The dose response curves of plasma calcium levels following the rectal administration with the gel base (0.1% w/v; pH 5.5) are shown in Fig. 3. The rapid decrease of the plasma calcium level was observed at doses of 1 and 5 U/kg but, at doses of 0.1 and 0.5 U/kg slight hypocalcemic effects were seen from 30 min to 2 h.

In the experiment shown in Fig. 4, the hypocalcemic effect following rectal administration in polyacrylic acid gel base (0.1% w/v; pH 5.5) was compared with that obtained following administration in a triglyceride fatty acid mixture base, polyethylene glycol 1000, or saline solution at doses of 5 U/kg. The saline solution produced no hypocalcemic effect whereas the triglyceride fatty acid mixture preparation produced little hypocalcemic effect. The polyethylene glycol 1000 preparation produced a slight hypocalcemic effect; the minimum calcium level observed at 30 min after administration of [Asu^{1,7}]-eel calcitonin was ~93% of the initial level. Figure 5 compares the hypocalcemic effect produced by rectally administered material in the polyacrylic acid gel base (0.1% w/v; pH 5.5) with that administered intravenously. The plasma [Asu^{1,7}]-eel calcitonin levels obtained with rectal administration were compared with those with intramuscular administration. An enzyme immunoassay method was used to determine the [Asu^{1,7}]-eel calcitonin levels (Table I).

0.1% Gel Base (pH 6.5) containing 0.9% NaCl	3	0.388 ± 0.043	6.01 ± 0.21
0.1% Gel Base (pH 7.5) containing 0.9% NaCl	3	0.347 ± 0.022	6.85 ± 0.60

[a] Each value is a mean ± *SEM*. [b] $p < 0.05$ when compared to saline using student's t test.

Rectal administration in a polyacrylic acid gel base (0.1% w/v; pH 5.5) required a dose 35 times greater than an intravenously administered dose to achieve an equivalent hypocalcemic effect (Fig. 5). When the calcitonin analogue was given rectally in the polyacrylic acid gel base, the apparent bioavailability was found to be ~0.80% (Table I) of a comparable intramuscular administration.

Protein and Calcium Releases from the Rectal Mucosa—In order to examine the effect of polyacrylic acid aqueous gel base on rectal mucosa, protein and calcium releasing effects were investigated. Table II shows the amounts of protein calcium released from the rectal mucosa. The protein and calcium releasing effects of 0.01 and 0.1% w/v polyacrylic acid gel base were increased by ~2 times that of saline. However, isotonic gel bases (at pH 5.5, pH 6.5, and pH 7.5 containing 0.9% NaCl) did not show the calcium and protein releasing effect.

DISCUSSION

It has been generally considered difficult for a peptide hormone such as [Asu[1,7]]-eel calcitonin to be absorbed through the intestinal mucosa. In this study, the rectal administration of [Asu[1,7]]-eel calcitonin in a saline solution at a dose of 5 U/kg did not lower the plasma calcium levels (Fig. 4). However, absorption from the rectum was significantly facilitated by a polyacrylic acid gel base. The pH of the gel and the concentration of polyacrylic acid in the gel base affected the rectal absorption. The rectal absorption increased with decreasing pH of the gel base in the range of pH 5.5–8.5 (Fig. 1). In the experiment where the concentrations of the polyacrylic acid in the gel base were varied, the increased absorption was in the following order of strength: 0.1% w/v > 0.05% w/v > 0.01% w/v > 1.0% w/v. The enhanced absorption (as noted by lowering of plasma calcium levels) was concentration dependent in the range of 0.01–0.1% w/v polyacrylic acid. The insignificant plasma calcium lowering effect noted with 1% w/v polyacrylic acid gel might have been due to the high viscosity of the gel and/or the interaction of the calcitonin analogue with the polyacrylic acid in the gel base.

When 1 U/kg was rectally administered in polyacrylic acid gel bases that were either isotonic (293 mOsm/kg) or hypertonic (865 mOsm/kg)—0.1% w/v; polyacrylic acid gel pH 5.5 containing 0.9% w/v and 3% w/v NaCl, respectively—the hypocalcemic effects were little or none (data not shown). Perhaps, the permeability of the calcitonin analogue through the rectal mucosal membrane in isotonic and hypertonic conditions was supressed by the exudation of fluids.

In order to clarify the mechanism of the promoting effect of the polyacrylic acid gel base, the authors studied the release of protein and calcium from the rectal mucosa. The 0.01% w/v and 0.1% w/v gel bases containing no additional sodium chloride (*viz* hypotonic) increased the release of protein and calcium from the rectum. However, the 0.1% w/v gel base containing 0.9% w/v NaCl did not show any such releasing effect. Further, microscopic examination of histological samples revealed that the polyacrylic acid gel base caused no damage to the surface of the rectal mucosa, as shown in a preliminary experiment (4). The amount of protein released by this gel base from the rectal mucosa was negligible compared with that by sodium deoxycholate and sodium lauryl sulfate (11).

The sequestering of calcium ions to polyacrylic acid was previously reported by Murata and Arai (12) and Robb and Sharples (13). These authors found that the polyacrylic acid gel base had chelating properties towards calcium. In the present study, the amount of calcium released by a hypotonic polyacrylic acid gel base from the rectal mucosa was also higher than that with a saline solution. Thus, the polyacrylic acid gel base may have altered the rectal epithelial barrier by depleting calcium ions at the mucosal membrane. Calcium ions are important for preserving a tight intercellular structure.

The comparative bioavailability of the calcitonin analogue following rectal and intramuscular administration showed that ~35 times as much drug was needed in a gel base (0.1% w/v; pH 5.5) given rectally to produce an equivalent hypocalcemic effect. The mechanism of enhancement of rectal absorption by the polyacrylic acid gel is unclear. Its major absorption pathway, perhaps, is *via* a paracellular route through the intercellular channels rather than *via* a transcellular route through the epithelial cells.

This study showed that polyacrylic acid aqueous gel base might be used to promote the rectal absorption of polypeptide drugs, such as [Asu[1,7]]-eel calcitonin.

Received September 12, 1983, from the *Department of Biomedicinal Chemistry, University of Nebraska Medical Center, Omaha, NE 68105.* Accepted for publication October 18, 1983.

Abstract □ The percutaneous absorption and disposition of iodochlorhydroxyquin (5-chloro-7-iodo-8-quinolinol; I) from a 3% cream were studied in five dogs over a 28-d topical treatment period. Plasma levels, determined by HPLC, were 0.275–0.525 μg/mL. The steady-state elimination rate of total I in urine was 2.4–3.0 mg/d. The apparent elimination rate constant and half-life were 0.25 ± 0.05 d^{-1} and 3.1 ± 0.5 d, respectively. Greater than 50% of topically applied I was absorbed over 16 h. Occlusion of the skin without the drug indicated that the skin acted as a reservoir for the drug. Feces analysis for iodochlorhydroxyquin from one dog showed that 27.1 ± 8.5 mg/d was eliminated *via* this route. Tissue levels of I 15 d after the 28-d topical treatment were 0.7 μg/g of liver, 0.2 μg/g of kidney, and 0.8 μg/g of mesenteric fat. The apparent rate constants of plasma level decline after a 100-mg iv bolus dose of I were $\alpha = 3.9\ h^{-1}$ and $\beta = 0.6\ h^{-1}$. The urinary elimination after intravenous administration was biphasic. The rate constant for the slow elimination phase was 0.4 ± 0.1 d^{-1}, and the half-life was 2.0 ± 0.5 d. The primary neurological symptoms observed during topical treatment were ataxia and hind limb paralysis. Microscopic examination revealed liver necrosis. A weight loss of 15.3 ± 2.7% was also observed over the 28-d topical treatment period. The results indicate that significant percutaneous absorption of I occurs, and that chronic high-dose topical treatment may lead to toxicity.

Keyphrases □ Iodochlorhydroxyquin—percutaneous absorption and disposition in dogs □ Absorption—percutaneous, disposition of iodochlorhydroxyquin in dogs □ Neurotoxicity—percutaneous absorption and disposition of iodochlorhydroxyquin in dogs

Iodochlorhydroxyquin (5-chloro-7-iodo-8-quinolinol; I), also known as clioquinol, is a dihalogenated derivative of 8-hydroxyquinoline. It is used widely as an amebicidal agent, and as an antibacterial and antifungal agent for the treatment of various dermatological disorders. Due to its neurotoxicity, the drug is no longer given orally in the United States and Japan, but it is still used orally in many countries (1, 2). Iodochlorhydroxyquin is still used topically for diaper rash and other skin disorders and is presumed to undergo little or no percutaneous absorption. Tateishi and Otsuki (3) first reported that oral administration to dogs, cats, and monkeys resulted in the occurrence of a myelo-opticneuropathy. The neurological symptoms seen in these animals were comparable with those seen in patients suffering from subacute myelo-opticneuropathy (3).

Worden and Heywood (4) have reported hind limb and proprioceptive reflexes and yellow staining of the fur when dogs were treated orally with 250–400 mg of I per kg of body weight daily for 25 weeks. The minimum serum levels of I at the beginning of intoxication during chronic studies in adult dogs were 6–22.6 μg/mL when given 100 mg/kg/d orally (5).

Hansson (6) has studied the oral absorption of the drug in normal humans and reported that 3–5% of a given oral dose was recovered in the urine. Berggren and Hansson (7) have observed that the proportion of an oral dose of halogenated hydroxyquinoline which is absorbed was as high as 46%.

Iodochlorhydroxyquin is believed to undergo limited absorption through the skin, although few data are available on the extent of this absorption. A child with generalized psoriasis treated with ointment containing I was reported to have 18.1 mg/100 mL of the conjugated drug in the urine (8). Fischer and Hartvig (9) treated four patients with widespread dermatitis of an unstated type with an ointment containing 3% I, and serum levels of I were estimated by electron-capture GC to be 0.8–1.2 μg/mL. In this study, we examined the percutaneous absorption and excretion of iodochlorhydroxyquin in dogs.

EXPERIMENTAL SECTION

Animals and Procedure—Five male mongrel dogs (weight, 16.5–19 kg) were used. The dogs were fed a solid diet[1] and had free access to water. All dogs were treated for parasites and vaccinated against hepatitis. The animals were maintained for at least 1 week before initiating the studies. Five grams of 3% iodochlorhydroxyquin cream[2] was applied topically twice daily at 8 a.m. and 4 p.m. for 28 d over a 200-cm^2 area on the back of each dog after the area was shaved. The area was occluded with plastic wrap[3] and gauze. Before application of each new dose of I, the skin was cleansed with water and dried. Blood samples were drawn at the following times during treatment: 0, 1, 2, 4, 6, 8, 10, 12, and 24 h and 2, 3, 4, 7, 14, 21, and 28 d. Blood samples were obtained during the first week through an indwelling catheter placed in the jugular vein. The tubing was tunneled under the skin from the jugular vein to the back behind the head and exteriorized. The exposed end of the catheter was covered with a padded collar around the neck to prevent damage to the catheter by the dog. Each dog was also inserted into an elastic stockinette which enclosed the collar, neck, and thorax and prevented scratching of the jacketed area. The patency of the catheter was maintained by flushing with normal saline and filling with heparin sodium (1000 USP U/mL) every day. A blood sample was withdrawn and discarded, and a 3-mL sample of blood was then withdrawn for analysis.

At the end of the first week of treatment, the catheter was closed. For the subsequent time intervals, blood samples were drawn from a foreleg using heparin as the anticoagulant. Plasma was separated by centrifugation at 3000×*g* for 10 min and refrigerated or frozen if the samples were not analyzed immediately. No plasma sample was kept for more than 3 days before analysis. Urine samples taken every 24 h were collected at the following times during treatment by using metabolism cages: 1, 2, 3, 4, 5, 6, 7, 10, 14, 21, and 28 d. Feces were collected every 24 h from one dog during the 28-d treatment on days 0, 1, 7, 14, 21, and 28.

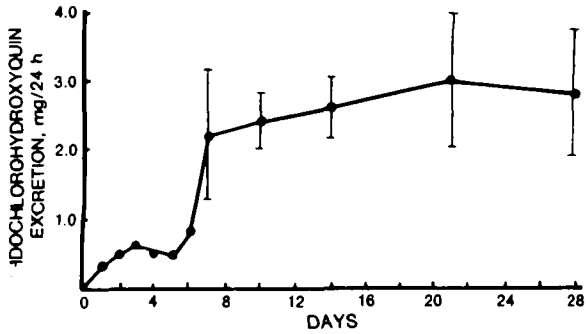

Figure 2—*Mean rate of excretion ± SD of total iodochlorhydroxyquin with time over 28 d of topical treatment of five dogs.*

After the 28-d topical treatment, blood and urine samples were collected at 2, 3, 4, 6, 8, 10, and 12 d posttreatment. Following this 12-d posttreatment interval, the backs of the dogs were again occluded with plastic wrap and gauze without drug, and blood and urine samples were obtained for an additional 6 d. The general condition of the dogs was examined daily, and the animals were weighed weekly.

Two months after topical treatment with I, three dogs were given a single bolus dose of 100 mg of I intravenously dissolved in 2.0 mL of dimethyl sulfoxide and 0.50 mL of ethanol. Blood samples were drawn at 15, 30, 45, 60, 120, and 180 min, and urine samples were collected each 24 h for 6 d.

Microscopic Examinations—The optic nerve from one dog that was killed after 28 d of topical treatment with I was isolated and fixed with glutaraldehyde and examined by electron microscopy. Kidney and liver tissues obtained from the dogs following sacrifice (after the intravenous treatment with I) were examined microscopically. Formalin (10%) was used to fix the tissues. Liver and kidney sections were also fixed and examined from one dog which died 15 d posttreatment.

Sample Analysis—The plasma concentration of nonconjugated iodochlorhydroxyquin was determined by HPLC after ether extraction by using a C_{18} reverse-phase column (10). The total urinary excretion of I after hydrolysis of conjugated metabolites according to Chen *et al.* (11) was assayed by a previously described HPLC procedure (12). The nonabsorbed I remaining on the backs of the dogs after topical treatment was also analyzed by HPLC as previously reported (13).

RESULTS AND DISCUSSION

Iodochlorhydroxyquin (I) cream was applied twice daily for 28 d, and the mean plasma level of nonconjugated I from five dogs were determined and plotted against time (Fig. 1). A steady-state plasma level was achieved in 4–5 d at ~0.5 μg/mL. Our results demonstrated that the drug is readily absorbed through the skin and presumably passes directly into the systemic circulation where easily measurable levels of the nonconjugated form occur after topical treatment (Fig. 1). Plasma levels could be detected 12 h after initial application, and accumulation of the drug in plasma did not occur.

During topical treatment, 24-h urine samples were collected, and the mean rate of elimination was plotted against time (Fig. 2). After day 7, the elimination rate reached steady state and ranged from 2.4 to 3.0 mg/24 h. In previous studies, it has been shown that >90% of the drug excreted in the urine

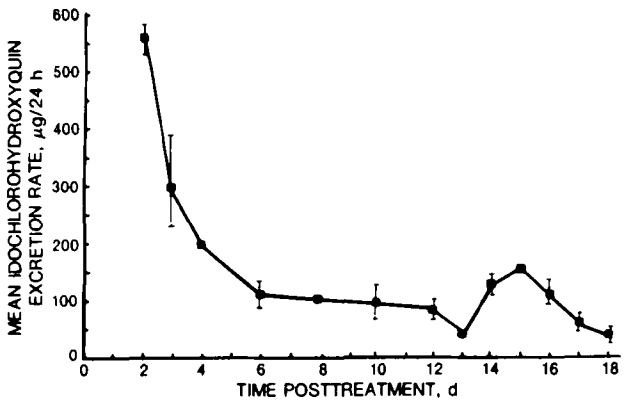

Figure 3—*Mean ± SD of total iodochlorhydroxyquin excreted with time after topical treatment and after again occluding the backs of the dogs with plastic wrap.*

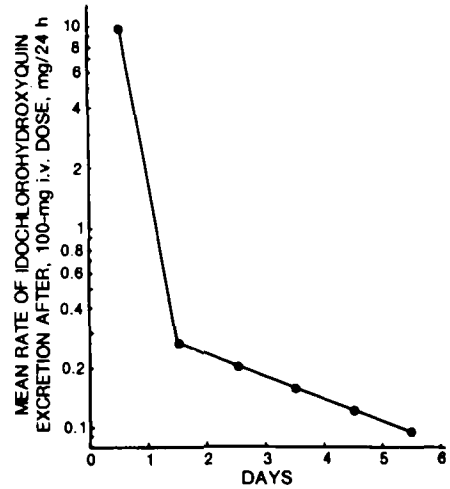

Figure 4—*Logarithmic plot of the mean excretion rate of iodochlorhydroxyquin with time after discontinuation of topical treatment in four dogs.*

is in the conjugated form, either as the glucuronide or sulfate (5). Therefore, the total amount of the drug eliminated in the urine during topical application was determined after hydrolysis of the conjugates. In spite of continuing topical treatment, the plasma levels and urine excretion rates remained constant, suggesting that the drug was being eliminated *via* another route and/or being stored in various tissues of the dogs. Therefore, feces from one dog were collected and analyzed over 28 d of topical treatment. The average total excreted in the feces was 27.1 ± 8.5 mg/24 h, indicating that the drug was being excreted largely by the fecal route as compared with urinary elimination. Previous studies have also shown excretion in the feces. Tamura (2) has reported that most of the iodochlorhydroxyquin conjugates are concentrated in the bile and are excreted into the intestinal lumen. A greenish-colored stool has also been seen in experimental dogs suffering from subacute myelo-opticneuropathy (3) and is due to the formation of an iron chelate of the drug.

