS

The alkaline hydrolysis of maleimide was carried out within the hydroxide ion concentration range 2.460×10^{-6}–2.0 M at 30°C. The range 2.460×10^{-6}–5.382×10^{-4} M was attained by carbonate, 2-amino-2-methyl-1, 3-propanediol and Tris buffer solutions while the range of 0.002–2.0 M was maintained by sodium hydroxide solution. The ionic strength of the reaction medium was kept constant at 1.0 M in the presence of buffer components and 2.0 M in presence of sodium hydroxide. The observed pseudo-first-order rate constants at pH 8.57 and 8.08 (Table I) were obtained in the presence of 0.5 M carbonate buffer. The contribution of buffer catalysis to k_{obs} at these pH values could be assumed to be negligible compared with both OH^- and water catalyses because even within the 10.42–9.37 pH range the increase in total buffer concentration from 0.1 to 0.7 M has increased k_{obs} only by 6–18%. The observed data as summarized in Table I were found to be best fitted to the empirical:

$$k_{obs} = \frac{A_1[OH^-] + A_2[OH^-]^2}{1 + A_3[OH^-]} \qquad \text{(Eq. 2)}$$

50	2.223 ± 0.026
60	1.573 ± 0.004
70	1.199 ± 0.011

[a] Conditions: $[Maleimide]_0 = 6.25 \times 10^{-4}$ M, 30°C, μ = 0.1 M, $[NaOH]_0$ = 0.03 M. [b] Error limits are standard deviations.

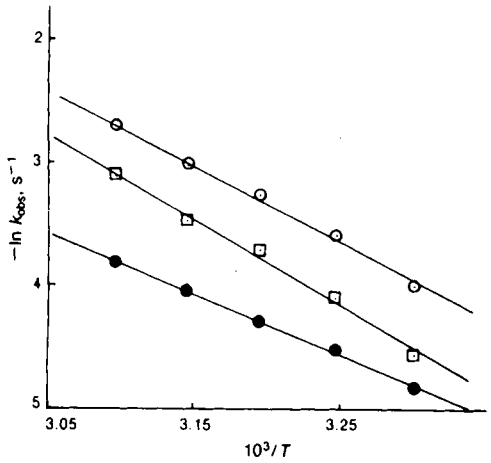

Figure 1—*Temperature dependence of* k_{obs} *for* k_1 *step* (●), ($k_1 + k_2$) *step* (⊙), *and* k_2 *step* (⊡). *The solid lines are drawn through the least-squares calculated points using the Arrhenius equation.*

where A_1, A_2, and A_3 are unknown parameters. The values of A_1, A_2, and A_3 were calculated from Eq. 2 by the use of a nonlinear least-squares technique and the respective values thus obtained were: 72.2 ± 9.1 $M^{-1} s^{-1}$, 113.0 ± 15.6 $M^{-2} s^{-1}$, and 9709.5 ± 1299.2 M^{-1}. The fitting of observed data to Eq. 2 is evident from the standard deviations of calculated unknown parameters as well as from the calculated values of rate constants (Table I).

The effect of solvent on hydrolysis was studied at 30°C with organic cosolvent prepared by mixing 1,4-dioxane and water by volume. The hydroxide ion concentration and ionic strength were kept constant at 0.03 M and 0.1 M, respectively. The observed data are summarized in Table II. The increase in k_{obs} with an increase in the dielectric constant (*i.e.*, increase of water content) of reaction medium cannot be explained by simple electrostatic theory (16) because under the experimental conditions employed, the proposed reaction mechanism involves a neutral and an anionic molecule. In the absence of any correct theoretical model which could be used to explain such rate dependence on mixed solvents and to assess, qualitatively, the effect of the solvating power of the mixed solvents on the rate of hydrolysis, we checked the fitting of the observed data with the empirical Grunwald-Winstein equation: $\log k_{obs} = \log k_0 + mY$ (18). Although the data were not in full agreement with the mY equation, the value of m was ~0.29 (determined by drawing a straight line through the observed points obtained within the mixed solvent range of 30-50%[6]).

[6] The plot of $\log k_{obs}$ *versus* Y was found to be a smooth nonlinear curve with initial and final slopes of ~0.17 and ~0.48, respectively.

Table IV—Effect of Ionic Strength on Hydrolytic Cleavage of Maleimide [a]

Ionic Strength, M	$[OH^-]$ = 0.03 M $10^3 k_{obs}$, s^{-1}	$[OH]$ = 1.0 M $10^3 k_{obs}$, s^{-1}
1.0	8.882 ± 0.064	18.73 ± 0.70
1.5	8.932 ± 0.049	20.58 ± 0.24
2.0	7.989 ± 0.030	18.32 ± 0.13
3.0	8.226 ± 0.073	21.78 ± 0.21
3.5	7.958 ± 0.077	—
4.0	—	23.35 ± 0.23

[a] Conditions: $[Maleimide]_0 = 6.25 \times 10^{-4}$ M, 30°C.

The effect of temperature on rate of hydrolysis was studied at 30–50°C, at 0.03 M, and 1.0 M hydroxide ion concentrations, keeping ionic strength constant at 2.0 M. The observed data are shown graphically in Fig. 1. The observed pseudo-first-order rate constants were found to follow Eyring and Arrhenius equations (7) and the activation parameters calculated from these equations with linear and nonlinear least-squares techniques are summarized in Table III. The activation parameters obtained at 0.03 M NaOH are attributed to only the k_1 step because the k_2 step has negligible contribution at 0.03 M NaOH. Similarly, the activation parameters obtained at 1.0 M NaOH are attributed to both k_1 and k_2 steps.

The ionic strength effect of hydrolysis was studied at two different $[OH^-]$

k'_2[g]	20.54	12.54 ± 0.73	26.1 ± 2.3	13.78 ± 0.81	18.37 ± 1.30	12.892

[a] Conditions: $[Maleimide]_0 = 6.25 \times 10^{-4}$ M, μ = 2.0 M. [b] ΔF^* was calculated from the relationship $k_{obs} = (K_B T/h) \exp(-\Delta F^*/RT)$ at 30°C. [c] $R_{ms} = [\Sigma_{i=1}(k_{obs_i} - k_{calcd_i})^2/(N-2)]^{1/2}$. [d] At 0.03 M NaOH. [e] Error limits are standard deviations. [f] At 1.0 M NaOH. [g] k'_2 (s^{-1}) was obtained from the relationship: $k'_2 = k_{obs}$ at 1.0 M NaOH $- k_{obs}$ at 0.03 M NaOH where $k'_2 = k_2[OH^-]$.

(0.03 and 1.0 M) within the ionic strength ranging from 1.0 to 4.0 M. The observed results are summarized in Table IV.

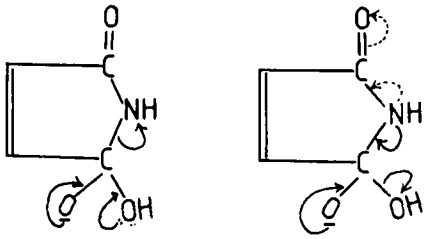
DISCUSSION

The linear variation of k_{obs} with $[OH^-]$ occurred at a pH much higher than the pK_a of maleimide. This revealed that the alkaline hydrolysis of maleimide was not a simple second-order process, but followed a complex rate law. The simplest mechanism which could explain the observed results may be shown in Scheme I. The intermediates T_1, T_2, and T_2' were considered short-lived chemical species and hence application of steady state approximation resulted in the kinetic equation:

$$k_{obs} = \frac{k_3(k_1 + k_1'K_i'[H_2O])[OH^-]}{(1 + K_i'[OH^-])(k_{-1} + k_{-1}' + k_3)} + \frac{k_4k_2KK_i'[OH^-]^2}{(1 + K_i'[OH^-])(k_{-2} + k_4K)} \quad \text{(Eq. 3)}$$

where $K_i' = K_i/[H_2O] = K_a/K_w$ with $K_a = [S^-]a_H/[SH]$.

Recently, Jencks *et al.* (19) demonstrated that in the nucleophilic substitution reactions, the rate of expulsion of the leaving group depends largely on the push provided by groups other than the leaving group attached to the same atom and the pull provided by the leaving group. Thus, in Scheme I, the



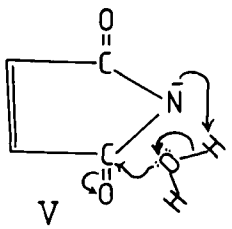
III IV

rate constant, k_3, should be considerably larger than k_{-1} and k_{-1}' because the push provided by the alcoholic oxygen atom to expel the amidic nitrogen atom would be larger than the push provided by the amidic nitrogen atom (since the nonbonded electrons on the nitrogen atom are not localized to the extent that they are localized on the alcoholic oxygen atom) to expel the alcoholic oxygen atom from T_1, as shown in III and IV. Furthermore, although the ionization constants of the conjugate acids of leaving groups involved in k_{-1}, k_{-1}', and k_3 steps are almost the same[7] (20), the high carbon basicity of oxygen compared with that of nitrogen would make k_3 larger than k_{-1} and k_{-1}'. These conclusions thus reveal that $k_3 \gg (k_{-1} + k_{-1}')$ and similarly $k_4K \gg k_{-2}$. Hence, application of these assumptions reduce Eq. 3 to:

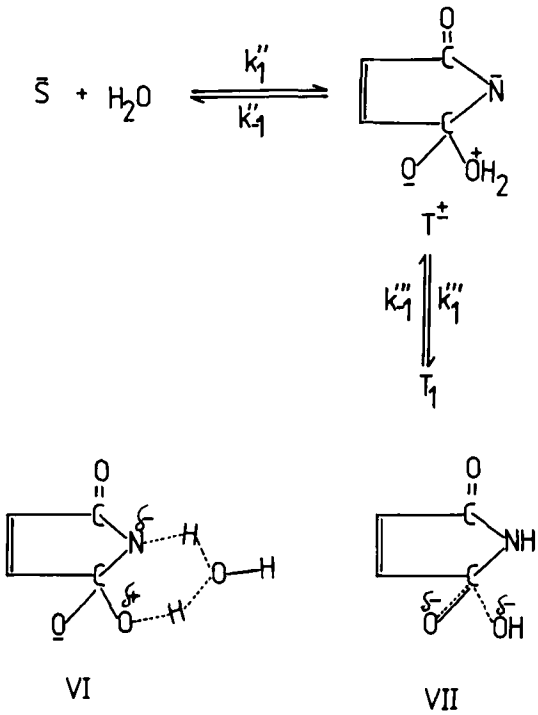
$$k_{obs} = \frac{(k_1 + k_1'K_i'[H_2O])[OH^-] + k_2K_i'[OH^-]^2}{1 + K_i'[OH^-]} \quad \text{(Eq. 4)}$$

Equation 4 is similar to Eq. 2 with $A_1 = (k_1 + k_1'K_i'[H_2O])$, $A_2 = k_2K_i'$, and $A_3 = K_i'$. The rate constant k_2 (A_2/A_3) was found to be 0.0116 M^{-1} s^{-1} and K_a was calculated from A_3 with a known value of K_w (1.449×10^{-14} M^2) (21). The value thus obtained (1.41×10^{-10} M) is comparable with the experimentally observed value of 3.3×10^{-10} M. The values of A_1/A_3 (7.44×10^{-3} s^{-1}) and A_2/A_3 are considerably larger than the respective values of 6.64×10^{-5} s^{-1} and 25.68×10^{-5} M^{-1} s^{-1} obtained at 80°C in the hydrolytic cleavage of succinimide (22) and 19.1×10^{-5} s^{-1} and 83.9×10^{-5} $M^{-1}s^{-1}$ obtained at 80°C in the hydrolysis of 3,3-methylethylsuccinimide (23).

The present data are not sufficient to differentiate between a concerted process with transition state V and a stepwise process (Scheme II) involved



V



VI VII

Scheme II

in the conversion of S^- to T_1. However, as Jencks (24) has pointed out, the concerted process should be expected to occur if the lifetime of an intermediate is shorter than that of a molecular vibration of 10^{-13} s. Classical one-step concerted S_N2 and E_2 mechanisms have been challenged by the proposal that such reactions occur through a stepwise mechanism (24); therefore, we prefer Scheme II for the conversion of S^- to T_1. It has been concluded in the aminolysis of maleimide[8] that k_{-1}'' is larger than k_1'' even when the leaving group in k_{-1}'' step is a cationic amine. It is therefore obvious that in Scheme II, k_{-1}'' should be larger than k_1'' because the acidity of H_2O^+— is much larger than $>NH_2^+$. However, the high leaving ability of H_2O^+—, compared with $>NH_2^+$ from $T^\pm$—, caused by the difference in their respective acidity, could partially be offset by larger basicity toward carbon of oxygen nucleophiles than of amine nucleophiles, for a given basicity toward the proton (25). These conclusions lead to k_1'' as the rate-determining step. The proton transfer in the k_1'' step is presumably taking place through a proton switch mechanism (26).

In previous related studies (27), the formation of the oxydianionic tetrahedral intermediate, T_2, was assumed to occur by an equilibrium:

$$T_1 \overset{OH^-,\,K'}{\rightleftharpoons} T_2' \quad \text{(Eq. 5)}$$

Such an equilibrium is most likely to be significant if the nucleophilic attack to form T_1 is not the rate-determining step.

The significantly low value of the Grunwald-Winstein coefficient ($m \simeq 0.29$) indicates that the rate is not sensitive to the solvating power of the organic cosolvent. However, the increase in rate of hydrolysis with increase in water concentrations of the mixed solvents reveals that the transition state involved is more polar than the reactants (28). The solvent effect was studied at 0.03 M NaOH where the contribution of the k_2 step compared with the k_1 step was most likely negligible. It is therefore conceivable to assume that the k_1' step should be dominant over the k_1 step in the formation of T_1 (Scheme I) because the transition state of the k_1' step (VI) is apparently more polar than that of the k_1 step (VII) and because the ionic reactant of the k_1 step is presumably more strongly solvated than that of the k_1' step in a polar solvent.

The sufficiently large negative value of ΔS^* for the k_1' step must be attributed to the necessity for the proper orientation of more than one water molecule in the transition state (29); this could be expected if the transition state involved is highly polar. It is interesting to note that the ΔS^* for the k_1' step is ~12.7 e.u. more negative compared with that for the k_2 step while the ΔH^* for the k_2 step is ~3.66 kcal/mol larger than that for the k_1' step. These observations are consistent with the proposed transition states VI and VII. As expected from the proposed mechanism, the k_1' step has been found to be

[7] The pK_a of acetamide [15.4 (20a), 17.1 (20b)] and the value of K_a/K_w of ~7 for succinamic acid (22) indicate that the acidity of the amide group is not much different from water.

[8] Unpublished observations.

insensitive to the ionic strength while a change in ionic strength from 1.0 to 4.0 M resulted in an increase of ~25% in k_{obs} obtained at 1.0 M NaOH.

Abstract □ With the aid of rapidly dissolving sodium chloride particles, cubic pores were made in the surface of a theophylline tablet. The influence of the pores on the dissolution rate of the surface was investigated in a rotating disk apparatus. Like the drilled pores used in earlier studies, downstream on the surface they caused a turbulent flow regimen with the development of a trough due to enhanced erosion. The phenomenon of a critical pore diameter, discovered with single, drilled pores, seems to be applicable to the cubic pores investigated in this study, although a higher degree of surface coverage with pores caused complications, probably due to particles bordering one another and forming larger pores. The behavior of the porous surfaces at different rotation speeds was studied. Due to the presence of pores the laminar character of the boundary layer flow changes to turbulent, which induces locally an increased dissolution flux in the wake of a pore.

Keyphrases □ Dissolution rates—pore effects, theophylline □ Pore effects—influence on dissolution rate, theophylline

The promoting effect of pores on the dissolution rate of a tablet surface and the effects of individual pores drilled into a dissolving surface have been reported (1–5). The objective of this study was to investigate the changes in dissolution rate of a solid surface when several pores, which can not be considered to act individually, are present. The hydrodynamic conditions around each pore will be influenced by surrounding pores and, as a consequence of the interaction of the turbulent zones behind the pores, the erosion troughs will overlap.

Pores can be drilled into a tablet surface by a drilling technique (1–5), but this method is not feasible for a large number of pores, and an alternative procedure was followed in this study. Sodium chloride particles, characterized by an almost cubic shape, were embedded in the surface of a theophylline tablet. In the dissolution experiment, the sodium chloride particles rapidly dissolved leaving (cubic) pores in the slowly dissolving theophylline surface. In this way a surface was easily supplied with a large number of pores.

EXPERIMENTAL SECTION

Materials—Theophylline monohydrate[1] was used as supplied. Sodium chloride was classified by sieving. Both compounds met the requirements of the European Pharmacopoeia (6).

Particle Size Determinations—The size distribution of the sieve fractions of sodium chloride particles was determined by microscopic examination. As nearly all particles had a cubic shape, the edge of each particle was measured as its characteristic diameter. Cumulative log-probability plots of the particle distribution data gave straight lines, from which the geometric mean diameter (d_g) and the geometric standard deviation (σ_g) of each fraction were obtained. The specific gravity (ρ) of sodium chloride is 2.17×10^3 kg·m^{-3} (7) and since on the whole the shape of the particles is cubic, d_g was used to compute the number of particles per unit weight by:

$$n = \frac{1}{\rho d_g^3} \qquad \text{(Eq. 1)}$$

Disk Preparation—Tablets with a 15.0-mm diameter and varying thicknesses were compressed individually using a hydraulic press. The flat surfaces of each tablet were perfectly smooth without rims or ridges, which was achieved by using an appropriate set of die and punches. After inserting the lower punch in the die, a quantity of theophylline powder, sufficient to obtain a tablet with a thickness of 2–4 mm, was poured into the die. Next, the upper punch was mounted and the powder was precompressed at 2000 N for 10 s. After removing the upper punch, a small amount of sodium chloride was put on the theophylline surface. The particles were carefully spread over the surface to obtain a homogeneous distribution. The actual compression was then performed at 12,000 N for ≥30 s. At this compressional force the sodium chloride crystals did not break or disintegrate (checked microscopically). This procedure provided tablets with an upper surface consisting of intact cubic sodium chloride particles embedded in a theophylline matrix.

Dissolution Rate Measurements—The rotating disk apparatus for determining the dissolution rate of the tablet surfaces has been described in detail (2). In this study the rotation speed of the mounted disk varied between 100 and 340 rpm. The concentrations of sodium chloride and theophylline were measured continuously and simultaneously. The quantity of dissolved sodium chloride was monitored by a conductivity cell[2] mounted in the vessel. The theophylline concentration was measured by circulating the solution through a spectrophotometer[3] equipped with a flow cell (10-mm path length) and set at a wavelength of 270 nm. An internal calibration of both measuring systems was performed by the preaddition method described previously (1).

To be sure that dissolved sodium chloride had no influence on the absorbance of theophylline, increasing amounts of solid sodium chloride were added to a theophylline solution: no change in absorbance was noticed and, conversely, adding solid theophylline to a sodium chloride solution had no effect on the measured conductance. The dissolution rate of a smooth theophylline surface into bulk solutions with different concentrations of sodium chloride was measured and, for the sodium chloride concentrations relevant to this study, the dissolution rate of theophylline was not affected by the amount of sodium chloride in the solution.

After a short initial period, during which the sodium chloride particles dissolved, the theophylline dissolution curves were straight up to ≥15 min. This was sufficient to obtain an accurate value for the dissolution rate. Dissolution data were collected at regular time intervals by a microcomputer[4]. After the experiment, the dissolution rate of the theophylline surface was computed from the least-squares regression line of those data that were obtained after the sodium chloride had dissolved completely, *i.e.*, after the conductance of the solution had reached a constant level (in all cases within 60 s). At that moment only a negligible quantity of theophylline had dissolved (~5–10% of the final amount), implying that the shape of the created pores had hardly changed during this initial period. The conductance of the solution was measured after complete dissolution of the embedded sodium chloride; from this measurement the number of crystals originally present in the surface, which equals the number of created pores, was calculated.

RESULTS AND DISCUSSION

The erosion pattern of a tablet after the dissolution rate experiment (Fig. 1), is the result of two processes. First, dissolution of the sodium chloride particles creates cubic pores. Due to the presence of these pores in the surface troughs develop, which are the consequence of an enhanced theophylline dissolution in the wake of the pores and which extend along a spiral trajectory in the theophylline surface (2).

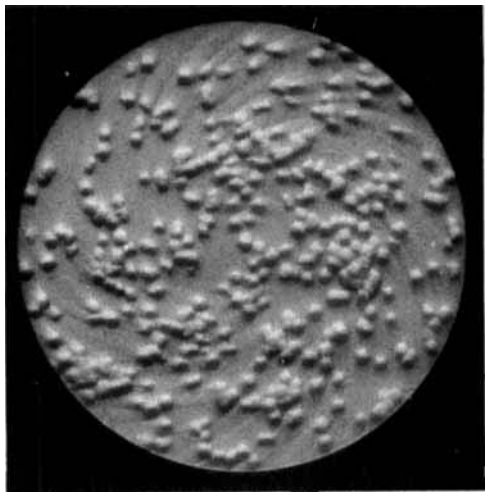

Figure 1—*The surface of a theophylline tablet after a dissolution experiment of ~15 min. Pores were created by sodium chloride particles (d_g = 308 μm), embedded in the surface.*

The dissolution rates of porous theophylline surfaces were determined at a rotation speed of 160 rpm using a varying number of sodium chloride particles of different sizes. Porous surfaces were made with the five sieve fractions listed in Table I. In all experiments the maximum coverage of the theophylline surface by sodium chloride particles remained <25%.

For each sieve fraction the dissolution rate of a theophylline surface with n pores (R_n) was measured at various values of n. In Fig. 2, I_n, the difference between the dissolution rates of a smooth surface (R_0) and a surface with n pores (R_n), is plotted as a function of the number of pores. Since the dissolution rate of a smooth theophylline surface at 160 rpm is 14.9 μg·s^{-1}, the largest pores can cause the dissolution rate to increase >50% at this rotation speed.

Figure 2 demonstrates that I_n is not only dependent on the number of pores but also on the pore size. This is not surprising in view of previous findings (1–5). It was established (3) that the critical pore diameter (the diameter a single pore must exceed to cause an increase of the dissolution rate) is related to the friction velocity v_f in the boundary layer at the rotating disk surface according to:

$$d_{crit} = 2.7 \frac{\nu}{v_f} \qquad \text{(Eq. 2)}$$

where ν is the kinematic viscosity of the solvent (mm^2·s^{-1}).

The friction velocity is a hydrodynamic variable that, for a rotating disk surface, can be computed from (8, 9):

$$v_f = 0.89 \nu^{1/4} x^{1/2} \omega^{3/4} \qquad \text{(Eq. 3)}$$

where x is the distance from the surface center (mm) and ω is the angular velocity (s^{-1}). Equation 3 implies that at the edge of the dissolving surface the friction velocity has a maximum value and, from Eq. 2, the critical pore diameter has a minimum value. With a rotation speed of 160 rpm the critical pore diameter at the edge (calculated from Eqs. 2 and 3) is ~0.13 mm. Nearer the disk center d_{crit} is larger, *e.g.*, at 2.5 mm from the surface edge a value of 0.19 mm was measured (3).

These considerations made it unlikely that the sodium chloride fractions with a d_g of ~ ≤130 μm would cause an increase in the dissolution rate. Even the 198-μm fraction could only increase the dissolution rate on a limited part

Table I—Sieve Fraction Data of Sodium Chloride

Sieve Fraction, μm	Geometric Mean Diameter (d_g), μm	Geometric *SD* (σ_g)	Calculated Particle Number (n)[a]
71–100	88	1.28	676
100–160	128	1.23	220
160–250	198	1.18	59
250–400	308	1.16	15.8
400–500	419	1.15	6.3

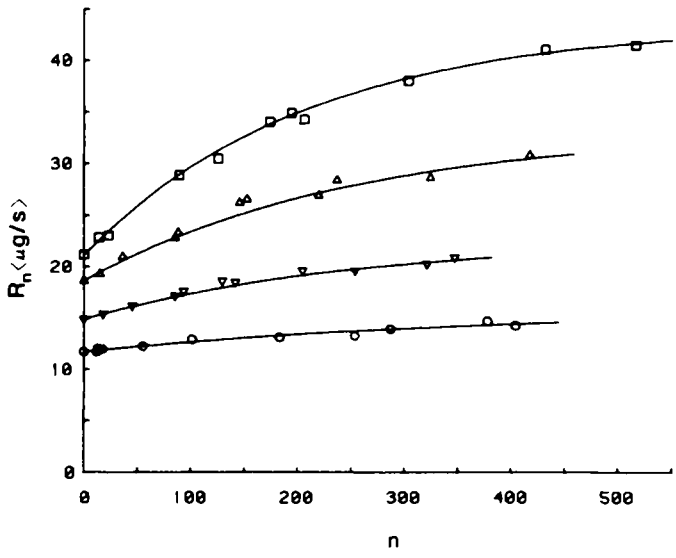

Figure 3—*Dissolution rate of a theophylline surface at different rotation speeds as a function of the number of sodium chloride particles used to create pores. Geometric mean diameter of the particles: 308 μm. Key: (□) 340 rpm; (△) 250 rpm; (▽) 160 rpm; (○) 100 rpm. Each symbol represents an individual experiment. Lines were computed by Eq. 7.*

of the surface; only particles positioned in a region of the tablet surface where d_{crit} is less than ~0.20 mm can cause a change in the dissolution rate. The more particles present in the surface, the more likely it is that somewhere a pore exceeds the local critical size. In the 198-μm fraction, the dissolution rate increases considerably with n, provided that n exceeds a minimum value of 30–40 particles (Fig. 2).

A second possible explanation for the shape of the lines in Fig. 2 must be mentioned. Single particles that create pores equal to or smaller than the local critical size, will not raise the dissolution rate, but when the number of particles in the surface increases, it is more likely that at least two particles lie against each other and together create a larger pore when the sodium chloride dissolves. The presence of these larger pores might be the reason that, at higher values of n, the two smallest particle fractions (128 and 88 μm) also cause a slight increase in the dissolution rate compared with a smooth surface.

The influence of the rotation velocity of the disk surface on the dissolution rate was investigated using the 308-μm particles. The relationship between dissolution rate and number of particles was determined at four different revolution speeds (Fig. 3). No linear relation exists between those two variables, but for every rotation speed the dissolution rate (R_n) increases asymptotically with increasing n to a maximum value. This leads to the assumption that for a certain number of pores a maximum dissolution rate (R_{max}) exists. The corresponding maximum increase of the dissolution rate, I_{max}, is defined by:

$$I_{max} = R_{max} - R_0 \qquad \text{(Eq. 4)}$$

Suppose that the relation between I_n and n can be described by the first-order equation:

$$\frac{d(I_{max} - I_n)}{dn} = -k(I_{max} - I_n) \qquad \text{(Eq. 5)}$$

then we obtain by rearranging and integrating:

$$\ln\left(1 - \frac{I_n}{I_{max}}\right) = -kn \qquad \text{(Eq. 6)}$$

A semilogarithmic plot of $(1 - I_n/I_{max})$ *versus* n should result in a straight line with a slope $-k$ and passing through the origin, provided that the assumption of a first-order relationship in Eq. 5 is justified. Since the value of I_{max} in Eq. 5 was unknown, an iterative calculation of the linear regression coefficients of the data $\ln(1 - I_n/I_{max})$ *versus* n was performed. New values for I_{max} were chosen until the best correlation coefficient was obtained. The computed coefficients were used to fit the data in Fig. 3 according to:

$$R_n = R_0 + I_n = R_0 + I_{max}(1 - e^{-kn}) \qquad \text{(Eq. 7)}$$

The points in Fig. 3 are fitted well by the lines obtained from these computations, so the assumption of a first-order relation appears to be a good approximation.

Table II—Dissolution Rates[a] of Theophylline Surfaces With Cubic Pores

Pores	Rotation Speed, rpm (ω) 100 (10.47)	160 (16.76)	250 (26.78)	340 (35.60)	p[b]	r[c]

The actual nature of the hydrodynamic conditions at the tablet surface can be determined from the relationship between the dissolution rate and the angular velocity of the rough pellet surface. The relationship between R_n and angular velocity (ω) can be written in the form (10):

$$R_n \sim \omega^p \qquad \text{(Eq. 8)}$$

At smooth rotating disk surfaces, p = 0.5 under laminar conditions and p = 0.9 in a completely turbulent flow pattern. At a rough rotating disk surface, consisting of a regular, geometric pattern of pyramids, the following results were obtained (11-14): with a pyramid height of >1 mm the mass flux varied with $\omega^{0.67}$. But when the height of the roughness elements diminished, the exponent of ω increased from 0.67 to >0.9 (14). The experimental data collected in Fig. 3 were used to investigate the effect of the presence of pores on the hydrodynamics at the tablet surface. Since the dissolution rates can be compared only for equal values of n at the different rotation speeds, interpolated values of R_n were calculated by Eq. 7 from the best fit of the experimental data for various numbers of pores at each rotation speed (Table II). A linear regression analysis of the plot of log R_n *versus* log ω for any number of pores was performed on the data collected in Table II. The slopes of these plots correspond to p in Eq. 8. Exponent p increases from ~0.5 at $n = 0$ (smooth surface) to 0.8-0.9 for surfaces with >250 pores. This confirms earlier observations that, due to the presence of pores, the flow regimen in the boundary layer near the surface shows a transition from laminar to turbulent, resulting in a changed dissolution mechanism of the surface.

Interaction of Povidone with Aromatic Compounds V: Relationship of Binding Tendency in a Macromolecular Solution Treated as a Pseudo Two Phase and a Monophase

J. A. PLAIZIER-VERCAMMEN

Received November 12, 1982, from the *Faculteit Geneeskunde en Farmacie, Vrije Universiteit Brussel, B-1090 Brussels, Belgium.* Accepted for publication April 13, 1984.

Abstract □ The pseudo-two-phase model is proposed to correlate complex formation of ligand molecules with povidone with partition coefficients (log P or II constants). The conditions which permit the use of the pseudo-two-phase model for binding of ligand onto macromolecules are determined. This model seems to be a more rational choice than the frequently used complex formation model (monophase). This is demonstrated theoretically and confirmed experimentally. The advantages of the use of such a model are also discussed.

Keyphrases □ Povidone—interaction with aromatic compounds, pseudo-two-phase and monophase systems, salicylic acid, complex formation □ Pseudo-two-phase model—compared with monophase, complex formation aromatic compounds with macromolecules

The important role of lipophilicity of ligand molecules and hydrophobic bonding in complex formation of a series of ligand molecules with povidone has been previously investigated; ligand molecules in the nonionic state showed a higher complexing tendency than those in the ionic state, (1-3). Complex formation of ligand molecules with povidone was explained in terms of hydrophobic bonding (1, 4-8). In earlier work, we studied the complexing tendency of ligand molecules in the nonionic and ionic state, and the importance of the hydrophobic bonding especially for nondissociated molecules was confirmed (9). The correlation observed between the solubility of the ligand molecule in solvent mixtures and its binding to povidone (10) also provided support for the occurrence of complex formation by hydrophobic interactions.

Hansch *et al.* (11) showed that complex formation by hydrophobic bonding of neutral organic molecules with macromolecules, such as serum albumin, can often be correlated with partition coefficients (log P or π constants) (12, 13) between 1-octanol and water. This correlation was found for phenols and serum albumin, barbiturates and homogenized rabbit brain (14), penicillin and serum albumin (15), aniline derivatives and nylon and rayon (16), and phenols and mitochondrial protein (17).

These results, correlated with octanol-water partition coefficients (log P), are expressed either as $1/C$ (11) (where C represents the molar concentration of ligand to produce a one-to-one complex of ligand and macromolecule), as log $B\%$ [percent bound ligand (14)], or as log B/F (15), where B refers to bound and F to free ligand concentrations, respectively. The methods for expressing complex formation are not comparable. As indicated by Bird and Marshall (15), B/F is a more rational choice than $B\%$ for correlating the results with log P, because B/F is analogous to an organic solvent-water partition coefficient. Moreover, as opposed to the other expressions, B is not a linear function of the association constants.

However, the use of the B/F expression has a disadvantage; one must work at a constant macromolecular concentration in order to compare the B/F expressions for the individual ligand molecules with the log P or π values. This implies that one must expect errors in the results obtained for ligand mol-

Interaction of Povidone with Aromatic Compounds V: Relationship of Binding Tendency in a Macromolecular Solution Treated as a Pseudo Two Phase and a Monophase

J. A. PLAIZIER-VERCAMMEN

Received November 12, 1982, from the *Faculteit Geneeskunde en Farmacie, Vrije Universiteit Brussel, B-1090 Brussels, Belgium.* Accepted for publication April 13, 1984.

Abstract □ The pseudo-two-phase model is proposed to correlate complex formation of ligand molecules with povidone with partition coefficients (log P or II constants). The conditions which permit the use of the pseudo-two-phase model for binding of ligand onto macromolecules are determined. This model seems to be a more rational choice than the frequently used complex formation model (monophase). This is demonstrated theoretically and confirmed experimentally. The advantages of the use of such a model are also discussed.

Keyphrases □ Povidone—interaction with aromatic compounds, pseudo-two-phase and monophase systems, salicylic acid, complex formation □ Pseudo-two-phase model—compared with monophase, complex formation aromatic compounds with macromolecules

The important role of lipophilicity of ligand molecules and hydrophobic bonding in complex formation of a series of ligand molecules with povidone has been previously investigated; ligand molecules in the nonionic state showed a higher complexing tendency than those in the ionic state, (1-3). Complex formation of ligand molecules with povidone was explained in terms of hydrophobic bonding (1, 4-8). In earlier work, we studied the complexing tendency of ligand molecules in the nonionic and ionic state, and the importance of the hydrophobic bonding especially for nondissociated molecules was confirmed (9). The correlation observed between the solubility of the ligand molecule in solvent mixtures and its binding to povidone (10) also provided support for the occurrence of complex formation by hydrophobic interactions.

Hansch *et al.* (11) showed that complex formation by hydrophobic bonding of neutral organic molecules with macromolecules, such as serum albumin, can often be correlated with partition coefficients (log P or π constants) (12, 13) between 1-octanol and water. This correlation was found for phenols and serum albumin, barbiturates and homogenized rabbit brain (14), penicillin and serum albumin (15), aniline derivatives and nylon and rayon (16), and phenols and mitochondrial protein (17).

These results, correlated with octanol-water partition coefficients (log P), are expressed either as $1/C$ (11) (where C represents the molar concentration of ligand to produce a one-to-one complex of ligand and macromolecule), as log $B\%$ [percent bound ligand (14)], or as log B/F (15), where B refers to bound and F to free ligand concentrations, respectively. The methods for expressing complex formation are not comparable. As indicated by Bird and Marshall (15), B/F is a more rational choice than $B\%$ for correlating the results with log P, because B/F is analogous to an organic solvent-water partition coefficient. Moreover, as opposed to the other expressions, B is not a linear function of the association constants.

However, the use of the B/F expression has a disadvantage; one must work at a constant macromolecular concentration in order to compare the B/F expressions for the individual ligand molecules with the log P or π values. This implies that one must expect errors in the results obtained for ligand mol-

0022-3549/84/1200-1774$01.00/0

© 1984, American Pharmaceutical Association

ecules with a low or a high tendency for complex formation (18). The $1/C$ expression offers the advantage over the B/F expression in that it is directly related to the association constant and is independent of the macromolecular concentration. However, for the determination of $1/C$, a series of ligand concentrations must be investigated to determine the concentration of ligand (F) where $r = 1$ [r is defined as mole of bound ligand/mole of macromolecule (11)]. Moreover, expressions used to correlate complex formation to log P values suffer from the fact that notations such as T (total ligand), F (free ligand), and B (bound ligand) calculated from a monophasic point of view (the theory of complex formation) are correlated to the same notations, calculated from a biphasic point of view (partition theory), but have different significance.

The purpose of this report was to investigate the possibilities of expressing complex formation of ligand molecules with macromolecules from a pseudo-two-phase point of view. For this purpose, we have regarded the macromolecular solution both as a true solution (monophase) and as a pseudo two phase comparable with a biphase. We have theoretically investigated the expression of results calculated according to the theory of complex formation in partition terms, and the relationship of the two systems. The theory is experimentally verified with two different experiments and the possibilities and limitations of the two systems are discussed.

EXPERIMENTAL SECTION

Materials and Methods—Povidone[1] was used as the macromolecule and salicylic acid[2] was used as the ligand molecule. The buffer employed was a phosphate buffer (pH 7.00) (19) containing dibasic sodium phosphate and monobasic potassium phosphate. Ultrafiltration was used to investigate the ligand-macromolecule interactions. Previously described equipment was employed (20). The concentration of unbound ligand was determined spectrophotometrically in the ultrafiltrate. The spectrophotometric measurements were performed at 296 nm with a double-beam spectrophotometer[3] after appropriate dilution.

Partial Specific Volume—The partial specific volume ($\overline{V}_2^\circ$) (21, 22) of povidone in water and phosphate buffer (pH 7.00) is calculated from the density increment with all other components at constant chemical potential using the equation:

$$\overline{V}_2^\circ = \frac{1}{\rho'}\left[1 - \left(\frac{\Delta_\rho}{\Delta C_2}\right)_m^\circ\right] \qquad \text{(Eq. 1)}$$

where $\overline{V}_2^\circ$ is the partial specific volume; C_2 is the povidone concentration; $\Delta_\rho/\Delta C_2$ is the density increment with respect to component 2; and ρ' is the buffer density. The densities of the macromolecular solution and the solvent were measured with a digital precision density meter[4], calibrated with air and solvent, at 25°C. In a second method, the partial specific volume was determined using a pycnometer.

Determination of the Binding Tendency—A solution containing salicylic acid and 2.50% povidone in a phosphate buffer (pH 7.00) was prepared. Ultrafiltration was carried out at 25°C, several ultrafiltrate fractions (~0.5-1.0 mL each) were collected, and the free ligand concentration in each sample was determined spectrophotometrically. The volume of the sample was calculated by weighing the sample and determining its density.

RESULTS AND DISCUSSION

Treatment of Povidone Solutions as Pseudo Two Phase—The question of homogeneity or heterogeneity of macromolecules in solution is still a point of discussion. Some authors (23, 24) consider that macromolecular dispersions are monophasic (homogeneous), while other authors (25, 26) believe they are clearly biphasic (heterogeneous). In fact, the problem of phases is a problem of scale. A phase dispersed in another phase ceases to exist, as such, when its degree of division reaches the molecular level. At any point along the chain, a macromolecule has a molecular size in two of the spatial dimensions and a macromolecular size in the third.

The "pseudo-two-phase" model (27, 28) was used by a number of investigators (29-33) to describe aqueous micellar solutions in general and solubilization in particular (28, 34). Such a model leads one to think of the solubilized dispersion as being distributed or partitioned between the micelles ("micellar phase") and the external "aqueous phase."

The elementary requirement that these "phases" be mechanically separable is satisfied, since such a separation can be effected with dialysis or ultrafiltration. Moreover, these micellar solutions are consistent with the Gibbs phase rule for two-phase systems; the intensive properties of the aqueous phase are nearly constant with overall surfactant concentration above the critical micellar concentration at constant temperature and pressure. The pseudo-two-phase treatment of micelles has gained strong support from the ultrafiltration and solubilization studies of Hutchinson *et al.* (30), which showed the number of free detergent molecules to be nearly constant above the micelle point.

The pseudo-two-phase model is useful if the micelles are both large and do not interact; these requirements, if they are fulfilled, should be reflected in the distribution coefficient, being independent of the surfactant concentration for a given micellar composition. All these requirements and limitations, valid for the micellar solutions, are also fulfilled in the case of macromolecular solutions. Moreover, macromolecular solutions are seen as gel particles (35) and occupy a definite volume in solution, indicated as their partial specific volume (21, 22).

Povidone, like other nonionic macromolecules, contains separate hydrophobic and polar groups, making it comparable to nonionic tensides. A molecular model of the povidone molecules showed that the polar pyrrolidone ring and the hydrophobic paraffin backbone were both accessible for the ligand molecules (36). Taking into account these considerations, we thought the pseudo-two-phase model, describing micellar solutions, could also be used for describing macromolecular solutions.

Relationship Between Binding Results, Expressed in a Monophasic (Complex Formation) and a Pseudo-Two-Phasic System (Partition)—According to the theory of complex formation (monophase) (18, 23, 37-39) the following equation is valid:

$$T = B + F \qquad \text{(Eq. 2)}$$

where T, B, and F represent the molarities of total, bound, and free ligand and are calculated on the total volume (V_T) of the solution.

Complex formation can be studied as a function of either macromolecule concentration or ligand concentration. In the first method, the ratio of T to F can be expressed as a function of the amount of povidone (40-42):

$$\frac{T}{F} = a g_{PVP} + 1 \qquad \text{(Eq. 3)}$$

where g_{PVP} is grams of povidone and a is a constant.

The second method permits the calculation of intrinsic binding constants (k) and the number of binding sites (n) on the macromolecule:

$$r = \frac{B}{g_{PVP}} = \frac{nkF}{1 + kF} \qquad \text{(Eq. 4)}$$

For isotherms of several ligand molecules with povidone, a straight line was obtained by plotting r as a function of F (3, 9, 43, 44). This finding implies that at $kF \ll 1$, $1/n$ equals zero or n is infinite, indicating a nearly infinitely large number of adsorption sites (9, 20). So Eq. 4 reduces to:

$$r = \frac{B}{g_{PVP}} = nkF \qquad \text{(Eq. 5)}$$

If both equations are valid, the constant a of Eq. 3 equals nk of Eq. 5.

According to the pseudo-two-phase model (partition), the general equation for partition between two phases is valid:

$$Kd = \left(\frac{T'V'_T - F \cdot V_F}{F}\right) \cdot \left(\frac{1}{V_B}\right) \qquad \text{(Eq. 6)}$$

where:

$$B' = T' - F, \qquad \text{(Eq. 7)}$$

Kd is the partition coefficient between "the pseudo or macromolecule phase" and the aqueous or "outer" phase; T' is the concentration (in molarity) of the aqueous phase before partition; V'_T is the volume of the aqueous phase before partition; F is the concentration (in molarity) of the aqueous phase after equilibrium (*i.e.*, the free ligand concentration); V_F is the volume of the "outer" or aqueous phase after equilibrium; B' is the concentration of ligand in the pseudo or macromolecule phase (*i.e.*, the bound ligand concentration); V_B is the volume of the "pseudophase," in our case, the volume occupied by

povidone in solution. The partial specific volume of povidone was taken. As $V'_T = V_F$, Eq. 6 can be written:

$$Kd = \left(\frac{T' - F}{F}\right)\frac{V_F}{V_B} \qquad \text{(Eq. 8)}$$

As in the pseudo-two-phase system, T' represents the total concentration of the "outer" or aqueous phase and the relationship between total concentration in the monophase and pseudo-two-phase system is given by:

$$T' = T\left(\frac{V'_T}{V_T - V'_B}\right) \qquad \text{(Eq. 9)}$$

By comparing Eqs. 2, 7, and 9, it is noted that B' expressed in a pseudo-two-phasic system is larger than B expressed in a monophasic system. Further, we can write:

$$V_B = b \cdot g_{PVP} \qquad \text{(Eq. 10)}$$

where g is grams of povidone used in the experiment and b is the volume occupied by one gram of povidone in solution.

Substitution of Eqs. 9 and 10 in Eq. 8 gives:

$$Kd = \left(\frac{\frac{T \cdot V_T}{V_T - b \cdot g_{PVP}} - F}{F}\right) \cdot \left(\frac{V_T - b \cdot g_{PVP}}{b \cdot n \cdot g_{PVP}}\right) \qquad \text{(Eq. 11)}$$

resulting in:

$$\frac{T}{F} = \left(\frac{b \cdot g_{PVP}}{V_T}\right) \cdot (Kd - 1) + 1 \qquad \text{(Eq. 12)}$$

or:

$$\frac{B}{F} = \left(\frac{b \cdot g_{PVP}}{V_T}\right) \cdot (Kd - 1) \qquad \text{(Eq. 13)}$$

Therefore, a plot of T/F as a function of g_{PVP} results in a straight line with slope, b/V_T $(Kd - 1)$ and an intercept of 1. The slope is equal to the slope a of Eq. 3 or nk of Eq. 5.

The relationship between Kd and a, the slope of Eq. 3, or nk of Eq. 5 can be calculated from Eqs. 3, 5, and 12 and results in:

$$Kd = a\frac{V_T}{b} + 1 = nk\frac{V_T}{b} + 1 \qquad \text{(Eq. 14)}$$

From Eq. 14, it can be concluded that the linear relationship between T/F and g_{PVP}, which is found using the theory of complex formation (Eqs. 3 and 5), can be directly correlated with the pseudo-two-phase theory. This holds true for all povidone concentrations.

It has only been assumed that $V_B = V_{PVP}$ is a linear function of g_{PVP}. The linearity has been investigated using a pycnometer and is graphically represented in Fig. 1. The volume occupied by povidone is indeed a linear function of g_{PVP}. From the slope of the line, the b value was calculated and equals 0.80 mL/g (*i.e.*, every gram of povidone occupies a volume of 0.80 mL). This holds true for both water and phosphate buffer. The partial specific volume, calculated from density increments of povidone solutions using Eq. 1, agreed with the results obtained with a pycnometer.

Comparison of Results in a Macromolecular Solution Treated as Monophase and Pseudo Two Phase—To verify the results experimentally, 100-mL solutions containing a constant concentration of salicylic acid as ligand (7.60×10^{-3} M) and different amounts of povidone were prepared in a phosphate buffer (pH 7.00). From the monophasic point of view, and according to Eq. 2, $T = 7.60 \times 10^{-3}$ M and $V_T = 100$ mL.

Ultrafiltration was carried out and the free ligand concentration (F) was determined. The results calculated from the mono- and pseudo-two-phasic points of view (Eqs. 2, 3, and 11) are presented in Table I and Fig. 2.

The slope of the straight lines, T/F, as a function of the povidone concentration was 0.260. The corresponding Kd value, according to Eq. 13 where $V_T = 100$ mL and $b = 0.80$, was 33.50. The mean of the Kd values from the data of Table I, calculated according to Eq. 11, was 33.11. The Kd values agree quite well.

The results of binding onto povidone can be interpreted from the monophasic as well as from the pseudo-two-phasic point of view. The results calculated in one system can easily and correctly be expressed in the other system by use of a simple equation. The calculated Kd values are independent of the macromolecular concentration, as can be expected with partition between two phases. The Kd values offer the advantage above the B/F and $1/C$ determinations, to correlate with log P constants (11, 14, 15) so that the desired information can be obtained from one experiment and the macromolecular concentration can be varied from one ligand to another to minimize the error in the results obtained for ligand molecules with a low or high complexing tendency (18).

[a] Calculations were made using Eqs. 2, 3, and 11. The total concentration of salicylic acid was 7.60×10^{-3} M; the pH was 7.00; the ionic strength was 0.25; the temperature was 25°C. [b] T, B, and F are molarities of total, bound, and free ligands, respectively; T', B', and Kd are molar concentrations of the aqueous phase before partition, the bound ligand concentration, and the partition coefficient between the "pseudo" and aqueous phase, respectively.

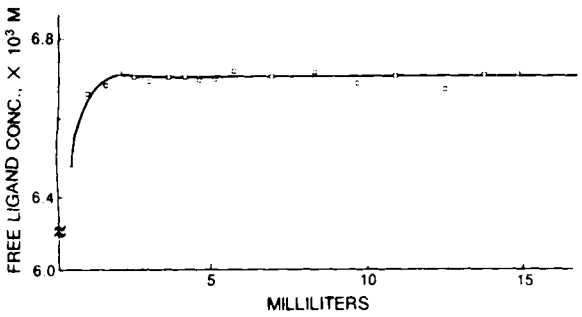

Figure 3—*Determination of the free ligand concentration of salicylic acid in the successive ultrafiltrate samples. Salicylic acid, 1.00 × 10⁻² M; povidone, 2.50%; pH 7.00; 25°C.*

Determination of the Complexing Tendency in Successive Ultrafiltrate Samples—The free ligand concentrations of successive fractions were determined from a solution containing salicylic acid (1.00×10^{-2} M) and 2.50% povidone dissolved in a buffer (pH 7.00) (Fig. 3). The free ligand concentrations in the successive aliquots remain constant, although the volume of the solution is more than halved while the povidone concentration is more than doubled.

The constancy of the free ligand concentration in the successive aliquots was tested in terms of the mono- and pseudo-two-phase models. The results are consistent with a pseudo-two-phase model. According to the partition theory (and Eq. 6), F corresponds to the concentration of the "outer" or the aqueous phase, in opposition to the theory of complex formation. Since we are dealing with concentrations and not with amounts, the free ligand concentration (F) at equilibrium is not changed by eliminating a portion of the "outer" or aqueous phase.

On the other hand, with complex formation, all results are expressed as the total volume of the solution. Therefore, the concentration of the macromolecule will increase due to solvent elimination during ultrafiltration. However, the change in total volume must simultaneously also affect the other factors. This change in the concentration of total ligand, total povidone concentration, bound ligand, and especially free ligand was theoretically investigated. These effects are considered first for a 1:1 complex:

$$M_F + F \rightleftarrows ML \qquad \text{(Eq. 15)}$$

$$k = \frac{(ML)}{(M_F) \cdot (F)} \qquad \text{(Eq. 16)}$$

where ML is the concentration of bound ligand or bound macromolecule, M_F is the free concentration of macromolecule, and F is the free ligand concentration. If T and M_T represent the total concentration of ligand and macromolecule, respectively, we may write:

$$M_F = M_T - T + F \qquad \text{(Eq. 17)}$$

so:

$$k = \frac{T - F}{(M_T - T + F) \cdot (F)} \qquad \text{(Eq. 18)}$$

Expressing Eq. 18 in terms of concentration (w/v), with the volume before ultrafiltration as V_0, then Eq. 18 can be written:

$$k = \frac{\frac{m_T}{V_0} - \frac{m_F}{V_0}}{\left(\frac{m_{M_T}}{V_0} - \frac{m_T}{V_0} + \frac{m_F}{V_0}\right)\left(\frac{m_F}{V_0}\right)} \qquad \text{(Eq. 19)}$$

where m_T, m_F, and m_{M_T} are the mass of total ligand, free ligand, and mac-

[a] Volume of the eliminated ultrafiltrate fraction. [b] $V_0 - \Sigma dv$ = volume remaining in the ultrafiltrate cell. [c] Povidone concentration in the ultrafiltrate cell, calculated according to Eq. 22. [d] Total ligand concentration in the ultrafiltrate cell, calculated according to Eq. 21. [e] F = free ligand concentration, determined in the ultrafiltrate fraction. [f] $B = T - F$ = bound ligand concentration. [g] r = moles of ligand bound/mole of macromolecule.

romolecule, respectively, or:

$$k = \frac{m_T - m_F}{(m_{M_T} - m_T + m_F)\left(\frac{m_F}{V_0}\right)} \quad \text{(Eq. 20)}$$

After eliminating a volume fraction dv, with mass dm, the total ligand concentration is also changed and equals:

$$T = \frac{m_T - dm}{V_0 - dv} \quad \text{(Eq. 21)}$$

and the total macromolecular concentration:

$$M_T = \frac{m_{M_T}}{V_0 - dv} \quad \text{(Eq. 22)}$$

the free ligand concentration is changed to:

$$F = x_F/(V_0 - dv) \quad \text{(Eq. 23)}$$

where x_F, the mass of free ligand, *a priori* is not known. The new equilibrium is then:

$$k = \frac{\frac{m_T}{V_0 - dv} - \frac{dm}{V_0 - dv} - \frac{x_F}{V_0 - dv}}{\left(\frac{m_{M_T}}{V_0 - dv} - \frac{m_T}{V_0 - dv} + \frac{dm}{V_0 - dv} + \frac{x_F}{V_0 - dv}\right) \cdot \left(\frac{x_F}{V_0 - dv}\right)} \quad \text{(Eq. 24)}$$

or:

$$k = \frac{m_T - dm - x_F}{(m_{M_T} - m_T + dm + x_F)\left(\frac{x_F}{V_0 - dv}\right)} \quad \text{(Eq. 25)}$$

The intrinsic binding constants before and after eliminating free ligand concentration must be equal. This is the case if:

$$\frac{m_F}{V_0} = \frac{x_F}{V_0 - dv} = \frac{dm}{dv} \quad \text{(Eq. 26)}$$

i.e., the free ligand concentrations before and after ultrafiltration are identical. This is also true for complex formation in general. In the equation, $r = nkF/(1 + kF)$ (18, 23, 37, 38), nk and F are constants, then r, the amount of bound ligand per mole of macromolecule, should also be constant.

The results from Fig. 3, were calculated according to Eqs. 21 and 22 (Table II). The results are given before and after the removal of a volume fraction. The molarity of povidone (Col. 4), as well as the total (Col. 5), and bound (Col. 7) ligand concentrations increase according to Eqs. 21 and 22, while the free ligand concentration (Col. 6) and r, the mole bound ligand/macromolecule ratio remain constant (Col. 8). Consequently, the results correspond to Eq. 26.

Using somewhat different calculations, the same conclusions were found in a study of the binding of manganese to concanavalin A (45). In the first aliquots (to ~2 mL), the free ligand concentrations are somewhat lower than in the following aliquots, resulting in an overestimation of B (Fig. 3 and Table II). This effect was also noted in experiments with other ligand molecules. This observation must be attributed to a dilution effect of the membrane, which is immersed in a buffer solution before use. Therefore, the first sample must always be eliminated to obtain correct values of B and F. We can conclude that the experiments are in accordance with the treatment of a macromolecular solution as a pseudo two phase as well as a monophase model.

Another important conclusion can be made. Some authors consider ultrafiltration as suspect due to changes in the macromolecular concentration during the experiment which disturb the binding equilibrium (46). The use of small aliquots of filtrate should overcome this objection (47, 48). Indeed, binding equilibrium is disturbed by removing small aliquots of filtrate, but the intrinsic binding constant must be a constant. From Eq. 26 it is seen that this is the case if free ligand concentrations are identical before and after ultrafiltration, whatever the volume fraction of filtrate taken; therefore, it is not necessary to take small aliquots of filtrate.

Indeed, since the free ligand concentration in the filtrate was constant, regardless of the volume fraction of filtrate taken, the concentration of bound ligand is also unchanged since it is calculated by subtracting the free from the total ligand concentration. The treatment of macromolecular solutions as a pseudo two phase is also generally applicable if Eqs. 3 and 5 are fulfilled.

It is expected that the treatment of a macromolecule solution as a pseudo two phase and calculation of partition coefficient (Kd) will have advantages over the theory of complex formation and will be useful to study and interpret complex formation between macromolecules and ligand molecules as a function of the pK_a and dissociation of the ligand and the pH of the solvent. This investigation will be reported in a following paper.

Improved Competitive Indicator Methods for the Study of α-Cyclodextrin Complexes

DAVID D. PENDERGAST * and KENNETH A. CONNORS ˣ

Received January 6, 1984, from the *School of Pharmacy, University of Wisconsin, Madison, WI 53706.* Accepted for publication March 9, 1984. • Present address: The Upjohn Company, Kalamazoo, MI 49001.

Abstract □ The competitive indicator method for studying molecular complexes is extended to systems forming 1:1 (SL) and 1:2 (SL_2) complexes of substrate (S) and ligand (L). A modification is described for slightly soluble substrates, in which the presence of solid substrate establishes a constant concentration of uncomplexed substrate. These methods are applied to complexes of α-cyclodextrin with some aromatic substrates, with methyl orange as the indicator in acid solution; nitrazine yellow is introduced as an indicator for these studies in basic solution.

Keyphrases □ α-Cyclodextrin—competitive indicator methods, methyl orange, nitrazine yellow □ Competitive indicator methods—α-cyclodextrin, methyl orange, nitrazine yellow complexes

The cyclodextrins are naturally occurring cyclic oligosaccharides possessing a central cavity into which smaller molecules may "partition," forming noncovalently bonded inclusion complexes. The physical and chemical properties of the included molecule (the substrate or guest) may be altered by complexation with the cyclodextrin (the ligand or host). This phenomenon has attracted much recent attention, in part because of its potential applications in drug dosage forms (1–3). Among the properties of a drug that can be affected by cyclodextrin complexation are its solubility, dissolution rate, chemical stability, and bioavailability.

Systematic studies in this laboratory have been designed to provide information on the stoichiometry and thermodynamic stability of cyclodextrin complexes, with the goal of understanding structure-stability relationships and thus developing predictive capability. It has been necessary, in these studies, to make use of several experimental techniques for the measurement of complex stability constants and in some instances to develop new methods. One technique that has been found useful is the so-called "competitive indicator" method. In this technique, an equilibrium is established between the ligand (cyclodextrin) and an indicator whose absorption spectrum differs significantly in its complexed and uncomplexed forms. This equilibrium is then perturbed by the addition of a substrate, which competes with the indicator for the ligand. By measuring the spectral change produced by this perturbation, the stability constant for the substrate–ligand complex can be deduced. The methyl orange–α-cyclodextrin equilibrium was exploited in this way by Broser and co-workers (4) to study the adrenalin–α-cyclodextrin complex and by Casu and Ravà (5) to study a series of substituted benzoic acids. The method was recently improved in this laboratory and was applied to the study of the α-cyclodextrin complexes of some phenols (6). All of these applications have made use of methyl orange as the indicator in acidic solution and have been limited to the study of 1:1 complexes between substrate and ligand.

Our most recent work has required three new capabilities of the competitive indicator method: (*a*) that it be applicable to systems containing both 1:1 (SL) and 1:2 (SL_2) complexes, where S and L represent substrate and ligand respectively; (*b*) that it be applicable to slightly soluble substrates; (*c*) that it be applicable in alkaline medium. The present paper describes extensions to the theory and practice of the method that permit its application in these circumstances.

THEORETICAL SECTION

Standard Competitive Indicator Method—Attention is restricted to systems containing a 1:1 complex IL of indicator I with ligand plus the 1:1 (SL) and 1:2 (SL_2) complexes of substrate with ligand. The average number of ligand molecules bound per substrate molecule ($\bar{n}$) is:

$$\bar{n} = \frac{\Sigma(\text{L bound to S})}{\Sigma(\text{all S})} \qquad \text{(Eq. 1)}$$

The mass balance equations for S and L are:

$$S_t = [S] + [SL] + [SL_2] \qquad \text{(Eq. 2)}$$

$$L_t = [L] + [SL] + 2[SL_2] + [IL] \qquad \text{(Eq. 3)}$$

where S_t and L_t are the (known) total concentrations of substrate and ligand. Further define the quantity P as Σ (L bound to S) can be defined by:

$$P = [SL] + 2[SL_2] = L_t - [L] - [IL] \qquad \text{(Eq. 4)}$$

Combining Eqs. 1, 3, and 4:

$$\bar{n} = \frac{P}{S_t} \qquad \text{(Eq. 5)}$$

The equilibrium constants in this system are given by:

$$K_{11} = \frac{[SL]}{[S][L]} \qquad \text{(Eq. 6)}$$

$$K_{12} = \frac{[SL_2]}{[SL][L]} \qquad \text{(Eq. 7)}$$

$$K_I = \frac{[IL]}{[I][L]} \qquad \text{(Eq. 8)}$$

Combining Eqs. 5, 6, and 7 yields:

Improved Competitive Indicator Methods for the Study of α-Cyclodextrin Complexes

DAVID D. PENDERGAST * and KENNETH A. CONNORS ˣ

Received January 6, 1984, from the *School of Pharmacy, University of Wisconsin, Madison, WI 53706.* Accepted for publication March 9, 1984. • Present address: The Upjohn Company, Kalamazoo, MI 49001.

Abstract □ The competitive indicator method for studying molecular complexes is extended to systems forming 1:1 (SL) and 1:2 (SL_2) complexes of substrate (S) and ligand (L). A modification is described for slightly soluble substrates, in which the presence of solid substrate establishes a constant concentration of uncomplexed substrate. These methods are applied to complexes of α-cyclodextrin with some aromatic substrates, with methyl orange as the indicator in acid solution; nitrazine yellow is introduced as an indicator for these studies in basic solution.

Keyphrases □ α-Cyclodextrin—competitive indicator methods, methyl orange, nitrazine yellow □ Competitive indicator methods—α-cyclodextrin, methyl orange, nitrazine yellow complexes

The cyclodextrins are naturally occurring cyclic oligosaccharides possessing a central cavity into which smaller molecules may "partition," forming noncovalently bonded inclusion complexes. The physical and chemical properties of the included molecule (the substrate or guest) may be altered by complexation with the cyclodextrin (the ligand or host). This phenomenon has attracted much recent attention, in part because of its potential applications in drug dosage forms (1–3). Among the properties of a drug that can be affected by cyclodextrin complexation are its solubility, dissolution rate, chemical stability, and bioavailability.

Systematic studies in this laboratory have been designed to provide information on the stoichiometry and thermodynamic stability of cyclodextrin complexes, with the goal of understanding structure-stability relationships and thus developing predictive capability. It has been necessary, in these studies, to make use of several experimental techniques for the measurement of complex stability constants and in some instances to develop new methods. One technique that has been found useful is the so-called "competitive indicator" method. In this technique, an equilibrium is established between the ligand (cyclodextrin) and an indicator whose absorption spectrum differs significantly in its complexed and uncomplexed forms. This equilibrium is then perturbed by the addition of a substrate, which competes with the indicator for the ligand. By measuring the spectral change produced by this perturbation, the stability constant for the substrate–ligand complex can be deduced. The methyl orange–α-cyclodextrin equilibrium was exploited in this way by Broser and co-workers (4) to study the adrenalin–α-cyclodextrin complex and by Casu and Ravà (5) to study a series of substituted benzoic acids. The method was recently improved in this laboratory and was applied to the study of the α-cyclodextrin complexes of some phenols (6). All of these applications have made use of methyl orange as the indicator in acidic solution and have been limited to the study of 1:1 complexes between substrate and ligand.

Our most recent work has required three new capabilities of the competitive indicator method: (*a*) that it be applicable to systems containing both 1:1 (SL) and 1:2 (SL_2) complexes, where S and L represent substrate and ligand respectively; (*b*) that it be applicable to slightly soluble substrates; (*c*) that it be applicable in alkaline medium. The present paper describes extensions to the theory and practice of the method that permit its application in these circumstances.

THEORETICAL SECTION

Standard Competitive Indicator Method—Attention is restricted to systems containing a 1:1 complex IL of indicator I with ligand plus the 1:1 (SL) and 1:2 (SL_2) complexes of substrate with ligand. The average number of ligand molecules bound per substrate molecule ($\bar{n}$) is:

$$\bar{n} = \frac{\Sigma(\text{L bound to S})}{\Sigma(\text{all S})} \qquad \text{(Eq. 1)}$$

The mass balance equations for S and L are:

$$S_t = [S] + [SL] + [SL_2] \qquad \text{(Eq. 2)}$$

$$L_t = [L] + [SL] + 2[SL_2] + [IL] \qquad \text{(Eq. 3)}$$

where S_t and L_t are the (known) total concentrations of substrate and ligand. Further define the quantity P as Σ (L bound to S) can be defined by:

$$P = [SL] + 2[SL_2] = L_t - [L] - [IL] \qquad \text{(Eq. 4)}$$

Combining Eqs. 1, 3, and 4:

$$\bar{n} = \frac{P}{S_t} \qquad \text{(Eq. 5)}$$

The equilibrium constants in this system are given by:

$$K_{11} = \frac{[SL]}{[S][L]} \qquad \text{(Eq. 6)}$$

$$K_{12} = \frac{[SL_2]}{[SL][L]} \qquad \text{(Eq. 7)}$$

$$K_I = \frac{[IL]}{[I][L]} \qquad \text{(Eq. 8)}$$

Combining Eqs. 5, 6, and 7 yields:

0022-3549/84/1200-1779$01.00/0
© 1984, American Pharmaceutical Association

$$\bar{n} = \frac{K_{11}[L] + 2K_{11}K_{12}[L]^2}{1 + K_{11}[L] + K_{11}K_{12}[L]^2} \quad \text{(Eq. 9)}$$

Equation 9 is the classical expression for the Bjerrum formation function, which occurs in the study of metal ion coordination complexes. It can be rearranged into the linear plotting form (7, 8):

$$\frac{\bar{n}}{(1-\bar{n})[L]} = K_{11} + K_{11}K_{12}[L]\frac{(2-\bar{n})}{(1-\bar{n})} \quad \text{(Eq. 10)}$$

To use Eq. 10, the quantities $\bar{n}$ and [L] are needed. These are obtained by spectrophotometric measurements at a wavelength at which the indicator absorbs light, but neither the substrate nor the ligand absorbs.

The ratio [I]/[IL] is labeled Q; this quantity is evidently inversely proportional to the free ligand concentration:

$$Q = \frac{[I]}{[IL]} = \frac{1}{K_I[L]} \quad \text{(Eq. 11)}$$

Combination of a mass balance on the indicator with Eqs. 4 and 8 gives:

$$P = L_t - \frac{1}{QK_I} - \frac{I_t}{Q+1} \quad \text{(Eq. 12)}$$

where I_t is the total indicator concentration. Moreover, Q is experimentally measurable by use of Eq. 13, where ϵ_I and ϵ_{IL} are the molar absorptivities of the indicator in the uncomplexed and complexed forms, respectively, and ϵ is the apparent molar absorptivity in a solution containing both forms:

$$Q = \frac{\epsilon - \epsilon_{IL}}{\epsilon_I - \epsilon} \quad \text{(Eq. 13)}$$

Thus, $\bar{n}$ can be experimentally measured. These symbols were introduced to achieve consistency with the earlier development (6); Eq. 10 becomes:

$$\frac{PQK_I}{S_t - P} = K_{11} + \frac{K_{11}K_{12}}{K_I} \cdot \frac{1}{Q} \cdot \frac{(2S_t - P)}{(S_t - P)} \quad \text{(Eq. 14)}$$

P and Q can be measured, S_t is known, and K_I can be determined in a separate experiment, so the stability constants K_{11} and K_{12} can be obtained from the slope and intercept of a plot according to Eq. 14. If $K_{12} = 0$, the slope of this line will be zero, and a simpler plotting form, Eq. 15, results, as was shown earlier (6).

$$\frac{S_t}{P} = 1 + \frac{K_I}{K_{11}}Q \quad \text{(Eq. 15)}$$

Solubility: Competitive Indicator Method— For substrates of low solubility, it is difficult to establish accurate values of S_t for use in the aforementioned competitive indicator method, and the following useful modification has been devised. The experiment is carried out by varying total ligand concentration, L_t, but by maintaining the free substrate concentration [S] constant at its saturation solubility S_o; this is accomplished by establishing the equilibria in the presence of solid substrate. Then Eq. 4 can be written:

$$P = K_{11}S_o[L] + 2K_{11}K_{12}S_o[L]^2 \quad \text{(Eq. 16)}$$

Substituting from Eq. 11 for [L] and rearranging gives:

$$\frac{PQK_I}{S_o} = K_{11} + \frac{2K_{11}K_{12}}{K_IQ} \quad \text{(Eq. 17)}$$

Thus, a plot of PQK_I/S_o against $1/Q$ should be linear.

This combined solubility-competitive indicator method can be extended to include systems in which a 1:1 substrate-indicator complex SI is formed, provided the stability constant, K_{SI}, can be independently measured and a wavelength can be selected such that the molar absorptivities of SI and I are equal. The analysis (9) shows that Eq. 17 remains applicable but Q and P must be evaluated by Eqs. 18 and 19, which may be compared with Eqs. 11 and 12.

$$Q = \frac{\epsilon - \epsilon_{IL}}{(\epsilon_I - \epsilon)(1 + K_{SI}S_o)} \quad \text{(Eq. 18)}$$

$$P = L_t - \frac{1}{K_IQ} - \frac{I_t}{1 + Q + QK_{SI}S_o} \quad \text{(Eq. 19)}$$

EXPERIMENTAL SECTION

Materials—α-Cyclodextrin[1] was dried for 3 h at 105°C. The methyl orange indicator was purified by the method of Lin and Connors (6). Nitrazine yellow indicator[2] (C.I. 14890) was recrystallized from water to a constant molar absorptivity of 4.045×10^4 at λ_{max} 588 nm; it was dried for 3 h at 105°C before use. Substrates were from commercial sources and were recrystallized before use (9). Buffer components were of reagent grade. Spectrophotometric[3] and pH[4] measurements were made at 25.0°C.

Procedures—*Measurement of* Q—Throughout a study, the total indicator concentration, I_t, is held constant; hence, absorptivities in Eq. 11 can be replaced by absorbances:

$$Q = \frac{A - A_{IL}}{A_I - A} \quad \text{(Eq. 20)}$$

A_I is readily measured in a solution of the indicator in the absence of ligand. A_{IL} is obtained as the product $\epsilon_{IL}I_t$; ϵ_{IL} is found as follows. In a solution containing only indicator and ligand, the mass balance on ligand is:

$$L_t = [L] + [IL] \quad \text{(Eq. 21)}$$

This, combined with Eq. 8 and the mass balance on indicator, gives:

$$[I] = \frac{I_t}{1 + K_I[L]} \quad \text{(Eq. 22)}$$

An iterative process is used. First, the assumption is made that $[L] = L_t$, and Eq. 22 is solved for [I] (making use of an independently measured value of K_I). Then, [IL] is found from the mass balance $I_t = [I] + [IL]$, and this is used in Eq. 21 to produce a refined estimate of [L]. This process is repeated until no change in [L] is noted in the fourth decimal place. The absorbance of the solution (path length = 1 cm) is $A = \epsilon_I[I] + \epsilon_{IL}[IL]$, hence:

$$\epsilon_{IL} = \frac{A - \epsilon_I[I]}{[IL]} \quad \text{(Eq. 23)}$$

This provides the information necessary to evaluate Q with Eq. 20.

Standard Method—Methyl orange studies were conducted in 0.10 M HCl, whereas nitrazine yellow studies were carried out in 0.05 M Tris buffer at pH 9.2 with the ionic strength adjusted to 0.10 M with NaCl. Portions of stock solutions of indicator, substrate, and ligand were added to 10-mL volumetric flasks to produce a series of solutions having constant indicator concentration ($2\text{-}4 \times 10^{-5}$ M) with substrate and ligand concentration varying as required by optimization considerations (to be described). In some instances, the substrate and ligand were weighed directly into the flasks. After equilibration of the solutions at 25.0°C, the absorbances were measured at the wavelength of maximal spectral shift.

Solubility Method—Indicator solutions containing varied ligand concentrations were prepared in 10-mL volumetric flasks. Each of these was transferred to a 15.5-mL vial containing solid substrate (in excess of its total solubility). After the vials were sealed, they were rotated end-over-end at 32 rpm in a 25.0°C water bath for 24 h. They were then placed upright in the 25°C bath for time sufficient for the solid substrate to settle. The clear solution was aspirated and its absorbance was measured at 25°C.

Data Treatment—Equations 14, 15, and 17 are linear, and the slopes and intercepts of these plots were obtained by conventional linear least-squares analysis. The variances of the stability constant estimates were then found by a propagation of errors treatment (9). Although in each of these equations the variable playing the role of x, the "independent" variable, has measurable uncertainty associated with it, the y variable possesses greater uncertainty; hence, the usual linear regression treatment is suitable.

If treatment according to Eq. 14 showed that the slope was not significantly different from zero, then the data were analyzed by means of Eq. 15.

Optimization of Conditions—For a system containing only a 1:1 (SL) complex, the quantity $\bar{n} = P/S_t$ can range from 0 to 1, whereas for a system capable of forming both SL and SL_2, $\bar{n}$ can range from 0 to 2. Thus, $\bar{n}$ is a useful indication of the extent of the binding isotherm that has been examined. In a 1:1 system, $\bar{n}$ is equal to f_{11}, the fraction of substrate present as the 1:1 complex, but in a 1:1 + 1:2 system, $\bar{n} = f_{11} + 2f_{12}$.

From Eq. 14, it is clear that the quantity $(S_t - P)$ control the reliability of the plotting variables. Combining Eqs. 2 and 4 gives:

$$S_t - P = [S] - [SL_2] \quad \text{(Eq. 24)}$$

Thus, $(S_t - P)$ may be positive, zero, or negative, whereas $2S_t - P$ must be positive, as must the other variables and parameters in Eq. 14. Therefore, data points plotted according to Eq. 14 must lie in either the first or third quadrants, with the point at $S_t = P$ being indeterminate. Points in the first and third quadrants correspond to the conditions $\bar{n} < 1$ and $\bar{n} > 1$, respectively. In the present studies, all systems appeared in the first quadrant.

The experimental data consist of absorbance values, which are bounded

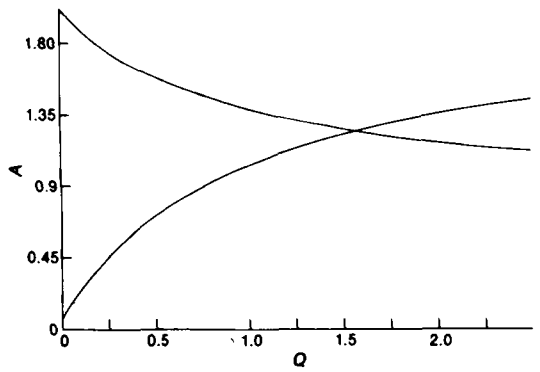

Figure 1—*Relationship between absorbance, A, and corresponding Q value (Eq. 20) for hypothetical indicator–α-cyclodextrin systems. Methyl orange (positive slope), $I_t = 4.17 \times 10^{-5}$ M; nitrazine yellow (negative slope), $I_t = 3.92 \times 10^{-5}$ M.*

by the limits A_I and A_{IL}. With Eq. 20 these are converted to Q values, which may range from 0 to ∞. The relationship between absorbance values, A, and corresponding Q values is shown in Fig. 1 for typical solutions of methyl orange and nitrazine yellow. At large Q values, the slope is so small that a small absorbance error results in a large error in Q. At low Q values, a small absorbance error results in a small absolute but large relative error in Q. These effects can be quantified by differentiating Eq. 20 to find dQ/dA. In the present work it was decided, for systems containing both 1:1 and 1:2 equilibria, to exclude data points having Q values outside the range 0.3–2.5.

According to Eq. 11, Q is uniquely related to free ligand concentration (for a given indicator). Thus, the limits placed on Q establish corresponding limits on [L]. To extend these limits in order to examine a greater range of the binding isotherm, it would be necessary to have available a series of indicators with different K_I values.

For a given indicator and substrate, each pair of plotting variables in Eq. 14 is associated with a unique Q ([L]), which may be realized by innumerable combinations of I_t, S_t, and L_t. It is necessary to limit these quantities to values that will give acceptable uncertainties in P and in $S_t - P$. This is done as follows:

1. Choose I_t such that A_I or A_{IL} (whichever is larger) ≈ 2.
2. Select a series of Q values in the 0.3–2.5 range and for each Q calculate the corresponding [L] with Eq. 11.
3. With preliminary estimates of K_{11} and K_{12}, calculate $\bar{n}$ values for each [L] value, using Eq. 9. Reject any systems giving $\bar{n}$ values ~ >0.7.
4. For each acceptable [L] value, choose L_t such that $L_t \geq 2[L]$. Calculate P with Eq. 12.
5. For each set of conditions, calculate S_t from $S_t = P/\bar{n}$.

Often it will be satisfactory to work with a fixed S_t and simply calculate the desired L_t levels from Eq. 25, which is obtained from Eqs. 5 and 12:

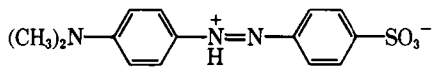
$$L_t = \bar{n}S_t + [L] + \frac{I_t}{Q+1} \qquad \text{(Eq. 25)}$$

S_t should be chosen such that $L_t \geq 2[L]$.

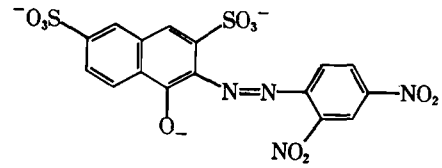
This procedure will result in data points in the first quadrant when plotted according to Eq. 14. All Q values will be in the desired range and the errors in P and $S_t - P$ will be acceptable. If the required S_t values exceed the solubility of the substrate, the solubility-competitive indicator method should be used.

RESULTS AND DISCUSSION

Indicator Properties.—A requirement of these competitive indicator methods is that the indicator must form only a 1:1 complex with the ligand. This imposes limits on acceptable indicator structures. However, indicator selection is greatly facilitated by adopting a point of view provided by a recently proposed binding site model of cyclodextrin complex formation (10, 11). To ensure only 1:1 complex formation, it is sufficient that the indicator possess only one potential binding site capable of entering the cyclodextrin cavity. For α-cyclodextrin, there is considerable evidence that uncharged substituents on an aromatic (benzene) ring, either *meta* or *para* to another group, can act as binding sites, but that charged groups have little affinity for the cavity. By inspection of indicator structures, it is therefore possible to identify likely candidates, and in this way nitrazine yellow was selected. Methyl orange has long been used (in strongly acid medium) (4). The structures of methyl orange (I) and nitrazine yellow (II) are shown:



I



II

A second requirement is that the indicator must exhibit a significant spectral change upon complexation with α-cyclodextrin. In Table I, the properties of these indicators pertinent to these studies are gathered. The K_I values were determined by a Benesi-Hildebrand treatment; the result for methyl orange is in excellent agreement with that reported by Lin and Connors (6). Several pieces of evidence are consistent with the assumption that nitrazine yellow forms only a 1:1 complex with α-cyclodextrin: (*a*) the K_I value is independent of wavelength; (*b*) there is a single isosbestic point (at 590 nm); (*c*) graphical treatment of a matrix of spectrophotometric data (12, 13) provides evidence

Table I—Properties of Indicators in Aqueous α-Cyclodextrin Solutions [a]

Stability Constant Results—These new modifications, consisting of the standard competitive indicator method for 1:1 + 1:2 systems, the solubility-competitive indicator method, and the introduction of nitrazine yellow as an indicator in basic media, were applied to the study of some substrates of interest in our systematic investigation of α-cyclodextrin complexation. The reference methods were UV spectrophotometry, potentiometry (11), and solubility (14, 15). Methyl orange was the indicator in studies (at pH 1.0) of 1,4-dimethoxybenzene, 4-nitrobenzoic acid, and 4-cyanobenzoic acid; nitrazine yellow (at pH 9.2) was employed to study the anions of benzoic, 3-nitrobenzoic, and 4-nitrobenzoic acids.

Table II lists the results. In basic medium, the carboxylate anions do not form 1:2 complexes, so the nitrazine yellow data were processed with Eq. 15. The systems studied with methyl orange in acidic medium showed both 1:1 and 1:2 complex formation, so Eqs. 14 and 17 were used. Figure 2 is a plot of Eq. 14, the standard competitive indicator method and Fig. 3 shows a plot of Eq. 17, the solubility-competitive indicator method. Table III compares the stability constants obtained by these competitive indicator methods with values obtained by other techniques. It is apparent that the competitive indicator approach is measuring the same quantity as the other methods. It must be pointed out that some of these systems, especially those in acidic media, are difficult to study, in part because of their limited solubilities. The 1,4-dimethoxybenzene system is especially interesting. The initial result on this system was obtained by the classical solubility method (14, 15), and it yielded the extremely unusual observation that $K_{12} > K_{11}$ (with rather large uncertainties in the stability constants). Application of the two new competitive indicator methods described in this paper gave results that were entirely consistent; this type of independent confirmation is useful. The only discordant result in Table III is K_{12} for 4-cyanobenzoic acid by the standard competitive indicator method. This is thought to be a consequence of the particular combination of the indicator and the substrate, possibly caused by the formation of a substrate-indicator complex. The low solubility of 4-nitrobenzoic acid did not permit a reliable application of the standard method, but preliminary results indicated behavior similar to that observed with 4-cyanobenzoic acid. Spectroscopic observations of more soluble benzoic acids in the presence of methyl orange showed small shifts in the spectrum of the indicator suggestive of the formation of complexes. It therefore seems possible that SI complexes may lead to systematic errors in methyl orange-substituted benzoic acid systems. The solubility competitive indicator method appears to be less susceptible to these errors.