After topical treatment for 28 d, the plasma levels and urinary excretion of the drug were followed for an additional 12 d. The elimination rate was plotted against time (Fig. 3). The 24-h rate of total elimination decreased from 568 ± 31 μg at 48 h posttreatment to 78 ± 26 μg after 12 d. The plasma concentration fell under the detection limit of our assay method 1 d after discontinuation of treatment. The rate constant of decline of elimination and the apparent half-life ($t_{1/2}$), were calculated from the slope of a plot of the logarithmic rate of elimination against time (Fig. 4) and Eq. 3 (see below). These values are 0.25 ± 0.05 d^{-1} and 3.0 ± 0.5 d, respectively.

The percentage of the drug absorbed was determined by measuring the amount of drug which remained on the back of each dog (14). Sixteen hours after a single 5-g application of 3% iodochlorhydroxyquin cream, 52.5 ± 4.5% of the drug was absorbed. This value is the mean of 10 determinations.

To determine whether the skin was simply acting as a permeable membrane or as a reservoir for the drug, the areas of application on the dogs were again occluded with plastic wrap and gauze without application of the drug, and the plasma levels and urinary elimination were followed for an additional 6

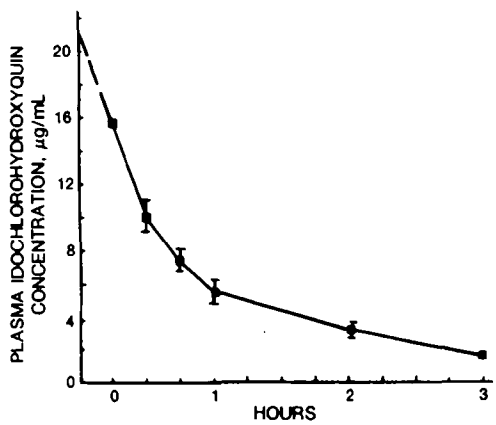

Figure 5—*Nonconjugated plasma concentration plotted with time after intravenous administration of a 100-mg iodochlorhydroxyquin dose in three dogs.*

Table I—Kinetic Parameters Calculated from 100-mg iv Bolus Injection of Iodochlorhydroxyquin in Three Dogs

α	3.9 h^{-1}
β	0.6 h^{-1}
Apparent $t_{1/2}$	1.16 h
A	20 ± 4 μg/mL
B	10 ± 2μg/mL
C_0	20.8 ± 2.6 μg/mL
Apparent Vd	4.91 ± 0.56 L
Apparent V_c	3.45 ± 0.46 L

d. Iodochorhydroxyquin was not detectable in the plasma, whereas the urinary excretion rate increased and, after 3 d of occlusion, again began to decline (Fig. 3). The elimination rate of total iodochlorhydroxyquin was 78 ± 26 μg/24 h at 12 d posttreatment, whereas the rate increased to 153 ± 8 μg/24 h during the third day of occlusion of the application site. These observations suggest that the skin acts as a reservoir for this drug, providing a slow release of I. Occlusion has been previously reported to increase the absorption and penetration of many drugs through the skin due to increased hydration of the stratum corneum and increased skin temperature (14, 15). This mechanism may explain the increase in the elimination of the drug when the site of application was again occluded without drug application.

A single intravenous administration study was conducted to obtain more kinetic data and to observe the effects of placing iodochlorhydroxyquin directly into the systemic circulation. Plasma and urine levels were monitored for 6 d. Three dogs were given 100 mg of I intravenously, and mean plasma concentrations of nonconjugated drug were plotted against time (Fig. 5). The kinetic data were calculated from the slope and intercept of a plot of the log plasma concentration with time (Fig. 6) by:

$$Vd = \frac{\text{dose}}{C_0} \quad \text{(Eq. 1)}$$

$$V_c = \frac{\text{dose}}{A + B} \quad \text{(Eq. 2)}$$

$$t_{1/2} = \frac{0.693}{k} \quad \text{(Eq. 3)}$$

where Vd is the apparent volume of distribution, V_c is the volume of the central compartment, $t_{1/2}$ is the apparent half-life, C_0 is the initial plasma concentration, A and B are the intercepts from the plot of log C against time, and, k is the apparent rate constant. The data are presented in Table I. The apparent rate constant (β) of the slow elimination phase was calculated from the slope of the plot, whereas apparent rate constant (α) for the rapid decline was calculated by the feathering method (16). A biphasic decline in the plasma levels of I was observed (Fig. 6), which may reflect in part the limited aqueous solubility of the drug (2). Furthermore, the rapid disappearance of the drug from plasma may be due to rapid metabolism as well as rapid tissue distribution as a result of the high lipid solubility of the drug.

Urine samples were also collected at various intervals after intravenous administration of I, and the mean rate of elimination with time is presented in Fig. 7. The urinary elimination of total I is biphasic, with an initial rapid elimination phase followed by a slow elimination phase, reflecting changes seen in plasma levels of the drug. The rate constant for the slow phase was determined from the slope, and the apparent $t_{1/2}$ was calculated by Eq. 3. The values are 0.4 ± 0.1 d^{-1} and 2.0 ± 0.5 d, respectively. The results shown in Figs. 6 and 7 suggest that a rapid distribution of I occurs from blood to tissue,

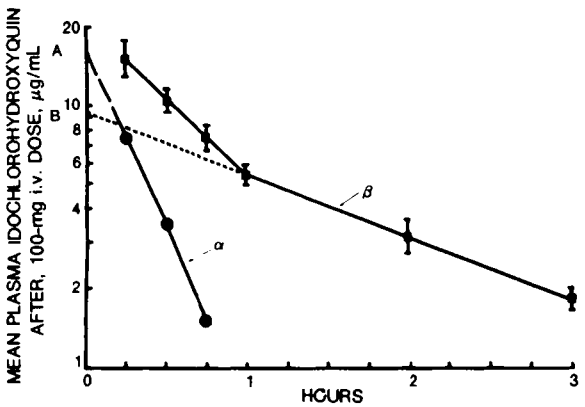

Figure 6—*Mean concentration* ± SD *of nonconjugated iodochlorhydroxyquin in plasma after a 100-mg iv bolus injection in three dogs.*

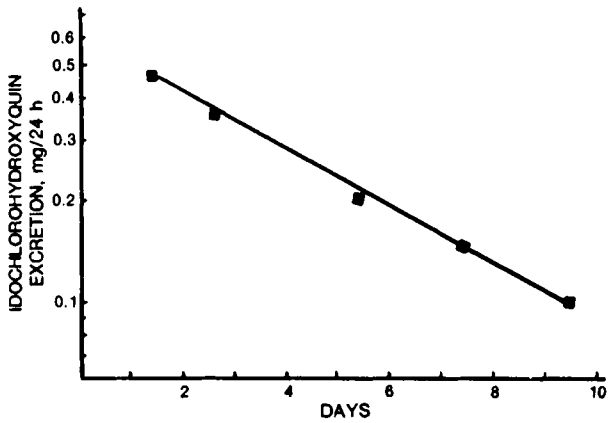

Figure 7—*Excretion rate of total iodochlorhydroxyquin after a 100-mg iv bolus dose.*

followed by a slow elimination of the drug due to the high lipid solubility of iodochlorhydroxyquin.

Liver, kidney, and mesenteric adipose tissue levels of I were analyzed from three dogs. The dogs were killed 2 weeks after intravenous treatment, and the following tissue levels were obtained: liver, 1.22 ± 0.23 μg/g; kidney, 0.83 ± 0.24 μg/g; mesenteric fat, 0.88 ± 0.14 μg/g. In addition, one dog died 15 d after topical treatment of I. The amounts of iodochlorhydroxyquin in the liver, kidney, and mesenteric adipose tissue were 0.74, 0.23, and 0.85 μg/g, respectively. Tissue retention of I has previously been reported. Tamura (2) has found 0.5, 0.3, and 0.1 μg of unconjugated I per gram of fresh liver, mesenteric adipose tissue, and sciatic nerve, respectively, in patients suffering from subacute myelo-opticneuropathy 9 months after oral treatment with I had ceased.

Weight loss occurred in all animals during topical treatment. An average loss of 15.3 ± 2.76% over 28 d was observed, while no weight loss occurred in control animals. Various neurological side effects have been reported after oral administration of iodochlorhydroxyquin (1, 17, 18). No toxicity has been reported after topical application because, in part, long-term studies have not been previously conducted; it has generally been assumed that I is not appreciably absorbed through the skin. During this 28-d study, all dogs became lethargic and less responsive to stimuli. In one of the dogs, partial hind limb paralysis was seen which was identical to that reported by Tateichi and Otsuki (3) after oral administration of iodochlorhydroxyquin. Three of the dogs developed rashes and inflammation of the treated areas. An optic nerve was removed from a dog which was sacrificed after 28 d of topical treatment and examined by electron microscopy. No damage or demyelination was observed. Optic nerve damage after long-term oral use of I has been reported (2). Either the concentrations of I achieved by topical application or the length of time the drug was applied were insufficient to produce optic nerve damage.

One of the dogs died 15 d after topical treatment. The liver was green-gray in color, suggesting hepatocellular toxicity. Microscopic examination of the liver demonstrated diffuse centrilobular and mid-zonal cell necrosis associated with marked dilation and congestion of the sinusoids, as well as the central lobular vein. No significant histological alterations were observed in the kidneys. Three other dogs were sacrificed after completion of the absorption and distribution studies. Histological examination of the kidneys indicated no renal toxicity[4]. However, examination of the livers in each case revealed centrilobular and mid-zonal vacuolization and necrosis with sinusoidal dilation and congestion[4]. The livers of control dogs did not demonstrate these changes. The results suggest that long-term topical application by an occlusion technique, as might be experienced with diaper dermatitis, can result in sufficient absorption to produce hepatotoxicity. Liver and kidney damage after oral treatment is well known and has been previously reported (19, 20).

The achievement of steady-state levels in plasma during topical treatment indicates that accumulation in plasma does not occur. Iodochlorhydroxyquin is rapidly absorbed through the skin. The liver is the main site of metabolism, primarily converting the drug to glucuronide and sulfate conjugates (2). Nonconjugated drug in plasma is transferred to the tissues due to its high lipid solubility (2). As a consequence, prolonged excretion of the drug occurs.

Nonconjugated iodochlorhydroxyquin is neurotoxic (5). Investigations by tissue culture techniques have shown direct toxic effects of the drug on nerves, whereas the glucuronide conjugate produced no cellular toxicity (21).

The results of this study indicate that it is important to use iodochlorhydroxyquin cautiously when topical application is required, particularly when

[4] Unpublished results.

it is used for a prolonged period of time and over a large body surface area, due to the extensive percutaneous absorption and the well-recognized toxicity of the drug.

In Vitro Adsorption–Desorption of Phenethylamines and Phenylimidazoles by a Bentonite and a Resin

M. S. STUL, D. P. VLIERS ˣ, and J. B. UYTTERHOVEN

Received June 17, 1982, from the *Katholieke Universiteit Leuven, Laboratorium voor Oppervlaktechemie, Kardinaal Mercierlaan 92, B-3030 Leuven (Heverlee), Belgium.* Accepted for publication August 4, 1983.

Abstract □ The adsorption of phenethylamines (dextroamphetamine, phentermine, mephentermine, diethylpropion), choline, and phenylimidazoles (levamisole and imazalil) was examined *in vitro* in aqueous solutions on bentonite and on lewatite at 25°C. An ion-exchange mechanism prevails for lewatite and for bentonite up to 0.8 mEq·g^{-1}. The organic cations are more strongly adsorbed on bentonite than on lewatite. On bentonite, the selectivity of adsorption follows the order: primary < secondary < tertiary phenethylamines. An interlamellar monolayer is formed. All drugs, except choline and imazalil, are adsorbed in excess of the cation exchange capacity of bentonite without observable Cl^- adsorption and pH changes. Desorption is reversible for lewatite and partially irreversible for bentonite.

Keyphrases □ Phenethylamines—*in vitro* adsorption-desorption by a bentonite and a resin □ Phenylimidazoles—*in vitro* adsorption-desorption by a bentonite and a resin

The prolonged action of drugs in the GI tract with a peak-and-valley pattern of the drug in the blood (1) is realized by binding, *e.g.*, phenethylamines as diethylpropion, to an ion-exchange resin. The same effect was also observed for an oral dose of a mixture of clay-drug compared to the pure drug [*e.g.*, amphetamine, (2)]. Clindamycine, tetracycline (3), and chlorpheniramine (4) are adsorbed by cation exchange under pH conditions favoring the cationic form of the drugs, and they penetrate into the interlayer spaces of montmorillonite, producing an increase in the basal distance.

There are many important clay-organic interactions, *i.e.*, some animal feed additives are adsorbed on vegetable carriers such as maize or soy starch or on resins; bentonites are used as binder and caloric extender for poultry (5); fungicides such as imazalil, used in the foliar treatment of bananas, contaminate the soil. Clay minerals constitute an interesting commercial alternative to resin. Therefore, the adsorption of phenethylamines, choline, a quaternary amine, and two imidazoles on bentonite and lewatite were investigated as model *in vitro* systems. Desorption behavior was tested with simulated gastric and intestinal fluids.

EXPERIMENTAL SECTION

The macroporous (100–200 mesh) sodium lewatite[1] and bentonite[2] were used as adsorbents. Air-dried resin was equilibrated for 2 weeks with an at-

S is the equivalent fraction of the organic cation in the equilibrium solution.*

mosphere of 40% relative humidity. The cation exchange capacity (CEC), measured by isotopic dilution of ^{22}Na, was 4 mEq·g^{-1} dry resin. The bentonite fraction, under 0.5 μm, was separated by centrifugation, washed with acidified (pH = 3.5) and neutral NaCl (1 M) solutions for removal of hydroxy-aluminum compounds, and stored in the dark as a 1% suspension. The CEC of the bentonite was 0.7 and 0.8 mEq·g^{-1} clay at pH 4 and 5, respectively.

The adsorbates were the organic cations dextroamphetamine[3], phentermine[4], mephentermine[5], diethylpropion[6], choline[7], levamisole[7], and imazalil[7]. All of these have Cl^- as the anion, except for mephentermine which was purchased as the sulfate. Amphetamine and imazalil were obtained as bases and titrated to the equivalence point with HCl.

Exchanges were carried out in polyethylene tubes by end-over-end shaking for 48 h at 25°C and 0.01 M. For lewatite, 30–50 mg of resin were equilibrated with 30–40 mL of mixed Na-organic cation solutions containing different proportions of the two ions. The lewatite was separated by centrifuging for 5 min at 14,000 rpm. In the case of bentonite, 10-mL portions of a 1% clay suspension, enclosed in dialysis tubing, were equilibrated with 20 mL of mixed Na-organic cation solution.