CONCLUSIONS

These results have usefully extended the competitive indicator method to systems containing both 1:1 and 1:2 complexes. It may be noted that the theoretical basis is general, although the applications reported here were to complexes of α-cyclodextrin. Nitrazine yellow has been found effective for studies in alkaline solution.

The competitive indicator method will seldom be viewed as the "method of choice" when other techniques are available, for the following reasons. The addition of another complex former, namely the indicator, complicates the equilibrium system. In this system, the formation of the SL complex generates a perturbation whose observation provides information about K_{11}. The presence of complex SL_2 produces a further perturbation that gives an estimate of K_{12}. Thus, the information about K_{12} is a consequence of a perturbation

of a perturbation. Despite this limitation, the competitive indicator method has one notable feature that will often make it a valuable resource, namely, it allows observations to be made of a substrate whose own properties do not provide quantitative measures of complex formation; the indicator spectral change is a surrogate property.

Metabolism of Meperidine in Several Animal Species

S. Y. YEH

Received June 4, 1983, from the *National Institute on Drug Abuse, Addiction Research Center, Lexington, KY 40583.* Accepted for publication February 8, 1984. Present address: NIDA, P.O. Box 5180, Baltimore, MD 21224.

Abstract □ Four new meperidine metabolites were identified by GC–MS in the urine of rats, guinea pigs, rabbits, cats, and dogs. In addition to known meperidine metabolites, 4-ethoxycarbonyl-4-phenyl-1,2,3,4-tetrapyridine (dehydronormeperidine; IV, the *N*-hydroxydehydro derivative of normeperidine (X), the dihydroxy derivative of meperidine (XII), and the dihydroxy derivative of normeperidine (XIII) were identified. The possible role of the *N*-hydroxy derivative of normeperidine (IX) in the pharmacological interaction of meperidine (I) with MAO inhibitors, seen selectively in the rabbit (and humans), is discussed. Following the administration of the *p*-hydroxy derivative of meperidine (VII), the major metabolite was conjugated VII. Trace amounts of the *p*-hydroxy derivative of normeperidine (VIII), the methoxy hydroxy derivative of meperidine (XI), XII, and XIII also were detected as metabolites of VII. The degree of *N*-demethylation of VII, both *in vitro* and *in vivo*, was small.

Keyphrases □ Meperidine—TLC, GC–MS, identification of metabolites, interaction with monoamine oxidase inhibitors □ Monoamine oxidase inhibitors—metabolites of meperidine, TLC, GC–MS

Meperidine is extensively metabolized by humans and animals. The major metabolites of meperidine identified in the urine of rats, guinea pigs, dogs, and humans are normeperidine and (1-methyl-4-phenyl-4-piperidine carboxylic) and (4-phenyl-4-piperidine carboxylic) acids (1–12), while the minor metabolites are the *p*-hydroxy derivative of meperidine (5), the *N*-oxide of meperidine (5, 6), the methoxy hydroxy derivative of meperidine (7), and the *N*-hydroxy derivative of normeperidine (7). In the urinary excretion studies of meperidine and its metabolites [normeperidine, and (1-methyl-4-phenyl-4-piperidine carboxylic) and (4-phenyl-4-piperidine carboxylic) acid], the amount of each excreted by the rabbit was found to be low (16–53% of the administered dose) when compared with other species (13). Of this total, meperidine and normeperidine accounted for only ~0.4 and 4–8.5%, respectively, of the administered dose. The remainder of the dose excreted represented unidentified metabolites. Severe interaction between monoamine oxidase inhibitors (MAOI) and meperidine have been observed in rabbits and humans, but seldom observed in other species (14–16). The purpose of this study was to identify new metabolites in rabbits and other species which might contribute to the severe interaction of meperidine and MAOI observed in the rabbit. The metabolism of the *p*-hydroxy derivative of meperidine (VII) was also investigated in a preliminary study in the rat in an attempt to determine if VII is metabolized *in vivo* to VIII.

EXPERIMENTAL SECTION

Drugs—Meperidine hydrochloride[1], normeperidine hydrochloride[1], and the *p*-hydroxy derivative of meperidine[2] (5) were obtained commercially. The *N*-oxide of meperidine was synthesized as follows. Meperidine hydrochloride (200 mg) was dissolved in 2 mL of water, basified with ammonium hydroxide, and extracted with benzene. After removal of the solvent under reduced pressure, the residue was dissolved in 1 mL of absolute ethanol, and 1 mL of 30% H_2O_2 was added. The solution was heated in a water bath at 70°C for 2 h. At that time, TLC showed no starting material. The solution was transferred to a dish and evaporated to near dryness on a steam bath. The residue was dissolved in isopropyl alcohol and transferred to a 15-mL centrifuge tube. The solvent was removed under a stream of nitrogen, to give a white liquid. Ether was added to the residue to give a white precipitate. The mixture was refrigerated and centrifuged, and the liquid phase was transferred to another centrifuge tube. By repeating this treatment, two products were obtained: ether-soluble material and a white precipitate. The solid material was recrystallized from absolute ethanol to yield 18 mg of white crystals, mp 173–175°C. The solid material showed a single spot on TLC (R_f 0.37 and

0.40) after development with the respective solvent systems as stated below. Elemental analyses of the crystalline product showed: C, 58.18; H, 7.12; N, 4.90. The respective theoretical values for the derived *N*-oxide VI were: C, 68.44; H, 7.98; N, 5.32.

The solvent was removed under a stream of nitrogen to give 95 mg of a white oil. TLC of the oil on instant thin-layer chromatography (ITLC)[3] showed a single spot [R_f 0.70, ethyl acetate–ammonium hydroxide (17:1) or R_f 0.54, benzene–methanol–diethylamine (48:1:1)] and visualized by spraying with iodoplatinate reagent. Treatment with 10% sodium bisulfite solution of both the liquid and the crystalline materials gave meperidine as evidenced by TLC R_f values.

GC–MS identification of VI was performed by solid probe or by injection on a 0.9-m column packed with 3% OV-17 coated on 60/80-mesh Gas Chrom Q after treatment with or without trimethylsilylimidazole in pyridine. The MS of the aforementioned oil (solid probe) showed a molecular ion at *m/z* 264 (M + H), and ions at *m/z* 276 (M + CH_3), *m/z* 292 (M + C_2H_5), *m/z* 248 (M − O_2), *m/z* 246 (M − H_2O), and *m/z* 234, indicative of the *N*-oxide of meperidine. The MS of the aforementioned solid material, mp 173–175°C (solid probe) showed a molecular ion at *m/z* 246 (M + H), and ions at *m/z* 262 (M + CH_3), *m/z* 274 (M + C_2H_5), and *m/z* 232, indicative of 4-ethoxycarbonyl-1-methyl-4-phenyl-1,2,3,4-tetrahydropyridine, a thermal-dehydrated product of the *N*-oxide of meperidine. Landberg and Bogentoft (17) have synthesized 4-ethoxycarbonyl-1-methyl-4-phenyl-1,2,3,4-tetrahydropyridine, and compared its MS with that of VI. In addition, the MS of meperidine, *m/z* 248 (M + H), *m/z* 264 (M + CH_3), *m/z* 276 (M + C_2H_5), and *m/z* 234, 218, and 149, were also observed. This appears to indicate that VI underwent thermal decomposition and loss of an oxygen atom. Chromatograms of both the aforementioned oily and solid materials, treated with or without trimethylsilylimidazole and injected on the column, showed two peaks. The retention time and the MS of the major peak corresponded to meperidine. The minor peak showed the MS of 4-ethoxycarbonyl-1-methyl-4-phenyl-1,2,3,4-tetrahydropyridine. These observations confirmed the reports in the literature (6, 7, 17). The IR[4] of the oily VI showed strong bonds at 2970, 1710 (ester C=O), 1430, 1213 [N—O stretching as shown in 4-methylpyridine *N*-oxide (18)], 1182, and 1130 cm^{-1}. ^{1}H-NMR ($CDCl_3$)[4] of the oily VI showed peaks at δ 2.6, 4.6, 6.4, and 6.7 ppm. Mitchar *et al.* (6) reported that the NMR spectrum of VI showed a characteristic downfield shift of the CH_3 group from δ 7.7 ppm of meperidine base to δ 6.4 ppm due to the inductive influence of the oxygen atom. Due to the limited amount of the material, a boiling point was not measured. Phillipson *et al.* (19) have investigated *N*-oxide of morphine, codeine, and thebaine and observed that each alkaloid forms two *N*-oxides, which have been separated and characterized by NMR and MS and reduced to the parent alkaloid.

The *N*-hydroxy derivative of normeperidine (IX) was synthesized by oxidation of normeperidine with *m*-chloroperbenzoic acid (7, 20). TLC of the product [benzene–methanol–diethylamine (48:1:1), visualized by spraying with iodoplatinate or ammoniacal silver nitrate reagent] showed two spots, one with an R_f value (equal to 0.24) corresponding to that of authentic normeperidine. The other spot (R_f 0.44), a black spot after spraying with ammoniacal silver nitrate, was due to the *N*-hydroxy derivative of normeperidine. Chromatography of the product, treated with trimethylsilylimidazole and injected on a 0.9-m column packed with 3% OV-17 coated on 60/80-mesh Gas Chrom Q and column temperature programmed from 160°C to 250°C at 10°C min, showed two major peaks with several minor peaks. One of the major peaks had a retention time and MS corresponding to that of authentic normeperidine. The other major peak (R_f 4.5) had a molecular ion at *m/z* 322 (M + H), with ions at *m/z* 350 (M + C_2H_5), *m/z* 306 (M − CH_3), *m/z* 232 [M − $(CH_3)_3SiOH$], and *m/z* 214, indicative of IX (7). Attempts to purify the IX failed. The crude product was used qualitatively to identify IX in the biological fluids.

Animal Experiments—Collection of urine samples from rats, guinea pigs, rabbits, dogs, and cats administered meperidine (20–35 mg/kg) has been described (13). The *p*-hydroxy derivative of meperidine (40 mg/kg sc) was administered to one rat (250 g), and urine was collected from a stainless steel metabolism cage for 24 h. All urine was frozen until drug analysis.

Extraction of Meperidine, the *p*-Hydroxy Derivative of Meperidine, and Their Metabolites—Meperidine, VII, and their metabolites were extracted from urine according to described procedures (20). On evaporation of the extract to dryness, the residues were used for TLC and GC–MS studies. For GC–MS studies, the residue was derivatized with trimethylsilylimidazole in pyridine[5] according to the procedure described previously (21).

Hydrolysis of Conjugated Meperidine Metabolites—Aliquots (0.5–2 mL) of urine samples were adjusted to pH 6 with acetic acid, buffered with 0.5 mL of 0.5 M sodium acetate buffer at pH 4.8, and incubated with 50 μL a solution of 9725 U of β-glucuronidase–4210 U of sulfatase[6] at 37°C for 18–20 h. After incubation, the solution was adjusted to pH 9–10 with sodium hydroxide solution, buffered with 0.1 mL of concentrated ammonium hydroxide, and extracted with ether as described previously (20).

Thin-Layer Chromatography—TLC identification of meperidine and its metabolites was by silica gel pre-coated TLC plates[7]. The chromatograms were developed with benzene–methanol–diethylamine (48:1:1) and visualized by spraying with ammoniacal silver nitrate solution for detection of IX or developed with ethyl acetate–methanol–ammonium hydroxide (17:2:1) and sprayed with iodoplatinate reagent for detection of I, II, VII, and VI (20).

Gas Chromatography–Mass Spectrometry—Chemical-ionization MS data were obtained from a gas chromatograph–mass spectrometer[8] equipped with an interactive data system[9]. The GC column consisted of a 91 cm × 2 mm glass column packed with 3% OV-17 coated on 80/100-mesh Gas Chrom Q. The temperature of the injector and ion source were 160°C and 100°C, respectively. Two temperature programs were employed: hold at 150°C for 3.33 min, followed by programming to 250°C at 6°C/min (referred to as column A) and program from 160°C to 250°C at 10°C/min (referred to as column B). Methane, with a flow rate giving an ion chamber pressure of ~1000 μm, was used as the carrier gas as well as the chemical-ionization reagent gas in the ion source. Other specifications of the MS were described elsewhere (21).

Drug and metabolites were identified by comparison of spectra with authentic standards. Other metabolites (Scheme I) were tentatively assigned structures based on MS.

RESULTS AND DISCUSSION

Thin-Layer Chromatographic Identification of Meperidine Metabolites—The limit of detection of I, II, VI, VII, and IX by TLC was ~10–25 μg/sample. In general, meperidine was found in the urinary extracts of all species studied, except the rabbit. Normeperidine was found in the urine of the rat and guinea pig, but not in the urine of the rabbit, cat, and dog. Metabolites VI and VII were not observed by TLC analysis.

TLC of extracts of rabbit urine visualized with ammoniacal silver nitrate solution showed two black spots with R_f values of 0.50 and 0.44, whereas that of a dog showed one black spot, R_f 0.50. The spot at R_f 0.50 corresponds to

Table I—TLC Identification of Meperidine Metabolites in the Urine of Several Species [a]

Compounds	R_f
I	0.78
II	0.33
VI	0.03
VII	0.17
IX	0.50
Extracts from urine	
Rat	0.78, 0.33
Guinea pig	0.78, 0.33
Rabbit	0.50, 0.44
Cat	0.78
Dog	0.78, 0.50

[a] Quantum Industries, Fairfield, N.J. Chromatogram was developed with benzene–methanol–diethylamine (48:1:1), or ethyl acetate–methanol–ammonium hydroxide (17:2:1).

that of authentic IX. The other spot was possibly due to X (detailed in the GC–MS identification). Metabolite IX was not seen in the TLC analysis of the urine of the rat, guinea pig, and cat (Table I).

Gas Chromatographic–Mass Spectrometric Identification of Meperidine Metabolites—Chemical-ionization GC–MS characteristics of peaks observed in the urinary extracts are compared with known standards, and previously unidentified peaks were assigned to new metabolites (Table II). Meperidine metabolites, the number of times the metabolite was identified, and the number of urine samples examined are listed in Table III.

Identification of Metabolites of Meperidine—Meperidine (I) and metabolites [*i.e.*, II, VI (detected as its thermal decomposition product, 4-ethoxycarbonyl-1-methyl-4-phenyl-1,2,3,4-tetrahydropyridine), IX, and VII (as the trimethylsilyl derivatives)] were identified in urine samples by comparison of retention times and spectra with authentic materials. The *N*-hydroxy metabolite of normeperidine was detected in urine samples only after enzymatic hydrolysis, suggesting that this material is excreted only in the conjugated form. In addition to the known metabolites, some new metabolites of meperidine were tentatively identified.

4-Ethoxycarbonyl-4-phenyl-1,2,3,4-tetrahydropyridine (Dehydronormeperidine) (IV)—This metabolite appeared at 3.75 min in the chromatogram of the extract of rabbit urine. The MS of the metabolite contains a pseudomolecular ion at *m/z* 232 (M + H) and ions at *m/z* 260 (M + C_2H_5), *m/z* 186 (232 − C_2H_5OH), and *m/z* 158 (232 − C_2H_5OH − CO). Also, the retention time of this metabolite bears the same relationship to normeperidine as does dehydromeperidine to meperidine. This metabolite was detected in all urine samples except those of the female rat, cat, and guinea pig (Table III). Based on the structure of the *N*-hydroxy derivative of normeperidine, the olefinic bond of dehydronormeperidine was arbitrarily assigned to positions 2 and 3.

Formation of dehydronormeperidine *in vivo* could occur either through the dehydration of the *N*-hydroxy derivative of normeperidine, observed to be a major metabolite in the urine of the rabbit, or by dehydration of the 2-hydroxy or 3-hydroxy derivatives of normeperidine. *In vivo* formation of the latter metabolites is plausible since analogues of these metabolites [the 2-hydroxy-*N*-nitro derivative of piperidine, a metabolite of the *N*-nitro derivative of piperidine (22) and the 3-hydroxy and 4-hydroxy derivatives of piperidine, major metabolites of piperidine in the rat (23)] have been reported. Formation of dehydronormeperidine by dehydration of the *N*-hydroxy derivative of normeperidine during GC–MS was considered possible; however, this was ruled out since the *N*-hydroxy derivative of dehydronormeperidine also has been observed in the urine (see below). If dehydronormeperidine is formed by dehydration of the *N*-hydroxy derivative of normeperidine, then the *N*-hydroxy derivative of dehydronormeperidine should not be detected.

N-Hydroxy Derivative of Dehydronormeperidine (X)—In the GC–MS analysis of rabbit urine, this metabolite (as the trimethylsilyl derivative) appeared at 5.2 min (Fig. 1). The MS of the metabolite shows a molecular ion at *m/z* 320 with abundant ions at *m/z* 348 (M + C_2H_5), *m/z* 304 (M − CH_3), *m/z* 246 (320 − C_2H_5OH − CO), *m/z* 230 [320 − $(CH_3)_3SiOH$], *m/z* 202 (230 − C_2H_4), and *m/z* 156 [246 − $(CH_3)_3SiOH$]. This metabolite was not detected in the urine without enzymatic hydrolysis, suggesting that the metabolite exists only in the conjugated form. Formation of the *N*-hydroxy de-

Table II—Chemical Ionization GC–MS Characteristics of Peaks Observed in the Urinary Extracts

Compound	Retention Time (R_t), min[a] Column A	Column B	Ions, *m/z*[b] Molecular $(m + H)^+$	Fragment $(m + C_2H_5)^+$	Fragment $(m - CH_3)^+$	Others
I	2.0	1.1	248(100)	276(15)		174(10)

Female	1/1	1/1	1/1	1/1	1/1	1/1	1/1	1/1	0/1	0/1

[a] Number of times the metabolite was detected/number of urine samples examined. [b] Not examined.

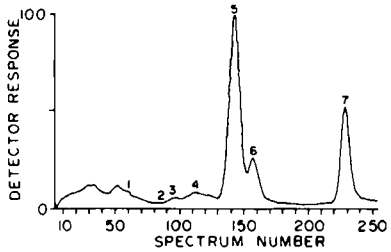

Figure 1—*GC-MS analysis of the extract of enzymatic hydrolyzed urine of a rabbit administered meperidine. The chromatogram was obtained using column A (see Table II). Key: (1) I; (2) VI; (3) II; (4) IV; (5) IX; (6) XV; (7) VII.*

rivative of dehydronormeperidine may be through *N*-hydroxylation of dehydronormeperidine.

p-*Hydroxy Derivative of Normeperidine* (*VIII*)—This metabolite (as the trimethylsilyl derivative) has the same molecular ion as the trimethylsilyl derivative of the *N*-hydroxy derivative of normeperidine, but the mass spectral characteristics and retention time (R_t = 4.5 min) are different. The MS of this peak showed a molecular ion at *m/z* 322 (M + H) and ions at *m/z* 350 (M + C_2H_5), *m/z* 306 (M − CH_3), *m/z* 248 (322 − C_2H_5OH − CO), and *m/z* 212. Since the retention time of this material is longer than that of the *p*-hydroxy derivative of meperidine, and *p*-hydroxylation of aromatic rings is a predominant metabolic pathway for this type of compound, it is reasonable to assume that this material is VIII. It is reasonable to assume that the hydroxyl group is in the *para* position based on the isolation of the *p*-hydroxy derivative of meperidine from urine (5).

The *in vitro* synthesis of VIII for use as a standard was attempted by incubating VII with rat liver homogenate and the NADPH-generating system used for *N*-demethylation of meperidine (24). After incubation, the medium was pooled, adjusted to pH 10 with sodium hydroxide solution, buffered with 1 mL of 40% K_2HPO_4 solution, and extracted. The extracted residue was dissolved in methanol and chromatographed on TLC. No spots other than those of VII and NADP were observed.

Biosynthesis of VIII has also been attempted without success by administration of VII to a rat. An aliquot of the urine of rat administered VII was hydrolyzed with β-glucuronidase-sulfatase[6] and extracted. The residue was derivatized with trimethylsilylimidazole and analyzed by GC-MS. No peak corresponding to VIII was observed.

Dihydroxy Derivative of Meperidine (*XII*)—The integrated total-ion-current chromatogram obtained by column B was scanned for *m/z* 424 the molecular ion of XII (as the trimethylsilyl derivative). A peak was localized at retention time 4.8 min (Fig. 2). The MS of this peak represents a mixture of at least two, probably three compounds, including XII and VIII both as the trimethylsilyl derivatives. The MS showed a molecular ion at *m/z* 424 (M + H) and ions at *m/z* 452 (M + C_2H_5) and *m/z* 408 (M − CH_3), which were tentatively identified as XII as the trimethylsilyl derivative. The formation of XII could result from oxide formation and hydroxylation of both the aromatic and piperidyl rings of the meperidine molecule. Based on the MS, it is difficult to assign positions to the hydroxyl groups in XII; however, *in vitro* hydroxylation of other opiates and phenolic compounds leads to *meta-para* hydroxylation (25). The MS showed a molecular ion at *m/z* 322 (M + H) and ions at *m/z* 350 (M + C_2H_5) and *m/z* 306 (M − CH_3), identified as VIII as the trimethylsilyl derivative. The MS also showed a molecular ion at *m/z* 234 (M + H) and ions at *m/z* 262 (M + C_2H_5) and *m/z* 248 (M − CH_3), which appear to be from normeperidine.

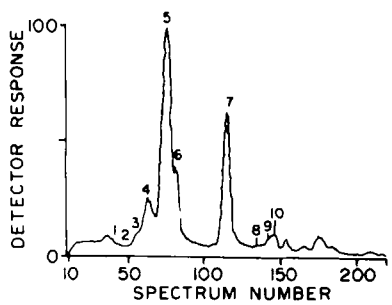

Figure 2—*GC-MS analysis of the extract of enzymatic hydrolyzed urine of a rabbit administered meperidine. The chromatogram was obtained using column B (see Table II). Key: (1–7) as in Fig. 1 legend; (8) VIII; (9) XII; (10) XI and XIII.*

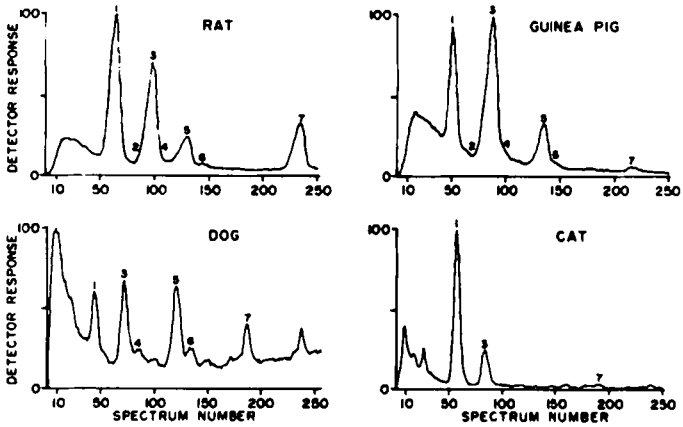

Figure 3—*GC-MS analysis of the extract of enzymatic hydrolyzed urine samples of animals administered meperidine, obtained using column A. The peaks are as listed in Fig. 1.*

Dihydroxy Derivative of Normeperidine (*XIII*) *and Methoxy Hydroxy Derivative of Meperidine* (*XI*)—The integrated total-ion-current chromatogram was scanned for *m/z* 410, indicative of XIII as the trimethylsilyl derivative. A peak with retention time at 5.0 min was located which overlapped another metabolite. One is due to XIII as the trimethylsilyl derivative, which has molecular ion at *m/z* 410 (M + H) and ions at *m/z* 438 (M + C_2H_5) and *m/z* 320 [410 − $(CH_3)_3SiOH$]. The other is due to XI as the trimethylsilyl derivative, which has molecular ion at *m/z* 366 (M + H) and ions at *m/z* 394 (M + C_2H_5) and *m/z* 350 (M − CH_3).

Formation of XI could result from hydroxylation to form a catechol, followed by methylation with catechol methyltransferase. Evidence for this metabolic pathway has been demonstrated *in vitro* for opiates and other phenolic compounds (25) and *in vivo* for naltrexone (26, 27).

Although the position of the hydroxyl and methoxy groups could not be assigned based on the MS, a reasonable assignment could be made based on the structure of the methoxy hydroxy derivative of naltrexone (isolated from urine), whose structure is secure (26). Therefore, it is reasonable to assign the structure for XI as illustrated in Scheme I.

Based on the ratio of meperidine to its metabolites observed in the total-ion-current chromatogram, it appears that IX was a major metabolite in the rabbit, while normeperidine was found in minor amounts (Fig. 1). On the other hand, normeperidine was found to be a major metabolite in the other species studied, while IX was minor (Fig. 3). As mentioned previously, severe interaction between MAOI and meperidine has been observed in humans and rabbits, but has seldom been observed in other species. The role of IX in the interaction between MAOI and meperidine observed in rabbits is not well understood.

Other major metabolites of meperidine, the corresponding free and conjugated carboxylic acids of V and III (4, 13), are not extracted by the assay used here.

Identification of Metabolites of the *p*-Hydroxy Derivative of Meperidine in the Urine of the Rat—The integrated total-ion-current chromatogram and MS of the extract (as the trimethylsilyl derivative) of an enzymatically hydrolyzed urine sample of a rat administered VII are shown in Fig. 4. The chromatogram showed a major peak and several small peaks. The retention time and MS of the major peak correspond to that of VII as the trimethylsilyl derivative. Minor metabolites of VII were also identified.

p-*Hydroxy and Dihydroxy Derivatives of Normeperidine*—The peak with retention time at 4.7 min was apparently due to a mixture of the *p*-hydroxy and dihydroxy derivatives of normeperidine, both as the trimethylsilyl derivatives (Fig. 4). The MS with a molecular ion at *m/z* 322 (M + H) and ions

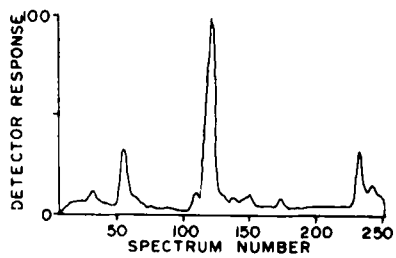

Figure 4—*GC-MS analysis of the extract of enzymatic hydrolyzed urine of a rat administered VII, obtained using column A. The peaks were identified as VII, VIII and XIII, and XI and XII.*

at m/z 350 (M + C_2H_5), m/z 306 (M − CH_3), m/z 276 (322 − C_2H_5OH), and m/z 248 (322 − C_2H_5OH − CO) was attributed to VIII as the trimethylsilyl derivative. The MS with a molecular ion at m/z 410 (M + H) and ions at m/z 438 (M + C_2H_5) and m/z 394 (M − CH_3) was attributed to XIII as the trimethylsilyl derivative. The concentration of XIII was low but detectable. Formation of VIII was apparently through *N*-demethylation of VII. Compound XIII appears to be formed *in vivo* by hydroxylation of VIII.

Methoxy Hydroxy and Dihydroxy Derivatives of Meperidine -The peak with retention time at 5.0 min was apparently due to a mixture of XI and XII, both as the trimethylsilyl derivatives (Fig. 4). The MS with a molecular ion at m/z 366 (M + H) and ions at m/z 394 (M + C_2H_5), m/z 350 (M − CH_3), and m/z 292 (366 − C_2H_5OH − CO) was attributed to XI as the trimethylsilyl derivative. The MS with a molecular ion at m/z 424 (M + H), and ions at m/z 452 (M + C_2H_5) and m/z 408 (M − CH_3) was attributed to XII as the trimethylsilyl derivative. Formation of XII and XI *in vivo* apparently occurs first by hydroxylation of VII and then by methylation of one of the hydroxyl groups. Evidence for this metabolic pathway has been mentioned above (26, 27).

Metabolites XII, VIII, XIII, and XI were not detected in the urine of rats administered either meperidine or VII without enzymatic hydrolysis, suggesting that these metabolites exist only in the conjugated form. The peak with retention time at 1.0 min has a MS with a molecular ion at m/z 306 (M + H) and ions at m/z 334 (M + C_2H_5) m/z 290 (M − CH_3), and m/z 232 (306 − C_2H_5OH − CO). The peak with retention time at 8 min showed a molecular ion at m/z 364 (M + H) and ions at m/z 392 (M + C_2H_5) and m/z 348 (M − CH_3). Peaks at 1.9, 3.6, 5.8, and 7.7 min were also observed in the extract of the control urine, indicating that these are due to natural urinary products and from the enzyme source.

N-Demethylation is a major metabolic pathway for biotransformation of meperidine, but plays only a minor role on the metabolism of VII. This is probably due to the fact that VII has a phenolic group available for conjugation. Conjugation has been shown to be a major metabolic pathway for compounds having both *N*-methyl tertiary amine and phenolic groups, such as morphine (28). In addition, *N*-demethylation of a compound depends on its lipid solubility, *N*-demethylation taking place to a greater degree with more lipid-soluble compounds (29). That the *p*-hydroxy derivative of meperidine (VII), a more polar compound than meperidine, would yield less of VIII than meperidine would yield normeperidine is understandable.

Biological Activity of the Hypolipidemic Agent, N^2-*n*-Butylindazolone

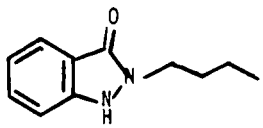
I. H. HALL ˣ, W. L. WILLIAMS, JR., S. D. WYRICK, and P. J. VOORSTAD

Received February 6, 1984, from the *Division of Medicinal Chemistry and Natural Products, School of Pharmacy, University of North Carolina at Chapel Hill, Chapel Hill, NC 27514.* Accepted for publication March 30, 1984.

Abstract □ Previously, a series of *N*-substituted indazolone derivatives proved to be effective hypolipidemic agents in rodents. The most effective agent, N^2-*n*-butylindazolone, at 20 mg/kg/d was shown to suppress the levels of cytoplasm acetyl coenzyme A required for cholesterol and fatty acid synthesis as well as *sn*-glycerol-3-phosphate acyl transferase and phosphatidate phosphohydrolase activities. Lipid content of the liver, small intestine, and serum lipoprotein fractions was lowered, whereas lipid content was increased in fecal excretions by drug treatment for 14 d. The absorption of orally administered cholesterol from the intestine was severely reduced after drug administration. The mode of action of N^2-*n*-butylindazolone appears to be similar to cyclic imides possessing hypolipidemic activity.

Keyphrases □ N^2-*n*-Butylindazolone—hypolipidemic activity in rodents, cholesterol and triglycerides reduction □ Antihyperlipidemic agents—N^2-*n*-butylindazolone, activity in rodents, cholesterol and triglycerides reduction

A series of *N*-substituted indazolone derivatives were previously screened for hypolipidemic activity in mice and were observed to be potent hypolipidemic agents at the low dose of 20 mg/kg/d (1). *N*-Substitutions of four carbon atom chain lengths in the indazolone (1) as well as in the phthalimide (2) and saccharin (2) series afforded the best hypolipidemic activity. Thus, N^2-*n*-butylindazolone (I) was selected for a more in-depth investigation of its effects on lipid synthesis and distribution in rodents.



I

EXPERIMENTAL SECTION

The N^2-*n*-butylindazolone was synthesized by the method of Schwartz *et al.* (3). The details of the synthesis and physical characteristics have been reported previously (1).

Antihyperlipidemic Screens in Normal Rodents—N^2-*n*-Butylindazolone was suspended in 1% carboxymethylcellulose–water, homogenized, and administered to CF_1 male mice (~25 g) intraperitoneally for 16 d or to Sprague–Dawley male rats (~350 g) orally by an intubation needle for 14 d. On days 9 and 14 or 16, blood was obtained by tail vein bleeding and the serum was separated by centrifugation for 3 min. The serum cholesterol levels were determined by a modification of the Liebermann–Burchard reaction (4). Serum was also collected on day 14 or 16 and the triglyceride content was determined by a commercial kit[1].

Testing in Hyperlipidemic Mice—CF_1 male mice (~25 g) were placed on a commercial diet[2] which produced a hyperlipidemic state. After the serum cholesterol and triglyceride levels were observed to be elevated, the mice were administered test drugs at 20 mg/kg/d intraperitoneally for an additional 14-d period. Serum cholesterol and triglyceride levels were measured.

Animal weights were obtained periodically during the experiments and were expressed as a percentage of the animal's weight on day zero. After dosing for 14 d with test drugs, selected organs were excised, trimmed of fat, and weighed.

The acute toxicity (LD_{50} values) (5) was determined in CF_1 male mice by administering test drugs at 100 mg–2 g/kg ip as a single dose. The number of deaths were recorded over a 7-d period for each group.

In vitro enzymatic studies were determined using 10% homogenates of CF_1 male mouse liver with 50–200 μM of test drug. *In vivo* enzymatic studies were determined using 10% liver homogenates (prepared in 0.25 M sucrose + 0.001 M ethylenediaminetetraacetic acid, pH 7.2) from CF_1 male mice obtained after administering the agents at a 10–60 mg/kg/d i.p. dose for 16 d. The enzyme activities were determined by following literature procedures (2) for: acetyl coenzyme A (CoA) synthetase (6); ATP-dependent citrate lyase (7); mitochondrial citrate exchange (8, 9); cholesterol side-chain oxidation (10); 3-hydroxy-3-methylglutaryl coenzyme A reductase (HMG CoA reductase) (11, 12); acetyl CoA carboxylase activity (13); fatty acid synthetase activity (14); *sn*-glycerol-3-phosphate acyl transferase activity (15); phosphatidate phosphohydrolase activity (16).

Rat Studies—In Sprague–Dawley rats that had been administered test drugs in 14 d, the liver, small intestine, and fecal materials (24-h collection) were removed, extracted (17, 18), and analyzed for cholesterol levels (4), triglyceride levels[3], neutral lipid content (19), and phospholipid content (20).

Sprague–Dawley rats (~400 g) were administered test agents for 14 d orally. On day 13, 10 μCi of [^{3}H]cholesterol was administered, orally in rats, and according to procedures described previously (2), tissue samples were combusted[4] or plated on filter paper, dried and digested for 24 h in base[5] at 40°C, and counted[6]. Results were expressed as disintegration/min (dpm) per total organ.

Sprague–Dawley rats (~400 g) were administered the test drug intraperitoneally for 14 d at 20 mg/kg/d. On day 13, 10 μCi of [1,2-^{3}H]cholesterol (40.7 Ci/mmol) was administered to the rat, orally. Twenty-four hours later, the blood was collected and the serum was separated by centrifugation (21).

Sprague–Dawley male rats (~350 g) were treated with test drugs at 20 mg/kg/d orally for 14 d. After anesthetizing the animal, the bile duct was cannulated as previously described (2). [1,2-^{3}H]Cholesterol (40.7 mCi/mmol) (10 μCi) was administered orally 18 h prior to commencing the surgery. The bile was collected over the next 6 h and the volume (mL) measured. Aliquots were counted[6] and analyzed for [^{3}H]cholesterol content (4).

Sprague–Dawley male rats (~350 g) were administered test drugs at 20 mg/kg/d orally. Blood was collected from the abdominal vein and lipoprotein fractions were obtained by the method of Hatch and Lees (22) and Havel *et al.* (23). Each fraction was analyzed for cholesterol (4), triglyceride[3], neutral lipids (19), phospholipids (20), and protein levels (24).

RESULTS

N^2-*n*-Butylindazolone proved to be a potent hypolipidemic agent in mice and rats after intraperitoneal and oral administration, respectively. In mice, the dose affording the maximal lowering effect was 20 mg/kg/d, reducing serum cholesterol 53% and serum triglyceride levels 56%. This dose was slightly less effective in rats, lowering the levels of cholesterol 44% and triglycerides 53% (Table I).

Examination of *in vitro* enzymatic activities in CF_1 mice (Table II) demonstrated that mitochondrial citrate exchange was effectively reduced 34% at 100 μM and 43% at 200 μM. *In vitro* ATP-dependent citrate lyase activity was suppressed 35% at 200 μM. Acetyl CoA synthetase activity was lowered 46% at 100 μM and 49% at 200 μM. HMG CoA reductase activity was reduced 28% at the lower concentration (50 μM) but returned to more normal levels of activity at 100–200 μM. Cholesterol side-chain oxidation was reduced

Phosphatidate phosphohydrolase	100 ± 7[l]	100 ± 8	74 ± 6[c]	57 ± 7[c]

[a] Expressed as percent of control (mean ± *SD*); $n = 6$. [b] $p \leq 0.01$. [c] $p \leq 0.001$. [d] 30.8% exchange of mitochondrial citrate. [e] 30.5 mg of citrate hydrolyzed/g wet tissue/20 min. [f] 28.5 mg of acetyl CoA formed/g wet tissue/20 min. [g] 384,900 dpm of cholesterol formed/g wet tissue/60 min. [h] 6080 dpm of CO_2 formed/g wet tissue/18 h. [i] 32,010 dpm/g wet tissue/30 min. [j] 37,656 dpm/g wet tissue/20 min. [k] 537,800 dpm/g wet tissue/20 min. [l] 16.7 μP_i/g wet tissue/15 min.

29% at 100 μM. The activities of regulatory enzymes of triglyceride synthesis, *sn*-glycerol-3-phosphate acyl transferase and phosphatidate phosphohydrolase were significantly inhibited by N^2-*n*-butylindazolone. The former was inhibited 55% at 100 μM and 47% at 200 μM. The latter was suppressed 26% at 100 μM and 43% at 200 μM. The effects of N^2-*n*-butylindazolone on *in vivo* enzyme activities of mouse liver (Table III) were a 38% suppression of acetyl CoA synthetase activity at 60 mg/kg/d and a 20% inhibition of HMG CoA reductase activity at 10 mg/kg/d. Acetyl CoA carboxylase activity was suppressed 20–30% for all of the doses tested. Fatty acid synthetase activity was reduced 25% at 20 mg/kg, but the agent had no effect at other doses. Phosphatidate phosphohydrolase activity was reduced in a dose-dependent manner with 60 mg/kg/d resulting in a 59% reduction. *sn*-Glycerol-3-phosphate acyl transferase activities were inhibited >20% at 10 and 20 mg/kg/d.

Lipid content was lowered 20% in the liver and 65% in the small intestine after dosing rats 20 mg/kg/d for 14 d. Cholesterol content in the liver was lowered to 29%, triglyceride level and neutral lipids were reduced 21 and 34%, respectively; phospholipid content was elevated 24%. In the small intestine, cholesterol, triglycerides, and neutral lipid levels were lowered 27, 84, and 80%, respectively. In the feces, lipid content and cholesterol levels were elevated 5% and 8% which is not significant, but there were elevations in the levels of neutral lipids and phospholipids which were significantly different from the control (Table IV).

The serum lipoprotein fractions obtained from rats treated for 2 weeks showed decreased cholesterol, triglyceride, and neutral lipid levels in all four lipoprotein fractions. Phospholipid levels were generally not affected with the exception of the high density lipoprotein which had a 14% reduction (Table IV).

[^{3}H]Cholesterol distribution after 2-weeks dosing in rats showed that cholesterol was not accumulated in the brain, lung, heart, liver, or spleen. On the other hand, higher concentrations of cholesterol were found in the small intestine (52%), large intestine (129%), chyme (80%), and feces (60%) when compared with control values. Bile excretion studies showed a 28% increase in [^{3}H]cholesterol excretion in the bile on day 14, and studies also demonstrated a 95% suppression of absorption of [^{3}H]cholesterol from the intestine after oral administration over a 24-h period (Table V).

Organ weights of the control and treated animals did not differ significantly although those of the treated animals were slightly lower. The weight of the control and treated animals increased 9.76% and 5.86%, respectively, over two weeks. Daily food intake (g/d) was 30.39 for the control and 28.75 for the treated group. Adrenal weights were not altered by drug treatment indicating that there was no compensating hypertrophy of the adrenal cortex to produce increased steroidogenesis.

Data in Tables I–V are expressed as percent of control ± *SD*. The probable significance level (p) between each test group and the control group was determined by the t test.

DISCUSSION

In comparing the mode of action of N^2-substituted indazolone to *N*-substituted cyclic imides and derivatives [e.g., phthalimide (2), saccharin (2), and 1′,8′-naphthalimide (25)], some similarities exist. All of these agents inhibit mitochondrial citrate exchange decreasing the availability of the key intermediate, acetyl CoA, which is required for fatty acid and cholesterol synthesis. All of the *N*-substituted imides block the two regulatory enzymes of triglyceride synthesis (*sn*-glycerol-3-phosphate acyl transferase and phosphatidate phosphohydrolase) and showed marginal inhibition of HMG CoA reductase, the regulatory enzyme of cholesterol synthesis. Differences which exist between *N*-substituted indazolone and *N*-substituted saccharin, phthalimide, and 1′,8′-naphthalimide cyclic imides include marginal inhibition

[a] 24 h after administration for 14 d; $n = 6$.

of fatty acid synthesis at the lower doses by the *N*-substituted indazolone; the latter agent also suppresses appetite. The *N*-substituted indazolone did lower lipid levels in the liver and small intestine of the rat with increased lipid levels in the fecal material after 14 d of dosing. Lower levels of cholesterol, triglycerides, and neutral lipids of the four blood lipoprotein fractions were evident after drug therapy. The *N*-substituted indazolone derivatives more consistently lowered lipid content of the four lipoprotein fractions when compared with cyclic imides. Whereas the ratio of cholesterol level of high density lipoprotein to low density lipoprotein probably did not change significantly, lower levels were noted in both lipoprotein fractions. Supposedly, lower levels of cholesterol in the low density fraction and higher levels of cholesterol in high density lipoprotein fraction protect against lipid deposition in the atherogenic plaque of the blood vessel and leads to clearance of lipoproteins from the blood.

Like *N*-substituted cyclic imides, [^{3}H]cholesterol distribution and excretion was altered by N^2-*n*-butylindazolone. First, after oral administration of cholesterol, GI tract absorption over a 24-h period was reduced markedly. Second, there was less cholesterol in the major organs, *e.g.*, brain, liver, heart, lung, and kidney. Third, drug therapy resulted in larger amounts of labeled cholesterol being excreted by the fecal route compared with the control. Fourth, the increase in fecal [^{3}H]cholesterol may reflect the decreased absorption of cholesterol caused by the drug and the increase in biliary excretion. The *N*-substituted indazolone derivatives appeared to be more effective than cyclic imides in reducing cholesterol absorption and appeared to be slightly less effective in reducing liver regulatory enzyme activity than cyclic imides. For example, phthalimide and saccharin reduced cholesterol absorption 56% and 33%, respectively, whereas N^2-*n*-butylindazolone resulted in a 95% reduction. However, phosphatidate phosphohydrolase activity was reduced 97% by phthalimide at 60 mg/kg/d and 70% by saccharin at 100 mg/kg/d, whereas N^2-*n*-butylindazolone at 60 mg/kg/d only lowered the activity 59%, its maximum effect. Thus, the modes of action of cyclic imides in lowering body lipids vary from compound to compound, usually affecting the same biochemical parameter but having different magnitudes of response. All of the tested cyclic imides to date appear to have multiple sites in metabolism on which they act to lower serum lipid levels in the body.

In conclusion, N^2-*n*-butylindazolone appears to be a potent hypolipidemic agent and, like cyclic imides tested, more potent than clofibrate which is commercially available. The therapeutic index was well within safe utilization of the compound and the compound[7] effectively suppressed both serum cholesterol and triglyceride levels.

Estimation of Tris(2-butoxyethyl) Phosphate in Biological Fluids: Novel Intersubject Variability in Recovery from Human Serum

GAIL D. ANDERSON, ALFRED T. ELVIN, and DAVID LALKA ˣ

Received July 25, 1983, from the *Department of Pharmaceutics, School of Pharmacy, State University of New York at Buffalo, Amherst, NY 14260* and the *Clinical Pharmacokinetics Laboratory, Buffalo General Hospital, Buffalo, NY 14203.* Accepted for publication April 13, 1984.

Abstract □ Tris(2-butoxyethyl) phosphate (I), a plasticizer commonly found in evacuated blood collection tubes, displaces many basic drugs from their binding sites on serum proteins and causes them to redistribute from serum into red blood cells (*i.e.*, artificially lowering serum or plasma drug concentration). Thus, the ability to quantitate I in serum or plasma may be helpful in establishing the suitability of various lots of evacuated blood collection tubes for use in drug level monitoring and pharmacokinetic studies. In the process of establishing a minor modification of an assay which has been reported, remarkable and reproducible interindividual variability ($n = 10$) in the slope of standard curves was observed (range, 0.0143–0.0486). This variability appeared to be caused by differences in the recovery of I from the serum of these individuals. The source of this difference seemed to be related to serum lipoprotein concentration since the slope of standard curves was highly correlated with serum triglyceride concentration ($r = -0.800$) as well as with the sum of serum triglyceride and cholesterol concentrations ($r = -0.881$). These observations suggest that the examination of interindividual differences in the recovery of drugs and related compounds from serum should be a routine part of assay development.

Keyphrases □ Tris(2-butoxyethyl) phosphate—recovery variability, human serum, correlation to lipoprotein, triglyceride and cholesterol levels

Tris(2-butoxyethyl) phosphate (I), a plasticizer found in the rubber stoppers of many evacuated blood collection tubes and in some catheter materials, has been shown to significantly displace basic drugs such as propranolol (1), quinidine (2), lidocaine (3), imipramine (4), and alprenolol (4) from their binding sites on α_1-acid glycoprotein (the principal base binding protein in human serum). Spuriously low (typically 25%) plasma or serum concentrations accompany this displacement due to increased partitioning of the drugs into red blood cells (1, 3). Artifacts related to this phenomenon may pervade much of the published data describing the pharmacokinetics of this type of compound. Furthermore, this artifact may adversely affect therapeutic drug monitoring. Specifically, it is likely that different lots of evacuated blood collection tubes cause varying amounts of "displacing activity" (3) and that different lots of tubes may be used to collect blood during a hospital admission. Thus, the capacity to approximate the concentration of I in plasma or serum samples is important.

A second reason to examine the analysis of I in biological fluids was that preliminary studies in this laboratory suggested remarkable intersubject variability in the slopes of standard curves for I in human serum. It is well known that the recovery of some compounds is dependent upon the biological fluid (urine, blood, serum, *etc.*) being extracted. For example the lidocaine metabolites, monoethyl-glycinexylidide and glycinexylidide, have a significantly lower recovery from serum than from urine (5). The present text describes the evidence for large (approximately threefold) interindividual differences in the recovery of I from serum, provides preliminary observations regarding the plasma constituents which exhibit covariance with these interindividual differences, and presents a description of analytical methods which allow the estimation of I in serum samples.

EXPERIMENTAL SECTION

Tris(2-butoxyethyl) phosphate[1] and dioctyl phthalate[1] were used as received. All solvents were spectral or HPLC grade.

Standard Assay of I in Serum—The concentration of I in serum samples was determined using a minor modification of a previously published procedure (4). The original extraction method was modified by increasing the organic to aqueous phase volume ratio from 2:1 to 10:1. To a 0.50-mL serum sample was added 5 mL of dichloromethane containing 1.0 μg/mL of dioctyl phthalate as an internal standard. The mixture was agitated on a fixed-angle rotary mixer (20 rpm) for 10 min and centrifuged (1000×*g*). The organic phase was transferred to a clean tube and evaporated to dryness. The residue was redissolved in 25 μL of ethyl acetate, and 1 μL was injected into a gas chromatograph equipped with flame-ionization detectors[2]. This instrument contained glass columns (122 × 0.2 cm) packed with 3% OV-101 on 80/100-mesh chromosorb W(HP)[3]. Helium was used as a carrier gas at a flow rate of 30 mL/min. The analysis was run isothermally at a column temperature of 220°C with injector and detector temperatures of 250°C. The flow rates of hydrogen and air were 30 and 300 mL/min, respectively.

Estimation of Tris(2-butoxyethyl) Phosphate in Biological Fluids: Novel Intersubject Variability in Recovery from Human Serum

GAIL D. ANDERSON, ALFRED T. ELVIN, and DAVID LALKA ˣ

Received July 25, 1983, from the *Department of Pharmaceutics, School of Pharmacy, State University of New York at Buffalo, Amherst, NY 14260* and the *Clinical Pharmacokinetics Laboratory, Buffalo General Hospital, Buffalo, NY 14203.* Accepted for publication April 13, 1984.

Abstract □ Tris(2-butoxyethyl) phosphate (I), a plasticizer commonly found in evacuated blood collection tubes, displaces many basic drugs from their binding sites on serum proteins and causes them to redistribute from serum into red blood cells (*i.e.*, artificially lowering serum or plasma drug concentration). Thus, the ability to quantitate I in serum or plasma may be helpful in establishing the suitability of various lots of evacuated blood collection tubes for use in drug level monitoring and pharmacokinetic studies. In the process of establishing a minor modification of an assay which has been reported, remarkable and reproducible interindividual variability ($n = 10$) in the slope of standard curves was observed (range, 0.0143–0.0486). This variability appeared to be caused by differences in the recovery of I from the serum of these individuals. The source of this difference seemed to be related to serum lipoprotein concentration since the slope of standard curves was highly correlated with serum triglyceride concentration ($r = -0.800$) as well as with the sum of serum triglyceride and cholesterol concentrations ($r = -0.881$). These observations suggest that the examination of interindividual differences in the recovery of drugs and related compounds from serum should be a routine part of assay development.

Keyphrases □ Tris(2-butoxyethyl) phosphate—recovery variability, human serum, correlation to lipoprotein, triglyceride and cholesterol levels

Tris(2-butoxyethyl) phosphate (I), a plasticizer found in the rubber stoppers of many evacuated blood collection tubes and in some catheter materials, has been shown to significantly displace basic drugs such as propranolol (1), quinidine (2), lidocaine (3), imipramine (4), and alprenolol (4) from their binding sites on α_1-acid glycoprotein (the principal base binding protein in human serum). Spuriously low (typically 25%) plasma or serum concentrations accompany this displacement due to increased partitioning of the drugs into red blood cells (1, 3). Artifacts related to this phenomenon may pervade much of the published data describing the pharmacokinetics of this type of compound. Furthermore, this artifact may adversely affect therapeutic drug monitoring. Specifically, it is likely that different lots of evacuated blood collection tubes cause varying amounts of "displacing activity" (3) and that different lots of tubes may be used to collect blood during a hospital admission. Thus, the capacity to approximate the concentration of I in plasma or serum samples is important.

A second reason to examine the analysis of I in biological fluids was that preliminary studies in this laboratory suggested remarkable intersubject variability in the slopes of standard curves for I in human serum. It is well known that the recovery of some compounds is dependent upon the biological fluid (urine, blood, serum, *etc.*) being extracted. For example the lidocaine metabolites, monoethyl-glycinexylidide and glycinexylidide, have a significantly lower recovery from serum than from urine (5). The present text describes the evidence for large (approximately threefold) interindividual differences in the recovery of I from serum, provides preliminary observations regarding the plasma constituents which exhibit covariance with these interindividual differences, and presents a description of analytical methods which allow the estimation of I in serum samples.

EXPERIMENTAL SECTION

Tris(2-butoxyethyl) phosphate[1] and dioctyl phthalate[1] were used as received. All solvents were spectral or HPLC grade.

Standard Assay of I in Serum—The concentration of I in serum samples was determined using a minor modification of a previously published procedure (4). The original extraction method was modified by increasing the organic to aqueous phase volume ratio from 2:1 to 10:1. To a 0.50-mL serum sample was added 5 mL of dichloromethane containing 1.0 μg/mL of dioctyl phthalate as an internal standard. The mixture was agitated on a fixed-angle rotary mixer (20 rpm) for 10 min and centrifuged (1000×*g*). The organic phase was transferred to a clean tube and evaporated to dryness. The residue was redissolved in 25 μL of ethyl acetate, and 1 μL was injected into a gas chromatograph equipped with flame-ionization detectors[2]. This instrument contained glass columns (122 × 0.2 cm) packed with 3% OV-101 on 80/100-mesh chromosorb W(HP)[3]. Helium was used as a carrier gas at a flow rate of 30 mL/min. The analysis was run isothermally at a column temperature of 220°C with injector and detector temperatures of 250°C. The flow rates of hydrogen and air were 30 and 300 mL/min, respectively.

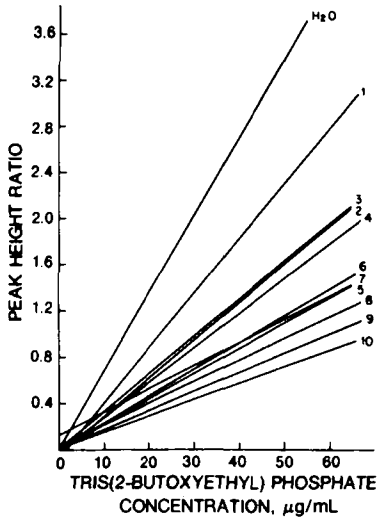

Figure 1—*The intersubject variability of peak height ratio [tris(2-butoxyethyl) phosphate/dioctyl phthalate] as a function of the concentration of tris(2-butoxyethyl) phosphate added to human serum with different normal volunteers. The identification number of each volunteer is given at the end of each standard curve.*

Preparation of Standard Curves for I—Serum samples for use in the preparation of standard curves were drawn into glass syringes. Ten normal adult volunteers (eight males and two females) ranging in age from 23 to 37 years served as study subjects. Each volunteer gave 50 mL of blood to allow the construction of standard curves for I (0, 10, 20, 30, 40, and 50 μg/mL) as well as to perform the battery of biochemical tests intended to identify the basis for the interindividual differences in standard curve slope (see below). Compound I was added to serum samples as a methanol solution[4]. Peak height ratios were plotted *versus* concentrations of I. Linear least-square regression analysis was used to determine the slopes, y-intercepts, and correlation coefficients of the lines of best fit. Repeated standard curves and single-concentration quality-control checks performed on numerous occasions were consistent with the interindividual slope differences observed in this study.

External Standard Experiments—In an effort to determine if the intersubject differences in the standard curves were due to variable recovery of the internal standard (dioctyl phthalate)[1], this compound was added as an external standard and as an internal standard to separate aliquots of serum from subjects 2 and 9 (concentration of I was 30 μg/mL). One set of the samples was extracted and assayed as described above with the exception of the transfer of an exact volume (3.0 mL) of organic phase to a clean tube. The other set of serum samples from the same subjects was extracted with 5 mL of blank dichloromethane (without internal standard) and 3.0 mL of this organic phase was transferred to a clean tube. Five micrograms of dioctyl phthalate in 1.0 mL of dichloromethane was added as an external standard. Blank dichloromethane (1.0 mL) was added to the control samples. All samples were then assayed as described above.

Effect of Alteration of Extraction Conditions—*Overview*—The primary objective of the following experiments was to establish a method which minimized or eliminated the intersubject differences in the extraction of I from serum. Pooled serum samples from individuals known to exhibit high recovery (subjects 1-3) or low recovery (subjects 8-10) of I were used for this series of studies.

Multiple Extraction Experiment—The assay procedure for I was modified to include repeated extractions of 0.5 mL of serum with dichloromethane (5.0 mL × 3). The first organic phase was transferred to a clean test tube leaving the aqueous phase in the original test tube. An additional 5 mL of dichloromethane (without internal standard) was added to the aqueous phase. This sample was then rotary mixed for 10 min, centrifuged, and transferred as described above. This procedure was repeated a third time and the pooled dichloromethane extracts containing I and internal standard were evaporated to dryness and chromatographed as described[5].

Ethyl Acetate Experiment—Serum samples (0.25 mL) were extracted as described above except that 5 mL of ethyl acetate containing 0.5 μg/mL of dioctyl phthalate was used instead of dichloromethane. Evaporation of the organic phase and GC was then performed as described above.

Assay of Serum Triglycerides, Total Cholesterol, High-Density Lipoprotein Cholesterol, Albumin, and α_1-Acid Glycoprotein—Serum concentrations of cholesterol, high-density lipoprotein cholesterol, and triglycerides were determined by previously described methods (7, 8). Serum albumin concentrations were determined using an auto analyzer[6] and the concentration of α_1-acid glycoprotein in serum was determined using a radial immunodiffusion assay[7]. This last procedure was performed in a manner to yield a coefficient of variation of 9.5%.

Statistical Analysis—All data are presented as population mean ± *SD* unless indicated otherwise. The quality of the various standard curves was estimated using linear regression analysis.

RESULTS AND DISCUSSION

Using the standard assay procedure described above, the lower limit of detection for I was 1 μg/mL and standard curves were linear to at least 50 μg/mL (standard curves were performed using single determinations at six concentrations; see above). A linear relationship between peak height ratio and serum concentrations of I was observed in all subjects. The range of correlation coefficients was 0.965-0.999 (mean = 0.984). A greater than threefold intersubject variability in slopes of standard curves was observed with a range of 0.0142-0.0486 (Table I, Fig. 1).

Addition of dioctyl phthalate as an external standard confirmed that the intersubject variability was related to the extraction of I and not the internal standard. The data presented in Table II demonstrate that a threefold range of slopes exists between "high" and "low" extraction sera independent of when the dioctyl phthalate is introduced. The diminished peak height ratio observed

[4] Preliminary studies indicated that initial evaporation of the methanol using either a stream of nitrogen or a 50°C water bath caused a loss >50% of I (*i.e.*, as estimated from reduction in peak height ratio). Later studies comparing samples dried at room temperature (18 h) to those prepared by the addition of I as a methanol solution yielded essentially identical results (*i.e.*, standard curves). The data from this series of studies were all obtained with serum samples containing <5% methanol (v/v).

[5] A number of other alterations in the extraction procedure, including protein precipitation with trichloroacetic acid and dilution of serum with distilled water, were also evaluated as methods to reduce the intersubject variability in the recovery of I. These approaches were all unsuccessful.

Table II—Influence of Selected Treatments on the Peak Height Ratio of Tris(2-butoxyethyl) Phosphate to Dioctyl Phthalate

	Peak Height Ratio from High-Extraction Serum	Peak Height Ratio from Low-Extraction Serum	Peak Height Ratio from High-Extraction Serum/ Peak Height Ratio from Low-Extraction Serum
		External Standard Experiment[a]	
Internal standard (control)	1.17 ± 0.0600	0.396 ± 0.0295	2.96
External standard	0.614 ± 0.0483	0.225 ± 0.0177	2.73
		Multiple Extraction Experiment[b]	
	0.871 ± 0.152	0.685 ± 0.118	1.27

[a] The serum used in this study was from subject 2 (high extraction) and subject 9 (low extraction). [b] The serum used in these studies were prepared by pooling serum from subjects 1, 2, and 3 (high extraction) and 8, 9, and 10 (low extraction).

Table III—Intersubject Variability in Peak Height Ratio When Ethyl Acetate is Used in Place of Dichloromethane[a]

Subject	Peak Height Ratio
2	1.1232 ± 0.1435
3	1.7668 ± 0.1319
5	1.5404 ± 0.0680
8	1.8942 ± 0.0400
9	1.1761 ± 0.0162
10	1.6229 ± 0.0235

[a] All serum samples contained I at a concentration of 30 μg/mL.

in the external standard component of this study is presumably related, at least in part, to the incomplete recovery of dioctyl phthalate when it is used as an internal standard.

The results of the experiments utilizing repeated extraction to eliminate the intersubject difference in the recovery of I are also presented. Multiple extractions with dichloromethane substantially reduced the intersubject variability in the peak height ratio of I/dioctyl phthalate (Table II). However, this procedure was substantially more laborious than the standard procedure. Replacing dichloromethane with ethyl acetate (Table III) did result in elimination of much of the variability. Though this assay still has limitations, it appears to be the best procedure presently available (*i.e.*, assuming that blank serum which could be used to prepare an individual's own standard curve is unavailable). The use of ethyl acetate as the organic phase for the extraction of I from serum samples eliminates much of the intersubject variability and enables investigators to ensure the absence of I from study samples.

The chemical basis for this variability has not been established. However, highly significant correlations were found between the slope of the individual standard curves and serum concentrations of triglycerides ($r = -0.80$, $p < 0.005$) and triglycerides plus cholesterol ($r = -0.881$, $p < 0.0025$). A much weaker correlation was also found between the standard curve slope and serum concentration of α_1-acid glycoprotein ($r = -0.578$, $p < 0.05$). However, significant covariance existed between α_1-acid glycoprotein concentration and the sum of triglycerides and cholesterol serum concentrations ($r = -0.563$, $p < 0.05$)[8]. There was no significant correlation between the standard curve slope and albumin ($r = -0.292$), total cholesterol ($r = -0.403$), or high-density lipoprotein cholesterol concentrations ($r = -0.289$). Based on the observation that the addition of α_1-acid glycoprotein to serum did not affect the extraction of I[8], it is presumed that the correlation between concentration of this protein and the slope of the individual standard curves is fortuitous (*i.e.*, it was observed because α_1-acid glycoprotein exhibited covariance with triglyceride concentrations, an indicator of the concentration of very low-density lipoproteins). The precise nature of the chemical basis for the intersubject variability in serum extraction of I cannot be established on the basis of the present series of experiments. However, given the lipophilic characteristics of I, it is reasonable to assume that association with or dissolution in lipoproteins plays a major role.

Part of the overall significance of these results lies in the widespread use of pooled serum by research investigators and analytical laboratories. The use of pooled serum in the preparation of standard curves for I could have resulted in a greater than threefold error in estimates of the concentration of I in serum of certain individuals. This variability in serum extraction observed with tris(2-butoxyethyl) phosphate may occur with other highly lipophilic compounds. Indeed, it has been observed recently that bis(2-ethylhexyl) phthalate behaves in a very similar manner (9). Therefore, it is necessary to rule out possible serum-dependent extractability during the early stages of assay development for at least certain classes of compounds.

Based upon the results of the present study, the use of ethyl acetate would appear to be the best approach to minimizing assay error due to intersubject variability in the extraction of I if a relatively simple assay is to be utilized.

[8] When α_1-acid glycoprotein (the gift of Dr. Kenneth Piafsky of the University of Toronto) was added to serum, the recovery of I was not altered.

Concentration-Dependent Enhancement of 1-Dodecylazacycloheptan-2-one on the Percutaneous Penetration Kinetics of Triamcinolone Acetonide

D. S-L. CHOW ˣ, I. KAKA, and T. I. WANG

Received October 7, 1983, from the *Department of Pharmaceutics, College of Pharmacy, University of Houston, Houston, TX 77004.* Accepted for publication December 5, 1983.

Abstract □ The enhancing effect of 1-dodecylazacycloheptan-2-one (I) on the penetration kinetics of triamcinolone acetonide (II) and the possible mechanisms of enhancement were studied using nonreinforced and reinforced silicone elastomer membranes and full-thickness hairless mouse skin as penetration barriers. Lactam I, at test concentrations of 0.1–10%, significantly promoted the extent and the rate of penetration of the acetonide II. Regardless of the barrier used the effect was concentration dependent, but the penetration profiles were different. The enhancement with synthetic membranes was attributed solely to the effect of lactam I doubling the diffusion constant (D), which resulted in the increase of the permeability coefficient (K_p) and the shortening of the lag time (τ); the partition coefficient (K_m), however, was not affected. With mouse skin, I exerted effects on both D and K_m. Compound I potentiated the retention of II in skin (a reservoir effect) about sevenfold; however, the enhancing reservoir effect was independent of the concentration of I. Pretreatment with I was found to be more efficient than the coapplication of I and II in the vehicle. The coexistence of I and II was not required for the enhancement, and the reduced enhancing efficiency suggested an interaction between I and II in the vehicle. Penetration impedance was observed after exposure to I with skin, but not with synthetic membranes. Interaction of I with the skin component, or the coexistence of I and II in the skin, could be responsible for such an impedance.

Keyphrases □ Penetration kinetics—triamcinolone acetonide, influence of 1-dodecylazacycloheptan-2-one, concentration dependence □ Mechanisms of enhancement—reservoir effect, diffusion constant, partition coefficient, promotion of skin hydration □ 1-Dodecylazacycloheptan-2-one—influence on penetration kinetics of triamcinolone acetonide, concentration dependence

1-Dodecylazacycloheptan-2-one[1] (I) enhances the biological activity of various topically active agents (antibiotics and antifungals, glucocorticoids, and antipsoriatic agents) using corresponding bioassays, the zonal inhibition of microorganism growth, vasoconstriction, and lesion clearance, respectively (1, 2). The enhancing effect of I was observed with concentrations as low as 1% (1, 2), which is much lower than that required with other enhancers, such as urea, dimethyl sulfoxide, and *N*,*N*-dimethylformamide. In addition, lactam I causes practically no irritation to human skin even at concentrations >50% (2). In the light of these advantages, this substance is a promising new enhancer for topical pharmaceutical formulations.

Therapeutic activity of a topical agent is known to be the result of drug release from the dosage form, penetration of released molecules through skin barrier, and intrinsic activity of the penetrating agent at the target sites (3). The reported enhancement may be due to the I effect on any one or combination of the three components. A few studies have attempted to evaluate the I effect on the individual processes. Using triamcinolone acetonide (1), methanol (4), 8-bromoadenosine 3′,5′-hydrogenphosphate (8-bromo-cAMP; III)[2], 9-β-D-arabinofuranosyladenine (vidarabine, ara-A; IV) (5), arabinofuranosyladenine 5′-valerate (ara-A-5′-valerate; V) (6), 5-fluorouracil, indomethacin, and hydroquinone (2), the enhancing effects of I have been demonstrated to be on the penetration process, with (6) or without the mechanism of drug release. Stoughton (1) reported that percutaneous penetration of triamcinolone acetonide (II) in the presence of 10% I (within 7 and 24 h) was 10- and 5-fold higher than that without I. Greater enhancement was observed with 5-fluorouracil and indomethacin at I concentrations of 1.8–45%, yet only a two- to threefold increase was observed with hydroquinone at 2 and 5% I (2). Stoughton also found that in the case of III, the same level of penetration enhancement induced by 1% I was barely achievable with 50% dimethylformamide[2].

Behl *et al.* (4) demonstrated that the permeability of methanol was promoted 200–400-fold by I (asymptotically with I concentrations) with maximal enhancement at 10–25% I. Vaidyanathan *et al.* (5) showed that I enhanced the delivery of IV with systematic increase in the presence of 0.1–3% I. The permeability of IV with 3% I was 1.4×10^{-7} cm/s, 10-fold greater than the control. The absolute amount that penetrated at 24 h was a 170-fold increase over the control value with 3% I and a 42-fold increase with 0.1%. Vaidyanathan *et al.* (6) also reported that 20% I promoted the total fluxes of IV and V from a suspension with emulsified I or from gel formulation, 20-fold greater than those found using dimethyl sulfoxide as the vehicle. Nevertheless, no complete profile of the penetration due to I has been established. In addition, the mechanisms of such enhanced penetrations have not been elucidated in terms of the modifications of I on the basic parameters of percutaneous penetration kinetics [other than the permeability coefficient (5)]: lag time, diffusion constant, and partition coefficient.

Penetration enhancement appeared to be dependent on the concentration of I. The extent of II penetration increased with increasing I up to 10%; further increase of I (40%) diminished the extent of enhancement (1). The highest level of enhancement on 5-fluorouracil penetration was achieved with 1.8% I among test cencentrations, 1.8, 9, and 45%. With indomethacin as a penetrant, 2% I exerted an effect similar to that of 8%; both were higher than that of 24%. Similarly, 2% I had a greater effect on hydroquinone penetration than 5% I (2). Optimal enhancement was also observed with methanol (4) at 10–25% I. The enhancing effect of I on biological activity, determined either by the vasoconstriction assay or other bioassays, seemed to be concentration dependent as well (1, 2), and the pattern of such a dependence also seemed to vary with test compounds. For instance, erythromycin and clindamycin had increasing antibacterial effect with increasing I, while glucocorticoids and fusidic acid gave the greatest biological effect with the lowest examined concentrations of I (1–3%). Therefore, we attempted to characterize such a dependence and to explore its possible mechanism.

One of the most frequently prescribed topical glucocorti-

[1] Azone; Nelson Research and Development Co., Irvine, Calif.

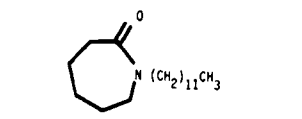
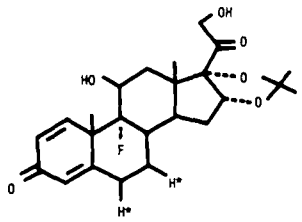
coids, II (7), was selected for the study. Unlike antifungal and other antimicrobial agents, glucocorticoids exert pharmacological effects only after the agents have penetrated through the skin barrier and reached the target cells in the epidermis and dermis. In regard to therapeutic efficacy, bioavailability of the active ingredient at the site of target cells is of more concern than the concentration of the drug in the dosage form. The importance of the bioavailability of glucocorticoids in various topical drug-delivery systems has received attention from both the pharmaceutical and medical communities during the past decade. However, vehicles in use are still inefficient or only marginally effective in providing satisfactory bioavailability (8, 9). Maibach studied the percutaneous penetration of radioactively labeled hydrocortisone in 18 subjects at a dose of 4 $\mu g/cm^2$ and found that only ~1% of the dose was actually absorbed from the forearm of a normal subject (10). This problem of low bioavailability of glucocorticoids called for an urgent need to develop more efficient systems for delivering this therapeutically useful agent.

This study is intended to evaluate the penetration enhancement of II by I (in terms of the modifications of I on the individual penetration parameters) and to elucidate the possible mechanisms of concentration-dependent effects of I using an *in vitro* penetration study with excised full-thickness hairless mouse skin. In addition, two synthetic, nonreinforced and reinforced, silicone elastomer membranes were evaluated for use as artificial skin models.



I



II

EXPERIMENTAL SECTION

Materials—Compound I[3] was used as supplied. Tritiated II[4] in benzene-ethanol (9:1), with a specific activity of 37.0 Ci/mmol, was used as the penetrant. Test solutions of II [3.01×10^{-10} mol/mL in propylene glycol[5] (11)], with or without 0.1, 0.5, 1, 2, 3, 4, 5, 8, and 10% (v/v) I were prepared with methanol[6] as an intermediate solvent (12).

Skin Preparation and Synthetic Membranes—Skin preparations from homozygous Hr/Hr hairless mice (HRS/J strain)[7] (age, 2–4 months) were used. The skin of all animals appeared normal and was free of bites, scratches, or bruises. The mice were sacrificed by ether inhalation, and the skin was dissected. Full-thickness skin was used for the penetration study. Tritiated water[8] served as a standard penetrant to check the intactness of the skin preparation. The thickness of the skin preparation was measured with a micrometer[9]. Membranes of silicone elastomer[10], nonreinforced and reinforced with plain weave fabric of polyethylene terephthalates, were 127.0 and 177.8 μm thick, respectively.

***In Vitro* Penetration Study**—The skin sample or synthetic membrane was mounted between the donor and receptor chambers of the Franz diffusion cell[11] (5 mL) with a 9 mm i.d. O-ring flange. The stratum corneum was exposed to ambient conditions, and the dermal side was oriented toward the saline-phosphate buffer (pH 7.4) (13), simulating the physiological pH of the dermis [pH 7.3–7.4 (14)], in the receptor chamber.

Prior to the application of the test sample, the solution in the receptor chamber was equilibrated by circulating water through a jacket surrounding the chamber at 32°C, which was chosen to reflect the temperature of the stratum corneum (15). The solution in the receptor chamber was stirred with a polytef-coated magnetic bar driven by a magnetic stirrer. A sample (0.2 mL) of II test solution, with or without I, was spread across the exposed stratum corneum surface of the mounted skin. Aliquots of saline-phosphate buffer containing the penetrated II (0.2 mL) were withdrawn from the side-arm of the receptor chamber; this volume was replaced with fresh buffer at 32°C. Samples were taken every 30 min for the initial 2 h and hourly thereafter to 12 h. The amount of II penetrated was measured by liquid scintillation counting of the withdrawn diffusate (0.2 mL in 4 mL of xylene-based cocktail[12]).

The reservoir effect of the skin to retain II was examined after the 12-h penetration study. The exposed skin was blotted dry, dissolved in 1 mL of quaternary ammonium hydroxide tissue solubilizer[13] at 55°C for 2 h, and decolorized with 0.1 mL of 30% hydrogen peroxide[14] for 30 min. The radioactivity in the solubilized skin was monitored by liquid scintillation counting in 10 mL of toluene-based cocktail[15]. The background counts and quenching effects of blank diffusate aliquot and solubilized skin were negligible. No quench correction was employed.

Data Analysis (16, 17)—The penetration parameters of II [lag time (τ), permeability coefficient through the membrane (K_p), diffusion constant within the membrane (D), and partition coefficient between the membrane and the vehicle (K_m)] were calculated from the penetration data. The penetration profiles were constructed by plotting the total amount of II penetrated *versus* time. The x-intercept of the extrapolated linear region of the curve gives τ. D was calculated from τ with known thickness of the penetration barrier (δ), using Eq. 1. The slope of the linear portion of the profile, determined by linear regression analysis, was J_s. K_p was calculated by dividing J_s by the employed concentration of II, C_s (Eq. 2), and K_m was calculated with Eq. 3:

$$\tau = \delta^2/6D \qquad \text{(Eq. 1)}$$

$$J_s = (K_m \cdot D \cdot C_s)/\delta = K_p C_s \qquad \text{(Eq. 2)}$$

$$K_p = (K_m \cdot D)/\delta \qquad \text{(Eq. 3)}$$

The significance of the difference in parameter values among groups with and without I was tested by a nonpaired Student's t test.

RESULTS AND DISCUSSION

Effects of I on Penetration Profiles and Kinetic Parameters of II—The penetration profiles of II, with and without I, through the nonreinforced and reinforced silicone elastomer membrane and full-thickness hairless mouse skin for 12 h, are shown in Figs. 1, 2, and 3, respectively. Regardless of the type of membrane used, both the extent and the rate of II penetration through the membrane were significantly enhanced with I. The penetration profiles through synthetic membranes always consisted of a lag phase followed by the linear rise. This profile was obtained with hairless mouse skin only when the concentration of I was ≤2% (Fig. 3). With I > 2%, the steady-state penetration was somewhat impeded after 8 h of exposure to I, as reflected by the plateau in the profile. The impedance was noticed only with the skin; this cautioned the use of synthetic membranes as artificial skin models for studies of I.

The percentage of II penetration at 12 h through synthetic membranes increased from two- to fourfold the control value with increasing concentrations of I (0.1, 2, and 10%, Table I). A different concentration dependence was observed with hairless mouse skin (Table II). Compound I effectively

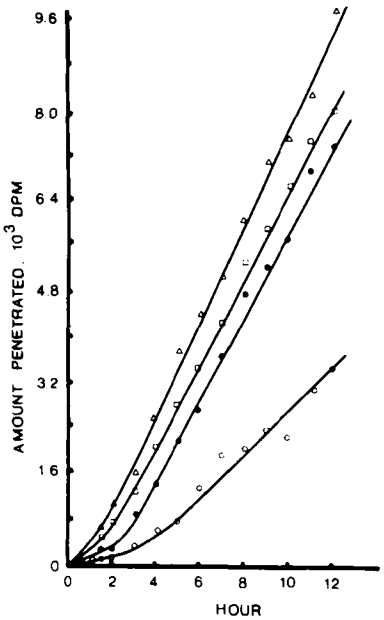

Figure 1—*Penetration profiles of II through nonreinforced silicone elastomer membrane with various concentrations of I. Key: (○) 0%; (●) 0.1%; (□) 2%; (△) 10%.*

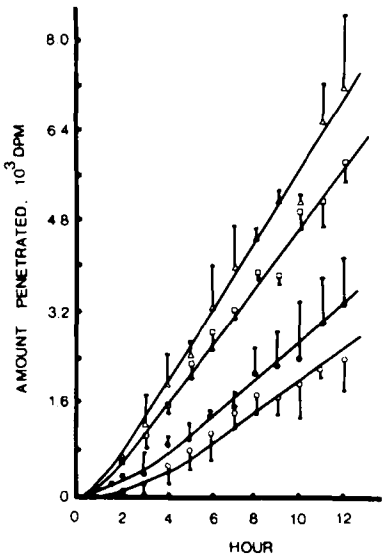

Figure 2—*Penetration profiles of II through reinforced silicone elastomer membrane with various concentrations of I. Key: (○) 0%; (●) 0.1%; (□) 2%; (△) 10%, (n = 3 each).*

elevated the percent of II penetrated through the skin with concentrations >0.5% ($p < 0.02$). Penetration increased 8-, 28-, and 124-fold over that observed without I, at 0.5, 1, and 2-3% I, respectively. However, increased concentrations of I (4-10%) reduced the promotion ($p < 0.005$, except $p < 0.1$ with 5% I) to 76-98-fold the control value (*i.e.*, only 61-79% of the maximum enhancement achieved at 2-3% I). This was a result of late-stage penetration impedance.

The steady-state penetration rate of II (J_s) through nonreinforced silicone elastomer membrane was doubled with as low as 0.1% I, but increases to 2 and 10% did not further promote the penetration rate. Similar results were observed with reinforced membrane, except that the effective concentration was >0.1% (Table I). The J_s value of II through the hairless mouse skin was also concentration dependent (Table II). The rate was 3.38×10^{-18} mol/cm^2/s without I, doubled with 0.1% I, and drastically increased 14-, 46-, and 138-fold with 0.5, 1, and 2-3% I, respectively. Increasing I to 4% reduced the effect to ~66% of the observed maximal enhancement (4.67×10^{-16} mol/cm^2/s) with 2-3% I) or ~90-fold greater than the control penetration rate. Relatively constant penetration rates ($3.05\text{-}3.38 \times 10^{-16}$ mol/cm^2/s) were obtained with I concentrations of 4-10% (Table II).

The effect of I on the gross penetration process can be explained by individual parameters of penetration kinetics as shown in Tables I and II. With synthetic membranes τ values were not appreciably altered with 0.1% I, but were shortened to about one-half with I concentrations of 2 and 10%. K_p values similarly increased with J_s values as a function of I concentrations. Since K_m values were not significantly affected by test concentrations of I, the increase in K_p and reduction in τ were due solely to the I effect of increasing D in synthetic membranes.

[a] J_s = slope/(A × 3600 × specific activity × 10^6 × 2.2 × 10^6), where slope was in the unit of dpm/h, A = 0.636 cm^2, and specific activity of tritiated II was 37 Ci/mmol. [b] $K_p = J_s/C_s$, where $C_s = 3.01 \times 10^{-10}$ mol/mL. [c] $D = \delta^2/6\tau$, where δ was measured as 570 μm for full-thickness skin, and D' was similarly calculated with δ estimated as 40 μm for hydrated stratum corneum. [d] $K_m = K_p\delta/D$, and K_m' was similarly calculated with D'.

With hairless mouse skin, τ values were significantly shortened from >12 h to 7.20, 4.39, and 1.48 h by increasing I from 0 to 0.5, 2, and 10%, respectively (Table II). K_p values gradually increased from 1.25×10^{-8} cm/s to a maximum of 1.73×10^{-6} cm/s (a 138-fold increase over the control value) by increasing I to 2-3%. Values then declined with I ≥4%, leveling off at 66% of maximum ($1.13-1.25 \times 10^{-6}$ cm/s, Table II). D and K_m values were calculated first with the measured full-thickness of the skin (570 ± 104 μm, n = 15). However, since the major penetration barrier of the skin is in the stratum corneum (18, 19), the derivations of D and K_m, considering the skin a uniform and invariant cellular matrix, might have overestimated D values, yet underestimated K_m values. A second attempt was therefore made to estimate D' and K_m', using the literature thickness value (20) for fully hydrated stratum corneum (40 μm). The D' value thus obtained with no I ($< 6.2 \times 10^{-11}$ cm^2/s) was similar to the literature values for steroids [ranging from 2×10^{-11} for progesterone to 3×10^{-13} cm^2/s for hydrocortisone (21)]. The K_m' value obtained without I, 0.81-6.57, was comparable to the literature value of 5 for hydrocortisone (19).