All adsorptions were carried out at pH 5, except for imazalil and diethylpropion, in order to minimize hydrolysis of the clay. The low pK_a of 6.53 for imazalil necessitated experiments carried out at pH 4 to ascertain the presence of the cation. In the case of diethylpropion, the decomposition of the molecule was minimized by exchange at pH 4. The extent of adsorption was determined by radiometric analyses using: ^{14}C-labeled amphetamine[8], choline[8], and diethylpropion[9]; ^{3}H-labeled imazalil[7] and levamisole[8]; ^{22}Na; ^{36}Cl[10]. Countings were performed on 5-mL aliquots of the supernatant solutions, using a liquid-scintillation counter[11] and a γ-scintillation counter[12]. The concentrations

of phentermine and mephentermine were determined by UV absorption at 252 nm[13].

The swelling of the clay was studied by X-ray diffraction. For this purpose the sediment, obtained after centrifuging for 5 min at 14,000 rpm, was transferred into a Lindemann capillary, which was sealed, transferred to a Debye-Scherrer camera, and irradiated with CuK_α. The remainder of the sediment was rinsed with distilled H_2O, centrifuged, air-dried, and dried under high vacuum for 1 d at 25°C before X-ray measurement.

Desorption experiments were carried out on the fully exchanged resins, prepared by mixing 50-mg resin and 40-mL (0.01 M) organic cation. In the case of the clay, the desorption was studied on samples containing a low and a high organic cation content. These were obtained by equilibrating 10 mL

Table I—Natural Log of the Mean Selectivity Coefficient for the Exchange of Na by the Organic Cation on Lewatite and Bentonite at 298 K

	pK_a	Formula	$\ln \overline{K}_c$ (lewatite)	$\ln \overline{K}_c$ (bentonite)
Amphetamine	9.6	$PhCH_2CH(CH_3)NH_3^+$	—	3.35
Phentermine	9.84	$PhCH_2C(CH_3)_2NH_3^+$	1.67	3.39
Mephentermine	10.11	$PhCH_2C(CH_3)_2NH_2CH_3^+$	—	4.63
Diethylpropion	8.78	$PhCOCH(CH_3)NH(C_2H_5)_2^+$	1.45	5.40
Choline		$HO—CH_2—CH_2—N(CH_3)_3^+$	—	3.26
Levamisole	8.00		—	6.39
Imazalil	6.53		3.9	7.56

of a 1% clay suspension with 30 mL 0.01 M and 30 mL 0.025 M solutions of the organic cation, respectively. The desorption procedure was as follows: after 5 min of centrifugation at 14,000 rpm, 30 mL of the supernatant was removed and used for radioassay. The addition and removal of 20-mL portions of the supernatant was performed every hour thereafter. The amount desorbed was obtained from the radioassay of the successive supernatants and was expressed as a fraction of the initially adsorbed amount. The desorbing agent used was part of a simulated gastric fluid (NaCl 0.1 M, pH 2). The drug release pattern, as a function of time, was followed for a simulated intestinal fluid [122 mmol NaCl, 5 mmol KCl, 1 mmol KH_2PO_4, and 26 mmol $NaHCO_3$/L, *i.e.*, a buffer solution of pH 8, (6)].

RESULTS

Figure 1 shows the adsorption isotherms for diethylpropion and imazalil on lewatite; phentermine follows the same pattern as diethylpropion. In all cases the maximum loading equals the CEC. The adsorption occurs by ion exchange because, at every loading, the Na^+ ion release equals the amount of adsorbed organic cation.

The adsorption isotherms for amphetamine, phentermine, mephentermine, diethylpropion, and imazalil on bentonite, together with basal spacings, are presented in Figs. 2 and 3, respectively. They have two characteristic features: (*a*) a stoichiometric ion-exchange process wherein the Na^+ ion release equals the amount of adsorbed organic cation, and (*b*) adsorption in excess of the CEC. The latter is more pronounced for amphetamine followed by phentermine, mephentermine, and diethylpropion. The excess adsorption is not accompanied by simultaneous adsorption of Cl^- or by pH changes.

The basal spacing of 1.56 nm is independent of the loading and of the type of phenethylammonium cation. For choline and imazalil they are 1.50 and 1.72, respectively. The thickness of a clay plate was 0.96 nm. The differences

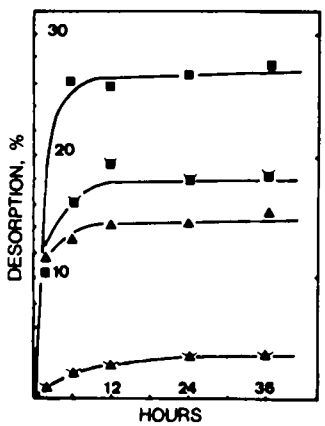

Figure 5—*Kinetic desorption profile with a buffer solution at pH 8 of: (■) phentermine-bentonite (1.06 mEq·g^{-1}), (▣) phentermine-bentonite (2.95 mEq·g^{-1}), (▲) diethylpropion-bentonite (1.14 mEq·g^{-1}), and (▲) diethylpropion-bentonite (1.78 mEq·g^{-1}).*

(*e.g.*, 1.56 − 0.96 nm = 0.60 nm) were indicative of a monolayer of organic cations on the surface.

Lewatite desorption of diethylpropion and imazalil was the reverse of the ion-exchange reaction as verified by the overlap of desorption and adsorption isotherms (Fig. 1). This is also the case for bentonite up to a loading with organic cations of ~0.7 mEq·g^{-1}. It should, however, be mentioned that since the H^+ concentration is much higher during desorption (but still 10 times smaller than the Na concentration), adsorption and desorption isotherms are not fully comparable.

When the loading on bentonite exceeds the CEC, adsorption and desorption curves are not superimposed, Fig. 4. The desorption experiments at pH 8 are presented in Fig. 5; 12 h were required to reach equilibrium. A smaller relative amount was desorbed for high loadings of organic cations as illustrated for phentermine and diethylpropion. Imazalil could not be desorbed at pH 8 because of the pK_a value and the limited solubility of the base (0.3 g·L^{-1}).

DISCUSSION

For lewatite, ion exchange was the only adsorption mechanism, whereas, for bentonite, ion exchange was followed by an excess adsorption process of the organic cations. From molecular models we estimated that 1.49 mEq·g^{-1} amphetamine and 0.9 mEq·g^{-1} diethylpropion can be adsorbed as monolayers in the interlamellar space of bentonite (700 m^2·g^{-1}) (7). Therefore, excess adsorption occurs to a large extent on the external surface, but the mechanism of adsorption is unclear.

For the exchange reaction between a solid exchanger (z) and a solution (s):

$$Na_z + B_s^+ \rightleftharpoons B_z + Na_s^+ \qquad \text{(Eq. 1)}$$

The selectivity coefficient, K_c, is defined as:

$${}^{B}_{Na}K_c = \frac{Z_B \cdot M_{Na}}{Z_{Na} \cdot M_B} \qquad \text{(Eq. 2)}$$

where Z and M refer to the equivalent fraction for the surface phase and the molality for the solution phase concentration. The latter can also be expressed in S units, *i.e.*, the equivalent fraction of the ion under consideration in the equilibrium solutions (8). The dependency of the selectivity coefficient on the organic loading is shown in Fig. 6. The mean $\overline{K}_c$ value is:

$$\ln {}^{B}_{Na}\overline{K}_c = \frac{1}{x_2 - x_1} \int_{x_1}^{x_2} \ln K_c dZ_B \qquad \text{(Eq. 3)}$$

Table II—Total Charge and Charge Density of the Ammonium Group of the Organic Cations [a]

	$-NH_xR_{(3-x)}$	$\sum_i$ (Charge/Volume)$_i$
$PhCH_2CH(CH_3)NH_3^+$	0.6239	0.1166

$PhCH_2C(CH_3)_2NH_2CH_3^+$	0.6300	0.0765
$PhCOCH(CH_3)NH(C_2H_5)_2^+$	0.7217	0.0494
$HO—CH_2—CH_2—N(CH_3)_3^+$	0.7506	0.0252

[a] Obtained from CNDO/2 calculations.

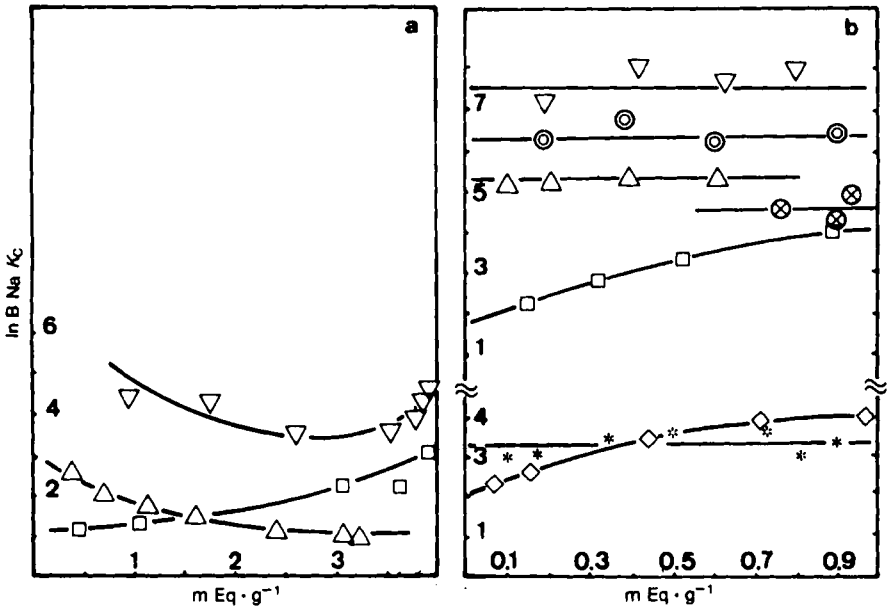

Figure 6—*Surface composition dependence of the selectivity coefficient for the exchange of Na by organic cation B at 25°C on (a) lewatite: phentermine (□), diethylpropion (△), and imazalil (▽) and, (b) bentonite: choline (*), d-amphetamine (◇), phentermine (□); mephentermine (⊗), diethylpropion (△), levamisole (◎), and imazalil (▽).*

The lower limit is necessary for the inaccuracy of the measurements at very small loadings, and the upper limit eliminates the excess adsorption. The mean selectivity coefficients are given in Table I. The data show that the organic cations are more strongly adsorbed on bentonite than on lewatite.

The selectivity order on bentonite was found to be: choline < amphetamine < phentermine < mephentermine < diethylpropion < levamisole < imazalil. This selectivity order is explained by the charge delocalization principle, which is also operative in the case of alkylammonium ions (9–11), histammonium, and ethyldiammonium ions (12). This principle states that selectivity increases with the increasing delocalization of the positive charge over a molecule.

We have calculated the charge on the N and the groups directly attached to it by CNDO/2 (13). This charge divided by the van der Waals volume is a measure of the charge density, as shown in Table II. Figure 7 shows that there is a linear correlation between the charge density and the average exchange selectivity coefficient of the organic cations investigated. There is a deviation for choline, but this is probably due to the absence of a phenyl ring.

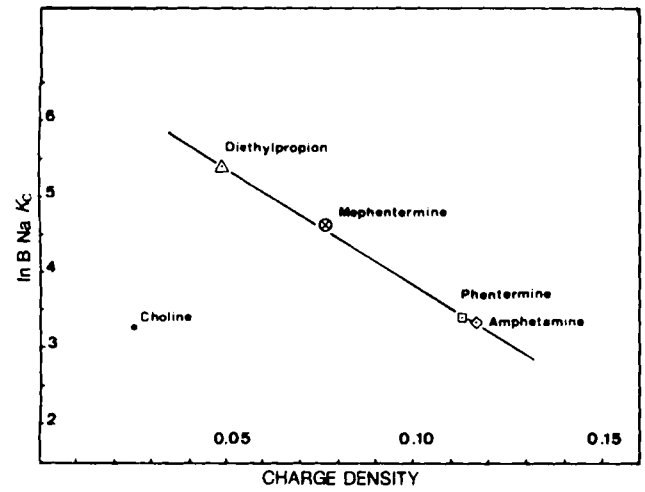

Figure 7—*The selectivity coefficient of exchange as a function of the charge density of the ammonium group.*

Pharmacokinetics and Bioavailability of Ranitidine in Humans

RAYMOND MILLER

Received March 4, 1983, from the *Department of Pharmacology, University of Potchefstroom for CHE, Potchefstroom 2520, South Africa.* Accepted for publication October 5, 1983. Present address: Department of Pharmacology, University of Durban-Westville, Private Bag X54001, Durban 4000, South Africa.

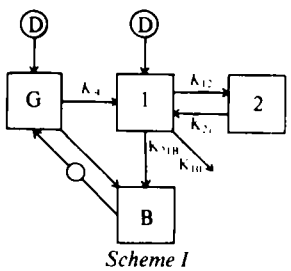
Abstract □ Ranitidine produces a blood concentration curve with a pronounced secondary peak when administered orally and parenterally. A pharmacokinetic model is proposed to describe this reabsorption phenomenon. The choice of a discontinuous cyclic transfer was justified on the basis of physiological considerations and the good agreement with data from oral and intravenous administration. It is proposed that ranitidine accumulates mainly from the systemic circulation into a depot from which drug and bioreversible drug are spontaneously released in response to food intake. The evaluation of the extent of the first-pass effect and the evaluation of bioequivalency are complicated by the model-independent AUC approach because the area under the concentration *versus* time curve (AUC) is dependent on the extent of recycling and thus does not properly reflect the extent of primary absorption. By using intravenous administration as a reference dosage form and the integrated form of the regression equations to calculate the AUC values, the bioavailability of the oral dose was found to be 0.56, which corresponds well with the value of 0.58 obtained by linear-log-linear integration. The least-squares parameter estimate of the primary absorption is 0.43.

Keyphrases □ Pharmacokinetics—bioavailability, ranitidine, humans □ Bioavailability—pharmacokinetics of ranitidine, humans □ Ranitidine—pharmacokinetics, bioavailability, humans

Evidence suggests that ranitidine, a new H_2-receptor antagonist, is at least five times more potent (on a molar basis) than cimetidine in inhibiting gastric acid secretion (1–3). Ranitidine shows unusual pharmacokinetic behavior by producing a significant secondary peak in the drug concentration profile after both oral dosing on a fasting stomach and intravenous administration (4). Cimetidine displays similar pharmacokinetic behavior after oral dosing on a fasting stomach but not after intravenous administration (5–7). Previous workers have concluded that a model requiring two exponential terms did not adequately describe ranitidine plasma level data after oral or intravenous administration (4). It is the purpose of this study to evaluate the pharmacokinetics of ranitidine with the data of Woodings *et al.* (4)[1]. It is proposed that ranitidine pharmacokinetics can be described by a two-compartment model and that the secondary peaks observed in the plasma level data can be described best in terms of discontinuous reabsorption.

EXPERIMENTAL SECTION

Theory—The proposed model (Scheme I) encompasses the kinetics of ranitidine after oral and intravenous administration (8). After oral administration, the drug is presented into the gut, the absorption compartment (G), from which a fraction (F_{G1}) of the dose (D) is absorbed by a first-order process into the central compartment (1) from which samples may be obtained. The remaining fraction ($1 - F_{G1}$) of the drug passes into compartment B in the first-pass transfer process. No assumptions are made about the type of transfer process from G to B because the kinetic behavior of the system does not depend on the rate of input into B but only on the amount of drug in B at the time that recycling takes place. At this time (t_B), a fraction (F_B) of the drug accumulated in B is spontaneously released into the absorption compartment. The drug is eliminated from the central compartment and transferred into compartment B and a peripheral compartment (2) by first-order processes. After intravenous administration, the same model applies, except that the input is a bolus input into the central compartment.



Scheme I

The choice of a discontinuous cyclic transfer process in the model is based on theoretical as well as simulation studies, which indicate that secondary peaks cannot be obtained from linear compartmental systems with continuous cyclic transfer processes (9, 10).

Data Treatment—By using the nonlinear regression program NONLIN (11), the equations describing this model (8) were fitted simultaneously by nonlinear least-squares regression to the intravenous and oral data for each of the six subjects at each dosage level. The data set for subject 1 (dose, 80 mg) was excluded from analysis since intravenous data were not available. The blood sample obtained 2 min after intravenous administration was excluded

from data analysis since at this time the drug was apparently not completely mixed in the blood. The intravenous data were, therefore, treated as a bolus administration with plasma concentrations obtained after 5 min.