Unlike the cases with synthetic membranes, I exerted effects on both D' and K_m' (Table II). D' was significantly promoted with I at as low as 0.5%; the extent of enhancement increased with increased I concentrations. On the other hand, K_m' increased with increasing I up to a maximum of sevenfold greater than the control value with 2% I while further increase in I from 3 to 10% reduced the enhancement from 67 to 21% of the maximum. The reduction in τ was a result of promoting D', whereas the increase in K_p was the net activity of I effects on D' and K_m'. With ≤2% I, both parameters were increased with increasing I; however, with I concentrations of ≥3%, K_m' dwindled from the maximum value, offsetting the I promoting effect on D'. The less favored partitions of II to stratum corneum with 3-10% I in vehicle, as compared with that at 2% I, dominated other effects of I and accounted for the decline in K_p at these high concentrations of I.

***In Vitro* Pretreatment of Hairless Mouse Skin with I**—To determine whether the coexistence of I and II in the vehicle is essential for penetration enhancement and impedance, the excised hairless mouse skin was pretreated *in vitro* with I prior to the penetration of II (instead of coapplication of I and II). Compound I (0.2 mL) in propylene glycol (2% or 10%), was applied on the skin mounted on the diffusion cell for 8 h. After the removal of I, 0.2 mL of II in propylene glycol without I was applied and the penetration profile was monitored. Controls were samples with pretreatments of 0.2 mL of propylene glycol for 8 h, followed by 0.2 mL of II with 0, 2, 4, 5, and 10% I.

The penetration profiles of II with I pretreatment in propylene glycol or with propylene glycol alone were established (Fig. 4), and the penetration parameters were evaluated (Table III). The 8 h contact of skin with propylene glycol, a skin-hydrating solvent, did not appreciably alter, or only marginally increased, the percent penetrated and K_p of II ($p > 0.2$, except for 0% I which had a significant increase, $p < 0.025$). Pretreatment of the skin with 2 or 10% I in propylene glycol, on the other hand, significantly augmented the I enhancements on the extent (percent penetrated), rate (J_s), and K_p of the penetration of II ($0.05 < p < 0.1$). [Compare the paired values C and B (obtained with the skin pretreatment of propylene glycol) or C and A (obtained without any skin pretreatment) in Table III.] The τ values were drastically shortened to 0.7 h after pretreatment with 2 or 10% I, as a result of the substantial promotion of D' within the skin by an 8-h pretreatment. Two percent I was as effective as 10% for pretreatment in increasing D', and significantly more effective than 10% ($p < 0.001$) in enhancing other parameters; both 2 and 10% pretreatments were more effective ($0.05 < p < 0.1$) than the coexistence of II and I of corresponding concentrations in the vehicle (Table III). This observation suggested that the penetration enhancement did not require the coexistence of I and II in the vehicle. Actually, penetration was more efficiently promoted with pretreatment of I than with coapplication of I and II, suggesting a possible interaction between I and II in the vehicle (unfavorable for the penetration process at the I concentrations tested). K_m values were low and of the magnitude obtained with coexisting 0.5% I; therefore, the great extent of penetration enhancement with pretreatment was mainly due to the D' promotion by I.

In addition, the previously reported penetration impedance of II with ≥3% I, still occurred with pretreatment of 10% I, and a similar onset of the impedance (~8 h) was observed (Fig. 4). With the pretreatment of 2% I, no plateau of the penetration profile (similar to that with coexisting 2% I) was evident after 12 h of penetration (Fig. 4). These observations suggested that 8-h skin exposure to I alone was unable to induce the penetration impedance; otherwise the impedance should have been observed from the initiation of the penetration study after pretreatment. Pretreatment of I, without the coexistence of I and II in the vehicle, could still bring about the impedance, again at 8 h after penetration began. The observations that coexistence in the vehicle (and consequently the simultaneous penetration of I and II) was not essential, yet I alone could not cause the impedance, suggested that the coexistence of II and a sufficient amount of I in the reservoir site (probably the stratum corneum of the skin) might be responsible for the observed penetration impedance by an as yet undefined mechanism.

[a] Pretreatment for 8 h.

Reservoir Effect—The so-called "reservoir effect" has been reported qualitatively or semiquantitatively for various topically applied glucocorticoids (19). The stratum corneum retains the penetrated drug molecules and makes the agents available for additional absorption even when the drug administration is ceased. To examine the I effect on the reservoir effect of II in hairless mouse skin, the II retentions in skin after 12-h penetration (with various concentrations of I) were evaluated. The presence of I in the vehicle significantly promoted the retention of II in full-thickness skin ($0.05 < p < 0.1$); the mean was 9.7 ± 3.5%, as compared with that without I, 1.4 ± 0.5% (Table IV). However, the enhancing effect was independent of the concentration of I. With the concentrations of I studied (1-10%), the II retained in the skin ranged from 8.4 ± 4.2% to 10.6 ± 5.6% (Table IV); variations were insignificant ($p > 0.7$).

The pretreatment of the skin with 2 or 10% I for 8 h further increased the I enhancing effect on II reservoir in the skin, from 8.9 ± 3.1% to 33.1 ± 2.2% for 2% I ($p < 0.001$) and from 8.4 ± 4.2% to 19.5 ± 3.6% ($0.1 < p < 0.2$) for 10% I (Table IV).

The promotion of skin hydration has been reported as a major mechanism of penetration enhancement induced by 8 M urea and dimethyl sulfoxide, as evidenced by the respective 280 and 150% weight gain of the epidermis (22). The possible I-induced hydration of stratum corneum was accordingly explored. The weights of skin samples, with an area of 0.636 cm^2, in contact with various concentrations of I for 12 h were measured (mean, 108.3 ± 17.7 μg; range, 84.9–146.5 μg; n = 12) and were not significantly different ($p > 0.6$) from the samples without I (mean, 103.5 ± 16.8 μg; range, 84.3 − 124.8 μg; n = 4).

Another possible mechanism of leaching out normally impermeable components of stratum corneum (lipoprotein or phospholipid) and leaving a permeable channel for easier penetration, reported by Allenby *et al.* (22) for urea and dimethyl sulfoxide, was not explored for I.

CONCLUSIONS

The penetration profiles of II with I through synthetic membranes were different from those through hairless mouse skin. This observation cautioned the use of synthetic membranes as skin models in the study of I.

Compound I significantly enhanced the extent of II penetration through hairless mouse skin, from 7-fold with 0.5% I, to 124-fold with 2-3% I, and then leveled off at 76-98-fold with 4-10% I. A similar pattern was obtained for the I enhancement on the penetration rate of II; a 2-fold increase with 0.1%, increasing to 138-fold with 2-3% and leveling off at 90-fold with 4-10%. The enhancing effect on the penetration of II was dependent on the concentration of I. With I concentrations >2%, penetration impedance was observed after an 8-h skin exposure to I. Optimal concentration of I on the penetration of II was 2% (v/v). Compound I exerted increasing promoting effects on the diffusion constant of II within the stratum corneum with increasing concentrations of I, manifested by the continuous reduction in lag time. On the other hand, I increased the partition coefficient of II between stratum corneum and propylene glycol with an optimal concentration of 2%. Further increment in I >2% diminished the enhancing effect.

Compound I potentiated the retention of II in skin (reservoir effect) about sevenfold; however, such an increase was independent of the concentration of I. The difference between the weights of the skin samples with and without I contact was insignificant, suggesting that the promotion of skin hydration was not a major mechanism in the penetration enhancement induced by I.

The pretreatment of I was found to be more efficient than coapplication of I and II in the vehicle. The pretreatment of skin with 2 or 10% for 8 h further augmented the enhancing effect of I on the extent and the rate of II penetration, and on the reservoir effect, due to the substantial promotion of the diffusion constant; also, pretreatment with 2% I was more effective than with 10% I. The observations indicated that coexistence of I and II was not required for penetration enhancement and that there was a possible interaction between I and II in the vehicle to lessen the enhancing efficiency.

The penetration impedance after 8-h skin exposure to I was observed only with skin, not with synthetic membranes. Interaction of I with the skin component could be responsible for such an impedance. In the pretreatment study, the penetration impedance after 8 h was still observed with 10% I, suggesting that I and II were required to coexist (not in the vehicle but probably in the stratum corneum) to elicit this impedance.

Pectin–Gelatin Complex Coacervates II: Effect of Microencapsulated Sulfamerazine on Size, Morphology, Recovery, and Extraction of Water-Dispersible Microglobules

JEAN N. McMULLEN *[x], DAVID W. NEWTON [‡], and CHARLES H. BECKER [§]

Received May 11, 1982, from the **Faculty of Pharmacy, University of Montreal, Montreal, Quebec H3C 3J7, Canada*, the [‡]*Department of Pharmaceutics, College of Pharmacy, University of Nebraska Medical Center, Omaha, NE 68105*, and the [§]*College of Pharmacy, University of Florida, Gainesville, FL 32610.* Accepted for publication March 23, 1984.

Abstract □ Spherical medicated microglobules were prepared by complex coacervation of Type A gelatin with pectin, having nominal diameters of 5, 10, and 25 μm and containing 37.3, 44.9, and 45.2% (w/w) sulfamerazine, respectively. They were recovered as water-insoluble powders and were spontaneously revertible to highly disperse systems when reconstituted in water or physiological electrolyte solution. The conditions affecting microglobule formation were studied. For complete formation, the crystals must be dispersed at ≥pH 5. The effect of the sulfamerazine mass added on microglobule morphology, yield, and contents were investigated. As much as 37.3, 44.5, and 69.1% (w/w) sulfamerazine in 5-, 10- and 25-μm microglobules could be formed without loss of spherical shape. The microglobule yield *versus* drug-to-colloid ratio curves were nonlinear below the critical drug-to-colloid ratio for loss of sphericity. Addition of sulfamerazine suppressed coacervation by 10–15% but it had no significant effect on microglobule size. The extraction of medicated microglobules in various media demonstrated the existence of a porous matrix that required hydration to facilitate extraction of the microglobular drug. Fifteen percent of the encapsulated sulfamerazine was extracted from 25-μm microglobules as opposed to 9% from 10-μm microglobules after equilibration for 24 h in replacement electrolyte solution.

Keyphrases □ Microencapsulation—pectin–gelatin coacervates, sulfamerazine □ Coacervates—pectin–gelatin, sulfamerazine, microglobules, recovery, size

Little consideration of the morphological character of complex coacervate-coated particles appears in the pharmaceutical literature until Newton *et al.* (1) produced spherical microglobules of uniform size with centrally located drug. The process of medicated microglobule formation is to be differentiated from microencapsulation; the latter usually yields nonspherical particles. Complex coacervates of gelatin–acacia or gelatin–pectin readily wet and surround suspended particles and emulsified droplets. On cooling and denaturation with formaldehyde, the liquid coacervate droplets congeal, forming microglobules that are recoverable as water-dispersible powders after flocculation in 2-propanol (1, 2).

Certain physicochemical conditions for preparing and recovering nonmedicated microglobules from type A gelatin–pectin complex coacervates were detailed previously (2). The purpose of this investigation was to characterize conditions for sulfamerazine microglobule formation in complex coacervates of pectin and gelatin, yielding microglobules of uniform size with centrally located drug that were recoverable as a dry powder. Medicated microglobules with diameters of <10 μm, spontaneously revertible to a polydisperse system in aqueous fluids, were sought for potential use in parenteral dosage forms.

EXPERIMENTAL SECTION

Materials—Type A gelatin[1] and pectin NF[2] were used in sols containing 1% benzyl alcohol for preservation. Sulfamerazine USP[3], micronized powder (≤5 μm); formaldehyde solution, USP; glycerin, 99.6%; 2-propanol, 99%; replacement electrolyte solution[4]; collagenase B[5]; pancreatin[5]; and pepsin[6] were used as received. Other reagents were of analytical reagent grade.

Preparation and Recovery of Microglobules – The method of preparation and recovery of microglobules employed by McMullen *et al.* (2) was used. Coacervates were prepared at 45°C from 40.0-g batches stirred by a magnetic stirrer at a speed sufficient to produce a vortex without air bubbles. Appropriate weights of 2% (w/w) stock solutions of pectin and gelatin were individually adjusted to the mixing pH (pH 8–10) with 1.0 M NaOH at 45°C to

give the desired pectin-to-gelatin ratio. The gelatin solution was added to the pectin solution with stirring and after 2 min the pH was lowered by addition of 0.5 M HCl to pH 5, then to the pH of coacervation (pH_c). After stirring for 30 min, 5 mL of 37% (w/w) HCHO was added and stirred for 30 min under ambient conditions. After 15–20 h, the suspension was centrifuged and the supernatant was decanted. The microglobules were resuspended in 5 mL of glycerin with a vortex mixer and 35 mL of isopropyl alcohol was slowly added as a flocculating agent while mixing. The flocculated microglobules were then filtered, washed with two 100-mL portions of isopropyl alcohol and dried for 15–20 h in an oven at 36°C ± 1°C. Pectin and gelatin sol concentrations of 2.0% were selected on the basis of earlier studies (2), which demonstrated optimum yield at this concentration. The pH of mixing (pH_m)[7], pH of coacervation (pH_c)[8], and colloid ratio were varied to yield microglobules of desired morphology and size (2).

Effect of pH—A sulfamerazine sample (0.8 g) was added to 40.0-g coacervate batches at three pH_m values, at pH 5.0, and at several pH_c values. The system was stirred for 3 min before addition of 0.5 M HCl except when sulfamerazine was added at pH_c, and the recovery procedure was completed as for nonmedicated microglobules (2). Each batch was evaluated for the extent of microencapsulation of the sulfamerazine particles and for microglobule morphology. The sulfamerazine content was determined for selected batches and the particle size was analyzed using a microscopic count technique. To produce a batch of medicated microglobules having a mean diameter of ~5 μm, it was necessary to modify the procedure to eliminate sulfamerazine crystals >2–3 μm. In this case, a sample of sulfamerazine (1.87 g) was added to a 40.0-g batch at the selected pH_m, stirred to disperse the crystals, and centrifuged at 1000 rpm for 3 min. The supernatant was transferred to a 50-mL beaker and the coacervation procedure was resumed.

Effect of Mass of Sulfamerazine—Samples of sulfamerazine (≤3.2 g) were added (at pH_m 10.0) to 40.0-g coacervate batches having a pectin–gelatin colloid ratio of 30:70. Coacervates formed at pH_c of 3.8 and produced microglobules of 25 μm. Samples of sulfamerazine (1.2 g) were added (at pH_m 10.0) to 40.0-g batches having a pectin–gelatin colloid ratio of 33:67. Coacervates formed at pH_c 4.5 and produced microglobules of 10 μm. The recovered batches were evaluated for morphology, total yield, and sulfamerazine content.

Observed Extent of Extraction and Digestion of Microglobules in Aqueous Media—Microglobules (~100 mg) containing 41% (w/w) of sulfamerazine were placed in 20-mL type I glass vials containing 10 mL, respectively, of simulated gastric fluid[9]; 0.1 M HCl, simulated intestinal fluid[9]; 0.1 M NaOH; collagenase B solution, 20 U/mL at pH 7.0 in 0.05 M Tris[10] and 0.005 M calcium chloride (3); replacement electrolyte solution[4]; or distilled water. The vials were sealed with pretreated rubber closures, crimped with aluminum caps and rotated at 25 ± 3 rpm at 37°C in an apparatus similar to that used by Souder and Ellenbogen (4). The suspensions were observed visually and microscopically at 7.5, 15, 30, 60, and 120 min to determine the effect of extraction with the various media on morphology and contents of the microglobules.

Determination of Sulfamerazine Released from Microglobules Extracted with Aqueous Media—Accurately weighed 10-mg samples of microglobules [25-μm average diameter containing 33% (w/w) sulfamerazine] were extracted in 10-mL portions of replacement electrolyte solution and distilled water in 20-mL type I glass vials sealed with pretreated rubber closures and rotated at 25 ± 3 rpm at 37°C. The suspensions were sampled at 0.5, 1.0, 2.0, 4.0, 8.0, and 20.0 h, filtered through a 0.22-μm micropore filter membrane[11], and assayed. Similarly, 10-μm microglobules containing 47% (w/w) sulfamerazine were extracted in replacement electrolyte solution only.

Determination of Sulfamerazine Released from Microglobules Extracted with Aqueous Acetone Solutions—Accurately weighed 50-mg samples of microglobules (25-μm average diameter) containing 41% (w/w) sulfamerazine were extracted for 15 min in 10 mL of aqueous acetone solutions of 0–100% (v/v) acetone in 10% increments. Each sample was filtered through a 0.25-μm membrane[12], 5 mL of filtrate was transferred to a 25-mL volumetric flask, and the solvent was evaporated to dryness. Each sample was brought to volume with 0.1 M NaOH and assayed spectrophotometrically.

Assay of Sulfamerazine Content in Microglobules—Batches of microglobules were washed with acetone, 100 mL/1.0 g of drug originally added, to dissolve any superficial drug. An accurately weighed 100-mg microglobule sample was transferred to a 100-mL volumetric flask and brought to volume with 0.1 M NaOH. A 10-mL aliquot was filtered using a 0.22-μm membrane[11]; 1.0 mL of the filtrate was transferred to a 50-mL volumetric flask and brought to volume with 0.1 M NaOH. The absorbance was read at 255 nm against a blank of 0.1 M NaOH. The concentration (mg/mL) was calculated from a standard (Beer's) curve.

Microglobule Formation of Various Drugs—Samples (0.8 g) of hydrocortisone acetate, chloramphenicol, barium sulfate, aluminum powder, phenobarbital, and cod liver oil were added (at pH_m 10.0) to 40.0-g batches having a pectin–gelatin colloid ratio of 30:70 and coacervates formed (pH_c 3.8). After recovery as a dry powder, each batch was examined microscopically at 1000× for microglobule morphology.

Table I—Effect of pH of Addition on Microencapsulation of Sulfamerazine

Pectin–Gelatin Colloid Ratio	pH_m	pH_c	Appearance[a]		
			pH_m	pH 5	pH_c
50:50	8	3.4	A	A	N
	9	3.4	P	A	N
	10	3.2	E	E	P
40:60	8	3.8	A	A	N
	9	3.8	E	P	N
	10	3.8	E	E	P
33:67	8	3.9	P	A	N
	9.5	4.6	E[b]	E	P
	10	4.5	E[c]	E	P
30:70	8	4.0	P	A	N
	9	3.8	E	E	P
	10	3.8	E[d]	E	P
25:75	8	4.4	P	A	N
	9	4.2	E	E	P
	10	3.8	E	E	P

[a] N is no affinity between drug and microglobules; A is surface adsorption; P is partial microencapsulation; E is complete microencapsulation. [b] Mean is 5.7 μm; SD = 0.93; 37.3% w/w sulfamerazine. [c] Mean is 9.2 μm; SD = 1.01; 44.9% w/w sulfamerazine. [d] Mean is 25.5 μm; SD = 4.3; 45.2% w/w sulfamerazine.

RESULTS AND DISCUSSION

Effect of pH of Addition on Microglobule Formation of Sulfamerazine—The results of studies carried out to determine the stage to add and disperse sulfamerazine are summarized in Table I. When the drug was added at the endpoint pH (pH_c), complete microencapsulation was never obtained for any of the colloid ratio–pH_m combinations studied. This confirms the highly stable nature of pectin–gelatin complex coacervate microglobules reported in a previous paper (2) which precluded their coalescence at temperatures well above the gelation point of gelatin. Adding the drug at the starting pH (pH_m) or at pH 5 resulted in uniform and complete microencapsulation in most cases (except pH_m 8). This information indicates that the drug is not included within microglobules by a surface-active phenomena of wetting and spreading as reported for the gelatin–acacia system (1, 2, 5, 6) but probably by entrapment; the adsorbed colloids on the surface react to form a coacervate layer as the pH is lowered below 5. In the cases where adsorption or partial microencapsulation was noted for the addition of drug at pH_m and pH 5 for batches with a starting pH of 8 and 9, the microglobule size was either equal to or smaller than the crystals to be formed. Consequently the forces of cohesion stabilizing the microglobules to a set size precluded the complete coating of irregularly shaped particles. It was possible to obtain medicated microglobules having mean diameters of 5.7, 9.2, and 25.5 μm as pictured in Fig. 1 containing 37.3, 44.9, and 45.2% (w/w) sulfamerazine, respectively.

Effect of Mass of Sulfamerazine—The effect of mass of sulfamerazine on 10-μm and 25-μm microglobules is plotted in Figs. 2 and 3, respectively, and demonstrated in the photomicrographs (Fig. 4). The spherical nature of the microglobules was maintained at ≤69% (w/w) sulfamerazine content for the 25-μm microglobules and ≤45.5% (w/w) for the 10-μm microglobules. Above these values the spherical shape was lost as a result of the increasing volume of suspended particles being coated by a constant volume of coacervate. It is interesting to note that the curves of yield *versus* drug-to-total colloid ratio became linear with the loss of microglobule sphericity. There was a 10–15% suppression in coacervate yield as shown by the curve for calculated colloid yield[13] *versus* drug-to-colloid ratio (Figs. 2 and 3). This can be attributed to

salt suppression by the slight amount of dissolved sulfamerazine at pH_c, which would insulate ionic groups on pectin and gelatin and decrease their reactivity (7). For both systems the curves of percent sulfamerazine in dry product *versus* drug-to-colloid ratio show a lag phase (more pronounced in Fig. 3) resulting from the initial saturation of the equilibrium liquid with sulfamerazine.

Extraction and Digestion of Microglobules—The results of extraction studies on microglobules containing 41% (w/w) sulfamerazine are summarized in Table II. Extraction with collagenase B seems to digest the gelatin portion (3, 8) of the microglobules as evidenced by their change to near transparency in ~2 h. They completely fragmented after 8 h, having released their sulfamerazine crystals and the fragments and crystals were visible after 24 h of extraction. Complete microglobule digestion was observed with gastric and intestinal fluid test solution only. No apparent morphological change in the appearance of the microglobules was observed during extraction in 0.1 M HCl, 0.1 M NaOH, replacement electrolyte, or distilled water.

The extractions in 0.1 M HCl and 0.1 M NaOH are of particular interest in that these seem to suggest the presence of a highly porous matrix which,

Table II—Effect of Extraction on Morphology and Contents of Microglobules

[a] Containing 41.0% (w/w) sulfamerazine (0.0205 g/10 mL).

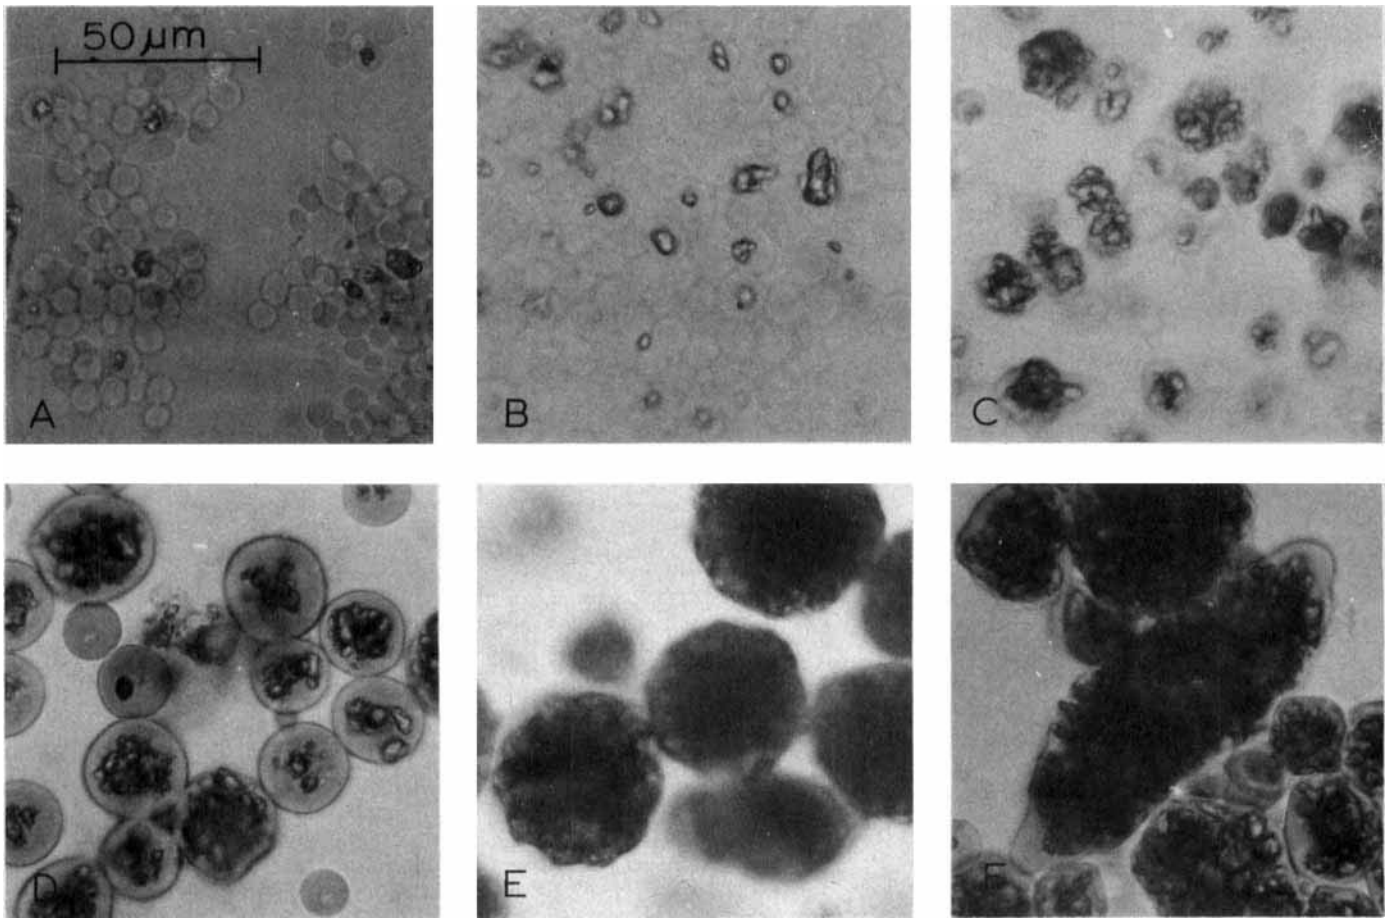

Figure 4—*Effect of mass of sulfamerazine on morphology of 10-μm microglobules containing 16.2% (A), 39.1% (B), and 53.6% (w/w) (C) sulfamerazine; 25-μm microglobules containing 30.5% (D), 58.5% (E), and 73.5% (w/w) (F) sulfamerazine.*

once the microglobules are hydrated, permits the formation and subsequent diffusion out of the microglobules of the soluble hydrochloride or sodium salts of sulfamerazine, respectively. The dependence on hydration for the pore or

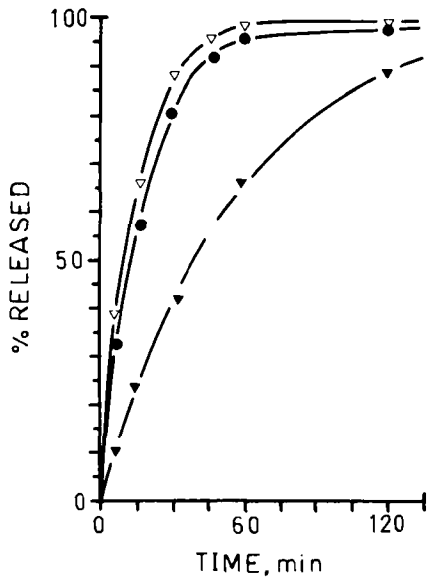

Figure 5—*Effect of extraction with replacement electrolyte solution and distilled water on 10- and 25-μm microglobules. Key: 25-μm microglobules containing 33% (w/w) sulfamerazine extracted in (▼) replacement electrolyte solution and (▽) distilled water; (●) 10-μm microglobules containing 47% (w/w) sulfamerazine extracted in replacement electrolyte solution.*

channel formation was confirmed by extraction of microglobules with aqueous acetone solutions of various concentrations. These results (Table III) indicate that with ≤30% acetone, the amount released is limited by the solubility of sulfamerazine in the binary mixture. For greater concentrations of acetone (≤60%) the microglobules are sufficiently hydrated to allow as much as a 76% release of the drug. At still higher concentrations, the amount of sulfamerazine released decreases although its solubility increases to a maximum at ~90% acetone. The higher acetone concentrations are accompanied by a progressive morphological change from uniform smooth microglobules with a smooth surface to smaller microglobules with a wrinkled surface, an indication of progressive dehydration of the hydrophilic colloids. In pure acetone the extraction of 10.2% of the sulfamerazine from the microglobules is attributed to solubilization of sulfamerazine imbedded superficially in the microglobules (1).

Determination of Sulfamerazine Released from Microglobules Extracted with Aqueous Media—The curves plotted in Fig. 5 demonstrate rapid dissolution of sulfamerazine from the microglobule matrix. The dissolution profile is first order with half-lives of 38.7 min and 9.8 min for 25-μm microglobules in replacement electrolyte and distilled water, respectively, and 12.2 min for 10-μm microglobules in replacement electrolyte. The reduced dissolution rate for microglobules containing sulfamerazine in replacement electrolyte as opposed to distilled water can be attributed to reduced hydration of the microglobule matrix. The higher dissolution rate for sulfamerazine from the 10-μm microglobules in replacement electrolyte results from the higher surface area. These results indicate a very porous matrix which would be more suitable to high molecular weight drugs, drugs microencapsulated as an oil or waxy dispersion, or drugs chemically linked to the polymer matrix.

Microencapsulation of Various Drugs—For successful drug microencapsulation by complex coacervates of pectin and gelatin, the solubility of the drug in the equilibrium liquid and the coacervate must be sufficiently low, it must not have any surfactant activity (9), it must have adequate stability in alkaline and acidic media, and it must have a uniform particle size lower than the desired microglobule size to maintain a spherical shape. Various organic and

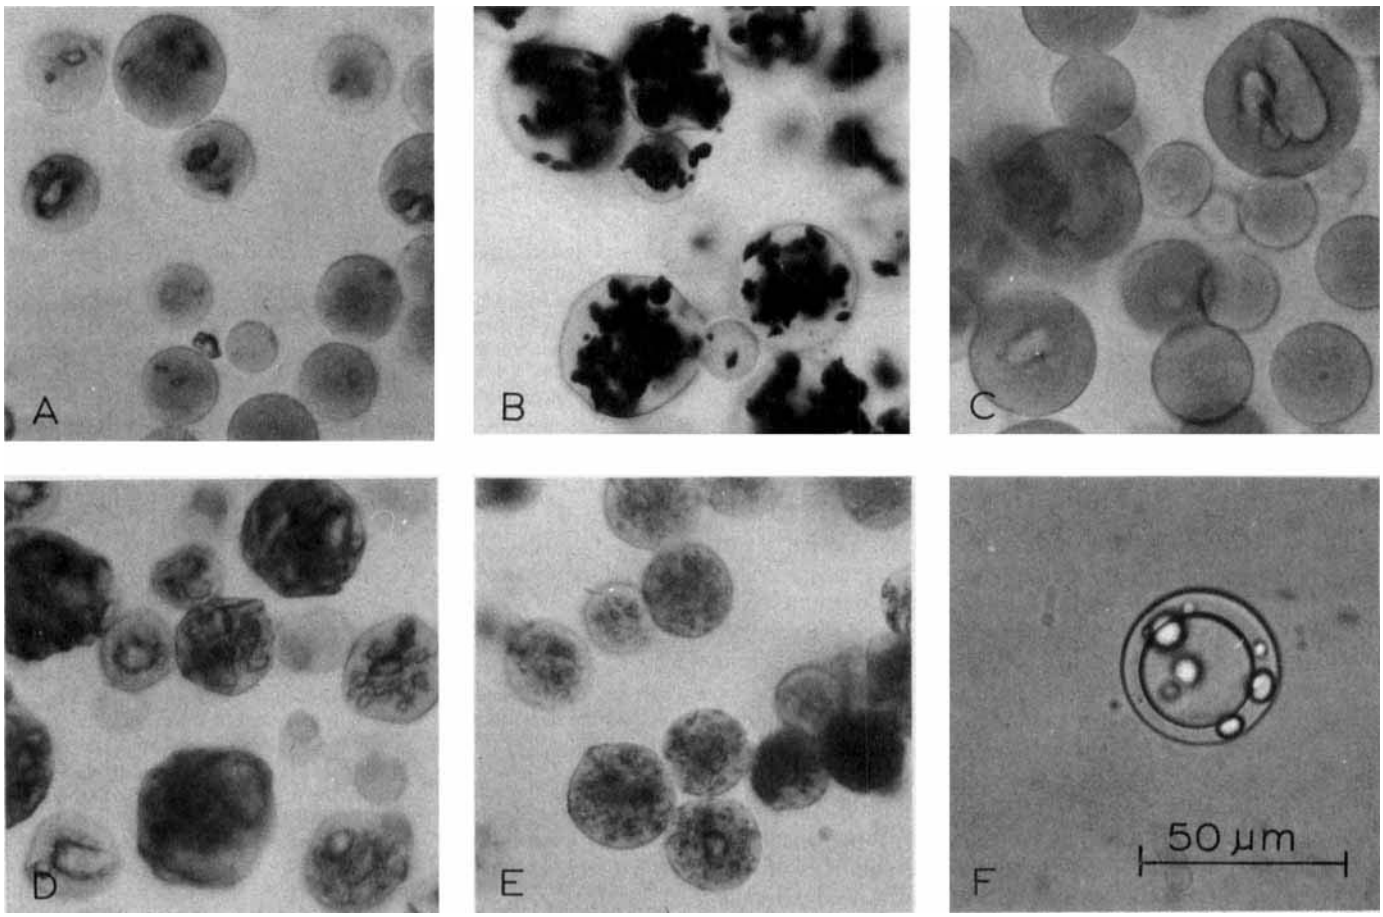

Figure 6—*Pectin-gelatin microglobules containing an undetermined amount of chloramphenicol (A), aluminum powder (B), phenobarbital (C), hydrocortisone acetate (D), barium sulfate (E), and cod liver oil (F).*

inorganic substances complying with these requirements were successfully microencapsulated (Fig. 6).

DC Polarographic Reduction of Chloroguanide Hydrochloride

F. VICENTE-PEDRÓS ˣ, F. TOMÁS-VERT, and J. VERA-SÁNCHEZ *

Received September 24, 1982, from the *Departamento de Química Física, Facultad de Química, Universidad de Valencia, Burjasot-Valencia* and the **Departamento de Química Física, Facultad de Ciencias, Murcia, Spain.* Accepted for publication February 29, 1984.

Abstract □ Chloroguanide hydrochloride, an antimalarial drug, shows one well-defined DC polarographic wave in Britton–Robinson buffered media. In the pH range 3–9 the observed reduction wave is related to the reduction of the two azomethine centers on the monoprotonated biguanide group (BH^+). The effects of pH and other experimental variables on the limiting current and half-wave potentials as well as the reduction mechanism are discussed.

Keyphrases □ Polarography—proguanil hydrochloride, effect of pH □ Proguanil hydrochloride—DC polarographic reduction

The different pharmacological and physical properties of each biguanide derivative depend on the chemical nature of the substituent radicals joined to the biguanide group. Nevertheless, in addition to its chemical properties, the specific applications for biguanides also depend on the solubility and surface-active characteristics (1–4).

The present study concerns results which have been obtained with the antimalarial (5) and antirheumatic (6–10) substance, chloroguanide hydrochloride [1-(*p*-chlorophenyl)-5-isopropylbiguanide hydrochloride] in Britton–Robinson media.

The general difficulties encountered in reducing the biguanide group of other monoprotonated biguanides on the dropping mercury electrode (11, 12) are associated with the great delocalization of its π-electronic system, as is the case of guanidine derivatives (13) since the π electrons are delocalized over the entire area of this monoprotonated or basic group. Under these circumstances, the particular behavior of chloroguanide should be associated with the configuration of its biguanide group. The X-ray studies have demonstrated, for this monohydrochloride in solid form, ~60° angle between the two "guanidine planes" (14), whereas this angle is substantially lower for other biguanides (15, 16). This leads us to speculate that chloroguanide shows a polarographic wave, like chlorhexidine (17–19), that is independent of the guanidine planes. The angle is larger than that in other cationic biguanides that do not show polarographic waves having the characteristics (12, 20) described in this work.

EXPERIMENTAL SECTION

The polarographic waves were obtained with a polarograph[1]. A digital pH meter[2] with a combined glass-reference electrode was utilized which enabled us to attain a pH precision of 0.01 pH unit. Thermostabilization was achieved with a ±0.1° C precision, using a cryostat[3] and a thermostat[4]. In the three-electrode coulometric cell, the working cathode was a mercury pool, the auxiliary electrode was platinum, and the reference electrode was Ag/AgCl, $KCl_{(s)}$.

The chloroguanide hydrochloride was used as supplied[5], mp 238 ± 2° C, and showed one spot on TLC. The UV and IR spectra were obtained with spectrophotometers[6]. Nonaqueous tritration in acetic media (21) was used to confirm the purity. The chemicals used to prepare the buffered solutions were analytical reagent grade; water was distilled and the mercury was double-distilled.

The polarographic measurements were carried out on freshly prepared samples in a total volume of 25 mL. Purified N_2 was passed through all sample solutions (7 min) for deaeration. Other polarographic conditions were: mercury flow, m = 0.88 ± 0.02 mg·s^{-1}; controlled drop time, τ = 0.6 s; depolarizer concentration (chloroguanide hydrochloride), $C = 4 \times 10^{-4}$ M; temperature, T = 298 K; and Britton–Robinson buffer mixture, I = 0.5 M. The diffusion current (i_d) was measured as shown in Fig. 1.

RESULTS AND DISCUSSION

Chloroguanide is electroactive in Britton–Robinson buffered solutions over the pH range studied, 3–9. The polargrams show one reduction wave (Fig. 1).

The drop time effect on the cathodic waves (Table I) is shown by slopes $\Delta E_{1/2}/\Delta \ln \tau = 22 \pm 2$ mV and $\Delta \ln i_l/\Delta \ln \tau = 0.18 \pm 0.02$, two characteristics of the diffusion-controlled processes (22). Also, the effects of both the mercury pressure and chloroguanide concentration on the diffusion current of the wave shows that this current appears to be diffusion controlled at every pH examined. The limiting current intensity remains essentially constant at pH 3.5–6.5 and decreases at pH > 6.5 (Fig. 2). The decreasing current intensity has the form of a dissociation curve with an apparent polarographic pK_s = 8.3 [pK_s = pH, where $i_l = i_d/2$ (23)]. To verify the pK_a value, a spectrophotometric study (24) of this compound was performed: pK_{a1} = 2.3 ± 0.1 and pK_{a2} = 10.4 ± 0.2. The pK_s value is apparently affected by the double layer structure. Due to this change, the overall absorptivities of the protonated and unprotonated forms are different. From the dependence of the half-wave potentials of quasi-diffusion kinetic surface waves on pH (Fig. 2), the K_a values cannot be determined directly, as was possible for quasi-diffusion kinetic volume waves (25).

The number of electrons involved in the electroreduction process at different pH values have been estimated by substituting the values of c, τ, m, and the x conductometric coefficient of diffusion, D° [5×10^{-6} cm^2·s^{-1} (26)] in the Ilkovic equation (22). In moderately acidic media the height of the cathodic

wave corresponds to the uptake of 4 electrons. Controlled-potential coulometry with a mercury pool electrode, performed at a controlled-applied potential corresponding to the plateau of the polarographic curve, verified a consumption of 4 electrons per molecule at all values of pH studied.

Plotting $E_{1/2}$ of the wave *versus* pH in the 3-7 range (Fig. 2) gives a straight line of slope, $\Delta E_{1/2}/\Delta pH = 93 \pm 2$ mV. From this slope, the number of H^+ ions (z_{H^+}) in the rate-determining step can be calculated using the following equation (27):

$$z_{H^+} = \frac{\alpha n_a \Delta E_{1/2}}{59 \Delta pH} \qquad \text{(Eq. 1)}$$

By substituting the value of αn_a, obtained from the slope of log $(i/i_l - i)$ *versus* $-E$ plots, the z_{H^+} values are ~1.0 (Table II). The most probable number of electrons (n_a) in the rate-determining step is one electron.

The addition of dimethylformamide to chloroguanide solutions decreases the absolute value of $E_{1/2}$ (Table III). This shows the strong influence exerted by the Helmholtz double layer around the electrode on the cathodic mechanism. The addition of gelatin in amounts $<6 \times 10^{-3}$ % by weight prevents registration of these waves. The electrocapillary curves (τ *versus* E) shows a slight adsorption of the monoprotonated chloroguanide on the dropping mercury electrode (DME) at the wave potentials (18). The wave has a surface character.

The ionic strength decreases the i_l values and causes displacement of the $E_{1/2}$ to more negative values (Table IV), whereas the effect of the decreased buffering capacity (Table V) is lower than that produced by variation of the ionic strength.

On the other hand, the energies of activation, Q, which are calculated by the following equation (28):

$$i_d = Ae^{-Q/RT} \qquad \text{(Eq. 2)}$$

are higher than typical for diffusion-controlled processes. Therefore, the value at pH 5.34 is $Q = 3.8 \pm 0.1$ kcal·mol^{-1} and at pH 7.11, the value is $Q = 4.1 \pm 0.1$ kcal·mol^{-1}. This slight dependence on pH values coincides with an increased irreversibility when pH is increased (Fig. 1). The $E_{1/2}$ values remain nearly constant at pH 7.11, when T is varied from 0°C to 50°C, which should be related to the fact that the first single electron transfer is not exceedingly slow.

As Hollek (29) has indicated, the adsorption of a depolarizer or a reaction product on the DME is a potential cause for deviation of the $\Delta E_{1/2}/\Delta pH$ value from −60 mV/pH unit. Therefore, although the $\Delta E_{1/2}/\Delta pH$ surface waves

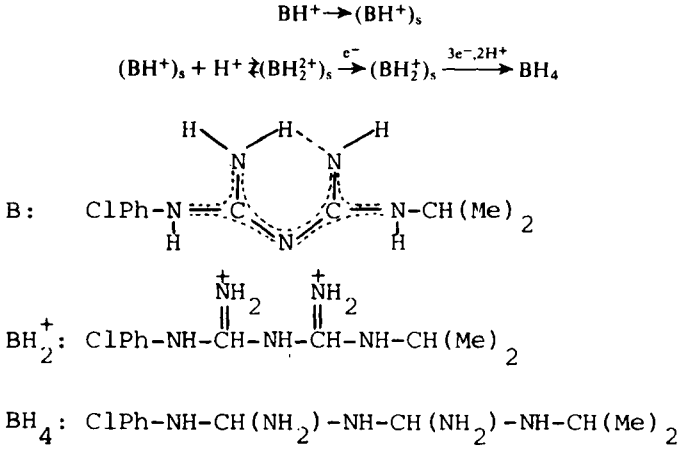
are smaller than the slope of their plots on semilogarithmic coordinates, the absolute value of $\Delta E_{1/2}/\Delta pH$ for surface waves is larger than the $\Delta E_{1/2}/\Delta pH$ volume for surface waves. Since the rate of the previous surface reaction is sufficiently high in chloroguanide reduction, the i_l value of the kinetic wave is close to the diffusion intensity. Under these conditions, the wave has a well-defined limiting current plateau, and the wave height is determined by the Ilkovic equation. The wave is a quasi-diffusion surface wave.

The biguanide group reduction is made evident by UV spectroscopy, since the chloroguanide absorption $\pi \rightarrow \pi^*$ transition at 232 and 251 nm decreases when chloroguanide is fully reduced, and a single band with one maximum value (~256 nm) is registered. This means a decrease of the electronic delocalization, and a new transition ($n \rightarrow \pi^*$) appears with a maximum absorption value at ~290 nm. This is a typical example of a reduced substance obtained when the two azomethine groups have been transformed into the corresponding amine groups, as Schultz (30) confirmed with the chemical reduction of chloroguanide using a zinc amalgam.

Based on the experimental results, the reduction of the biguanide group is likely to take place as shown in Scheme I:



Scheme I

As stated earlier, this reduction seems to take place through an intermediate $(BH_2^+)_s$ which disappears quickly with the complete reduction of the double bonds at the potentials at which the polarographic wave is detected. The *p*-chlorophenyl substituent in chloroguanide seems to be transformed into a state of reduced electron delocalization with respect to the other biguanides. Perhaps as is the case in the solid state (14), the monoprotonated molecule-cation, (BH^+), which exists at physiological pH in solution, is present as a result of a certain independence of the guanidine groups, as occurs with other efficient antimalarial drugs which show the independent imine groups (31).

The polarographic method can be applied for the analytical determination of chloroguanide at pH 3-7 in buffered media. The plots of i_d *versus* C give linear calibrations at 10^{-5}–5×10^{-3} M concentrations. For example, at pH 5.01: $i_d(\mu A) = (4.25 \times 10^3) \cdot C\ (\text{mol} \cdot \text{L}^{-1})(SD = 5 \times 10^{-3})$.

The assay is rapid and has great sensitivity. The lowest sensitivity limit recorded is 0.05–0.1 $\mu g \cdot mL^{-1}$. At $\tau = 0.6$ s the limit of detection is less favorable than in conventional DC polarography because the ratio of charging current to faradic current increases when drop time decreases (32).

Any substance having a half-wave potential within the range of ±100 mV with respect to the $E_{1/2}$ of chloroguanide produces an overlapping of both waves. Also, the presence of gelatin, Triton X-100, or another strongly absorbable substance on the DME produces interferences since the chloroguanide electroreduction is a heterogeneous process.

Design of a Slow-Release Capsule Using Laser Drilling

N. K. JAIN ˣ and S. U. NAIK

Received August 29, 1983, from the *Pharmaceutics Laboratory, Pharmacy Department, Faculty of Technology & Engineering, M. S. University of Baroda, Baroda, India.* Accepted for publication December 13, 1983.

Abstract □ Conventional hard gelatin capsules were made GI-tract resistant by formalin vapor treatment. The residual formalin content was 80 μg/capsule 24 h after treatment, which decreased with increased storage time. An *in vitro* GI-tract resistance test was performed by exposing the capsules to simulated gastric fluid for 4 h and then to simulated intestinal fluid for 4 h at 37°C. The resistance was further confirmed by *in vivo* X-ray studies in human volunteers. Minute pores were drilled on the hardened shells of the capsules with a carbon dioxide gas laser. This permitted the slow passage of the encapsulated tetracycline hydrochloride when subjected to 0.1 M HCl in *in vitro* dissolution studies. *In vitro* drug release from these capsules followed zero-order kinetics after an initial lag period of 30 min. The factors influencing the *in vitro* release rate of tetracycline hydrochloride from these capsules are discussed.

Keyphrases □ Gelatin capsules–drug release, GI-tract resistance, laser-drilled design □ Laser-drilled capsules–drug release, GI-tract resistance, X-ray studies

The potential application of the laser in the fields of communication, industry, military science, chemistry, biology, and medicine has been well established and well documented (1). The possible use of the laser in designing a controlled-release capsule dosage form has been recently reported (2). Theeuwes *et al.* (3) reported the use of automated laser drilling in making exit pores for indomethacin in the design of an elementary osmotic pump.

Conventional hard-gelatin capsules normally disintegrate rapidly and the encapsulated drug exhibits a cube-root dissolution pattern (4). Exposure to formalin vapors causes the cross-linkage of the gelatin molecule, resulting in an unpre-

As stated earlier, this reduction seems to take place through an intermediate $(BH_2^+)_s$ which disappears quickly with the complete reduction of the double bonds at the potentials at which the polarographic wave is detected. The *p*-chlorophenyl substituent in chloroguanide seems to be transformed into a state of reduced electron delocalization with respect to the other biguanides. Perhaps as is the case in the solid state (14), the monoprotonated molecule-cation, (BH^+), which exists at physiological pH in solution, is present as a result of a certain independence of the guanidine groups, as occurs with other efficient antimalarial drugs which show the independent imine groups (31).

The polarographic method can be applied for the analytical determination of chloroguanide at pH 3-7 in buffered media. The plots of i_d *versus* C give linear calibrations at 10^{-5}–5×10^{-3} M concentrations. For example, at pH 5.01: $i_d(\mu A) = (4.25 \times 10^3) \cdot C\ (\text{mol} \cdot \text{L}^{-1})(SD = 5 \times 10^{-3})$.

The assay is rapid and has great sensitivity. The lowest sensitivity limit recorded is 0.05–0.1 $\mu g \cdot mL^{-1}$. At $\tau = 0.6$ s the limit of detection is less favorable than in conventional DC polarography because the ratio of charging current to faradic current increases when drop time decreases (32).

Any substance having a half-wave potential within the range of ±100 mV with respect to the $E_{1/2}$ of chloroguanide produces an overlapping of both waves. Also, the presence of gelatin, Triton X-100, or another strongly absorbable substance on the DME produces interferences since the chloroguanide electroreduction is a heterogeneous process.

Design of a Slow-Release Capsule Using Laser Drilling

N. K. JAIN ˣ and S. U. NAIK

Received August 29, 1983, from the *Pharmaceutics Laboratory, Pharmacy Department, Faculty of Technology & Engineering, M. S. University of Baroda, Baroda, India.* Accepted for publication December 13, 1983.

Abstract □ Conventional hard gelatin capsules were made GI-tract resistant by formalin vapor treatment. The residual formalin content was 80 μg/capsule 24 h after treatment, which decreased with increased storage time. An *in vitro* GI-tract resistance test was performed by exposing the capsules to simulated gastric fluid for 4 h and then to simulated intestinal fluid for 4 h at 37°C. The resistance was further confirmed by *in vivo* X-ray studies in human volunteers. Minute pores were drilled on the hardened shells of the capsules with a carbon dioxide gas laser. This permitted the slow passage of the encapsulated tetracycline hydrochloride when subjected to 0.1 M HCl in *in vitro* dissolution studies. *In vitro* drug release from these capsules followed zero-order kinetics after an initial lag period of 30 min. The factors influencing the *in vitro* release rate of tetracycline hydrochloride from these capsules are discussed.

Keyphrases □ Gelatin capsules–drug release, GI-tract resistance, laser-drilled design □ Laser-drilled capsules–drug release, GI-tract resistance, X-ray studies

The potential application of the laser in the fields of communication, industry, military science, chemistry, biology, and medicine has been well established and well documented (1). The possible use of the laser in designing a controlled-release capsule dosage form has been recently reported (2). Theeuwes *et al.* (3) reported the use of automated laser drilling in making exit pores for indomethacin in the design of an elementary osmotic pump.

Conventional hard-gelatin capsules normally disintegrate rapidly and the encapsulated drug exhibits a cube-root dissolution pattern (4). Exposure to formalin vapors causes the cross-linkage of the gelatin molecule, resulting in an unpre-

0022-3549/84/1200-1806$01.00/0

dictable decrease in solubility of these capsules (5). The objectives of this study were: (*a*) to prepare GI-tract resistant hard-gelatin capsules by formalin vapor treatment and to confirm their resistance by *in vitro* and *in vivo* studies; (*b*) to make minute pores on the hardened shells of the capsules by laser drilling to allow the contents to release slowly through these minute pores; (*c*) to report on the different factors that are likely to influence the *in vitro* drug release rate from these capsules.

EXPERIMENTAL SECTION

Preparation of GI-Tract Resistant Capsules—The conventional hard-gelatin capsules were exposed to formalin vapor under normal temperature and pressure conditions. After the vapor contact time, the capsules were dried in an oven at 50°C. The formalin vapor contact time and drying time were optimized with respect to GI-tract resistance, residual formalin content, drilling requirements, physical characteristics of the capsules, *etc.*, by trial experiments.

Residual Formalin Content—The analytical procedure used to determine the residual formalin content was based on the method of Macfadyan (6). The method involves the spectrocolorimetric measurement (at 490 nm) of the violet color produced when 1.0 mL of the sample, containing ~2–3 μg of formalin with 9.0 mL of 0.2% (w/v) solution of chromotropic acid[1] in 80% (v/v) sulfuric acid, was heated on a boiling-water bath for 30 min.

The sample was prepared by placing one formalin-treated capsule in each of the three clean, dry, 20.0-mL vials containing 10.0 mL of distilled water. After closing with rubber stoppers and sealing with aluminum seals, the vials were agitated on a mechanical agitator for 1.0 h. The saturation solubility of the formalin capsule in 10.0 mL of distilled water was optimized with respect to agitation time by trial experiments. A sample (1.0 mL) was withdrawn from each vial with a syringe, and the residual formalin content was determined. The average content of the three vials was reported as the residual formalin content.

***In Vitro* GI-Tract Resistance Test**—The studies were carried out by the rotating-basket method (7). A flask containing 900.0 mL of simulated gastric fluid as the dissolution medium (8) was immersed in a constant-temperature bath at 37 ± 0.5°C. The empty formalin-treated capsule (with laser drilled pores on the body) was then inserted, and the basket was rotated at 100 rpm for 4 h. At the end of 4.0 h, 900.0 mL of the simulated gastric fluid was replaced by the same quantity of simulated intestinal fluid (8), and the experiment was repeated for 4.0 h.

***In Vivo* X-ray Studies**—Two human male volunteers (age, 27 and 29 years; weight, 65.5 and 71.5 kg.) were selected for the study. The subjects had no history of GI disease and neither used any medication regularly. Both volunteers were asked to abstain from alcoholic beverages for 48 h preceding each experiment and fasted overnight. At 8:30 a.m. one capsule containing 250.0 mg of barium sulfate (band sealed with a suitable GI-tract resistant material) was administered orally with ~25.0 mL of water. Volunteers were allowed to take food 4.0 h after administration of the capsule. X-ray photographs were taken at 0.5, 1.0, 2.0, 4.0, 6.0, and 8.0 h after capsule administration.

Laser Drilling—A CO_2 (CW/pulsed) laser[2] (Fig. 1) was used to drill small pores into the hardened shells of the capsules. This laser can be operated in continuous or pulsed modes. In the pulsed mode, the pulse width of the laser can be varied from 100 μs to 1 s, and the frequency can be varied from 1 to 1000 pulses/s. Pulse width and frequency variations changed the diameter of the drilled pores and the number of drilled pores, respectively. The laser was internally pulsed through an electronically controlled trigger switch. This type of pulsing provides a power output four to five times the average output, depending on the pulse width selected. This laser system had well-insulated high-voltage terminals and an automatic switch to ground the capacitor bank when switching off or tripping off the power supply; the power supply and the coolant flow were interlocked.

In this investigation, laser-drilled capsules were studied with respect to variation in the number of drilled pores, diameter of the drilled pores, and the drilling pattern of the pores. To vary the number of pores, the capsule was mounted on a linear drive (speed, 2 mm/s). By changing the laser frequency and keeping the power and pulse width (220 μs) constant, 25, 50, 75, and 100 pores with an SD_2 size distribution were drilled on the body of the capsule shell.

Table I—Pulse Width Variations with Corresponding Pore Size Distributions and Average Diameters

Pore Size Distribution	Pulse Width, μs	Average Pore Diameter, μm	
		dln[a]	*dg*[b]
SD_1	100	83–88	78.50 ± 1.57
SD_2	220	103.60	100.00 ± 1.41
SD_3	300	160.20	155.00 ± 1.52
SD_4	420	207.80	205.00 ± 1.38

[a] Statistical length-number mean diameter. [b] Geometric mean diameter from the probability plot (±*SD*).

The pores were placed equidistant in three lines with an almost equal number of pores per line.

For the study of diameter variation, 50 drilled pores with size distributions of SD_1, SD_2, SD_3, and SD_4, with an average length-number mean diameter (*dln*) equal to 83.58, 103.60, 160.20, and 207.80 μm, respectively [determined by the optical microscopic method (9)], were obtained by varying the pulse width of the laser and keeping the frequency constant at 1 pulse/s (Table I). The variation in the pore drilling pattern was studied with 50-pore capsules (of SD_2 distribution) on the body only and on both the cap and body. Laser-drilled pores on the hardened shells of the capsules are shown in Fig. 2.

Factors Influencing Release Rate—GI-tract resistant capsules with 50 laser-drilled pores (SD_2 size distribution) on the body, containing tetracycline hydrochloride[3] (as a model drug) and band sealed with GI-tract resistant seals, were used for the study. The average weight of the filled capsules was determined by weighing 10 capsules. Friability testing of the capsules was done on a friabilator[4] (10). The bulk density of the sample was determined by the

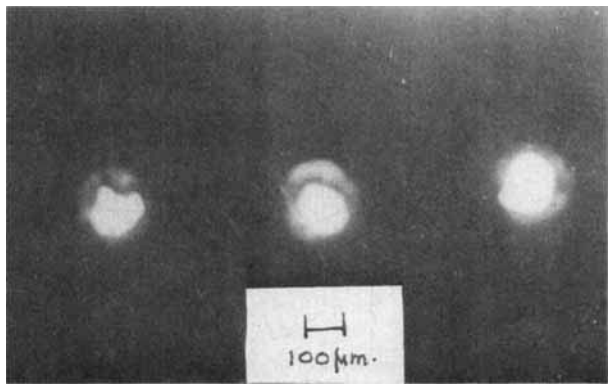

Figure 2—*Different sizes of laser-drilled pores on the hardened capsule shell.*

[3] Synbiotics, Wadi Wadi, Baroda, India.
[4] Roche.

standard three-tap method suggested by Butler and Ransey (11). The particle size and size distribution analyses were made by the optical microscopic method (9), by preparing a suspension of the sample in glycerol.

To study the effect of diluents, capsules containing 250.0 mg of tetracycline hydrochloride were prepared using lactose or microcrystalline cellulose as diluent. Differences in bulk density between the drug and the diluents were taken into consideration when calculating the fill weight of individual capsules.

The effect of powder properties such as particle size and distribution and bulk density were studied by using capsules filled with three powder samples with different characteristics. The original sample of tetracycline hydrochloride (sample I) was screened through a 360-mesh standard sieve; an oversized fraction (sample II), and an undersized fraction, which was pulverized with a pestle and mortar (sample III), were also used for the study. Tetracycline hydrochloride capsules were prepared by filling tetracycline hydrochloride with 2.0% talc or 1.0% magnesium stearate to study the effect of common lubricants.

Saturated solutions of dioctyl sodium sulfosuccinate[5] and polysorbate 80[6] in alcohol were sprayed separately on the tetracycline hydrochloride to give 0.5% (w/w) and 1.0% (w/w) of these wetting agents uniformly distributed in the dried (at 40°C) tetracycline hydrochloride. These samples were used to study the effect of wetting agents.

***In Vitro* Dissolution Rate Studies**—The dissolution rate studies were carried out by a method similar to that used in the *in vitro* GI-tract resistance test. However, the dissolution medium was 0.1 M HCl, 5.0-mL samples were withdrawn at 30-min intervals and the volume of the dissolution medium was maintained by replacing an equal volume of the medium after each withdrawal. The samples were analyzed at 353 nm using a spectrocolorimeter[7].

RESULTS AND DISCUSSION

All the samples tested for *in vitro* GI-tract resistance showed resistance in both simulated gastric and intestinal fluids. The capsules remained intact throughout the GI tract in the X-ray studies, confirming *in vivo* resistance in the subjects tested. Figure 3 shows the position of the capsule in the GI tract at 0.5, 1.0, 2.0, 4.0, 6.0, and 8.0 h after the capsule was administered in one of the subjects. The capsule remained in the stomach for more than 1.0 h; 2.0 h after administration, the capsule was seen in the duodenal area of the small intestine. The capsule was traced intact in the ileum after 4.0 h, in the colon after 6.0 h, and finally in the rectum at 8.0 h. The residual formaldehyde content after 24.0 h of treatment was 80 μg/capsule, which reduced to 68 and 60 μg/capsule after 15 and 30 d of storage, respectively.

The number of drilled pores considerably influenced the release rate of tetracycline hydrochloride from the capsule (Fig. 4). A plot of percentage of

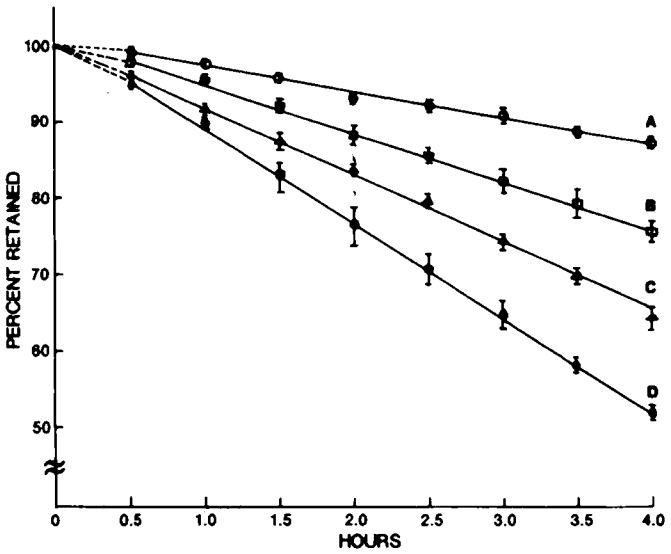

Figure 4—*Effect of variation in number of drilled pores, n (with SD_2 type of size distribution) on percent drug retained as a function of time. Key: (A) n = 25; (B) n = 50; (C) n = 75; (D) n = 100.*

the drug retained against time indicates that the drug release follows a zero-order pattern after an initial lag period of 30 min in all cases. This lag period may be attributed to the time required for the dissolution fluid to penetrate the capsule, wet and dissolve the drug, and finally allow the drug to pass through the pores.

The slope values were calculated by (12):

$$\alpha = \frac{\{\sum xy - (\sum x \cdot \sum y/n)\}}{\{\sum x^2 - [(\sum x)^2/n]\}} \qquad \text{(Eq. 1)}$$

where α is the slope, x is the time (in hours), and y is the percentage drug retained. Since the release follows zero-order kinetics, the slope represents the rate of the release (k_n) and n indicates the number of pores drilled. The calculated values of k_{25}, k_{50}, k_{75}, and k_{100} were 3.30, 6.32, 8.92, and 12.27%/h, respectively. The variations in number of drilled pores were in the ratio of 1:2:3:4; the release rate constant, k_n, showed a similar ratio. This indicates a proportionate increase in the release rate of the drug with an increase in the number of drilled pores (n).

The effect of pore size and size distribution on the release rate constant of tetracycline hydrochloride is shown in Fig. 5 for the size distribution ranges SD_1, SD_2, SD_3, and SD_4. The statistical mean diameter of each size distribution was calculated by (12):

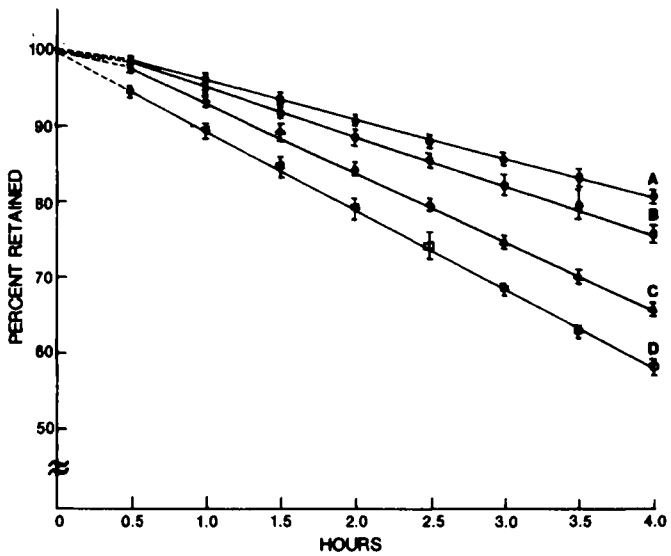

Figure 5—*Effect of variation in size distribution of drilled pores on percent drug retained as a function of time. Key: (A) SD_1; (B) SD_2; (C) SD_3; (D) SD_4.*

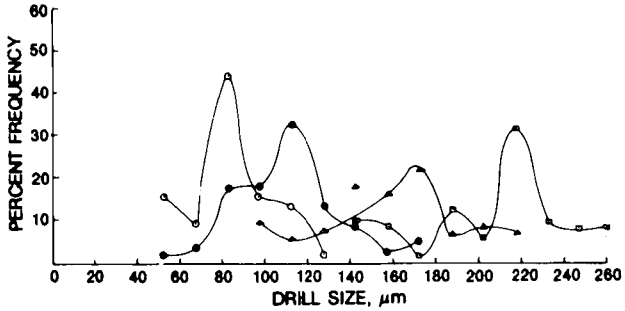

Figure 6—*Frequency distribution plots of different size ranges of drilled pores. Key: (⊙) SD_1; (●) SD_2; (▲) SD_3; (⊡) SD_4.*

$$d_{mean} = \left(\frac{\sum nd^{p+f}}{\sum nd^f}\right)^{1/p} \quad \text{(Eq. 2)}$$

where n is the number of pores in a size range whose midpoint, d, is one of the equivalent arithmetic, geometric, or harmonic mean diameters; p is the index related to size of an individual pore, since d raised to the power $p = 1$ or $p = 2$ is an expression of the pore length or surface, respectively. The frequency with which the pores in a certain size range occur is expressed by nd^f. When the frequency index has values of 0, 1, or 2 the size frequency distribution is expressed in terms of total number, length, or surface of pores, respectively. The frequency distribution and the log probability plots of SD_1, SD_2, SD_3, and SD_4 pore size distributions are shown in Figs. 6 and 7, respectively. The arithmetic length-number mean diameters, *dln*, were calculated by (12):

$$dln = \frac{\sum nd}{\sum n} \quad \text{(Eq. 3)}$$

and were 83.58, 103.60, 160.20, and 207.80 μm. These values correlated well with the corresponding geometric mean diameters of 78.50, 100.00, 155.00, and 205.00 μm obtained from the log probability plot. The respective standard deviations calculated from the slopes of the lines were 1.57, 1.41, 1.52, and 1.38. The total surface area available for the release of the drug with 50 pores on the body of the capsule for each of the four groups was 1.10, 1.68, 4.03, and 6.78 cm^2/capsule. The calculated release rate constants indicate that the drug was released at the rate of 5.04, 6.32, 8.96, and 10.60%/h for the respective release areas. The release rate followed zero-order kinetics after an initial lag period of 30 min in all cases, except the capsules with SD_4 pore size distribution had no lag period. Such a deviation for larger pore sizes may be due to a decrease in the time required for the dissolution fluid to penetrate the capsule with a larger surface area. The capsules with pores of SD_1 and SD_2 size distributions showed a loss of <0.8%/capsule when subjected to friability tests, unlike the capsules with SD_3 and SD_4 distributions, where the loss was >1%/capsule.

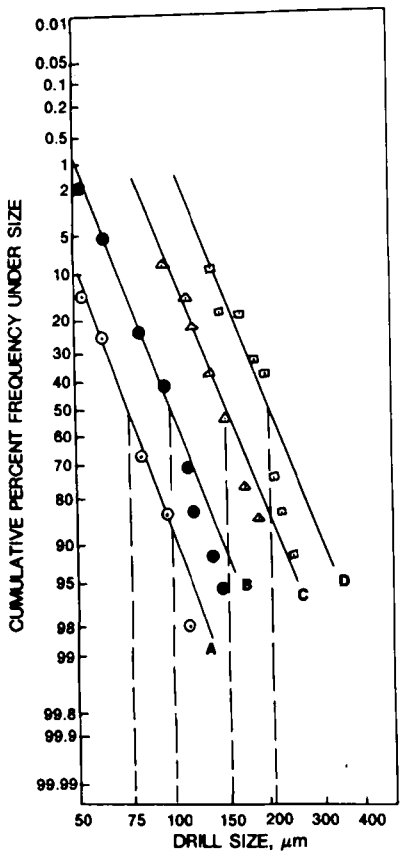

Figure 7—*Log probability plots of different size ranges of drilled pores. Key: (A) SD_1; (B) SD_2; (C) SD_3; (D) SD_4.*

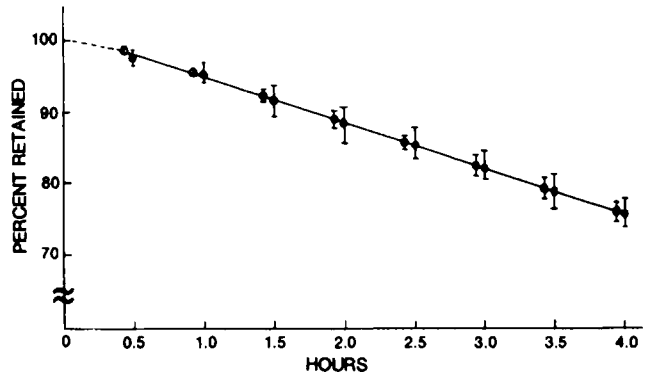

Figure 8—*Influence of variation in pattern of drilling on percent drug retained as a function of time. Key: (○) only body drilling; (●) cap and body drilling.*

The variation in drilling pattern did not show statistically significant differences ($t = 0.037$, $d = 16$, $p < 0.01$) in release rates of the drug (Fig. 8). The higher standard deviations observed in the values for cap and body drilling as compared with body drilling alone may be attributed to incomplete drilling when the comparatively thicker cap and body surface was drilled simultaneously.

The release rate of the drug from the capsule was considerably affected by the powder characteristics, *i.e.*, bulk density and particle size distribution, of the encapsulated drug samples I, II, and III. The bulk densities were 0.61, 0.60, and 0.73 g/cm^3. Average length number mean diameters (*dln*) were 51.20, 95.74, and 23.30 μm and showed release rates of 6.32, 5.00, and 8.11%/h, respectively (Fig. 9). This probably indicates an increase in release rate with decreased particle size of the encapsulated drug. The frequency distributions and log probability plots of the three samples are shown in Figs. 10 and 11, respectively. The aforementioned statistical diameters correlated well with the geometric mean diameters (*dg*) of 48.50, 85.0, and 17.50 μm, respectively, obtained from the log probability plot. The corresponding standard deviations calculated from each slope were 3.03, 1.67, and 2.8.

Figures 12 and 13 show the effect of different additives on the release rate of the drug from the capsules. The use of lactose and microcrystalline cellulose

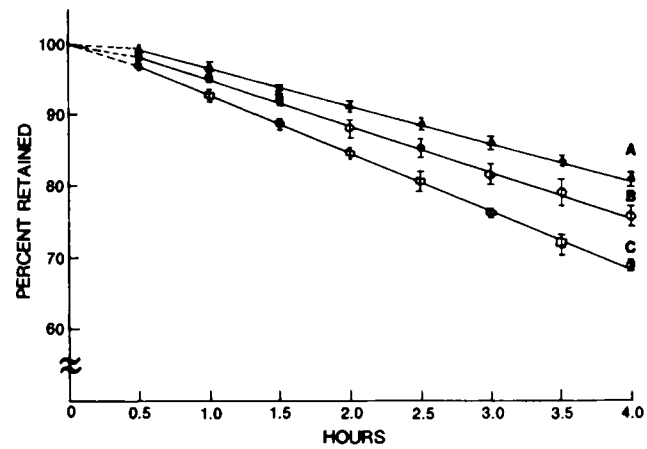

Figure 9—*Effect of particle size and size distribution of the encapsulated drug sample on percent drug retained as a function of time. Key: (A) sample I; (B) sample II; (C) sample III.*

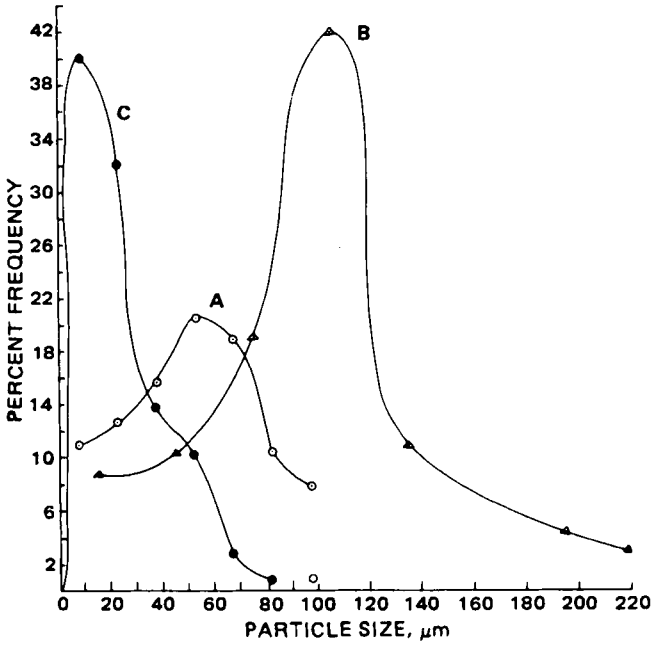

Figure 10—*Frequency distribution plots of different samples of powder. Key: (A) sample I; (B) sample II; (C) sample III.*

as diluents and magnesium stearate and talc as lubricants did not significantly affect the release rate of the drug. Of the two wetting agents used, dioctyl sodium sulfosuccinate showed a statistically significant enhancement of the release rate, unlike polysorbate 80 which showed some enhancement but was not statistically significant. Table II is the analysis of variance (13) to compare the effect of additives on the release rate of the drug. The calculated F ratio is higher than the F value obtained from the table (13) ($f_1 = 6, f_2 = 56, p =$ 0.05) which clearly indicates that the samples do not have the same release rate *i.e.*, they are statistically different. To determine which samples are different from each other, a least-significant procedure (13) was applied; Table III shows the ranked means. The calculated value of 5% allowance is 7.05

Total	$N - 1 = 62$				

[a] From the tables. [b] F value at $f_1 = 6$, $d_2 = 56$, and $p = 0.05$; $\bar{x} = 5457.87$, $\bar{x}^2 = 479957.48$, $N = 63$, $\Sigma ni - 1 = 56$, and $t = 7$.

Table III—Ranked Means [a]

Drug	Talc	Magnesium Stearate	Microcrystalline Cellulose	Lactose	Polysorbate 80	Dioctyl Sodium Sulfosuccinate
88.48	88.70	89.10	83.54	88.38	82.78	80.53

[a] Any two means not underscored by the same line are statistically significantly different; $t = 2.00$, $S_2 = 55.99$, $ni = 9$, $n = 9$, degrees of freedom = 56, $p = 0.05$, and 5% allowance = 7.05.

which indicates dioctyl sodium sulfosuccinate has a statistically significant difference in release rate than the other additives studied ($p = 0.05$, $t = 2.0$, $S_2 = 55.99$, $n_1 = 9$, degrees of freedom = 56).

CONCLUSIONS

GI-tract resistant hard-gelatin capsules were prepared by formalin treatment. The contents of the capsule were released slowly through minute laser-drilled pores. Variations in number and diameter of drilled pores changed the rate of release of the drug from these capsules. Common additives like lactose, microcrystalline cellulose, magnesium stearate, and talc did not significantly affect the rate of release of the drug; neither did variations in drilling patterns. The presence of dioctyl sodium sulfosuccinate significantly affected the release rate; although polysorbate 80 enhanced the release, the effect was not statistically significant.

The results of the present investigation clearly indicate that the technique of laser drilling could be successfully used in designing slow-release capsule dosage forms. A proportionate increase in release rate with the number of pores drilled and with increased average diameter of the pores suggests the possibility of using the laser technique to design controlled-release capsule dosage forms.

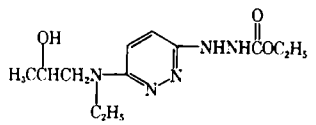
Received February 24, 1983, from the *ISF—Laboratories for Biomedical Research, Milan, Italy.* Accepted for publication February 16, 1984.

Abstract □ The degradation of cadralazine in aqueous solution was investigated in relation to pH, concentration, and temperature, under aerobic and anaerobic conditions in light and dark. The appearance of three main degradation products was also studied. Drug disappearance was dependent on temperature, pH, concentration, and oxygen and followed three different mechanistic pathways: thermal, hydrolytic, and oxidative. The individual rate constants were determined by nonlinear regression fitting.

Keyphrases □ Cadralazine—degradation kinetics, antihypertensive agent, identification of oxidative, hydrolytic, and thermal degradation products □ Antihypertensive agent—cadralazine, degradation kinetics, identification of oxidative, hydrolytic, and thermal degradation products □ Degradation kinetics—cadralazine, antihypertensive agent

Cadralazine, ethyl 6-[ethyl-(2-hydroxypropyl)amino]-3-pyridazinecarbazate (I) (1), is a new potent peripheral vasodilator (2, 3) which has been shown to be active in hypertensive patients (4–11). Like the chemically related antihypertensive drugs hydralazine (12) and pildnalazine (13), cadralazine is stable in the solid state, whereas it is susceptible to decomposition in water.

A study was therefore initiated to identify the degradation products of I; it was performed in stress conditions that are different than the physiological ones, in order to accelerate the decomposition processes. Further investigations were conducted to establish the kinetics of cadralazine degradation. The effects of pH, temperature, drug concentration, and other factors on cadralazine decomposition and on the appearance rate of the main degradation products were also investigated.



I

EXPERIMENTAL SECTION[1]

Cadralazine (I), the working standard (14) [MS: *m/z* 283 (37), 238 (100), 210 (50), 192 (53) and 164 (60)] was used as received. 6-[Ethyl-(2-hydroxypropyl)amino]-1,2,4-triazolo[4,3-*b*]pyridazin-3(2*H*)-one (II) was synthesized according to the method of Parravicini *et al.* (1) [MS: *m/z* 237 (12), 192 (38), and 164 (100)]. *N*-Ethyl-*N*-(2-hydroxypropyl)-6-oxo-3(1*H*)-pyridazinylamine (III), synthesized by the hydrolysis of 6-chloro-*N*-ethyl-*N*-(2-hydroxypropyl)-3-pyridazinylamine (15) by a literature method (13), was obtained as a white powder, mp 106–107°C; MS[2]: *m/z* 197 (15% $M^{\ddagger}$), 152 [100, $(M - CH_3CHOH)^+$], 139 (20), and 124 (40); ^{1}H-NMR[3] (60 Hz, Me_2SO-d_6): δ 7.25 and 6.78 (ABq, 2, *J* = 10 Hz, H-5 and H-4), 4.25 (br s, 1, OH), 4.00 (m, 1, CH), 3.46 (q, 2, *J* = 6.5 Hz, NCH_2CH_3), 3.22 (d, 2, *J* = 6.5 Hz, NCH_2CH), 1.15 (d, 3, *J* = 5.3 Hz, CH_3CH), and 1.10 ppm (t, 3, *J* = 6.5 Hz, CH_2CH_3).

Anal.—Calc. for $C_9H_{15}N_3O_2$: C, 54.81; H, 7.66; N, 21.30. Found: C, 54.56; H, 7.82; N, 21.51.

N-Ethyl-*N*-(2-hydroxypropyl)-3-pyridazinylamine (IV), synthesized by hydrogenolysis of 6-chloro-*N*-ethyl-*N*-(2-hydroxypropyl)-3-pyridazinylamine (15) by a literature method (13), was obtained as a pale-yellow oil; MS[2]: *m/z* 181 (22% $M^{\ddagger}$), 136 [100, $(M - CH_3CHOH)^+$], 123 (30), and 108 (90); ^{1}H-NMR[3] (60 Hz, $CDCl_3$): δ 8.44 (dd, 1, *J* = 4.6, 1.0 Hz, H-6), 7.18 (dd, 1, *J* = 4.6, 9.5 Hz, H-5), 6.90 (dd, 1, *J* = 9.5, 1.0 Hz, H-4), 5.00 (br s, 1, OH) 4.10 (m, 1, CH), 3.56 (d, 2, *J* = 6.2 Hz, NCH_2CH), 3.53 (q, 2, *J* = 7.0 Hz, NCH_2CH_3), 1.22 (d, 3, *J* = 7.0 Hz, CH_3CH), and 1.18 ppm (t, 3, *J* = 7.0 Hz, CH_2CH_3).

Anal.—Calc. for $C_9H_{15}N_3O$: C, 59.66; H, 8.34; N, 23.19. Found: C, 60.00; H, 8.04; N, 23.34.

Ethyl 2-[6-[ethyl-(2-hydroxypropyl)amino]-3-pyridazinyl]azocarboxylate (V) was synthesized according to Gaviraghi *et al.* (16) [MS: *m/z* 283 (28), 238 (48), 237 (32), 181 (36), and 136 (100)]. The following internal standards were used: 1-[3,4,5-trimethoxythiobenzoyl]-4-methylpiperazine hydrochloride (VI) synthesized according to Farina *et al.* (17) and (L)-α-(3,4,5-trimethoxythiobenzamido)caprolactam (VII) synthesized according to Farina *et al.* (18). All the compounds synthesized gave the expected NMR and mass spectral data.

Identification of the Degradation Products—Aliquots (25 mL) of a 0.1% (w/v) cadralazine (I) solution in phosphate buffer (pH 7.4) were kept overnight at 80°C in a water bath under constant tungsten light, then extracted three times with 40 mL of chloroform. The organic layer was evaporated to dryness, and the residue was dissolved in 5 mL of methanol; 200 μL of the solution was spotted and eluted on silica gel plates with the following eluants: chloroform–methanol–water (95:10:1), chloroform–methanol–water (70:27:5), 1-butanol–acetic acid–water (80:20:20), benzene–methanol (80:20), tetrahydrofuran–methanol (96:4); on aluminum oxide plates with methyl ethyl ketone–methanol–chloroform (40:5:55); on silanized silica gel plates with benzene–ethyl acetate–acetonitrile–methanol (35:45:15:5). The spots were detected under UV light, scraped, examined by MS[2] and compared with synthetic samples.

Decomposition Rate of Cadralazine—The degradations were performed on 0.1% solution of cadralazine buffered at pH 3.0, 5.0, 7.4, and 10.0, and stored at 30 ± 0.1°C, 50 ± 0.1°C, and 80 ± 0.1°C in air and light; analogous solutions buffered at pH 0.2 and 1 were followed at 50 ± 0.1°C in the same conditions. Degradations at pH 7.4 and 10 were also studied at 80°C in a nitrogen atmosphere (both in light and in the dark) and in a dark and aerobic atmosphere. Solutions of 0.093, 0.93, 5.15, 10.3, and 18.3 mg/mL of cadralazine in acetate buffer (pH 5.0) were tested at 80 ± 0.1°C in a light and aerobic atmosphere. All samples were taken at various intervals. The internal standard VI was added, and the samples were suitably diluted and assayed by TLC–photodensitometry[4] at 254 nm as previously described (19).

Appearance Rate of II, III, and IV—The appearance rates of II, III, and IV were tested on 0.1% solutions of cadralazine buffered at pH 7.4 and 10.0, submitted to decomposition at 80 ± 0.1°C in an aerobic or a nitrogen atmosphere, in light or dark. Quantitation was performed by adding VII (an internal standard for II and III) and VIII (an internal standard for IV) to the samples. The undiluted solutions were assayed by TLC–photodensitometry as previously described (19).

RESULTS AND DISCUSSION

Characterization of the Degradation Products—TLC of the degraded cadralazine mixture in several eluant systems indicated the presence of four major and three minor compounds. The degradation products were isolated (TLC) and characterized by comparison of their R_f values and MS data with those of authentic samples of I–V (1, 16). The four major compounds were identical with cadralazine (I) (1), triazolone II (1), pyridazinone III, pyridazine IV; one of the minor compounds was the azocarboxylate V (16, 20). Two

[1] All reagents and solvents were analytical grade. Hydrochloric acid–potassium chloride buffer (Normex, pH 0.2 and 1.0, respectively), sodium citrate buffer (pH 3.0), potassium phthalate buffer (pH 5.0), sodium acetate buffer (pH 5.0), potassium phosphate buffer (pH 7.4), and sodium borate buffer (pH 10.0) were purchased from Carlo Erba, Milan, Italy. Sodium chloride was added to all buffers to a constant ionic strength (μ = 0.115). TLC plates silica gel 60 F 254, HPTLC silica gel 60 F 254, silanized silica gel 60 F 254, and aluminum oxide type E F 254 were obtained from Merck, Darmstadt, West Germany.

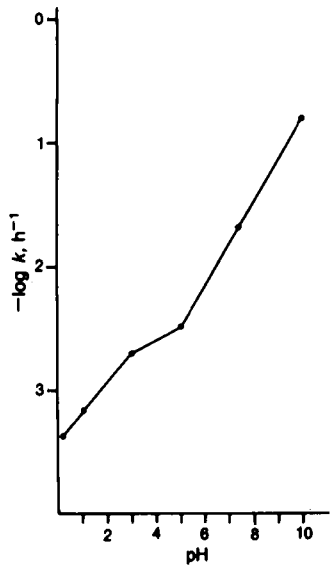

Figure 1—*The pH-rate profile of cadralazine (0.1%, w/v) in aqueous solutions at 50°C.*

of the minor products were not identified. Compounds II, III, IV, and V were treated under the same conditions used for cadralazine degradation, and no decomposition was found except for V, which rapidly converted to III and IV.

Order of Reaction—Semilogarithmic plots of residual concentrations of cadralazine *versus* time exhibited good linearity ($r^2 > 0.98$) for experiments at all pH levels studied. The disappearance of cadralazine from aqueous solutions followed pseudo-first-order kinetics under the experimental conditions. The degradation rate constants of cadralazine were computed by the least-squares linear regression method. The calculated pseudo-first-order rate constants at fixed concentration of cadralazine (0.1%, w/v), buffer ionic strength ($\mu = 0.115$) and temperature (50 ± 0.1°C) were: 4.17×10^{-4} h^{-1} at pH 0.2; 6.72×10^{-4} h^{-1} at pH 1; 2.00×10^{-3} h^{-1} at pH 3; 3.17×10^{-3} h^{-1} at pH 5; 2.14×10^{-2} h^{-1} at pH 7.4; 0.1570 h^{-1} pH 10.

pH Dependency—The pH-rate profile for the degradation of cadralazine was constructed from the logarithm of the pseudo-first-order rate constants and the pH values at 50 ± 0.1°C. The buffering capacities of all the solutions were sufficient to keep constant pH values (±0.05) throughout the experiment. The pH-rate profile (Fig. 1) showed a sigmoid curve superimposed on one branch of a V-graph and revealed a profound degradation rate increase in the neutral and basic pH region, where cadralazine was in the neutral form. In the acidic pH region, the degradation rate appeared low, whereas between pH 3 and 5 it was less sensitive to pH changes. At pH 7.4 and 50°C, the apparent first-order rate constant was 2.14×10^{-2} h^{-1}, which corresponds to a half life of ~32.4 h.

Concentration Effect—The effect of cadralazine concentration on its degradation constant was investigated at 80°C in pH 5 acetate buffer. As shown in Fig. 2, the highest concentrations stabilized the solutions of cadralazine.

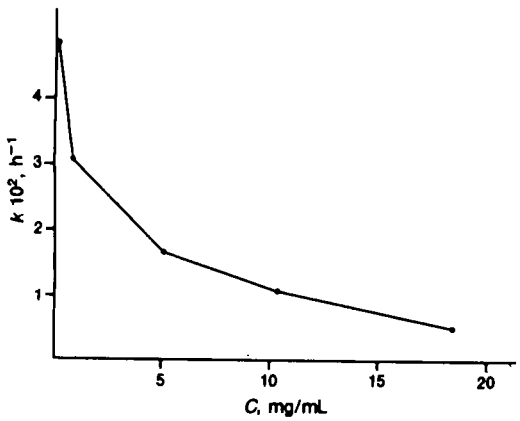

Figure 2—*Influence of cadralazine concentration on the rate degradation constants at 80°C and pH 5.0.*

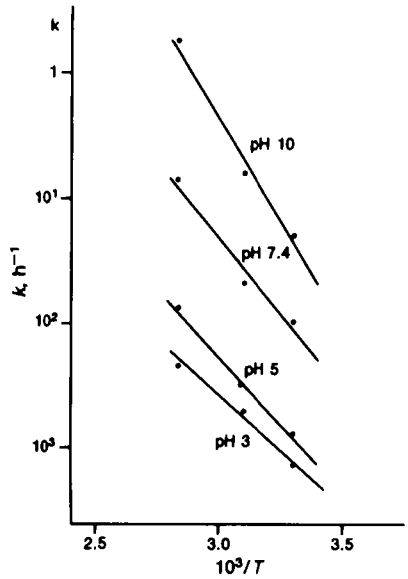

Figure 3—*Arrhenius plot depicting the temperature dependency of cadralazine degradation.*

Table I—Arrhenius Parameters for Degradation of Cadralazine

pH	$E^{\neq}$, kcal/mol	log A	r^2
3	7.72	2.46194	0.976
5	10.12	4.38242	0.997
7.4	11.00	5.89449	0.963
10	15.36	9.74349	0.983

Influence of Temperature, Light, and Air on Cadralazine—The Arrhenius plots of the pseudo-first-order rate constant (k) at varying temperatures (30, 50, and 80 ± 0.1°C) at different pH levels (10, 7.4, 5, and 3) are shown in Fig. 3. The apparent Arrhenius parameters for the disappearance of cadralazine, calculated from the regression equations, are reported in Table I. The degradation of cadralazine was greatly influenced by the presence of air and, to a lesser extent, by light, as shown in Fig. 4.

Light, pH and Air Effects on Formation of II, III and IV—The appearance rate of triazolone II at pH 7.4 and 80°C (Fig. 5A) was independent of the presence of air or light, whereas its formation rate was moderately pH dependent. Moreover, it has been reported that II is obtained from I by thermal cyclization (1). The weak influence of pH and the independence of the formation of II from light and air suggests that the mechanism of formation of II may be essentially thermal in degradative conditions.

In contrast, the appearance rate of pyridazinone III (Fig. 5B) was independent of the presence of air, greatly dependent on pH, and moderately influenced by the presence of light. This excludes an oxidative mechanism in its formation and suggests a hydrolytic pathway.

Finally, pyridazine IV was not detected in the absence of air, whereas its formation was independent of light, and moderately related to the increase in pH (Fig. 5C). This behavior is essentially in agreement with an oxidative reaction.

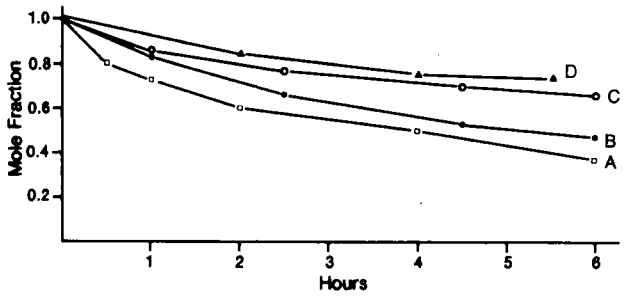

Figure 4—*Experimental time-concentration profile of cadralazine at 80°C and pH 7.4 in light and air (A), dark and air (B), light and nitrogen (C), and dark and nitrogen (D).*

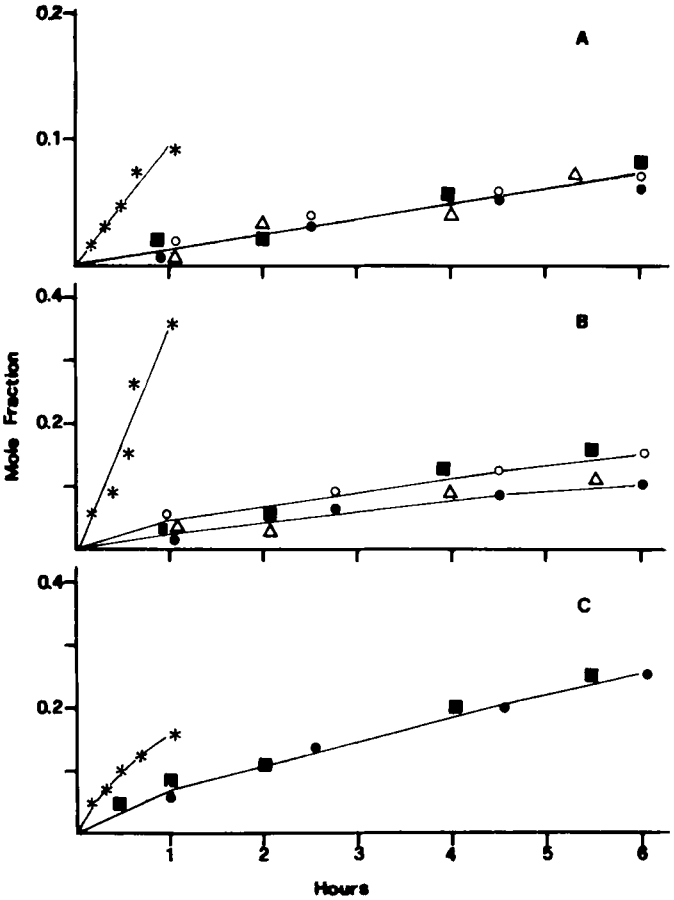

Figure 5—*Experimental time-concentration profile of II (A), III (B), and IV (C) at 80°C in pH 10, light and air (*), pH 7.4, light and air (■), light and nitrogen (○), dark and air (●), and dark and nitrogen (▲). No traces of IV were found at pH 7.4 in light and nitrogen, or in dark and nitrogen.*

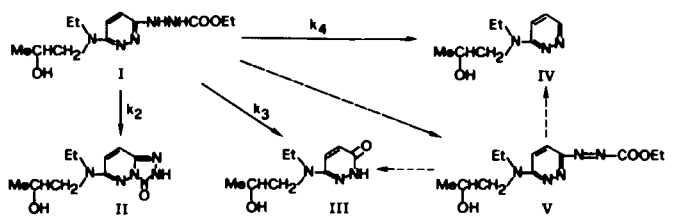
Possible Degradation Pathway—The degradation of cadralazine yields triazolone II, pyridazinone III, pyridazine IV, and minor quantities of azocarboxylate V. Cadralazine decomposition at pH 7.4 and 80°C can be hypothesized as a combination of three parallel reactions (Scheme I). On the basis of this hypothesis, the disappearance of cadralazine can be described as a pseudo-first-order process expressed by:

$$-\frac{d[I]}{dt} = (k_2 + k_3 + k_4)[I] = k_1[I] \qquad \text{(Eq. 1)}$$



Scheme I—Proposed degradation pattern of cadralazine in aqueous solution.

Table II—Rate Constants for Cadralazine Degradation [a]

Constant	k, h^{-1} [b]	r^2
k_1	0.1346 ± 0.0190	0.989
k_2	0.0179 ± 0.0047	0.994
k_3	0.0452 ± 0.0049	0.990
k_4	0.0744 ± 0.0050	0.997
$k_2 + k_3 + k_4$	0.1375	

[a] Determined at pH 7.4, 80°C. [b] Confidence limits of ±95%.

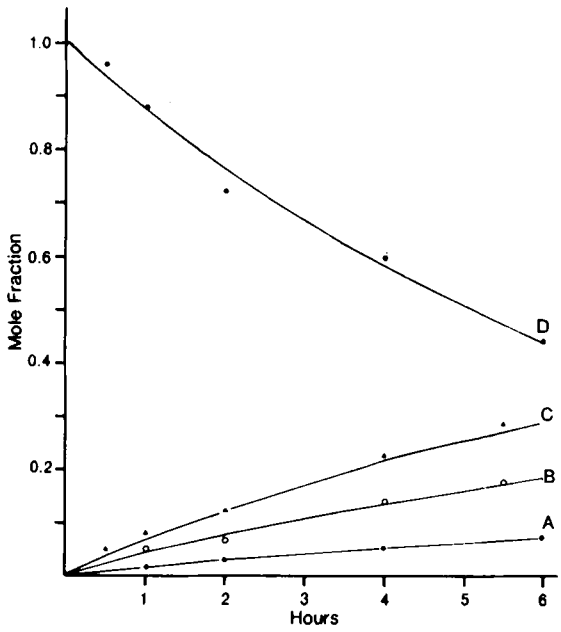


Figure 6—*Time-concentration profile of cadralazine (A) and its degradation products II (B), III (C), and IV (D) in an aqueous solution (0.1%, w/v) of cadralazine at pH 7.4 incubated at 80°C. The experimental data are superimposed on calculated curves.*

Rate expressions describing the appearance of II, III, and IV take similar forms (pseudo-first-order reactions):

$$\frac{d[II]}{dt} = k_2[I] \qquad \text{(Eq. 2)}$$

$$\frac{d[III]}{dt} = k_3[I] \qquad \text{(Eq. 3)}$$

$$\frac{d[IV]}{dt} = k_4[I] \qquad \text{(Eq. 4)}$$

These differential equations can be solved and the amount of each component in the mixture can be expressed as the mole fraction of the initial concentration of cadralazine as a function of time:

$$\frac{[I]}{[I]_0} = e^{-k_1 t} \qquad \text{(Eq. 5)}$$

$$\frac{[II]}{[I]_0} = \frac{k_2}{k_1}(1 - e^{-k_1 t}) \qquad \text{(Eq. 6)}$$

$$\frac{[III]}{[I]_0} = \frac{k_3}{k_1}(1 - e^{-k_1 t}) \qquad \text{(Eq. 7)}$$

$$\frac{[IV]}{[I]_0} = \frac{k_4}{k_1}(1 - e^{-k_1 t}) \qquad \text{(Eq. 8)}$$

Initial conditions were defined so that at $t = 0$ the amount of cadralazine was equal to $[I]_0$, and no degradation products were present, *i.e.*, [II], [III], and [IV] were equal to zero.

Equations 5–8 were used to calculate simultaneously k_1, k_2, k_3, and k_4 from the experimental data derived from the degradation of I carried out at 80°C and pH 7.4, in air and light, using a nonlinear regression program (NOLIN). The values obtained for k_i and their 95% confidence limits are reported in Table II. The quality of the fit between experimental and theoretical concentrations is shown in Fig. 6. The accuracy of the calculated k_i was demonstrated by comparing the pseudo-first-order rate constant k_1, determined experimentally, with the sum of the individually calculated rate constants $k_2 + k_3 + k_4$.

The minor compound, V, was not considered in the kinetic study, because its yield was small, near the range of detectability. However, this product could be a possible intermediate in the formation of III and IV.

Binding Parameters of Interactions of Monomer–Polymer Systems Based on Quenching of Their Completely Overlapped Fluorescence: A Theory

HANNA N. BORAZAN

Received March 3, 1983, from the *Department of Pharmaceutical Chemistry, College of Pharmacy, University of Baghdad, Baghdad, Republic of Iraq.* Accepted for publication September 12, 1983.

Abstract □ A theory is presented which describes the interactions between completely overlapping fluorescing monomer–polymer systems and affords a method to calculate binding parameters. The theory is based on the assumptions that the complex formed from the fluorescing binding site and the monomer molecule does not fluoresce and that the fluorescence intensity is linearly related to concentration. The relationships derived from this theory have provided a sensitive and easy method for calculating the number of binding sites on a polymer molecule from only three emission-intensity values. The theory has been tested on systems containing trimethoprim–serum albumins and found to yield results which are consistent with a curve-fitting approach to the experimental data. This reflects the validity of the theoretical model presented and the various assumptions and approximations made.

Keyphrases □ Monomer–polymer systems—binding parameters, overlapped fluorescence quenching □ Binding parameters—overlapped fluorescence quenching, monomer–polymer system □ Fluorescence quenching—binding parameters, monomer–polymer systems

Fluorescence quenching has been applied to the study of complex formation (1); for example, the interactions of amino acids containing aromatic nuclei and their amines, and oligopeptides containing aromatic amino acids with nucleic acids, were studied by this method (2, 3). Recently, Koumriqian (4) and Borazan and Koumriqian (5) have applied the technique to study interactions between catecholamines and polyadenylic acid. In these studies, the emissions of the polynucleotides were negligible compared with those of the monomers. It was, therefore, easy to derive equations for calculating the binding parameters using the fraction remaining from the fluorescence intensity of the monomers or the observed quantum yield.

However, due to the inherent properties of many systems, both the monomers and polymers in the binary mixtures exhibit almost complete emission overlap over a wide range of excitation and emission wavelengths. Examples for such systems can be found in the fluorescence quenching studies of the interactions of steroids–polynucleotides (6), antineoplastics–polynucleotides (7), and antibacterials–serum albumins (8). Thus, these types of systems impose a difficult problem when analyzing the experimental data to calculate the binding constants. These authors (6–8) have applied an empirical approach involving a curve-fitting technique to analyze the fluorescence data.

The present study is concerned with a theoretical treatment which utilizes the fluorescence technique in situations where complete fluorescence overlap is taking place. This allowed us to determine the number of fluorescing binding sites on a polymer molecule available to the monomer molecules and to calculate the equilibrium constant for the process.

THEORETICAL SECTION

To calculate the binding constants for an interaction between a monomer, M, and a binding site on a polymer, Pb, the following simple mathematical model was assumed:

$$M + Pb = MPb \qquad \text{(Eq. 1)}$$

where MPb, is the complex formed. When using the fluorescence technique to calculate the binding parameters, the solution of the problem is straight-

Binding Parameters of Interactions of Monomer–Polymer Systems Based on Quenching of Their Completely Overlapped Fluorescence: A Theory

HANNA N. BORAZAN

Received March 3, 1983, from the *Department of Pharmaceutical Chemistry, College of Pharmacy, University of Baghdad, Baghdad, Republic of Iraq.* Accepted for publication September 12, 1983.

Abstract □ A theory is presented which describes the interactions between completely overlapping fluorescing monomer–polymer systems and affords a method to calculate binding parameters. The theory is based on the assumptions that the complex formed from the fluorescing binding site and the monomer molecule does not fluoresce and that the fluorescence intensity is linearly related to concentration. The relationships derived from this theory have provided a sensitive and easy method for calculating the number of binding sites on a polymer molecule from only three emission-intensity values. The theory has been tested on systems containing trimethoprim–serum albumins and found to yield results which are consistent with a curve-fitting approach to the experimental data. This reflects the validity of the theoretical model presented and the various assumptions and approximations made.

Keyphrases □ Monomer–polymer systems—binding parameters, overlapped fluorescence quenching □ Binding parameters—overlapped fluorescence quenching, monomer–polymer system □ Fluorescence quenching—binding parameters, monomer–polymer systems

Fluorescence quenching has been applied to the study of complex formation (1); for example, the interactions of amino acids containing aromatic nuclei and their amines, and oligopeptides containing aromatic amino acids with nucleic acids, were studied by this method (2, 3). Recently, Koumriqian (4) and Borazan and Koumriqian (5) have applied the technique to study interactions between catecholamines and polyadenylic acid. In these studies, the emissions of the polynucleotides were negligible compared with those of the monomers. It was, therefore, easy to derive equations for calculating the binding parameters using the fraction remaining from the fluorescence intensity of the monomers or the observed quantum yield.

However, due to the inherent properties of many systems, both the monomers and polymers in the binary mixtures exhibit almost complete emission overlap over a wide range of excitation and emission wavelengths. Examples for such systems can be found in the fluorescence quenching studies of the interactions of steroids–polynucleotides (6), antineoplastics–polynucleotides (7), and antibacterials–serum albumins (8). Thus, these types of systems impose a difficult problem when analyzing the experimental data to calculate the binding constants. These authors (6–8) have applied an empirical approach involving a curve-fitting technique to analyze the fluorescence data.

The present study is concerned with a theoretical treatment which utilizes the fluorescence technique in situations where complete fluorescence overlap is taking place. This allowed us to determine the number of fluorescing binding sites on a polymer molecule available to the monomer molecules and to calculate the equilibrium constant for the process.

THEORETICAL SECTION

To calculate the binding constants for an interaction between a monomer, M, and a binding site on a polymer, Pb, the following simple mathematical model was assumed:

$$M + Pb = MPb \qquad \text{(Eq. 1)}$$

where MPb, is the complex formed. When using the fluorescence technique to calculate the binding parameters, the solution of the problem is straight-

0022-3549/84/1200-1815$01.00/0
© 1984, American Pharmaceutical Association

forward if one of the reactants does not fluoresce. In the present theoretical treatment, however, one case of concern is when both the monomer and binding site fluoresce at a given set of excitation and emission wavelengths (fluorescence overlap). Another source of concern is the quenching of the emissions of the interacting species when the complex is formed. It is assumed in the following derivations that the polymer molecule contains n fluorescing binding sites and that the emission intensity is linearly related to concentration. When working with dilute solutions:

$$\text{concentration} = \text{constant} \times \text{fluorescence intensity} \qquad \text{(Eq. 2)}$$

Accordingly:

$$I_{obs}^{\lambda} = I_M^{\lambda} + I_{Pb}^{\lambda,\Sigma} \qquad \text{(Eq. 3)}$$

where I_{obs}^{λ} and I_M^{λ} are the observed and free monomer emission intensities and $I_{Pb}^{\lambda,\Sigma}$ is the fluorescence intensity of the polymer sites without a bound substrate. The summation sign, Σ, is used to emphasize that the fluorescence originates from different sites on one polymer molecule.

I_{obs}^{λ} can be related to the total unquenched emission intensity, as:

$$I_{obs}^{\lambda} = \beta_{tot} I_{tot}^{\lambda} = \beta_M I_{M,0}^{\lambda} + \beta_{Pb} I_{Pb_0}^{\lambda,\Sigma} \qquad \text{(Eq. 4)}$$

β_{tot}, β_M, and β_{Pb} are the fractions of remaining fluorescence intensities for the total emission, monomer, and binding sites, and $I_{M,0}^{\lambda}$ and $I_{Pb_0}^{\lambda,\Sigma}$ are the initial emission intensities of the monomer and polymer binding sites. Therefore, from Eqs. 3 and 4:

$$I_M^{\lambda} = \beta_M I_{M,0}^{\lambda} \qquad \text{(Eq. 5)}$$

$$I_{Pb}^{\lambda,\Sigma} = \beta_{Pb} I_{Pb,0}^{\lambda,\Sigma} \qquad \text{(Eq. 6)}$$

According to Eq. 1, the concentration of the complex (MPb) can be expressed in three different ways:

$$(MPb) = (M_0) - (M) \qquad \text{(Eq. 7)}$$

$$(MPb) = (Pb_0) - (Pb) \qquad \text{(Eq. 8)}$$

$$(MPb) = n(P_0) - n(P) \qquad \text{(Eq. 9)}$$

where (M_0) and (M) are the initial and free concentrations of the monomer, respectively; (Pb_0) and (Pb) are the concentrations of the initial and the remaining free polymer binding sites, respectively; and (P_0) and (P) represent the total and free concentrations of the polymer, respectively.

According to the assumption presented in Eq. 2, one can easily verify the following equations:

$$(M) = \beta_M (M_0) \qquad \text{(Eq. 10)}$$

$$(Pb) = \beta_{Pb} (Pb_0) \qquad \text{(Eq. 11)}$$

$$(P) = \beta_{Pb} (P_0) \qquad \text{(Eq. 12)}$$

It is evident from Eqs. 10–12, that β_M and β_{Pb} are essentially equal to the fractions which remain free of interaction. Combining Eqs. 5, 7, and 10:

$$(MPb) = (M_0)\left(1 - \frac{I_M^{\lambda}}{I_{M,0}^{\lambda}}\right) \qquad \text{(Eq. 13)}$$

and Eqs. 6, 9, and 12:

$$(MPb) = n(P_0)\left(1 - \frac{I_{Pb}^{\lambda,\Sigma}}{I_{Pb_0}^{\lambda,\Sigma}}\right) \qquad \text{(Eq. 14)}$$

Equating Eqs. 13 and 14, substituting for $I_{Pb}^{\lambda,\Sigma}$ (Eq. 3), and rearranging equations:

$$I_M^{\lambda} = \frac{(M_0) I_{Pb_0}^{\lambda,\Sigma} I_{M,0}^{\lambda} - n(P_0) I_{M,0}^{\lambda} (I_{Pb_0}^{\lambda,\Sigma} - I_{obs}^{\lambda})}{n(P_0) I_{M,0}^{\lambda} + (M_0) I_{Pb_0}^{\lambda,\Sigma}} \qquad \text{(Eq. 15)}$$

Rearranging Eq. 3 and combining with Eq. 6:

$$\beta_{Pb} = \frac{I_{obs}^{\lambda} - I_M^{\lambda}}{I_{Pb_0}^{\lambda,\Sigma}} \qquad \text{(Eq. 16)}$$

Substituting for I_M^{λ} (Eq. 15) into Eq. 16:

$$\beta_{Pb} = \frac{(M_0) I_{obs}^{\lambda} - (M_0) I_{M,0}^{\lambda} + n(P_0) I_{M,0}^{\lambda}}{n(P_0) I_{M,0}^{\lambda} + (M_0) I_{Pb_0}^{\lambda,\Sigma}} \qquad \text{(Eq. 17)}$$

According to the mathematical model presented in Eq. 1, the equilibrium constant expression, K, can be written as:

$$K = \frac{(MPb)}{(M)(Pb)} \qquad \text{(Eq. 18)}$$

Incorporating Eqs. 9 and 12 into Eq. 7:

$$(M) = (M_0) - n(P_0)(1 - \beta_{Pb}) \qquad \text{(Eq. 19)}$$

The equilibrium constant equation (Eq. 18) can be written in the following form after substituting for (MPb) (Eqs. 9 and 12), M (Eq. 19), and for (Pb) (Eqs. 11 and 12):

$$K = \frac{\left[\frac{1 - \beta_{Pb}}{\beta_{Pb}}\right]}{[(M_0) - n(P_0)(1 - \beta_{Pb})]} \qquad \text{(Eq. 20)}$$

Thus, the value of n must be determined in addition to the other experimental parameters in order to solve for β_{Pb} (Eq. 17) and K (Eq. 20).

In principle, one may be able to arrive at the values of n by performing a curve-fitting technique through assigning values to n and calculating the equilibrium constant, K, at different concentration levels to minimize percent variation (6–8). Thus, the present investigation is undertaken to study the problem from a fundamental point of view, in the hope of arriving at the exact relationships controlling such complicated systems. This can be done through optimizing the K expression (Eq. 20) with respect to n, *i.e.*:

$$\frac{\partial K}{\partial n} = 0 \qquad \text{(Eq. 21)}$$

Therefore, Eq. 20 should lead to the following:

$$[(M_0) - n(P_0) + n(P_0)\beta_{Pb}] \frac{1}{\beta_{Pb}^2} \frac{d\beta_{Pb}}{dn} + \left[\frac{1 - \beta_{Pb}}{\beta_{Pb}}\right]\left[-(P_0) + (P_0)\beta_{Pb} + n(P_0)\frac{d\beta_{Pb}}{dn}\right] = 0 \qquad \text{(Eq. 22)}$$

Rearranging Eq. 22 and setting it up in an integral form, we can write:

$$\int \frac{\gamma d\beta_{Pb}}{(1 - \beta_{Pb})^2 n} - \int \frac{d\beta_{Pb}}{(1 - \beta_{Pb})^2} + \int \frac{2\beta_{Pb} d\beta_{Pb}}{(1 - \beta_{Pb})^2} - \int \frac{\beta_{Pb}^2 d\beta_{Pb}}{(1 - \beta_{Pb})^2} - \int \frac{\beta_{Pb}}{n} dn = 0 \qquad \text{(Eq. 23)}$$

where:

$$\gamma = \frac{(M_0)}{(P_0)} \qquad \text{(Eq. 24)}$$

Eq. 17 can be rearranged to yield n in terms of intensities and concentrations:

$$n = \frac{(M_0)(I_{obs}^{\lambda} - I_{M,0}^{\lambda}) - (M_0)\beta_{Pb} I_{Pb_0}^{\lambda,\Sigma}}{(P_0)\beta_{Pb} I_{M,0}^{\lambda} - (P_0) I_{M,0}^{\lambda}} \qquad \text{(Eq. 25)}$$

To simplify the notations, set:

$$a = I_{obs}^{\lambda} - I_{M,0}^{\lambda} \qquad \text{(Eq. 26)}$$

$$b = I_{Pb_0}^{\lambda,\Sigma} \qquad \text{(Eq. 27)}$$

$$c = I_{M,0}^{\lambda} \qquad \text{(Eq. 28)}$$

$$\beta = \beta_{Pb} \qquad \text{(Eq. 29)}$$

Therefore, Eq. 25 can be written in the following form:

$$n = \frac{\gamma(b\beta - a)}{c(1 - \beta)} \qquad \text{(Eq. 30)}$$

Taking the differential of Eq. 30:

$$dn = \frac{\gamma b d\beta}{c(1 - \beta)} + \frac{\gamma bc\beta d\beta}{c^2(1 - \beta)^2} - \frac{\gamma ac d\beta}{c^2(1 - \beta)^2} \qquad \text{(Eq. 31)}$$

Substituting for n (Eq. 30) and dn (Eq. 31) into Eq. 23:

$$c \cdot \int \frac{d\beta}{(1 - \beta)(b\beta - a)} - \int \frac{d\beta}{(1 - \beta)^2} + 2 \cdot \int \frac{\beta d\beta}{(1 - \beta)^2} - \int \frac{\beta^2 d\beta}{(1 - \beta)^2} - b \cdot \int \frac{\beta d\beta}{(b\beta - a)} - b \cdot \int \frac{\beta^2 d\beta}{(1 - \beta)(b\beta - a)} + a \cdot \int \frac{\beta d\beta}{(1 - \beta)(b\beta - a)} = 0 \qquad \text{(Eq. 32)}$$

The above integrals can be evaluated to yield the following (9, 10):

$$c \cdot \int \frac{d\beta}{(1 - \beta)(b\beta - a)} = \frac{c}{b - a} \cdot \ln \frac{(b\beta - a)}{(1 - \beta)} \qquad \text{(Eq. 33)}$$

$$\int \frac{d\beta}{(1 - \beta)^2} = \frac{1}{1 - \beta} \qquad \text{(Eq. 34)}$$

$$2 \cdot \int \frac{\beta\, d\beta}{(1-\beta)^2} = 2 \cdot \ln(1-\beta) + \frac{2}{1-\beta} \quad \text{(Eq. 35)}$$

$$\int \frac{\beta^2 d\beta}{(1-\beta)^2} = \beta + 2 \cdot \ln(1-\beta) + \frac{1}{1-\beta} \quad \text{(Eq. 36)}$$

$$b \cdot \int \frac{\beta\, d\beta}{(b\beta - a)} = \beta + \frac{a}{b} \cdot \ln(b\beta - a) \quad \text{(Eq. 37)}$$

$$b \cdot \int \frac{\beta^2\, d\beta}{(1-\beta)(b\beta - a)} = -\beta - \frac{a+b}{b} \cdot \ln(b\beta - a) + \frac{b}{b-a} \cdot \ln \frac{(b\beta - a)}{(1-\beta)} \quad \text{(Eq. 38)}$$

$$a \cdot \int \frac{\beta\, d\beta}{(1-\beta)(b\beta - a)} = \frac{a^2}{b(b-a)} \cdot \ln(b\beta - a) - \frac{a}{b-a} \cdot \ln(1-\beta) \quad \text{(Eq. 39)}$$

Substituting for the integral values (Eqs. 33-39) into Eq. 32:

$$\left[\frac{c}{b-a} - \frac{a}{b}\right] \cdot \ln(b\beta - a) - \left[\frac{c}{b-a} - 1\right] \cdot \ln(1-\beta) - \beta = 0 \quad \text{(Eq. 40)}$$

One can easily verify that Eq. 40 holds for $|b\beta - a|$, and when expressing it in its original notations (Eqs. 26-29) it yields the following:

$$\left[\frac{I_{M,0}^{\lambda}}{I_{Pb_0}^{\lambda,\Sigma} + I_{M,0}^{\lambda} - I_{obs}^{\lambda}} - \frac{I_{obs}^{\lambda} - I_{M,0}^{\lambda}}{I_{Pb_0}^{\lambda,\Sigma}}\right] \cdot \ln\left|I_{Pb_0}^{\lambda,\Sigma}\beta_{Pb} + I_{M,0}^{\lambda} - I_{obs}^{\lambda}\right| - \left[\frac{I_{obs}^{\lambda} - I_{Pb_0}^{\lambda,\Sigma}}{I_{Pb_0}^{\lambda,\Sigma} + I_{M,0}^{\lambda} - I_{obs}^{\lambda}}\right] \cdot \ln(1-\beta_{Pb}) - \beta_{Pb} = 0 \quad \text{(Eq. 41)}$$

RESULTS AND DISCUSSION

Solving the nonlinear equation (Eq. 41) is a difficult task using conventional mathematical methods. An approximate solution to the problem is obtained by expanding the logarithmic terms and expressing the equation in terms of the power series of β. This method yields highly approximate results because terms having exponents greater than four are omitted. Higher order equations are almost impossible to solve, however, if one seeks better results. Thus, the most reasonable technique remaining is to solve Eq. 41 numerically with a programmable calculator.

To test the theory, experimental data involving fluorescence quenching studies, where complete emission overlap characterizes the systems, were taken from Saoud (8). His investigation was concerned with interactions between trimethoprim and serum albumins taken from different species. The measured emission intensity data were computed into the coefficients of the natural logarithms of Eq. 41, while the equation is solved by assigning values to β and calculating the value of the equation $[F(\beta)]$. Obviously, the acceptable solution is $F(\beta) = 0$. In all cases, β is solved to 1×10^{-6}. The value of $|F(\beta)|$ that corresponds to this level of accuracy ranged from 3.6×10^{-5} to 6.6×10^{-7}. The results are summarized in Table I.

Applying Eq. 25, the value of β_{Pb}^1 yields unrealistic results, since negative values of the number of binding sites are obtained. Thus the values of β_{Pb}^2 are the ones taken as a base for calculating the binding parameters. It is evident from Table I that as the monomer-polymer ratio is increased by 400%, the equilibrium constant varies only in the range from 8.5 to 19.8%. Furthermore, the estimated difference in the number of binding sites for the same magnitude of increase in the ratio is found to be 20.3–57.8%. These variations reflect the combined effects of the experimental errors, the inherent factors in the systems themselves, and the various assumptions and approximations made. For example, it was assumed in the derivations presented in the theory that all of the binding sites are independent (no site-site interaction took place), equivalent, and fluorescing. Based upon different physical methods, deviations from linearity of the Scatchard plots are reported in the literature. The explanations given include site-site interactions (11, 12), competitive binding between fluorescing and nonfluorescing binding sites, and the presence of nonequivalent binding sites (13).

Saoud (8) has applied Eq. 17 to calculate β_{Pb} by assigning values to the number of binding sites, n. The best n value is the one that generates the least variation in K. Indeed, the n values obtained by the author that induce minimum variation in K were close to the values obtained from Eq. 41. This gives supporting evidence to the validity of the relationships derived in this theory.

It may be concluded that the present theory has provided a powerful tool to calculate the binding parameters for the monomer-polymer interactions

[a] In 1 mM aqueous cacodylate buffer, pH 7, based on fluorescence data taken from Ref. 8. [b] The concentration of the albumins was 1.449×10^{-8} M and the measurements were at 25°C. [c] The excitation wavelength was 290 nm and the emission intensities were measured at 335 nm for human serum albumin, 345 nm for camel serum albumin, 352 nm for bovine serum albumin, and 340 nm for rat serum albumin.

from fluorescence quenching, even when a complete overlap in their emission properties is taking place. The method is sensitive and easy, where only three experimental values are necessary to calculate the number of fluorescing binding sites on the polymer: the emissions of the two pure components and the emissions of a mixture containing equimolar concentrations of the components.

Hypolipidemic Activity of 4-Pyrimidinecarboxylic Acids in CF_1 Mice

I. H. HALL ˣ, G. H. COCOLAS, and W. L. WILLIAMS, JR.

Received September 19, 1983, from the *Division of Medicinal Chemistry and Natural Products, School of Pharmacy, University of North Carolina at Chapel Hill, Chapel Hill, NC 27514.* Accepted for publication February 16, 1984.

Abstract □ A series of 4-pyrimidinecarboxylic acids were evaluated for hypolipidemic activity in mice at 20–30 mg/kg/d ip. A number of these derivatives were observed to be active at this dose. Substitution of the hydroxyl group in position 2 and 6 of the 4-pyrimidinecarboxylic acid with a sulfhydryl and an amino group, respectively, led to a compound which produced a >40% reduction of serum cholesterol and triglyceride levels in mice. Similarly, a compound which was substituted with an amino group in position 2 and an isobutyl group in position 5 led to equally potent activity as a hypolipidemic agent.

Keyphrases □ 4-Pyrimidinecarboxylic acids—antihypolipidemic activity, mice □ Antihypolipidemic agents—4-pyrimidinecarboxylic acids, activity in mice

Windmueller and co-workers (1–4) demonstrated that 1% orotic acid (2,6-dihydroxy-4-pyrimidinecarboxylic acid) in the diet of rats decreased plasma lipids. Ravi Subbiah (5) later showed that both serum cholesterol and triglycerides were reduced in rats treated with 1% orotic acid, but there was an increase in cholesterol, fatty acid, and triglyceride levels in the liver with a decrease in cholesterol excretion into the bile and feces. Subsequent studies showed that orotic acid reduced the serum lipoprotein fractions, *i.e.*, low-density lipoprotein, very low-density lipoprotein, and high-density lipoprotein (6–8) induced hyperlipidemic states in animals (7). Protein synthesis required for the apoprotein was not inhibited; rather, there was an inability to incorporate the lipid with the apoprotein for the lipoprotein fractions by the liver (6). The present study deals with the structure modification of orotic acid to yield other 4-pyrimidinecarboxylic acids which hopefully will possess hypolipidemic activity at a relatively low dose.

EXPERIMENTAL SECTION

Source of Compounds—Orotic acid was commercially available[1]. The chemical synthesis and physical characteristics of the 4-pyrimidinecarboxylic acids have been previously reported in the literature (9–11). Chemical syntheses were conducted by these methods and melting points are reported in Table I. Melting points were determined on a melting point apparatus[2] and are uncorrected.

Hypolipidemic Activity—Test compounds were suspended in 1% carboxymethylcellulose–water, homogenized, and administered intraperitoneally to CF_1 male mice (~25 g) for 16 d. On days 9 and 16, blood was obtained by tail vein bleeding and the serum was separated by centrifugation for 3 min. The serum cholesterol was determined by a modification of the Liebermann–Burchard reaction (12). Serum triglyceride levels were determined in blood collected on day 16 by a commercial kit[3]. The data for these assays is presented as a percent of control ± *SD*; the probability level was calculated by the Student's *t* test. Clofibrate[4] at 150 mg/kg/d was used as a standard for comparisons in the hypolipidemic screens.

RESULTS AND DISCUSSION

A number of the 4-pyrimidinecarboxylic acid derivatives demonstrated potent hypolipidemic activity at 20 mg/kg/d ip in mice (Table II). Compounds I, IV, V, VI, VIII, XIII, XV, XVII, XVIII, XIX, and XX afforded ≥30% reduction of the serum cholesterol level at 20 mg/kg/d after dosing for 16 d and III produced a similar reduction at 30 mg/kg/d. Compounds IV, V, VI, VIII, X, XI, XIII, XV, XVIII, XX, and XXI resulted in ≥30% reduction of serum triglycerides after dosing for 16 d. Compounds I, II, and III were also effective at this level at a dose of 30 mg/kg/d. Compounds V and XIII appeared to be the most effective in this dose range with a >40% reduction of both serum lipids. Those carboxylic acids with a methyl group in the 5 position and a sulfhydryl group substituted in the 2 or 6 position (IV, V, and VI) at a dose of 20 mg/kg/d, and III at a dose of 30 mg/kg/d, resulted in lowering of both serum cholesterol and triglyceride levels after dosing for 16 d.

When positions 2 and 6 were substituted with an amino group while varying the R group substitutions, the *n*-propyl derivative (VIII) resulted in the best hypolipidemic activity of this series, with a 40% reduction of serum cholesterol and a 43% reduction of serum triglycerides after dosing for 16 d at 20 mg/kg/d. Compound X, with a substitution of isobutyl in position 5, was also active with a 26 and 47% reduction of cholesterol and serum triglycerides, respectively.

Substitution of a hydroxyl group in the 2 position, an amino in the 6 position with an isobutyl in position 5 (compound XIII) resulted in one of the best activities, with a 44% reduction of serum cholesterol and a 57% reduction of serum triglycerides. Of those compounds with a substituted aromatic ring in the 5 position, compound XVIII with a sulfhydryl group in position 2 and an amino group in position 6 resulted in a reduction of 31% in serum cholesterol and 50% in serum triglycerides. Compound XV, similar to XVIII but with an ethyl group substituted in the 5 position, also afforded good activity with a 32% reduction of serum cholesterol and a 37% reduction in triglyceride levels. Compound XX with a substituted sulfhydryl group in position 2, a hydroxyl group in the 6 position, and an ethyl group in the 5 position also afforded good activity by lowering serum cholesterol levels 44% and triglyceride levels 36% on day 16.

Substitution of an alcohol in place of a carboxylic acid group in position 4, with the same substitutions on 2, 6, and 5 (compare XXI to III) resulted in approximately the same degree of reduction of serum cholesterol at a dose of 20 mg/kg/d (20–25%), but the serum triglycerides were reduced from 26% to 45% with XXI at a dose of 20 mg/kg/d.

These studies have shown that a number of substituted 4-pyrimidinecarboxylic acids are potent hypolipidemic agents when compared with clofibrate at 150 mg/kg in rodents (Table II). Further studies are currently being conducted to establish the effects of the more potent derivatives on lipid metabolism and liver and serum lipoprotein levels. It would be desirable if the new agents did not cause lipid deposition in the hepatocyte, resulting in fatty livers similar to the observed effect of orotic acid on diet (2, 5).

Orotic acid is known to have no effect on cholesterol-7-α-hydroxylase activity and thus does not affect bile excretion of cholesterol (5); however, it does decrease mitochondrial fatty acid oxidation and acetyl-CoA dehydrogenase but not β oxidation by the peroxisomal system (13). A more in-depth study of orotic acid derivatives is required to assess their usefulness as hypolipidemic agents.

Determination of Dextromethorphan in Biological Fluids by Liquid Chromatography by Using Semi-microbore Columns

RAJA G. ACHARI ˣ, HEINZ M. EDERMA, DAVID CHIN, and STANLEY R. OLES

Received August 23, 1983, from *Bristol-Myers Products Research and Development Center, Hillside, NJ 07207.* Accepted for publication February 3, 1984.

Abstract □ A sensitive, specific procedure for the determination of dextromethorphan in plasma and urine in dogs is described. The use of a semi-microbore column, 2.1 mm i.d. × 25 cm resulted in a detection limit of 1 ng/mL in plasma and 25 ng/mL in urine. Plasma (3 mL) is extracted in CCl_4 and the drug is back-extracted with 3% acetic acid. The chromatographic separation is carried out using a 5-μm particle size octadecyl-bonded column, and the drug is monitored by a fluorescence detector. The results after 10-mg oral administrations of dextromethorphan to dogs are provided.

Keyphrases □ Dextromethorphan—HPLC determination, semi-microbore column, dog plasma, urine

Dextromethorphan is a widely used synthetic antitussive agent. Due to significant first-pass hepatic metabolism, only a trace amount of unmetabolized drug is found in circulation, usually <5 ng/mL after oral administration (1, 2). Previous reports of dextromethorphan analysis involved electron-capture GC, nitrogen-phosphorus detection GC and RIA (1–3). There has been no report in the literature on the assay of dextromethorphan in biological fluids by high-performance liquid chromatography (HPLC) due to a lack of sensitivity of the instrument at this level. We report here an HPLC method for determining dextromethorphan using semi-microbore columns capable of measuring the drug in amounts as low as 1 ng/mL.

EXPERIMENTAL SECTION

Materials—All chromatographic solvents were HPLC grade, reagents were ACS, U.S.P., or N.F. quality and were used as received without further purification. Dextromethorphan HBr[1] was U.S.P. grade and was used as received. The apparatus was a modular unit consisting of a reciprocating pump[2], a fluorescence detector[3], an autoinjector[4], and a strip-chart recorder[5]. All columns were prepacked and octadecylsilane bonded[6]. The average particle size of the packing material was 5 μm. The mobile phase was acetonitrile–water (45:55) containing 0.01 M monobasic ammonium phosphate and 0.005 M sodium lauryl sulfonate. The pH was adjusted to 3.0 using phosphoric acid. The flow rate was maintained at 300 μL/min.

Sample Preparation—*Plasma Extraction Procedure*—Plasma (3 mL) was transferred into a screw-cap disposable tube (16 mm × 125 mm), 0.5 mL of 6 M HCl was added, and the mixture was vortexed; 10 M NaOH (0.4 mL) was then added and mixed until a clear mixture was obtained. Immediately, 10 mL of CCl_4 was added and the mixture was first handshaken gently a few times and then shaken for 30 min on a mechanical horizontal shaker. After a 10-min centrifugation at 2500 rpm, the top aqueous layer of the sample was completely removed by suction and discarded. The organic layer was poured into a 20 × 150 mm wide-mouth test tube. The carbon tetrachloride layer (8 mL) was transferred into another 16 × 125 mm disposable screw-cap tube. (In this step, it is essential to avoid having any of the residual aqueous layer enter the pipette.) Acetic acid (3%) was added (0.5 mL) and shaken for 30 min on a horizontal shaker. The tube was centrifuged for 5 min at 2500 rpm and a portion of the acid layer was removed for analysis.

A urine sample (5 mL) was diluted to 50 mL with 3% acetic acid. The diluted urine was injected directly into the liquid chromatograph for dextromethorphan analysis. Three healthy beagle dogs (weight, ~10 kg) were dosed orally with 10 mg of dextromethorphan hydrobromide in a physiological saline solution. Blood (8 mL) was withdrawn with a heparinized syringe at predose, 0.5, 1, 2, 4, 8, and 24 h after dosing. The blood was immediately centrifuged and the plasma was extracted for dextromethorphan analysis as described above. Urine samples were collected over a 24-h period and pooled.

Standard Curve and Calibration—Aqueous solutions of dextromethorphan hydrobromide were added to blank plasma samples such that the plasma contained 1–5 ng/mL of dextromethorphan hydrobromide. These standard plasma samples were extracted as described under sample preparations. Calibration curves were plotted using peak height *versus* the plasma drug concentration using the least-squares method. The concentrations of the drug in samples were interpolated from the standard curve.

Aqueous solutions of dextromethorphan hydrobromide were added to the blank urine samples to yield concentrations of 50–500 ng/mL dextromethorphan hydrobromide. These samples were diluted 5–50 mL with 3% acetic acid solution.

RESULTS AND DISCUSSION

Dextromethorphan has a UV maximum at 280 nm, so the initial experiments were carried out at this wavelength. The detection limit at 280 nm was not satisfactory for plasma analysis. By changing the wavelength to 200 nm, a 20-fold increase in sensitivity was obtained, but endogenous materials from plasma interfered. Since dextromethorphan has good fluorescent properties, the detection mode was changed from UV to fluorescence. Although the detection limit by fluorescence was similar to that by UV at 200 nm, the specificity improved significantly. The plasma blank showed no interference due to endogenous substances in the dextromethorphan elution region of the chromatogram. The use of semi-microbore columns (2.1 mm i.d.) increased the sensitivity of dextromethorphan fivefold with conventional 4.6 mm i.d. columns.

The chromatograms of the extracts of both human plasma and canine plasma were identical. For this reason, pooled human plasma was used to obtain a standard curve for dog plasma analysis since blank dog plasma was in short supply. Figure 1 shows the chromatograms of unspiked and dextromethorphan hydrobromide-spiked (1 ng/mL) human plasma. Figure 2 shows the chromatograms of dog urine blank and that spiked with 50 ng/mL. The detection limit in the urine samples is ~20 ng/mL.

Linearity—A linearity study was conducted on plasma samples by spiking with known amounts of dextromethorphan hydrobromide; levels of 0, 1, 2, 3, and 5 ng/mL were investigated. Between-day variation was examined by an analysis of variance of slopes and intercepts from 11 standard curves run over a period of 3 weeks. The slopes of these curves had an *RSD* of ±8.7%. This variation is not unusual and is related to a slight change in the chromatographic column performance over a period of time. A small interference is indicated by a positive intercept which amounted to an equivalent of 0.30 ng/mL of dextromethorphan hydrobromide. The data are summarized in Table I.

A linearity study on the urine sample was done by spiking blank urine with dextromethorphan hydrobromide at levels of 50–500 ng/mL. A correlation coefficient of 0.9996 was found. This much improved correlation for the urine standards as compared to the plasma standards is due to the fact that no extraction was involved in urine standards.

Absolute Recovery of Dextromethorphan from Biological Fluids—Recovery studies of dextromethorphan from spiked plasma were carried out. Recovery data were calculated against an unextracted standard (Table II). A small interference was found in the blank plasma and this peak height was subtracted from the sample peak height for the calculation of the recovery data. The *RSD* values were ~7–9% at the 2–5 ng/mL level, and 15% at 1 ng/mL, which is about the lower limit of detection by this method.

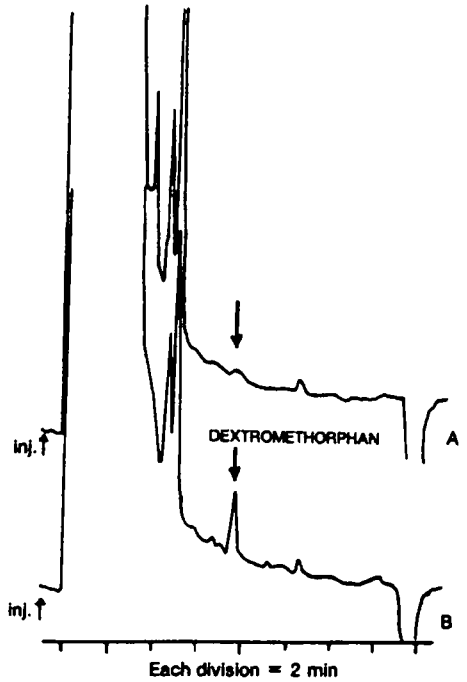

Figure 1—*Chromatograms of plasma blank (A) and plasma spiked with 1 ng/mL of dextromethorphan hydrobromide (B). Arrows indicate dextromethorphan elution areas.*

Recoveries of dextromethorphan hydrobromide from urine samples were essentially 100% since the fluorescence responses in the spiked urine samples were similar to those of the aqueous standards at the same concentration. The results were expected since there was no simple extraction involved. The urine samples were simply diluted with 3% acetic acid solution and then injected into the HPLC system.

Dextromethorphan Level After Oral Administration To Dogs—A typical plasma dextromethorphan concentration *versus* time curve in dogs after 1 mg/kg oral administration is shown in Fig. 3. These results compare well with those found by Barnhart and Massad (1, 4) who found 2.1 ng/mL peak maximum in dog plasma after 1 mg/kg oral administration. No detectable

Table I—Between-Day Variation of Dextromethorphan Linearity [a]

n	ng/mL	Peak Height, mm ± *SD*
9	0	4.3 ± 1.4
8	1	15.6 ± 1.4
9	2	29.6 ± 1.3
9	3	44.1 ± 3.7
11	5	72.7 ± 6.3

[a] The regression yielded $r = 0.9965$ and $y = 13.8x + 3.2$.

Table II—Recovery of Dextromethorphan From Plasma

n	Spiked Plasma, ng Dextromethorphan Hydrobromide/mL	Recovery, % ± *SD*
8	1	41.1 ± 5.8
9	2	48.7 ± 3.8
9	3	51.6 ± 3.3
11	5	53.3 ± 4.6

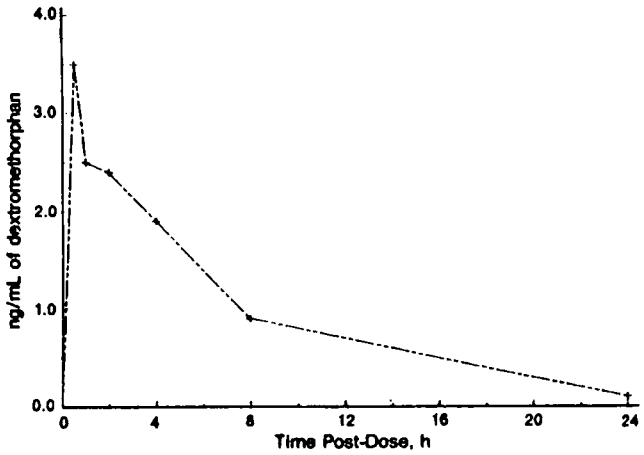

Figure 3—*Plasma dextromethorphan concentration* versus *time curve in the dog after 1-mg/kg oral administration of dextromethorphan hydrobromide.*

amount of dextromethorphan was found in pooled urine. This finding is also consistent with that found by Barnhart and Massad who recovered only a trace of the drug (0.12% of the total dose) after a 1.073 mg/kg oral administration.

The method described above is simple, accurate, and specific for determining dextromethorphan in plasma and urine. The use of semi-microbore columns allows detection limits of 1 ng of dextromethorphan/mL of plasma and 20 ng/mL of urine.

Determination of Flurbiprofen in Human Serum by Reverse-Phase High-Performance Liquid Chromatography with Fluorescence Detection

K. S. ALBERT *x, W. R. GILLESPIE *, A. RAABE ‡, and M. GARRY ‡

Received September 6, 1983, from *The Upjohn Company, Kalamazoo, MI 49001 and ‡Hazelton Raltech, Inc., Madison, WI 53707. Accepted for publication February 8, 1984.

Abstract □ A reverse-phase high-performance liquid chromatographic method is described for the determination of flurbiprofen in human serum. Flurbiprofen is extracted from hydrochloric acid-acidified serum with pentane–ether (80:20). An octadecylsilane column was used with a mobile phase of acetonitrile–water–phosphoric acid (650:350:0.5, v/v/v). A fluorescence detector with excitation at 250 nm and emission at 315 nm provided a quantifiable peak for 0.1 μg/mL of flurbiprofen in 0.5 mL of plasma. A comparison between UV and fluorescence detection systems is presented. The method is applicable to human bioavailability and pharmacokinetic studies with flurbiprofen.

Keyphrases □ Flurbiprofen– HPLC detection compared with fluorescence detection, human serum

Flurbiprofen [(±)-2-(2-fluoro-4-biphenylyl)propionic acid] is an orally active, nonsteroidal, anti-inflammatory drug found to be effective in the treatment of rheumatoid arthritis (1–3). We have developed a simple, sensitive, specific, and rapid analytical procedure to measure levels of flurbiprofen (0.1–10 μg/mL) in serum generated in clinical studies. Previous methods either required specialized sample preparation apparatus (4) or time-consuming TLC separation followed by derivatization and GC analysis (5). Investigations into the fluorescence of flurbiprofen suggested that sufficient sensitivity and selectivity could be achieved by employing reverse-phase high-performance liquid chromatography (HPLC) with fluorescence detection. Liquid–liquid extraction proved to be a satisfactory sample preparation technique and 4-biphenylacetic acid exhibited partition and fluorescence characteristics similar enough to flurbiprofen to be used as an internal standard. A method for measuring up to 0.1 μg/mL in 0.5 mL of plasma is described herein.

EXPERIMENTAL SECTION

Reagents and Materials—Reagents were at least analytical reagent grade quality. Acetonitrile[1], methanol[1], and pentane[1] were distilled in glass. Deionized water was supplied[2]. Stock solutions of 4-biphenylacetic acid[3] and flurbiprofen[4] were prepared at 1 mg/mL in methanol. Anhydrous ether[5], phosphoric acid[5] and 1 M hydrochloric acid[6] were used as supplied. The ether was monitored daily for peroxide formation.

Instrumentation—A fluorescence detector[7], solvent pump[8], and an autoinjector[8] were used for the routine chromatographic analysis. A variable-wavelength UV detector[9] was used for comparison with the fluorescence detector. A recorder[10] and an integrator[11] were used for data acquisition. A two-speed reciprocating shaker[12] and centrifuge[13] were used in the sample preparation.

Chromatographic Conditions—Chromatography took place on a 0.46 cm i.d. × 25-cm column packed with octadecylsilane bonded to microparticulate silica (6 μm)[14]. A guard column[15], 0.46 cm × 3 cm, packed with octadecylsilane bonded to microparticulate silica (5 μm), preceded the analytical column. The mobile phase was acetonitrile–water–phosphoric acid (650:350:0.5, v/v/v) filtered through a 0.45-μm membrane[16].

The flow rate was 1.0 mL/min, the column temperature was ambient, and the column back pressure was ~1000 psi. The injection volume was 20 μL, and the run time was 8 min. The retention times for flurbiprofen and 4-biphenylacetic acid were 5.0 min and 6.1 min, respectively. The settings for the fluorescence detector were: excitation wavelength, 250 nm; emission wavelength, 315 nm; slit width, 5 nm; range, 3.0; photomultiplier gain, normal; response, normal; output to recorder, 1 V; output to integrator, 10 mV.

Sample Preparation—Appropriate spiking solutions of flurbiprofen in methanol were prepared from the 1-mg/mL stock solution. A methanolic solution (10 μg/mL) of the internal standard (4-biphenylacetic acid) was prepared from the 1-mg/mL stock solution.

The appropriate standard spiking solution (50 μL for standard tubes) or 50 μL of methanol (for controls, samples, and the blanks) was added to culture tubes (16 × 125 mm) equipped with polytef-lined screw caps. Internal standard (50 μL), 0.5 mL serum, and 0.5 mL of 1 M hydrochloric acid was added to the tube and the contents were mixed on a vortex mixer. Pentane–ether (80:20, 10 mL) was added, the tube was shaken at high speed for 10 min and then centrifuged at 2000 rpm for 10 min. The organic layer was transferred to an empty culture tube (16 × 125 mm), and it then was evaporated under nitrogen in a water bath maintained at 30°C. When dry, the residue was dissolved in 5.0 mL of acetonitrile by mixing on a vortex mixer. A portion of the solution was transferred to a vial for autoinjection.

Two normal healthy male adult volunteers were administered flurbiprofen. These volunteers fasted 9 h before and 4 h after administration. One 50-mg film-coated flurbiprofen tablet was administered with ~188 mL of water, and blood (7 mL) was drawn by venipuncture into blood collection tubes[17] just before drug administration (0 h) and at 0.5, 1, 2, 3, 4, 6, 8, 12, 16, 24, and 30 h. Serum was harvested from the blood samples immediately after collection and kept frozen until assayed by the above procedure.

Calculations—Data were processed by a data system[11] using computer-generated, baseline-corrected peak heights. Peak height ratio curves (concentration flurbiprofen/concentration internal standard) were established and checked daily with standards to ensure acceptable slope and y-intercept values.

The apparent elimination rate constant for each subject, λ_z, was determined from a least-squares regression fit of the terminal log-linear region of the semilogarithmic plasma concentration–time curves. Area under the concentration–time curve, AUC_∞, was estimated by the trapezoidal rule with extrapolation to infinity. Apparent clearance after oral dosing, CL/F, was calculated from the expression:

$$CL/F = \frac{\text{Dose}}{AUC_\infty} \qquad \text{(Eq. 1)}$$

Apparent volume of distribution, Vd/F was calculated according to:

$$Vd/F = \frac{\text{Dose}}{\lambda_z AUC_\infty} = \frac{CL/F}{\lambda_z} \qquad \text{(Eq. 2)}$$

RESULTS AND DISCUSSION

A comparison of chromatograms with UV and fluorescence detection (Fig. 1) of blank and flurbiprofen-spiked serum illustrates the sensitivity and selectivity of the fluorescence assay. The blank (Fig. 1C) reveals no interfering peaks and the peak height of the flurbiprofen at required limit of sensitivity is adequate for quantitation. Because of the interferences evident in the chromatograms from UV detection, fluoresence is the preferred detection technique.

The precision and linearity of the method was investigated. A standard curve (eight points) was analyzed on 4 consecutive days. Table I summarizes the experimental data. The low deviation from linearity within each curve and the low relative standard deviation for the different runs demonstrates the efficacy of the method.

Table II summarizes the recovery results for flurbiprofen and internal standard (4-biphenylacetic acid) from spiked serum as compared with direct injection of standards prepared from stock solutions. The integrator peak height information was used in the calculations (*i.e.*, no internal standards were used). The results of 97.4 + 4.7% for flurbiprofen and 94.9 + 3.9% for 4-biphenylacetic acid show the essential quantitative recovery from serum.

The strong native fluorescence of flurbiprofen allowed achievement of the desired sensitivity of 0.1 μg/mL without approaching the design capability limits of the detector. Likewise, the amount of acetonitrile added to dissolve the extract residue in the sample preparation was chosen for convenience and can be decreased significantly, thus increasing the assay sensitivity. The limit of quantitation might also be improved by increasing the volume of solution injected.

The serum concentration–time profiles resulting from the administration of single oral 50-mg doses of flurbiprofen to two human subjects are shown in Fig. 2. Estimates of selected pharmacokinetic parameters are presented in Table III. The results are consistent with previously published reports describing flurbiprofen pharmacokinetics (6).

In conclusion, a sensitive, precise, and specific HPLC method with fluorescence detection has been described for the detection of 0.1 μg/mL of flurbiprofen in 0.5 mL of plasma. The method is readily applicable to routine analysis of plasma samples from bioavailability–pharmacokinetic studies in humans. Moreover, because of the strong native fluoresence of flurbiprofen,

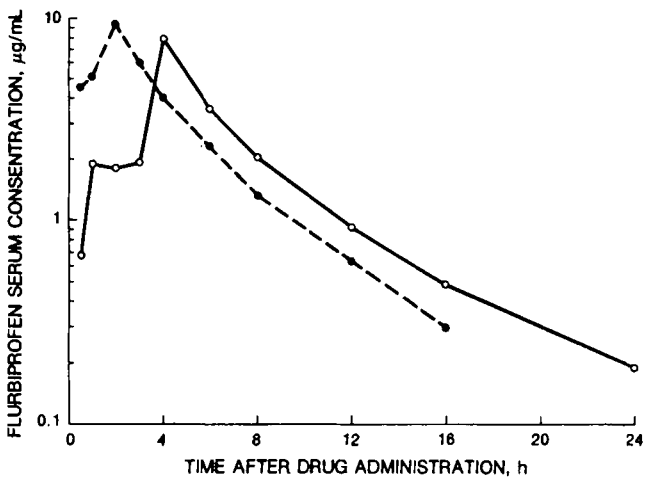

Figure 2—*Flurbiprofen serum concentrations following the administration of single oral 50-mg doses to two adult volunteers. Key: (○) subject 1; (●) subject 2.*

Table III—Flurbiprofen Pharmacokinetics Following the Administration of Single Oral 50-mg Doses to Two Adult Volunteers

	Subject 1	Subject 2
Age, years	26	30
Body weight, kg	80.7	62.6
Peak concentration, μg/mL	8.01	9.44
Peak time, h	4	2
Area under the concentration–time curve, μg·h/mL	39.8	41.2
Apparent clearance, mL/h/kg	15.6	19.4
Apparent distribution volume, mL/kg	131	104
Apparent elimination rate constant, h^{-1}	0.118	0.186

the sensitivity of the method can no doubt be extended making it an attractive technique for studying the bioavailability and pharmacokinetics of flurbiprofen in pediatric populations where small sample volumes and lower doses are required.

Direct, Simultaneous Determination of Propranolol and Its 4-Hydroxy Metabolite by Liquid Chromatography

G. TAMAI, I. MORITA, T. MASUJIMA, H. YOSHIDA, ˣ and H. IMAI

Received August 3, 1983, from the *Institute of Pharmaceutical Sciences, Hiroshima University School of Medicine, Hiroshima 734, Japan.* Accepted for publication November 28, 1983.

Abstract □ Propranolol and its active 4-hydroxy metabolite are determined by direct injection of spiked plasma samples onto a protein-coated ODS liquid chromatographic column. The recovery of propranolol and the 4-hydroxy metabolite is essentially quantitative and the reproducibility is good. The reproducibility and simplicity may be superior to the conventional HPLC analyses which include pretreatment, *i.e.*, solvent extraction or deproteinization.

Keyphrases □ Protein-coated ODS column—reverse-phase, direct injection analysis of plasma sample □ Propranolol—analysis and its 4-hydroxy metabolite, plasma

Propranolol, a β-adrenergic blocking drug, is widely used for the treatment of cardiac arrhythmia, sinus tachycardias, hypertension (1), and other pathological states (2, 3). The therapeutic drug level of propranolol is considered to be in the range of 50–100 ng (193–386 pmol)/mL of plasma (4). The 4-hydroxy metabolite, formed by hydroxylation of propranolol (5), has been reported to be an equipotent β-adrenergic blocker (6). Thus, for drug level monitoring, both propranolol and the 4-hydroxy derivative should be determined. Determination of propranolol (7, 8) and the 4-hydroxy metabolite using a reverse-phase HPLC method including sample pretreatment, such as solvent extraction or deproteinization has been reported previously (9–11). We reported that the protein-coated ODS column had no affinity for proteins, but did have an affinity for small hydrophobic molecules (12). The simultaneous plasma determination of propranolol and the 4-hydroxy metabolite reported herein is rapid and reproducible, and deproteinization can be carried out by the direct injection of plasma samples onto a protein-coated ODS liquid chromatographic column.

EXPERIMENTAL SECTION

Chemicals and Reagents—Propranolol hydrochloride[1], the 4-hydroxy metabolite (as the hydrochloride)[2], and bovine serum albumin[3] were obtained commercially. All other chemicals were analytical reagent grade.

Preparation of the Protein-Coated Octadecylsilane Column—An ODS column (pore size, 10-nm) was packed by the balanced-slurry method (slurry solvent, chloroform; purge solvent, 50% methanol). After the ODS column was equilibrated with phosphate-buffered saline (pH 7.4), 6% bovine serum albumin solution was injected to saturate the column. After the column was equilibrated with 0.1 M phosphate solution (pH 3.0), bovine serum albumin solution (6%) was again injected, and the column was then washed with absolute methanol. This procedure was repeated several times. The same procedure was repeated, using dialyzed rabbit plasma instead of the bovine serum albumin solution. The column treated by the aforementioned procedure is referred to as the protein-coated ODS column below.

Liquid Chromatographic Apparatus—An HPLC apparatus with a single plunger pump[4] and a sample injector[5] was assembled in our laboratory. For stepwise elution, solvent switching was performed by a solvent selector[6] and controlled by a sequence programmer[7]. For double-column analysis, a flow-direction switch valve[8] was placed between the precolumn and the analytical column. The valve was controlled by the sequence programmer[7]. Two fluorometers[9] were used in series: one for detection of propranolol (Ex, 297 nm; Em, 347 nm); the other for the 4-hydroxy metabolite (Ex, 327 nm; Em, 427 nm).

Preparation of Standard and Sample Solutions—A stock solution of propranolol and the 4-hydroxy metabolite containing 2% sodium metabisulfite (13) was prepared in distilled water at 10^{-5} M. Heparinized human and rabbit plasma samples were obtained by centrifuging whole blood (1000×*g*, at 25°C, for 10 min) and filtering[10] to remove solid materials. A plasma sample (0.25 mL) with or without propranolol and the 4-hydroxy derivative at the drug monitoring level, was injected onto the column. If the pressure of the column increased during successive analyses, the inlet filter of the column was washed with 1 M NaOH.

Single-Column Analysis—An ODS column of 100 mm × 6 mm i.d.[11] (particle size 5 μm, pore size 10 nm) was protein-coated and then used at room temperature. The protein-coated ODS column was equilibrated with phosphate-buffered saline (flow rate, 2 mL/min). The plasma sample spiked with propranolol and its 4-hydroxy derivative (0.25 mL) was injected onto the column. After eluting plasma proteins and hydrophilic components with phosphate-buffered saline for 5 min, the column was washed with phosphate-buffered saline containing 22% acetonitrile for 4 min. Propranolol and the 4-hydroxy derivative were then eluted with 0.1 M citrate buffer (pH 4.0) containing 22% acetonitrile.

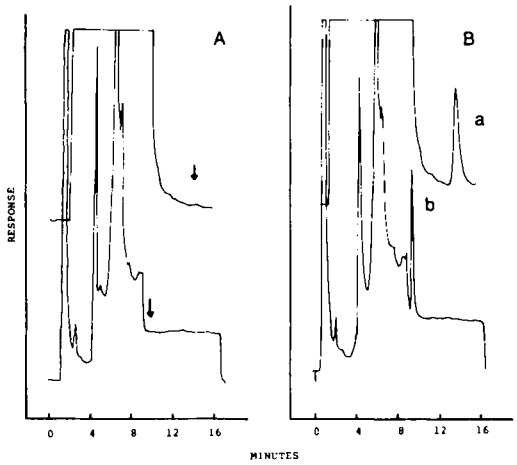

Figure 1—*Chromatograms obtained by a single protein-coated ODS column. Key: (A) human plasma blank; (B) human plasma sample spiked with propranolol (a) (Ex 297 nm, Em 347 nm) and the 4-hydroxy metabolite (b) (Ex 327 nm, Em 427 nm). Samples were 100 pmol of drug/0.25 mL of plasma.*

Double-Column Analysis—A protein-coated ODS column, 60 mm × 4 mm i.d.[12] (particle size 20 μm, pore size 10 nm), was used as the precolumn at room temperature. A 60 mm × 4 mm i.d. column[13] (particle size 5 μm, pore size 10 nm) was used as the analytical column at 35°C. The precolumn was equilibrated with phosphate-buffered saline (flow rate, 1.2 mL/min). A 0.25-mL plasma sample spiked with propranolol and the 4-hydroxy metabolite was injected onto the precolumn. Plasma proteins and hydrophilic compounds were eluted with phosphate-buffered saline for 5 min, and then the column was washed with phosphate-buffered saline containing 15% acetonitrile for 2 min. After being washed with 0.1 M citrate buffer (pH 4.0) containing 5% acetonitrile for 4 min, the precolumn was connected to the analytical column which was equilibrated with 0.1 M citrate buffer (pH 4.0) containing 15% acetonitrile. The propranolol and 4-hydroxy derivative retained on the precolumn were eluted with 0.1 M citrate buffer (pH 4.0, containing 15% acetonitrile) through the analytical column (flow rate, 1.7 mL/min). For elution from the analytical column, the 15% acetonitrile concentration was suitable for separatory elution. Chromatograms obtained by the flow-through and back-flush methods were compared.

RESULTS AND DISCUSSION

Determination By the Single-Column Technique—Propranolol, a basic drug [pK_a 9.45 (14)], has an affinity for ODS resin at pH 7.4. After the protein-coated ODS column was equilibrated with phosphate-buffered saline, a plasma sample (0.25 mL) spiked with propranolol and the 4-hydroxy metabolite (100–400 pmol/mL of plasma) was injected onto the column. Plasma proteins and hydrophilic compounds were eluted by phosphate-buffered saline, but propranolol and the 4-hydroxy metabolite were retained on the column. It was confirmed that the 4-hydroxy metabolite was eluted by phosphate-buffered saline containing 22% acetonitrile within 7 min, and propranolol was eluted after 30 min. The column was then washed with phosphate-buffered saline containing 22% acetonitrile for 4 min. Propranolol and the 4-hydroxy metabolite were eluted with 0.1 M citrate buffer (pH 4.0) containing 22% acetonitrile. In Fig. 1 are shown chromatograms of a human plasma blank and a plasma sample spiked with propranolol and the 4-hydroxy derivative. A calibration curve is shown in Fig. 2. The recoveries were 101.8 and 101.4%, respectively, with good reproducibilities (*CV*, 1.6 and 1.2%, respectively; n = 5). The practical drug monitoring level of propranolol and the 4-hydroxy metabolite was determined with good reproducibility and recovery. The levels of propranolol and the 4-hydroxy metabolite, analyzed by the present method, were totals in plasma, regardless if free or bound to proteins [binding of propranolol to plasma proteins has been reported to be as high as 90–96% (15)]. In the determination of propranolol with a single protein-coated ODS column, at least 50 samples were analyzed without deterioration of the column.

Determination By the Double-Column Technique—Representative chromatograms showing the separation of propranolol and the 4-hydroxy metabolite by the flow-through and back-flush methods are shown in Figs. 3 and 4. With the flow-through method, a slight peak broadening was observed after 150 successive analyses (Fig. 3). The reason might be due to reduced efficiency of the precolumn. With the back-flush method, sharp chromatograms were obtained and 150 successive analyses could be performed without deterioration of the column (Fig. 4). Propranolol was concentrated at the top of the precolumn by eluting with phosphate-buffered saline containing 15% acetonitrile. Both methods gave quantitative recoveries of propranolol and 4-hydroxy

Table I—Comparison of Deproteinization Methods [a]

Deproteinization Method	Recovery, %	CV, %
Protein-coated ODS column	100.1	0.9
5% Acetonitrile	101.0	3.2
5% Trichloroacetic acid	25.9	4.0

[a] Conditions: 300 ng of propranolol/mL of plasma; injection of 100 μL of plasma; $n = 5$.

metabolite; therefore, an internal standard was not required. By using a flow direction switching valve, the deterioration of the analytical column was minimized. At least 150 successive analyses with almost no column deterioration were carried out by the back-flush method.

Table I shows the comparison of the methods of deproteinization. Note that in the present method the deproteinization was performed at the initial stage after the injection of sample onto the column. In comparison with common HPLC analyses that include pretreatment, *i.e.*, solvent extraction or deproteinization, the proposed method proved superior in simplicity and accuracy.

Determination of "Brompton's Cocktails" by Circular Dichroism

W. MARC ATKINSON, JOHN M. BOWEN, and NEIL PURDIE ˣ

Received November 21, 1983, from the *Chemistry Department, Oklahoma State University, Stillwater, OK 74078.* Accepted for publication February 23, 1984.

Abstract □ Circular dichroism spectropolarimetry has been applied to the simultaneous determination of chiral compounds in binary mixtures without separation or sample preparation steps. A strategy which uses data measured at equivalent wavelength pairs simplifies the calculations. Correspondence is within ±2% of the compositions of prepared standard mixtures.

Keyphrases □ Circular dichroism—spectropolarimetry, UV absorption, Brompton's solutions, *R*-(−)-cocaine hydrochloride, morphine sulfate, (±)-methadone, (−)-fructose, β-cyclodextrin □ Brompton's solutions—circular dichroism, spectropolarimetry, UV absorption

A medically approved practice used to relieve the physical distress from chronic pain, such as is experienced by some terminally ill cancer patients, is to administer a mixture of controlled, addictive substances in an oral preparation commonly referred to as "Brompton's cocktails." Cocaine is common to all preparations. Other components differ, but are most often either morphine or (±)-methadone. The mixture is served in a fruit-flavored alcohol base.

Although documented evidence for the abuse of this prescription is limited at this time, the potential exists. We have developed a simple protocol for a rapid direct determination of the drugs by circular dichroism (CD) spectropolarimetry which requires no separation or sample prepreparation. We have previously reported data for opium alkaloids (1, 2), *R*-(−)-cocaine (3, 4), (+)-lysergide (D-LSD) (5), and tetracycline (6). The CD technique focuses only on those components which absorb light and which are simultaneously chiral. Chirality may be either intrinsic to the molecule (1–6) or induced by its complexation with a chiral substrate molecule (4).