RESULTS

All estimated microparameters are common for the functions describing the intravenous and oral data except for the time t_B and the fraction F_{BI} of drug release from B (Table I). The results are summarized in Tables I and II and Figs. 1–3. The conventional two-compartment model (12) fitted to the data in the same way as described above performed consistently poorer, as judged by the information criterion of Akaike (13).

The secondary peak in the plasma concentration–time curves after ranitidine administration (Figs. 1–3) appears to be due to a rapid release of ranitidine from a drug depot. The bile and hepatic parenchymal tissues are the most likely primary storage areas (14–16). The time for the release appears to coincide with the intake of food in most cases and is intermediate between the time when free fluids were permitted, 2 h after administration of ranitidine, and the time when a light lunch was provided, 3 h after administration[1]. The mean value of t_B after intravenous administration is 2.5 h, and after oral administration is 2.4 h (Table I).

The transfer of drug into the depot occurs after both oral and intravenous administration of ranitidine since a pronounced secondary peak can be observed after either form of administration. Cimetidine, on the other hand, shows a pronounced secondary peak only after oral administration (5–7). The transfer rate of cimetidine into the depot from the systemic circulation is slow compared with the first-pass transfer (8). The transfer of ranitidine into the depot, however, appears to be mainly from the systemic circulation. The mean transfer of ranitidine from the systemic circulation into the depot is 7.05 h^{-1} (Table I), which is 19 times more rapid than that of cimetidine (0.37 h^{-1}), as determined in a different group of subjects using the same model as in Scheme I (8). The area under the concentration *versus* time curve (AUC) due to ranitidine recycling was calculated by integrating the second half of the regression equations (8). The mean AUC due to recycling, normalized for dose, after intravenous and oral administration is 5.33 $ng \cdot mL^{-1} \cdot h^{-1} \cdot mg^{-1}$ (*CV* 86%) and 6.03 $ng \cdot mL^{-1} \cdot h^{-1} \cdot mg^{-1}$ (*CV*, 44%), respectively. The larger AUC after oral administration may indicate that a certain amount of ranitidine is transferred to the depot during the first-pass transfer. The difference, however, is not statistically significant.

DISCUSSION

The pharmacokinetic model proposed (Scheme I) is a highly simplified functional model constructed according to the given interpretation. The B compartment represents the depot of the drug that is partly released, (F_B) at some time (t_B) soon after or during a meal or spontaneously before a meal. Spontaneous contractions of the gallbladder have been shown to occur in the fasting stage (17). The secondary peak in the plasma concentration–time curves after ranitidine administration (Figs. 1–3) could be explained by enterohepatic circulation of ranitidine, but no information with respect to concentrations of ranitidine in bile is presently available in humans. Biliary accumulation studies in anesthetized rats showed that, in this species, up to 17% of an intravenous dose was excreted in the bile during 4–5 h (14). The model appears to agree well with the data (Figs. 1–3) and shows that the transfer of the drug into compartment B from systemic circulation (1 to B) is primarily responsible for the accumulation of the drug in B, whereas the transfer of the drug into B in the first pass (G to B) only plays a minor role (Figs. 1–3, Table I). Secondary peaks are evident but not pronounced if ranitidine is taken with food (18). The excretion of bile in response to food may play a role if the smaller amount of bile in the hepatic system reduces the uptake rate or capacity of the system.

An interesting aspect of the recycling phenomenon is its influence on the AUC values and the interpretation of bioavailability. The ratio between AUC values cannot be used as a relative measure of the extent of the drug absorption since the AUC is dependent on the extent of recycling. The AUC, therefore, does not properly reflect the extent of primary absorption (F_{GI}). By using the intravenous administration as a reference dosage form and the integrated form of the regression equations to calculate the AUC values, the bioavailability (F) of the oral dosage was 0.56 (Table II). The value obtained by linear trapezoidal integration is 0.49 (4). The linear trapezoidal method is particularly suitable when area estimates are to be compared among data which have similar shapes and sampling schemes; however, in cases in which changes in curvature between data points are excessive or there are long intervals between data points, large algorithm errors are known to occur (11, 19). No single numerical integration procedure presently available can be used to achieve maximal accuracy over all regions of the plasma concentration *versus* time curve. The best approach at present appears to be the use of the spline method during the absorption phase followed by the log-linear trapezoidal method

[a] AUC_t = AUC (i.v.) − $AUC_{(B)}$ where $AUC_{(B)}$ = area under curve resulting from recycling. [b] $D_t = FD(po) + F_BD_B(po)$. [c] The mean value is only applicable if normalized for dose.

during the elimination phase (20). However, since the computer program for the spline method is not generally available, the use of the linear trapezoidal method during the absorption phase and the log-linear trapezoidal method in the postabsorption phase is the most logical general approach. The linear-log-linear trapezoidal combination has the advantage that it is simple to apply and yields very acceptable results (21).

The AUC after intravenous and oral administration was calculated by the linear trapezoidal method for the ascending portions of the curve, whereas the log-linear trapezoidal method was used during the descending parts of the curve. The AUC was extrapolated to infinity by using the least-squares-fitted terminal log-linear slope. The model-independent bioavailability of 0.58 (*CV* 35%) thus calculated corresponds very well to the value of 0.56 calculated from the model-dependent integrated form of the regression equations (Table II).

It is evident that in the presence of recycling it is not possible to calculate F_{G1} by a model-independent approach. With the present model, F_{G1} can be determined by the nonlinear least-squares regression to the intravenous and oral data. The mean value of 0.43 (Table I) corresponds well with the extent of cimetidine primary absorption of 0.45 (8). The AUC is still a useful parameter since, physiologically and pharmacologically, it is a more meaningful parameter than one which measures the extent of primary absorption. The extent of recycled drug, however, plays a large and varying role in the determination of total bioavailability. Those times at which accumulation of drug in the recycling compartment is mainly due to the first-pass effect the secondary peak would usually be observed mainly after oral administration, as is the case for cimetidine (4). Bioavailability calculated by using the AUC after intravenous administration as a reference, therefore, varies, depending on the extent of recycling after intravenous and oral administration. F may appear to be smaller than F_{G1} if recycling after intravenous administration is greater, similar to F_{G1} if the extent of recycling is similar after intravenous and oral administration, and greater than F_{G1} if the extent of recycling after oral administration is greater. This phenomenon can be illustrated by comparing F (Table II) and F_{G1} (Table I) in subject 5. After the 40-mg dose, the secondary peak was negligible after intravenous administration and relatively large after oral administration (Fig. 2). This is reflected by a relatively large F of 0.92, as compared with the F_{G1} of 0.42. After the 80-mg dose, the secondary peaks appear to be equally large after intravenous and oral administration (Fig. 3). This is reflected by a value for F of 0.41 which is still larger than but very similar to the F_{G1} of 0.32. After the 20-mg dose, the secondary peaks after intravenous and oral administration are not very extensive and appear to be similar. The value of 0.78 for F, however, is now smaller than 0.93 for F_{G1}, which reflects more extensive recycling after intravenous administration. For ranitidine, F is generally larger than F_{G1}, except for subject 3 (80-mg dose), subject 5 (20-mg dose), and subject 6 (80-mg dose) in which the opposite is true (Tables I and II). The bioavailability of ranitidine (0.56) is lower than that of cimetidine (0.61), although the extent of primary absorption is very similar (8). This may simply be an artifact of the method of calculating bioavailability, since the greater AUC after intravenous administration of ranitidine due to recycling may artificially reduce this value.

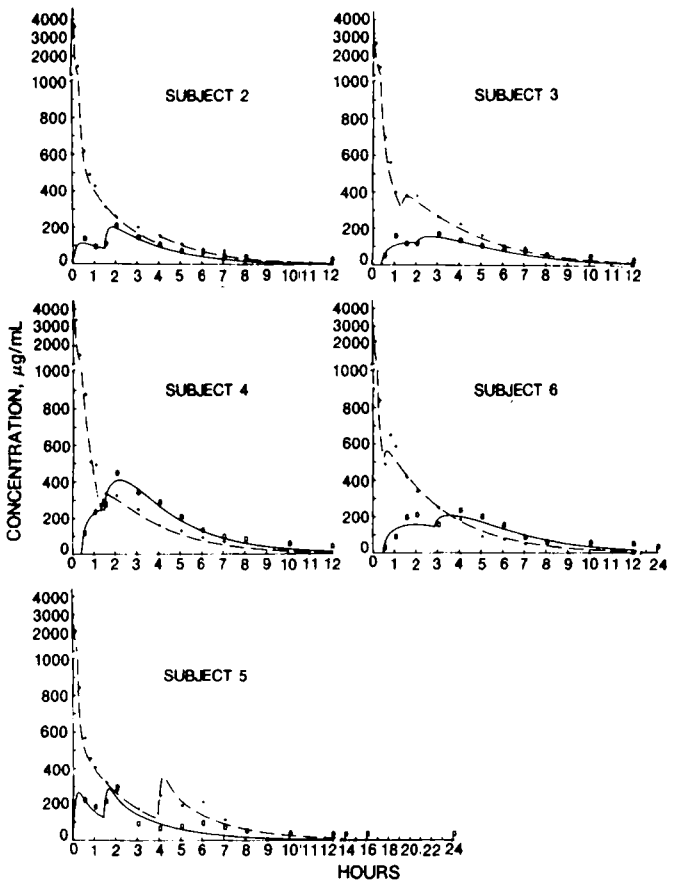

Figure 3—*Simultaneous least-squares fit of appropriate equations (8) for the pharmacokinetic model* (Scheme I) *to ranitidine data from oral (——) and intravenous (- - -) administrations of 80 mg of ranitidine.*

Ranitidine clearance, calculated as the ratio of the dose to AUC after intravenous administration, is 36.9 L/h (Table II), which is similar to cimetidine clearance, which is 35.5 L/h (8). If the AUC is corrected for recycling, the clearance of ranitidine is 45.7 L/h (Table II). Recycling of ranitidine, therefore, apparently decreases the clearance of ranitidine by ~20%. The lower clearance parameter is pharmacokinetically more meaningful and relates to the average plasma concentration attained with any particular dose.

The major difference in the pharmacokinetics of ranitidine and cimetidine appears to be that recycled ranitidine is accumulated mainly from the systemic circulation, whereas accumulation of cimetidine takes place mainly during first-pass transfer. This may be due to high affinity of ranitidine from the systemic circulation for bile. The secondary peak, however, does not seem to be present when cimetidine is taken orally with food (22), and the same phenomenon may occur after intravenous administration. The excretion of bile in response to food may play a role if the smaller amount of bile in the hepatic system reduces the uptake rate or capacity of the system. In this case, neglecting to adhere strictly to the oral administration fasting protocol when administering the drug intravenously could result in secondary peaks that are greatly reduced or absent. Under these circumstances, the assumption that cimetidine is accumulated mainly during the first-pass transfer would not be valid. To avoid any ambiguity, the identical protocol should be followed when the drug is administered extravascularly and intravascularly. In any event, this difference, whether real or spurious, would probably not account for the large difference in potency.

GLOSSARY

AUC = $\int_0^\infty C dt$

B = drug depot compartment

C = blood cimetidine concentration

D = dose
$D_B = X_B + (1 - F_{G1})D$
$D_T = F_{G1}D + F_BD_B$, the apparent amount of the dose absorbed
F = AUC_{po}/AUC_{iv}, the apparent fraction of the dose absorbed
F_B = fraction of drug accumulated in B that is released to G at time $t = t_B$
F_{G1} = fraction of D absorbed by first-order absorption into the central compartment
$1 - F_{G1}$ = fraction of D transferred from G to B
G = compartment from which absorption takes place
K_{ZZ} = first-order transfer rate constants
t = time
t_L = lag time
t_B = time when a part (F_BD_B) of the drug accumulated in B is released to G
Vd = volume of distribution
X_B = amount of drug transferred from compartment 1 to compartment B at time $t = t_B$

Dose-Dependent Pharmacokinetic Study of Pefloxacin, A New Antibacterial Agent, in Humans

J. BARRE, G. HOUIN, and J. P. TILLEMENT ˣ

Received June 29, 1983 from the *Laboratoire de Biochimie I et de Pharmacologie, Centre Hospitalier Intercommunal de Créteil, 94010 Créteil Cedex, France.* Accepted for publication September 26, 1983.

Abstract □ A dose-dependent pharmacokinetic study of pefloxacin was performed after four intravenous infusions and four orally administered doses. After intravenous infusion, the pharmacokinetic profiles of the plasma concentrations showed a biphasic decline, with half-lives (mean ± *SD*) of 8.55 ± 4.20 min and 11.50 ± 1.75 h, respectively. Intravenous infusion and oral administration yielded similar results. The pharmacokinetic parameters remained constant in the dose range of 200–800 mg from the plasma and urine data.

Keyphrases □ Pharmacokinetics—dose-dependent, pefloxacin, new antibacterial agent □ Pefloxacin—new antibacterial agent, dose-dependent pharmacokinetics □ Antibacterial agent—dose-dependent pharmacokinetics of pefloxacin

Pefloxacin[1], 1-ethyl-6-fluoro-1,4-dihydro-7-(4-methyl-1-piperazinyl)-4-oxo-3-quinolinecarboxylic acid (I), is a new antibacterial compound shown to be highly active against both Gram-negative and Gram-positive bacteria (1, 2). A large percentage (85%) of the drug administered is transformed into several metabolites, the *N*-oxide, the demethyl, and the oxodemethyl analogues (3). Since the pharmacokinetic data for this drug have not been reported in humans, a preliminary study was performed to investigate the plasma and urine profiles of pefloxacin in a dose-dependency study in humans.

EXPERIMENTAL SECTION

Materials—Pefloxacin and its 6-chloro analogue[1] (II) (the internal standard) showed no impurities in two different TLC systems. All reagents were commercially available analytical grades and used without further purification.

Pefloxacin Analysis—Unchanged pefloxacin in plasma or urine was measured by HPLC (3) using a liquid chromatograph[2] equipped with a UV spectrophotometer (280 nm) and a continuous flow cell with an 8-μL capacity. A 200-mm steel column was used, packed with a monomolecular layer of octadecyltrichlorosilane chemically bonded to silica beads with an average particle size of 7 μm[3].

D = dose
$D_B = X_B + (1 - F_{G1})D$
$D_T = F_{G1}D + F_BD_B$, the apparent amount of the dose absorbed
F = AUC_{po}/AUC_{iv}, the apparent fraction of the dose absorbed
F_B = fraction of drug accumulated in B that is released to G at time $t = t_B$
F_{G1} = fraction of D absorbed by first-order absorption into the central compartment
$1 - F_{G1}$ = fraction of D transferred from G to B
G = compartment from which absorption takes place
K_{ZZ} = first-order transfer rate constants
t = time
t_L = lag time
t_B = time when a part (F_BD_B) of the drug accumulated in B is released to G
Vd = volume of distribution
X_B = amount of drug transferred from compartment 1 to compartment B at time $t = t_B$

Dose-Dependent Pharmacokinetic Study of Pefloxacin, A New Antibacterial Agent, in Humans

J. BARRE, G. HOUIN, and J. P. TILLEMENT ˣ

Received June 29, 1983 from the *Laboratoire de Biochimie I et de Pharmacologie, Centre Hospitalier Intercommunal de Créteil, 94010 Créteil Cedex, France.* Accepted for publication September 26, 1983.

Abstract □ A dose-dependent pharmacokinetic study of pefloxacin was performed after four intravenous infusions and four orally administered doses. After intravenous infusion, the pharmacokinetic profiles of the plasma concentrations showed a biphasic decline, with half-lives (mean ± *SD*) of 8.55 ± 4.20 min and 11.50 ± 1.75 h, respectively. Intravenous infusion and oral administration yielded similar results. The pharmacokinetic parameters remained constant in the dose range of 200–800 mg from the plasma and urine data.

Keyphrases □ Pharmacokinetics—dose-dependent, pefloxacin, new antibacterial agent □ Pefloxacin—new antibacterial agent, dose-dependent pharmacokinetics □ Antibacterial agent—dose-dependent pharmacokinetics of pefloxacin

Pefloxacin[1], 1-ethyl-6-fluoro-1,4-dihydro-7-(4-methyl-1-piperazinyl)-4-oxo-3-quinolinecarboxylic acid (I), is a new antibacterial compound shown to be highly active against both Gram-negative and Gram-positive bacteria (1, 2). A large percentage (85%) of the drug administered is transformed into several metabolites, the *N*-oxide, the demethyl, and the oxodemethyl analogues (3). Since the pharmacokinetic data for this drug have not been reported in humans, a preliminary study was performed to investigate the plasma and urine profiles of pefloxacin in a dose-dependency study in humans.

EXPERIMENTAL SECTION

Materials—Pefloxacin and its 6-chloro analogue[1] (II) (the internal standard) showed no impurities in two different TLC systems. All reagents were commercially available analytical grades and used without further purification.

Pefloxacin Analysis—Unchanged pefloxacin in plasma or urine was measured by HPLC (3) using a liquid chromatograph[2] equipped with a UV spectrophotometer (280 nm) and a continuous flow cell with an 8-μL capacity. A 200-mm steel column was used, packed with a monomolecular layer of octadecyltrichlorosilane chemically bonded to silica beads with an average particle size of 7 μm[3].

CL_R, mL/min	15.3 ± 3.8	12.9 ± 2.6	14.7 ± 3.6	21.9 ± 4.8

The detection limit of the technique was 0.05 μg/mL in plasma and 0.5 μg/mL in urine, with an overall recovery of 90% from both plasma and urine. Standard curves showed good linearity from 0.125 μg/mL to 10 μg/mL, $r > 0.995$.

Human Experiments—Three subjects gave informed consent to participate in the study. They were found to be free from cardiac, renal, hepatic, respiratory, and allergic diseases by clinical and biological examinations. None of the subjects received any drugs for at least 15 d prior to the study. Each subject received four doses (200, 400, 600, and 800 mg) at weekly intervals both by intravenous infusion over 1 h and orally in 200-mg tablet form. Oral administrations were given after a 15-d wash-out period.

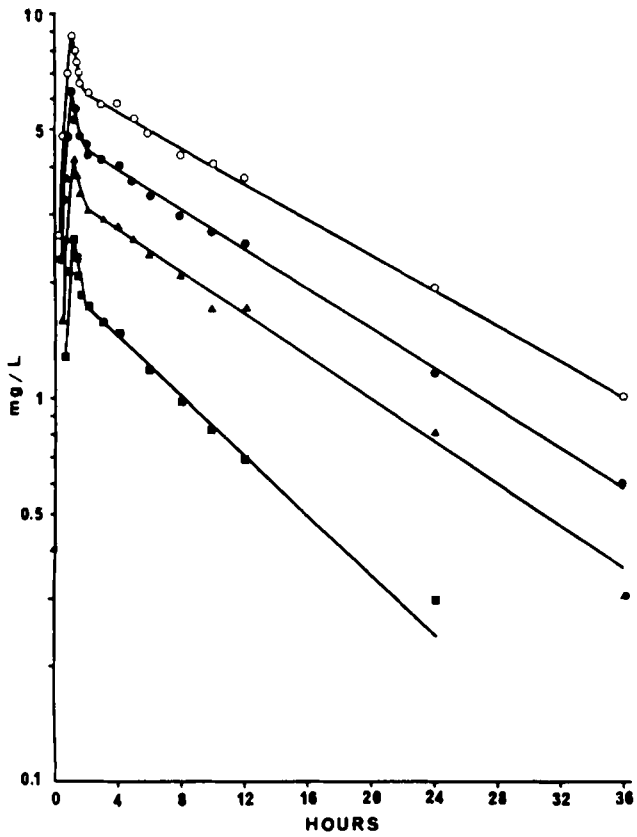

Figure 1—*Plots of mean plasma concentrations of pefloxacin* versus *time obtained in three subjects for each infused dose. The lines were generated from the best-fit pharmacokinetic parameters. Key: (■) 200 mg; (▲) 400 mg; (●) 600 mg; (○) 800 mg.*

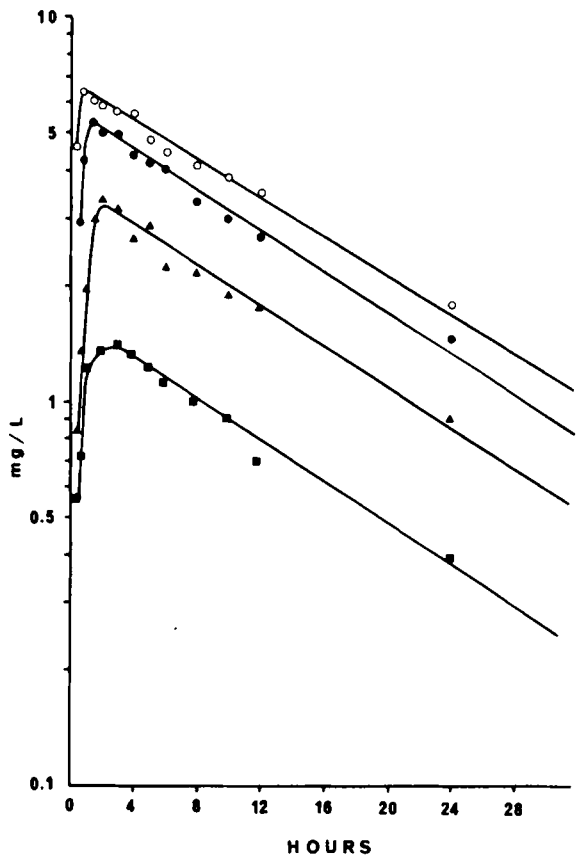

Figure 2—*Plots of mean plasma concentrations of pefloxacin* versus *time obtained in three subjects for each orally administered dose. The lines were generated from the best-fit pharmacokinetic parameters. Key: (■) 200 mg; (▲) 400 mg; (●) 600 mg; (○) 800 mg.*

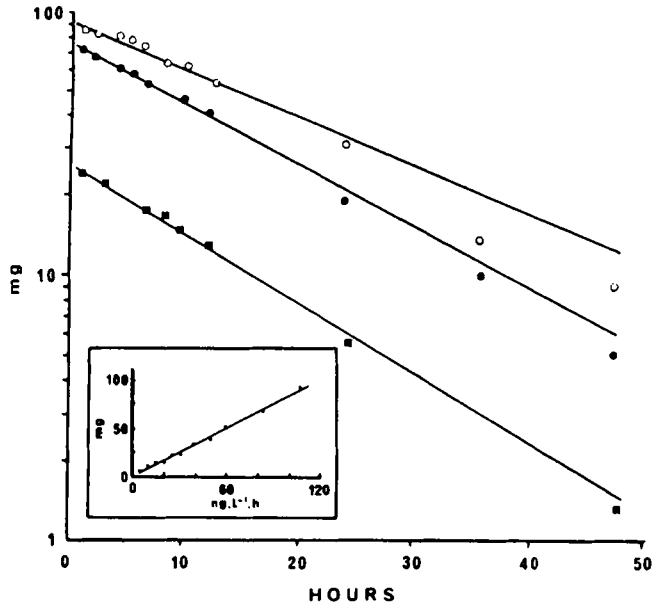

Figure 3—*Semilogarithmic plots of the amounts remaining to be excreted* versus *time in three subjects after an infused dose. Key: (■) 200 mg; (●) 600 mg; (○) 800 mg. Inset: An example of a clearance plot obtained in subject A after an infused dose of 800 mg.*

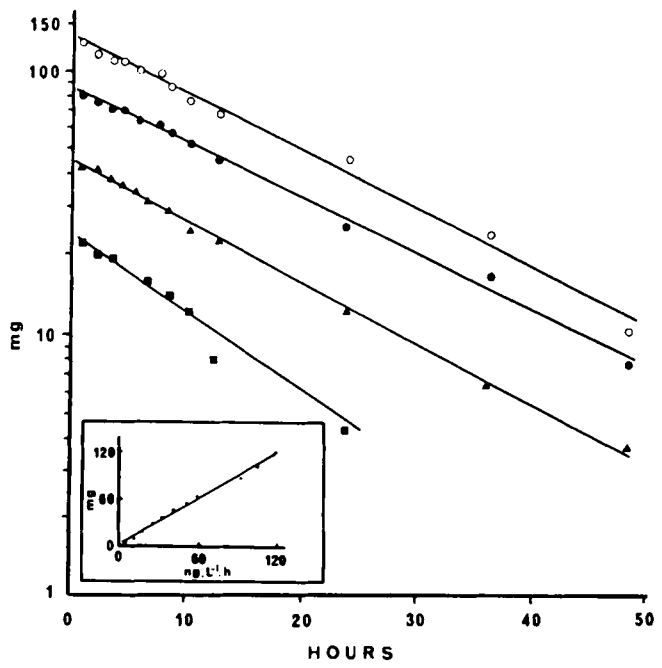

Figure 4—*Semilogarithmic plots of the amounts remaining to be excreted* versus *time in three subjects after an orally administered dose. Key: (■) 200 mg; (▲) 400 mg; (●) 600 mg; (○) 800 mg. Inset: An example of a clearance plot obtained in subject A after the orally administered dose of 800 mg.*

A 7-mL heparinized blood sample was drawn at 0, 0.25, 0.5, 0.75, and 1 h during the infusion and at 10, 15, 30, and 45 min, 1, 1.5, 2, 2.5, 3, 4, 6, 8, 10, 24, 36, and 48 h after the cessation of the infusion. After oral administration, sampling took place at 0, 0.25, 0.5, 0.75, 1, 1.5, 2, 2.5, 3, 4, 5, 6, 8, 10, 12, 24, 36, and 38 h. When variations of the infusion period or the sampling times occurred, the actual times were noted.

Urine samples were collected every hour during the first 6 h, every 2 h during the next 6 h, and every 12 h for the next 3 d.

Calculations—Statistical and pharmacokinetic calculations were performed with a table computer[4] using programs developed previously (4).

RESULTS AND DISCUSSION

Blood Sample Analysis—*Intravenous Infusion*—The mean pefloxacin plasma concentrations obtained from the three subjects receiving intravenous doses are shown in Fig. 1. Individual concentrations were systematically interpreted according to three different pharmacokinetic models, *i.e.*, one-, two-, or three-compartment open models using a Gauss–Newton algorithmic method. When pefloxacin was infused, the rate of input of the drug into the compartmental model was treated as a zero-order process; however, it was a one-order process when given orally.

At each step, the benefit of increasing the number of compartments was evaluated with a statistical Fischer test using the least-squares criterion. It showed that the two-compartment open model was the most suitable. The mean pharmacokinetic parameters (mean ± *SD*) are listed in Table I. It shows a rapid distribution phase corresponding to a 0.146 ± 0.04 h half-life (range: 0.084–0.477) and an elimination phase with an 11.5 ± 2.5 h mean half-life (range: 7.3–15.5). The volumes of distribution are large with a mean of 40.1 ± 19.1 L (range: 6.9–66.7 L) for the central compartment and 78.2 ± 28.5 L (range: 46.2–101.0 L) for the peripheral compartment.

Oral Administration—Mean pefloxacin concentrations obtained from the three subjects receiving oral doses are shown in Fig. 2. With this route of administration, the best fit was obtained with the one-compartment open model and first-order absorption. The mean pharmacokinetic parameters are presented in Table II. All parameters are in the same range as those obtained after intravenous infusion. The apparent elimination half-lives and the areas under the plasma concentration curves are essentially identical. From this last observation, it can be stated that the absolute availability of the tablets was complete, in these subjects, at each dose so that apparent volumes of distribution and total elimination clearances need not be corrected after oral administration of the drug. The distribution phase does not appear after oral administration, being masked by the absorption phenomenon from the GI tract.

Urine Sample Analysis—*Intravenous Infusion*—The rate of unchanged pefloxacin elimination was plotted against the plasma concentration at the corresponding mid-point time of urine collection. It showed a roughly linear renal clearance in each subject for all doses administered ($r > 0.85$). If the renal clearance is constant as a function of time and drug concentration, it is then possible to compute concomitantly the plasma concentrations and the rate of urinary elimination according to the general relation:

$$\frac{dU}{dt} = CL_R \cdot C \cdot dt$$

In each case, a single set of exponential terms adequately described both the plasma concentrations and the urinary elimination of the drug ($r > 0.95$ between observed and calculated values). The total amount excreted in the urine and the estimated renal clearance were added up and are presented in Table I. Furthermore, this concomitant analysis of plasma and urine data clearly show that the renal clearance was independent of the plasma drug concentrations. The urinary data, shown in Fig. 3, are plotted as the semilogarithmic amounts remaining to be excreted *versus* time. As one urine sample could not be collected after the intravenous infusion of the 400-mg dose, the corresponding plot was not drawn.

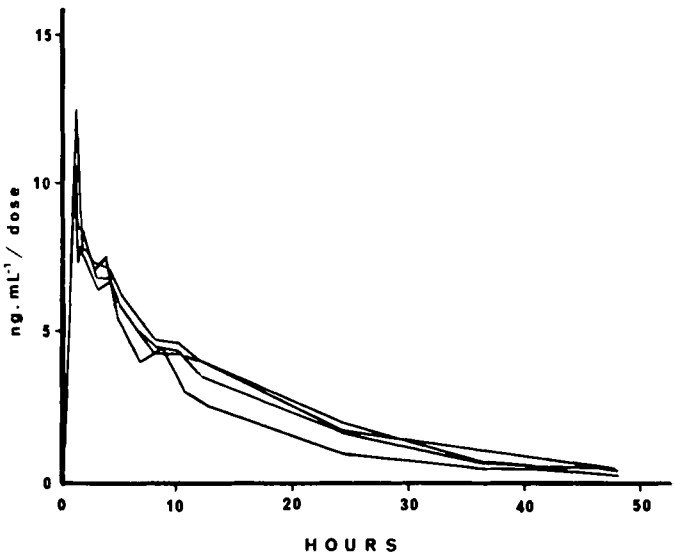

Figure 5—*Superposition of the plasma concentration curve divided by the intravenously administered dose as a function of time, in subject M.*

[4] Model 4052; Tektronix, Paris, France.

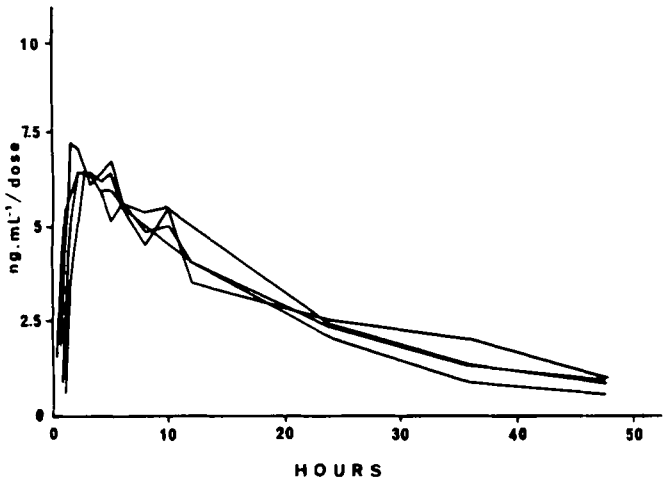

Figure 6—*Superposition of the plasma concentration curve divided by the orally administered dose as a function of time, in subject A.*

The examination of the cumulative excretion curves showed that the time of urinary collection, 4 d, was enough to have a good approximation of the total amount of the drug excreted at infinity. This result was in good accordance with a mean apparent elimination half-life of 12 h. It showed that the urinary excretion of unchanged drug accounted for 14.5 ± 6.5% of the infused drug, which was close to the results obtained in one subject in a preliminary study (3).

Oral Administration—The same pharmacokinetic analysis was performed with the data obtained after oral pefloxacin administration. The urinary data are shown in Fig. 4. The overall recovery of unchanged drug was 13.5 ± 4.1% of administered dose, similar to that observed after intravenous infusion. From this result, a high availability (close to 100% of the dose) could again be expected.