By being able to focus on only the CD-active components, the problem of deconvoluting the cumulative UV spectra of the mixtures is considerably simplified. Absorption by the other CD-inactive components only affects the signal-to-noise ratio of the detector.

EXPERIMENTAL SECTION

Standard samples of *R*-(−)-cocaine hydrochloride[1], morphine sulfate[1], and (±)-methadone[2] were used without further purification. The fruit-flavored syrups commonly used contain (−)-fructose. Standard (−)-fructose[3] was obtained commercially. In-house standard mixtures were prepared by weight. Samples of unknown composition were either blind in-house preparations, or were provided[4]. Chirality is induced into (±)-methadone by complexation with the chiral cyclic oligosaccharide β-cyclodextrin[5] present in large excess in aqueous solution, $\sim 10^{-2}$ M.

CD measurements were made on an automatic recording spectropolarimeter[6], and data analyses were made on the ancillary data processor[7]. Daily calibration of the ellipticity scale was made against a standard solution of androsterone in dioxane, as recommended. Samples were diluted with the appropriate volume of dilute hydrochloric acid or water, usually 1:10.

5% Acetonitrile	101.0	3.2
5% Trichloroacetic acid	25.9	4.0

[a] Conditions: 300 ng of propranolol/mL of plasma; injection of 100 μL of plasma; $n = 5$.

metabolite; therefore, an internal standard was not required. By using a flow direction switching valve, the deterioration of the analytical column was minimized. At least 150 successive analyses with almost no column deterioration were carried out by the back-flush method.

Table I shows the comparison of the methods of deproteinization. Note that in the present method the deproteinization was performed at the initial stage after the injection of sample onto the column. In comparison with common HPLC analyses that include pretreatment, *i.e.*, solvent extraction or deproteinization, the proposed method proved superior in simplicity and accuracy.

Determination of "Brompton's Cocktails" by Circular Dichroism

W. MARC ATKINSON, JOHN M. BOWEN, and NEIL PURDIE ˣ

Received November 21, 1983, from the *Chemistry Department, Oklahoma State University, Stillwater, OK 74078.* Accepted for publication February 23, 1984.

Abstract □ Circular dichroism spectropolarimetry has been applied to the simultaneous determination of chiral compounds in binary mixtures without separation or sample preparation steps. A strategy which uses data measured at equivalent wavelength pairs simplifies the calculations. Correspondence is within ±2% of the compositions of prepared standard mixtures.

Keyphrases □ Circular dichroism—spectropolarimetry, UV absorption, Brompton's solutions, *R*-(−)-cocaine hydrochloride, morphine sulfate, (±)-methadone, (−)-fructose, β-cyclodextrin □ Brompton's solutions—circular dichroism, spectropolarimetry, UV absorption

A medically approved practice used to relieve the physical distress from chronic pain, such as is experienced by some terminally ill cancer patients, is to administer a mixture of controlled, addictive substances in an oral preparation commonly referred to as "Brompton's cocktails." Cocaine is common to all preparations. Other components differ, but are most often either morphine or (±)-methadone. The mixture is served in a fruit-flavored alcohol base.

Although documented evidence for the abuse of this prescription is limited at this time, the potential exists. We have developed a simple protocol for a rapid direct determination of the drugs by circular dichroism (CD) spectropolarimetry which requires no separation or sample prepreparation. We have previously reported data for opium alkaloids (1, 2), *R*-(−)-cocaine (3, 4), (+)-lysergide (D-LSD) (5), and tetracycline (6). The CD technique focuses only on those components which absorb light and which are simultaneously chiral. Chirality may be either intrinsic to the molecule (1–6) or induced by its complexation with a chiral substrate molecule (4).

By being able to focus on only the CD-active components, the problem of deconvoluting the cumulative UV spectra of the mixtures is considerably simplified. Absorption by the other CD-inactive components only affects the signal-to-noise ratio of the detector.

EXPERIMENTAL SECTION

Standard samples of *R*-(−)-cocaine hydrochloride[1], morphine sulfate[1], and (±)-methadone[2] were used without further purification. The fruit-flavored syrups commonly used contain (−)-fructose. Standard (−)-fructose[3] was obtained commercially. In-house standard mixtures were prepared by weight. Samples of unknown composition were either blind in-house preparations, or were provided[4]. Chirality is induced into (±)-methadone by complexation with the chiral cyclic oligosaccharide β-cyclodextrin[5] present in large excess in aqueous solution, $\sim 10^{-2}$ M.

CD measurements were made on an automatic recording spectropolarimeter[6], and data analyses were made on the ancillary data processor[7]. Daily calibration of the ellipticity scale was made against a standard solution of androsterone in dioxane, as recommended. Samples were diluted with the appropriate volume of dilute hydrochloric acid or water, usually 1:10.

Table I—Circular Dichroism Spectral Characteristics [a]

Compound	Characteristic[b]	Wavelength, nm	[θ], degree/M-cm
Morphine Sulfate	λ^-_{max}	286	−66
	λ^o	263	0
	λ^+_{max}	244	372
Cocaine hydrochloride	λ^+_{max}	278	11.5
	λ^o	262	0
	λ^-_{max}	245	−55
(−)-Fructose	λ^+_{max}	273	0.3[d]
	λ^o	235	0
(±)-Methadone[c]	λ^+_{max}	290	9.6[e]
	λ^+_{max}	273	6.4[e]
	λ^+_{max}	266	5.6[e]

[a] For 0.1 M HCl aqueous solutions. [b] λ^+_{max} and λ^-_{max} are wavelengths of the maximum positive or negative signals. λ^o is the wavelength of zero ellipticity. [c] In β-cyclodextrin solution only. [d] Value is calculated for total sugar although only the open-chain form is CD active in the 220–350-nm region. [e] Values for 1:1 complex with β-cyclodextrin.

Table II—Determinations of Binary Mixtures [a]

Sample[b]	Cocaine	Morphine	(−)-Fructose	(±)-Methadone	λ Pairs
S1	1.06 (1.05)	—	—	(0.98)	—
S2	2.31 (2.32)	—	—	(1.55)	—
S3	1.72 (1.74)		9.65 (9.87)	—	7
S4	2.61 (2.55)	—	15.94 (16.23)	—	4
S5	4.15 (4.18)	—	15.04 (14.23)	—	6
S6	2.22 (2.24)	3.44 (3.28)	—	—	6
S7	5.78 (5.81)	1.59 (1.56)	—	—	6
S8	2.95 (2.99)	1.06 (1.05)	—	—	6
B1	0.95 (1)[c]	1.53 (1.5)[c]	—	—	10
B2	0.98 (1)[c]	1.55 (1.5)[c]	—	—	7
B3	1.08 (1)[c]	—	133[d]	present	7
B4	1.01 (1)[c]	—	137[d]	present	6
B5	0.95 (1)[c]	1.46 (1.5)[c]	119[d]	—	6

[a] In mg/mL. Data in parentheses are calculated from known weights. [b] S represents an in-house preparation and B represents an externally supplied Brompton's solution. [c] Figures correspond with pharmacist's recipe. [d] Results are for (−)-fructose in fruit-flavored additives; no composition given.

(−)-Fructose solutions have low ellipticities (7, 8), so solution concentrations were as high as 0.2 M.

RESULTS AND DISCUSSION

CD spectral parameters for the four compounds are collected in Table I. Molar ellipticity [θ] values calculated from the slopes of the respective Beer's law calibration curves at the reported wavelength maxima are also presented. Significant spectral overlap is observed for mixtures of *R*-(−)-cocaine and morphine and *R*-(−)-cocaine and (−)-fructose. The compositions of the in-house preparation of these mixtures were made to be consistent with the pharmacy prepared prescriptions which are on the order of 1.5 mg/mL of morphine sulfate and 1 mg/mL *R*-(−)-cocaine hydrochloride or (±)-methadone. If the binary mixture consists of *R*-(−)-cocaine and (±)-methadone, the problem reduces to the determination of only *R*-(−)-cocaine by direct measurement of the aqueous solution which is conveniently done at the 278 nm positive maximum for the analyte.

For binary mixtures of CD-active components, the observed ellipticity at any wavelength for a 1-cm cell is given by the expression:

$$\psi_{exp} = [\theta]_1 C_1 + [\theta]_2 C_2$$

where the subscripted [θ] and *C* terms refer to the molar ellipticities and molar concentrations of the two components, respectively. The resolution of broad UV absorption bands into positive and negative components in CD spectra offers a simpler option to the simultaneous solution of the equation which is fairly general. The equation reduces to a single unknown if data are measured at preselected wavelength pairs on the standard spectrum of either component at which the absolute values of [θ] are equal in magnitude. Experience with the blind in-house mixtures shows us that the best correspondence in determinations is obtained if the pairs are chosen from the standard spectrum of the component which has the lower [θ]; namely cocaine in mixtures with morphine, and fructose in mixtures with either cocaine or morphine. Results from the calculations and the number of wavelength pairs used are given in Table II for several binary mixtures.

Compared with the direct determination of complex mixtures by UV absorption spectrophotometry, which is commonly done using computer simulation methods, CD effectively reduces the number of analytes contributing to the overall spectrum by focusing on only those which are CD active. The number of curve-fitting parameters is reduced accordingly, and the precision in the determination of each component is improved. Matrix distortions of the CD spectra of the analyte(s) by the simultaneous absorption of energy by achiral components are not observed.

Determinations made on the unknowns obtained from external sources indicated that the preparations were within the recommended limits prescribed for administration to patients (Table II). One ternary mixture was investigated in which tampering with the prescription was suspected. The mixture was reported to consist of morphine, *R*-(−)-cocaine, and (−)-fructose in alcohol. The CD spectrum was a close replica of the mixture prepared according to the prescription. Measurements of data at wavelength pairs for (−)-fructose and the simultaneous solution of the equation for the remaining constituents yielded 1.46 mg/mL for morphine and 0.95 mg/mL for *R*-(−)-cocaine.

At its present state of development, CD spectropolarimetry offers a rapid and quantitative procedure for drug assay and as such has a useful application to product quality control. As the spectral library is extended to include more and more standards, anonymous compound recognition and identification can be anticipated. With the appropriate computer software the same simulation techniques applied to UV absorption determination of multiple-component mixtures can be applied equally well.

High-Performance Liquid Chromatographic Method for the Determination of Tiflamizole in Plasma

DARIEL C. RAKESTRAW ˣ **and CHARLES C. WHITNEY, JR.**

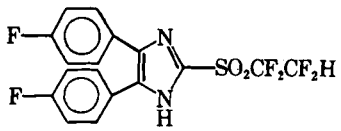
Received October 27, 1983, from *E. I. duPont de Nemours and Company, Inc., Pharmaceuticals Research and Development Division, DuPont Pharmaceuticals, Newark, DE 19714.* Accepted for publication February 24, 1984.

Abstract □ A sensitive, specific, high-performance liquid chromatographic procedure was developed for the measurement of plasma tiflamizole levels. Acidic plasma samples were extracted with three volumes of ether. The ether extracts were combined and evaporated to dryness. The residue was dissolved in acetonitrile, washed with hexane, and the acetonitrile was evaporated to dryness. The residue was dissolved in 0.5 mL of mobile phase consisting of acetonitrile and 0.007 M pH 3 sodium phosphate buffer (70:30, v/v) and then chromatographed on a octadecylsilane bonded microparticulate silica column. The assay is specific, precise, accurate, and can measure 10 ng of tiflamizole in 5 mL of plasma. The method was applied to human pharmacokinetic studies.

Keyphrases □ HPLC—tiflamizole, human plasma □ Tiflamizole—HPLC, human plasma

Tiflamizole, 4,5-bis(4-fluorophenyl)-2-[(1,1,2,2-tetrafluoroethyl)sulfonyl]-1*H*-imidazole (I), is a potent nonsteroidal antiarthritic drug that both prevents and treats adjuvant-induced arthritis in rats (1, 2). Tiflamizole is presently being evaluated in clinical studies.

The chemistry, pharmacology, and pharmacokinetics of tiflamizole were recently discussed (1–4). In the initial human studies low doses of tiflamizole were used. This required a specific and highly sensitive GC method[1] for tiflamizole analysis. However for the larger doses currently in use, the high sensitivity is not required and a simpler, more rapid method was developed. This paper describes a specific high-performance liquid chromatographic (HPLC) plasma assay for tiflamizole. The sensitivity of the method is 10 ng/mL.



I

EXPERIMENTAL SECTION

Reagents and Apparatus—Tiflamizole[2], 1 M pH 5.3, and 0.007 M pH 3.0 sodium phosphate (monobasic), acetonitrile[3], ether[4], and hexane[3] were used without further purification. The liquid chromatograph consisted of a variable-wavelength UV detector[5] set at 280 nm, a solvent pump[6], a reporting integrator[7], a valve-loop injector[8] with a 100-μL loop, and a 0.46 cm i.d., × 25 cm octadecylsilane bonded microparticulate column[9]. The mobile phase was acetonitrile–0.007 M pH 3 sodium phosphate buffer (70:30). The flow rate was 1.5 mL/min, the column temperature was ambient, and the column back pressure was ~1000 psi. The approximate retention times of tiflamizole and naphthalene were 4.5 and 5.8 min, respectively.

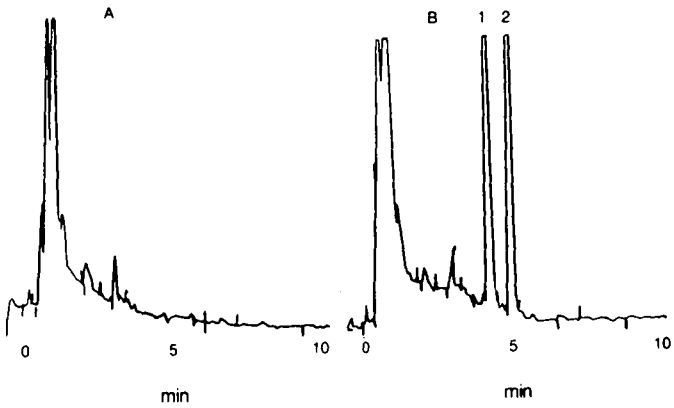

Figure 1—*Chromatograms of extracts from a plasma blank (A) and spiked (0.5 μg) plasma sample (B). Key: (1) tiflamizole; (2) naphthalene.*

Table I—Stability of Tiflamizole in Human Plasma [a]

Day	Amount Spiked, μg[b]	Amount Found, μg	*CV*, %
1	0.48	0.49	4.7
11	0.48	0.50	1.2
21	0.48	0.49	2.0
117	0.48	0.49	1.2
530	0.48	0.48	2.1

[a] Stored at −20°C. [b] $n = 3$.

Standards—Standard curves were prepared from unextracted tiflamizole standards. These standards (0.1, 0.2, 0.5, and 1 μg/mL) were prepared in a mobile phase containing 1 μg/mL of the internal standard, naphthalene, and 100 μL of each was injected into the column and chromatographed.

The peak areas of tiflamizole and naphthalene were measured and the ratio of tiflamizole/naphthalene was calculated. Linear regression least-squares fit was used to calculate the standard curve. Concentration of tiflamizole in unknown samples was determined from the peak area ratio of tiflamizole/naphthalene and the standard curve.

Extraction—A measured volume of plasma (0.5–10 mL) was transferred to a 15-mL polytef-lined screw-cap test tube[10] containing 5 mL of 1 M pH 5.3 sodium phosphate buffer. The mixture was extracted with one 10-mL and two 5-mL portions of ether. After shaking the extract for 30 min, the tube was centrifuged to separate the ether and the aqueous layers.

The organic layers were combined in another 15-mL tube and evaporated to dryness using a gentle stream of air. The residue was dissolved in 5 mL of acetonitrile and washed with three 5-mL volumes of hexane. After shaking for 20 min, the tube was centrifuged to separate the acetonitrile and hexane layers. The hexane layer was discarded by aspiration, then the acetonitrile was evaporated to dryness. The residue was dissolved in 0.5 mL of mobile phase containing 1 μg/mL of naphthalene; 100 μL was then injected into the liquid chromatograph.

Recovery Study—Control plasma samples (1 mL) spiked with 0.1, 0.2, 0.5, and 1.0 μg of tiflamizole were used to determine the extraction recovery. Control plasma samples (1 mL) spiked with 0.5 μg of tiflamizole were run concomitantly with the plasma of each subject to monitor daily recovery of tiflamizole.

Plasma Level Study—Tiflamizole (5 mg) was administered orally with ~237 mL (8 oz.) of water to 3 healthy human males, 64–76 kg, who had fasted

overnight. Blood samples (10 mL) were withdrawn[11] prior to dosing and at specified times up to 57 d after dosing. The blood samples were centrifuged and the plasma was stored frozen in clean plastic tubes[10]. The elimination half-lives for these individuals were determined using linear regression analysis of the terminal plasma level–time data points.

[11] Heparinized vacutainers.

RESULTS AND DISCUSSION

Typical chromatograms of extracted control plasma and plasma spiked with tiflamizole are shown in Fig. 1. Tiflamizole/naphthalene peak area ratios were linear (from 0.1 to 1.0 μg/mL) and the correlation coefficients for the fit of experimental points were 0.99995. The intercepts were not significantly different from zero. There was no interference from constituents in control plasma or in the plasma from subjects or patients prior to administration of tiflamizole. Tiflamizole is stable in plasma stored at −20°C for at least 530 d. The results are shown in Table I.

Tiflamizole recoveries from spiked plasma (0.1–1.0 μg/mL) were 87.0–100% with *SD* values of 1.0–3.0% (Table II). Daily recoveries of 0.5 μg of tiflamizole spiked to 1 mL of control plasma were 99.7% ($n \simeq 131$) with a *SD* of 3.2%. Tiflamizole can be determined at levels as low as 0.01 μg/mL using 5 mL of plasma.

Figure 2 illustrates the plasma tiflamizole concentration profile in three healthy subjects given a single oral 5-mg dose. Peak concentrations of 0.36–0.61 μg/mL occurred between 4 and 12 h. The elimination half-lives were 9.9–18.0 d.

Analysis of Tablets Containing Aspirin, Acetaminophen, and Ascorbic Acid by High-Performance Liquid Chromatography

R. THOMIS, E. ROETS, and J. HOOGMARTENS ˣ

Received March 25, 1983, from the *Katholieke Universiteit Leuven, Laboratorium voor Farmaceutische Chemie, Instituut voor Farmaceutische Wetenschappen, B-3000 Leuven, Belgium.* Accepted for publication February 8, 1984.

Abstract □ The high-performance liquid chromatographic method described enables the quantitation of the components and the main impurities of tablets containing aspirin, acetaminophen, and ascorbic acid. A C_8 reverse-phase column was used; the mobile phase was methanol–0.2 M phosphate buffer (pH 3.5)–water (20:10:70). Results obtained for a brand of effervescent tablets, normally aged for 5 years and stressed at 37°C, 50°C, or in 79% relative humidity at room temperature, are reported. Salicylic acid was the main product of decomposition. Diacetyl-*p*-aminophenol was observed to be formed by transacetylation.

Keyphrases □ Acetaminophen—HPLC with ascorbic acid and aspirin □ Aspirin—HPLC with acetaminophen and ascorbic acid □ Ascorbic acid—HPLC with acetaminophen and aspirin

During the last decade, phenacetin has been often replaced by acetaminophen in analgesic tablet formulations containing aspirin as the main component (1). Acetaminophen–aspirin mixtures have lower stability due to acetylation of the former by the latter, producing diacetyl-*p*-aminophenol (2, 3). This acetylation, however, was not evident in another study (4).

Tablets containing ascorbic acid were reported to be stable for over 5 years under normal storage conditions (5), but in combination with aspirin the eventual acetylation of ascorbic acid should be considered. Acetylation, in aqueous medium, of ascorbic acid by acetic anhydride has been described (6). Acetylation of other compounds present in tablet formulations,

This acetylation, however, was not evident in another study (4).

Tablets containing ascorbic acid were reported to be stable for over 5 years under normal storage conditions (5), but in combination with aspirin the eventual acetylation of ascorbic acid should be considered. Acetylation, in aqueous medium, of ascorbic acid by acetic anhydride has been described (6). Acetylation of other compounds present in tablet formulations,

0022-3549/84/1200-1830$01.00/0
© 1984, American Pharmaceutical Association

such as phenylephrine (7), codeine (8), or homatropine (9), has also been reported. Acetylation of proteins by aspirin was proposed as an explanation for the hypersensitivity to aspirin in humans (10).

This paper reports on the stability of an effervescent tablet from one manufacturer[1]. The tablets contain aspirin, acetaminophen, and ascorbic acid as the active components. High-performance liquid chromatography (HPLC) was chosen as the method for analysis. HPLC has been used previously for the analysis of multicomponent tablets containing aspirin and acetaminophen (11-17), but to our knowledge this is the first time that ascorbic acid was included in the analysis.

EXPERIMENTAL SECTION

Reagents and Chemicals—Some of the reference products were obtained through synthesis according to literature procedures: diacetyl-*p*-aminophenol, mp 151-154°C [lit. (2, 18) mp 152-156°C and 151-154°C]: *O*-acetyl-*p*-aminophenol, mp 79-81°C [lit. (19) mp 73-74°C and 75°C][2]. A mixture of 3-*O*-acetylascorbic acid and 2-*O*-acetylascorbic acid was obtained in solution[3] (6). Aspirin, salicylic acid, acetaminophen, and ascorbic acid were of Ph. Eur. quality. Sodium saccharin[4], *p*-hydroxybenzoic acid[4], and *p*-aminophenol[4] were of reagent quality. Formic acid[5], potassium hydrogen phosphate[5], and phosphoric acid[5] were of *pro analysi* quality. Reagent-grade methanol[6] was distilled in glass before use; water was distilled twice.

Apparatus and Operating Conditions—A high-pressure pump[7] was connected to a 10-μL loop injector[8], a column packed in-house with 10-μm C_8 reverse-phase material[9], a 254-nm fixed-wavelength detector[10], an integrator (used in the area mode)[11], and a recorder[12]. Some chromatograms were obtained with a variable-wavelength detector[13].

The mobile phase, CH_3OH-0.2 M phosphate buffer (pH 3.5)-water (20:10:70, v/v) was deaerated by sonication; the flow rate was 1 mL/min. The UV detector was set at 0.05 AUFS and the integrator at attenuation 4; the chart speed was 5 mm/min. The column was kept at room temperature (~20°C). The variable-wavelength detector was used at 280 nm.

Preparation of Sample Solutions—Two tablets (average mass, 3.45 g) were pulverized, and 1.000 g was weighed into a 50.0-mL volumetric flask. Formic acid (1.0 mL) and methanol (25 mL) were added, and the flask was mechanically shaken for 10 min. The mixture was brought to volume with methanol, 10 mL was clarified by centrifugation, and 5.0 mL of the supernatant was transferred into a 25.0-mL volumetric flask. Internal standard solution (5.0 mL) was added, and the solution was diluted to volume with water. The solution was analyzed within 1 h after preparation. A 0.0025% (w/v) solution of *p*-hydroxybenzoic acid in methanol-water (20:80) was used as the internal standard solution.

Sample and Storage Conditions—The tablets were prepared to contain 300 mg of aspirin, 200 mg of acetaminophen, and 300 mg of ascorbic acid. Sodium hydrogen carbonate, tartaric acid, citric acid, sodium saccharin, lactose, starch, dimethyl polysiloxane, povidone, and citrus oil were the excipients. Eleven batches, naturally aged 4-61 months at the time of analysis, were available. All samples were kept in their original, unopened plastic tubes; the stoppers had a drying agent. Tubes from the most recent batch were stored for 12 weeks in stressed conditions, *i.e.*, at 37°C (closed tubes), at 50°C (closed tubes), and at room temperature (~20°C) with a relative humidity of 79% (closed and open tubes).

Chromatographic Analysis—Least-squares regression lines (y, peak area ratio; x, amount injected in μg) were obtained with suitably prepared standard solutions for ascorbic acid ($y = 2.235x + 0.0005$), acetaminophen ($y = 2.717x + 0.0153$), salicylic acid ($y = 0.1226x + 0.0012$ at 254 nm, $y = 0.3774x + 0.0001$ at 280 nm), aspirin ($y = 0.2022x + 0.0010$), and diacetyl-*p*-aminophenol ($y = 2.182x + 0.0031$). The coefficient of correlation was >0.999 in all cases. When immediate analysis was impossible, standard solutions were kept at 5°C. The reproducibility was checked by a quadruple extraction of the same powdered tablet mixture and a twofold injection of each resulting solution. The mean and *CV* values obtained for the eight experiments were: ascorbic acid (107.0%, 0.9); acetaminophen (99.8%, 1.0); salicylic acid, measured at 280 nm, (0.81%, 1.8); aspirin (98.9%, 0.6); diacetyl-*p*-aminophenol (0.14%, 3.8). The results are expressed as a percentage of the label claim, except for the impurities where the mass of substance found (*e.g.*, salicylic acid) is reported as a percentage of the label content of the corresponding component (*e.g.*, aspirin).

Four tablets were retained for analysis from each tube, *i.e.*, the pair closest to the orifice and that closest to the bottom. Both pairs were extracted and the solutions were analyzed twice. Significant differences between top and bottom tablets were never found; therefore, the mean of four results is reported.

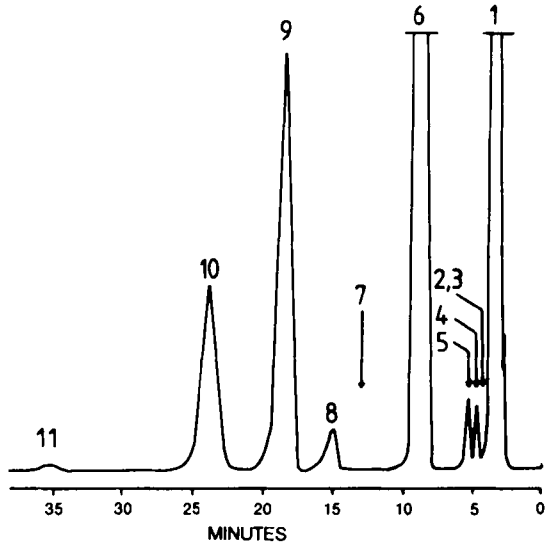

Figure 1—*Chromatogram of 45-month-old tablets; detection at 254 nm. Key: (1) ascorbic acid; (2) p-aminophenol; (3) 3-O-acetylascorbic acid; (4) 2-O-acetylascorbic acid; (5) sodium saccharin; (6) acetaminophen; (7) O-acetyl-p-aminophenol; (8) salicylic acid; (9) p-hydroxybenzoic acid (internal standard); (10) aspirin; (11) diacetyl-p-aminophenol.*

RESULTS AND DISCUSSION

A typical chromatogram, obtained for 45 month-old tablets, is shown in Fig. 1. The influence of the pH of the mobile phase on the separation of *p*-hydroxybenzoic acid, salicylic acid, and aspirin is shown in Fig. 2. A mobile phase containing methanol and a buffer (pH 3.4) was described recently for the analysis of bulk aspirin (20, 21). In all tablets examined, a small peak possibly corresponding to 2-*O*-acetylascorbic acid is present, but a peak cor-

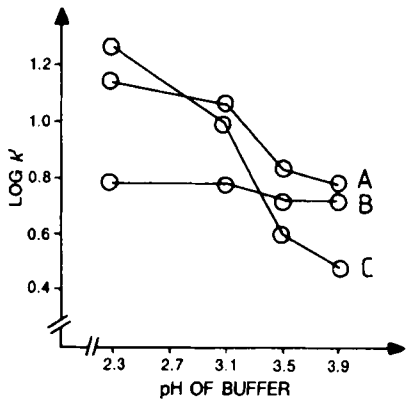

Figure 2—*Influence of the mobile phase buffer pH on the capacity factor (k') of aspirin (A), p-hydroxybenzoic acid (B), and salicylic acid (C).*

recoveries, and since all lots were kept in the same conditions, this must be due to striking differences in the manufacturing quality.

The results obtained in stressed conditions are given in Table II. At 37°C, the USP 3% limit for salicylic acid is reached after ~1 month; at 50°C, the limit is reached after 2 weeks. In open tubes, kept at room temperature and in humid conditions such as frequently occurs in bathrooms, this limit can be reached in ~1 d. Results for the experiment with closed tubes at room temperature and in 79% relative humidity are not reported in detail since the stability was not affected, thus proving the quality of the container.

Although ascorbic acid seems to withstand moderate heating quite well, the effect of high humidity is disastrous. It should, however, be kept in mind that the stability is influenced not only by the conditions of conservation, but also by the presence of other tablet components. The hydrolysis of aspirin involves formation of acetic acid, which lowers the pH and acts as a solvent, thus facilitating reaction. The eventual influence of acetic acid formation is supported by the fact that in the 50°C experiment, ascorbic acid starts to decompose only after 4 weeks, when appreciable amounts of acetic acid have already been formed. A similar effect is observed for diacetyl-*p*-aminophenol

responding to the assumed 3-*O*-acetylascorbic acid has never been detected. This substance was observed to be very unstable in solution, which confirms an earlier report (6). Quantitative determination of the ascorbic acid derivatives was not attempted since the only reference available was a solution containing a mixture of these impurities. *p*-Aminophenol, which has the same retention time as 3-*O*-acetylascorbic acid, was never detected during our experiments. Due to the rather poor separation in this area of the chromatogram, the detection limit for *p*-aminophenol was not better than 2%. *p*-Aminophenol has been reported as an impurity present in tablets containing acetaminophen, but only when codeine phosphate or magnesium stearate were also present (3); these products were not present in the tablets examined. *O*-Acetyl-*p*-aminophenol was never detected in significant amounts. Diacetyl-*p*-aminophenol was not detected at 280 nm (a more appropriate wavelength for the detection of salicylic acid, present in all the samples as the predominant impurity). Detection at ~300 nm (close to the absorption maximum for salicylic acid) was not applied due to the low absorbance of *p*-hydroxybenzoic acid, used as the internal standard. Samples were extracted with a mixture of formic acid and methanol. The presence of formic acid favors the drug release from the excipients (22). The stability at ~5°C of a solution to be analyzed was followed by HPLC, and the decrease of the content was noted: ascorbic acid, 0.003%/h; acetaminophen, 0.001%/h; aspirin, 0.02%/h; diacetyl-*p*-aminophenol, 0.001%/h. The value for aspirin corresponds well with a value reported for a chloroform–formic acid extract (22).

Table I lists the results for the naturally aged samples. No significant decrease in ascorbic acid or acetaminophen content was observed, and diacetyl-*p*-aminophenol was not formed in appreciable amounts although a small increase was observed. A linear correlation ($r = 0.983$) exists between diacetyl-*p*-aminophenol and salicylic acid formation. The formation of diacetyl-*p*-aminophenol from acetaminophen by transacetylation with aspirin has been discussed previously (3). The formation of salicylic acid is rapid. The 3.0% limit for buffered tablets of the USP XX (23) is exceeded in <2 years, and the BP 80 (24) 1.0% limit for dispersible tablets is exceeded after ~0.5 year. The decrease of aspirin is completely explained by the increase of salicylic acid. Some lots (45 and 55 months) show exceptionally high salicylic acid which, in the 50°C experiment, reaches a maximum after 4 weeks, corresponding to a minimum for acetaminophen. This maximum is followed by a rapid decrease, paralleled by an increase of acetic acid (or salicylic acid) and acetaminophen, which suggests formation of the latter through hydrolysis of diacetyl-*p*-aminophenol.

In all the stressed experiments, the loss of aspirin is completely explained by the formation of salicylic acid. This agrees with recently published results for aspirin tablets, stressed at 50°C and at 80°C, where appreciable amounts of non-salicylic-acid salicylates were only observed at the higher temperature (17).

Effects of Benztropine Mesylate on Haloperidol-Induced Prolactin Secretion and Serum Haloperidol Levels in Rats

JACK M. ROSENBERG *x, MARTIN SIDEMAN *, INGO S. KAMPA ‡, HOWARD McGUIRE §, and LIDIJA KAMPA ¶

Received November 7, 1983, from the **Arnold & Marie Schwartz College of Pharmacy and Health Sciences, Long Island University, Brooklyn, NY 11201*, the ‡*Department of Pathology, The Valley Hospital, Ridgewood, NJ 07451*, §*Long Island University, Brooklyn, NY 11201*, and ¶*Kean College of New Jersey, Union, NJ 07087*. Accepted for publication February 22, 1984.

Abstract □ The effects of benztropine mesylate on haloperidol-induced prolactin secretion and serum haloperidol levels were investigated in 240 rats. Animals were pretreated with benztropine mesylate or saline 20 min prior to receiving haloperidol or saline. Serum prolactin and haloperidol levels were analyzed at six time periods over 150 min. There was no significant difference in prolactin levels of control animals, *i.e.*, saline pretreated/saline treated rats compared to benztropine mesylate pretreated/saline treated rats. Haloperidol caused a significant rise ($p < 0.0001$) in serum prolactin compared with controls. The prolactin concentration for the 30–150-min sampling period was significantly higher when the rats received benztropine mesylate prior to haloperidol ($p < 0.05$). There was a significant correlation ($r = 0.57, p < 0.001$) between serum haloperidol levels and serum prolactin levels in haloperidol-treated animals pretreated with either saline or benztropine mesylate. Additionally, serum haloperidol levels were not significantly different in animals pretreated with benztropine mesylate compared with those pretreated with saline. Thus, the enhancement of prolactin levels by benztropine mesylate was independent of any effect of haloperidol metabolism. This study appears to indicate that in the rat, cholinergic mechanisms exert a weak inhibitory effect on prolactin secretion under conditions of dopamine blockade.

Keyphrases □ Benztropine mesylate—prolactin secretion, serum haloperidol levels, rats □ Haloperidol—prolactin secretion, benztropine mesylate, serum levels, rats

The secretion of the anterior pituitary hormone, prolactin, appears to be dominantly regulated by a prolactin-inhibitory factor liberated by the hypothalamus as a result of afferent dopaminergic impulses (1–3). Dopamine is believed to be the major prolactin-inhibitory factor (4). In addition, prolactin release appears to be mediated to some extent by prolactin-releasing factors (5). Evidence also exists in animals that cholinergic and serotonergic mechanisms modulate the secretion of prolactin at the level of the pituitary (6–9). Although pilocarpine and physostigmine inhibited prolactin secretion in rats (8, 10, 11), no effect was observed on neuroleptic-induced prolactin secretion in this species (11). There are complex and conflicting reports concerning the effects of cholinergic blocking drugs on serum prolactin levels in humans and animals (6, 11, 12).

A fairly good correlation between the antipsychotic potency of various neuroleptics and their prolactin-stimulating effects has been demonstrated both in humans and rats (9, 13–15). Neuroleptics differ considerably in their intrinsic central anticholinergic properties (16). According to Lal *et al.* (17) such differences may account, at least in part, for variations in serum prolactin-stimulating properties found among antipsychotic agents. This suggestion was based on their demonstration in humans that intramuscularly administered benztropine mesylate, a muscarinic receptor-blocking agent, significantly enhanced the elevated prolactin levels induced by intramuscularly administered haloperidol (17). However, no attempt was made to determine if benztropine mesylate influenced prolactin secretion by altering haloperidol metabolism (17).

In this laboratory, comparison of the rank-order of reported central anticholinergic activity of nine antipsychotic drugs belonging to five chemical classes of neuroleptics appeared not to have significant effect upon either the magnitude or duration of prolactin stimulation in rats (18). However, there are no assurances that central anticholinergic threshold levels had been reached with the doses of drugs utilized.

In light of the above, it appeared desirable to further investigate the possible role of anticholinergic activity in enhancing neuroleptic-induced prolactin secretion in rats, to help clarify if a species difference exists between humans and rats in regard to this effect, and to determine if benztropine mesylate influences haloperidol plasma levels. The present investigation examined the effects of benztropine mesylate on haloperidol-induced prolactin secretion and serum haloperidol levels in rats.

EXPERIMENTAL SECTION

Two hundred and forty male Sprague–Dawley adult rats[1] (225–300 g) were divided into 24 equal groups. The rats were housed for 14 d prior to the study

However, no attempt was made to determine if benztropine mesylate influenced prolactin secretion by altering haloperidol metabolism (17).

In this laboratory, comparison of the rank-order of reported central anticholinergic activity of nine antipsychotic drugs belonging to five chemical classes of neuroleptics appeared not to have significant effect upon either the magnitude or duration of prolactin stimulation in rats (18). However, there are no assurances that central anticholinergic threshold levels had been reached with the doses of drugs utilized.

In light of the above, it appeared desirable to further investigate the possible role of anticholinergic activity in enhancing neuroleptic-induced prolactin secretion in rats, to help clarify if a species difference exists between humans and rats in regard to this effect, and to determine if benztropine mesylate influences haloperidol plasma levels. The present investigation examined the effects of benztropine mesylate on haloperidol-induced prolactin secretion and serum haloperidol levels in rats.

EXPERIMENTAL SECTION

Two hundred and forty male Sprague–Dawley adult rats[1] (225–300 g) were divided into 24 equal groups. The rats were housed for 14 d prior to the study

[1] Taconic Farms, Germantown, N.Y.

© 1984, American Pharmaceutical Association

in a temperature-controlled (23 ± 3°C) artificially illuminated (lights on from 7:00 a.m. to 7:00 p.m. daily) room. The animals were given food[2] and water *ad libitum*. Between 12:30 p.m. and 2:00 p.m., each group was injected intraperitoneally with a 2-mg/kg dose of benztropine mesylate[3] [a dose previously shown to produce a rapid onset of central anticholinergic action (19) with a duration of action of ~24 h (20)] or an equal volume of normal saline. Twenty minutes following pretreatment, 12 groups of rats received 0.5 mg/kg of haloperidol injection[4] administered intraperitoneally and the remaining animals received an equal volume of normal saline. Haloperidol was chosen because of its weak central anticholinergic effects (16). The dose utilized was previously shown in this laboratory to produce a significant increase in serum prolactin secretion above baseline levels for a period of 180 min (15).

Blood samples were obtained by decapitation from the trunk portions at 0, 30, 60, 90, 120, and 150 min after haloperidol or normal saline administration. Blood samples were allowed to stand for 10 min at 4°C; the serum was separated and stored at −20°C until prolactin and haloperidol analyses could be performed. Serum samples were analyzed for prolactin by a double-antibody competitive binding assay. Iodinated rat prolactin, prepared by a modification of the Hunter-Greenwood method (21), was obtained commercially[5]. Rat prolactin antiserum and the reference prolactin standard were supplied by the Rat Pituitary Distribution Program[6]. The procedure for prolactin analysis was modified by the use of a precipitating second antibody suspended in polymer solution[7]. All results are expressed in terms of National Institute of Arthritis, Diabetes, and Digestive Diseases and Kidney (NIADDK) rat prolactin. Each serum sample was assayed in duplicate and the mean was taken as representative of true prolactin concentration. All test and control samples were determined concurrently; the intra-assay variation was 4.2%.

Serum haloperidol concentrations were determined utilizing a commercially available RIA kit[8] according to the instructions supplied. The procedure uses a tritiated label and the bound and free haloperidol are separated by adsorption on dextran-coated charcoal. All tests and control samples were determined concurrently and the results are expressed in μg/mL. The intra-assay variation was 4.7%. Statistical significance was determined by a two-way fixed analysis of variance and factorial analysis of variance with repeated measurements (22).

RESULTS

Evaluation of serum prolactin levels over 150 min, in rats pretreated with normal saline followed by intraperitoneal injection of haloperidol (Fig. 1), indicated a significant rise in serum prolactin compared with controls (saline pretreated/saline treated rats; $F_{(1,91)} = 53.51, p < 0.0001$). Likewise, there was a significant rise in serum prolactin in the 150-min period following intraperitoneal injection of haloperidol (Fig. 1) in rats pretreated with benztropine mesylate compared with controls (benztropine pretreated/saline treated rats; $F_{(1,98)} = 74.64, p < 0.0001$). There was no significant difference in the prolactin levels of the control animals (Fig. 1), *i.e.*, saline pretreated/saline treated rats *versus* benztropine pretreated/saline treated rats over the time period of this experiment ($F_{(1,87)} = <1.0$, not significant). Additionally, there were no significant differences in the mean prolactin levels of the haloperidol-treated rats pretreated with either saline or benztropine mesylate ($F_{(1,87)} = 3.80, p > 0.05$). However, when the data were analyzed by a factorial analysis of variance the prolactin concentrations for the 30–150-min sampling period were significantly higher when the rats received benztropine mesylate prior to haloperidol than when they received saline prior to haloperidol ($F_{(1,89)} = 4.36, p < 0.05$). This approach more fully captured the interrelations between the drugs and prolactin than standard straight baseline comparisons and permitted the use of simple main effects to isolate the locus of effect on prolactin due to haloperidol within benztropine mesylate.

Table I shows the effects of benztropine mesylate and normal saline pretreatments on serum haloperidol levels over a period of 150 min. Serum haloperidol levels were not significantly different in animals pretreated with benztropine mesylate compared with animals pretreated with saline ($F_{(1,89)} < 1.0$, not significant). There was a significant correlation ($r = 0.57, p < 0.001$) between the serum prolactin and serum haloperidol levels in haloperidol-treated animals pretreated with either benztropine mesylate or saline.

DISCUSSION

Prolactin-elevating potency of neuroleptics in rats has previously been shown to correlate well with dopamine receptor blockade (23). The presence of a tuberoinfundibular cholinergic pathway has been described in rats (24). Adrenergic neurons regulating prolactin release have receptors for acetylcholine, and cholinergic neurons in the hypothalamus may terminate on adrenergic neurons (11). Pilocarpine has been shown to inhibit prolactin secretion in rats, and atropine reversed this effect (11). Atropine has been shown to potentiate neuroleptic-induced prolactin secretion in the monkey (6). These data are consistent with an inhibitory muscarinic mechanism on prolactin secretion. Although cholinergic drugs reduce prolactin secretion in the rat, after blockade of catecholamine receptors by chlorpromazine, haloperidol, or pimozide, no reduction in serum prolactin could be seen (11). Paradoxically, atropine may also reduce prolactin levels in the rat (8).

In humans it has been demonstrated that some patients who were receiving anticholinergic antiparkinsonian drugs in addition to chronic neuroleptic treatment had higher circulating prolactin concentrations than subjects on neuroleptics alone (25). However, in this laboratory previous comparisons of the rank-order of reported intrinsic central anticholinergic activity of nine antipsychotic drugs (belonging to five chemical classes of neuroleptics) with the experimentally determined rank-orders of time of maximum serum prolactin levels, magnitude of prolactin secretion at each sampling period, or the maximum serum prolactin elevation for each drug, demonstrated no significant correspondence (18). These comparisons suggested that reported intrinsic anticholinergic activity of neuroleptics did not have a significant effect upon either the magnitude or duration of prolactin stimulation produced by these drugs in rats. Although the doses of neuroleptics employed correspond well with human therapeutic dosages and produced marked prolactin stimulation, central anticholinergic activity was not experimentally determined. It is possible that anticholinergic threshold levels may not have been reached in rats with the doses utilized for some or all of the drugs; this requires further investigation.

In the present study the antimuscarinic agent, benztropine mesylate, had no effect on basal prolactin secretion in the rat but did significantly enhance the prolactin elevation promoted by haloperidol. This finding in the rat exactly corresponds to the observation in humans that intramuscularly administered benztropine mesylate did not significantly influence basal prolactin levels but did significantly enhance prolactin levels induced by intramuscularly administered haloperidol (17).

The present study also demonstrated that benztropine mesylate enhanced prolactin secretion independent of an effect on haloperidol metabolism, since pretreatment with benztropine did not significantly alter serum haloperidol levels. It appears that in both species cholinergic mechanisms have no effect on basal prolactin secretion but exert a weak inhibitory effect under conditions of dopamine receptor blockage.

Table I—Effects of Benztropine Mesylate and Saline Pretreatments on Serum Haloperidol Levels

Pretreatment	Serum Haloperidol Levels, μg/mL[a]					
	0 min	30 min	60 min	90 min	120 min	150 min
Saline[b]	0.15 ± 0.05	16.92 ± 2.80	10.80 ± 1.41	8.47 ± 1.25	7.00 ± 0.78	6.60 ± 0.49
Benztropine Mesylate[c]	0.32 ± 0.30	15.71 ± 3.42	9.20 ± 1.17	8.38 ± 0.96	6.76 ± 1.04	6.20 ± 0.97

[a] Mean ± *SEM*; n = 10 animals per group. [b] 2 ml/kg ip 20 min prior to a 0.5-mg/kg ip injection of haloperidol. [c] 2 mg/kg ip 20 min prior to a 0.5-mg/kg ip injection of haloperidol.

It is unlikely that the antihistaminic properties of benztropine (26) or its inhibiting effect on the uptake of dopamine in certain brain regions (27) accounted for the reported observations. Libertun and McCann (28) found, in rats, that a dose-dependent rise in prolactin produced by histamine was blocked by the antihistamine diphenhydramine. It has also been reported that the inhibition of dopamine uptake by benztropine mesylate may potentiate the synaptic actions of dopamine (27), and dopamine has been shown to be a highly effective inhibitor of prolactin secretion (29). Lastly, although serum prolactin and serum haloperidol levels are statistically highly correlated, they should not be used interchangeably as the basis for experimental observations since >67% of the variance remains unknown.

Chromatographic Separation of the C(1), C(1a), and C(2) Components of Gentamicin and the Assessment of Their Individual Binding to Serum Proteins

WILLIAM C. GRIFFITHS *x, JAMES F. BELLIVEAU ‡, CHARLENE L. BENSTED *, STEVEN G. CALABRESI *, and ISRAEL DIAMOND *

Received December 21, 1983, from the **Department of Pathology and Laboratory Medicine, Division of Biology and Medicine, Roger Williams General Hospital and Brown University, Providence, RI 02908* and the *‡Department of Chemistry, Providence College, Providence, RI 02918.* Accepted for publication March 9, 1984.

Abstract □ [^{3}H]gentamicin and [^{14}C]gentamicin samples were purified by Sephadex column chromatography and separated by an HPLC technique into the three major, medicinally active gentamicin components. These separated components were used in equilibrium dialysis studies to determine their percent binding to serum proteins. The bindings of the components were inversely related to concentrations of ionized calcium and magnesium. When dialyzed against a buffer containing physiological concentrations of the divalent cations, the binding of the C(1) component was 2.2 ± 1.0%, the binding of the C(1a) component was 1.2 ± 1.9%, and the binding of the C(2) component was 5.0 ± 2.0%. The percent bindings are not identical and, due to their low values, probably have negligible clinical significance. The radioactive composition and purity of the ^{3}H- and ^{14}C-labeled gentamicin samples differed and these may be important factors in the variance of reported gentamicin bindings.

Keyphrases □ Gentamicin—component separation serum protein binding, radiolabels, HPLC □ Serum protein binding—radiolabeled gentamicin, component separation, HPLC

Since its discovery in 1963, the use of the broad spectrum antibiotic gentamicin has found acceptance in the treatment of gram negative infections (1). Because nephrotoxicity and ototoxicity are associated with gentamicin administration, its use has been somewhat limited (2). In evaluating the pharmacokinetics and renal cortical uptake of gentamicin, its binding to serum proteins was investigated. However, reported gentamicin binding varies from 0 to 30% (3–8). Parameters which influence the binding of gentamicin to serum proteins and which must be controlled in these binding studies are the levels of ionized calcium and magnesium (6, 7) and the use of serum rather than heparinized plasma (6). However, the chemical purity of the radioactively labeled gentamicin used in some studies was not well defined. To further examine gentamicin binding to serum proteins, our study was designed to separate both ^{3}H- and ^{14}C-labeled gentamicin samples into the three major, medicinally active components [C(1), C(1a), and C(2)] and to determine the percent binding of these components to the proteins of a serum pool prepared from hospital patient samples.

EXPERIMENTAL SECTION

Gentamicin sulfate[1] and [^{14}C]gentamicin sulfate[2] (120 mg, specific activity 830 μCi/mg) were generously donated. Unlabeled gentamicin (100 mg) was tritium labeled[3] by the high-pressure gas phase technique (crude product specific activity 0.37 mCi/mg). The scintillation cocktail was commercially obtained[4]. Unless otherwise specified, all other chemicals were reagent grade. The serum used in the experiments was prepared by pooling the excess of >2000 specimens from adult hospital patients. The pool was divided into 5-mL aliquots, which were kept at −5°C until use, to a maximum of 6 months.

Purification of Radioactive Gentamicin with Thin-Layer Chromatographic Detection—Radioactive gentamicin was partially purified with Sephadex column chromatography using a modification of the method of Mahon *et al.* (9). Aliquots (1 mL) were collected into test tubes. One microliter from each aliquot was placed into scintillation vials containing 10 mL of the scintillation fluid. The vials were counted in a liquid scintillation counter[5]. The fractions showing the highest level of radioactivity were saved and the others were discarded. The fractions containing gentamicin were identified by TLC. Aliquots (100 μL) were spotted on a silica gel TLC plate[6]. A 1-mg/mL nonradioactive gentamicin solution (25 μL) in water was used as a marker on either side of the plate. The solvent system was chloroform–17% NH_4OH–methanol–H_2O (1:2:4:1, by volume). One percent ninhydrin in ethanol was used as the visualization agent. This system separates gentamicin into three bands which correspond to the three major components of the active drug.

Liquid Chromatographic Separation into Gentamicin Components—The HPLC separation of radioactive gentamicin into its three major components was accomplished by a modification of the ion-pair method of Anhalt and Brown (10). This was done with an HPLC unit using a C_{18} column[7] with a mobile phase of 0.2 M Na_2SO_4, 0.02 M sodium pentane sulfonate, and 0.1% (v/v) acetic acid in water–methanol (97:3) at a flow rate of 2 mL/min at ambient temperature. Samples (25 μL) were injected and collected fractions were analyzed both by TLC and liquid scintillation counting.

Dialysis Studies—Equilibrium dialysis was carried out in a multicavity dialysis cell[8] (eight chambers, 1.0-mL capacity each) with cellulose dialysis membranes[9]. Human pooled serum was dialyzed against an equivalent amount of a buffer containing a radioactive gentamicin component (purified by Sephadex and HPLC) and nonradioactive gentamicin at a concentration of 10 μg/mL. Divalent cation concentrations were varied by changing the concentration of these species in the buffer from zero to four times the physiological concentrations. Divalent cation concentrations of the serum samples were varied by adding equivalent amounts of EDTA to the serum to reduce their concentrations to zero or by adding the appropriate amount of these cations to the buffer to bring the concentrations to four times the physiological value. Dialysis membranes were prepared by boiling them in distilled water three times and then soaking them overnight in the dialysis buffer of 0.05 M Tris, 0.1% sodium azide, and 0.15 M NaCl (adjusted to pH 7.4 with 1 M HCl). All dialysis experiments were equilibrated for a 48-h period in a thermally controlled (37°C) shaking waterbath[10]. Control experiments, consisting of buffer with gentamicin against buffer without gentamicin, were also run.

^{14}C-Label data			−0.4 ± 1.1 (21)			
^3H- and ^{14}C-Label data			0.4 ± 0.6 (55)			

[a] All bindings are given as: mean ± 95% confidence limit (number of data points); p values are the probabilities for the t test comparing the percent binding values to the control values. Total gentamicin concentrations in serum at equilibrium were at 5 μg/mL during this study.

Liquid scintillation counting was done on the serum and buffer portions after minimizing quenching differences through a matrix equalization procedure. In this procedure, pooled serum without gentamicin was dialyzed against buffer without gentamicin to reproduce the slight changes due to the osmotic effect during dialysis. The dialyzed serum without gentamicin was added to an equal volume of radioactive buffer, and the dialyzed buffer without gentamicin was added to an equal volume of radioactive serum before counting on the liquid scintillation counter. The percentage of drug bound to the serum proteins was calculated as published by Olsen (11, 12). Radiochemical analysis of the dialysis membrane indicated that negligible binding-absorption of gentamicin had occurred to this membrane.

RESULTS AND DISCUSSION

TLC analysis of the Sephadex-enriched [^3H]gentamicin showed significant amounts of radioactive material at the origin and in locations other than those attributable to known gentamicin components, demonstrating incomplete purification.

The results of the HPLC separation of Sephadex-treated radioactive gentamicin into its components is presented in Table I. Essentially all of the radioactivity of the [^{14}C]gentamicin can be ascribed to the gentamicin components, whereas significant radioactivity (~25%) of the [^3H]gentamicin was found in HPLC fractions that contained negligible gentamicin, mostly in the fractions eluting early. Some tritiated impurities possibly also bind to serum proteins. This binding of impurities may explain the observation that a tritiated gentamicin sample, purified by Sephadex but not HPLC, gave 15, 10, and 6% binding with zero, normal, and elevated divalent cation levels as compared with 5.1, 3.6, and 3.6% for the combined bindings of the HPLC purified-separated tritiated components.

Multiple equilibrium dialysis experiments were carried out using either [^3H]gentamicin components or [^{14}C]gentamicin components. The data are summarized in Table II. There were also 34 control experiments using [^3H]gentamicin and 21 control experiments using [^{14}C]gentamicin, all run concurrently with one or another serum dialysis experiment. The criterion for assessing the difference in binding from zero of a given gentamicin component in a given environment was the comparison of the average test experiment data with the average control result, using the Student's t test.

The bindings are inversely related to concentrations of ionized calcium and magnesium as reported earlier (6, 7). In the absence of ionized calcium and magnesium in the serum pool, partially separated gentamicin components, C(1), C(1a), and C(2), all showed binding different from zero, at 7.4, 3.1, and 6.5%, respectively. In the presence of physiological concentrations of calcium and magnesium, components C(1) and C(2) showed binding. The averages were 2.2 and 5.0%, respectively. Component C(1a) showed no binding under these conditions. In the presence of calcium and magnesium concentrations which were four times the usual physiological concentrations, none of the components showed binding when average data were used. There were two discrepancies, however, in that the tritium-labeled C(1) and C(2) components showed binding at 3.6 and 5.1%, respectively. This finding is probably due either to incomplete separation of the tritiated gentamicin components from nondrug impurities, or to a large precision error. A three-way analysis of variance using the Fisher F ratio showed that the 4X physiological divalent cation, physiological divalent cation, and no divalent cation binding results were different for the C(1) component ($p < 0.001$), for the C(2) component ($p = 0.030$), but not for the C(1a) component [for which the only binding was in the absence of calcium and magnesium ($p = 0.179$)].

Several fresh serum samples, drawn from volunteers, were used in dialysis experiments and showed degrees of binding comparable to those obtained using pooled serum. The bindings of the individual gentamicin components to serum proteins are different and, due to their low values, this binding effect probably has no clinical significance. This study indicates that, besides the use of serum rather than heparinized plasma and control over the divalent cation concentrations, other significant factors in the variance of reported gentamicin bindings may be the radioactive purity and relative composition of labeled gentamicin mixtures. Thus, these factors must be better controlled or, at least, better documented in protein binding studies.

Determination of Nitroglycerin and Its Dinitrate Metabolites in Human Plasma by High-Performance Liquid Chromatography with Thermal Energy Analyzer Detection

A. J. WOODWARD ˣ, P. A. LEWIS, M. AYLWARD, R. RUDMAN, and J. MADDOCK

Received December 23, 1983, from *Simbec Research Ltd., Merthyr Tydfil, Mid Glamorgan, United Kingdom.* Accepted for publication March 30, 1984.

Abstract □ A highly selective and sensitive high-performance liquid chromatographic assay employing a thermal energy analyzer as the detector for nitroglycerin and its dinitrate metabolites in human plasma has been developed. Prior to chromatography the method employs a simple one-stage extraction step. Nitroglycerin and its dinitrate metabolites are then chromatographed on a 10-μm nitrile bonded phase column using an internal-external standard method. The nitroglycerin and its 1,2,3-propanetriol-1,3- and -1,2-dinitrate metabolites (glyceryl-1,3- and -1,2-dinitrate) have a retention time of 8.5, 10.5, and 11.5 min, respectively at a flow rate of 2.0 mL/min for a mobile phase of 5% v/v acetone in *n*-hexane. The limits of sensitivity were 0.05 ng/mL for nitroglycerin and 0.25 ng/mL for the dinitrate metabolites. Linearity of response was observed over the 0.1–2.0-ng/mL range for nitroglycerin and 0.5–10.0-ng/mL range for the dinitrate metabolites. Blood level data from a pilot study with human volunteers in receipt of an oral form of nitroglycerin is presented.

Keyphrases □ Nitroglycerin—HPLC, parent drug, dinitrate metabolites, human plasma □ Thermal energy analyzer—HPLC, nitroglycerin, dinitrate metabolites, human plasma

Nitroglycerin has been shown to be an effective vasodilator used prophylactically in the treatment of angina (1). The majority of published methods for the analysis of nitroglycerin in plasma employ GC with electron-capture detection (ECD) (2–4). These sensitive methods require complicated extraction procedures and careful handling to ensure reproducibility.

A recent publication (5) describes a very sensitive and rapid assay employing negative ion GC–MS; however ionization techniques are not suitable for analyses of large routine workloads due to continuous contamination of the ion source. A high-performance liquid chromatographic (HPLC) procedure with a thermal energy analyzer as detector has been reported for determining nitroglycerin and its metabolites in beagle dog blood (6). This method has been criticized (7) as being insufficiently sensitive for the determination of the compound in humans following therapeutic doses.

Our laboratories have successfully used HPLC combined with the thermal energy analyzer for the analysis of isosorbide dinitrate in human plasma (8). This report describes the development of a highly sensitive and robust procedure for the assay of nitroglycerin and its dinitrate metabolites in human plasma using similar techniques.

EXPERIMENTAL SECTION

Materials and Apparatus—Pure authentic trinitroglycerin[1] and isosorbide dinitrate[2] were used as received without purification as a standard and internal standard, respectively. 1,2,3-Propanetriol-1,2-dinitrate (glyceryl-1,2-dinitrate)[3] and 1,2,3-propanetriol-1,3-dinitrate (glyceryl-1,3-dinitrate)[3] were supplied as 10% dispersions in cornstarch and purified by extraction with a dichloromethane–ethyl acetate (1:1, v/v) solution before use. All chemicals used were Analar[4] grade. All solvents used were glass distilled[5] or HPLC[5] grade.

The HPLC pump[6] was fitted with a loop injector[7] with a 100-μL loop. The system was interfaced to a thermal energy analyzer[8] with the following conditions: furnace temperature, 575°C; argon flow rate, 15 mL/min; oxygen flow rate, 25 mL/min; range × 8. The slush bath of the instrument consisted of methanol and solid carbon dioxide pellets and was maintained at −77°C. The signal was recorded on a 10.0-mV recorder[9].

A 25-cm × 0.46-mm i.d. column containing a polar bonded-phase packing material[10], was employed at ambient temperature. The material is uniformly spherical, and each particle is ~6 μm in diameter. The mobile phase was prepared by mixing acetone and *n*-hexane in a ratio of 5:95. The solution was deaerated in an ultrasonic bath[11] and was purged with pure helium immediately prior to use. The mobile phase was pumped in an isocratic manner through the column at ambient temperature at a flow rate of 2.0 mL/min, giving a back-pressure ≃500 psi. All glassware was treated with a siliconizing agent[12] and allowed to dry prior to use.

Standard Solutions—Solutions of nitroglycerin, glyceryl-1,2-dinitrate, glyceryl-1,3-dinitrate, and isosorbide dinitrate were prepared daily and stored at 4°C. These solutions were prepared as follows; a working standard solution of nitroglycerin was prepared at a concentration of 1 mg/100 mL in *n*-hexane; the internal standard, isosorbide dinitrate, was prepared at a concentration of 10 mg/100 mL in *n*-hexane. Working standard solutions were prepared for isosorbide dinitrate, glyceryl-1,2-dinitrate, and glyceryl-1,3-dinitrate at concentrations of 100 μg/100 mL in *n*-hexane.

Plasma standards were produced by spiking 5.0-mL aliquots of fresh human plasma with appropriate volumes of the plasma standard solutions to give a range of calibrators with concentrations of nitroglycerin at 0, 0.1, 0.25, 0.5, 1.0, 1.5, and 2.0 ng/mL and glyceryl-1,2-dinitrate and glyceryl-1,3-dinitrate at 0, 0.5, 1.0, 2.5, 5.0, 7.5, and 10 ng/mL. These standards were vortex mixed for 30 s and then allowed to stand at 4°C for 15 min to equilibrate.

The range of calibrators were taken through the complete extraction procedure as described below. Calibration curves were constructed by plotting the peak height ratio of nitroglycerin and its dinitrate metabolites to isosorbide dinitrate, the internal standard, *versus* the appropriate concentrations of the compounds. Plasma samples were similarly treated and the peak height ratios referred to the appropriate calibration curve to read the concentration of nitroglycerin and its dinitrate metabolites present.

Method—All blood samples withdrawn from subjects in receipt of nitroglycerin were collected into treated glass syringes and transferred into treated glass tubes containing 250 U of heparin and 25 μL of 0.002 M silver nitrate solution. The tubes were immediately mixed by inversion and centrifuged at 1000×*g* for 10 min at 4°C.

Aliquots (5.0 mL) of the fresh plasma samples were transferred into 25.0-mL glass extraction tubes fitted with screw caps with polytef liners. Working isosorbide dinitrate internal standard solution (10 μL) was added to all tubes giving a concentration of 2.0 ng/mL of internal standard. Dichloromethane–ethyl acetate (1:1, v/v, 15.0 mL) was added to all tubes, which were then capped tightly and shaken mechanically on a horizontal shaker[13] at 250 cycles/min for 5 min. The tubes were then centrifuged at 750×*g* for

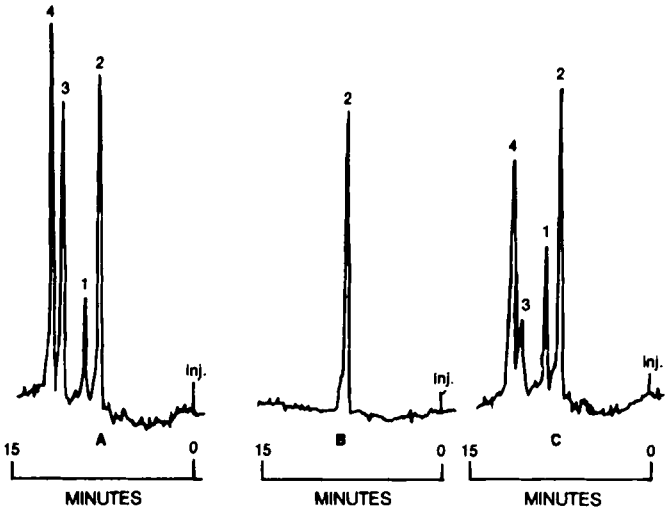

Figure 1—*Determination of nitroglycerin and its metabolites in plasma. Key: (A) spiked test plasma extract containing 0.5 ng/mL of nitroglycerin (1), 2 ng/mL of isosorbide dinitrate internal standard (2), 2.5 ng/mL of glyceryl-1,3-dinitrate (3), and 2.5 ng/mL of glyceryl-1,2-dinitrate (4); (B) spiked plasma extract containing 2 ng/mL of isosorbide dinitrate internal standard (2); (C) plasma extract from a sample withdrawn 15 min following dosing of 2 × 400-μg nitroglycerin sublingual tablets to an adult healthy volunteer indicating the presence of nitroglycerin (1), isosorbide dinitrate (2) (internal standard), glyceryl-1,3-dinitrate (3), and glyceryl-1,2-dinitrate (4).*

5 min at 0°C. The upper aqueous phases were aspirated to waste using a water pump[14] and the lower organic phases were carefully transferred to 20-mL glass vials. The organic phases were then evaporated just to dryness under a gentle stream of nitrogen at room temperature. The vials were capped and stored at −20°C. Immediately prior to analysis on the HPLC, the residues were reconstituted in 150 μL of *n*-hexane.

RESULTS AND DISCUSSION

The chromatographic conditions described were implemented to give the best compromise between chromatographic resolution and peak symmetry and relatively short retention times to permit the analysis of a large throughput of samples with good accuracy and precision. Using these HPLC conditions, isosorbide dinitrate, nitroglycerin, glyceryl-1,3-dinitrate, and glyceryl-1,2-dinitrate give retention times of 7.3, 8.5, 10.5, and 11.5 min, respectively, with a run time between each injection of 15 min.

Figure 1 illustrates a typical plasma chromatogram, chromatograms of spiked plasma samples, drug-free control plasma, and plasma following dosing of a sublingual preparation of nitroglycerin (for comparison). Standard calibration lines were constructed by plotting the peak height ratios of nitroglycerin and its dinitrate metabolites to the isosorbide dinitrate internal standard against the respective concentrations of the compounds. Linearity was found over the standard calibration ranges employed for the parent drug and metabolites. Coefficients of variation of 11.6% at 0.1 ng/mL and 6.6% at 2.0 ng/mL were found for nitroglycerin; comparable data were obtained for the metabolites. The 95% confidence limits obtained for five replicate plasma standard calibrations are shown in Table I and indicate good precision throughout the ranges employed.

Within- and between-batch reproducibility is demonstrated with the following data. Ten replicate plasma control samples were assayed on the same day for each parameter at two levels. Nitroglycerin spiked at 0.4 and 1.0 ng/mL gave mean results of 0.43 (*SD*, ± 0.06) and 1.06 (*SD*, ± 0.18). Between-batch reproducibility on a series of seven control samples for each parameter was 1.7–11.5% (mean, 6.1%) for nitroglycerin, 2.4–14.2% (mean, 6.7%) for glyceryl-1,3-dinitrate, and 3.0–9.0% (mean, 6.1%) for glyceryl-1,2-dinitrate. Spiked pooled plasma samples, when assayed after 7 and 14 d storage at −25°C, appeared not to have deteriorated on storage. Nitroglycerin determined in duplicate samples giving initial mean values of 0.26 and 0.78 ng/mL gave a mean value of 0.22 and 0.66 ng/mL at 7 d and 0.22 and 0.77 ng/mL at 14 d. Glyceryl-1,3-dinitrate and glyceryl-1,2-dinitrate were spiked at concentrations of 1.75 and 3.45 ng/mL and also proved to be stable over the 14-d period. The mean overall recoveries for nitroglycerin and its dinitrate metabolites were calculated over the calibration ranges by comparing peak height ratios for unextracted standards to those taken through the extraction procedure and corrected for the recovery of the internal standard. The recoveries were 76.4% for nitroglycerin, 70.2% for glyceryl-1,3-dinitrate, and 77.0% for glyceryl-1,2-dinitrate.

[14] Filter pump; Baird and Tatlock Ltd.

Table I—Confidence Limits of the Analysis of Spiked Plasma Standards for Nitroglycerin and Its Dinitrate Metabolites

Nitroglycerin		Glyceryl-1,2-Dinitrate		Glyceryl-1,3-Dinitrate	
ng/mL	95% Limits	ng/mL	95% Limits	ng/mL	95% Limits
0.1	0.02	0.5	0.04	0.5	0.07
0.25	0.018	1.0	0.04	1.0	0.09
0.5	0.08	2.5	0.14	2.5	0.31
1.0	0.07	5.0	0.12	5.0	0.35
1.5	0.14	7.5	0.35	7.5	0.45
2.0	0.18	10.0	0.41	10.0	0.27

The minimum detectable levels of nitroglycerin and the 1,3- and 1,2-dinitrate metabolites, determined as the lowest levels discernible over a baseline signal-to-noise ratio of 2:1, were 50, 250, and 250 pg/mL, respectively. These data demonstrate that the developed procedure is sufficiently sensitive and robust for the investigation of the pharmacokinetics of nitroglycerin in humans and further, for the first time, data on two important metabolites of the parent compound can be studied in humans.

Figure 2 illustrates plasma concentration–time profiles representing mean data obtained from 13 subjects in receipt of 800 μg (2 × 400 μg) of nitroglycerin as sublingual tablets. The data on nitroglycerin and its dinitrate metabolites is accompanied by the 95% confidence limits for the individual subject data at each time point. It can be seen that the dinitrate data can prove to be useful in monitoring the elimination of formulations which produce low plasma nitroglycerin concentrations. We have undertaken a preliminary investigation of oral controlled-release formulations and have found that the levels of nitroglycerin are extremely low, in most cases indiscernible from the base line, and yet substantial absorption has occurred as demonstrated by the levels of the two dinitrate metabolites. These findings are contradictory to data obtained by GC–ECD methods (9), where the metabolites are not measured and no data may be available to confirm the specificity of those procedures with regard to the dinitrates.

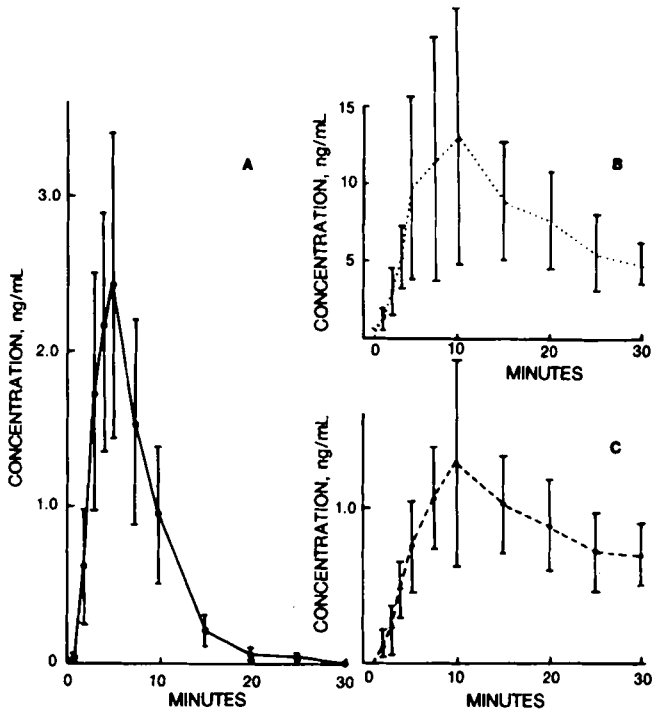

Figure 2—*Mean concentration–time plasma curves and 95% confidence limits for nitroglycerin (A) and its metabolites glyceryl-1,2-dinitrate (B) and glyceryl-1,3-dinitrate (C), for 13 subjects in receipt of 2 × 400-μg sublingual nitroglycerin tablets.*

Antifungal Properties of 2-*n*-Alkyn-1-ols

HERMAN GERSHON *x, GAIL E. ROWE *, ROBERT C. SANTORE *, JOHN R. GILBERTSON ‡, and HERMAN LANGKAMP §

Received September 19, 1983, from the **Boyce Thompson Institute for Plant Research at Cornell University, Ithaca, NY 14853* and the ‡*Departments of Pharmacology and Physiology and* §*Microbiology, School of Dental Medicine, University of Pittsburgh, Pittsburgh, PA 15261.* Accepted for publication March 12, 1984.

Abstract □ Fourteen 2-*n*-alkynols (C_3-C_{14}, C_{16}, and C_{18}) were tested against *Aspergillus oryzae*, *Aspergillus niger*, *Trichoderma viride*, and *Myrothecium verrucaria* in Sabouraud dextrose agar at pH 5.6 and 7.0. Toxicity to *Candida albicans*, *Candida tropicalis*, *Trichophyton mentagrophytes*, and *Mucor mucedo* was determined in the same medium at pH 5.6 and 7.0 in the absence and presence of 10% beef serum. Fungitoxicity was strongly influenced by chain length, slightly by the pH of the medium, and significantly by the presence of beef serum. 2-*n*-Undecyn-1-ol was the most active member of the series, and there was marked synergism between it and ketoconazole.

Keyphrases □ *n*-2-Alkyn-1-ols—*in vitro* antifungal activity, effect of chain length, pH, adsorbents □ Antifungal activity—*n*-alkynols, *in vitro*, effect of chain length, pH, adsorbents □ Structure-activity relationships—*n*-alkynols, antifungal activity, *in vitro* □ Synergism—2-undecyn-1-ol and ketoconazole, *in vitro*, *Candida albicans* and *Candida tropicalis*

In our studies of the effect of structural modification on the fungitoxicity of alkanoic acids (1), 2-alkenoic acids (2), 2-alkynoic acids (3), 2-fluoroalkanoic acids (1), 2-bromoalkanoic acids (2), α,ω-alkanedicarboxylic acids (4), alkoxyacetic acids (5), and *n*-alkanols (6), two major physical factors were observed to influence the activities of the toxicants. These included the partition coefficient and absence or presence of adsorbents such as albumin in the growth medium. Factors that affect partition coefficients of the acids include chain length, pK_a, and pH of the medium (3). The pH of the medium had no significant effect on the activity of the alcohols, and for increased fungitoxicity, a lipophilic substituent at the terminal end of the alkanol is useful (6).

Since the alkynoic acids (3) were considerably more toxic to fungi than the alkanoic acids (1), it was of interest to compare the alkanols (6) with an analogous series of alkynols. It was reported that 1-hydroxy-2-nonyn-4-one, a metabolite from *Ischnoderma benzoinum* (Wahl.) Karst had antifungal activity (7). Also of interest was the observation that alcohol oxidase was irreversibly inhibited by propargyl alcohol and 1,4-butynediol, acetylenic alcohols (8).

The present work is concerned with a systematic evaluation of the homologous series of 2-*n*-alkyn-1-ols of chain lengths C_3-C_{14}, C_{16}, and C_{18} against eight fungi: *Aspergillus oryzae*, *Aspergillus niger*, *Trichoderma viride*, *Myrothecium verrucaria*, *Candida albicans*, *Candida tropicalis*, *Trichophyton mentagrophytes*, and *Mucor mucedo*. Since synergism was demonstrated between ketoconazole, a promising antimycotic agent (9), and amphotericin B and other fungitoxicants (10), it was also desired to determine if there would be any synergism between the most active of the alkynols and ketoconazole.

EXPERIMENTAL SECTION

Some compounds were obtained from commercial sources[1]. Literature methods were used for the preparation of the remaining alkynols: C_{12} (11), C_{14} (12), and C_{16} and C_{18} (13).

The test fungi included *A. oryzae* (ATCC 1101), *A. niger* (ATCC 1004), *T. viride* (ATCC 8678), *M. verrucaria* (ATCC 9095C), *C. albicans* (ATCC 10231), *C. tropicalis* (ATCC 9741), *T. mentagrophytes* (ATCC 9129), and *M. mucedo* (ATCC 7941) (14)[2]. The compounds were tested against *A. oryzae*, *A. niger*, *T. viride*, and *M. verrucaria* in Sabouraud dextrose agar[3] at pH 5.6 and 7.0 according to published methods (1). Graded levels of test compound dissolved in dimethyl sulfoxide (Me_2SO) were incorporated into the growth medium which was subsequently inoculated with the respective fungus. The inoculum was one drop of spore suspension. The preparation of spore suspensions of *A. niger*, *T. viride*, *M. verrucaria*, and *A. oryzae* was accomplished by growing the fungi on potato dextrose agar[3] for several weeks at 28°C in flat, wide-mouth bottles until extensive sporulation had occurred. The spores were harvested by adding 5 mL of sterile 0.85% NaCl solution to the bottles together with ~10 sterile beads, 5 mm in diameter. The spores were freed of the mycelia by shaking, and the suspension was transferred to sterile test tubes and counted in a hemocytometer. The spore concentration was adjusted to 6×10^6 spores/mL by diluting with sterile saline. Inoculations were carried out with Pasteur pipets which deliver 40 drops/mL. Incubation took place at 28°C for 5 d.

For *T. mentagrophytes*, *M. mucedo*, *C. albicans*, and *C. tropicalis* previously described methods were employed (15). Graded levels of test compound

[1] The C_3, C_5-C_{11}, and C_{13} 2-alkyn-1-ols were purchased from Farchan Labs, Willoughby, Ohio, and the C_4 alkynol was obtained from Aldrich Chemical Co., Milwaukee, Wis. Ketoconazole is a product of Janssen Pharmaceutica Inc., New Brunswick, N.J.

[2] These authors present evidence that ATCC 7941 is *Mucor cirinelloides*. We will retain the ATCC nomenclature until it is changed by the American Type Culture Collection.

Since synergism was demonstrated between ketoconazole, a promising antimycotic agent (9), and amphotericin B and other fungitoxicants (10), it was also desired to determine if there would be any synergism between the most active of the alkynols and ketoconazole.

EXPERIMENTAL SECTION

Some compounds were obtained from commercial sources[1]. Literature methods were used for the preparation of the remaining alkynols: C_{12} (11), C_{14} (12), and C_{16} and C_{18} (13).

The test fungi included *A. oryzae* (ATCC 1101), *A. niger* (ATCC 1004), *T. viride* (ATCC 8678), *M. verrucaria* (ATCC 9095C), *C. albicans* (ATCC 10231), *C. tropicalis* (ATCC 9741), *T. mentagrophytes* (ATCC 9129), and *M. mucedo* (ATCC 7941) (14)[2]. The compounds were tested against *A. oryzae*, *A. niger*, *T. viride*, and *M. verrucaria* in Sabouraud dextrose agar[3] at pH 5.6 and 7.0 according to published methods (1). Graded levels of test compound dissolved in dimethyl sulfoxide (Me_2SO) were incorporated into the growth medium which was subsequently inoculated with the respective fungus. The inoculum was one drop of spore suspension. The preparation of spore suspensions of *A. niger*, *T. viride*, *M. verrucaria*, and *A. oryzae* was accomplished by growing the fungi on potato dextrose agar[3] for several weeks at 28°C in flat, wide-mouth bottles until extensive sporulation had occurred. The spores were harvested by adding 5 mL of sterile 0.85% NaCl solution to the bottles together with ~10 sterile beads, 5 mm in diameter. The spores were freed of the mycelia by shaking, and the suspension was transferred to sterile test tubes and counted in a hemocytometer. The spore concentration was adjusted to 6×10^6 spores/mL by diluting with sterile saline. Inoculations were carried out with Pasteur pipets which deliver 40 drops/mL. Incubation took place at 28°C for 5 d.

For *T. mentagrophytes*, *M. mucedo*, *C. albicans*, and *C. tropicalis* previously described methods were employed (15). Graded levels of test compound

[1] The C_3, C_5-C_{11}, and C_{13} 2-alkyn-1-ols were purchased from Farchan Labs, Willoughby, Ohio, and the C_4 alkynol was obtained from Aldrich Chemical Co., Milwaukee, Wis. Ketoconazole is a product of Janssen Pharmaceutica Inc., New Brunswick, N.J.

[2] These authors present evidence that ATCC 7941 is *Mucor cirinelloides*. We will retain the ATCC nomenclature until it is changed by the American Type Culture Collection.

[a] In the presence and absence of beef serum. *C. albicans*, *C. tropicalis*, and *M. mucedo* were incubated at 37°C for 20 h and *T. mentagrophytes* at 28°C for 5 d. [b] Compounds were incorporated in test medium at 10^4, 10^3, and 10^2 μg/mL. Key: (3) inhibition at all levels of compound; (2) inhibition at the two highest levels; (1) inhibition at the highest level only; (0) compound inactive at the highest level tested; numbers in parentheses are MIC values, μg/mL. [c] Antifungal spectrum index = sum of the number of levels of inhibition multiplied by the number of organisms inhibited.

dissolved in Me_2SO were added to Sabouraud dextrose agar at pH 5.6 and 7.0 alone and supplemented with 10% beef serum[4] and inoculated with the respective fungi. Inocula for *T. mentagrophytes* and *M. mucedo* were prepared as above except that the growth media were Mycocel agar[5] and Sabouraud dextrose agar[3], respectively. One drop of spore suspension was used. The inocula of *C. albicans* and *C. tropicalis* were obtained from 20-h cultures in Sabouraud dextrose broth[3]. The cell counts ranged from 3 to 7.5 × 10^6 cells/mL. The tests with *T. mentagrophytes* were incubated at 28°C for 5 d; those with *C. albicans*, *C. tropicalis*, and *M. mucedo* were incubated for 20 h at 37°C. All tests were carried out in duplicate in "I" plate Petri dishes[6]. Data of growth or no growth were recorded.