Analysis for Dose-Dependent Kinetics—The phamacokinetic analysis showed that urinary elimination, namely the renal clearance, was independent of the administered dose and plasma concentrations. Since this urinary elimination of the parent drug accounted for only 14.5% of the dose administered, 85.5% of the dose was likely to be eliminated by metabolic routes. Therefore, it was necessary to check the dose independency with parameters which took into account the overall mechanisms of drug elimination. Three methods were used to check the dose dependency from plasma results. Examples of the superposition method are shown in Figs. 5 and 6. The plasma concentrations divided by the administered dose as a function of time show a reasonable superposition for the four doses tested, either after intravenous infusion or oral administration.

According to Dost's law (5), if pharmacokinetic parameters are independent of the dose, the area under the plasma concentration curve must be linearly related to the injected dose. The mean correlation coefficients were 0.956, 0.990, and 0.998 for each subject after infusion and 0.994, 0.993, and 0.919 after oral administration. Despite the good correlation observed, there was little confidence in these results due to limited data available for a linear regression analysis. Accordingly, an analysis of variance (ANOVA) (6) was performed on the area under the curve divided by the administered dose, with the total data available, obtained after either intravenous or oral administration. It failed to show a significant difference at the 5% level between the administered doses (${}_{16}{}^{3}F = 0.46$), route of drug administration (${}_{16}{}^{1}F = 0.02$), and among the subjects (${}_{16}{}^{2}F = 0.68$). Similarly, the same ANOVA failed to show any difference between administered doses (${}_{16}{}^{3}F = 0.51$) and dosage forms (${}_{16}{}^{1}F = 0.26$) when considering urinary unchanged pefloxacin percentages. For this parameter, the analysis showed significant differences among individuals ($p < 0.05$).

Therefore, from all statistical calculations performed, it can be concluded that, within the range of the doses administered, the pharmacokinetic parameters of pefloxacin are not sensitive to dose variations. This includes both systemic and presystemic drug elimination because dose independency is observed after both intravenous and oral administration. The availability of the tablet form can be expected to be complete.

Radioimmunoassay for the Sulfoxide Metabolite of Trifluoperazine and Its Application to a Kinetic Study in Humans

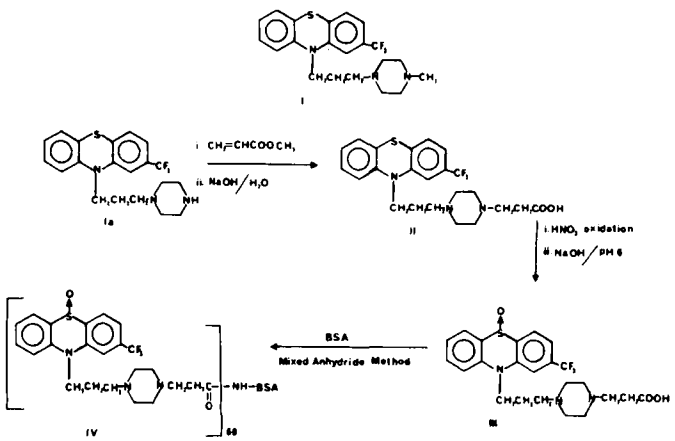
M. ARAVAGIRI, E. M. HAWES, and K. K. MIDHA ˣ

Received June 2, 1983, from the *College of Pharmacy, University of Saskatchewan, Saskatoon, Saskatchewan S7N 0W0 Canada.* Accepted for publication September 8, 1983.

Abstract □ Antibodies were produced in rabbits immunized with 10-[[3-[4-(2-carboxyethyl)-1-piperazinyl]-propyl]]-2-trifluoromethyl-10*H*-phenothiazine sulfoxide–bovine serum albumin conjugate. The subsequently developed radioimmunoassay (RIA) procedure enables, for the first time, the quantitation of the sulfoxide metabolite of trifluoperazine in the plasma of humans after administration of therapeutic doses of trifluoperazine, in which 60 pg of the sulfoxide metabolite in 200 μL of plasma can be measured with a *CV* of <3%. Similar results were obtained by this assay with or without a benzene extraction step and also in the presence or absence of a large excess of trifluoperazine and suspected major metabolites of trifluoperazine. This RIA procedure, together with a previously developed RIA for trifluoperazine was used to directly determine plasma concentrations of trifluoperazine and its sulfoxide metabolite after administration of a single, low, oral dose of trifluoperazine to five healthy volunteers. The rapidly appearing, relatively high concentrations of the sulfoxide metabolite are indicative of presystemic sulfoxidation. The mean plasma elimination half-life for the sulfoxide metabolite of trifluoperazine was 5.8 ± 1.3 h.

Keyphrases □ Pharmacokinetics—trifluoperazine and its sulfoxide metabolite, quantitation by radioimmunoassay □ Radioimmunoassay—trifluoperazine and its sulfoxide metabolite, humans □ Trifluoperazine—pharmacokinetics, radioimmunoassay, sulfoxide metabolite

Phenothiazine antipsychotic agents are extensively metabolized into numerous metabolites, some of which may be of importance with regard to the therapeutic and/or toxic effects of drug treatment. For example, in the case of the sulfoxide metabolite of chlorpromazine, high plasma levels of the drug, which is reputed to be inactive, are associated with poor clinical response in schizophrenic patients under chronic treatment with chlorpromazine. Also, in the case of chlorpromazine, some workers have demonstrated that clinical response correlates better with plasma level ratios involving active drug–inactive drug (such as the 7-hydroxylated material plus chlorpromazine–sulfoxide metabolite) rather than with the steady-state levels of chlorpromazine (1–3). With the piperazine-type, phenothiazine, antipsychotic agent trifluoperazine (I; Scheme I), the importance in clinical therapy of the presumed major metabolites of this drug, including the sulfoxide which is reputed to be inactive, is unknown. The major reason for this is that suitable, sensitive, and specific analytical methods have not been available to measure metabolite concentrations in the plasma of patients under treatment. This slow development of analytical methods can be largely attributed to the reputed instability and adsorptive loss of phenothiazines in all stages of sample handling for analysis and the low plasma levels encountered due to the low doses of trifluoperazine given to patients. In fact, only recently were ultrasensitive analytical methods such as GC–MS (4, 5) and radioimmunoassay (RIA) (6, 7) reported for the quantitation of trifluoperazine in plasma. By these methods, trifluoperazine concentrations were quantitated in plasma after administration of low, single, oral doses of this drug. On the other hand, less sensitive techniques may not be adequate for trifluoperazine plasma level monitoring in most patients; for example, by a method based on HPLC with UV detection, measurement of trifluoperazine in plasma was obtained only while the patient was under chronic treatment with doses of trifluoperazine well above the recommended therapeutic dose (8).



Scheme I

The ultrasensitive biological method of RIA has the advantage over chemical methods of analysis such as GC–MS in that extraction of the biological sample may not be necessary and such methods are more amenable to routine clinical monitoring. In this report, a rapid, sensitive, and specific RIA for the sulfoxide metabolite of trifluoperazine is described. By using this method and a previously reported RIA for trifluoperazine (6), the concentrations of trifluoperazine and the sulfoxide metabolite were determined in plasma samples up to 24 h after the administration of a single 5-mg oral dose of trifluoperazine to five healthy volunteers.

EXPERIMENTAL SECTION

Materials—The sulfoxide, *N*-demethyl, and 7-hydroxy metabolites of trifluoperazine were synthesized in this laboratory by modified literature

Table I—Cross-Reactions [a] of Antiserum Against the Sulfoxide Metabolite of Trifluoperazine

Compound Tested	Cross-Reaction, %
Sulfoxide metabolite of trifluoperazine	100
Trifluoperazine	<1
Sulfone metabolite of trifluoperazine	8
N-Oxide metabolite of trifluoperazine	<1
7-Hydroxy metabolite of trifluoperazine	<1
N-Demethyl metabolite of trifluoperazine	<1
Ethylenediamine metabolite of trifluoperazine	<1
Sulfoxide metabolite of prochlorperazine	39
Sulfoxide metabolite of fluphenazine	62
Sulfoxide metabolite of perphenazine	77
Sulfoxide metabolite of chlorpromazine	<1
Ring sulfoxide metabolite of thioridazine	<1
Prochlorperazine	<1
N-Demethyl sulfoxide metabolite of trifluoperazine	55

[a] Cross-reactions were assessed by the criteria of Abraham (15).

n	7	7	7	7	7	7	7	7
CV, %	3.0	2.3	1.4	2.1	2.7	2.7	1.6	0.8

[a] Intra-assay variance was calculated from assay readings of plasma standards obtained on a single day of analysis. [b] Interassay variance was calculated from assay readings of plasma standards obtained on four different days of analysis.

procedures (9, 10), whereas trifluoperazine dihydrochloride[1] and the other phenothiazines and their metabolites[2] were donated. Aromatic ring-labeled, tritiated trifluoperazine (12.8 Ci/mmol) was procured from a commercial source[3].

Liquid scintillation counting, in which a commercial cocktail was used[4], was performed in a counter equipped with automatic quench compensation[5]. All solvents were analytical grade. The dextran-coated charcoal suspension and the various buffers were prepared in this laboratory. TLC sheets precoated with silica gel without fluorescence indicator (250-xx thickness), used for tracer isolation, were obtained commercially[6]. All experimental procedures were carried out under subdued lighting.

Synthesis of the Immunogen (IV)[7]—To an aqueous solution (10 mL) of 10-[[3-[4-(2-carboxyethyl)-1-piperazinyl]-propyl]]-2-trifluoromethyl-10*H*-phenothiazine sulfoxide dihydrochloride (II) (1.1 g, 2 mmol) (11), was added concentrated HNO_3 in a dropwise manner. The mixture was left in the dark at room temperature for 2 h. During this time the mixture changed from a reddish-brown precipitate to a clear pale-yellow solution. The mixture was adjusted to pH 6.0 with 1 M NaOH solution and subsequently saturated with NaCl. The product was extracted into dichloromethane (5 × 20 mL) and dried over anhydrous sodium sulfate to give the desired hapten III (0.82 g, 80% yield) as pale-yellow flakes, mp 98–102°C, which showed one spot on TLC: R_f 0.15 (benzene–methanol–diethylamine) (100:5:5) (II, R_f 0.25); IR: 1025 cm^{-1} (S → O); ^{1}H-NMR ($CDCl_3$): δ 2.1 (t, 2, J = 6.0 Hz, propyl central CH_2), 2.5 (m, 14, piperazine methylene, CH_2-piperazine, and CH_2CH_2—COOH), 4.2 (t, 2, J = 6.0 Hz, CH_2-phenothiazine), 7.8 (m, 7, ArH), and 10.0 ppm (s, 1, COOH); MS (ammonia CI): quasi-molecular ion $(M + H)^+$ at *m/z* 482 for III and *m/z* 496 for the methyl ester of III.

Anal.—Calc. for $C_{23}H_{26}F_3N_3O_3S$: C, 57.38; H, 5.41; N, 8.73. Found: C, 58.00; H, 5.57; N, 8.66.

The hapten III (0.130 g) was coupled to bovine serum albumin[8] (0.19 g) in dioxane by using a modified mixed-anhydride method (12, 13). This was followed by dialysis first against bicarbonate buffer (0.1 M; pH 8), then against acetate buffer (0.1 M; pH 5.2), and finally against distilled water. During the dialysis against acetate buffer, there was some precipitation, which disappeared when dialyzed again with bicarbonate buffer. After lyophilization, the immunogen IV was obtained as a white crystalline solid (0.27 g). A blank was prepared by subjecting the bovine serum albumin to the coupling conditions, but without the hapten. The number of hapten residues coupled per mole of bovine serum albumin conjugate was determined by the UV[9] method (12, 13) to be 60.

Synthsis of the Sulfoxide Metabolite of [^{3}H]Trifluoperazine—To a solution of [^{3}H]trifluoperazine[3] in ethanol (200 μL, 1 mCi/mL) was added 20 μL of concentrated HNO_3 (11 M). The reaction mixture was left in the dark at room temperature for 3 h and subsequently diluted with water (5 mL), basified with 0.2 mL of saturated sodium carbonate, and extracted with benzene (5 × 3 mL). The benzene was evaporated under a stream of nitrogen at 65°C[10]. The residue, which was reconstituted with 0.2 mL of methanol, was injected into the HPLC system[11], which was operated at ambient temperature with a flow rate of 3 mL/min. The eluted peak corresponding to the sulfoxide metabolite (2.5–3 min) was collected.

To determine the specific activity of the tracer, aliquots of the collected fraction were injected into the HPLC system. The amount of tritiated sulfoxide metabolite was determined by comparing the peak height of the sulfoxide metabolite of [^{3}H]trifluoperazine to that obtained from injections of known amounts of unlabeled metabolite. The tritiated sulfoxide metabolite peak was collected and counted by a liquid scintillation technique. The specific activity of the tritiated sulfoxide metabolite was calculated to be ~12.2 Ci/mmol. The chemical yield was found to be 50.5% by comparing the ratio of the radioactivity of the tritiated sulfoxide product with that of the [^{3}H]trifluoperazine used in the reaction.

The purity of tracer, when required for RIA, was checked by TLC: R_f 0.2 (benzene–methanol–diethylamine; 100:5:5). The purity was always >95%. The working solution of the tritiated sulfoxide metabolite was prepared on the day of assay by diluting the required quantity of the metabolite, freshly collected from the HPLC system, with 0.01 M HCl such that the diluted solution contained 2000–2500 cpm/μL.

Pilot synthesis experiments with unlabeled trifluoperazine using the oxidation procedure and isolation techniques described above gave the sulfoxide metabolite of trifluoperazine as white crystals, uncorrected mp 139–140°C [lit. (9) mp 140–141°C], which gave satisfactory C, H, and N analytical data.

Immunization—Four New Zealand White rabbits[12] (age, 4 months) were each given an intradermal injection of 1 mg of the immunogen emulsified with 0.5 mL of Freund's complete adjuvant–0.5 mL of isotonic saline. Thereafter, rabbits were reimmunized by intradermal injection at 2-week intervals with the same amount of immunogen emulsified with Freund's incomplete adjuvant. After five intradermal injections, the sera of three rabbits showed binding activity to the sulfoxide metabolite of [^{3}H]trifluoperazine. After administration of four intravenous booster doses of 1 mg of the immunogen in 0.25 mL of isotonic saline, which were given *via* the ear vein at 2-week intervals, the three rabbits produced antisera of adequate titer (1:1300 w/v). These rabbits were then sacrificed, and the antisera of each of the rabbits was lyophilized and stored at −20°C. The lyophilized antiserum of one of the rabbits was used for the RIA of trifluoperazine sulfoxide.

Direct Radioimmunoassay Procedure—An aqueous solution of the sulfoxide metabolite of trifluoperazine was prepared by dissolving the sulfoxide in 0.01 M HCl whenever required. Subsequently, standard solutions containing 0.3, 0.5, 1, 2, 3, 5, 7.5, and 10 ng of the sulfoxide/mL were prepared in pooled plasma[13]. The working antiserum solution was prepared by dissolving the lyophilized antiserum in phosphate buffer (0.2 M, pH 7.2). Of this solution, 100 μL was used in each assay tube.

To each polystyrene tube (12 × 75 mm), containing a 200-μL plasma

[a] Pharmacokinetic parameters of trifluoperazine and its sulfoxide metabolite in the plasma of five healthy volunteers after a 5-mg oral dose of trifluoperazine. [b] AUC_{0-24} was calculated by the trapezoidal rule. [c] Plasma half-life was calculated by the equation $t_{1/2} = 0.693\ k_{el}$, where k_{el} was estimated by using the plasma concentrations between 6 and 24 h. In the case of volunteer 4, the 24-h plasma concentration was estimated, since there was found to be <0.3 ng/mL of the sulfide metabolite present. [d] Plasma half-life was calculated by the equation $t_{1/2} = 0.693/k_{el}$, where k_{el} was estimated by the plasma concentration between 4.5 and 24 h for subjects 1 and 2 and between 4.5 and 12 h for subjects 3–5.

sample (standard or from a volunteer), was added 200 μL of phosphate buffer (0.2 M; pH 7.2) and 5 μL of the sulfoxide metabolite of [^{3}H]trifluoperazine solution (10,000–12,500 cpm). The contents of the tube were mixed[14] for 10 s, and 100 μL of antiserum solution (1:1300 w/v) was added. All of the additions were carried out in an ice bath. The solution was mixed[14] well for 10 s and incubated at 37°C for 80 min. The tubes were then cooled to 4°C in an ice bath, and cold dextran-coated charcoal suspension (1 mL) was added. Each tube was again mixed[14] for 10 s and subsequently incubated for 10 min at 4°C. The samples were then centrifuged (1720×*g* for 10 min at 4°C). The supernatant solution was decanted by a standardized procedure into a scintillation vial containing 10 mL of scintillation cocktail, mixed well, and counted for 5 min. Each plasma sample, standard or unknown, was assayed in triplicate.