The compounds were tested at 10^4, 10^3, and 10^2 μg/mL. Minimal inhibitory concentrations (MIC) were sought in increments of 10 μg/mL for 10–100 μg/mL and in 1-μg/mL increments for 1–10 μg/mL. The results were weighted by calculating the antifungal spectrum index which is defined as the sum of the number of levels of complete inhibition multiplied by the number of organisms inhibited at the concentrations of 10^4, 10^3, and 10^2 μg/mL (16, 17).

It should be mentioned that serum was used with the second set of four fungi because they are animal pathogens, except that *M. mucedo* is a model for a pathogenic *Mucor* species. These compounds are also being studied as potential chemotherapeutic agents in animal infections.

The effect of ketoconazole on the inhibition of 2-*n*-undecyn-1-ol of *C. albicans* and *C. tropicalis* in Sabouraud dextrose agar at pH 7.0 containing 10% human serum[3] was examined. The MIC values of ketoconazole and the undecynol were codissolved in Me_2SO and added to the agar in increments of 0.1 ranging from 1 to 0.1. The plates were incubated at 37°C for 20 h, and the MIC for the mixture was determined.

RESULTS

The results of the 2-alkyn-1-ols against *A. oryzae*, *A. niger*, *T. viride*, and *M. verrucaria* are given in Table I, and those against *C. albicans*, *C. tropicalis*, *T. mentagrophytes*, and *M. mucedo* are in Table II. The study of the effect of ketoconazole on the toxicity of 2-*n*-undecyn-1-ol to *C. albicans* and *C. tropicalis* is shown in Table III.

On comparing the activity of the alkynols at pH 5.6 and 7.0 against *A. oryzae*, *A. niger*, *T. viride*, and *M. verrucaria*, it is apparent from the antifungal spectrum indices (Table I) that the alcohols of 10–12 carbon atom chain length are most toxic. The order of toxicity of the homologous series is: 12 = 11 = 10 > 9 = 8 > 7 > 6 = 5 = 4 > 13 > 3 > 14 = 16 = 18.

The most fungitoxic alkynol against *C. albicans*, *C. tropicalis*, *T. mentagrophytes*, and *M. mucedo* was the C_{11} homologue, and the overall order of toxicity was: 11 > 12 > 10 = 9 > 8 > 7 > 6 > 13 > 5 > 4 > 3 > 14 > 16 = 18 (Table II). The data of Table III indicate that the MIC for undecynol is 120 μg/mL for both *Candida* species in the presence of human serum at pH 7.0. This level of compound is one-third higher than the corresponding MIC values

Table III—Effect of Ketoconazole (K) on the Minimal Inhibitory Concentration of 2-*n*-Undecyn-1-ol (U) Against *C. albicans* and *C. tropicalis*[a]

	C. albicans	*C. tropicalis*
U	120	120
K	50	50
U + K[b]	36 + 15	36 + 15

[a] In Sabouraud dextrose agar containing 10% human serum at pH 7.0 at 37°C for 20 h; MIC values, μg/mL. [b] Combined MIC values of U and K in increments of 1, 0.9, 0.8 . . . 0.1 parts of the mixture. The numbers represent 0.3 of the combined MIC.

using beef serum. The minimal inhibitory concentrations for ketoconazole was 50 μg/mL against both fungi. A solution containing 30% of the MIC of both compounds was completely inhibitory to both organisms.

DISCUSSION

It was demonstrated previously that in a homologous series of normal alcohols the most fungitoxic member was the C_{10} alkanol (6). In the present study, the C_{11} alkynol was the most active against the fungi. Since biological activity in a homologous series of compounds is influenced by the partition coefficient, which in turn is determined by chain length (lipophilicity) and pK_a (hydrophilicity), the longer chain length of the alkynol required for maximal activity can be rationalized as follows. Aliphatic monobasic hydroxylic compounds in water have a pK_a of 15.5, whereas 2-alkyn-1-ols have a pK_a of 13.6 in water (18). Since water solubility increases with decreasing pK_a, it requires a longer chain length to restore the necessary amphiphilicity for optimal biological activity. The pH of the growth medium has a minor effect on the activity of the test compounds. This can be observed best where low levels of toxicant were required for inhibition of the fungus. It is generally consistent in that at the higher pH more compound is needed for inhibition.

The presence of beef serum reduced the activity of the toxicant (Table II). It was most noticeable against organisms which were inhibited by low levels of compound. Although hydrogen bonding may be responsible for this in part, it is also possible that the alkynol reacted by a nucleophilic reaction with the proteins or other components of the serum.

Although it is not firmly established, the mechanism of action of the acetylenic alcohols, once penetration of the spore had taken place, is by the irreversible inhibition of the enzyme alcohol oxidase. This inhibition was demonstrated with the enzyme, *in vitro*, using propargyl alcohol (8). The lower acetylenic alcohols were not fungitoxic because they are too water soluble to penetrate the fungal spore membrane. Ketoconazole was able to potentiate the toxicity of 2-undecyn-1-ol toward the two *Candida* species (Table III). It was reported that ketoconazole inhibited ergosterol biosynthesis. Thus, it is believed to cause functional changes in the membrane, such as permeability (19).

If we compare the fungitoxicities of the most active member of each of the series of alkynoic acids (3), ω-chloroalkanols (6), alkanols (6), and alkynols by comparing the sums of the antifungal spectrum indices for *A. niger*, *T. viride*, and *M. verrucaria* at pH 5.6 and *C. albicans*, *T. mentagrophytes*, and *M. mucedo* at pH 5.6 and 7.0 with and without beef serum, the order of activity is as follows: 2-*n*-undecyn-1-ol (135) > 2-*n*-hexadecynoic acid (117) > 9-*n*-chlorononan-1-ol (111) = 10-*n*-chlorodecan-1-ol (111) > *n*-nonan-1-ol (93).

An Improved Synthesis of Captopril

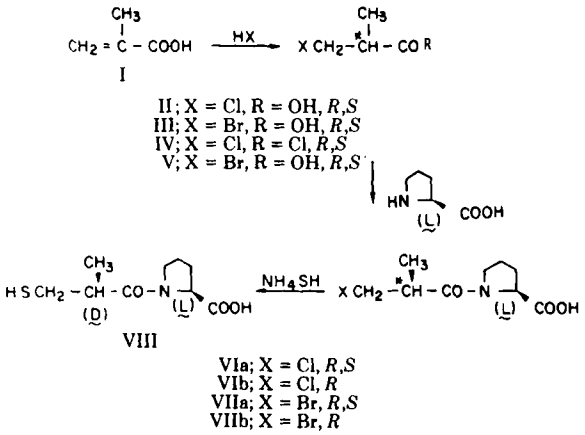
DOO H. NAM *, CHOON S. LEE *, and DEWEY D. Y. RYU ‡x

Received June 13, 1983, from **The Korea Advanced Institute of Science, Seoul, Korea* and the ‡*University of California, Davis, CA 95616.* Accepted for publication February 22, 1984.

Abstract □ An improved synthesis of captopril using methacrylic acid as the starting material is described. Treatment of methacrylic acid (I) with a hydrogen halide gave the 3-halogeno-2-methylpropanoic acids II and III, which were treated with thionyl chloride to yield the corresponding 3-halogeno-2-methylpropanoyl chlorides IV and V. Treatment of IV or V with L-proline yielded the *N*-(*R,S*-3-halogeno-2-methylpropanoyl)-L-prolines VI and VII, which were separated into optically pure *R*- and *S*-diastereoisomers using dicyclohexylamine. Treatment of halides of VI or VII with methanolic ammonium hydrosulfide gave captopril in 28% yield.

Keyphrases □ Captopril—new synthetic method, antihypertensive, inhibitor of angiotensin-converting enzyme □ Antihypertensive—captopril, new synthetic method

Captopril[1], an orally active hypertensive agent, is a competitive inhibitor of angiotensin I-converting enzyme (1, 2). The synthesis of captopril was first reported by Cushman *et al.* (2) in an overall yield of 12%, starting with 3-acetylthio-2-methylpropanoic acid. More recently, a facile synthesis of captopril was reported (3). This synthesis is convenient and the yield is good (26%); however, the conversion of methacrylic acid to the optically active starting material, *R*-3-hydroxy-2-methylpropanoic acid, using a microbial oxidative transformation (4, 5) is poor. We have developed a more convenient synthesis of captopril using methacrylic acid as a starting material (Scheme I).



Scheme I

EXPERIMENTAL SECTION[2]

***R,S*-3-Halogeno-2-methylpropanoyl Chloride (IV, V)**—Methacrylic acid (I)[3] was treated with anhydrous hydrogen halide to give *R,S*-3-halogeno-2-methylpropanoic acid (II and III) according to the method of Groszkowski *et al.* (6); II (bp_{15} 106–107°C) and III (bp_{15} 106–108°C) were identical with the reported materials (6) by IR and NMR spectroscopy. Treatment of II and III with thionyl chloride to yield IV and V was also carried out by the procedure of Groszkowski *et al.* (6), except a small quantity of *N,N*-dimethylformamide (0.1 mol of II or III) was used as the catalyst (7). Compounds IV (bp_{45} 74–75°C) and V (bp_{30} 72–73°C) were identical with those previously reported by Horii *et al.* (8) by IR and NMR spectroscopy.

***N*-(*R*-3-Halogeno-2-methylpropanoyl)-L-proline (VI, VII)**—For the *N*-acylation of L-proline with IV or V, the procedure of Hongo *et al.* (9) was employed. L-Proline (13.8 g, 0.12 mol) was allowed to react with IV (14.1 g, 0.1 mol) or V (20.1 g, 0.1 mol) in the presence of 84 mL of 2 M NaOH at 0°C for 1 h and then at room temperature for 3 h. The mixture was acidified to pH 1.5 with concentrated hydrochloric acid, and extracted with 500 mL of ethyl acetate. The organic phase was dried over anhydrous magnesium sulfate, and the solvent was removed under reduced pressure to yield the syrupy residue (VIa[4] or VIIa[4]). This material was dissolved in acetonitrile, and dicyclohexylamine (21.7 g, 0.12 mol) was slowly added in a dropwise manner with rapid stirring and cooling in an ice bath. The product was removed by filtration to give 36.1 g of the dicyclohexylammonium salt of VIa (90% yield), mp 179–183°C (dec.), or 37.8 g of the salt of VIIa (85% yield), mp 175–180°C (dec.). The crude dicyclohexylammonium salt was dissolved in refluxing acetonitrile–dichloromethane (1:1), and the saturated solution was cooled at room temperature. The dicyclohexylammonium salt of the *R,S*-diastereoisomer of the chloro compound was obtained in 43% yield (15.5 g, white crystals), mp 184–187°C (dec.), $[\alpha]_D^{20}$ −40° (*c*, 2.0, ethanol); the salt of the *R,S*-diastereoisomer of the bromo compound was obtained in 40% yield (15.2 g, white crystals)[5], *mp* 180–183°C (dec.), $[\alpha]_D^{20}$ −44° (*c*, 2.0, ethanol). The optically purified dicyclohexylammonium salt of *R,S*-diastereoisomers dissolved in 1 M $KHSO_4$ was extracted with ethyl acetate. The extract was dried over anhydrous magnesium sulfate, and the solvent was removed under reduced pressure. The residue was crystallized from ethyl acetate–hexane (1:1) to recover 7.8 g of VIb[6] as white crystals (90% yield), mp 110–112°C, $[\alpha]_D^{20}$ −98.9° (*c*, 2.0, ethanol) [IR (KBr): 1710 (amide C=O) and 1590 cm^{-1} (amide C—N); ^{1}H-NMR ($CDCl_3$): δ 1.38 (d, 3, J = 3 Hz, —CH_3), 2.30 (m, 4, —CH_2— in proline), 3.11 (m, 1, —CH—), 3.79 (m, 4, Cl—CH_2—, N—CH_2—), 4.69 (t, 1, J = 2.3 Hz, N—CH—), and 11.30 ppm (s, 1, —COOH)] or 8.6 g of VIIb[6] as white crystals (95% yield), mp 113–115°C, $[\alpha]_D^{20}$ −103.2° (*c*, 2.0, ethanol) [IR (KBr): 1720 (amide C=O) and 1600 cm^{-1} (amide C—N); ^{1}H-NMR ($CDCl_3$): δ 1.50 (d, 3, J = 3 Hz, —CH_3), 2.33 (m, 4, —CH_2— in proline), 3.38 (m, 1, —CH—), 3.86 (m, 4, Br—CH_2—, N—CH_2—), 4.77 (t, 1, J = 2.5 Hz, N—CH—), and 11.40 ppm (s, 1, —COOH).

Anal.—Calc. for VIb ($C_9H_{14}ClNO_3$): C, 49.21; H, 6.42, N, 6.38. Found: C, 49.00; H, 6.69; N, 6.19. Calc. for VIIb ($C_9H_{14}BrNO_3$): C, 40.93; H, 5.34, N, 5.30. Found: C, 41.05; H, 5.43; N, 5.26.

***N*-(*R*-3-Mercapto-2-methylpropanoyl)-L-proline (VIII)**—To the solution of 100 mL of methanolic ammonium hydrosulfide[7], VIb (2.1 g, 0.01 mol) or VIIb (2.6 g, 0.01 mol) was added at room temperature. The resulting mixture was refluxed for 24 h with stirring under a nitrogen atmosphere. The mixture was concentrated to 20 mL under reduced pressure, acidified with 5 M HCl (pH 1), and then extracted with ethyl acetate. The organic phase was dried over anhydrous magnesium sulfate, and the solvent was removed under reduced pressure. The residue was fractionated by column chromatography using Wakogel C200 by linear gradient of methanol in ethyl acetate (0 to 100%), and the fractions positive to sodium nitroprusside were combined. Recrystallization from ethyl acetate–hexane (1:1) gave 1.86 g of VIII as white crystals from VIb or 1.95 g of VIII from VIIb, mp 105–106°C [lit. (2) mp 104–105°C; lit. (3) mp 105–106°C; $[\alpha]_D^{20}$ −128.2° (*c*, 2.0, ethanol); lit. (2) $[\alpha]_D^{22}$ −131.0°; lit. (3) $[\alpha]_D^{25}$ −129.8°], which was identical by IR and NMR spectroscopy (3) with authentic captopril[8].

RESULTS AND DISCUSSION

To develop a more convenient synthesis of captopril from methacrylic acid, the addition of hydrogen halide to methacrylic acid was attempted using the

[1] *N*-(*R*-3-mercapto-2-methylpropanoyl)-L-proline (*S,S*), SQ 14,225.

[2] Melting points were determined by using a Thomas-Hoover capillary melting point apparatus. IR spectra with a Perkin-Elmer 735B grating IR spectrometer and NMR spectra with a Varian T-60A NMR spectrometer were recorded with each sample. An Autopol III automatic polarimeter (Rudolph Research, N.J.) for the determination of optical rotation, and a Perkin-Elmer 240 elemental analyzer for elemental analysis were also employed.

[3] Methacrylic acid stabilized with 200–300 ppm of *p*-methoxyphenol was obtained from Eastman Kodak Co., Rochester, N.Y.

[4] *N*-(*R,S*-3-halogeno-2-methylpropanoyl)-L-proline.

[5] Optical resolution was performed by the preferential crystallization technique of dicyclohexylammonium salts until its optical rotation was no more increased.

method of Groszkowski *et al.* (6). The carboxylic acids (II and III) were converted to their corresponding acyl halides (IV and V) in nearly 95% yield using *N*,*N*-dimethylformamide as a catalyst (7). To avoid protecting the carboxylic function of L-proline, the direct *N*-acylation of L-proline with IV or V was carried out in 90% yield using the procedure of Hongo *et al.* (9). *N*-(*R*,*S*-3-Halogeno-2-methylpropanoyl)-L-proline (VIa or VIIa) was successfully separated into optically pure diastereoisomers using dicyclohexylamine. Treatment of halides of VIb or VIIb with methanolic ammonium hydrosulfide afforded captopril in 28% overall yield. This synthetic method is an improvement over that reported by Cushman *et al.* (12%) (2) and is more convenient than the method reported by Shimazaki *et al.* (3), which involves a fermentation step.

Phosphorous-Containing Analogues of Aspartame

VICTOR NELSON *§x and PRZEMSLAW MASTALERZ ‡

Received October 18, 1983, from the **Department of Chemistry and Chemical Engineering, Michigan Technological University, Houghton, MI 49931* and the ‡*Institute of Organic and Physical Chemistry, Technical University of Wroclaw, Wroclaw, Poland.* Accepted for publication March 9, 1984.

§Present address: NCI-Frederick Cancer Research Facility, Frederick, MD 21701.

Abstract □ Four analogues of aspartame (aspartylphenylalanine methyl ester) were prepared in which one of the carboxylate groups was replaced by a phosphonate group. None of the peptides so obtained was sweet, in contrast with the parent compound which is over 100 times sweeter than sucrose. These results contrast with several published reports of phosphonate analogues of amino acids and peptides which are potent inhibitors of enzymes containing acceptor sites for the parent compound.

Keyphrases □ Aspartame—phosphonate analogues, sweetness

Since the discovery in 1969 that the synthetic dipeptide aspartame (*S*-aspartyl-*S*-phenylalanine methyl ester, I) was over 100 times sweeter than sucrose (1), many analogues have been prepared to ascertain which structural features are responsible for the sweetness. Quite early it was shown that alteration of the aspartyl moiety often result in loss of sweetness, but the phenylalanine moiety can be modified significantly with retention of sweetness (1, 2). More recent work (3) has shown that there are many exceptions to this simple rule, and that the structure-taste relationships are subtle and complicated.

One modification not yet reported is the replacement of one of the two carboxylate groups with a phosphonic acid function. There are several examples in the literature of amino acid and peptide analogues in which carboxylate groups have been replaced by phosphonate groups with retention of biological activity. For example, 1-amino-2-phenylethanephosphonic acid, the phosphonic acid analogue of phenylalanine, is a competitive inhibitor of phenylalanyl-tRNA synthetase (4), 1-amino-3-phosphonobutyric acid inhibits glutamine synthetase (5), and a series of peptides incorporating 1-aminoethanephosphonic acid as the C-terminal residue are shown to have antibacterial properties (6).

These results prompted us to synthesize the following aspartame analogues as diastereomeric mixtures (Scheme I): *R*,*S*-2-amino-3-phosphonopropionyl-*S*-phenylalanine methyl ester (IV); the free acid thereof (V); *S*-aspartyl-*R*,*S*-aminobenzylmethanephosphonate diethyl ester (VIII) and its free acid (IX).

RESULTS AND DISCUSSION

The peptide analogues were made by a standard coupling method (7) from the blocked amino acids. Although other coupling methods have been used to prepare dipeptides incorporating amino phosphonic acids (8), in our hands the mixed anhydride method employing ethyl chloroformate as coupling agent (7, 9) proved most successful. Compound IV was synthesized from *S*-phenylalanine methyl ester and the *N*-benzoxycarbonyl derivative of racemic 2-amino-3-dimethylphosphonopropionic acid (II). After coupling, the fully blocked peptide was partially deblocked to the methyl carboxylate (IV) by treatment with hydrogen bromide in acetic acid. The remaining methyl group was shown to reside on the carboxylate rather than the phosphonate group by recovery of starting material after attempted reesterification with thionyl chloride and methanol, a method which esterifies carboxylic acids but not phosphonic acids. This ester was converted to the fully deblocked peptide (V) by treatment with methanolic sodium hydroxide. Compound VIII was synthesized by coupling *S*-aspartic acid in the form of its *N*-benzoxycarbonyl-γ-benzyl ester derivative (10) with the diethyl ester of racemic aminobenzylmethanephosphonic acid (VI) (11), followed by hydrogenolysis. Deblocking with hydrogen bromide in acetic acid yielded the fully deblocked peptide analogue IX. Spectral data for the blocked aminophosphonic acid (II), blocked peptides (IV and VII), and deblocked peptides (V and IX) are presented in the *Experimental Section*. No attempt was made to separate the diastereomers in each product mixture since a significantly sweet isomer could have been detected by taste in the presence of a large amount of tasteless material.

Following the method previously used for testing sweetness in aspartame analogues (1), cotton swabs were soaked in water solutions of compounds to be tested, and the solutions were sucked off the swab. Usually compounds are not considered significantly sweet unless solutions of ≤2% concentrations evoke a sweet taste. However, even with 5% solutions, each peptide was found to be tasteless or slightly bitter by three different people. The lack of sweetness in IV and V is perhaps not surprising when one considers which modifications of the aspartyl residue of aspartame have previously been found to destroy sweetness. Replacement with an α-aminomalonyl moiety (*i.e.*, removing a methylene group from the aspartyl side chain) yields a compound even sweeter than aspartame (12), while replacing the aspartate by a glutamate moiety (thus adding an extra methylene group to the side chain) destroys sweetness (1). All other modifications of the aspartyl residue have led to nonsweet compounds. This suggests (3) that the N-terminal end of the molecule must incorporate a five- or six-membered zwitterionic ring in order to exhibit

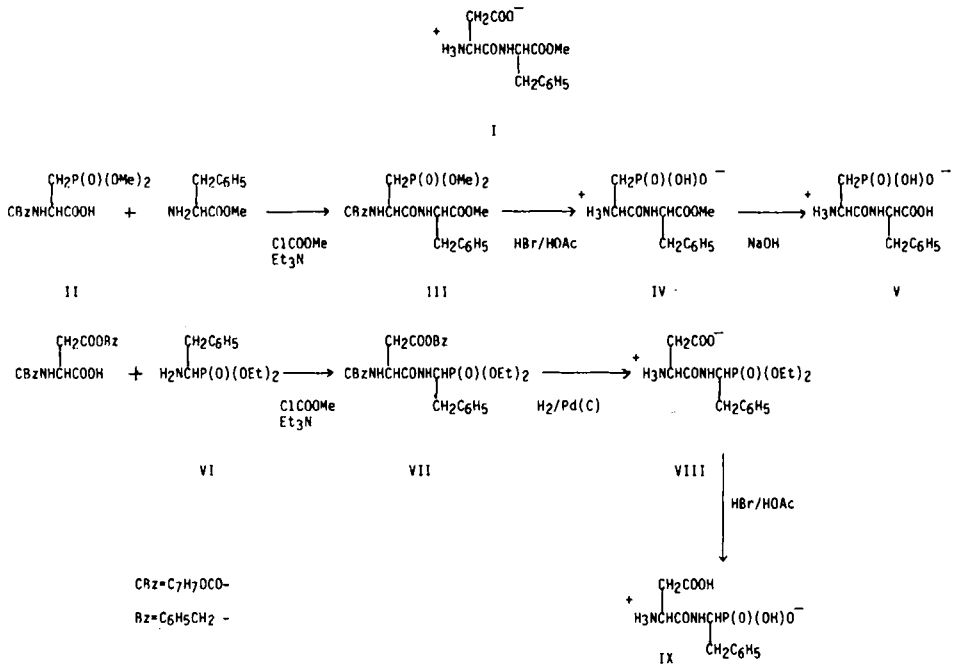

Scheme I

sweetness. According to this model, the negative carboxylate oxygen of the aspartyl moiety in aspartame is hydrogen bonded to the positive ammonium group, forming a six-membered ring. A seven-membered ring, which would be formed by a glutamate residue, is apparently too large. Since a phosphonate group is larger than a carboxylate group, replacement of the carboxylate group in the aspartyl side chain of aspartame would result in a six-membered ring larger than that in aspartame. Furthermore, the phosphonate group is pyramidal as opposed to the planar carboxylate group, so this ring could not be flat, as it is in aspartame.

Turning to the C-terminal end of aspartame, we find more leeway for modification. Many sweet analogues have been prepared incorporating a variety of amino acid esters and amides in place of phenylalanine methyl ester (13). However, in all these analogues two substituents of dissimilar size are attached to the carbon of the C-terminal residue. The orientation of the groups is always such that the large group corresponds to the benzyl side chain of aspartame and the smaller group corresponds to the methoxycarbonyl moiety. Apparently a difference in size between these two groups is important. For example, exchanging the methyl ester for the larger ethyl ester diminishes sweetness (1). Perhaps VIII and IX are not sweet because the phosphonate group, being larger than a methoxycarbonyl group, is too close in size to, or even larger than, the benzyl group. Also, it is noteworthy that replacement of the methoxycarbonyl group of aspartame with the free carboxylic acid or carboxamide destroys the sweetness. Evidently this part of the molecule must be relatively nonpolar. It is possible that both the diethylphosphonate group and the free phosphonic acid group are too polar to permit VIII and IX to be sweet.

In view of the exacting stereochemical requirements of the taste receptors it is not surprising that neither the charged, pyramidal phosphonic acid group nor the bulky diethylphosphonate group is a good replacement for the planar methylcarboxylate group of aspartame.

EXPERIMENTAL SECTION[1]

***N*-Benzyloxycarbonyl-2-*R*,*S*-amino-3-dimethylphosphonopropionic Acid (II)**—Racemic 2-amino-3-phosphonopropionic acid (14) (17 g, 0.1 mol) was stirred in water (100 mL) with KOH (33.5 g, 0.6 mol) at 0°C as a solution of carbobenzoxy chloride (35 g, excess) in ether was added in a dropwise manner. The solution was stirred overnight at room temperature, washed twice with ether, and acidified with hydrochloric acid to precipitate an oil. The aqueous layer was extracted with ethyl acetate and the combined oil and extract was dried with anhydrous sodium sulfate. Evaporation of the solvent yielded an oil, which was converted to the trimethyl ester by treatment for several hours with a methanolic solution of diazomethane according to a published method (15). After removal of volatile material, the oily triester (22.5 g, 0.065 mol) was refluxed in methanol (100 mL) with 0.55 M NaOH (118 mL, 0.065 mol) for 2 h. After evaporation of the solvent, the residue was triturated with hot ethyl acetate, dissolved in water, and neutralized with Dowex-50 (H^+). The water solution was extracted repeatedly with ethyl acetate, the combined extracts were dried, and the solvent was evaporated to yield the product as a glass (37%), which softens without melting at 150°C. TLC on silica gel (ethyl acetate–methanol, 9:1) shows one spot, R_f 0.3; ^{1}H-NMR ($CDCl_3$): δ 2.88 (m, CH_2), 4.03 (d, OCH_3), 5.48 (s, $ArCH_3$), 6.63 (m, NH), and 8.78 ppm (s, ArH); IR ($CHCl_3$): 3400–2400 (OH and NH), 1720 (C=O), 1500, 1210 (OH), and 1040 cm^{-1} (P=O).

Diethyl Aminobenzylmethanephosphonate (VI)—This material was prepared by diborane reduction (16) of the *O*-methyl oxime of diethyl phenylacetylphosphonate to give product identical with that of a published method (11).

Coupling Procedure—The blocked amino acids were coupled according to a published method (7), in which ethyl chloroformate is added to a solution of triethylamine and the blocked N-terminal amino acid in chloroform. The blocked C-terminal amino acid is added and the mixture is stirred for 12 h at room temperature.

Compound III was isolated as a thick oil in 78% yield. TLC on silica gel (ethyl acetate–methanol, 9:1) showed one spot, R_f 0.6; ^{1}H-NMR ($CDCl_3$): δ 2.73 (m, CH_2P), 3.48 (m, CHCO), 4.05 (m, OCH_3), 4.50 (m, CH), 5.05 (m, $ArCH_2$), 5.48 (s, $ArCH_2$), and 7.55 and 7.65 ppm (2 s, ArH); IR ($CHCl_3$): 2950–3420 (NH), 1680–1750 (C=O), 1500 (NH), 1190–1250 (OCH_3), and 1040 cm^{-1} (P=O).

Compound VII was isolated as a thick oil in 52% yield. TCL on silica gel (benzene–ethyl acetate, 7:3) showed one spot, R_f 0.2; ^{1}H-NMR ($CDCl_3$): δ 1.20 (m, CH_3), 3.00 (m, CH_2CO and CH), 4.03 (m, OCH_2), 4.60 (m, $ArCH_2$), 5.00 (m, $ArCH_2$ and CH), and 7.23 ppm (s, ArH); IR ($CHCl_3$): 3400 (NH), 3060 (ArH), 1740 (C=O), 1500 (NH), 1220 (OCH_2), and 1040 cm^{-1} (P=O).

Deblocking Procedures—Compound VII was deblocked to give VIII by hydrogenolysis over palladium on charcoal in methanol using 1 atm of hydrogen at room temperature. Filtration and evaporation of solvent yielded the product as a glass. Compounds III and VIII were deblocked to IV and IX, respectively, by a standard method (17) in which the blocked peptide was stirred at 60°C for 20 min in 48% hydrogen bromide–acetic acid (30 mL/g). The volatile material was evaporated, the residue was dissolved in ethanol, and the peptide was precipitated by addition of pyridine. Ester IV (0.0076 mol) was saponified to acid V by refluxing in 50 mL of methanolic sodium hydroxide (0.6 M) for 1 h. The solid so formed was isolated by filtration and

[1] NMR Spectra were obtained on a Tesla 80-MHz spectrometer, either in $CDCl_3$ with Me_4Si as standard, or in D_2O with sodium trimethylsilylpropanesulfonate as standard. IR spectra were obtained on a Specord spectrophotometer.

dissolved in aqueous acetic acid, and the product was precipitated by addition of ethanol.

Compound IV was an amorphous solid (59% yield) which did not melt up to 300°C. ^{1}H-NMR (D_2O): δ 2.50 (m, CH_2P), 3.48 (m, CHCO), 4.04 (s, OCH_3), 4.58 (m, ArCH_2), and 7.63 ppm (m, ArH). IR (KBr): 3700–2500 (NH and OH), 1680, 1740 (C=O), 1200 (OCH_3), and 1070 cm^{-1} (P=O).

Anal.—Calc. for $C_{13}H_{19}N_2O_6P \cdot 3.5\ H_2O$: N, 7.12; P, 7.87. Found: N, 6.64; P, 8.33.

Compound V was an amorphous solid (55% yield) which did not melt up to 300°C. ^{1}H-NMR (D_2O–D_2SO_4): δ 2.00–5.10 (m, aliphatic H) and 7.70 ppm (ArH); IR (KBr): 3700–2500 (NH and OH), 1650–1660 (C=O), and 1070 cm^{-1} (P=O).

Anal.—Calc. for $C_{12}H_{17}N_2O_6P$: N, 8.86; P, 9.80. Found: N, 8.18; P, 10.25.

Compound VIII was an amorphous gum which softened without melting at 90°C. TLC on silica gel (methanol) showed one spot, R_f 0.5.

Compound IX was an amorphous solid (50% yield) which did not melt up to 260°C. ^{1}H-NMR (D_2O–D_2SO_4): δ 2.75–3.88 (m, CH and CH_2), 4.38–5.25 (m, ArCH_2 and CH), and 7.62 cm^{-1} (s, ArH). IR (KBr): 2700–3500 (OH, ArH, and CH), 1700 (C=O), 1150 (C—O), and 1050 cm^{-1} (P=O).

Anal.—Calc. for $C_{12}H_{17}N_2O_6P \cdot H_2O$: N, 8.38; P, 9.26. Found: N, 8.40; P, 9.02.

Induction of Hyperpyrexia by Dihydrocurvularin, a Metabolic Product of *Penicillium gilmanii*

FREDERICK A. H. RICE ˣ and CHESTER G. CHEN

Received May 24, 1983, from the *Department of Chemistry, American University, Washington, DC 20016.* Accepted for publication March 12, 1984.

Abstract □ The previously reported rise in rectal temperature that follows the intravenous injection of the mixture of metabolic products (extractable with ether from the Czapek Dox medium on which *Penicillium gilmanii* has grown) is due to a single compound, dihydrocurvularin. Intravenous injection of 1–10 μg of dihydrocurvularin into rabbits causes a rise of at least one degree in rectal temperature of rabbits in 2–8 h. The degree of temperature rise depends more on the individual rabbit than on the quantity of dihydrocurvularin injected. Treatment with lipopolysaccharide abolishes the ability of dihydrocurvularin to cause a rise in rectal temperature. Treatment with dihydrocurvularin, however, does not abolish the ability of lipopolysaccharide to induce a temperature response or a leukocytosis. Rabbits respond to repeated treatment with dihydrocurvularin with a rise in rectal temperature that is indistinguishable from that observed on their first injection. Treatment with dihydrocurvularin does not affect differential counts or the concentration of leukocytes or red blood cells in the circulatory system.

Keyphrases □ Dihydrocurvularin—intravenous injection, hyperpyrexia, rabbits, effect of lipopolysaccharide

The intravenous injection of microgram quantities of the mixture of metabolic products elaborated by *Penicillium gilmanii* grown on a Czapek Dox medium induces a temporary rise in rectal temperature and leukocytosis in rabbits (1, 2). After extraction with ether the medium no longer induced a temperature rise but afforded a pure crystalline enolic heterocyclic compound, leucogenenol (2), of which 0.002 μg/kg, on intravenous injection, induces a temporary leukocytosis in animals (1, 3), but even milligram quantities do not induce hyperpyrexia. On the other hand, intravenous injection of microgram quantities of the mixture of compounds extractable from the culture medium with ether induces a hyperpyrexia in rabbits comparable to that observed following the injection of microgram quantities of lipopolysaccharides.

Investigations on leucogenenol established that it acted on cells in the peripheral circulation by increasing the rate at which committed cells of the bone marrow develop into functional cells such as neutrophils and lymphocytes (4–7). Undoubtedly as a consequence of its ability to increase the rate of development of cells involved in the immune response, treatment with leucogenenol enhances the immunocompetence of an animal and increases the rate at which immunosuppressed animals recover immunocompetence (8–13). Leucogenenol is also found as a thymo-thyroid hormone (14–16).

Induction of Hyperpyrexia by Dihydrocurvularin, a Metabolic Product of *Penicillium gilmanii*

FREDERICK A. H. RICE ˣ and CHESTER G. CHEN

Received May 24, 1983, from the *Department of Chemistry, American University, Washington, DC 20016.* Accepted for publication March 12, 1984.

Abstract □ The previously reported rise in rectal temperature that follows the intravenous injection of the mixture of metabolic products (extractable with ether from the Czapek Dox medium on which *Penicillium gilmanii* has grown) is due to a single compound, dihydrocurvularin. Intravenous injection of 1–10 μg of dihydrocurvularin into rabbits causes a rise of at least one degree in rectal temperature of rabbits in 2–8 h. The degree of temperature rise depends more on the individual rabbit than on the quantity of dihydrocurvularin injected. Treatment with lipopolysaccharide abolishes the ability of dihydrocurvularin to cause a rise in rectal temperature. Treatment with dihydrocurvularin, however, does not abolish the ability of lipopolysaccharide to induce a temperature response or a leukocytosis. Rabbits respond to repeated treatment with dihydrocurvularin with a rise in rectal temperature that is indistinguishable from that observed on their first injection. Treatment with dihydrocurvularin does not affect differential counts or the concentration of leukocytes or red blood cells in the circulatory system.

Keyphrases □ Dihydrocurvularin—intravenous injection, hyperpyrexia, rabbits, effect of lipopolysaccharide

The intravenous injection of microgram quantities of the mixture of metabolic products elaborated by *Penicillium gilmanii* grown on a Czapek Dox medium induces a temporary rise in rectal temperature and leukocytosis in rabbits (1, 2). After extraction with ether the medium no longer induced a temperature rise but afforded a pure crystalline enolic heterocyclic compound, leucogenenol (2), of which 0.002 μg/kg, on intravenous injection, induces a temporary leukocytosis in animals (1, 3), but even milligram quantities do not induce hyperpyrexia. On the other hand, intravenous injection of microgram quantities of the mixture of compounds extractable from the culture medium with ether induces a hyperpyrexia in rabbits comparable to that observed following the injection of microgram quantities of lipopolysaccharides.

Investigations on leucogenenol established that it acted on cells in the peripheral circulation by increasing the rate at which committed cells of the bone marrow develop into functional cells such as neutrophils and lymphocytes (4–7). Undoubtedly as a consequence of its ability to increase the rate of development of cells involved in the immune response, treatment with leucogenenol enhances the immunocompetence of an animal and increases the rate at which immunosuppressed animals recover immunocompetence (8–13). Leucogenenol is also found as a thymo-thyroid hormone (14–16).

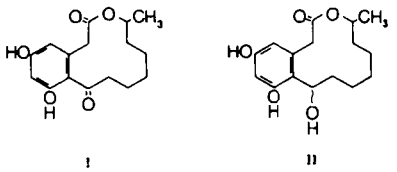
Having established that the effect of the mixture of metabolic products of *P. gilmanii* on circulating leukocytes is due to a single compound, leucogenenol, we turned our attention to identifying the compound(s) that induce a rise in rectal temperature of rabbits.

Raistrick and Rice (17) reported the isolation of 2,3-dihydro-3,6-dihydroxy-2-methyl-4-pyrone and curvularin from those metabolic products of *P. gilmanii* that are extractable from the culture medium by ether. Therefore, either or both of these compounds could be responsible for the temperature rise observed when the mixture of compounds extracted from the culture medium with ether is injected intravenously into rabbits (1). Accordingly, rabbits were treated with 2,3-dihydro-3,6-dihydroxy-2-methyl-4-pyrone and with curvularin (I) in quantities up to 100 μg/kg, and the effect on rabbit rectal temperature was measured. Neither compound had any effect; therefore, it was apparent that a hitherto unrecognized compound(s) was present in the ether-extractable metabolic products.



I

II

RESULTS AND DISCUSSION

Preparative TLC following column chromatography of the ether-extractable metabolic products afforded curvularin (I), $C_{16}H_{20}O_5$, and a compound, $C_{16}H_{22}O_5$, in yields of ~35 mg and ~3 mg, respectively, from 1800 mL of culture medium. The compound $C_{16}H_{22}O_5$ induced a rise in the rectal temperature of rabbits when injected 1-10 μg/kg iv. Individually, or as a mixture, the other ether-extractable compounds did not affect rabbit rectal temperature.

The difference in molecular formula of $C_{16}H_{22}O_5$ from that of curvularin ($C_{16}H_{20}O_5$) and the similarity of their IR spectra suggested that $C_{16}H_{22}O_5$ resulted from the reduction of curvularin (I) to dihydrocurvularin (II). Accordingly, curvularin was reduced with sodium borohydride to yield two isomers of dihydrocurvularin (R_f 0.4 and 0.6, EtOAc) one of which (R_f 0.4) was found to be identical with that isolated from the metabolic products of *P. gilmanii*. It was not possible to identify the configuration of the isomers. Injection of either isomer of dihydrocurvularin induces a rise in the rectal temperature of rabbits. The naturally occurring isomer of R_f 0.4 was used for further biological studies.

Figure 1 shows the effect of the injection of 3 μg/kg iv of dihydrocurvularin (R_f 0.4) on the rectal temperature of rabbits. Unlike lipopolysaccharides, repeated dihydrocurvularin injections produce a rise in rectal temperature indistinguishable from that observed on initial injection (Fig. 1). The time required for the rabbit to show a maximum rise in rectal temperature varies with the animal. In a group of 12 rabbits, 8 showed a maximum rise in rectal temperature at ~6 h while 4 rabbits showed a maximum rise at ~2 h. No significant differences in the degree or time of temperature rise were observed when 1, 3, or 10 μg/kg of dihydrocurvularin was injected in groups of rabbits. Injection of 0.1 μg/kg of dihydrocurvularin had no significant effect on rectal temperature.

There are no significant changes in differential blood cell counts made at half-hour intervals for 24 h following treatment with dihydrocurvularin, nor do the rabbits show a leukocytosis or change in red blood cell counts in their peripheral circulation.

For some unexplained reason, previous treatment with lipopolysaccharide prevents a rise in temperature following injection of dihydrocurvularin. Since rabbits respond to treatment with dihydrocurvularin with either an immediate or delayed temperature rise, it was considered important to consider the two groups separately. Accordingly, rabbits were first treated with dihydrocurvularin, then with lipopolysaccharide, and then with dihydrocurvularin. None of the rabbits that responded with either an immediate or delayed temperature response responded to treatment with dihydrocurvularin 2 d or 1 or 2 weeks following their treatment with lipopolysaccharide. All the rabbits showed a maximum increase in rectal temperature 6-8 h after their initial injection with

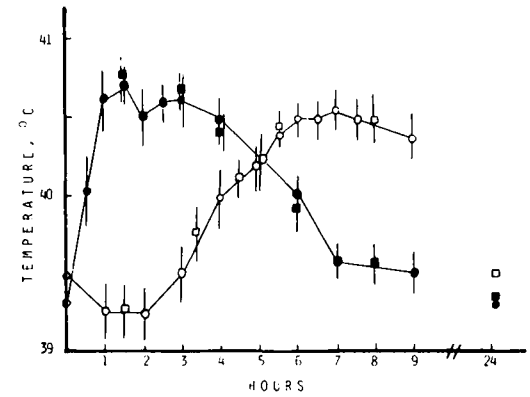


Figure 1—*Effect of the intravenous injection of dihydrocurvularin on the rectal temperature of rabbits injected with 3 μg/kg iv of dihydrocurvularin dissolved in pyrogen-free isotonic saline at a concentration of 10 μg/mL. Key: (●) initial injection; (■) reinjected 48 h later; (○) initial injection; (□) reinjected 7 d later. Vertical bars represent* SD. *Animals that responded with an increase in rectal temperature in 2 h (n = 4) were considered as one group; the remaining animals (n = 8) were considered as a second group. Before treatment rabbits showed a mean diurnal variation of 0.2 ± 0.1°C.*

lipopolysaccharide as well as the expected leukocytosis (18). Treatment with dihydrocurvularin had no significant effect on the response to lipopolysaccharide. On the other hand, none of the rabbits that were treated again with lipopolysaccharide 1 or 2 weeks following their initial injection showed a significant increase in rectal temperture.

It is possible that dihydrocurvularin could be of considerable use for investigating the effect of increased temperatures on physiological responses, as a tool to elucidate the mechanism of temperature regulation, as an important tool to study the role of fever (possibly isolated from other effects of leukocyte endogenous mediator) on the pathogenesis of infection, and possibly as a therapeutic agent.

EXPERIMENTAL SECTION[1]

Solvents and other chemicals were redistilled or recrystallized as appropriate before use. Evaporation of solutions to lesser volumes or to dryness were carried out under reduced pressure in a rotary evaporator at 40-50°C (bath temperature). Where indicated, solutions were filtered under suction through a medium-porosity fritted glass Buchner funnel. Compounds were recrystallized until they showed a single peak on GC.

Rectal temperatures were taken with a telethermometer[2] and pyrogen-free isotonic saline solutions[3] were used for injection in the marginal ear vein of rabbits. Smears of peripheral blood, obtained from the marginal ear vein opposite the one used for injection, were made and the cells examined and enumerated in the usual manner. White blood cells and red blood cells were counted with a Coulter counter[4].

Groups of six rabbits (New Zealand White) (~2.5 kg) were used to determine the ability of each compound or mixture of compounds to induce hyperpyrexia. Prior to treatment rabbits showed a mean diurnal variation of 0.2 ± 0.1°C. The rabbit was weighed and then injected intravenously in the marginal ear vein with the calculated quantity (usually 1-10 μg) of the metabolic compound or compounds dissolved in 1-5 mL of pyrogen-free isotonic saline. Rectal temperatures were recorded at half-hour intervals for 12 h and again at 24 h. A rise of temperature of 1°C was considered significant. Standard deviations were not calculated for the experiments that led to the isolation of the compound that induces a temperature rise in rabbits. However, if one or more rabbits failed to respond with a significant rise in temperature, the experiment was repeated using greater quantities (≤100 μg) of the compound or mixture of compounds being investigated.

[1] Melting points were determined with a Kofler micro hot stage apparatus. UV spectra were determined with a Perkin-Elmer 323 spectrophotometer. IR spectra were determined with the Perkin-Elmer 727 spectrometer, and optical rotations were measured with a Perkin-Elmer 141 spectrometer using a 1-dm tube holding approximately 1 mL. GC were obtained on a Perkin-Elmer 900 gas chromatograph programmed from 200°C to 300°C at 12°C/min, using a flame detector and a column (30.48 cm × 2 mm i.d.) packed with 1% OV-17 on Gas-Chrom Q (18-100 mesh). Florisil (80-100 mesh) obtained from Fisher Scientific Co., Fair Lawn, N.J. was used for column chromatography and precoated silica gel plates (2000 μm, 20 × 20 cm), made fluorescent by the addition of zinc silicate (Anal Tech., Newark, Del.), were used for preparative TLC with the indicated solvents.

[4] Model F.

Isolation of Curvularin and Dihydrocurvularin—*Penicillium gilmanii* was grown as previously reported (1) at room temperature on Czapek Dox medium containing added zinc and copper ions (19) for ~6 weeks. The medium (1800 mL) then was separated from the mycelia by filtration through fluted filter paper[5] and continuously extracted[6] with ether (500 mL) for ~8 h. The ether extract was dried over anhydrous sodium sulfate, filtered, and evaporated to ~25 mL. The solution was then allowed to flow under gravity through a column (15 × 2 cm) of Florisil previously washed with absolute ethanol (500 mL) and ether (500 mL) and still wet with ether. An additional 200 mL of anhydrous ether was allowed to flow through the column followed by 100 mL of ethyl acetate. The ether and ethyl acetate that had flowed through the column was evaporated to dryness. The combined weight was ~1 g. The dry residue was dissolved in 10 mL of isotonic saline and ~1 mL/kg was injected into each of six rabbits. There was no significant rise in the rectal temperature of the rabbits.

The column was then eluted with dioxane (250 mL) which was evaporated to dryness and separated into four fractions by preparative TLC using ethyl acetate as the developing agent. Zones were made visible under UV light. Each zone (R_f 0.8, 0.45, 0.1, and 0.0) was scraped off the plate and its contents eluted with dioxane.

The contents of the zone with R_f 0.8 on evaporation to dryness appeared as a crystalline mass (35 mg) which on recrystallization from ether or ethyl acetate yielded ~30 mg of curvularin as white needles, mp 209°C [lit. (17) mp 205°C]. There was no depression in melting point on admixture with authentic curvularin. Curvularin sublimed unchanged at 140°C (bath temperature) under reduced pressure (0.05 mm Hg); $[\alpha]_{589}^{22}$ −35°, $[\alpha]_{578}^{22}$ −37°, $[\alpha]_{546}^{22}$ −45°, $[\alpha]_{436}^{22}$ −128°, $[\alpha]_{365}^{22}$ −240° (*c*, 1, EtOH); λ_{max}(EtOH): 273 nm (ε 8000) and 303 nm (ε 7100). The MS[13] (70 eV) showed M^+ 292.

Anal.—Calc. for $C_{16}H_{20}O_5$: C, 65.7; H, 6.9. Found: C, 65.8; H, 6.9.

The contents of the zone with R_f 0.45 on evaporation to dryness yielded a syrup (3 mg) which crystallized from dichloromethane to give white needles (~2 mg), mp 175°C; $[\alpha]_{589}^{22}$ −38°, $[\alpha]_{546}^{22}$ −44°, $[\alpha]_{436}^{22}$ −64°, $[\alpha]_{365}^{22}$ −61° (*c*, 1, EtOH); λ_{max} (EtOH): 284 nm (ε 2800); IR (KBr) ν_{max}: 3440 s, 3390 s, 3260 m, 2970 m, 2950 s, 2930 s, 2910 s, 2850 m, 1740 s, 1630 s, and 1460 s cm^{-1}. The MS[7] (70 eV) showed M^+ 294 with clusters of major peaks at 276, 180, 161, and 147; CI − NH_3: M^+ 294.

Anal.—Calc. for $C_{16}H_{22}O_5$: C, 65.3; H, 7.5. Found: C, 65.3; H, 7.5.

Intravenous injection of the contents of the zone with R_f 0.45 induced a febrile response. On elution and evaporation to dryness zones with R_f 0.1 and 0.0 yielded syrups. Injection of rabbits with either fraction (1–20 μg/kg iv) did not induce a febrile response. The fractions were not investigated further.

Sodium Borohydride Reduction of Curvularin to Dihydrocurvularin—An excess (25 mg) of sodium borohydride was added to a cooled (ice water) solution of 50 mg of curvularin in absolute ethanol (5 mL) and set aside at room temperature. Water (2.5 mL) and acetic acid (2.5 mL) then was added and after standing at room temperature for several hours, the solution was evaporated to dryness and the solid residue was extracted with dioxane (5 × 5 mL). The dioxane extract was filtered and evaporated to dryness to yield a thick syrup, which on preparative TLC (ethyl acetate) showed two compounds with R_f 0.45 and 0.65, which were scraped off the plate and eluted with dioxane.

Evaporation of the eluate of the zone with R_f 0.45 yielded dihydrocurvularin (II) as a syrup (20 mg) which crystallized from dichloromethane (~15 mg), mp 175°C, which showed no depression on admixture with the naturally occurring compound of the same R_f given above. The optical rotation, IR spectrum, UV spectrum, and MS were identical with those of the naturally occurring dihydrocurvularin of R_f 0.45.

Anal.—Calc. for $C_{16}H_{22}O_5$: C, 65.3; H, 7.5; M^+, 294. Found: C, 65.3; H, 7.5; M^+, 294.

Evaporation of the eluate of the zone with R_f 0.65 afforded isodihydrocurvularin as a crystalline mass of needles (30 mg), which on recrystallization from ethyl acetate (weight ~20 mg) had mp 186°C. The melting point was depressed on admixture with dihydrocurvularin. $[\alpha]_{589}^{22}$ −40°, $[\alpha]_{578}^{22}$ −41°, $[\alpha]_{546}^{22}$ −45°, $[\alpha]_{436}^{22}$ −66°, $[\alpha]_{365}^{22}$ −63°, (*c*, 1, EtOH). The IR and UV spectra were essentially indistinguishable from the corresponding spectra of dihydrocurvularin. Intravenous injection into rabbits induced a febrile response. The compound was not investigated further.

Effect of Dihydrocurvularin on Rectal Temperatures and Circulating Blood Cells—Twelve rabbits (weight, ~2.5 kg) selected at random from 50 animals were injected in the marginal ear vein with 3 μg/kg iv of synthetic dihydrocurvularin dissolved (10 μg/mL) in pyrogen-free isotonic saline. At half-hour intervals thereafter rectal temperatures were recorded and, in addition, a sample of blood (~0.4 mL) was taken from the marginal ear vein opposite to that used for injection. Smears of the blood were made on microscope slides, stained with Wright's stain, and differential counts were made in the usual manner. Additionally, the concentration of white and red blood cells was determined with a Coulter counter. Means and standard deviations were calculated from the results obtained from 4 of the 12 rabbits whose rectal temperatures rose within 2 h; means and standard deviations were also calculated from results obtained from the remaining 8 rabbits. The experiment was repeated using 0.1, 1, 3, and 10 μg/kg of dihydrocurvularin.

Effect on the Temperature Response of Repeated Treatment with Dihydrocurvularin—Each of the 12 rabbits that were injected with 3 μg/kg of dihydrocurvularin were reinjected with 3 μg/kg of dihydrocurvularin 24 h later, and their rectal temperatures were recorded at half-hour intervals for 12 h. At 2-d intervals for 2 weeks, each rabbit was reinjected with 3 μg/kg of dihydrocurvularin, and again their rectal temperatures were recorded at half-hour intervals for 12 h.

Effect of Lipopolysaccharide on the Temperature Rise Induced by Dihydrocurvularin—Each of six rabbits (group I) was injected with 3 μg/kg iv of dihydrocurvularin, and their rectal temperatures were measured at half-hour intervals for 12 h and again at 24 h as described above. Two days later each rabbit, and each of six additional rabbits (group II), received 1 μg/kg iv of lipopolysaccharide (*Escherichia coli* preparation, L-3129[8]), and their rectal temperatures were again recorded. Two days following their treatment with lipopolysaccharide each rabbit in group I was injected with 3 μg/kg iv of dihydrocurvularin and again their rectal temperatures were recorded at half-hour intervals as described. One week and 2 weeks later each rabbit in group I received 3 μg/kg iv of dihydrocurvularin, and each rabbit in group II received 1 μg/kg of lipopolysaccharide. Rectal temperatures were again recorded. Differential and white blood cell counts were made only on the rabbits that were treated with lipopolysaccharide.

Abstract □ Laser Raman spectroscopy is used for the investigation of the drug-polymer conjugates, sulfathiazole-povidone. Specifically, Raman spectra, both in the lattice vibration and the intramolecular vibration regions, are used to characterize various polymorphic forms of sulfathiazole. It is found that sulfathiazole exists in two unsolvated forms, untreated sulfathiazole and another form grown from propanol. The crystals grown from ethanol include varying amounts of ethanol depending on the growth condition. The nature of the povidone-sulfathiazole coprecipitates of various compositions are studied. We find no evidence of any new polymorphic form of sulfathiazole in these coprecipitates. The coprecipitates are found to consist of one of the unsolvated forms of sulfathiazole.

Keyphrases □ Sulfathiazole-conjugate with povidone, laser Raman spectroscopy □ Povidone-conjugate with sulfathiazole, laser Raman spectroscopy

The potential of a polymer matrix to produce a high-energy form of a drug has been realized for a long time. Interest in drug-polymer conjugates stems from the fact that the bioavailability of a drug, and therefore its therapeutic utility, can be increased. The strength and the specificity of interactions between a drug and a polymer play important roles in determining the lattice energy of the drug-polymer conjugate and, thus, the dissolution rate of the drug. The dissolution rate of one drug-polymer conjugate, sulfathiazole-povidone, has been studied by Simonelli *et al.* (1, 2). Povidone produced a high-energy form of the drug which exhibited much faster dissolution than the previously known polymorphic forms of sulfathiazole. When a drug is present in a polymer matrix, its enhanced dissolution rate may be derived from any of the following: (*a*) chemical attachment to the polymer; (*b*) existence of a metastable form of the drug stabilized by specific interactions with polymer; (*c*) the reduction of particle size and crystallinity due to the presence of the polymer. For the sulfathiazole-povidone conjugate, the drug does not appear to chemically bond with the polymer (2). The nature and the effect of the sulfathiazole–povidone interaction on enhancement of dissolution rates is not fully understood.

In this paper we present the investigation of the sulfathiazole-povidone conjugate by the technique of laser Raman spectroscopy. Raman spectroscopy provides spectra of both lattice vibrations (phonons) and intramolecular vibrations (3-5). Phonon spectra provide valuable information on the crystalline interactions; they are used to characterize the crystalline modifications and the effect of various external perturbations (including interactions with a matrix). The intramolecular vibrations are used to study the chemical stability of the various forms (5). These probes are based on the principle that a physical transformation in the solid state shows a dominant effect on the phonon motions but only a small effect on the intramolecular vibrations. On the other hand, a chemical change leads to a change both in the phonon spectra and in the spectra of intramolecular vibrations (6).

Laser Raman spectroscopy was used for the following investigations of sulfathiazole and sulfathiazole-povidone conjugates: (*a*) to identify and characterize the various polymorphic forms of sulfathiazole; (*b*) to determine if povidone produces a high-energy polymorphic form of sulfathiazole that is different from the known polymorphic forms; (*c*) to study the nature and strength of interaction between the drug and the polymer.

EXPERIMENTAL SECTION

Sulfathiazole was grown from ethanol solution by using two different procedures: slow growth at room temperture to generate large crystals, or rapid growth from a warm ethanol solution. The latter method was used by Higuchi *et al.* to produce their polymorphic form I (7). Sulfathiazole was also grown from 1-propanol[1] (80°C and room temperature) and 2-butanol[2] (room temperature) solutions as well as from the melt. The sulfathiazole-povidone[3] conjugates were prepared by the alcohol-evaporation method described by Simonelli *et al.* (1).

Raman spectra were obtained using a double monochromator[4] and the 514.5-nm line of a coherent radiation argon ion laser. Spectra were taken at room temperatures. Direct current detection was used.

RESULTS AND DISCUSSIONS

Polymorphic Forms of Sulfathiazole—Higuchi *et al.* have reported two polymorphic forms of sulfathiazole (7). The recrystallization of sulfathiazole from a warm ethanol solution gave form I. The second form of sulfathiazole was obtained either from the melt, or from a 1-propanol or 2-butanol solution. The room temperature Raman phonon spectra of four sulfathiazole samples are shown in Fig. 1. The phonon spectra obtained were for untreated sulfathiazole (A), rapidly recrystallized from warm ethanol (B), slowly recrystallized from ethanol (C) and recrystallized from 1-propanol (D), respectively. Sulfathiazole B phonon spectra appear to correlate with the phonon spectra of the untreated sulfathiazole. But there are some notable differences. The weak band at 82.0 cm^{-1} of sulfathiazole A splits into a doublet at 81.5 and 89.5 cm^{-1} in the sulfathiazole B spectrum. Additionally, the doublet at 135.0 and 145.0 cm^{-1} in the sulfathiazole A spectrum shifts to 134.5 and 139.5 cm^{-1} for the ethanol-grown sample. We carefully compared the intramolecular vibrations of sulfathiazole A and sulfathiazole B. In the 200–650 cm^{-1} and 900–1600 cm^{-1} regions, the vibrational spectra of sulfathiazole B were essentially similar to that of sulfathiazole A. However, the spectral region 650–900 cm^{-1} showed the following changes (Fig. 2): an extra band was observed at 878.5 cm^{-1} in the sulfathiazole B spectrum; the 681.5, 733.0, and 838.0 bands of pure sulfathiazole shifted to 684.5, 730.0, and 842.5 cm^{-1}, respectively, in the sulfathiazole B spectrum. The observed internal vibration at 878.5 cm^{-1} was identified as belonging to the solvent, ethanol. When frequency shifts are small (<3 cm^{-1}) the interaction between two components is generally weak and of a van der Waals type. In the ethanol-grown sulfathiazole, the observed shifts were ≥3 cm^{-1}. These results may indicate specific interaction between the solvent and some functional group of the drug, *i.e.*, hydrogen bonding. Our analysis was not able to detect the O—H stretching of the ethanol due to its broad and weak nature. However, we found these ethanol-sulfathiazole crystals to be stable for >6 months.

The third phonon spectrum (Fig. 1C) is of sulfathiazole grown slowly from ethanol. New bands were observed at 22.0, 24.5, 27.5, 64.0, and 126.5 cm^{-1}. In addition to these extra features, a comparison of the 30–70 cm^{-1} region for the sulfathiazole B and the sulfathiazole C samples reveal shifts to higher frequencies in the sulfathiazole C spectrum. Again, an inspection of the intramolecular vibrations for the sulfathiazole C sample shows the ethanol band (~878 cm^{-1}) and shifting of bands in the spectral region from 650 to 900

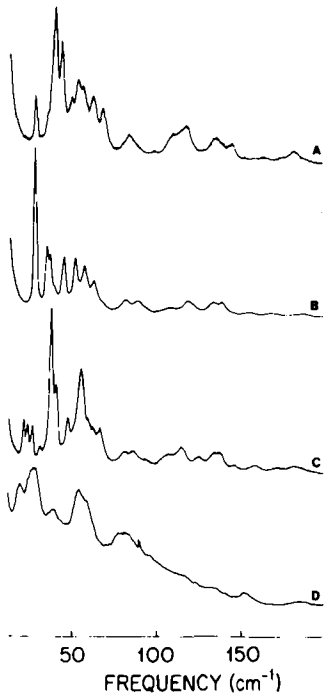

Figure 1—*Room temperature phonon spectra of four sulfathiazole samples. Key: (A) untreated sulfathiazole; (B) sulfathiazole rapidly recrystallized from warm ethanol; (C) sulfathiazole slowly recrystallized from ethanol; (D) sulfathiazole recrystallized from 1-propanol.*

cm^{-1}, similar to what was observed in the sulfathiazole B spectrum. We have also found that some ethanol-grown crystals exhibit phonon features which are in between that observed for sulfathiazole B and sulfathiazole C (*i.e.*, smaller shifts and fewer peaks than the sulfathiazole C spectrum). The ethanol band (~878 cm^{-1}) was present in all spectra of sulfathiazole grown from ethanol.

The results indicate that sulfathiazole incorporates the solvent (ethanol) into its crystal lattice and thus forms a solvate. The differences we observed in the phonon spectra of the various ethanol solvates may be due to varying intake of the solvent by the drug lattice. In other words, sulfathiazole and ethanol do not crystallize in one fixed stoichiometry.

The phonon spectrum of sulfathiazole grown from the 1-propanol solution is also shown (Fig. 1D). The phonon spectrum of this polymorph is distinctly different from the phonon spectra of sulfathiazole A or the ethanol solvates. Only five broad features are observed in the 10–100-cm^{-1} region. Identical broad phonon spectra were also obtained for crystals grown from the 2-butanol solution and from the melt. The intramolecular region 200–1600 cm^{-1} of the sulfathiazole D crystals were compared with that observed for sulfathiazole A. Some notable differences were observed: two new bands were observed at

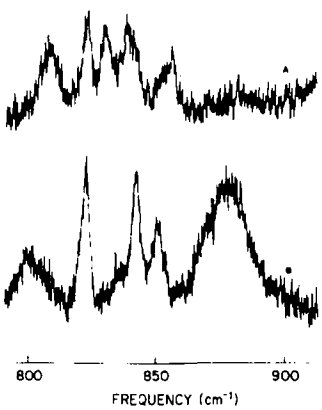

Figure 2—*The 800–900 cm^{-1} internal vibration regions are compared for the untreated sulfathiazole (A) and the sulfathiazole sample rapidly recrystallized from warm ethanol (B). In spectrum B, the broad peak at 878.5 cm^{-1} belongs to the solvent, ethanol.*

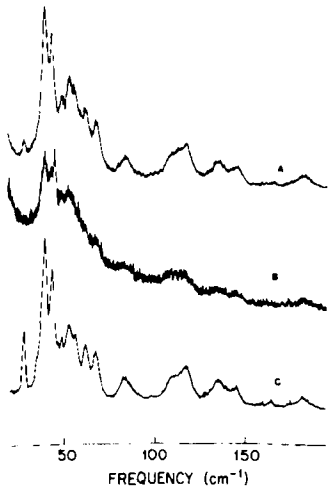

Figure 3—*Phonon spectra of the conjugates having sulfathiazole–povidone weight ratios of 10:1 (A) and 1:1 (B) are compared with the phonon spectra of untreated sulfathiazole (C).*

552.0 and 1502.0 cm^{-1} in the sulfathiazole D spectrum; the 304.0 and 649.5 cm^{-1} bands of pure sulfathiazole shifted to 288.0 and 656.5 cm^{-1} in the sulfathiazole D spectrum; the doublet, 632.5 and 638.5 cm^{-1}, in pure sulfathiazole shifted to 630.0 and 635.5 cm^{-1}. The extra features at 552.0 and 1502.0 cm^{-1} were also present in the 2-butanol-grown sulfathiazole spectra and in some of the drug–polymer conjugates (see next section) that were grown from ethanol. Thus, we do not attribute these new features to the solvent, 1-propanol. The appearance of new features and the shifting of peaks are believed to result from the formation of a different polymorph of sulfathiazole. From the broad nature of phonon bands, it appears that this polymorphic form is more disordered than the ethanol solvate.

Sulfathiazole–Povidone Conjugates—The phonon and the intramolecular vibrational spectra at room temperature were obtained for conjugates having sulfathiazole–povidone weight ratios of 10:1, 5:1, 3:1, 1:1, and 1:2. The phonon spectra of the conjugates 10:1, 1:1, and the sulfathiazole A sample are shown in Fig. 3. The phonon spectra of the 10:1 and 5:1 conjugates were essentially identical with that of sulfathiazole A. The only observable change is that the 27.5-cm^{-1} phonon band decreases in intensity as the weight ratio of sulfathiazole to povidone decrease. A decrease in the weight ratio of sulfathiazole to povidone appears to decrease the resolution of the phonon bands. This can be seen with the phonon spectrum of the 1:1 weight ratio. The 27.5 cm^{-1} transition is no longer visible. This poorly resolved spectrum still correlates with the spectrum of sulfathiazole A. The intramolecular vibrations of the 5:1 and 1:1 conjugates consisted of essentially unperturbed sulfathiazole bands. Also, the ethanol band (~878 cm^{-1}) was not present in either spectra. Therefore, we find no evidence of any chemical interaction between the drug and the polymer. Sulfathiazole appears in an unsolvated form even though the conjugate was precipitated from ethanol.

The phonon spectra of the conjugates 3:1, 1:2, and that of sulfathiazole grown from 1-propanol are shown in Fig. 4. The broad phonon features of the 3:1 conjugate correlates with those observed in the sulfathiazole D spectrum. The intramolecular vibrations of the 3:1 conjugate also correlate with the sulfathiazole D internal vibrations. Thus, sulfathiazole is present in the 3:1 conjugate as the polymorph grown from propanol. Again, no specific interactions between the polymer and the drug were observed.

The phonon spectrum of the 1:2 conjugate (Fig. 4) has a broad transition at 48 cm^{-1} and a weak broad feature at 57 cm^{-1}. While the phonon region of povidone is not shown in Fig. 4, the phonon spectrum of the 1:2 conjugate correlates with that of povidone. Thus, at ratios ≥1:2, the phonon spectra are dominated by povidone. With the lower ratios of sulfathiazole to povidone, the intermolecular vibrations of sulfathiazole were so weak that even the most intense vibrations were barely visible. No correlation of the 1:2 conjugate spectrum could be made. A 1:1 conjugate was prepared by rapidly cooling a sulfathiazole–povidone solution. The phonon spectrum of this conjugate was also dominated by povidone. However, the intramolecular vibrations were observed. Sulfathiazole was present in the 1:1 conjugate as the polymorphic form obtained from 1-propanol.

Simonelli *et al.* have correlated the dissolution rates of sulfathiazole–povidone conjugates to povidone weight fractions (2). They found two plateaus at low povidone weight fractions. They concluded that the lower plateau (lower dissolution rate) resulted from form I (sulfathiazole grown from warm ethanol) being present in the drug–polymer conjugates. Our results of the phonon

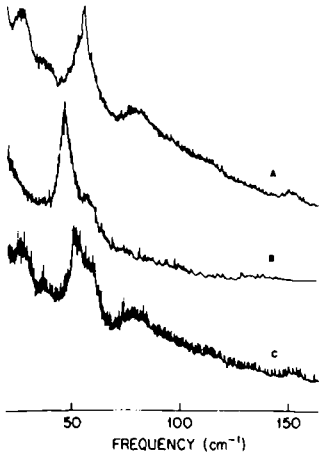

Figure 4—*Phonon spectra of the conjugates having sulfathiazole–povidone weight ratios of 3:1 (A) and 1:2 (B) are compared with that of sulfathiazole grown from propanol (C).*

and intramolecular vibrations have shown that at low povidone weight fractions (10:1, 5:1, and 1:1 conjugates), sulfathiazole was not present as the ethanol solvate but as the unsolvated sulfathiazole. In the sulfathiazole–povidone conjugate region 3:1–1:1.5, a second (higher dissolution rates) plateau was observed. Simonelli *et al.* postulated that the initial rate of dissolution exhibited at the higher plateau could rise from the presence of a new higher energy form of sulfathiazole. However, this higher energy form of sulfathiazole exhibited much faster dissolution than the previously known polymorphic forms of sulfathiazole. In the sulfathiazole–povidone region 3:1–1:1, we observed two different kinds of phonon and intramolecular spectra, one belonging to the sulfathiazole A form and the other being the polymorphic form obtained from propanol. The method of preparation (*i.e.*, temperature and/or concentration of solution) probably determines which of the two forms of sulfathiazole is present in the conjugates with drug–polymer ratios of 3:1–1:1.5. No other crystalline forms of sulfathiazole were observed in the drug–polymer conjugates. We therefore attribute the higher dissolution rate observed to arise from the particle size reduction of the drug in the presence of the polymer, whereby the increased effective surface area leads to an enhanced dissolution rate.

Electrostatic Effects in Acylation of Hemoglobin by Aspirins

SOLOMON E. MASSIL, GUEY-YUEH SHI, and IRVING M. KLOTZ ˣ

Received October 24, 1983, from the *Department of Chemistry, Northwestern University, Evanston, IL 60201.* Accepted for publication April 11, 1984.

Abstract □ Carboxylate substituents added to the salicylate ring increase the effectiveness of a variety of aspirins and diaspirins in acylating hemoglobin. Even more effective are a series of monoesters of dicarboxylate derivatives. Bis(5-carbomethoxysalicyl)fumarate and -succinate at 5 mM concentrations modify ~100% of the hemoglobin in solution and should alter the aggregation behavior of sickle hemoglobin.

Keyphrases □ Diaspirin—hemoglobin, sickle cell anemia, carboxylate substituents □ Hemoglobin—carboxylate-substituted diaspirins, acylation, sickle cell anemia

Previous studies have shown that aspirin and its analogues are capable of acylating hemoglobin (1). Acetylsalicylate, the prototype monoester, tends to transfer its acetyl group largely to the βLys[1] 59 and βLys 144 residues. These are in areas of the protein with a high local concentration of cationic side chains; *e.g.*, βLys 59 is part of a surface constellation constituted of βLys residues 59, 61, 65, and 66. The double-headed bissalicylates, in turn, preferentially go to the β-cleft of hemoglobin. In this canyon, both β chains contribute their βVal 1, βHis 2, βLys 82, and βHis 143 residues to provide a highly cationic environment.

In view of these observations, it seemed likely that even greater acylation of hemoglobin might be achieved with salicylate esters carrying additional negative charges. Furthermore, different structural dispositions of anionic charges on the reagents might lead to alternative specificities in binding to and acylation of Lys residues in hemoglobin. These might be directed toward placing substituents near βVal 6 or near βPhe 85 or βLeu 88 of hemoglobin S, residues evidently at a contact interface in sickled hemoglobin (2, 3). Therefore, several aspirin analogues with added substituents, particularly anionic ones, have been prepared. These substances are members of different classes of compounds: substituted monosalicylates [substituted carboxyphenyl acetates (I–V)]; substituted bissalicylates of succinic acid [bis(substituted carboxyphenyl)succinates (VI, VII, X, and XI)], of fumaric acid [bis(substituted carboxyphenyl)fumarates (VIII and IX)], or of anhydromethylene citric acid [bis(substituted

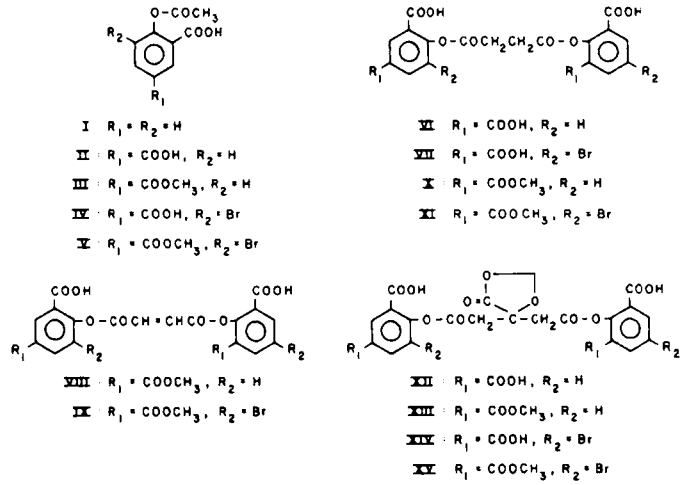
carboxyphenyl)4-oxo-1,3-dioxolane-5,5-diacetate (XII–XV)]. The extent of modification of hemoglobin by these compounds has been explored.



RESULTS AND DISCUSSION

Chemistry—Some of the compounds (Table I) proved to be very elusive. One of the key intermediates, 4-hydroxy-5-bromo-isophthalic acid monomethyl ester could not be obtained from the diester by conventional methods (4), which in this case produced the diacid. However, the simple procedure of stirring the diester in an appropriate alkaline solution yielded the desired monoester, from which V and IX could be prepared. The bisfumarates of the diacids 4-hydroxy-isophthalic and its 5-bromo analogue were so sensitive to traces of water in the environment that they could not be isolated even though their presence was established (TLC) in the dry solvent in which their synthesis was carried out. In contrast, the corresponding monoesters were comparatively stable.

As mentioned previously (5), the methylene citrate derivatives had to be protected under petroleum ether in the cold, but they were sufficiently stable to carry out modification experiments if they were added quickly to the hemoglobin solution.

Activity—A comparison (Table I) of aspirin (I) with its doubly anionic analogue 4-(acetyloxy)-1,3-benzenedicarboxylic acid (II) shows that the extent of modification of hemoglobin is significantly greater for the latter. This increase was expected for the doubly charged reagent. To our surprise, however, the monomethyl ester, 4-(acetyloxy)-1,3-benzenedicarboxylic acid 1-methyl ester (III), is much more effective than either analogue I or II. We conclude, therefore, that the presence of the added carbomethoxy moiety is much more influential than the additional charge. Evidently this second electron-withdrawing group in the *para* position to the acetoxy substituent activates the latter substantially so that it is much more effective in transferring its acetyl radical to the hemoglobin. The dipole of the $-COOCH_3$ moiety may also provide some electrostatic interaction with a cationic locus on the protein.

A bromo substituent on the aromatic ring, producing IV, also increases effectiveness (compared with II) of the aspirin analogue in modifying hemoglobin. This effect of the polarizable bromine atom has been seen previously (1). A particularly marked increase in modification is manifested with the monoanionic monoester V, the bromo analogue of III. Again we see that the *para* carbomethoxy substituent has a marked activating effect on the acetoxy group.

Turning to the bissalicylates, we find similar substituent effects, even more marked in these diaspirins. Bissalicyl succinate, the single-COOH reference analogue of VI, at 5 mM concentration modifies ~15% of hemoglobin (1, 6). In contrast, the additional —COOH provided by VI increases the degree of modification to almost 80%. An additional bromo substituent increases the reactivity even further, as is evident with VII (Table I).

It has been shown previously (5, 6) that the fumarate diaspirin, bis(2-carboxyphenyl)fumarate, is more effective than the corresponding salicylate derivative. This superiority is maintained in the present series of compounds. Thus, VIII is more reactive than X, and IX is better than XI. With all of these compounds the extent of modification of hemoglobin is very high.

In the methylene citric acid series (XII–XV), the beneficial effects of the $-COOCH_3$ substituent continue to be expressed. Thus, XIII is superior to XII, and XV is better than XIV.

The shifts in p_{50} values (oxygen pressure at half-saturation of hemoglobin) provide some insight into the location of the acyl group affixed by the aspirin

[a] Some qualitative experiments with this compound have been described by Kokkini *et al.* (11). [b] Satisfactory analytical data (±0.4% for C, H) were reported for each of these compounds. [c] Calc. for Br, 26.44; found, 25.82. [d] Calc. for Br, 25.36; found 24.91. [e] Calc. for Br, 25.28; found 24.83. [f] Melting points (°C): VI, 228–230; VII, 212–213; VIII, 200–202; IX, 233–235; X, 179–181; XI, 178–180.

reagent. If p_{50} is shifted back to near 40 mm (Table I) when inositol hexaphosphate is added to the hemoglobin solution, then this effector is clearly able to enter the β-cleft of the protein to shift the conformation to the low-affinity form. As has been shown previously (1), the diaspirins are capable of denying inositol phosphate access to the β-cleft by forming a covalent blocking bridge across the portal. It is apparent that these features of the double-headed aspirins are maintained in the current series of compounds (VI–XI), all of which, at least at a concentration of 5 mM, keep p_{50} from returning to the normal value in the presence of inositol hexaphosphate. The

two most striking agents in this regard are the monomethyl esters VIII and IX, which at 5 mM concentration keep p_{50} in the presence of inositol hexaphosphate at essentially the same value as in its absence. Thus, these two compounds are essentially 100% effective in blocking access to the β-cleft. The bis(carbomethoxysalicyl)fumarate (VIII), devoid of the bromo substituent, should be a particularly attractive compound from a pharmacological viewpoint for testing as an antisickling agent.

EXPERIMENTAL SECTION[2]

3-Bromo-5-carbomethoxy Salicylic Acid—Partial hydrolysis of 5-bromo-4-hydroxy-isophthalic acid dimethyl ester was affected by stirring the mixture of diester (2.0 g) with 25 mL of 33% KOH in methanol and 25 mL of water for several hours at room temperature. The unchanged diester in suspension was removed by filtration. The filtrate was cooled and acidified with 1 M HCl. The resulting precipitate was removed by filtration and then recrystallized from dilute ethanol to give the monoester, mp 237–238°C. IR: 1720 cm^{-1}; ^{1}H-NMR (Me_2SO-d_6): δ 3.85 (3, s, —$COOCH_3$) and 8.0–8.4 ppm (2, t, ArH).

Anal.—Calc. for $C_9H_7BrO_5$: C, 39.30; H, 2.57; Br, 29.05. Found: C, 39.34; H, 2.58; Br, 29.18.

Preparation of Substituted Isophthalic Acids and Methyl Esters—*4-(Acetoxy)-isophthalic Acid (II) and 4-Acetoxy-isophthalic Acid 1-Methyl Ester (III)*—These compounds were prepared as described in the literature (4).

4-(Acetoxy)-5-bromo-isophthalic Acid (IV)—Compound IV was prepared in a manner similar to that in the literature (4) for II and was recrystallized from chloroform–petroleum ether, mp 197–199°C. ^{1}H-NMR (Me_2SO-d_6): δ 2.45 (3, s, —$OCOCH_3$), 8.4 (2, t, ArH), and 11.61 ppm (br s, 2, 2-COOH).

Anal.—Calc. for $C_{10}H_7BrO_6$: C, 39.63; H, 2.33. Found: C, 39.74; H, 2.32.

4-Acetoxy-5-bromo-isophthalic Acid Monomethyl Ester (V)—Ester V was also prepared by a procedure (4) analogous to that used for III and was recrystallized from chloroform–petroleum ether, mp 133–135°C. IR: 1725 cm^{-1}; ^{1}H-NMR ($CDCl_3$-Me_2SO-d_6): δ 2.37 (3, s, —$OCOCH_3$), 3.92 (3, s, $COOCH_3$), and 8.34–8.53 ppm (2, d, ArH).

Anal.—Calc. for $C_{11}H_9BrO_6$: C, 41.67; H, 2.86; Br, 25.20. Found: C, 41.40; H, 2.80; Br, 25.75.

General Method for the Synthesis of Bissuccinates (VI and VII)—Sodium hydride (0.06 mol) was added to a solution of substituted salicylic acid (0.02 mol) in 30 mL of dry tetrahydrofuran, and the mixture was stirred overnight at room temperature. Succinyl chloride (0.01 mol) was dissolved in a minimum quantity of tetrahydrofuran (~5 mL) and added in a dropwise manner, over a period of 0.5 h, to the stirred suspension of sodium salt of the substituted salicylate. The resulting mixture was further stirred for an additional day. After removal of solvent under reduced pressure, the gummy residue was treated with ethyl acetate and acidified with aqueous 1 M HCl while being cooled in an ice bath. The organic layer was removed, washed with cold saturated NaCl solution, and dried over $MgSO_4$. After removal of solvent, the residue was recrystallized from a mixture of ethyl acetate–petroleum ether. Properties of the compounds obtained (VI and VII) are summarized in Table I.