The calibration curve was constructed by plotting the logit values of B/B_0 on the *y*-axis and the log values of the sulfoxide metabolite concentrations on the *x*-axis, where B and B_0 are the antibody-bound radioactivity in the presence and absence of the sulfoxide metabolite, respectively. Logit B/B_0 is defined as:

$$\text{Logit } B/B_0 = \text{Log}_e \frac{B/B_0}{1 - B/B_0}$$

Extraction Radioimmunoassay Procedure—Each 1-mL plasma sample (standard or from a volunteer) was basified (pH 12) with saturated Na_2CO_3 (1 mL) and extracted with benzene (2 × 3 mL). The resultant extract was evaporated to dryness under a stream of nitrogen at 65°C, and the residue was reconstituted with 1 mL of phosphate buffer (0.2 M; pH 7.2). Subsequently, the RIA procedure described above was followed, in which 200 μL of 7% aqueous bovine serum albumin solution and 200 μL of reconstituted extract were used in the place of plasma and phosphate buffer, respectively.

The efficiency of the benzene extraction of the sulfoxide metabolite of trifluoperazine was checked by repeating the extraction procedure with spiked plasma samples containing known amounts of the tritiated sulfoxide. Of the total radioactivity added, 98% was found to be extracted from samples containing 0.3–10 ng/mL of the sulfoxide metabolite of trifluoperazine.

Plasma Samples—A 5-mg dose of trifluoperazine[15] was given orally with 50 mL of water to each of five healthy male volunteers, who fasted overnight[16]. Blood samples were withdrawn by venipuncture using evacuated heparinized tubes[17], and contact between blood and the rubber stopper was carefully avoided, as spurious results have been found in the RIA determination of trifluoperazine when blood has been allowed to touch the rubber stopper of these evacuated tubes (14). Blood samples were taken at 0 (predose), 0.5, 1, 1.5, 2, 3, 4.5, 6, 8, 12, and 24 h postdose. The plasma was immediately separated and stored at −20°C until analysis by the procedures described above for the sulfoxide metabolite and by the previously reported RIA method for trifluoperazine (6).

RESULTS

Sensitivity and Specificity of the Radioimmunoassay for the Sulfoxide Metabolite of Trifluoperazine—The amount bound at a zero concentration of the sulfoxide metabolite was determined at 30, 60, 80, 120, and 180 min and at temperatures of 4°C, 22°C (room temperature), and 37°C for the first incubation step in the assay procedure. From the results of these experiments, the optimal conditions for the assay were found to be an incubation time of 80 min at 37°C, where the B_0 was ~30%.

When 200-μL plasma samples are used, as low as 60 pg of the sulfoxide can be measured by the RIA. Under the assay conditions described above, the standard curve was linear from 0.3 to 10 ng/mL; a typical calibration curve can be defined by: logit $y = -2.27 \cdot \log_{10} x + 1.496$ ($r^2 = 0.999$). This range was adequate for the determination of all but one of the unknown concentrations of the sulfoxide metabolite in the plasma samples obtained after administration of a single oral dose of 5 mg of trifluoperazine. These concentrations were determined by running a calibration curve with each set of unknown samples. Concentrations of the sulfoxide metabolite of <0.3 ng/mL, reported for one plasma sample in the present study, were estimated.

The specificity of the antiserum was assessed by the criteria of Abraham (15). The antiserum did not cross-react markedly with trifluoperazine or the available, supposed, major metabolites of trifluoperazine; however, the cross-reactivity of the *N*-demethyl sulfoxide metabolite of trifluoperazine as well as the sulfoxide metabolites of other piperazine-type phenothiazines is understandable (Table I). Interestingly, the sulfoxide of the aliphatic phenothiazine, chlorpromazine, did not cross-react.

Also, to check cross-reactivities, plasma samples containing the sulfoxide metabolite of trifluoperazine over the standard curve range were additionally spiked with trifluoperazine at five times the sulfoxide concentrations, and the sulfoxide concentrations were subsequently determined by the direct RIA procedure. These experiments were repeated an additional four times, and the values obtained were compared with those for the sulfoxide metabolite standard curve samples prepared at the same time in the usual manner. There were no significant differences ($p > 0.05$) in the values obtained for the sulfoxide metabolite among samples of the same sulfoxide concentrations with or without trifluoperazine. Similar results were obtained when the 7-hydroxy, *N*-oxide, and *N*-demethyl metabolites were each separately added at five times the sulfoxide concentrations to plasma samples containing the sulfoxide over the concentration range of the standard curve (Table II).

Intra- and Interassay Variations—Both intra- and interassay variations were determined with plasma standards prepared in accordance with the described procedure. Intra-assay variations were determined from assay readings obtained from a single day, whereas interassay variations were calculated from the assay data obtained on four separate days of analysis (Table III). The *CV* was <4% for both intra- and interassay determinations at all the sulfoxide concentrations studied.

Plasma Concentrations of the Sulfoxide Metabolite of Trifluoperazine and Trifluoperazine—The plasma concentration–time profiles (Fig. 1) obtained by direct RIA after administration of a single 5-mg oral dose of trifluoperazine to five healthy volunteers showed considerable intersubject variations in the plasma concentration of the sulfoxide metabolite and trifluoperazine. The sulfoxide metabolite was present in detectable concentrations at all sampling times. However, in three volunteers (subjects 3–5), no trifluoperazine was detected in the 24-h plasma sample.

The areas under the plasma concentration–time curve from 0 to 24 h (AUC_{0-24}) were calculated by the trapezoidal rule and ranged from 33.9 to 56.9 ng·h/mL for the sulfoxide metabolite and 8.0 to 29.4 ng·h/mL for trifluoperazine. The values of $AUC_{0\ 24}$ for the sulfoxide metabolite were, on the average, 320% of those of trifluoperazine (range, 115–710%). The time required to reach the peak concentrations (t_{max}) in plasma were similar for the sulfoxide metabolite and trifluoperazine and ranged from 3 to 4.5 h, except in one volunteer (subject 2), for whom the t_{max} for the sulfoxide was 6 h. The peak concentrations (C_{max}) ranged from 2.5 to 4.5 ng/mL for the sulfoxide metabolite and from 1.0 to 3.2 ng/mL for trifluoperazine (Table IV).

After reaching these C_{max} values, plasma concentrations declined rapidly in all subjects, so that for the sulfoxide metabolite, the elimination half-life ($t_{1/2}$) from 6 to 24 h was calculated to range from 3.7 to 7.2 h in the five subjects, whereas for trifluoperazine the $t_{1/2}$ was in the range of 2.5–15.2 h. In the latter case, $t_{1/2}$ (4.5–24 h) was calculated for the only two subjects, in

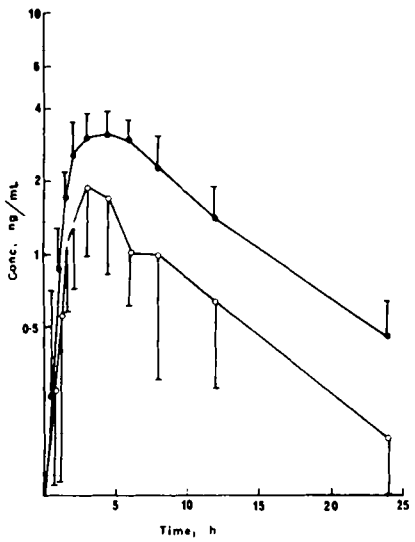

Figure 1—*Mean plasma trifluoperazine (○) and sulfoxide metabolite (●) concentrations in five healthy volunteers after single 5-mg oral doses of trifluoperazine dihydrochloride. Each point represents mean ± SD.*

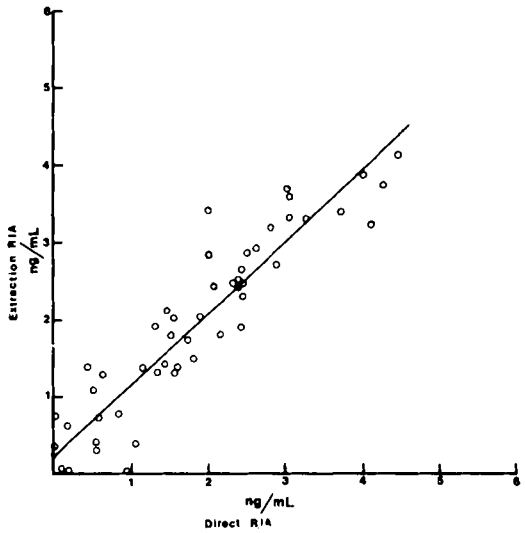

Figure 2—*Comparison of plasma concentrations of the sulfoxide metabolite of trifluoperazine determined for five volunteers after ingestion of 5 mg of trifluoperazine and analyzed by the extraction RIA and the direct RIA procedures (n = 50, r^2 = 0.92, slope = 0.89).*

whom the trifluoperazine plasma concentrations at 24 h could be determined by RIA, whereas for the other three volunteers, $t_{1/2}$ was calculated from the concentration time points at 4.5–12 h. Closer inspection of the data indicated that in the case of one volunteer (subject 2), plasma concentrations of trifluoperazine and the sulfoxide metabolite declined biexponentially after the C_{max} was reached. For this subject, the ($t_{1/2,\alpha}$) and ($t_{1/2,\beta}$) values were calculated as 1.9 and 12.8 h, respectively, for the sulfoxide, whereas the analogous values for trifluoperazine were 1.4 and 16.4 h. All plasma half-lives were estimated from the raw data using the equation $t_{1/2} = 0.693/k_{el}$, where k_{el} is the calculated rate constant of elimination.

The plasma concentrations of the sulfoxide metabolite of trifluoperazine for all plasma samples obtained from the five volunteers were also determined by the extraction RIA procedure. The values obtained were plotted *versus* those obtained by the direct RIA (Fig. 2). The slope of the regression line for this comparison had a value of 0.89, with r^2 = 0.92. The 95% confidence bounds (±0.179) of the slope of this regression line were calculated, and thus, the slope is not significantly different statistically from 1.0. Also, when both techniques were performed on three separate occasions for one of the volunteers (subject 5) and the mean of the extraction technique values were plotted *versus* the mean of the direct RIA technique, the correlation coefficient was determined to be 0.98, and the slope of the regression line was 0.80. These results indicate that the two methods compare favorably.

DISCUSSION

The previously reported trifluoperazine hapten (II) was the starting material used for the synthesis of the desired sulfoxide hapten (III). This starting material (II) was prepared as previously described (11) or by an equally successful alternate routine (Scheme I), in which the *N*-demethylmetabolite of trifluoperazine (Ia) was treated successively with methyl acrylate and base. Subsequent nitric acid oxidation of II gave the desired hapten (III) in good yield, although the relatively high water solubility of this compound necessitated saturation of the reaction mixture with sodium chloride so that organic solvent extraction of the product was feasible. A similar nitric acid treatment procedure was adopted to obtain the tracer required for the RIA of the sulfoxide metabolite of trifluoperazine in which the commercially available ethanolic solution of [^{3}H]trifluoperazine was directly oxidized: The tritiated sulfoxide product was identified by its chromatographic properties (TLC and HPLC), as well as by indirect pilot experiments in which unlabeled trifluoperazine was treated by the same nitric acid procedure and the product was examined by qualitative spectral analysis (CI-MS, EI-MS, IR, ^{1}H-NMR), as well as by elemental analysis.

The development of the present RIA was based on the most successful of the approaches taken in order to develop an RIA for trifluoperazine, in which the drug molecule was linked to bovine serum albumin *via* a two-carbon bridge attached through the N-10 side chain of the trifluoperazine structure (11). The antisera raised to such an immunogen should be specific to the ring portion of the drug molecule, and indeed, the sulfoxide antisera reported here did not cross-react with trifluoperazine, whereas there was significant cross-reactivity with the sulfoxide metabolites of the other available marketed piperazine-type phenothiazines, *i.e.*, fluphenazine, perphenazine, and prochlorperazine. Thus the antisera can be used for the quantitative RIA analysis of the sulfoxide metabolites in plasma. Antibody recognition was not dramatically affected when the 2-trifluoromethyl ring substituent of the sulfoxide metabolite of trifluoperazine was altered to a 2-chloro substituent, as with the sulfoxide metabolite of perphenazine, yet the 2-thioether, a thioridazine ring sulfoxide which has a piperidine side chain, was not recognized by the antibody. Also, regarding other ring-substituted compounds, there was no measured cross-reactivity with the 7-hydroxy metabolite of trifluoperazine, whereas the sulfone metabolite of trifluoperazine demonstrated low binding activity.

This is the first report of a suitable analytical method for the quantitation of the sulfoxide metabolite of trifluoperazine in plasma. This RIA procedure can measure 60 pg of the sulfoxide metabolite in a 200-μL plasma sample, thus obviating the need for large blood samples. Also, similar results were obtained for the assay irrespective of whether the procedure was carried out directly on plasma or on plasma extracts. Thus, a plot of the B/B_0 values obtained in the direct RIA for various plasma standards, covering the range 0.3–10 ng of the sulfoxide per mL, *versus* those obtained in the extraction RIA procedure for the same plasma standards, gave an r^2 value of 0.998.

Regarding the specificity of the antiserum (Tables I and II), there were no significant changes in binding when plasma standards of the sulfoxide metabolite over the standard curve concentration range were spiked with trifluoperazine at concentrations five times those of the sulfoxide. Therefore, it is unlikely that trifluoperazine will interfere with sulfoxide plasma concentration determinations in samples from healthy volunteers or patients treated with trifluoperazine. Also, the available suspected major metabolites of trifluoperazine in humans (the 7-hydroxy, *N*-oxide, and *N*-demethyl compounds) failed to demonstrate cross-reactivity either by the criteria of Abraham (15) or when added to spiked samples of the sulfoxide metabolite at five times the concentration of the sulfoxide. However, as expected, the *N*-demethyl sulfoxide metabolite cross-reacts appreciably with the antiserum. Whether or not the concentrations of the *N*-demethyl sulfoxide metabolite in plasma samples from patients or healthy volunteers are high enough to interfere in the determination of the sulfoxide concentrations awaits study of the levels of this metabolite in humans after single-dose and chronic administration of trifluoperazine. Additional proof for the specificity of the RIA procedure for the sulfoxide metabolite was obtained by comparison of the data for extraction RIA with that for direct RIA determined for the plasma samples from the volunteers dosed with a single 5-mg oral dose of trifluoperazine. Similar results were obtained irrespective of whether the procedure was carried out directly on plasma or on plasma extracts, indicating that physiological material and metabolites nonextractable in benzene do not dramatically interfere in the sulfoxide determinations.

Plasma concentration–time profiles for trifluoperazine after administration of low, single, oral doses of trifluoperazine, in which trifluoperazine plasma concentrations were determined by RIA, have been previously reported (16). The mean values for this previous study with 24 healthy male volunteers, in which the t_{max}, C_{max}, $AUC_{0\text{-}24}$, and $t_{1/2}$ values for one of the tested 5-mg trifluoperazine formulations were 4.0 ± 1 h, 1.9 ± 0.9 ng/mL, 19.3 ± 11

ng·h/mL, and 9.3 ± 7 h, respectively, are in agreement with the values reported here of 3.6 ± 0.8 h, 1.9 ± 0.9 ng/mL, 17.2 ± 9 ng·h/mL, and 8.9 ± 5 h, respectively, for the five volunteers given a single 5-mg oral dose of trifluoperazine. On the other hand, pharmacokinetic parameters in humans for the sulfoxide metabolite of trifluoperazine have not been previously reported. The mean sulfoxide concentrations were of the same order as the mean trifluoperazine concentrations at the first (0.5 h) time point and thereafter were greater (Fig. 1). The presence of significant amounts of the sulfoxide (98% of trifluoperazine) at the 0.5-h sampling point and the fact that the plasma sulfoxide concentrations peaked at about the same time as the plasma trifluoperazine concentrations indicates that a significant proportion of trifluoperazine is metabolized to the sulfoxide metabolite during presystemic absorption. Also, in all volunteers the percent AUC_{0-24} sulfoxide-AUC_{0-24} trifluoperazine ratio was >100%. The 115–710% range for this value in the five volunteers is indicative of large interindividual variation resulting from presystemic metabolism of trifluoperazine by routes such as sulfoxidation.