General Method for the Synthesis of Bisfumarates and Bissuccinates (VIII–XI)—To a stirred mixture of substituted salicylic acid (2.0 mmol) and *N,N*-dimethylaniline (6.2 mmol) in 80 mL of dry benzene was added in a dropwise manner fumaryl or succinyl chloride (1.02 mmol) dissolved in 20 mL of benzene. The resultant mixture was stirred overnight at room temperature. After removal of the solvent under reduced pressure, the residue was suspended in 50 mL of ethyl acetate and extracted several times with ice-cold 1 M HCl (50 mL) and once with water (50 mL). The organic layer was dried ($MgSO_4$), filtered, and evaporated under reduced pressure. The residue was further recrystallized from either ethanol or a mixture of ethyl acetate–petroleum ether. The compounds obtained (VIII–XI) are listed in Table I. ^{1}H-NMR spectra were consistent with the structures.

General Method for the Synthesis of Biscitrates (XII–XV)—The preparations of XII–XV were described in a previous publication (5).

Hemoglobin Experiments—Whole blood (with anticoagulant) was obtained from local hospitals. Hemolysate was prepared by the method of Drabkin (7) except that chloroform was used to facilitate separation of the membranes. Hemolysate from normal adults was used without further purification. After freezing in liquid nitrogen, the hemolysate and hemoglobin samples were stored at −80°C. Hemoglobin concentrations in solution were measured after conversion to the cyanomet derivative (8).

Chemical modifications with the acylating compounds were performed with 1–5-fold molar ratio of reagent to hemoglobin for the bissalicylate esters and with a 5–20-fold molar excess for the monosalicylates. The reactions were carried out in 0.1 M Tris-HCl buffer, pH 7.3, which the hemoglobin had been dialyzed against. All reactions were performed with oxyhemoglobin. Modification reactions were initiated by suspending the compound in buffer, partially dissolving it, and adding hemoglobin within 30 s. Stirring was continued for 2 h at 37°C. The reaction mixture was then dialyzed overnight against cold 0.13 M glycine (pH 6.0).

The extent of modification of the hemoglobin was assessed by isoelectric focusing (9, 10) in a flat gel[3] using the procedures described by the manufacturer, with the following alterations. A 1-mm gel (instead of 3 mm) was prepared between a glass plate (bottom) and a piece of plexiglass (top) with a polytef gasket between plates. The gel composition for 100 mL of solution was 4 g (0.56 M) of acrylamide[4], 0.16 g (0.01 M) of *N,N'*-methylenebisacrylamide[5], 5 g (0.54 M) of glycerol, 5.4 mL of ampholytes, pH 6.5–9[6], 1.8 mL of ampholytes, pH 6–8[7], 0.05 g (4.3 mM) of *N,N,N',N'*-tetramethylethylenediamine[4], and 0.05 g (2.2 mM) of ammonium persulfate[8]. All hemoglobin samples were saturated with gaseous CO and made 0.01 M in NaCN; 2.5 μL was then applied to the gel surface on small pieces of filter paper. The anolyte was 1 M H_3PO_4; 2 M NaOH served as catholyte. Isoelectric focusing was carried out at 10°C for ~90 min with a power level of 30 W. Immediately after the power was turned off, the gel was fixed in an aqueous solution of 10 g/100 mL (0.6 M) of trichloroacetic acid[9] and 6 g/100 mL (0.2 M) of 5-sulfosalicylic acid[10] for 20–30 min, and then placed for 30–60 min in a preservative solution of water–ethanol–acetic acid–glycerol (35:5:1:1). After the gel had dried overnight, the modification pattern in each reaction channel was analyzed by recording a densitometric scan with a soft laser scanning densitometer with an integrator[11]. Oxygen affinities of chemically modified and unmodified hemoglobins were determined in the presence and in the absence of 2 mM inositol hexaphosphate[12] using an oxygenator[13].

Bromo-6-methoxy-8-aminoquinolines: Preparation and ^{13}C-NMR Assignments

JAMES D. McCHESNEY ˣ, S. SARANGAN, and CHARLES D. HUFFORD

Received April 26, 1982, from the *Department of Pharmacognosy, School of Pharmacy, The University of Mississippi, University, MS 38677.* Accepted for publication January 25, 1984.

Abstract □ Preparation of all possible monobromo-6-methoxy-8-aminoquinolines is reported. These materials provided an opportunity to assess the effect of bromine substitution on ^{13}C-NMR chemical shift patterns. An explanation of the isomerization of 5-bromo-6-methoxy-8-acetamidoquinoline to 7-bromo-6-methoxy-8-aminoquinoline during hydrolysis is presented.

Keyphrases □ Bromine substitution—^{13}C-NMR chemical shifts, bromoaminoquinoline isomerization □ Bromoaminoquinolines—^{13}C-NMR chemical shifts, isomerization, bromine substitution

Various isomers of bromo-6-methoxy-8-aminoquinoline were required as intermediates in connection with syntheses of deuterated derivatives of the antimalarial drug primaquine (I) (1). Primaquine, 6-methoxy-8-(4-amino-1-methylbutyl)-aminoquinoline, is used for the radical cure of vivax malaria and, in combination with other antimalarial drugs such as chloroquine, for prophylaxis in endemic areas (2).

An obvious route of preparation of these bromoaminoquinolines should involve the reduction of the corresponding bromo nitro compounds. Examination of the literature showed that while 3-bromo-6-methoxy-8-aminoquinoline had indeed been prepared by this method (3), the 5-bromo derivative had been obtained by the bromination of 6-methoxy-8-acetaminoquinoline and the subsequent hydrolysis of the acetyl group (4). Reduction of 5-bromo-6-methoxy-8-nitroquinoline gave poor yields of the amino compound (4). The 7-bromo compound was prepared by a rather unusual transformation of the 5-bromo derivative in refluxing 10% hydrobromic acid (4). The 2- and 4-bromo derivatives have not been previously reported.

The present work describes the preparation of these two unknown compounds as well as a study of the ^{1}H- and ^{13}C-NMR spectra of all these monobromo and the 5,7-dibromo-6-methoxy-8-aminoquinolines. In addition we have reexamined the unusual transformation of the 5-bromo isomer into the 7-bromo material. The reduction of the various bromo-8-nitroquinolines was examined to develop an efficient nitro reduction without accompanying debromination.

EXPERIMENTAL SECTION[1]

6-Methoxy-8-nitroquinoline (II)—Nitrobenzene (50 mL) was added slowly with stirring to fuming sulfuric acid (30% sulfur trioxide, reagent grade, 150 mL) at room temperature. The mixture was stirred at 60–65°C for ~8 h (until a drop of the mixture was found to be miscible when poured into water). The "sulfo mix" (5) was then added slowly with vigorous stirring to a paste of 2-nitro-4-methoxyaniline (85 g, 0.5 mol), glycerol (230 g, 2.5 mol), and water (230 mL). The resulting mixture was heated gradually in an oil bath to 130–135°C and kept at that temperature for 6 h. The color of the mixture changed from orange-red to dark brown. The mixture was allowed to cool, was poured into crushed ice, and then neutralized with 10% NaOH. The solid material was removed by filtration, washed with water, and dried. Recrystallization from chloroform gave 64.0 g (63% yield) of II as straw-colored crystals, mp 158–160°C [lit. (6) mp 158–160°C].

2-Bromo-6-methoxy-8-nitroquinoline (III)—1-Methyl-6-methoxy-8-nitroquinoline-2-one (7) (7.0 g, 0.03 mol) and phosphorus oxybromide (17.3 g, 0.113 mol) were heated at 120–125°C for 6 h. The mixture was cooled, poured into crushed ice, and neutralized with excess ammonium hydroxide. The pale-yellow solid was removed by filtration, washed, and dried. Recrystallization from ethanol gave 6.7 g (80% yield) of III as pale-yellow needles, mp 228–230°C.

Anal.—Calc. for $C_{10}H_7BrN_2O_3$: C, 42.23; H, 2.49; N, 9.89. Found: C, 42.08; H, 2.60; N, 9.90.

4-Bromo-6-methoxy-8-nitroquinoline (V)—In a similar manner, 4-hydroxy-6-methoxy-8-nitroquinoline (3.3 g, 0.015 mol) (8) was treated with phosphorus oxybromide (5.8 g, 0.02 mol) in quinoline to give V as yellow crystals (chloroform), 3.1 g (64% yield), mp 191–193°C.

Anal.—Calc. for $C_{10}H_7BrN_2O_3$: C, 42.23; H, 2.49; N, 9.89. Found: C, 42.52; H, 2.70; N, 10.20.

General Procedure for Nitro Group Reduction—The nitro compound (~10 mmol) was dissolved in concentrated hydrochloric acid (~30 mL), and the solution was cooled in an ice-salt bath. The ice-cold solution was added slowly with vigorous stirring to an ice-cold solution of stannous chloride (anhydrous, 98%, ~10 g) in 30 mL of concentrated hydrochloric acid. The resulting mixture was stirred at 0–5°C for 1 h and then poured into crushed ice. The mixture was made alkaline with concentrated ammonium hydroxide and extracted with ethyl acetate (5 × 50 mL). The combined organic layers were washed

[1] The ^{1}H-NMR spectra (90 MHz) were recorded on a Varian EM 390 spectrometer using Me_2SO-d_6 as solvent and tetramethylsilane as an internal standard. The ^{13}C-NMR spectra (15.03 MHz) were recorded on a JEOL-FX60 FT spectrometer using Me_2SO-d_6 as solvent and tetramethylsilane as internal standard. NMR data are reported as δ values (ppm). Mass spectra were obtained using a Finnigan 3200 GC–MS coupled to an INCOS data system. HPLC was accomplished on a μ-Bondapak C_{18} reverse-phase column and a mobile phase of 2.2 g of potassium dihydrogen phosphate, 3.3 g of potassium hydrogen phosphate, 1.2 L of distilled water, and 2.8 L of HPLC-quality methanol. TLC was accomplished on silica G (254) precoated plates; GC was done on base-deactivated 3% OV-17 packed on a 183 m × 0.6 cm o.d. glass column with flame-ionization detection on a Beckman GC-65, with a flow rate of 30 mL/min of nitrogen. All compounds gave satisfactory elemental analyses. Starting compounds were prepared by literature procedures or purchased from Aldrich unless otherwise noted.

twice with water and once with saturated brine, dried over anhydrous sodium sulfate, and concentrated under reduced pressure. Recrystallization was from ethanol.

2-Bromo-6-methoxy-8-aminoquinoline (VII)—The aforementioned 2-bromo-6-methoxy-8-nitroquinoline (4.2 g, 0.015 mol) dissolved in concentrated hydrochloric acid (25 mL) was added to stannous chloride (15 g, 0.066 mol) dissolved in concentrated hydrochloric acid (25 mL). This afforded 3.44 g (90% yield) of colorless crystals, mp 88–90°C. ^{1}H-NMR: δ 8.00 (1, d, J = 8 Hz, H-4), 7.50 (1, d, J = 8 Hz, H-3), 6.51 (2, br s, H-5 and H-7), and 3.83 ppm (3, s, OCH_3); ^{13}C-NMR: 159.2 (s, C-6), 145.5 (s, C-8), 138.1 (d, C-4), 134.9 and 134.7 (s, C-2 and C-8), 128.8 (s, C-4a), 125.8 (d, C-3), 101.0 (d, C-7), 93.8 (d, C-5), and 55.1 ppm (q, OCH_3).

Anal.—Calc. for $C_{10}H_9BrN_2O$: C, 47.45; H, 3.58; N, 11.07. Found: C, 47.54; H, 3.68; N, 11.27.

3-Bromo-6-methoxy-8-aminoquinoline (VIII)—3-Bromo-6-methoxy-8-nitroquinoline (5.6 g, 0.02 mol) dissolved in concentrated hydrochloric acid (30 mL) was added to stannous chloride (20 g, 0.089 mol) dissolved in concentrated hydrochloric acid (30 mL). This afforded 4.57 g (90% yield) of colorless needles, mp 95–96°C [lit. (3) mp 95–96°C]. ^{1}H-NMR: δ 8.58 (1, d, J = 2 Hz, H-2), 8.31 (1, d, J = 2 Hz, H-4), 6.67 (1, d, J = 2 Hz, H-5 or H-7), 6.55 (1, d, J = 2 Hz, H-5 or H-7), and 3.91 ppm (3, s, OCH_3); ^{13}C-NMR: 159.8 (s, C-6), 146.3 (s, C-8), 144.6 (d, C-2), 135.7 (d, C-4), 132.8 (s, C-8a), 131.1 (s, C-4a), 117.5 (s, C-3), 100.4 (d, C-7), 93.0 (d, C-5), and 55.1 ppm (q, OCH_3).

4-Bromo-6-methoxy-8-aminoquinoline (IX)—The aforementioned 4-bromo-6-methoxy-8-nitroquinoline (4.2 g, 0.015 mol) dissolved in concentrated hydrochloric acid (25 mL) was added to stannous chloride (15 g, 0.066 mol) dissolved in concentrated hydrochloric acid (25 mL). The resulting mixture was stirred at 0–5°C for 1 h, poured into crushed ice, and neutralized to pH 8–9 with concentrated ammonium hydroxide. A solid (4-bromo-6-methoxy-8-aminoquinoline hydrochloride) separated and was removed by filtration and recrystallized from ethanol. This afforded 3.3 g (76% yield) of IX as pale-yellow needles, mp 98–100°C. ^{1}H-NMR: δ 8.35 (1, d, J = 5 Hz, H-2), 7.73 (1, d, J = 5 Hz, H-3), 6.63 (2, br s, H-5 and H-7), and 3.90 ppm (3, s, OCH_3); ^{13}C-NMR: 160.1 (s, C-6), 147.2 (s, C-8), 143.8 (d, C-2), 135.2 (s, C-8a), 131.3 (s, C-4), 129.0 (s, C-4a), 125.7 (d, C-3), 100.2 (d, C-7), 92.1 (d, C-5), and 55.1 ppm (q, OCH_3).

Anal.—Calc. for $C_{10}H_9BrN_2O$·HCl: C, 41.48; H, 3.48; N, 9.67. Found: C, 41.00; H, 3.00; N, 9.64.

5-Bromo-6-methoxy-8-aminoquinoline (X)—5-Bromo-6-methoxy-8-nitroquinoline (9) (1.5 g, 0.005 mol) dissolved in concentrated hydrochloric acid (10 mL) was added to stannous chloride (5 g, 0.022 mol) dissolved in concentrated hydrochloric acid (10 mL). This afforded 1.16 g (92% yield) of colorless needles, mp 152–153°C [lit. (4) mp 153–154°C]. ^{1}H-NMR: δ 8.73 (1, dd, $J_{2,3}$ = 5 Hz, $J_{2,4}$ = 2 Hz, H-2), 8.37 (1, dd, $J_{4,2}$ = 2 Hz, $J_{4,3}$ = 8 Hz, H-4), 7.63 (1, dd, $J_{3,2}$ = 5 Hz, $J_{3,4}$ = 8 Hz, H-3), 7.03 (1, s, H-7), and 3.91 ppm (3, s, OCH_3); ^{13}C-NMR: 155.0 (s, C-6), 146.7 (s, C-8), 144.8 (d, C-2), 134.0 (s, C-8a), 133.2 (d, C-4), 128.0 (s, C-4a), 123.1 (d, C-3), 96.3 (d, C-7), 89.9 (s, C-5), and 56.4 ppm (q, OCH_3).

5-Bromo-6-methoxy-8-acetaminoquinoline (XIII)—6-Methoxy-8-acetaminoquinoline (3.2 g, 0.015 mol) was dissolved in glacial acetic acid (30 mL). Pyridinium hydrobromide perbromide (4.8 g, 0.015 mol) was added slowly, and the mixture was stirred at room temperature for 2 h. The solution was cooled in an ice bath and neutralized with excess concentrated ammonium hydroxide. The precipitate was removed by filtration and washed with ice-cold water; the dried material was recrystallized from ethyl alcohol to give 3.4 g (77% yield) of colorless needles, mp 167–169°C [lit. (4) mp 167–169°C].

7-Bromo-6-methoxy-8-aminoquinoline (XI)—The method of Lauer *et al.* (4) was used to give material with mp 110–112°C [lit. (4) mp 111.5–112.5°C]. ^{1}H-NMR: δ 8.63 (1, dd, $J_{2,3}$ = 5 Hz, $J_{2,4}$ = 2 Hz, H-2), 8.13 (1, dd, $J_{4,2}$ = 2 Hz, $J_{4,3}$ = 8 Hz, H-4), 7.47 (1, dd, $J_{3,2}$ = 5 Hz, $J_{3,4}$ = 8 Hz, H-3), 6.83 (s, H-5), and 4.00 ppm (3, s, OCH_3); ^{13}C-NMR: 154.2 (s, C-6), 145.5 (d, C-2), 143.8 (s, C-8), 134.9 (d, C-4), 134.1 (s, C-8a), 128.1 (s, C-4a), 122.3 (d, C-3), 95.6 (s, C-7), 93.5 (d, C-5), and 56.1 ppm (q, OCH_3).

5,7-Dibromo-6-methoxy-8-aminoquinoline (XII)—The method of Lauer *et al.* (4) was used to give off-white crystals from ethanol, mp 86–87°C [lit. (4) mp 87–88°C]. ^{1}H-NMR: δ 8.77 (1, dd, $J_{2,3}$ = 5 Hz, $J_{2,4}$ = 2 Hz, H-2), 8.33 (1, dd, $J_{4,2}$ = 2 Hz, $J_{4,3}$ = 8 Hz, H-4), 7.63 (1, dd, $J_{3,2}$ = 5 Hz, $J_{3,4}$ = 8 Hz, H-3), and 3.91 ppm (3, s, OCH_3); ^{13}C-NMR: 152.6 (s, C-6), 147.7 (d, C-2), 144.4 (s, C-8), 135.3 (s, C-8a), 134.6 (d, C-4), 126.7 (s, C-4a), 123.6 (d, C-3), 99.1 (s, C-7), 98.0 (s, C-5), and 60.5 ppm (q, OCH_3).

RESULTS AND DISCUSSION

2-Bromo-6-methoxy-8-nitroquinoline (III) was obtained by treatment of 1-methyl-6-methoxy-8-nitroquinoline-2-one with phosphorus oxybromide. The quinoline-2-one derivative was prepared in two steps from 6-methoxy-8-nitroquinoline (7). 6-Methoxy-8-nitroquinoline (II) may be prepared in good yield by the use of "sulfo mix" (5) in place of arsenic pentoxide (10), the duration of reaction being shorter and the workup of the reaction being comparatively easier. 4-Bromo-6-methoxy-8-aminoquinoline (V) was made from the corresponding 4-hydroxy compound (8).

The unexpected result of isomerization of the 5-bromo isomer into the 7-bromo isomer, which was reported previously (4), was confirmed; the spectral data clearly distinguish the 5- and 7-bromo isomers. A clue to the explanation of this result is the observed rapid exchange of the hydrogen atoms at both C-5 and C-7. This suggests that protonation occurs at C-5 of the highly activated ring to form an iminium intermediate (XIV). Nucleophilic attack of this material by bromide ion would generate 6-methoxy-8-acetaminoquinoline and molecular bromine. Subsequent bromination of the 6-methoxy-8-acetaminoquinoline may proceed at C-5 to regenerate the starting bromo isomer, or alternatively, since C-7 is also activated, bromination may take place at C-7 to generate the isomeric product. Since protonation seems to be favored at C-5, this process should ultimately transform all of the 5-bromo derivative to the 7-bromo substance (4).

With all the bromo-8-nitroquinolines in hand, we turned our attention to the formation of the 8-aminoquinolines. The reduction of the nitro to an amino group caused several problems. It was found that use of either 10% palladium on charcoal or Raney Nickel-catalyzed reduction with hydrazine hydrate in refluxing ethanol resulted in considerable hydrogenolysis of the bromo group. Catalytic hydrogenation with Raney Nickel (50 psi, room temperature) also gave inconsistent results with the bromonitro compounds. Hence, a detailed study was undertaken to find the best method for the reduction of the nitro group without accompanying hydrogenolysis of the bromo substituent. The reduction was attempted under three different pH conditions (neutral, basic, and acidic), and the course of the reduction was monitored by GC; and bromoaminoquinolines were well separated from 6-methoxy-8-aminoquinoline and the starting nitro derivatives. It was found that reduction with stannous chloride in concentrated hydrochloric acid at low temperature for a period of 1 h gave the best results in all the cases examined. Longer reaction times resulted in extensive hydrogenolysis especially in the case of the 2- and 5-bromo derivatives. Hydrazine hydrate reduction catalyzed by Raney Nickel at room temperature gave satisfactory results only in the case of 3- and 4-bromo compounds. Raney Nickel-catalyzed reduction with hydrogen gas at 50 psi and room temperature for ≥6 h gave fair to poor yields of bromoamino compounds. Shorter duration of hydrogenation resulted in incomplete reduction and the recovery of the starting bromonitro compounds. Thus, the stannous chloride–hydrochloric acid method was found to be the best, and yields ranging from 85 to 95% could be achieved in all the cases. 5,7-Dibromo-6-methoxy-8-aminoquinoline (XII) was prepared as reported earlier (4).

The ^{1}H-NMR data of all these compounds are readily assigned by simple chemical-shift theory and coupling patterns. Since little data is available concerning the effects of bromine on carbon resonances, the complete assignments of the ^{13}C-NMR data were also examined.

The use of long-range coupling patterns of quinoline derivatives can be used to confirm assignments (11). The fully coupled ^{13}C-NMR spectra of 6-methoxy-8-aminoquinoline (III) readily confirms those assignments listed. The protons of the amino group also show long-range coupling to C-7 just like that observed for primaquine (12). This coupling can be removed by exchange using deuterium oxide, and the C-7 signal appears as the expected doublet of doublets (J = 158.2, 5.9 Hz). The carbon atom at the 5-position, on the other hand, remains unchanged after exchange [dt (J = 162.1, 4.9 Hz)]. The carbon atom at the 4a-position appears as a doublet (J = 6.8 Hz), C-6 as a quartet (J = 3.9 Hz), C-8 as a singlet, and C-8a as a complex multiplet. The coupling patterns for C-2, C-3, and C-4 appear just as for quinoline (11).

The assignments of the signals for the various bromo derivatives (VII–XI) were made using chemical-shift theory, single-frequency off-resonance decoupling, and long-range coupling patterns in the proton-coupled spectrum. Introduction of a bromine substituent in benzenes causes a shielding of the substituted carbon (5–6 ppm) and a deshielding of the *ortho* carbon (3–4 ppm) (13). The *meta* and *para* effects are much smaller. This general trend appears to hold for the substituted carbon and the protonated carbons of the bromoquinolines as well. The shift of the nonprotonated *ortho* carbon, on the other hand, is in the opposite direction (shielded) by several ppm. It is also interesting to compare the 5,7-dibromo derivative (XII) with VI, X, and XI. The C-7 signal in XII appears at nearly the same place as in VI, whereas C-5 is deshielded by ~5 ppm. Also, C-5 in X appears near 90 ppm, while in XII it appears at 98 ppm, showing that introduction of a bromine at C-7 (*meta* position) causes a deshielding effect of ~8 ppm. Comparison of C-7 in XII and XI shows a deshielding effect of only ~2 ppm. Clearly, we can conclude that one must be careful in drawing any generalizations with bromine substituents, particularly in highly substituted systems.

Determination of the Structure of a Synthetic Impurity in Guaifenesin: Modification of a High-Performance Liquid Chromatographic Method for Phenylephrine Hydrochloride, Phenylpropanolamine Hydrochloride, Guaifenesin, and Sodium Benzoate in Dosage Forms

GARY W. SCHIEFFER ˣ, WARREN O. SMITH, GWEN S. LUBEY, and DANIEL G. NEWBY

Received October 13, 1983, from the *Analytical Chemistry Division, Norwich Eaton Pharmaceuticals, Inc., Norwich, NY 13815.* Accepted for publication March 12, 1984.

Abstract □ An impurity present in all commercial guaifenesin-containing dosage forms examined was isolated and identified as 2-(2-methoxyphenoxy)1,3-propanediol (VI). The eluant of a previously developed stability-indicating liquid chromatographic method for phenylephrine hydrochloride (I), phenylpropanolamine hydrochloride (II), and guaifenesin (III) was modified to yield a better separation between phenylpropanolamine and the impurity. The method was expanded to include sodium benzoate (IV), a preservative found in some liquid formulations.

Keyphrases □ Guaifenesin—synthetic impurity, HPLC with phenylephrine hydrochloride, phenylpropanolamine hydrochloride, and sodium benzoate

A stability-indicating reverse-phase high-performance liquid chromatographic (HPLC) method for phenylephrine hydrochloride (I), phenylpropanolamine hydrochloride (II), and guaifenesin (III), primarily in capsule formulations, was recently presented (1). However, on further examination of a wide variety of capsule, tablet, and liquid formulations from various manufacturers, it became evident that all chromatograms of products containing III (and even standard III solutions) yielded an impurity that eluted immediately following the II peak. In early method development work involving the capsule formulations, the peak area of this III impurity was only slightly more than 2% of the area of II (~0.2% of the III area) and barely discernable in the tail of the II peak (*cf.* Fig. 2 of Ref. 1). The separation was sufficient to yield good analytical data. However, impurity peak areas were later observed in other commercial formulations that were >20% of the area of the II peak. Because of the relatively large amount of the III impurity in some formulations, the ubiquitous nature of the impurity, and the danger of loss of resolution between II and the impurity for less efficient columns, both elucidation of the impurity structure and modification of the chromatographic eluant system to yield better resolution between II and the impurity were sought.

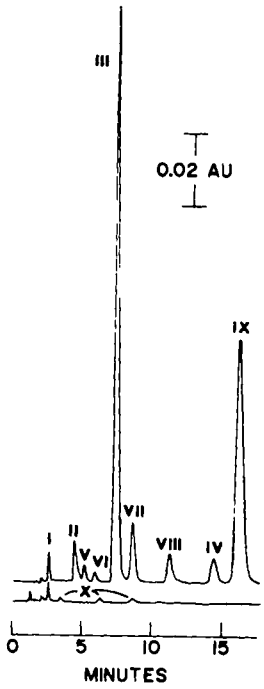

Figure 1—*Chromatogram of 40 μg/mL of phenylephrine hydrochloride (I), 400 μg/mL of phenylpropanolamine hydrochloride (II), 1.8 mg/mL of guaifenesin (III), 40 μg/mL of benzoic acid (IV), and possible impurities and degradants: 1 μg/mL of α-aminopropiophenone (V), 20 μg/mL of 2-(2-methoxyphenoxy)-1,3-propanediol (VI), 4 μg/mL of* m*-hydroxybenzaldehyde (VII), 100 μg/mL of guaiacol (VIII), 40 μg/mL of benzaldehyde (IX), and forced degraded phenylephrine hydrochloride products (X).*

pared according to a general procedure for synthesis of α-glyceryl phenyl ethers (3). Recrystallization from ethyl acetate–hexane yielded a white powder, mp 80–82°C [lit. (4) mp 76–78°C]. IR (KBr): 818 cm^{-1} (*para*-substituted benzene ring); otherwise, the spectrum was similar to that for III.

Degradation products of I were formed by storing I in 0.5 M KOH at 80–90°C for 1 week (1).

Apparatus—The HPLC apparatus described previously (1) was used. The system used for quantitative assay of I, II, III, and the preservative sodium benzoate [as benzoic acid (IV)] consisted of an absorbance detector at 254 nm, a 20-μL loop injector, and a C_8 column[2] pumped at 2.0 mL/min with an eluant containing 50 mL of methanol, 170 mL of acetonitrile, 755 mL of water, and 25 mL of pentanesulfonic acid sodium salt in glacial acetic acid[3]. The resulting eluant was 5 mM in ion-pairing salt and 1.7% in acetic acid. The HPLC system used for collection of the impurity consisted of a C_{18} column[4] with water–methanol (80:20) as eluant at a 1.5-mL/min flow rate. To collect the impurity, 10 fractions from 100-μL injections of a 107-mg/mL aqueous solution of III were collected from the chromatographic region just prior to the elution of the III peak. The combined fractions were evaporated to a total volume of 1 mL.

A GC apparatus[5] was used with a photoionization detector at 10.2 eV and a 1.8 m × 2 mm i.d. glass column packed with 3% OV-17 on Chromasorb G-HP. Both III and the collected impurity were treated with *n*-butylboronic acid for 30 min. One microliter or less of both derivatized and underivatized solutions were injected at a column temperature of 200°C and nitrogen flow rate of 25 mL/min.

^{1}H-NMR spectra were obtained on an 80-MHz Fourier-transform instrument[6]. Samples were dissolved in 99.96 atom-%D hexadeuterated acetone with tetramethylsilane as internal standard. IR spectra were obtained from KBr pellets with a Fourier-transform instrument[7].

Standard Solution Preparation—The final HPLC method used aqueous standard solutions containing 0–0.1 μg/mL of I, 0.24–0.45 μg/mL of II, 2–5.6 μg/mL of III, and 0–0.12 μg/mL of IV, depending on the label claim of the dosage form assayed.

Sample Preparation—For the capsule and tablet samples not containing I, 200 or 300 mg of ground sample was leached with water or mobile phase and diluted to 50 mL. For capsule samples containing I, to obtain a more homogenous sample, 1–1.3 g of ground sample was leached with water and diluted to 250 mL. The samples were injected directly after a 10-min sonication and 5-min centrifugation at 2500 rpm. For the liquid samples, 4.0–25.0 mL (depending on label claim) was diluted to 250 mL with water and then injected directly.

Table I—Area Linearity

Parameter	Phenylephrine Hydrochloride	Phenylpropanolamine Hydrochloride	Guaifenesin	Sodium Benzoate[a]

Intercept, %[b]	−0.3	0.7	1.4	1.4
Variation, %[c]	0.7	0.6	1.2	1.2

[a] As benzoic acid. [b] (y-Intercept/$\bar{y}$) × 100, where $\bar{y}$ is the average y. [c]($S_{y/x}$ / $\bar{y}$) × 100.

RESULTS AND DISCUSSION

Elucidation of Impurity Structure—Gas chromatograms of both derivatized and underivatized III and collected impurity samples revealed that cyclic butylboronate derivatization increased the retention time of both compounds by ~50%. This indicated that, like III, the impurity required two hydroxyl groups, no more than one carbon atom apart, for formation of the cyclic butylboronate derivative (5). Logical possibilities included the *para* isomer of III and 2-(2-methoxyphenoxy)-1,3-propanediol (VI). The former was immediately excluded since it was found to possess nearly the same HPLC retention time as III.

^{1}H-NMR of both the collected impurity and the synthesized compound (VI) in hexadeuterated acetone yielded practically identical spectra, provided the concentration of the synthesized compound was dilute (≤1 mg/mL)[8]. Intermolecular hydrogen bonding resulted in peak shifts in the spectra at higher concentrations.

The collected impurity sample was lyophilized to remove the eluant and pressed into a KBr pellet. The IR spectrum of the impurity was practically identical to that of the synthesized compound, again provided that the concentration of the synthetic compound was low enough to minimize hydrogen bonding effects[8].

HPLC of the synthesized compound using both C_8 and C_{18} columns yielded a retention time identical to that for the impurity observed in III samples. The ratio of molar absorptivities of III to VI at 254 nm was found to be 1:1.

Modification of the Liquid Chromatographic Stability-Indicating Assay—Any HPLC system developed should be specific for the analytes I, II, III, and IV with respect to the following known and postulated impurities and degradation products (1): α-aminopropiophenone (V), a precursor and postulated (but so far undetected) trace impurity of II; 2-(2-methoxyphenoxy)-1,3-propanediol (VI), the identified III impurity; *m*-hydroxybenzaldehyde (VII), an observed degradation product of I; guaiacol (VIII), an observed hydrolysis product of III; benzaldehyde (IX), an observed hydrolysis product of II; forced-degradation products of I (X).

To achieve the desired resolution between II and VI and maintain the separation from the above compounds, the organic modifier of the original eluant system (1) was changed from 30% methanol to 5% methanol and 17% acetonitrile (Fig. 1). The separation was maintained on several C_8 columns, including one that had seen heavy use. An internal standard was not deemed necessary, due to the high precision obtained with fixed-loop injectors.

The linearity data for I, II, III, and IV, determined by plotting peak areas *versus* standard weights, are presented in Table I. Linearity was observed over the ranges of 0.4–3.4 μg for I, 3.3–31 μg for II, 14.5–138 μg for III, and 1–9.3 μg for IV.

Assay of 12 synthetic capsule samples made by spiking placebo with solutions containing known amounts of standard I, II, and III at levels of 50–150% of the theoretical values yielded average recoveries and *RSD* values of 99.8

± 1.1%, 99.7 ± 1.2%, and 99.3 ± 1.0%, respectively. Similarly, assays of 12 synthetic liquid samples for II, III, and IV yielded average recoveries and *RSD* values of 99.7 ± 1.5%, 100.1 ± 1.5%, and 100.5 ± 1.5%, respectively.

The assay results for I, II, III, and IV in several commercial dosage forms representing liquid, tablet, and capsule preparations are presented in Tables II and III. In addition, assay values for VI (as percentage of III concentration) in seven different formulations from six different manufacturers are also presented in Table III. The impurity VI was observed in each formulation examined at concentrations ranging from 0.2 to 2.3% of the III concentration.

The widespread distribution of VI in formulations containing III prompted assessment of the potential toxicity of VI. According to literature data (16), when administered to mice, impurity VI is actually less toxic [mean paralyzing dose (PD_{50}) = 800 mg/kg, mean lethal dose (LD_{50}) = 1710 mg/kg] than III (PD_{50} = 320 mg/kg, LD_{50} = 1200 mg/kg). This information, coupled with the similarity in structure between III and VI, indicates the potential toxicity of VI is minimal.

Ethylene–Vinyl Acetate Copolymer Microspheres for Controlled Release of Macromolecules

MICHAEL V. SEFTON *, LARRY R. BROWN ‡, and ROBERT S. LANGER ‡x

Received May 26, 1983, from the *Department of Chemical Engineering and Applied Chemistry, University of Toronto, Toronto, Ontario M5S 1A4, the ‡Department of Nutrition and Food Science and Whitaker College of Health Sciences and Technology, Massachusetts Institute of Technology, Cambridge MA 02139 and the Department of Surgery, Children's Hospital Medical Center, Boston MA 02115. Accepted for publication March 26, 1984.

Abstract □ A simple technique has been devised for preparing ethylene–vinyl acetate copolymer microspheres containing macromolecular drugs. Beads with good sphericity were formed by a simple extrusion process that can easily be repeated by any laboratory without special equipment. The extruded droplets gelled on immediate contact with cold ethanol in a dry ice–ethanol bath. The ethanol also served to remove the solvent and harden the microspheres as they warmed to room temperature. Release of bovine serum albumin followed the expected trends, *i.e.*, initial linearity with the square root of time and faster release rates with greater drug loading.

Keyphrases □ Microencapsulation—ethylene–vinyl acetate copolymer microspheres, release kinetics, sustained release systems □ Ethylene–vinyl acetate copolymer microspheres—drug delivery, release kinetics

Monolithic systems composed of ethylene–vinyl acetate copolymer have been used for the controlled delivery of macromolecular drugs such as insulin (1), heparin (2), enzymes (3), DNA (2), tumor angiogenesis factor (2) and its inhibitor (4), and has provided a basis for various bioassays (5–7) and chemotactic studies (8). In all these cases, the drug and polymer solution were mixed together and cast as a film on a precooled plate to yield a matrix device in the form of a slab (~5 × 5 cm, 0.75–1.75 mm thick), which could be further divided into 1 × 1 cm squares (9). These systems have been designed to release at decreasing rates (9), constant rates (10), and increasing rates (11).

A new procedure is described here for making nearly spherical beads of ethylene–vinyl acetate copolymer for controlled release of macromolecular drugs. Such microspheres may prove to be useful as an injectable dosage form. In addition, the simplicity of the technique may facilitate its widespread application in new areas.

EXPERIMENTAL SECTION

Microsphere Preparation—Microsphere preparation is shown diagrammatically in Fig. 1. Ethylene–vinyl acetate copolymer[1] (40% vinyl acetate) was washed in water and ethanol[2] (12) and dissolved in methylene chloride[3] to give a 10% (w/v) solution. Bovine serum albumin[4] was sieved[5] to give 106–150-μm particles. The polymer solution (2 mL) was added to a weighed amount of powder in a 5-mL glass vial[6] and the mixture was vortexed[7] to give a uniform suspension. The mixture was quickly drawn into a disposable 3-mL syringe[8] *via* a 1.27-cm 16-gauge needle[9] that had been trimmed to a blunt end with a standard machine shop grinder wheel. After vortexing again for a few seconds, the suspension was carefully extruded through the same 16-gauge needle drop by drop into 20 mL of cold unstirred absolute ethanol in a 50-mL beaker immersed in a dry ice–ethanol bath (−78°C). The mixture gelled virtually immediately on contact with the cold ethanol in the near-spherical shape of the droplets, and the hard, gelled spheres sank to the bottom of the beaker. The mixture was extruded as quickly as possible drop by drop to minimize methylene chloride evaporation and plugging of the needle. It was also found that extrusion was facilitated by conducting it outside of a fume hood. Microspheres were prepared with loadings of 10–50% protein by weight.

After 5–10 min, the beaker containing the microspheres was removed from the dry ice bath and allowed to warm to room temperature. The microspheres turned white as the solvent was extracted into the ethanol. After ≥1 h, the liquid was replaced with ~10 mL of fresh ethanol and set aside overnight in a 20-mL glass vial[6]. The ethanol was decanted and the microspheres were dried for 4–5 h in a vacuum desiccator. The duration of the various process steps were not considered critical as long as solvent and ethanol removal was largely complete. For example, removal of the microspheres from the cold ethanol immediately after extrusion caused the microspheres to agglomerate since insufficient methylene chloride had been removed for the microspheres to remain gelled at room temperature.

Release Kinetics—A 30–50-mg aliquot of microspheres was weighed and placed in a vial containing 10 mL of saline (0.154 M NaCl[10]) at room temperature (23°C). The liquid was sampled periodically and the concentration of protein was determined spectrophotometrically[11] at 280 nm. Each sample was returned to the vial after measurement. Release was monitored in duplicate for a period of 6 d; release values were within ≤10% of the mean.

Bead Characterization—Dry microspheres were sliced with a razor blade, mounted on studs using silver paint, sputter coated, and examined by scanning electron microscopy[12]. Average bead diameter was estimated with the aid of a metallograph microscope[13] at low magnification (15×).

RESULTS AND DISCUSSION

The formation of polymer microspheres by precipitation of a polymer solution in contact with a nonsolvent is a standard microencapsulation technique (13). A process based on this technique and the extrusion of the polymer solution in a dropwise manner into a nonsolvent for the preparation of controlled-release formulations was patented by Sternberg *et al.* (14). This procedure did not work for our system: the extruded droplets of methylene

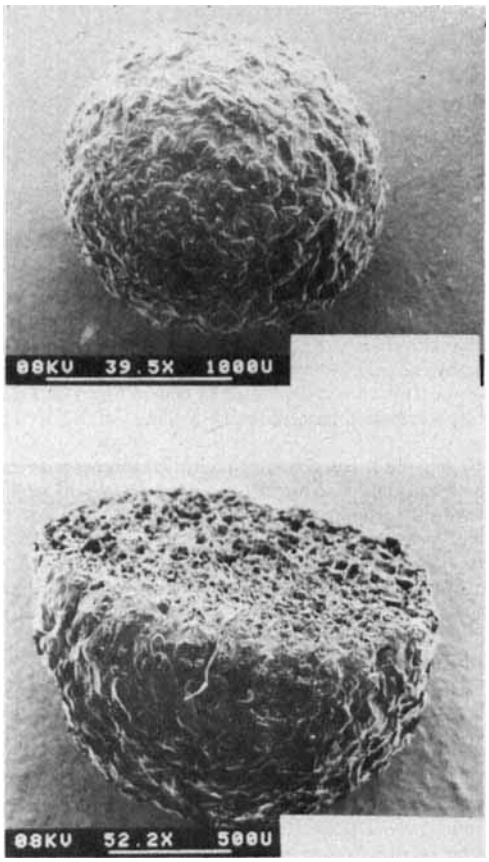

Figure 2—*Scanning electron micrographs of a whole microsphere, and a microsphere sliced with a razor blade, both containing 50% (w/w) albumin.*

chloride solution of polymer-containing dispersed protein lost their shape on contact with ethanol at room temperature; the polymer precipitated as a shapeless coagulum on the bottom of the beaker. Regularly shaped beads could be formed only by extruding into cold ethanol. Presumably, the polymer solution gelled rapidly on contact with the cold ethanol, preserving the shape of the droplets and giving time for the methylene chloride to slowly diffuse into the surrounding ethanol.

Beads prepared from 10% polymer in methylene chloride were almost perfectly spherical immediately after formation in cold ethanol. As the beads warmed and methylene chloride was removed, the polymer became softer and more easily deformed. The beads flattened slightly and became more ellipsoidal; this was accentuated for the beads with low loadings of albumin [*i.e.*, <20% (w/w) albumin]. The softness of the beads with lower albumin loadings was noted particularly when they were dry; it was difficult to handle the beads with forceps or a spatula without further changing their shape. Since these lower loading beads were also tacky (in the "dry" state), they stuck to the walls of glass or plastic containers and further increased handling difficulties. Scanning electron micrographs of beads containing 50% (w/w) bovine serum albumin are shown in Fig. 2, illustrating the sphericity of these beads.

When a 5% solution of ethylene–vinyl acetate copolymer in methylene chloride was used to fabricate the microspheres, it was less viscous than the 10% solution and, therefore, easier to use in making microspheres with high drug loading. However, this 5% solution resulted in beads with poorly defined shapes. Beads with 50% drug loading were teardrop shaped while smaller loadings (<20%) resulted in large aggregates of irregularly shaped beads. It appeared that the low ratio of polymer to solvent in these beads resulted in a slower cold ethanol solidification process than when beads were made from a 10% polymer solution. Consequently, the beads could be deformed and changed shape while the newly formed beads sank to the bottom of the cold ethanol. The beads with 50% loading were not as easily deformed so that only a small tail was produced while the beads with lower loadings were still tacky at the bottom of the cold ethanol and stuck to the previously formed beads. The most desirable shape was obtained with the 10% solution; thus, kinetic studies were conducted with the beads made from this solution. An intermediate concentration may be a better compromise between low polymer–drug mixture viscosity and good bead shape, particularly for higher drug loadings.

Table I—Estimated Microsphere Diameter

30	1.43
50	1.37

[a] Average of 10–20 beads; precision = ±0.07 mm.

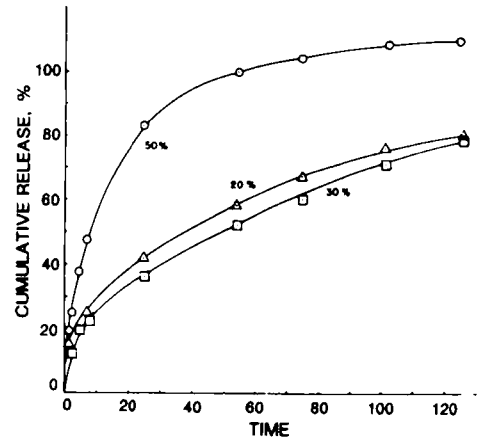

Figure 3—*Cumulative release of albumin from ethylene-vinyl acetate microspheres. Values are the mean of two measurements; release values were within ≤10% of the mean.*

The average size of microspheres made from a 10% solution are listed in Table I. As expected, the less drug in the microspheres and therefore the more polymer and solvent, the smaller (in general) the microspheres. Although the initial bead size was determined by the extruding needle diameter (16-gauge needle, 1.19 mm i.d. × 1.65 mm o.d.), the lower loading microspheres shrank more in the cold ethanol since there was more solvent to remove. The microspheres were reasonably uniform in size despite the crude nature of the extrusion process: the variation in bead size was less than the ±0.07-mm precision of the metallograph measurements. It is expected that greater microsphere uniformity could be obtained with better blending of the drug and polymer solution and by using a syringe pump to extrude the drug–polymer mixture at a constant rate.

Only to a limited extent can smaller microspheres be prepared effectively by using a smaller gauge needle, or by using a lower polymer concentration. For example, microspheres with 30% albumin were ~1.20 mm in diameter when prepared with a 20-gauge needle. However, viscosity effects and the need to grind the drug into even finer particles limit this approach, while some deterioration in bead shape may need to be tolerated if less concentrated polymer solutions are used. Smaller beads may be prepared more readily by a vibratory prilling process (15) or by blowing droplets off the end of a needle by a coaxial air stream (16). In the latter case it would be necessary to prevent the volatile methylene chloride from evaporating before the droplets leave the needle.

Typical release kinetics are shown in Fig. 3 as a plot of cumulative release against time. The release kinetics for 10% loading were not included because of the irregular shape of the beads and the difficulties in handling them.

The kinetic data is consistent with previous studies with this macromolecule-controlled release system (3). Cumulative release is generally greater at any time (*i.e.*, faster release rate) with higher drug loadings. This is presumed to result from the greater porosity of the polymer matrix at higher drug loadings (9). The seemingly faster initial release for the 20% albumin-loaded spheres compared with the 30% loaded matrices (Fig. 3) was not considered statistically significant. The release of albumin from the beads was relatively rapid with one-half of the content released in 50 h. In retrospect, such a release rate might have been predicted on the basis that a 1.0-cm thick slab of similar composition released one-half of its drug from a single face in 28 d (17). The differences in the time to release half of their content are completely attributable to the differences in the sizes and shapes of the two matrix preparations (especially the sizes).

The particle sizes of the albumin particles (106–150 μm) were ≤15% of the diameter of the microspheres themselves. It is probable that a significant portion of the albumin merely dissolved from the surface of the bead when the microspheres were placed into release media. Thus, this early burst of drug

from the microsphere can be primarily attributed to dissolution of drug from the surface with a minor contribution of matrix diffusion of albumin. To slow the release rate to levels practical for long term therapy, the beads can be coated with polymer containing no drug. A sevenfold decrease in release rate was observed after coating insulin-containing slabs with 20% ethylene-vinyl acetate solution (9).

The microsphere preparation technique can be used for other drugs and polymers other than ethylene-vinyl acetate, but it is important that the polymer-solvent solutions have glass transition temperatures > −78°C. Nonsolvents for the polymer, other than ethanol, could be used as long as they do not freeze at −78°C. In addition, the low-temperature nature of the process makes it ideally suited for thermally labile compounds that cannot be processed at the higher temperatures of conventional prilling processes [*e.g.*, 60°C for gelatin encapsulation (18)].

Comparison of ^{99m}Tc-*N*-Pyridoxyl-5-Methyltryptophan and ^{99m}Tc-*N*-(3-Bromo-2,4,6-trimethylacetanilide)-Iminodiacetate as Hepatobiliary Radiopharmaceuticals in Rats

ALAN R. FRITZBERG *§x, DUANE C. BLOEDOW ‡, DENNIS ESHIMA *, and DENNIS L. JOHNSON *

Received June 13, 1983, from the **Department of Radiology, University of Colorado, Health Sciences Center, Denver, CO 80262* and the ‡*School of Pharmacy, University of Colorado, Boulder, CO 80309.* Accepted for publication March 21, 1984. §Present address: NeoRx Corporation, Seattle, WA 98119.

Abstract □ ^{99m}Tc - *N* - (3-bromo-2,4,6-trimethylacetanilide)iminodiacetate (I) and ^{99m}Tc-*N*-pyridoxyl-5-methyl-tryptophan (II) have been described as having optimal properties as hepatobiliary radiopharmaceuticals. This study compared specificity for hepatobiliary excretion, blood disappearance, rates of biliary appearance, and pharmacokinetic parameters including hepatic clearance, volumes of distribution, and mean residence times in normal and sulfobromophthalein-treated rats. The specificity of I was higher as indicated by 94% in the bile at 90 min compared to 91% for II in normal rats and a urine excretion of 0.3% for I compared with 1.9% for II. In sulfobromophthalein-treated animals, urine excretion increases were only to 0.5 and 3.0% for I and II, respectively. In control rats, blood disappearance was similar for both I and II, but II disappeared faster in treated animals. The clearance of II was 70 mL/min/kg in normal and 47 mL/min/kg in treated rats; clearance of I was 51 and 30 mL/min/kg in normal and treated rats, respectively. Volumes of distribution were larger for II. Compound I was superior in specificity while II was superior in clearance and excretion kinetics.

Keyphrases □ Hepatobiliary radiopharmaceuticals—^{99m}Tc-labeled compounds compared, sulfobromophthalein-treated and normal rats □ Radiopharmaceuticals—^{99m}Tc-labeled hepatobiliary compounds compared, sulfobromophthalein-treated and normal rats □ Sulfobromophthalein—effect on hepatobiliary radiopharmaceuticals, rats

Efforts to develop an optimal ^{99m}Tc-labeled hepatobiliary agent (I) have followed either a series beginning with ^{99m}Tc-labeled pyridoxylidene glutamate (2) or ^{99m}Tc-*N*-(2,6-dimethylacetanilide)iminodiacetate (3). These studies have resulted in improvements in hepatobiliary specificity, kinetics, and resistance to transport competition from elevated bilirubin levels. The currently "best" agents, based on animal and clinical studies, are ^{99m}Tc-*N*-(3-bromo-2,4,6-trimethylacetanilide)iminodiacetate (I) (4, 5) and ^{99m}Tc-*N*-pyridoxyl-5-methyltryptophan (II) (6).

To try to answer the question of which agent is superior, short of clinical paired comparisons in normal volunteers and patients, we have carried out detailed studies in rats. These studies were designed to compare rates of blood disappearance, rates of biliary appearance, specificity for hepatobiliary excretion, hepatic clearance of the complexes, and ability of the

agents to compete with sulfobromophthalein as a member of the dye anion and bilirubin pathway for hepatobiliary excretion.

EXPERIMENTAL SECTION

Radiopharmaceutical Preparation—Kits for the preparation of I for animal use were obtained as a gift[1]. They were prepared by the addition of 2–3 mL of generator eluate saline containing [^{99m}Tc]pertechnetate at a concentration of ~5 mCi/mL. The percent of ^{99m}Tc-radioactivity bound to the ligand was determined by TLC[2]. Saturated sodium chloride was used to develop silicic acid strips (R_f of pertechnetate = 1, R_f of I = 0–0.2) for the determination of free [^{99m}Tc]pertechnetate. An acetonitrile–water mixture (3:1) was used to develop silica gel strips (R_f of pertechnetate and I = 1, R_f of insoluble radioactive material = 0) for the determination of insoluble activity. The percent bound was calculated as 100 − (percent [^{99m}Tc]pertechnetate + percent insoluble radioactivity). Values were ≥98%. The ligand of II was supplied[3]. The preparation of kits for II was performed essentially as described (6). Radioactivity was added to a thawed kit (~30–50 mCi to 1.0 mL of kit volume) and the vial was heated in a boiling water bath for 30 min. At that time, small amounts of free pertechnetate were sometimes present. A 250-μL aliquot was therefore purified by HPLC to remove any free pertechnetate or insoluble radioactive material. Chromatographic conditions were: 0.01 M sodium phosphate buffer (pH 6) and acetonitrile with a gradient of 20–70% acetonitrile programmed over 20 min at a flow rate of 1.0 mL/min on an ODS column[4]. Fractions from three different peaks were collected without fractionation at 8–10 mL eluate volume [these fractions were shown to contain stereoisomeric chelate isomers that were only slightly different in their biological properties (7)]. The eluate was collected in a tube containing 1.5 mg of freshly dissolved ascorbic acid, as an antioxidant stabilizer, in 1 mL of water. Fifteen- to twenty-fold dilutions were made with saline containing 1 mg/mL ascorbic acid. The final injection volume of 0.25 mL contained ~50 μCi.

Animal Studies—Male Sprague–Dawley rats (300–430 g) were anesthetized with sodium pentobarbital. Catheters were placed in the femoral vein for injections, hydration, and infusions and in the carotid artery for blood sampling. The common bile duct was cannulated and bile was collected in tubes in a fraction collector. The body temperature of the rats was maintained at 37°C with external heat from a lamp. For competitive studies, sulfobromophthalein was infused at a transport maximum level of 2.5 μmol/min/kg for 15 min prior to and for 60 min postinjection of the radiopharmaceutical (8). The infusion flow rate was 0.1 mL/min. Urine normally was retained in the bladder during the 90-min studies. At that time the bladder was tied off, removed, and counted together with portions of the urinary tract that might contain urine. Bile and urine samples were counted in a well counter with appropriate dose standards. Total blood volume was assumed to be 7% of body weight (9). Blood samples of 0.3–0.4 mL were taken at 1, 2, 3, 4, 5, 6, 9, 12, 15, 20, 25, 45, 60, 75, and 90 min postinjection. Bile samples were collected at 0 and 2 min and then at 4-min intervals to 90 min postinjection.

Pharmacokinetic Calculations—Blood radioactivity concentration (cpm/mL of blood) *versus* time curves for each animal were used to calculate distribution volume, blood clearance, and mean residence time using standard methods (10, 11). All comparisons were made using Student's *t* test (12).

RESULTS

The preparations of II were purified by HPLC to remove unbound label as pertechnetate. This was necessary because the presence of small amounts of oxygen during the heating period decomposed some of the chelate and reoxidized the technetium. The isomeric chelated forms were not separated since they have been shown to have small *in vivo* differences (7) and ultimate use of this preparation in clinical situations would not involve HPLC purification (hence no possibility for separation of chelate forms).

Blood disappearance curves for the radioactivities of I and II under normal and sulfobromophthalein conditions are shown in Figs. 1 and 2. In control rats, II levels were somewhat lower in the first 5 min while I levels were slightly lower afterwards. Both compounds are rapidly cleared with <1% of the injected dose remaining in the blood at 14 min for I and at 18 min for II. In rats treated with sulfobromophthalein the blood disappearance of both compounds was slowed; however, the disappearance of II was faster than that of I at all times.

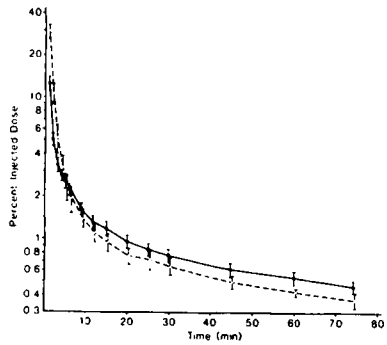

Figure 1—*Disappearance of radioactivity from I (- -○- -) and II (-●-) from blood of normal rats. Data are plotted as mean* ± SEM (n = 5) *and represent percent of injected dose remaining in total blood.*

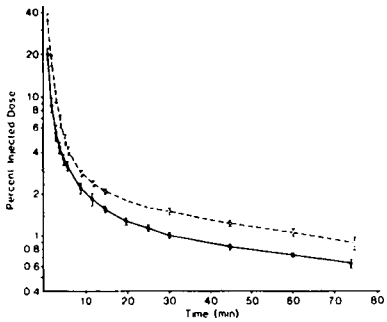

Figure 2—*Disappearance of radioactivity from I (- -○- -) and II (-●-) from the blood of rats treated with sulfobromophthalein. Data are plotted as mean* ± SEM (n = 5) *and represent percent of injected dose remaining in total blood.*

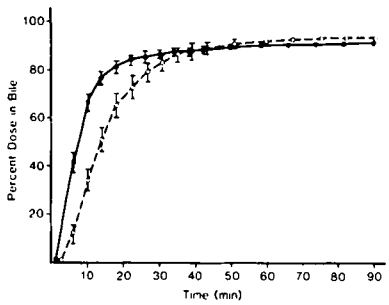

Figure 3—*Comparative rates of appearance of radioactivity from I (- -○- -) and II (-●-) in bile in normal rats. Data are plotted as mean* ± SEM *of percent of injected dose.*

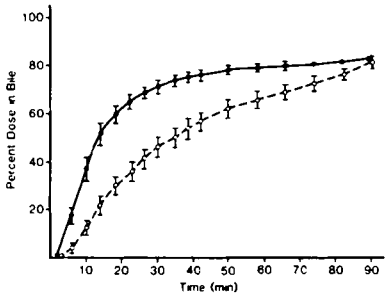

Figure 4—*Comparative rates of appearance of radioactivity of I (- -○- -) and II (-●-) in bile of rats treated with sulfobromophthalein. Data are mean* ± SEM (n = 5) *percent of injected dose.*

Bile cumulative radioactivity curves for the radiopharmaceuticals are shown in Figs. 3 and 4. In normal rats II appeared significantly faster. Forty-one percent of the dose of II was found in the bile by 6 min compared with 12%

Table I—Excretion and Pharmacokinetic Parameters of Hepatobiliary Agents in Control and Treated Rats [a]

Radiopharmaceutical	Urine Excretion, %[b]	Biliary Excretion, %[b]	CL_t, mL/min/kg	Vd, mL/kg	Mean Residence Time, min
I					
Control	0.27 ± 0.08	93.86 ± 1.13	50.8 ± 4.6	743 ± 73[c]	14.6 ± 0.56[c]
Sulfobromophthalein	0.47 ± 0.08	81.02 ± 1.48	29.5 ± 0.93[c]	564 ± 36	19.2 ± 1.00
II					
Control	1.89 ± 0.25	91.45 ● 1.30	70.0 ± 8.0	1695 ± 209	24.1 ± 0.51
Sulfobromophthalein	3.00 ± 0.39	81.98 ± 1.17	46.8 ± 2.7	1042 ± 88	22.1 ± 0.89

[a] Data are mean ± *SEM*. [b] Urine and biliary excretion are percent injected dose at 90 min postinjection. [c] Statistically significant difference ($p < 0.05$) from II (sulfobromophthalein).

for I. Comparative values at 10 min were 66 and 34%; by 40 min, equivalent percentages of each had been excreted. The high final values indicate the high specificity of both compounds.

In sulfobromophthalein-treated animals the rates of appearance of radioactivity in the bile were significantly decreased. Moreover, the differences between compounds I and II were more marked in treated animals than controls. Over the first 20 min II appeared at a lower rate than in the normal animals, but essentially at the same rate as I in normal animals.

Quantitative comparisons of renal and hepatobiliary excretion of the complexes and pharmacokinetic parameters are shown in Table I. Both agents exhibited high specificity for hepatobiliary excretion. However, the percentage of I (94.9%) was higher than II (91.4%) in bile. This was consistent with a lower renal excretion of I (0.27% compared with 1.89% for II). In animals treated with sulfobromophthalein, biliary excretion was reduced for both radiopharmaceuticals to ~82% at 90 min. Conversely, renal excretion at 90 min was increased for both, but only by a small percentage (from 0.3 to 0.5% for I and from 1.9 to 3.0% of the injected dose for II).

Statistically, the blood clearances for I and II were not significantly different for the controls ($p < 0.05$). Since both agents are highly specific for hepatobiliary excretion, the correction of blood clearances for renal clearances was considered negligible. The magnitude of clearances for the two agents indicates efficient hepatobiliary excretion of both agents at rates which would depend primarily on hepatic blood flow. The clearances of both II and I were reduced in the presence of sulfobromophthalein. In this case the difference in clearance values was statistically significant ($p < 0.05$). The distribution volume for II was greater than that for I ($p < 0.05$) and the volumes of both compounds were decreased during the administration of sulfobromophthalein.

The mean residence time (MRT) for II was greater than the MRT for I ($p < 0.05$). The MRT is directly related to distribution volume and inversely related to blood clearance (MRT = distribution volume/blood clearance). Thus, although the hepatobiliary excretion (blood clearance) of II is more efficient than that of I, the II distribution volume is greater, resulting in a greater MRT for II. Caution should be exercised however, since interpretations of MRT values are difficult if the clearing organ (in this case the liver) is also responsible for significant distribution of the compound (13).

DISCUSSION

Both of the ^{99m}Tc-labeled hepatobiliary agents evaluated here are the result of the synthesis and biological study of a long series of chelating agents beginning with *N*-(2,6-dimethylacetanilide)iminodiacetate for I and pyridoxylidene glutamate for II. They both rate highly with regard to the clinical objectives of rapid hepatocyte uptake from the blood, short hepatocyte transit times, high specificity for hepatobiliary excretion, and ability to be taken up and excreted by the liver with high specificity in the presence of bilirubin or other competing transport pathway members. The questions of this study are whether or not one agent is significantly superior and whether or not a comparative evaluation in animals can indicate which will be superior in clinical use.

In this study sulfobromophthalein was used as a model for the determination of the ability of these technetium complexes to be taken up and excreted by the liver in the jaundiced or hyperbilirubinemic patient. A more direct way would have been to use bilirubin. However, it has been difficult to achieve sufficiently high serum bilirubin levels for significant effects on the transport of ^{99m}Tc-labeled iminodiacetate radiopharmaceuticals without causing toxic reactions (14, 15). The secretion of bilirubin is competitively inhibited by sulfobromophthalein (16) and many examples of similar effects on the transport of bilirubin and sulfobromophthalein are known (17). In addition, studies in isolated hepatocytes, in which sulfobromophthalein and bilirubin were separately added, both were reported to have comparable effects on the uptake of ^{99m}Tc-labeled iminodiacetate complexes by the hepatocytes (14).

Short hepatocyte transit times result in a "bolus" effect on the passage of radioactivity from liver to bile. This effect allows imaging of the hepatic ducts superimposed on the liver and often provides information on the location of problems in the biliary ductule network (14). The data from these studies demonstrate that with similar blood disappearance rates and thus hepatic uptake,the more rapid biliary excretion of II results in an advantage in bile-to-liver ratio comparisons.

Under normal liver function conditions the blood disappearance rates of both agents were similar. The bile appearance of II was significantly faster and indicates a shorter hepatocyte transit time for II. Final values of collected activity in the bile were consistent with their reported specificities for hepatobiliary excretion (4, 6).

Studies in which the transport capacity of the liver was stressed by sulfobromophthalein resulted in greater differences between the complexes. Under this condition the blood percent dose values for II were lower at all times and biliary excretion differences were more marked than in normal control studies. Thus, II was superior in its uptake and excretion in competition with sulfobromophthalein and, as such, appears to have a higher affinity for the transport proteins.

The results of these studies support a small specificity superiority for I and a significant kinetic superiority for II as hepatobiliary radiopharmaceuticals. However, species differences are well known (18) and it must be emphasized that there is still a need to compare these agents in humans.

Agonist–Antagonist Actions and Stereoselectivity of Optical Pairs of Some *N*-Substituted α-*N*-Normetazocines

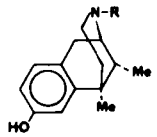
MARIO D. ACETO *, EVERETTE L. MAY *x, LOUIS S. HARRIS *, ARTHUR E. JACOBSON ‡, and HIROYOSHI AWAYA *§

Received November 21, 1983, from the *Department of Pharmacology, Medical College of Virginia, Virginia Commonwealth University, Richmond, VA 23298 and the ‡National Institutes of Health, Bethesda, MD 20205. Accepted for publication March 21, 1984. §Present address: 1-Ku Maragouchi Onoda, Yamaguchi 756 Japan

Abstract □ α-(−)-, (+)-, and (±)-*N*-4-Methylpentyl-, (−)- and (+)-*N*-*cis*-3-chloroallyl-, and (−)- and (+)-*N*-propynyl-*N*-normetazocine (I, II, and III, respectively) have been prepared from α-(−)-, (+)-, and (±)-*N*-normetazocine (IV) and tested for antinociceptive activity in mice and in morphine-dependent rhesus monkeys. The results obtained with Ia and b somewhat resemble the results obtained with the corresponding phenazocine isomers, whereas those observed with IIa and b more nearly correspond with those reported for (+)- and (−)-*N*-allyl-*N*-normetazocine (SKF 10,047; NANM). The propynyl isomers (IIIa and b) display profiles of activity more closely like the corresponding isomers of metazocine. Evidence is considered which suggests that some of the (+)-isomers merit closer scrutiny in animal and human studies.

Keyphrases □ α-Normetazocine—alkylation, optical pairs, antagonism, antinociception, psychotomimetic, mice, morphine-dependent rhesus monkeys □ Antagonists—α-normetazocine, alkylation, antinociception, psychotomimetic, mice, morphine-dependent rhesus monkeys

N-Substituted *N*-normetazocines of the α-series[1] (1) have attained importance not only in current medicine[2] but also in behavioral studies (2) and as receptor probes (3). Optical pairs are of particular interest (2–4). The present note describes the chemistry and some basic pharmacology of three optical pairs and one racemate belonging to the α-series.



I: R = $(CH_2)_3CHMe_2$
II: R = $CH_2CH{=}CHCl$ (Cis)
III: R = $CH_2C{\equiv}CH$
IV: R = H

a = (+), b = (−), c = (±)

EXPERIMENTAL SECTION

Chemistry[3]—The compounds were synthesized by alkylation of α-*N*-normetazocine (IV) using a tetrahydrofuran–dimethylformamide solvent mixture[4] and the halides 4-methylpentyl bromide for I, *cis*-1,3-dichloropropene for II, and propynyl chloride for III. Potassium carbonate or potassium bicarbonate was the hydrogen bromide or hydrogen chloride acceptor. Antipodes IIa and IIb were also prepared by optical resolution of α-(±)-3-*cis*-chloropropenyl-*N*-normetazocine (IIc) (5)[5] with *d*- and *l*-mandelic acids.

Mouse Antinociception Tests—Male mice weighing 20–30 g were used. All drugs were administered as salts, dissolved in distilled water, and administered subcutaneously in a volume of 0.1 mL/10 g of body weight. At least three doses per curve were tested and 6–10 animals per dose were used. ED_{50} values were calculated using computerized probit analysis.

Tail-Flick (TF) Tests—The procedure and modification (6) have been described. Briefly, the mouse tail was placed in a groove which contained a slit under which was a photoelectric cell. When the heat source or noxious stimulus was turned on, it focused on the tail and the animal responded by flicking its tail out of the groove. Thus, light passed through the slit and activated the photocell which, in turn, stopped the recording timer. The apparatus was calibrated so that control mice would flick their tails in 2–4 s. Mice were injected subcutaneously with drug and tested 20 min later. Vehicle controls were also tested.

In the antagonism experiments (tail-flick *versus* morphine), the antagonists were administered subcutaneously 10 min before morphine, and the animals were tested 20 min later.

Phenylquinone (PPQ) Abdominal Stretching Test (7)—The mice were injected subcutaneously with drugs and 10 min later received 2 mg/kg of a fresh *p*-phenylquinone solution intraperitoneally. The mice were then placed in cages in groups of two. At 10 min after the phenylquinone injection, the total number of stretches per group were counted within a 1-min period. A stretch was characterized by an elongation of the body, development of tension in the muscles in the abdominal region, and extension of the forelimbs. The antinociceptive response was expressed as the percent inhibition of the phenylquinone-induced stretching response. Appropriate controls were used.

Hot Plate (HP) Assay (8)—The hot plate was held at a constant 55°C *via* a refluxing 1:1 mixture of ethyl formate and acetone. Mice were placed on the hot plate, and activity was noted as a delay of ≥5 s but no more than 30 s beyond the control time for the movement of the hind limb of the mouse, over at least two consecutive time periods. The mice were tested at 5, 10, 20, 30, 60 min, and longer if necessary, until responses returned to control levels.

Dependent Rhesus Monkey—In the single-dose substitution (SDS) test, for the most part, the recommendations of Seevers (9) and Seevers and Deneau (10) were utilized. A brief description of the procedure, including modifications (11), is as follows. Male and female rhesus monkeys (*Macaca mulatta*) weighing 2.5–7.5 kg were used. The animals were housed in pens, four or five to a group, and received 3 mg/kg sc of morphine every 6 h. This dose schedule was reported to produce maximal physical dependence (10). All the animals had received morphine for ≥3 months. A minimal, 2-week, wash-out and recuperation period was allowed for each animal between tests. The SDS test was initiated by the subcutaneous injection of the test drug or control substances (morphine and vehicle water, respectively) into the animals in a group that had not received morphine for 14–15 h and showed definite signs of withdrawal. Each animal was randomly allocated to one of four or five treatments: (*a*) two or three dose levels of the compound under investigation; (*b*) the morphine control, 3.0 mg/kg; (*c*) the vehicle control, 1 mL/kg. The animals were scored for suppression of withdrawal signs during a 2.5-h ob-

[1] α-Metazocine is 2′-hydroxy-2,5,9α-trimethyl-6,7-benzomorphan. For a comprehensive review and alternative chemical names for the 6,7-benzomorphans see Ref. 1.

[2] Pentazocine (see Refs. 1 and 5) is marketed as Talwin for both oral and parenteral use; phenazocine (Ref. 13) is sold in England as Narphen.

[3] Melting points (capillary, uncorrected, Table III) were taken in a Thomas–Hoover apparatus; mass spectral (molecular weights in agreement with theory) and C, H, and N data (Table III) are from the Section on Instrumentation and Analytical Services, National Institutes of Health. Optical rotations (Table III) were taken in a Perkin-Elmer 261 instrument using methanol as a solvent with the exception of IIIa and IIIb (bases) which were in ethanol. Rotation temperatures were 21–26°C. Free bases were recrystallized from acetone or acetone–hexane; hydrobromide salts were recrystallized from methanol–acetone. All compounds crystallized as white needles or prisms.

[4] This solvent mixture was suggested by Dr. H. Merz, C. H. Boehringer Sohn, Ingelheim, West Germany, who also kindly supplied 1,3-*cis*-dichloropropene.

[5] Compound IIc was supplied by Dr. A. E. Soria, Sterling-Winthrop Research Institute, Rensselaer, N.Y.

Nalorphine[c]	Inactive	0.6 (0.3-1.4)	9.9 (5.7-17.1)	2.6 (0.7-9.8)

[a] Range of values is in parentheses. [b] Hydrobromide salt. [c] Hydrochloride salt. [d] Sulfate salt.

servation period. The observer was "blind" regarding the allocation of treatments. At the end of the study, the data were grouped according to dose and drug, and the results were analyzed using the Mann-Whitney U-test (12).

Precipitated Withdrawal (PPTW) Test in Rhesus-Monkeys—The PPTW test was performed under the conditions described above for the SDS test, except that the animals of a group were challenged 2 or 3 h after the last dose of morphine. Naloxone at a dose of 0.05 mg/kg sc served as the positive control.

(±)-5,9α-Dimethyl-2′-hydroxy-2-(4-methylpentyl)-6,7-benzomorphan (Ic)—A mixture of 2.0 g of IVc (1, 13), 1.6 g of 4-methylpentyl bromide, 2.5 g of potassium bicarbonate, 4 mL of tetrahydrofuran, and 8 mL of dimethylformamide[4] was stirred at reflux for 2-3 h, cooled, diluted with 20-25 mL of water, and extracted with 30-40 mL of ether. The ether was washed twice with water, dried (sodium sulfate), and evaporated to dryness giving 1.9 g of Ic, mp 138.0-138.5°C after recrystallization[3].

The hydrochloride salt of Ic was prepared in acetone with hydrogen chloride. Compounds Ia and Ib were similarly prepared using IVa and IVb, respectively (14). The hydrobromide salts were prepared in acetone-33% hydrogen bromide in acetic acid.

Similarly, IIa and IIb were synthesized from IVa and IVb and *cis*-1,3-dichloropropane[4], and IIIa and IIIb were obtained from IVa and IVb and propynyl chloride; they were characterized as free bases and hydrobromide salts. Compounds IIa and IIb were also characterized as *d*- and *l*-mandelate salts, respectively.

Optical Resolution of α-(±)-2-(3-*cis*-Chloropropenyl)-5,9-dimethyl-2′-hydroxy-6,7-benzomorphan (IIc)—A mixture of 4.3 g of IIc (5)[5], 2.6 g of *d*-mandelic acid, and 75 mL of absolute ethanol was heated until a solution was obtained and allowed to stand at room temperature for 4-5 h to give 2.5 g of the *d*-mandelate salt of IIa, mp 181-186°C. This was dissolved in 40 mL of boiling absolute ethanol. This solution deposited 2.0 g of pure IIa *d*-mandelate after standing overnight at room temperature. It was converted to 1.2 g of the base IIa by dissolving in boiling methanol (10 mL)-water (5 mL) and treating the solution with 5 mL of concentrated ammonium hydroxide, mp 136.0-138.5°C after a recrystallization from acetone-hexane.

Table II—Effects of *N*-Substituted Normetazocine in the Morphine-Dependent Rhesus Monkey

Compound	Single-Dose Substitution Test, mg/kg sc	Precipitated Withdrawal Test, mg/kg sc
Ia[a]	Did not substitute (3.0-12.0)	Weak activity; convulsions (6.0-18.0)
Ib[a]	Substituted completely (1.5-3.0)	Not tested
Ic[a]	Did not substitute; convulsions (12.0)	Not tested
IIa[a]	Did not substitute (0.25-4.0)	Did not precipitate withdrawal, 1.0-12.0 mg/kg
IIb[a]	Did not substitute (0.125-0.5)	Precipitated withdrawal (0.015-1.0)
IIIa[a]	Partial brief substitution (1.25-10.0)	Not tested
IIIb[a]	Did not substitute (0.015-0.25)	Precipitated withdrawal (0.125-0.5)
Morphine[b]	Substituted (3.0)	Did not precipitate withdrawal, (1.5-6.0)
Nalorphine[c]	Did not substitute (0.1-1.0)	Precipitated withdrawal (0.5)

[a] Hydrobromide salt. [b] Sulfate salt. [c] Hydrochloride salt.

The filtrates from isolation and recrystallization of the *d*-mandelate salt above were combined and evaporated to dryness under reduced pressure. The residue in warm methanol was treated with dilute ammonium hydroxide, affording 2.7 g of a mixture of IIa and IIb. This mixture, 1.7 g of *l*-mandelic acid and 30 mL of absolute ethanol, was heated to solution and left at room temperature for 4.5 h, affording 1.9 g of the *l*-mandelate salt of IIb, mp 181-186°C. This was dissolved in 20 mL of boiling absolute ethanol. The solution was concentrated to 12-15 mL and allowed to stand at room temperature overnight, affording 1.6 g of pure IIb *d*-mandelate which was converted to base IIb with methanol ammonium hydroxide as described for IIa above. Bases IIa and IIb and their mandelate salts were identical to those obtained from IVa and IVb, respectively, and *cis*-1,3-dichloropropene.

RESULTS

The different *N*-substituted normetazocines showed dissimilar profiles of activity (Tables I and II). None of the isomers nor the racemate of the *N*-4-methylpentyl-substituted normetazocine (Ia-c) showed antagonist activity *versus* morphine antinociception. Both the (−)-isomer and racemate were active in the TF, PPQ, and HP tests; the (−)-isomer was more potent than the racemate. In morphine-dependent monkeys, none of the compounds precipitated withdrawal and only the (−)-isomer substituted for morphine. The (+)-isomer and racemate produced convulsions, precluding testing at higher doses. Regarding the *N*-substituted chloroalkyl isomers, both IIa and b antagonized morphine antinociception; the (−)-isomer was clearly the more potent, ~50 times more so than nalorphine. Neither isomer was active in the TF or HP tests. In the PPQ test, the (−)-isomer was decidedly the more active antipode. Both isomers antagonized morphine antinociception; again, the (−)-isomer was far more potent. Neither isomer substituted for morphine in the addicted monkeys: the (−)-isomer, as expected, precipitated withdrawal, the (+)-isomer did not.

Finally, with the *N*-propynyl-substituted (+)- and (−)-normetazocines (IIIa,b) the following results were obtained. The (+)-isomer showed very weak activity in the HP test only and was devoid of antagonist activity. However, it partially substituted for morphine in addicted monkeys. The (−)-isomer showed weak agonist activity in the HP test and was equipotent with morphine in the PPQ test. As an antagonist, the (−)-isomer was much more active than nalorphine.

DISCUSSION

Results obtained with the 4-methylpentyl (I) isomers are vaguely reminiscent of those obtained with phenazocine antipodes (13), potency differences notwithstanding[6]. In both series, (−)-isomers supported morphine dependence although, relatively, a much larger dose of (−)-phenazocine was needed. Neither (+)-isomer would substitute for morphine, and with Ia severe tremors were noted. In retrospect, (+)-phenazocine, nearly as potent as morphine in the HP test, should have been tested more extensively.

Observations noted with the *N*-chloroallyl isomers (IIa,b) are quantitatively similar to those reported (15) for (+)- and (−)-*N*-allyl-*N*-normetazocine (NANM); IIb is a very powerful antagonist. It is interesting to note that Brady and co-workers recently showed (2) in rats and squirrel monkeys trained to discriminate the psychotomimetic phencyclidine hydrochloride (PCP) from saline that the (+)-isomer of NANM produced dose-dependent responses appropriate for PCP. The (−)-isomer did not produce responses appropriate for PCP at any dose. These data suggest a separation of psychotomimetic and

[6] Phenazocine is α-(±)-*N*-phenethyl-substituted *N*-normetazocine. It and its antipodes are 20-30 times more potent antinociceptively than corresponding I compounds.

[a] All compounds were analyzed for C, H, and N; all values were within 0.4% of theoretical value. [b] Another crystalline modification melted at 115°C with gas evolution. [c] Another crystalline modification melted at 189-190°C.

analgesic effects. Whether in humans (−)-NANM or the chloroallyl *N*-substituted derivative are free of psychotomimetic effects remains to be shown. The racemate (IIc) was reported in 1964 (5), as was IIIc whose antipodes (IIIa,b) displayed profiles of activity reminiscent of *N*-methyl-6,7-benzomorphans of the α-series. This series was unique in two respects: (*a*) (+)-isomers substituted partially or completely for morphine; (*b*) the more antinociceptively potent (HP test) (−)-isomers would not. In fact, like IIIb, the (−)-isomers of this *N*-methyl series precipitated abstinence signs in morphine-dependent monkeys (4), yet two were more morphine-like than nalorphine-like in humans (16). In view of these different profiles of activity in animals and the remarkable separation of morphine-like effects in different species, these compounds [especially the (+)-isomers] deserve more extensive testing, perhaps in humans.

The exploitation of these differences may expand our knowledge of the basic mechanisms involved and possibly lead to a development of an ideal analgesic. It is also evident that studies with racemates may at times be misleading and that whenever possible pure optical isomers should be used.

9α- and 9β-Hydroxyphenylmorphans

HIROYOSHI AWAYA *§, EVERETTE L. MAY *x, ARTHUR E. JACOBSON ‡, and MARIO D. ACETO *

Received November 25, 1983, from the **Department of Pharmacology, Medical College of Virginia, Virginia Commonwealth University, Richmond, VA 23298* and the ‡*National Institutes of Health, Bethesda, MD 20205.* Accepted for publication March 21, 1984. §Present address: 1-Ku Marugouchi Onoda, Yamaguchi 756 Japan.

Abstract □ Platinum-oxide hydrogenation of 5-*m*-methoxyphenyl-2-methyl-9-oxomorphan (I) gave the 9α-hydroxy racemate (II) whose phenolic analogue (III) is a strong antinociceptive agent, fully supportive of morphine dependence in rhesus monkeys. The di-*O*-acetyl derivative (VI) of III was similar to III in its profile of activity. The diastereoisomer of III (VII), obtained by hydrogenation of the methobromide of I (IV), extrusion of methyl bromide, and *O*-demethylation of the resultant free base (VIII), was almost inactive antinociceptively and did not suppress withdrawal symptoms in morphine-dependent monkeys. The orientation of the C-9 hydroxyl groups was deduced from spectral data and by analogy.

Keyphrases □ 9α- and 9β-Hydroxyphenylmorphans—hydrogenation, diastereoisomer spectral data, synthesis □ Antinociceptive activity—9α- and 9β-hydroxyphenylmorphans, potency, withdrawal symptoms, substitution for morphine, antagonism

The introduction of a 9α-methyl group (1) into 5-*m*-hydroxyphenyl-2-methylmorphan (IX) (2), whose antipodes are strong antinociceptive agents showing a separation of morphine-like effects (1, 3), gives low-potency antagonists without appreciable pain-relieving properties. It was desired to determine the effect of hydroxyl substitution in the 9-position of IX. One of the two possible diastereoisomers (VII) resulting from such substitution would be similar to the very potent (10 times morphine) oxymorphone (4) with respect to 9-OH—N geometry. The synthesis of VII and its diastereoisomer (III) and some pharmacological findings are presented herein.

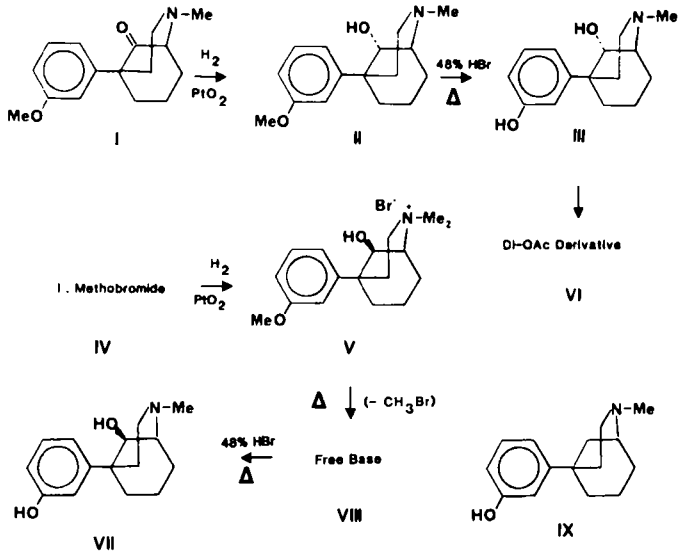
RESULTS AND DISCUSSION

Chemistry—When bicyclic ketone I (free base of hydrochloride salt) was hydrogenated in ethanol (platinum oxide), addition of hydrogen was stereoselective; the 9α-alcohol (II) was isolated in 98% yield. To obtain the 9β-alcohol (VIII), the methobromide of I (IV) was similarly hydrogenated, giving V which was converted to free base VIII pyrolytically (Scheme I).

Hydroxyl assignments are based principally on IR spectral data, which indicated strong 9-OH N bonding for VIII. Only free hydroxyl absorption and 9-OH-π bonding were seen for II. The ^{1}H-NMR data also appeared to support these assignments (see C-9 H values for ^{1}H-NMR and IR maxima in the *Experimental Section*). Finally, this stereochemical pattern of addition of hydrogen to the carbonyl group of I would be similar to that observed in the benzomorphan series (5) and for 5-*m*-methoxyphenyl-2-methyl-9-methylenemorphan (1).

Phenols III and VII were prepared from II and VIII, respectively, with boiling 48% hydrobromic acid or with boron tribromide in methylene chloride (6). Diacetate VI resulted from treatment of III with acetic anhydride containing a little pyridine.

Pharmacology—As recorded in Table I, the 9α-hydroxy racemate (III) is comparable to morphine in antinociceptive activity in mice by the tail-flick (TF) (7), *p*-phenylquinone-writhing (PPQ) (7), hot-plate (HP) (8), and Nilsen (9) tests, while the 9β-isomer (VII) had low-order potency in the PPQ test only. Compound III fully supported morphine dependence in rhesus monkeys at 1–16 mg/g, but VII, as expected, did not substitute for morphine at 3–18 mg/kg (10). The antinociceptive potency of the di-*O*-acetyl derivative of III (VI) was similar to that of the parent III in the TF, PPQ, and HP tests. In opiate-dependent monkeys, VI completely suppressed abrupt withdrawal at 10.0 mg/kg[1]. It was reported earlier (11) that VI did not suppress withdrawal at 1–10 mg/kg, results that seem inconsistent with the antinociceptive profiles



Scheme I

of activity of VI and its precursor III. None of the three racemates (III, VI, and VII) elicited properties of antagonism in the opiate-dependent monkey (10, 11) or in the TF *versus* morphine test (10).

It seems noteworthy that VII, with 9-OH—N geometry similar to that of oxymorphone (4) is relatively inactive. It would therefore be of interest to synthesize the 14α-hydroxy epimer of oxymorphone which would correspond to the very active III.

EXPERIMENTAL SECTION[2]

9α-Hydroxy-5-*m*-methoxyphenyl-2-methylmorphan (II) Hydrochloride—Compound I (1.0 g, 3.9 mmol) in 60 mL of methanol was hydrogenated (Parr apparatus, 30 psig, 25°C) with 0.15 g of platinum oxide during 2 h. The filtered solution was evaporated to dryness under reduced pressure giving 0.98 g of II, mp 98–100°C (from ether–petroleum ether). IR ($CHCl_3$): 3650 w (free OH) and 3570 m cm^{-1} (OH-π bonding); ^{1}H-NMR ($CDCl_3$): δ 2.52 (3, s, N—CH_3), 3.81 (3, s, O—CH_3), and 4.32 ppm (1, d, J = 3 Hz, C-9). The hydrochloride salt (from acetone–hydrogen chloride) crystallized from methanol–ether in prisms, mp 225–227°C. ^{1}H-NMR (Me_2SO-d_6): δ 2.80 (3, s, N—CH_3), 3.75 (3, s, O—CH_3) and 5.51 ppm (1, d, J = 3 Hz, C-9); EI-MS: m/z 261 (M^+ − HCl).

Anal.—Calc. for $C_{16}H_{24}ClNO_2 \cdot 0.25\ H_2O$: C, 63.6; H, 8.2; N, 4.6. Found: C, 63.6; H, 8.4; N, 4.4.

9α-Hydroxy-5-*m*-hydroxyphenyl-2-methylmorphan (III)—The hydrochloride salt of II (0.5 g, 2.0 mmol) was added to 5 mL of nearly boiling 48% hydrobromic acid. The solution was refluxed for 12–15 min, cooled, and made alkaline with ammonium hydroxide. The liberated base was dissolved in chloroform (6–8 mL, three extractions). On standing for 30 min, the combined extracts deposited 200 mg of III, mp 193–196°C. From the filtrate and chloroform washings of the precipitate, an additional 140 mg of III separated after cooling to 0°C, total yield 80%. It was nearly pure [TLC: R_f 0.25, silica gel, chloroform–methanol–ammonium hydroxide (90:9:1)] and was recrystallized by dissolving 200 mg in 200 mL of boiling acetone, filtering the hot

[1] Unpublished results.

[2] Melting points (uncorrected) were taken in a Thomas-Hoover capillary apparatus. IR and NMR spectra were obtained with a Beckman Aculab 8 and a 60-MHz Hitachi-Perkin Elmer Model R-24, respectively. Mass and analytical data are from the Section on Microanalytical Services and Instrumentation (Dr. David Johnson, Chief), National Institutes of Health.

[a] Hydrochloride salt. [b] Hydrobromide salt. [c] *dl*-Mandelate salt. [d] Essentially inactive; 46% of mice affected at 60 mg/kg. [e] Essentially inactive; 30% of mice affected at 100 mg/kg. [f] Sulfate salt.

solution, concentrating the filtrate to 4 mL, and cooling to 5°C. The yield was 140 mg, mp 197–198°C.

Anal.—Calc. for $C_{15}H_{21}NO_2 \cdot 0.5\ H_2O$: C, 72.8; H, 8.5; N, 5.7. Found: C, 72.8; H, 8.4; N, 5.7.

The hydrochloride salt of III (acetone–hydrogen chloride) was recrystallized from methanol–acetone, mp 225.5–227.0°C. EI-MS: *m/z* 247 ($M^+ - HCl$).

Anal.—Calc. for $C_{15}H_{22}ClNO_2$: Cl, 12.5. Found: Cl, 12.2.

By the method of Rice (5), III could be obtained equally well from II, using boron tribromide.

9α-Acetoxy-5-*m*-acetoxyphenyl-2-methylmorphan (VI) Hydrobromide—Acetic anhydride (20 mL), 0.7 g (2.8 mmol) of III (hydrochloride salt) and a drop of pyridine were refluxed for 1 h. The cooled mixture was poured into 50 mL of ice water, made alkaline by careful addition of potassium carbonate (stirring), and extracted with chloroform–ethanol (10:1, 4 × 25 mL). The combined extracts were washed twice with water, dried (sodium sulfate), and evaporated under reduced pressure to afford 0.62 g (68%) of oily VI which, in acetone, was converted to 0.63 g of the hydrobromide salt with 32% hydrogen bromide–acetic acid. It was recrystallized from acetone–methylene chloride, mp 220–223°C. IR (Nujol): 1760 and 1750 cm^{-1}; EI-MS: *m/z* 331 ($M^+ - HBr$).

Anal.—Calc. for $C_{19}H_{26}BrNO_4$: C, 55.4; N, 6.4; N, 3.4. Found: C, 55.4; H, 6.6; N, 3.3.

9β-Hydroxy-5-*m*-hydroxyphenyl-2-methylmorphan (VII) *dl*-Mandelate—The methobromide (IV) (2) of I (0.5 g, 1.4 mmol) in 30 mL of methanol was hydrogenated (0.15 g of platinum oxide, 23–25°C, 30 psig) for 42 h. The filtered solution was evaporated to dryness under reduced pressure to afford 0.56 g of hygroscopic solid, which was dissolved in 5 mL of 1-nonanol. The solution was refluxed for 5 min under nitrogen, cooled, diluted with 20 mL of ether, and extracted with 20 mL of 10% hydrochloric acid in four portions. The combined extracts were made basic with ammonium hydroxide and extracted with 50 mL of ether in four portions. The ether was washed twice with water, dried (sodium sulfate), and evaporated to dryness under reduced pressure (0.3 mm, 18 h) giving 0.23 g (55% yield) of VIII, mp 68–70°C. IR ($CHCl_3$): 3640 w (free OH), 3560 w (OH–π bonding), and 3400 s cm^{-1} (OH—N bonding); ^1H-NMR ($CDCl_3$): δ 2.40 (3, s, N—CH_3), 3.80 (3, s, O—CH_3), and 4.14 ppm (1, d, J = 4 Hz, C-9); EI-MS: *m/z* 261 (M^+), 244, 232, and 218.

To this base was added 5 mL of hot 48% hydrobromic acid. The solution was refluxed for 10 min, cooled, poured into 20 mL of saturated saline, made alkaline with ammonium hydroxide, and extracted with 50 mL of ether in four portions. The extracts were washed twice with saturated saline, dried (sodium sulfate), and evaporated giving 0.18 g of VII. Treatment of VII with 0.11 g (1 equivalent) of *dl*-mandelic acid in acetone furnished 0.25 g (14% based on starting IV) of the *dl*-mandelate salt of VII, which crystallized from methanol–acetone as a hemihydrate, mp 93–94°C; EI-MS: *m/z* 247 (M^+ – mandelic acid).

Anal.—Calc. for $C_{23}H_{29}NO_5 \cdot 0.5\ H_2O$: C, 67.6; H, 7.4; N, 3.5. Found: C, 67.2; H, 7.2; N, 3.3.

Effects of Solvent Medium on Solubility IV: Comparison of the Hydrophilic–Lipophilic Character Exhibited by Functional Groups in Ethanol–Water and Ethanol–Cyclohexane Mixtures

RUBEN H. MANZO ˣ, AMELIA A. AHUMADA, and ERNESTINA LUNA

Received November 3, 1983, from the *Departamento de Farmacia, Facultad de Ciencias Químicas, Universidad Nacional de Córdoba, Suc. 16, C.C. 61, 5016 Córdoba, Argentina.* Accepted for publication April 13, 1984.

Abstract □ Solvent effects on the solubility of a set of structurally related solid compounds (A_x, A_y, *etc.*) in ethanol-water (system 1) and ethanol-cyclohexane (system 2) are compared by the equation, $\log S_y = P_y \log S_x + C$. For a given structural change, $A_x \rightarrow A_y$, it yields the respective medium-effects parameters, P_{y1} and P_{y2}. They are used to compare the sensitivity of both solvent systems with the structural changes in the substrates by the equation, $\Delta_{12} = (P_{y1} - 1) - (1 - P_{y2})$. Structural changes involving the full replacement of the hydrogen atoms bonded to either O or N afford $\Delta_{12} < 0$, while those involving solely an increase in the alkyl chain of the substrates yield $\Delta_{12} > 0$. A structural change where the donor-acceptor capacity of hydrogen bonding is maintained yields a Δ_{12} approaching zero.

Keyphrases □ Solubility—effects of solvent medium, hydrophilic-lipophilic character, ethanol-water, ethanol-cyclohexane □ Hydrophilic-lipophilic character—effects of solvent medium, ethanol-water, ethanol-cyclohexane, solubility

In previous papers of this series (1-3) Eq. 1 has been used successfully to correlate solvent effects with solubility equilibria:

$$\log S_y = P_y \log S_x + C \qquad \text{(Eq. 1)}$$

S_y and S_x are, respectively, two sets of solubility data of a pair of structurally related compounds, A_y and A_x, which arise from measurements in the same set of adequately selected solvent conditions. This linear free energy relationship (LFER) affords the medium effect parameter P_y, which in a given system of solvents measures the difference in hydrophilicity (or lipophilicity) between A_y and A_x. Equation 1 has been used to measure the hydrophilic-lipophilic character exhibited by a variety of functional groups in ethanol-water mixtures (3).

A theoretical model to rationalize solvent effects on solubility was developed (1). In two-solvent systems, each consisting of binary mixtures of increasing lipophilicity, one (system 1) in which the solubility of both substrates (A_x and A_y) increases, and the other (system 2) in which the solubilities decrease as the lipophilicity of the mixtures is raised, the model predicts the following: in system 1, P_y will be higher than unity when A_y is more lipophilic than A_x and *vice versa;* in system 2, P_y will be lower than unity when A_y is more lipophilic than A_x and higher than unity in the reverse situation.

This paper deals with the comparison of the sensitivity of two-solvent systems with a variety of structural changes in the substrates. Thus, if the sensitivities of systems 1 and 2 to a given structural change ($A_x \rightarrow A_y$) are the same, the following relation between P_{y1} and P_{y2} would be expected to hold (1):

$$(P_{y1} - 1) = (1 - P_{y2}) \qquad \text{(Eq. 2)}$$

which is conveniently expressed as:

$$(P_{y1} - 1) - (1 - P_{y2}) = \Delta_{12} = 0 \qquad \text{(Eq. 3)}$$

However, when the solvent systems have different sensitivities to the structural change, Δ_{12} becomes different from zero, having a positive value when system 1 is more sensitive than system 2, and a negative value in the reverse situation.

In this paper, the former measurements of solvent effects in ethanol-water mixtures (2,3), now system 1, were extended to a nonaqueous medium consisting of ethanol-cyclohexane mixtures which were selected as system 2. System 2 forms a less structured environment of lower dielectric constant than system 1 and the hydroxyl groups are less disponible and freer to interact with the substrates through hydrogen bonding.

EXPERIMENTAL SECTION

The compounds of the basic structure p-X_1—C_6H_4—X_2 were used for the solubility measurements. The numbers assigned to each compound in a previous paper (3) were maintained. The corresponding X_1 and X_2 are, respectively: H_2N—, —$COOCH_3$ (I); H—, —$NHCOCH_3$ (III); HO—, —$NHCOCH_3$ (IV); $(CH_3)_2N$—, —$COOCH_3$ (VII); CH_3O—, —$NHCOCH_3$ (X); C_2H_5O—, —$NHCOCH_3$ (XI); CH_3COO—, —$NHCOCH_3$ (XII); H—, —$N(CH_3)COCH_3$ (XIII); H_2N—, —$COOC_2H_5$ (XIV); H_2N—, —$COO(CH_2)_2CH_3$ (XV); HO—, —$COO(CH_2)_2CH_3$ (XVI).

Preparation and physical constants of I, III, IV, VI, VII, XV, and XVI were reported (2, 3); X and XII were prepared through acetylation, X from *p*-anisidine (4), and XII from IV (5). The following were commercially available: XI[1], XIV[1], and XIII[2]. The melting points for these compounds were: X, mp 127.0-127.5°C (water) [lit. (6) mp 129-131°C]; XI, mp 134-135°C (ethanol-water, 50:50) [lit. (6) mp 134-135°C]; XII, mp 153.0-154.5°C (water) [lit. (5) mp 152-156°C]; XIII, mp 99.0-99.5°C (water) [lit. (6) mp 101-102°C]; XIV, mp 88-89°C (ethanol-water, 15:85) [lit. (6) mp 88-90°C]. 5,5′-Diethylbarbituric acid (barbital) (XVII)[1], mp 189-191°C (water), and 5-ethyl-5-isoamylbarbituric acid (amobarbital) (XVIII), mp 155.5-156.5°C (ethanol-water, 20:80), were also used. Compound XVIII was extracted with chloroform from commercial tablets[3].

Solvent mixture preparations and solubility determinations have been reported (2, 3). Solubility data of XVII and XVIII in ethanol-water mixtures (0-70% ethanol) were taken from Breon and Paruta (7).

RESULTS AND DISCUSSION

Solubility data of the structurally related derivatives p-X_1—C_6H_4—X_2 in systems 1 and 2 are reported in Table I with data of a pair of barbituric acid derivatives (XVII and XVIII). The data of p-X_1—C_6H_4—X_2 derivatives complement previously reported results (2, 3, 7). The solubility of all compounds of the set is raised with increasing amounts of ethanol in system 1 and lowered by the increase of the cyclohexane content in system 2.

To incorporate low solubility values into the data set of system 2, measurements were performed in mixtures having cyclohexane content as high as 94 and 96%. P_{y1} and P_{y2} were obtained from the correlation of the solubility data according to Eq. 1, and are reported in Table II. These values can be used to compare the sensitivity of both solvent systems with a variety of structural changes in the substrates.

[a] Solubility data in molality units were used in all cases except those of the correlation XVIII/XVII in system 1, which were taken from Ref. 7 and are expressed in mg/mL. However, as previously discussed (1), P_y obtained by using different units to express solubility, remains essentially unchanged. It should be emphasized that all the solubility data of barbituric derivatives reported in Ref. 7 can be correlated according to Eq. 1.

Table III contains Δ_{12} values of some relevant structural changes. They were grouped under the headings of the structural change involved after clearly defined patterns were recognized.

$\Delta_{12} < 0$—Inspection of Table III reveals that a structural change ($A_x \rightarrow A_y$) involving the full replacement of the hydrogen atoms bonded to either O or N affords a negative value of Δ_{12} (correlations 1-4). Therefore, the sensitivity of system 2 to such structural modification is greater than that of system 1. One reason for this behavior might be that an aqueous medium, such as system 1, has a number of ways to interact with both A_x and A_y structures due to its high donor-acceptor capacity toward hydrogen bonding. System 2, having a lower ability to produce specific interactions, has an enhanced sensitivity toward a structural change involving the full replacement of the hydrogen atoms and thus the number of potential interactions are limited.

$\Delta_{12} > 0$—A structural change which solely involves the increase of the alkyl chain yields a positive value of Δ_{12}. This behavior was observed with chain extensions of ether, ester, and barbituric acid derivatives (correlations 5-8). Consequently, in this situation system 1 appears to be more sensitive than system 2. This could be explained by considering that an increase in the size of the hydrocarbon moiety of a substrate is better accepted by a less rigid system such as 2 than by a highly structured system such as 1.

Δ_{12} Approaching Zero—For a structural change like —OH→ —NH_2, where the donor-acceptor capacity toward hydrogen bonding is maintained, a similar sensitivity in both systems is expected. From the values reported previously (2), a random value of Δ_{12} approaching zero (−0.04) is calculated for such a structural change.

On the other hand, the direct comparison of the structural difference —OH → —OC_2H_5 between two pharmacologically related drugs, IV (acetaminophen) and XI (phenacetin), affords a Δ_{12} of zero. This result can be seen as a consequence of two opposite effects: the hydrogen atom replacement generates a negative Δ_{12} for —OH→—OCH_3, as occurs in IV→X (correlation

	XVI/XV	+0.05
Hydrogen Replacement Plus Chain Extension		
$-OH \rightarrow -OC_2H_5$	XI/IV	0.00

1); the chain extension $-OCH_3 \rightarrow -OC_2H_5$ (X→XI) generates a positive Δ_{12} (correlation 5). Obviously, the extent of the affinity of a functional group for a given medium is the result of a number of well-defined molecular interactions usually described as specific, nonspecific, solvophobic, *etc.* (8).

Because of the importance of the hydrophilic-lipophilic concept, considerable effort has been made to measure such properties from partition coefficient or solubility measurements (9, 10) and more recently from solvent effects on solubility (2, 3).

The results discussed here show that functional groups may exhibit different hydrophilic-lipophilic properties in different environments, *i.e.*, XVIII appears to be 16-fold more lipophilic than XVII in ethanol-water, but only ~1.2-fold more lipophilic in ethanol-cyclohexane. Thus, it is now clear that the order of hydrophilic strength of different functional groups in ethanol-water reported previously (3) should be quite different from the order of the same groups in ethanol-cyclohexane.

Just as Hammett pointed out the ambiguity of the concepts of acidity and basicity (11), the inherent ambiguity of the hydrophilic-lipophilic concept should be emphasized. However, Eq. 1 appears to be a useful tool to obtain information about the hydrophilic-lipophilic properties of different solvent media.

Abstract □ A novel series of estrone derivatives having a free 3-phenolic group with the 2- or 4-position substituted with a thiourea function was synthesized. None of the products showed significant binding to the estrogen receptor, and the cytotoxic activity on MCF-7 cells for VII and X was weak.

Keyphrases □ Estrone 2- and 4-thiourea derivatives—free phenolic group, synthesis, binding to the estrogen receptor, cytotoxic activity □ Steroidal thiourea derivatives—2- or 4-position of estrone, synthesis binding to the estrogen receptor, cytotoxic activity

Several types of compounds containing structural modifications of steroidal and nonsteroidal estrogens were synthesized during past years, in the hope of developing agents with a high binding affinity to the estrogen receptor (1, 2) and reduced estrogenic properties. These, in accordance with their capabilities in antagonizing the action of estradiol at the estrogen receptor (3), can be used as antiestrogens (4–9) or as cytotoxic agents with selective activity against the hormone-dependent tumor cells (10–13). In connection with an extensive program studying the effect of structural modifications on the biological activity of hormones, a variety of modified steroids were synthesized and tested for antiestrogenic (14), endocrinological (15–17), and anticancer (15, 17, 18) properties. As a supplemental investigation, a novel series of estrone thiourea derivatives (V–XI) were synthesized to check their binding to

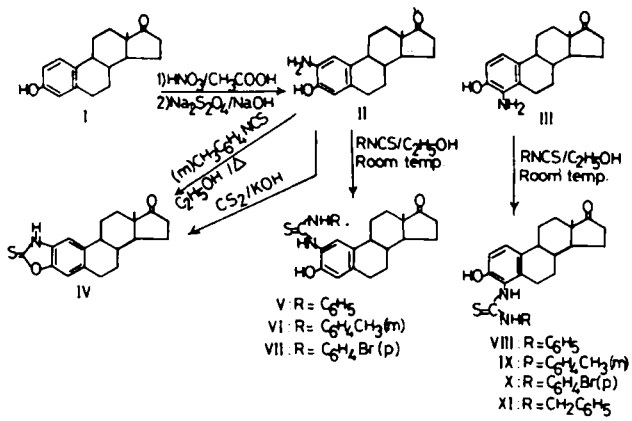

Scheme I

the estrogen receptor and *in vitro* cytotoxic activity on the growth of cells from the estrogen receptor-positive breast cancer cell line MCF-7.

RESULTS AND DISCUSSION

Chemistry—The synthesis of *N*-substituted *N'*-(3-hydroxy-17-oxoestra-1,3,5(10)-trien-2-yl)thioureas (V–VII) and the corresponding *N*-substituted *N'*-(3-hydroxy-17-oxoestra-1,3,5(10)-trien-4-yl)thioureas (VIII–XI) was accomplished as shown in Scheme I. The 2- and 4-aminoestrones (II and III, respectively), prepared by nitration of estrone (19) and reduction of the produced 2- and 4-mononitroestrones as previously reported (20), were allowed to react at room temperature with the equivalent amount of the selected arylisothiocyanate derivatives in ethanol or ethanol–acetone to give the estrone-2-thiourea derivatives (V–VII). The attempt to crystallize VI from boiling ethanol led to the elimination of *m*-toluidine and the formation of 2'-thio-17-oxoestra-1(10),4-dieno[2,3-*d*]oxazoline (IV). The same oxazoline derivative IV was obtained when equimolar amounts of 2-aminoestrone (II) and *m*-tolylisothiocyanate were heated in boiling ethanol for a short period or, as previously reported for other heat-sensitive thioureas (21), when VI was heated above its melting point. The separation of the estrone-4-thiourea derivatives (VIII–XI), on the other hand, necessitated the evaporation of the mixture to dryness, without application of heat, and then purifying the residues by precipitation from different cold solvent systems (Table I). *N*-Benzyl-*N'*-(3-hydroxy-17-oxoestra-1,3,5(10)-trien-4-yl)thiourea (XI) was found to be insensitive to heat; hence, its preparation and purification were carried out in boiling ethanol. The structures of V–XI were confirmed by elemental analysis, IR, ^{1}H-NMR spectra (Table I), and (for VII and X) MS.

Biological Screening—The relative binding affinity of the steroidal thioureas (V–XI) was evaluated by measuring their ability to inhibit the binding of tritiated estradiol to the cytoplasmic estrogen receptor, obtained from immature rat uteri (2, 10). The steroidal thiourea derivatives (V–VII) did not produce any inhibition of binding, indicating that they were totally devoid of binding affinity. Compounds VIII–XI produced only a slight inhibition, indicative of a weak (most probably insignificant) binding affinity (≤0.1%). Moreover, VII and X were evaluated *in vitro* for their inhibition of the growth of cells from the estrogen receptor-positive breast cancer (MCF-7) cell line (12). As shown in Table II, at a concentration of 10^{-6} M, both compounds produced a slight inhibition of the growth of MCF-7 cells. These effects were only significant ($p < 0.05$) in the case of VII. In addition, the combination of varying molar concentrations of estradiol with the two thioureas (at a concentration of 10^{-6} M) did not suppress the growth inhibition of MCF-7 cells (Table II), indicating that the estrogen receptor was not involved in this weak antitumor activity exhibited by VII and X (12). This behavior totally contrasted with the inhibited growth of MCF-7 cells produced by 1-[2-[*p*-(3,4-dihydro-6-methoxy-2-phenylnaphth-1-yl)phenoxy]ethyl]pyrrolydine hydrochloride (nafoxidine)[1], which was suppressed by addition of estradiol (*cf.*, footnote *b* in Table II). Such a slight inhibition of the growth of MCF-7 cells by the thioureas is consistent with their lack of binding affinity for the estrogen receptor. The presence of the thiourea function, although fulfilling the polar structural requirements for association with the receptor (4, 8, 10), seems to be bulky spatial arrangement as compared with several nitrogen mustard functions (23). Hence, the product was sterically hindered from fitting in the estrogen receptor sites (6).

Table I—Synthesized Estrone-2- and -4-thiourea Derivatives (V–XI)

Compound	Yield, %	mp, °C	Molecular[a] Formula	^{1}H-NMR (δ), ppm[b]
V	81	186–188[c]	$C_{25}H_{28}N_2O_2S$	0.87 (s, 3, C(18)—CH_3), 6.62 (s, 1, C(4)-H), 7.30 (br m 5, ArH), 7.71 (s, 1, C(1)—H), 8.81 (s, 2, NHCSNH, disappearing on deuteration), 9.47 (s, 1, OH, lost on deuteration).
VI	96	174–176[c]	$C_{26}H_{30}N_2O_2S$	0.86 (s, 3, C(18)—CH_3), 2.3 (s, 3, tolyl-CH_3), 6.75 (s, 1, C(4)—H), 7.1 (m, 4, ArH), 7.49 (s, 1, C(1)—H), 8.38 (s, 1, tolyl-NH, lost on deuteration), 8.51 (s, 1, NH, lost on deuteration), 8.86 (s, 1, OH).
VII	86	187–189[c]	$C_{25}H_{27}BrN_2O_2S$	0.86 (s, 3, C(18)—CH_3), 6.62 (s, 1, C(4)—H), 7.35 (d, 2, J = 10 Hz, ArH), 7.52 (d, 2, J = 10 Hz, ArH), 7.72 (s, 1, C(1)—H), 8.94 (s, 2, NHCSNH, lost on deuteration), 9.6 (s, 1, OH).
VIII	89	140–142[d]	$C_{25}H_{28}N_2O_2S$	
IX	95	163–165[d]	$C_{26}H_{30}N_2O_2S$	0.88 (s, 3, C(18)—CH_3), 2.36 (s, 3, (tolyl-CH_3), 6.89 (d, 1, J = 8 Hz, C(2)—H), 7.10–7.41 (m, 6, ArH + C(1)—H + tolyl-NH), 8.02 (br s, 1, NH, lost on deuteration).
X	89	161–163[e]	$C_{25}H_{27}BrN_2O_2S$	
XI	87	165–167[f]	$C_{26}H_{30}N_2O_2S$[g]	0.87 (s, 3, C(18)—CH_3), 4.79 (d, 2, J = 6 Hz, $C_6H_5CH_2$, becoming singlet at 4.77 on deuteration), 6.20 (m, 1, benzyl-NH, lost on deuteration), 6.83 (d, 1, J = 8 Hz, C(2)—H), 7.18 (d, 1, J = 8 Hz, C(1)-H), 7.25 (s, 5, ArH), 7.78 (s, 1, NH, lost on deuteration).

[a] Compounds V–XI were analyzed for C, H, and N; unless otherwise noted, all values were within ±0.4% of the theoretical value. [b] In $CDCl_3$ or Me_2SO-d_6 plus D_2O. [c] The compounds solidified and remelted at 310°C. [d] Recrystallized from benzene–petroleum ether (bp 60–80°C). [e] Recrystallized from chloroform–petroleum ether (bp 60–80°C). [f] Recrystallized from ethanol–water. [g] Calc.: C, 71.86; N, 6.45. Found: C, 71.40; N, 6.00.

EXPERIMENTAL SECTION[2]

***N*-Substituted *N'*-(3-Hydroxy-17-oxoestra-1,3,5(10)-trien-2-yl)thioureas (V–VII)**—A solution of 2-aminoestrone (II) (200 mg, 0.7 mmol) was dissolved in hot absolute ethanol (15 mL), allowed to cool to room temperature, and then treated with the solution of one molar equivalent of the appropriate arylisothiocyanate derivative in absolute ethanol (5 mL). The solution was allowed to stand at room temperature overnight. The resulting crystals were removed by filtration and washed with petroleum ether. The yields, physical constants, and ^{1}H-NMR spectral data of the products are presented in Table I.

2'-Thio-17-oxoestra-1(10),4-dieno[2,3-d]oxazoline (IV)—A solution of equimolar amounts of 2-aminoestrone (II) and *m*-tolylisothiocyanate (0.87

[2] All melting points are uncorrected. IR spectra were measured as Nujol mulls on a Beckman 4210 Spectrophotometer. ^{1}H-NMR and MS were measured on a Perkin-Elmer R32 and an AEI-MS-50, respectively.

Table II—Growth Inhibition of MCF-7 Cells by VII and X Alone or Combined with Estradiol

Compound	Molarity	DNA, μg[a]			
		Alone	Estradiol 10^{-8} M	Estradiol 10^{-7} M	Estradiol 10^{-6} M[b]
Control		9.1 ± 1.8 (100)			
VII[c]	10^{-8}	9.6 ± 1.3 (105)			
	10^{-7}	9.6 ± 1.2 (105)			
	10^{-6}	6.9 ± 0.7 (76)	6.6 ± 0.9 (72)	6.0 ± 1.1 (66)	5.7 ± 0.3 (63)
X	10^{-8}	9.0 ± 1.0 (99)			
	10^{-7}	7.8 ± 0.7 (86)			
	10^{-6}	7.6 ± 1.4 (83)	9.6 ± 1.0 (105)	7.7 ± 1.0 (84)	7.4 ± 0.5 (81)

[a] Experiments were performed in quadruplicate; the results are given as mean ± *SD*. The percent of control is given in parentheses. [b] Inhibition produced by 5×10^{-7} M nafoxidine alone was 6.2 ± 0.6 (68); the value after addition of 10^{-8} M estradiol was 7.6 ± 0.8 (83). [c] Variance analysis showed that VII produced a significant growth inhibition at 10^{-6} M ($p < 0.05$); this effect was not suppressed by estradiol. The slight inhibition of X was not significant ($p > 0.10$).

mmol) in ethanol (15 mL) was heated at reflux for 30 min. The solution was concentrated and the product, obtained after cooling, was recrystallized from ethanol to give IV as white shiny scales (95% yield), mp 308–310°C. Compound IV was also produced when thiourea VI was heated in ethanol for recrystallization, or heated above its melting point for a short time. The mixed melting point with a sample of IV, prepared from 2-aminoestrone (II), carbon disulfide, and potassium hydroxide [as previously reported (21)] showed no depression. IR and ^{1}H-NMR spectra of IV obtained from both sources were superimposable. IR (mineral oil): ν 1730 (C=O), 1595 (C=C, Ar), 1510, 1495, 1140, and 930 cm^{-1} (NCS amide I, II, III, and IV bands, respectively); ^{1}H-NMR ($CDCl_3$ + D_2O): δ 0.92 (s, 3, C(18)—CH_3), 7.05–7.30 (two m, 2, ArH), and 10.55 ppm [br s (diffuse), oxazoline-H, exchangeable].

***N*-Substituted *N'*-(3-Hydroxy-17-oxoestra-1,3,5(10)-trien-4-yl) thioureas (VIII–XI)**—A solution of 4-aminoestrone (III) (200 mg, 0.7 mmol) and the equivalent amount of the isothiocyanate derivative in a mixture of absolute ethanol (15 mL) and acetone (5 mL) was allowed to stand at room temperature for 24–30 h. The solvent was evaporated to dryness without application of heat. The oily residues were dissolved in cold benzene or chloroform (10 mL); the precipitates were removed by filtration and treated with petroleum ether to give the thiourea derivatives (VIII–X) as white amorphous solids. The benzyl derivative XI was prepared by heating at reflux a mixture of 4-aminoestrone (III) (250 mg, 0.87 mmol) and benzylisothiocyanate (130 mg, 0.87 mmol) in absolute ethanol (30 mL) for 30 min. The solution was concentrated to 10 mL, water was added in a dropwise manner, and the solution was allowed to stand overnight to deposit colorless needles. The application of this method to prepare thioureas VIII–X gave impure products. The yields, physical constants, and ^{1}H-NMR spectral analyses are recorded in Table I. IR data for the thiourea derivatives (V–XI) (mineral oil): ν 3340–3310, 3310–3120 (NH), 3120–3050 (OH), 1730–1700 (C=O), 1595–1580 and 1490–1485 (C=C, Ar), 1540–1515, 1340–1330, 1165–1140, and 950–920 cm^{-1} (NCS amide mixed vibrational I, II, III, and IV bands, respectively); MS for VII: *m/z* (relative abundance %); M^+ absent, 216 (100), 214 (100), 174 (24), 173 (48), 172 (29), 171 (48), 134 (26), 93 (56), 87 (19), 86 (19), 77 (18), 65 (76); MS for X: 216 (100), 214 (100), 173 (21), 171 (21), 157 (19), 155 (19), 135 (27), 84 (60), 76 (15), 75 (21).

Relative Binding Affinity for the Estrogen Receptor—The ability of the compounds to bind to the uterine estrogen receptors was estimated according to a previously described experimental procedure (24). Briefly, uterine estrogen receptor cytosol was incubated at 18°C for 30 min with 5×10^{-9} M [^{3}H]estradiol (saturation amount) in the absence or presence of increasing amounts of the test compound (X) or unlabelled estrone (control). After incubation, unbound compounds were removed by dextran-coated charcoal and bound [^{3}H]estradiol was measured. The relative concentration of unlabelled estrone and test compound required to achieve 50% inhibition of the estradiol binding gave the relative binding affinity ($RBA_X = ([I_{50}]\text{estrone}/[I_{50}]_X) \times 100$).

Effect of VII and X on the Growth of MCF-7 Breast Cancer Cells—The action of the compounds on MCF-7 cell growth was estimated by measuring the amounts of DNA after 120 h of culture in the absence or presence of the test compound. In practice, MCF-7 cells were grown at 37°C in closed flasks (75 cm^2) containing Earle's minimal essential medium supplemented with L-glutamine (0.6 mg/mL), gentamicin (40 μg/mL), penicillin (100 μg/mL), streptomycin (100 μg/mL) and 10% fetal calf serum. At confluency, the cells were removed by trypsinization (0.05% trypsin, 0.025% EDTA) and suspended ($\sim 1 \times 10^5$ cells/mL) in the growth medium supplemented with charcoal-stripped fetal calf serum (0.5% charcoal and 0.005% dextran in 1.5 mL of medium, incubated overnight at 4°C). They were then plated in 35-mm Petri dishes containing this medium and cultured at 37°C in a 95% air–5% CO_2 atmosphere. After 24 h, the compounds (solvent: ethanol at the final concentration of 0.1%) were added to the culture dishes. After 48 h, the medium was replaced by fresh medium containing the drugs. The cultures were then grown for an additional 72-h period before final harvest. Both at 24 h (compound addition) and 144 h (end of experiment) the cells were washed twice with 2 mL of Earle's base before being suspended in 1.5 mL of trypsin–EDTA. Total DNA of the collected cells was precipitated in 0.5 M perchloric acid and evaluated by the diphenylamine method (25). The control was run in parallel, without the drug (solvent only added).

Liquid Chromatographic Microassay for Carbamazepine and Its 10,11-Epoxide in Plasma

Keyphrases □ Carbamazepine—carbamazepine 10,11-epoxide, HPLC □ Carbamazepine 10,11-epoxide—HPLC with carbamazepine

To the Editor:

MacKichan (1) has developed a high-performance liquid-chromatographic assay (HPLC) to measure carbamazepine and one of its active metabolites the corresponding 10,11-epoxide in plasma and saliva using double internal standardization. The double internal standard technique provides a more accurate means of quantitating these substances, since the concentrations of the parent compound and metabolite can vary in the same biological specimen by an order of magnitude or more. The HPLC technique described herein is a micronization of the assay developed by MacKichan and allows carbamazepine and its 10,11-epoxide to be accurately quantitated in biological specimens of 100 μL.

The HPLC system utilized in this procedure consists of a liquid chromatograph with an integrative data system and absorbance detector[1]. Injections were made with an auto injector[2] onto a reverse-phase column[3] equipped with a 70 × 6 mm stainless steel precolumn[4] packed with reverse-phase packing material[5]. A μ-Bondapak phenyl column was employed in these analyses since this column is routinely used in our laboratory. The tribasic sodium phosphate and chloroform used in the extraction procedure were ACS certified[6]. All solvents used in the mobile phase were HPLC grade. The carbamazepine[7], the 10,11-epoxide[7], lorazepam[8], and the *N*-demethyl derivative of diazepam[9] were gifts.

A methanolic solution of carbamazepine and the 10,11-epoxide (400 μg/mL) was employed in the preparation of the following plasma standards: 0.5, 1.0, 2.5, 5.0, 10.0, 15.0, and 30.0 μg/mL. Stock solutions of lorazepam and the *N*-demethyl derivative of diazepam were prepared in methanol at a concentration of 100 μg/mL. These solutions were then combined and diluted with distilled deionized water to create an internal standard solution containing lorazepam and the *N*-demethyl derivative of diazepam at concentrations of 10 and 15 μg/mL.

The extraction procedure is a scaled-down version of the extraction process outlined by MacKichan (1). Samples of plasma (100 μL) and an aliquot of the internal standard solution (50 μL) were added to disposable glass test tubes. Each tube was vortexed to mix the internal standard and sample. To this mixture, 100 μL of an aqueous saturated solution of tribasic sodium phosphate was added and vigorously vortexed for 10 s. Chloroform (2 mL) was then added to the tubes, which were then vigorously vortexed (30 s). The samples were centrifuged (10 min at 1500 rpm) and the aqueous phase was aspirated. The organic phase was decanted into clean test tubes and evaporated to dryness under reduced pressure at 42°C. The residues were reconstituted with 100 μL of mobile phase and ~50 μL was injected onto the column. UV absorbance was monitored at 254 nm. The mobile phase consisted of a deionized water–acetonitrile–methanol mixture (62:35:3). The addition of methanol to the mobile phase rectified some peak broadening which was encountered with the phenyl column. The chromatograms resulting from the injection of blank human plasma, human plasma with internal standards added, as well as human plasma with carbamazepine, the 10,11-epoxide, lorazepam, and the *N*-demethyl derivative of diazepam are presented in Fig. 1. All of the peaks were well resolved from each other and from endogenous components of plasma with the exception of the 10,11-epoxide peak which possessed a minor interference similar to that observed by MacKichan (1). This interfering peak can be seen in Fig. 1A and B and poses no appreciable problem with regard to quantitation of the epoxide, representing the equivalent of 0.2 μg/mL of epoxide. The retention times for the epoxide, carbamazepine, lorazepam, and the *N*-demethyl derivative of diazepam were 4.1, 5.7, 6.7, and 8.9 min, respectively.

The mean extraction recovery was 80.3% for carbamazepine and 73.3% for the corresponding 10,11-epoxide, which is lower than the essentially complete recovery of carbamazepine and the epoxide by the method of MacKichan (1). These lower recoveries may be, in part, related to the greater percentage of tribasic sodium phosphate and methanol in the extraction procedure compared with the original method. The approximate sensitivity limits for the assay are 0.1 μg/mL for carbamazepine and 0.3 μg/mL for the epoxide, based on a signal-to-noise ratio of 2.5. The calibration plot is linear in the 0.5–30 μg/mL range. Intraday and interday variability studies, based on six replicate measurements for a period of 6 d at concentrations of 1.0 and 30.0 μg/mL, have demon-

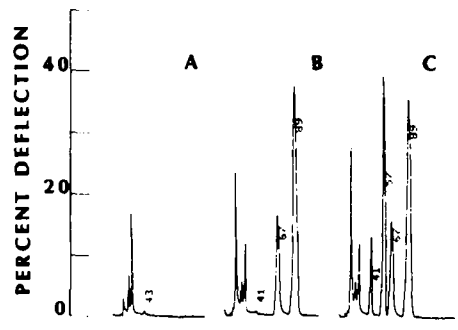

Figure 1—*Chromatograms of a blank human plasma extract (A), a plasma extract with 500 ng of lorazepam (peak 67) and 750 ng of the N-demethyl derivative of diazepam (peak 89) added (B), and a plasma extract containing 10 μg/mL of the 10,11-epoxide of carbamazepine (peak 41) and carbamazepine (peak 57) and 500 ng of lorazepam (peak 67) and 750 ng of the N-demethyl derivative of diazepam (peak 89) added (C). Detector and recorder responses for each chromatogram are 10 mV and 0.005 A full scale. The numbers beside each peak represent its retention time in tenths of minutes.*

strated assay coefficients of variation of <8.5% for both compounds.

In summary, this micronized assay provides a means for simultaneous analysis of carbamazepine and its 10,11-epoxide from small volumes of plasma. This is of particular value when analyzing samples from pediatric patient populations. In addition, this assay makes possible quantitation of these compounds in the biological fluids of many laboratory animals, where constraints may exist on the volume of blood that can be collected.

OPEN FORUM

The Ulcerogenic Potential of Copper Aspirinate Seems to be More Imaginary than Real

Alich *et al.*[1] interpreted the appearance of an intravenously injected protein-bound dye in the gastric mucosa and submucosa of rats given $Cu(II)SO_4$, $Cu(II)_2$(aspirinate)$_4$, or $Cu(II)SO_4$ plus aspirin administered with or without dihydroxyaluminum glycinate and magnesium carbonate buffer as erosions. Leakage of the protein-bound dye from the vasculature was suggested as due to damaged blood vessels. Appearance of the protein-bound dye in the mucosa and submucosa in association with the above treatments does not provide evidence of either erosions or vascular damage.

Appearance of the protein-bound dye in the mucosa and submucosa of copper compound-treated rats is more likely due to leakage associated with absorption-induced hyperemia, as shown for the vehicle control, and the quantity of protein-bound dye found in these two tissues is more likely due to the amount of copper-containing compounds absorbed and their subsequent formation of quaternary dye-protein-copper complexes which produced colorations of varying intensity. Copper sulfate, which is not lipid soluble, was poorly absorbed in the time course of this experiment while more of the lipid-soluble copper aspirinate was absorbed[2]. The combination of aspirin plus copper probably produced an aspirin- and/or salicylate-copper complex as a result of the 10-min sonication, and these complexes were nearly equally well absorbed following instillation. Appearance of the dye-protein-copper complexes in the mucosa and submucosa in association with absorption of administered copper compounds is also consistent with the poor agreement between the two "lesion" grading techniques found when aspirin was administered without a copper-containing compound.

Alich *et al.*[1] suggested that, in general, the presence of buffer had no significant effect on the extent of "damage" produced under these experimental conditions. Exception is also taken to this suggestion since it seems clear that there was a statistically significant reduction in coloration in the group given the buffered copper aspirinate preparation. This reduction in coloration is consistent with a reduction in absorption of copper complex following the formation of an insoluble form of copper, $CuCO_3$, or some other nonabsorbable form of copper during the 10-min sonication of a suspension containing 27 μmol of $Cu(II)_2$(aspirinate)$_4$, 71 μmol of $MgCO_3$, and 22 μmol of dihydroxyaluminum glycinate/mL. The formation of $Cu(II)$(glycinate)$_2$, $Cu(II)$(salicylate)$_2$, and $Cu(II)_2$(aspirinate)$_4$ during the 10-min sonication of buffer, aspirin, and $CuSO_4$ may have only partially overcome the effects of $MgCO_3$ when the copper plus aspirin preparation was used. The absorption of copper when it was given as $CuSO_4$ also appeared to have been impeded by the buffer.

In their discussion of the existing literature pertaining to effects of $Cu(II)_2$(aspirinate)$_4$, Alich *et al.*[1] further reduce the credibility of their interpretation of their results as indicating gastric erosions and vascular damage. They did point out that Williams *et al.*[2] found no gastric erosions with $Cu(II)_2$(aspirinate)$_4$, but failed to mention that Williams *et al.*[2] had used doses of 115, 345, 690, and 1380 mg of $Cu(II)_2$(aspirinate)$_4$/kg of body weight, doses much greater than the 115-mg/kg dose used in their study[1].

Alich *et al.*[1] did point out that Williams *et al.*[2] reported "some evidence" of hemorrhage without gastric erosions in rats given $Cu(II)_2$(aspirinate)$_4$, but failed to mention that this hemorrhage which was observed at 345, 690, and 1380 mg/kg was not observed at 115 mg/kg. Alich *et al.*[1] offered no rationale as to how this hemorrhage, which occurred in the absence of gastric erosions, was relevant to their gastric study or in any way supported their interpretation of their results. We have determined the $LD_{50/7}$ of $Cu(II)_2$(aspirinate)$_4$ to be 895 ± 222 and 977 ± 297 mg/kg, respectively, in male and female rats using doses ranging up to 1500 mg/kg. Doses of 1000 and 1500 mg/kg did not produce gastric ulcers but did produce diarrhea. A diarrheal-inducing bolus may cause intestinal bleeding, but this cannot be mistaken for gastric bleeding, and these doses are much greater than the 115-mg/kg dose used by Alich *et al.*[1]. We have also reported results of our chronic toxicity study of $Cu(II)_2$(aspirinate)$_4$ in rats given 100 mg/kg *for 5 d/week* for 3 months[3]. No gastric histopathology was found at the light microscopic level with this more challenging treatment regimen.

Alich *et al.*[1] incorrectly indicated that we had reported that aspirin was an active antiulcer agent in the Shay rat[4]. They also failed to notice that we reported a reduction in gastric acid secretion in response to treatment of the Shay rat with copper complexes and not an accumulation of gastric acid following pyloric ligation as they indicated. The antisecretory effects of copper complexes have been confirmed and extended by others[5-8]. These results support the suggestion that antisecretory activity, in part, accounts for their mechanism of antiulcer activity. Alich *et al.*[1] also overlooked the report by Hayden *et al.*[9] that $Cu(II)_2$(aspirinate)$_4$ prevents aspirin-potentiated ulcers in the Shay rat.

Alich *et al.*[1] questioned the significance of data obtained in nonfasted rats in comparison with their data, but failed to recognize that our Shay rat preparation, like theirs, includes fasting.

Alich *et al.*[1] did point out that Rainsford and Whitehouse[10] reported the production of ulcers in rats with $Cu(II)_2$(aspirinate)$_4$ (200 mg/kg), but overlooked the response to that report which pointed out that those studies were flawed by the use of an inappropriate suspending agent, which has the potential of removing the copper from the administered complex, and the solution of copper complexes in 20 mM hydrochloric acid, which has the potential of destroying the "dissolved" complex and freeing the ulcerogenic ligand[11].

Alich *et al.*[1] did point out that Boyle *et al.*[12] found an antiulcer effect for $Cu(II)_2$(aspirinate)$_4$, but failed to mention that the dose was 345 mg/kg, a dose 3 times as large as their 115-mg/kg dose, and dismissed their results for specious reasons, the inclusion of both number and size of lesions in their assessment of the ulcerogenicity of aspirin.

Alich *et al.*[1] also pointed out that the results reported by Lewis[13,14] and Brown *et al.*[15] were "about the same for free aspirin and $Cu(II)_2$(aspirinate)$_4$" and indicated that the method used for quantitation of was less than state of the art, but failed to mention that doses of 300 mg/kg were used.

The significance of $Cu(II)_2$(aspirinate)$_4$-induced gastric irritation, even if it did occur with doses of 100 mg/kg and higher, remains obscure since the antiulcer dose of this compound is 5–10 mg/kg[4,9,13]. The 10-mg/kg dose has also been shown to markedly increase the rate of interstitial tissue repair in the surgically induced ulcer using histochemical techniques and light microscopy[13].

strated assay coefficients of variation of <8.5% for both compounds.

In summary, this micronized assay provides a means for simultaneous analysis of carbamazepine and its 10,11-epoxide from small volumes of plasma. This is of particular value when analyzing samples from pediatric patient populations. In addition, this assay makes possible quantitation of these compounds in the biological fluids of many laboratory animals, where constraints may exist on the volume of blood that can be collected.

OPEN FORUM

The Ulcerogenic Potential of Copper Aspirinate Seems to be More Imaginary than Real

Alich *et al.*[1] interpreted the appearance of an intravenously injected protein-bound dye in the gastric mucosa and submucosa of rats given $Cu(II)SO_4$, $Cu(II)_2$(aspirinate)$_4$, or $Cu(II)SO_4$ plus aspirin administered with or without dihydroxyaluminum glycinate and magnesium carbonate buffer as erosions. Leakage of the protein-bound dye from the vasculature was suggested as due to damaged blood vessels. Appearance of the protein-bound dye in the mucosa and submucosa in association with the above treatments does not provide evidence of either erosions or vascular damage.

Appearance of the protein-bound dye in the mucosa and submucosa of copper compound-treated rats is more likely due to leakage associated with absorption-induced hyperemia, as shown for the vehicle control, and the quantity of protein-bound dye found in these two tissues is more likely due to the amount of copper-containing compounds absorbed and their subsequent formation of quaternary dye-protein-copper complexes which produced colorations of varying intensity. Copper sulfate, which is not lipid soluble, was poorly absorbed in the time course of this experiment while more of the lipid-soluble copper aspirinate was absorbed[2]. The combination of aspirin plus copper probably produced an aspirin- and/or salicylate-copper complex as a result of the 10-min sonication, and these complexes were nearly equally well absorbed following instillation. Appearance of the dye-protein-copper complexes in the mucosa and submucosa in association with absorption of administered copper compounds is also consistent with the poor agreement between the two "lesion" grading techniques found when aspirin was administered without a copper-containing compound.

Alich *et al.*[1] suggested that, in general, the presence of buffer had no significant effect on the extent of "damage" produced under these experimental conditions. Exception is also taken to this suggestion since it seems clear that there was a statistically significant reduction in coloration in the group given the buffered copper aspirinate preparation. This reduction in coloration is consistent with a reduction in absorption of copper complex following the formation of an insoluble form of copper, $CuCO_3$, or some other nonabsorbable form of copper during the 10-min sonication of a suspension containing 27 μmol of $Cu(II)_2$(aspirinate)$_4$, 71 μmol of $MgCO_3$, and 22 μmol of dihydroxyaluminum glycinate/mL. The formation of $Cu(II)$(glycinate)$_2$, $Cu(II)$(salicylate)$_2$, and $Cu(II)_2$(aspirinate)$_4$ during the 10-min sonication of buffer, aspirin, and $CuSO_4$ may have only partially overcome the effects of $MgCO_3$ when the copper plus aspirin preparation was used. The absorption of copper when it was given as $CuSO_4$ also appeared to have been impeded by the buffer.

In their discussion of the existing literature pertaining to effects of $Cu(II)_2$(aspirinate)$_4$, Alich *et al.*[1] further reduce the credibility of their interpretation of their results as indicating gastric erosions and vascular damage. They did point out that Williams *et al.*[2] found no gastric erosions with $Cu(II)_2$(aspirinate)$_4$, but failed to mention that Williams *et al.*[2] had used doses of 115, 345, 690, and 1380 mg of $Cu(II)_2$(aspirinate)$_4$/kg of body weight, doses much greater than the 115-mg/kg dose used in their study[1].

Alich *et al.*[1] did point out that Williams *et al.*[2] reported "some evidence" of hemorrhage without gastric erosions in rats given $Cu(II)_2$(aspirinate)$_4$, but failed to mention that this hemorrhage which was observed at 345, 690, and 1380 mg/kg was not observed at 115 mg/kg. Alich *et al.*[1] offered no rationale as to how this hemorrhage, which occurred in the absence of gastric erosions, was relevant to their gastric study or in any way supported their interpretation of their results. We have determined the $LD_{50/7}$ of $Cu(II)_2$(aspirinate)$_4$ to be 895 ± 222 and 977 ± 297 mg/kg, respectively, in male and female rats using doses ranging up to 1500 mg/kg. Doses of 1000 and 1500 mg/kg did not produce gastric ulcers but did produce diarrhea. A diarrheal-inducing bolus may cause intestinal bleeding, but this cannot be mistaken for gastric bleeding, and these doses are much greater than the 115-mg/kg dose used by Alich *et al.*[1]. We have also reported results of our chronic toxicity study of $Cu(II)_2$(aspirinate)$_4$ in rats given 100 mg/kg *for 5 d/week* for 3 months[3]. No gastric histopathology was found at the light microscopic level with this more challenging treatment regimen.

Alich *et al.*[1] incorrectly indicated that we had reported that aspirin was an active antiulcer agent in the Shay rat[4]. They also failed to notice that we reported a reduction in gastric acid secretion in response to treatment of the Shay rat with copper complexes and not an accumulation of gastric acid following pyloric ligation as they indicated. The antisecretory effects of copper complexes have been confirmed and extended by others[5-8]. These results support the suggestion that antisecretory activity, in part, accounts for their mechanism of antiulcer activity. Alich *et al.*[1] also overlooked the report by Hayden *et al.*[9] that $Cu(II)_2$(aspirinate)$_4$ prevents aspirin-potentiated ulcers in the Shay rat.

Alich *et al.*[1] questioned the significance of data obtained in nonfasted rats in comparison with their data, but failed to recognize that our Shay rat preparation, like theirs, includes fasting.

Alich *et al.*[1] did point out that Rainsford and Whitehouse[10] reported the production of ulcers in rats with $Cu(II)_2$(aspirinate)$_4$ (200 mg/kg), but overlooked the response to that report which pointed out that those studies were flawed by the use of an inappropriate suspending agent, which has the potential of removing the copper from the administered complex, and the solution of copper complexes in 20 mM hydrochloric acid, which has the potential of destroying the "dissolved" complex and freeing the ulcerogenic ligand[11].

Alich *et al.*[1] did point out that Boyle *et al.*[12] found an antiulcer effect for $Cu(II)_2$(aspirinate)$_4$, but failed to mention that the dose was 345 mg/kg, a dose 3 times as large as their 115-mg/kg dose, and dismissed their results for specious reasons, the inclusion of both number and size of lesions in their assessment of the ulcerogenicity of aspirin.

Alich *et al.*[1] also pointed out that the results reported by Lewis[13,14] and Brown *et al.*[15] were "about the same for free aspirin and $Cu(II)_2$(aspirinate)$_4$" and indicated that the method used for quantitation of was less than state of the art, but failed to mention that doses of 300 mg/kg were used.

The significance of $Cu(II)_2$(aspirinate)$_4$-induced gastric irritation, even if it did occur with doses of 100 mg/kg and higher, remains obscure since the antiulcer dose of this compound is 5–10 mg/kg[4,9,13]. The 10-mg/kg dose has also been shown to markedly increase the rate of interstitial tissue repair in the surgically induced ulcer using histochemical techniques and light microscopy[13].

Alich *et al.*[1] claimed that many possible variables introduced by others had been eliminated from their studies, but failed to recognize that they had introduced new variables that others had not introduced and that their results are subject to an alternative interpretation. As it turns out, this is the second paper coauthored by Alich and Wittmers on the subject of $Cu(II)_2(aspirinate)_4$ wherein conclusions were not supported by the evidence provided. In an earlier paper[14] these authors contended that salicylic acid was a contaminant of $Cu(II)_2(aspirinate)_4$, but failed to provide evidence in support of this contention[15]. The present contention by Alich *et al.* that $Cu(II)_2(aspirinate)_4$ causes erosions and vascular leakage at a dose of 100 mg/kg is not supported by evidence and it is also clearly inconsistent with results reported by ourselves and others they cited. Results obtained by Alich *et al.*[1] may be better interpreted in terms of absorption of copper compounds.

Response to: "The Ulcerogenic Potential of Copper Aspirinate Seems to be More Imaginary than Real"

Dr. John Sorenson has responded to a paper in which we showed that when intact rat stomachs were subjected to aspirin or copper aspirinate under normal conditions of absorption, and when mucosal damage was highlighted with a protein-binding dye, observations differed from those made on Shay-prepared rats by Sorenson[1]. Our data indicated that copper aspirinate gave much larger superficial lesion indices and slightly smaller deep lesion indices than aspirin alone[2]. Dr. Sorenson's article contains several comments deserving of our response.

1. Dr. Sorenson, in taking exception to our results, makes frequent reference to studies which employed the Shay rat as a model. As we indicated in our paper, the Shay rat is quite a different model from ours. We attempted to approximate normal conditions under which drugs are presented to and absorbed from the stomach. We wish to reiterate that our model is different from the Shay model, and appears to produce different results. Since the Shay rat has frequently been used by other laboratories, an effort was made to refer to such data where appropriate.

2. Dr. Sorenson interprets the lesion index graphs incorrectly. The lesion index does not measure depth of color, but sums over the number of lesions of each diameter within one of the two color groups. Therefore, the index gives a number related to total area of mucosa damaged for each kind of lesion. Our paper indicates that the two color groups were independently verified by microscopic examination to be deep and superficial erosions, the deep erosions being a very dark blue, the superficial a royal blue. Dr. Sorenson hypothesizes that the color in the mucosa is caused by a dye-protein-copper complex formed when the copper is absorbed into the mucosa and the dye-protein complex leaves the vascular system. While this is an interesting hypothesis, it does not account for all of our results portrayed in Fig. 1A and B of our paper[2]. Dr. Sorenson's hypothesis may be possible or appropriate in A, for the sets of data containing Cu(II), but does not account for the lesion index in the controls or in those rats treated with aspirin. Likewise, in B of Fig. 1, the hypothesis may fit the last two sets of bars, but not the copper sulfate control or the rats treated with aspirin. Our observations from past work indicate that Cu(II) is absorbed into the mucosa whether complexed or not. In 1- or 2-h experimental periods similar to those described in our paper, but in which no dye was used, mucosal tissue exposed to copper-containing compounds, became a uniform grey-blue color and yielded extremely high values for copper analysis indicating that copper was absorbed into the tissue[3].

In any case, the amounts of copper present in our experiments would be too small to account for the extent of the coloration of the lesions. Likewise the hypothesis does not explain why there are two distinct shades of blue. Finally, the hypothesis cannot be applied to all the data presented in the paper.

3. Sorenson states that appearance of the protein-dye complex in the mucosa under the conditions of our experiment "does not provide evidence of either erosions or vascular damage." He attributes the leakage to absorption-induced hyperemia. Under normal physiological conditions, Pontamine Sky Blue 6BX, and other protein-binding dyes, do not leak from the vascular system in any significant amount[4]. The protein movement from the vascular volume into the interstitial space is very slow, as indicated by the small permeability coefficients for molecules of this size range. All animals in our experiments were sacrificed 10 min post dye injection. The discussion in our paper details the damage to blood vessels which allows leakage of the protein–dye complex into the tissue. Use of a protein-bound dye to aid assessment of mucosal damage is not unique with us. Dr. Sorenson is aware of the papers of West and co-workers[5,6] who also used this method.

4. Dr. Sorenson, commenting on our observations of hemorrhage in the absence of visible erosions, claims we ". . . offered no rationale as to how this hemorrhage which occurred in the absence of erosions was relevant to their gastric study or in any way supported their interpretation of their results." Sorenson appears not to have understood the description of Robins' work[7]. Robins observed (electron microscope) that prior to the appearance of visible mucosal erosions, and within minutes of being placed in the stomach, aspirin caused small blood vessels to develop fenestrations and later to break down completely[7]. These observations lend support to our suggestion that bleeding occurs prior to the appearance of visible lesions. Our paper describes samples which were found, on microscopic examination, to have no lesions, but by the dye method to present superficial erosions. The extravascular accumulation of the protein-dye complex in these cases indicated that the capillary endothelium was damaged prior to the development of the lesions. We also observed complete ischemia in the centers of a number of erosions, suggesting that the circulation was severely disrupted in these areas within the 2-h exposure to the drug.

5. Dr. Sorenson refers to a reduction in gastric acid secretion in response to the treatment of the Shay rat with copper complexes. The Sorenson reference given[8] contains no mention of the measurement of acid secretion. Further, other references described inhibition of acid secretion in Shay rats by copper–amino acid complexes[9,10]. Since controls were also Shay rats, it is not possible to determine whether the acid secretion was more or less than that in a non-Shay rat. It does not appear legitimate to extrapolate such results, in Shay rats, treated with copper–amino acid complexes, to non-Shay rats treated with copper aspirinate. West and co-workers (whose work Sorenson uses to buttress his arguments in this discussion) did not find the Shay-prepared rat to be the perfect model for testing activities of drugs[6].

6. Dr. Sorenson proposes that the complex of copper aspirinate is formed by the 10-min sonication of the Cu^{2+} and aspirin mixture to be placed in the stomach. He also proposes that $CuCO_3$ or "some other nonabsorbable form of copper" is formed from copper aspirinate during the sonication in the buffered system. This is an interesting proposal, the decomposition appearing more plausible than the formation of the complex (although in our thermal analysis experiments decomposition is not observed below 265°C). In any case, it does not seem to be legitimate to propose two opposite effects by the same sonication.

7. Dr. Sorenson states that we "incorrectly indicated" that he had reported that aspirin was an active antiulcer agent in the Shay rat. Our reference is to a specific paper[1], in which the statement is made (on p. 139): "Aspirin and anthranilic acid were active at 225 mg/kg ig. Again, if this is real activity in this model then these two compounds lack potency. The question as to whether or not these are irritant-induced or false positive results remains to be answered."

These are the major points relevant to this study on which we would differ from Dr. Sorenson's interpretation of our work. It is somewhat difficult to respond to some of his statements because no data is given to support the claims made. For example, Dr. Sorenson challenges the widely accepted use of a protein-binding dye and proposes in its place an "absorption-induced" hyperemia; no substantiating evidence is presented. He proposes a difference in the rate of absorption of the different copper-containing species, giving as evidence only an oleyl alcohol/water partition coefficient for copper aspirinate/aspirin[11]. He proposes both formation and decomposition of copper complexes by sonication, again with no evidence given. Dr. Sorenson states that we neglected to report, in our survey of experiments, that he had pointed out in print[12] that a Rainsford and Whitehouse paper was flawed by the use of an inappropriate suspending agent[13]. No supporting evidence was given.

In conclusion, this challenge of our results is not a legitimate one. We believe that under the experimental conditions employed, copper aspirinate does not appear to be less damaging than aspirin. Further work is in process on the mechanism and characteristics of the gastric mucosal damage inflicted by the copper complex of aspirin as well as that of aspirin in combination with copper.

After consideration of Dr. Sorenson's concerns, as well as a review of the literature, we believe that a more thorough comparison of models is warranted. West and co-workers[5,6] have compared mucosal damage from aspirin and copper aspirinate in the stress-induced, Shay, and drug-induced ulcer models. A study is planned to compare these with the unstressed model in which the ulcers or erosions are caused by the presentation of the drug under study.

Pharmaceutical Company Data on Drugs in Breast Milk

The World Health Organization Regional Office for Europe has recently established a Working Group to produce a monograph describing the present state of information about drug excretion in breast milk and the hazards, if any, to the suckling infant. The Group is currently reviewing published literature but is aware that other data may be maintained by drug companies in internal files. The Group would welcome the opportunity to evaluate such information with a view to including it in the monograph. Drug companies which have in their possession unpublished data on excretion of drugs in breast milk are asked to contact:

These are the major points relevant to this study on which we would differ from Dr. Sorenson's interpretation of our work. It is somewhat difficult to respond to some of his statements because no data is given to support the claims made. For example, Dr. Sorenson challenges the widely accepted use of a protein-binding dye and proposes in its place an "absorption-induced" hyperemia; no substantiating evidence is presented. He proposes a difference in the rate of absorption of the different copper-containing species, giving as evidence only an oleyl alcohol/water partition coefficient for copper aspirinate/aspirin[11]. He proposes both formation and decomposition of copper complexes by sonication, again with no evidence given. Dr. Sorenson states that we neglected to report, in our survey of experiments, that he had pointed out in print[12] that a Rainsford and Whitehouse paper was flawed by the use of an inappropriate suspending agent[13]. No supporting evidence was given.

In conclusion, this challenge of our results is not a legitimate one. We believe that under the experimental conditions employed, copper aspirinate does not appear to be less damaging than aspirin. X-ray Crystallography and Drug Action. Edited by A. S. HORN and C. J. DE RANTER. Oxford University Press, 200 Madison Avenue, New York, NY 10016. 1984. 514 pp. 16 × 24 cm. Price: $59.00.

The International School of Crystallography at the Ettore Majorana Centre in Erice, Sicily, sponsors an annual week-long course devoted to one of the various interdisciplinary subdivisions of crystallography. In the spring of 1983, the ninth course was devoted to the subject of X-ray crystallography and drug action. This book is a collection of the twenty-seven papers presented at the course.

The first six papers are general reviews of the ways in which the results of both small molecule and macromolecular crystal structure determinations are applied to problems in pharmaceutical chemistry. Discussions of selected basic principles of crystal structure determination and of quantum chemical calculations are included. They are technically sound, but not so rigorous as to encourage a noncrystallographer to pass on to the next paper. The last four papers in the book are similarly comprehensive in their coverage of aspects of graphics and molecular modeling.

Most of the volume is devoted to presentations of research studies of a variety of biological systems. Pharmacologists, biochemists, and crystallographers interact in many mutually supportive ways. Two papers on the dihydrofolate reductase-thymidylate synthetase system as a therapeutic target for the treatment of a variety of diseases describe this relationship with exceptional clarity. Analgesics and neuroactive drugs are treated with similar thoroughness. The remaining presentations are so broad in scope that no summary of reasonable length could do them justice.

As with any effort involving many authors, there are places where this book falls short of its potential. The reader is denied the benefit of summaries of what must have been exciting discussions after each presentation. No single paper is concerned primarily with polymorphism, an omission which will disappoint pharmaceutical chemists. Perhaps an even more serious omission is that, with several of the contributions discussing enantiomeric effects upon drug activity, crystallographic studies of spontaneous resolution in drugs are not even considered in the review papers.

From a technical point of view, the book is extremely well produced. The typescripts provided by the authors are generally clear. Very few typographical errors were discovered. For the most part, the figures are well done and clearly labeled. A few of the stereoscopic pairs are so closely set that some individuals may encounter difficulty in achieving stereopsis, even with the aid of a viewer. The subject index could have been more complete and consistent, particularly with reference to citations of drugs by name. Computer programs are indexed by name rather than by function. This is unnecessarily confusing, since the former might well be obscure to the noncrystallographer, as well as being unrelated to the latter.

When one considers the price of this volume in relation to others of similar coverage, it is certainly modestly priced. Even with the omissions and technical shortcomings noted, the overall strength of the discussions of structure activity relationships in proteins, enzymes, and their complexes with smaller molecules makes this book a worthwhile addition to the personal library of most pharmaceutical chemists.

Fungal Metabolites. Vol. II. By W. B. TURNER and D. C. ALDRIDGE. Academic Press, 111 Fifth Avenue, New York, NY 10003. 1983. 631 pp. 16 × 23.5 cm. Price: $80.00.

As a frequent and happy user of the first volume of *Fungal Metabolites* by Turner, it was a great pleasure to see the publication of this second volume in 1983. The first volume, published in 1971, is an extensive compilation of secondary (specific) metabolites of fungi organized into chapters largely on the basis of their biogenesis. Volume II is essentially a 10-year update that includes nearly 2,000 new metabolites. Chapters 1 and 2 from Volume I dealt with primary and secondary metabolism, and aspects of cultivation and secondary metabolism. These chapters are not included as separate topics in the new book, but the few developments in these areas are covered in other sections where appropriate. References to labeling experiments used in Volume I have been deleted, but Volume II contains much new important information on carbon-13 isotopic labeling experiments extensively utilized during the past decade in the elucidation of biosynthetic pathways.

The 1983 edition of *Fungal Metabolites* is divided into seven chapters of varying length. Chapters describe groups of metabolites which are: not from acetate (40 pp.—215 references); from fatty acids (10 pp.—59 references); from polyketides (168 pp.—731 references); from terpenes (141 pp.—593 references); from tricarboxylic acid cycle intermediates (16 pp.—75 references); from amino acids (72 pp.—389 references); miscellaneous compounds (37 pp.—180 references); and an addendum chapter (62 pp.—281 references). References for all but the last chapter date largely in the 1970's with a few citations from the 1960's and 1980. The addendum chapter is essentially an update of information on all classes of fungal metabolites covered in earlier chapters, and it includes literature citations from 1980, 1981, and a few into 1982.

The bulk of this book is loaded with useful illustrations and references, and the text provides good concise coloring for the structures shown. The empirical formula, organism, and subject indices make the book practically useful. This is especially so, since the authors took great care to maintain the same organization used in the original volume. It is also easy to cross-reference between the two volumes. This is an outstanding reference-work and it is a must for any laboratory seriously engaged in research on the topic of fungal metabolites.

Pattern Recognition Approaches To Data Interpretation. By DIANE D. WOLFF and MICHAEL L. PARSONS. Plenum Press, 233 Spring St., New York, NY 10013. 1983. 223 pp. 17 × 26 cm. Price: $29.50.

This book is a "how to" description of the use of multivariate statistical packages in the evaluation of large arrays of chemical data. The authors focus primarily on techniques popularized in recent years under the general term, "pattern recognition" with a major emphasis on how to use and interpret ARTHUR (B. R. Kowalski, Laboratory of Chemometrics, Seattle, WA), SPSS (SPSS, Inc., Chicago, IL), and BMDP (Health Sciences Computing Facility, Los Angeles, CA). SAS (SAS Institute Inc., Cary, NC) and CLUSTAN (Scotland) are described to a somewhat lesser degree. The book is intended for investigators with little or no prior experience with data analysis nor with the above-mentioned statistical packages. Program descriptions, strengths, and implementation are linked to the particular versions of the packages used by the authors. For example, users of the 1977 and later versions of the ARTHUR program would be advised to refer to the manuals for those programs for program description and implementation and to the book for suggestions on problem statement, analysis, and interpretation.

Through the example of a single set of pollution data, the authors take the reader through the steps of data analysis from problem statement and data coding to final evaluation. The numerical techniques described and applied to the pollution data include data mapping, supervised and unsupervised learning algorithms, and univariate and bivariate statistics. The excellent discussion and demonstration of preliminary data evaluation and variable relationships is the major strength of this book. A minor weakness is that the opinions expressed by the authors concerning the utility-specific numerical techniques seem to be based on their experiences rather than rigorous statistical studies. The comparison of numerical techniques available in two or more packages will certainly be valued by chemists who are uncertain as to which packages better address a particular application.

Pattern Recognition Approaches to Data Interpretation is a long overdue addition to the wealth of monographs on chemometrics published over the past few years. It is unique in its applications oriented approach. The book is a recommended reader for novices and a resource for more experienced investigators.

For example, users of the 1977 and later versions of the ARTHUR program would be advised to refer to the manuals for those programs for program description and implementation and to the book for suggestions on problem statement, analysis, and interpretation.

Through the example of a single set of pollution data, the authors take the reader through the steps of data analysis from problem statement and data coding to final evaluation. The numerical techniques described and applied to the pollution data include data mapping, supervised and unsupervised learning algorithms, and univariate and bivariate statistics. The excellent discussion and demonstration of preliminary data evaluation and variable relationships is the major strength of this book. A minor weakness is that the opinions expressed by the authors concerning the utility-specific numerical techniques seem to be based on their experiences rather than rigorous statistical studies. The comparison of numerical techniques available in two or more packages will certainly be valued by chemists who are uncertain as to which packages better address a particular application.

Pattern Recognition Approaches to Data Interpretation is a long overdue addition to the wealth of monographs on chemometrics published over the past few years. It is unique in its applications oriented approach. The book is a recommended reader for novices and a resource for more experienced investigators.

X-ray Crystallography and Drug Action. Edited by A. S. HORN and C. J. DE RANTER. Oxford University Press, 200 Madison Avenue, New York, NY 10016. 1984. 514 pp. 16 × 24 cm. Price: $59.00.

The International School of Crystallography at the Ettore Majorana Centre in Erice, Sicily, sponsors an annual week-long course devoted to one of the various interdisciplinary subdivisions of crystallography. In the spring of 1983, the ninth course was devoted to the subject of X-ray crystallography and drug action. This book is a collection of the twenty-seven papers presented at the course.

The first six papers are general reviews of the ways in which the results of both small molecule and macromolecular crystal structure determinations are applied to problems in pharmaceutical chemistry. Discussions of selected basic principles of crystal structure determination and of quantum chemical calculations are included. They are technically sound, but not so rigorous as to encourage a noncrystallographer to pass on to the next paper. The last four papers in the book are similarly comprehensive in their coverage of aspects of graphics and molecular modeling.

Most of the volume is devoted to presentations of research studies of a variety of biological systems. Pharmacologists, biochemists, and crystallographers interact in many mutually supportive ways. Two papers on the dihydrofolate reductase-thymidylate synthetase system as a therapeutic target for the treatment of a variety of diseases describe this relationship with exceptional clarity. Analgesics and neuroactive drugs are treated with similar thoroughness. The remaining presentations are so broad in scope that no summary of reasonable length could do them justice.

As with any effort involving many authors, there are places where this book falls short of its potential. The reader is denied the benefit of summaries of what must have been exciting discussions after each presentation. No single paper is concerned primarily with polymorphism, an omission which will disappoint pharmaceutical chemists. Perhaps an even more serious omission is that, with several of the contributions discussing enantiomeric effects upon drug activity, crystallographic studies of spontaneous resolution in drugs are not even considered in the review papers.

From a technical point of view, the book is extremely well produced. The typescripts provided by the authors are generally clear. Very few typographical errors were discovered. For the most part, the figures are well done and clearly labeled. A few of the stereoscopic pairs are so closely set that some individuals may encounter difficulty in achieving stereopsis, even with the aid of a viewer. The subject index could have been more complete and consistent, particularly with reference to citations of drugs by name. Computer programs are indexed by name rather than by function. This is unnecessarily confusing, since the former might well be obscure to the noncrystallographer, as well as being unrelated to the latter.

When one considers the price of this volume in relation to others of similar coverage, it is certainly modestly priced. Even with the omissions and technical shortcomings noted, the overall strength of the discussions of structure activity relationships in proteins, enzymes, and their complexes with smaller molecules makes this book a worthwhile addition to the personal library of most pharmaceutical chemists.

Fungal Metabolites. Vol. II. By W. B. TURNER and D. C. ALDRIDGE. Academic Press, 111 Fifth Avenue, New York, NY 10003. 1983. 631 pp. 16 × 23.5 cm. Price: $80.00.

As a frequent and happy user of the first volume of *Fungal Metabolites* by Turner, it was a great pleasure to see the publication of this second volume in 1983. The first volume, published in 1971, is an extensive compilation of secondary (specific) metabolites of fungi organized into chapters largely on the basis of their biogenesis. Volume II is essentially a 10-year update that includes nearly 2,000 new metabolites. Chapters 1 and 2 from Volume I dealt with primary and secondary metabolism, and aspects of cultivation and secondary metabolism. These chapters are not included as separate topics in the new book, but the few developments in these areas are covered in other sections where appropriate. References to labeling experiments used in Volume I have been deleted, but Volume II contains much new important information on carbon-13 isotopic labeling experiments extensively utilized during the past decade in the elucidation of biosynthetic pathways.

The 1983 edition of *Fungal Metabolites* is divided into seven chapters of varying length. Chapters describe groups of metabolites which are: not from acetate (40 pp.—215 references); from fatty acids (10 pp.—59 references); from polyketides (168 pp.—731 references); from terpenes (141 pp.—593 references); from tricarboxylic acid cycle intermediates (16 pp.—75 references); from amino acids (72 pp.—389 references); miscellaneous compounds (37 pp.—180 references); and an addendum chapter (62 pp.—281 references). References for all but the last chapter date largely in the 1970's with a few citations from the 1960's and 1980. The addendum chapter is essentially an update of information on all classes of fungal metabolites covered in earlier chapters, and it includes literature citations from 1980, 1981, and a few into 1982.

The bulk of this book is loaded with useful illustrations and references, and the text provides good concise coloring for the structures shown. The empirical formula, organism, and subject indices make the book practically useful. This is especially so, since the authors took great care to maintain the same organization used in the original volume. It is also easy to cross-reference between the two volumes. This is an outstanding reference-work and it is a must for any laboratory seriously engaged in research on the topic of fungal metabolites.

Pattern Recognition Approaches To Data Interpretation. By DIANE D. WOLFF and MICHAEL L. PARSONS. Plenum Press, 233 Spring St., New York, NY 10013. 1983. 223 pp. 17 × 26 cm. Price: $29.50.

This book is a "how to" description of the use of multivariate statistical packages in the evaluation of large arrays of chemical data. The authors focus primarily on techniques popularized in recent years under the general term, "pattern recognition" with a major emphasis on how to use and interpret ARTHUR (B. R. Kowalski, Laboratory of Chemometrics, Seattle, WA), SPSS (SPSS, Inc., Chicago, IL), and BMDP (Health Sciences Computing Facility, Los Angeles, CA). SAS (SAS Institute Inc., Cary, NC) and CLUSTAN (Scotland) are described to a somewhat lesser degree. The book is intended for investigators with little or no prior experience with data analysis nor with the above-mentioned statistical packages. Program descriptions, strengths, and implementation are linked to the particular versions of the packages used by the authors. For example, users of the 1977 and later versions of the ARTHUR program would be advised to refer to the manuals for those programs for program description and implementation and to the book for suggestions on problem statement, analysis, and interpretation.

Through the example of a single set of pollution data, the authors take the reader through the steps of data analysis from problem statement and data coding to final evaluation.