For four of the five subjects, the terminal elimination half-life of trifluoperazine was longer than that of the more polar sulfoxide metabolite, which suggests a generally faster elimination of the sulfoxide. A similar phenomenon has been reported on comparison of the sulfoxide metabolite of chlorpromazine and chlorpromazine terminal elimination half-lives after administration of low, single, oral doses of chlorpromazine to healthy male volunteers (17). However, pharmacokinetic data obtained from the RIA measurement of plasma concentrations should be viewed with suspicion. Indeed, the RIA antisera used here for trifluoperazine plasma concentration determinations cross-reacts with the *N*-demethyl and 7-hydroxy metabolites of trifluoperazine to the extent of 26 and 24%, respectively (6). When these antisera were used to determine plasma concentrations in an oral single-dose bioequivalency study of two trifluoperazine tablet formulations in five healthy volunteers, a longer mean elimination half-life (11.5 ± 3.7 compared with 8.3 ± 2.4 h for one of the formulations) was found than when the plasma concentrations were determined for the same plasma samples by a specific GC–MS method (18). The RIA method for the sulfoxide metabolite needs to be compared with a sensitive and specific chemical method for the determination of the sulfoxide in plasma to validate the pharmacokinetic data reported here. Due to such reasons as the demonstrated heat sensitivity of the sulfoxide metabolite of trifluoperazine (19) and the low concentrations encountered after administration of this highly potent antipsychotic agent, such development will not be easy. In the meantime, due to the specificity demonstrated in this report, the RIA for the sulfoxide metabolite can be investigated as to its suitability to compare measured sulfoxide concentrations in responding and nonresponding patients under chronic treatment with trifluoperazine. The resultant data will assist in establishing the relationship, if any, between plasma concentrations of the sulfoxide metabolites of trifluoperazine, therapeutic response, and/or adverse drug reactions.

Evaluation of Diethyl Malonate as a Simulant for 1,2,2-Trimethylpropyl Methylphosphonofluoridate (Soman) in Shower Decontamination of the Skin

WILLIAM G. REIFENRATH *x, MILLARD M. MERSHON ‡, FLOYD B. BRINKLEY ‡, GEORGE A. MIURA ‡, CLARENCE A. BROOMFIELD ‡, and H. BRUCE CRANFORD §¶

Received August 16, 1983, from the **Division of Cutaneous Hazards, Letterman Army Institute of Research, The Presidio, San Francisco, CA 94129*, ‡*U.S. Army Medical Research Institute of Chemical Defense, Aberdeen Proving Ground, MD 21010*, and the §*U.S. Army Medical Bioengineering R&D Laboratory, Fort Detrick, Frederick, MD 21701.* Accepted for publication October 20, 1983. ¶ Present address: U.S. Department of Energy, Office of Industrial Programs, Washington, DC 20585.

Abstract □ A shower decontamination bench model has been used to assess quantitatively the importance of several variables (water pressure and temperature, surfactant concentration in the decontamination fluid, nozzle type, and shower time) on decontamination of nontoxic chemical warfare-agent simulants diethyl malonate and thickened diethyl malonate from pig skin *in vitro*. Diethyl malonate was validated as a simulant for 1,2,2-trimethylpropyl methylphosphonofluoridate (soman) by comparison of the skin penetration and decontamination of radiolabeled diethyl malonate to the radiolabeled phosphonofluoridate in shower decontamination trials of pig skin *in vitro*. Percutaneous penetration of diethyl malonate was significantly greater than that of the phosphonofluoridate during the 15-min period after application. However, both were <0.1% of the applied dose. Showering or thickener had no significant effect on the percutaneous penetration of diethyl malonate or the phosphonofluoridate. Most of the phosphonofluoridate removed by showering or scrubbing the skin was inactivated. The quantity of intact 1,2,2-trimethylpropyl methylphosphonofluoridate that penetrated through the skin was below the detection limit of the enzymatic analysis. There was no statistically significant difference between the phosphonofluoridate and diethyl malonate in efficacy of shower decontamination. The presence of thickener did not have a significant effect on decontamination efficacy.

Keyphrases □ Shower decontamination—percutaneous absorption, pig skin □ Diethyl malonate—percutaneous absorption, pig skin □ 1,2,2-Trimethylpropyl methylphosphonofluoridate—percutaneous absorption, pig skin

In the event of skin exposure to toxic chemicals, involved armed forces and civilian groups will need to decontaminate nonambulatory chemically contaminated casualties before they receive medical treatment for wounds. Besides decontamination of the patient, another purpose of decontamination is to protect medical personnel and prevent their exposure to detrimental levels of toxic chemicals. It is generally not possible for medical personnel in protective clothing to provide necessary medical treatment to patients. Consequently, medical personnel must operate in a shirt-sleeve environment.

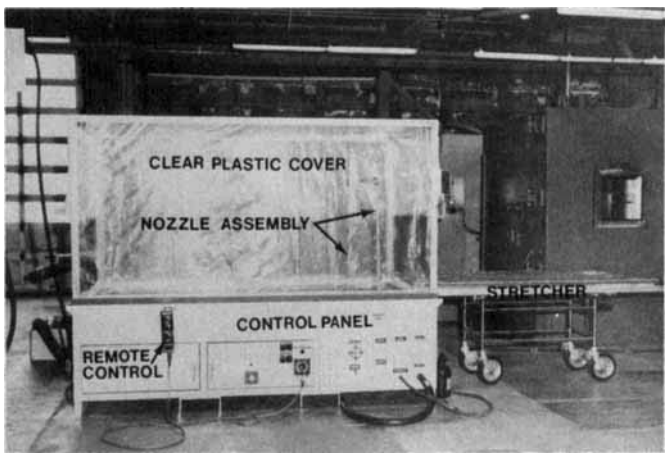

Figure 1—*United States Air Force litter patient decontamination shower (breadboard model).*

Equipment designers do not have sufficient information on nonambulatory casualty decontamination to construct a prototype device for deployment and installation in fixed facilities. To obtain the necessary information, a breadboard model (an experimental item of hardware fabricated during the conceptual phase to reduce technological uncertainty, prove feasibility, and provide realistic cost estimates) of a decontamination device has been fabricated by the U.S. Army Medical Bioengineering Research and Development Laboratory (Fig. 1). The decontamination device is conceived to work as follows. The chemically contaminated patient is placed on a stretcher where all clothes, dressings, *etc.* are removed and the patient is rolled into the decontamination device. (During the entire process, the gas mask will remain on the patient.) The device is surrounded by a clear plastic cover which allows observation of the patient, permits easy access to the patient, and prevents escape of contaminated water. The device, activated and controlled by an operator, can apply soap and water (or other chemicals) to the entire body, except the area under the mask. With the patient stationary, the nozzle assembly cycles back and forth, applying water, soap, and rinse water for a predetermined time. When decontamination is considered complete, the clean side of the machine is opened and the stretcher with patient is removed. Additional background information on the Litter Patient Decontamination Shower is available (1).

In a previous study (1), an assessment was made of the effect of variables functioning in the breadboard device (water pressure, surfactant concentration, water temperature, nozzle

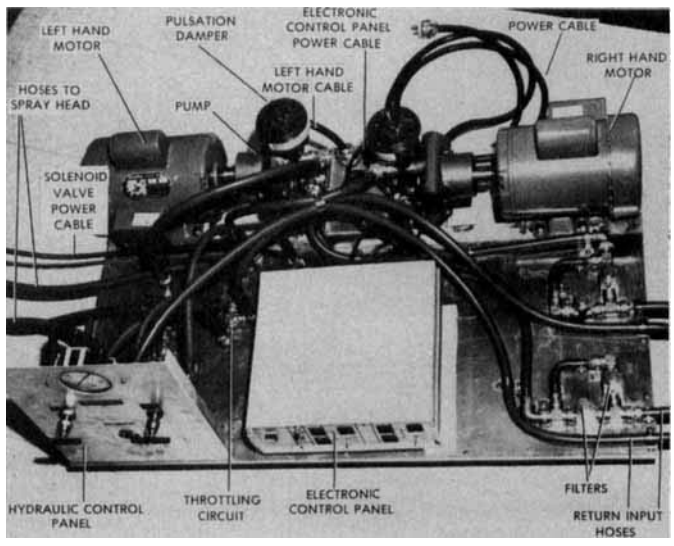

Figure 2—*Litter patient decontamination unit, bench model; top view showing dual water circuits.*

type, and shower time) on removal of nontoxic chemical warfare agent simulants from the surface of excised pig skin. Diethyl malonate was used as a simulant for the nerve agent 1,2,2-trimethylpropyl methylphosphonofluoridate (soman), and diethyl malonate thickened with acrylate polymer was used as a simulant for the thickened phosphonofluoridate. Diethyl malonate was chosen because its physical properties (vapor pressure, water solubility, and surface tension) are similar to those of the phosphonofluoridate (1). A decontamination bench model (Figs. 2 and 3) was used to simulate the function of the breadboard decontamination device. The bench model is a single stationary nozzle model of the breadboard device. In the previous report (1), it was found that the force per unit area exerted by the shower water on the skin surface was the major variable responsible for differences in decontamination efficiency. Compared with trials where no showering was done, showering always increased the mean percutaneous penetration of simulant. However, the significance of these results was in question since the effect was small and varied in magnitude and the ability of diethyl malonate to simulate the percutaneous penetration of the phosphonofluoridate was unknown. Therefore, the present study was conducted to compare the percutaneous penetration of radiolabeled diethyl malonate and radiolabeled 1,2,2-trimethylpropyl methylphosphonofluoridate (both unaltered and in the thickened state) in shower decontamination trials of pig skin *in vitro*.

EXPERIMENTAL SECTION

Radiolabeled and Thickened Radiolabeled Diethyl Malonate—Diethyl [2-^{14}C]malonate[1] had a radiochemical purity of 98%; diethyl malonate[2] had a purity of 99%. Radiolabeled diethyl malonate was diluted with unlabeled diethyl malonate to give a specific activity of 5 μCi/mg. Applying 0.27 μL of this dilution to a skin area of 2.85 cm^2 gave a chemical dose of 0.1 mg/cm^2 and a radioactive dose of 1.35 μCi. A sample of thickened radiolabeled diethyl malonate was prepared by adding 20 mg of radiolabeled diethyl malonate to 100 μL of a mixture of acrylate polymer[3] in unlabeled diethyl malonate with a viscosity of 1000 centistokes at 25°C to give a final viscosity of ~200 centistokes at 25°C. Applying 0.28 μL of this mixture to a skin target area of 2.85 cm^2 gave a chemical dose of 0.1 mg/cm^2 and a radioactive dose of 1.76 μCi.

Preparation of Radiolabeled and Thickened Radiolabeled 1,2,2-Trimethylpropyl Methylphospbonofluoridate—Into a 12-mL capped centrifuge tube equipped with a triangular stirring bar was placed 30 μL of triethylamine, 1 mmol (~125 μL) of [1-methyl-^{14}C]3,3-dimethyl-2- butanol[4], and an excess

[1] Batch no. 53, specific activity 4.9 mCi/mmol; Amersham Radiochemicals, Arlington Heights, Ill.
[2] Lot no. 47C-0374; Sigma Chemical Co., St. Louis, Mo.
[3] Polymer K125EA, a polymer made from the following monomers: methyl methacrylate, ethyl acrylate, and butyl acrylate; Rohm and Haas Co., Philadelphia, Pa.

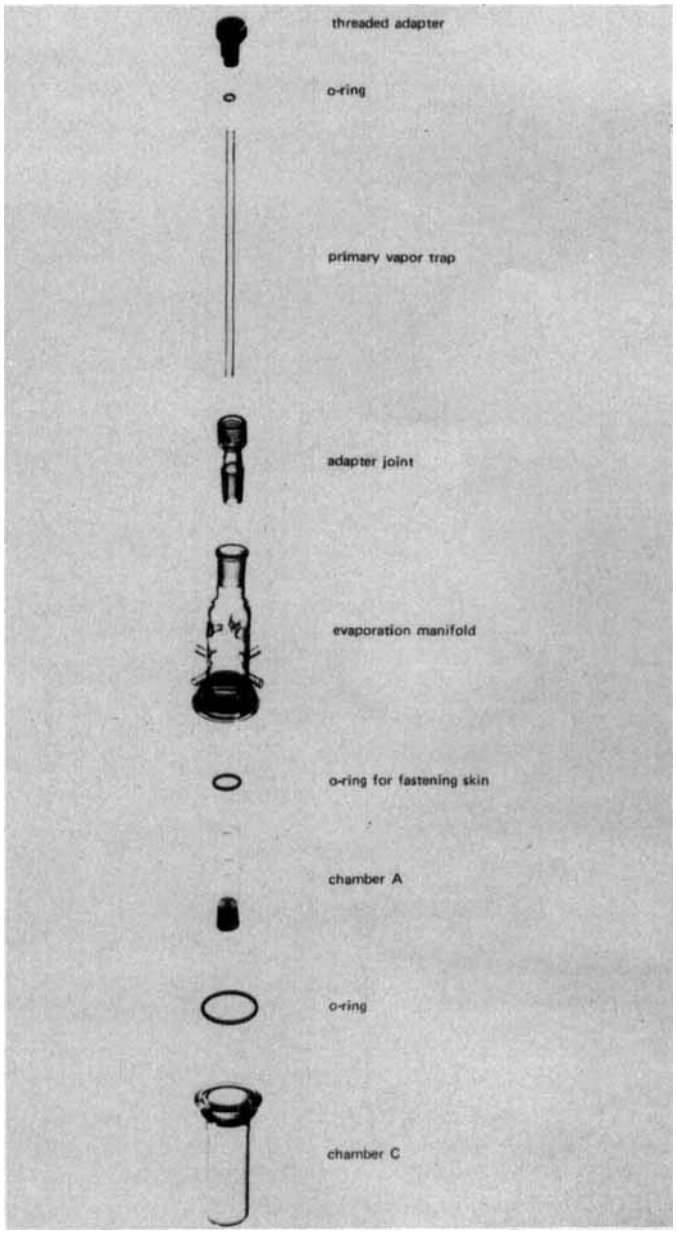

Figure 4—*Apparatus for collection of diethyl malonate and phosphonofluoridate evaporation.*

(~200 μL, 2 mmol) of methylphosphonic difluoride, of which 100 μL was used to rinse the residual pinacolyl alcohol from the vial before it was added to the centrifuge tube. The resultant mixture was allowed to stand at room temperature overnight. One milliliter each of distilled water and $CDCl_3$ were added, the mixture was shaken vigorously, and then centrifuged in a clinical centrifuge[5] at one-half speed for 2 min. The aqueous layer was carefully removed with a pipet, and another 1 mL of distilled water was added. The mixture was shaken and centrifuged as before, the top layer was again carefully removed, and the organic layer was transferred to a flask with molecular sieves. After drying overnight the solution was transferred to an NMR tube for analysis. By ^{1}H- and ^{31}P-NMR, the sample contained 75–82% of the phosphonofluoridate; the remainder was 3,3-dimethyl-2-butanol. The sample was distilled to yield a homogeneous sample by TLC[6] (5% methanol–chloroform) with single spot at R_f 0.82; all of the radioactivity was associated with this single spot.

The radiolabeled phosphonofluoridate was diluted with unlabeled compound so that when 0.27 μL was applied to a 2.85 cm^2 skin area, a chemical dose of 0.1 mg/cm^2 and a radioactive dose of 0.9 μCi were given. A sample of the thickened radiolabeled phosphonofluoridate was prepared by adding 20 mg of radiolabeled compound to 100 μL of a mixture of acrylate polymer

and unlabeled phosphonofluoridate (1000 centistoke at 25°C) to give a final viscosity of ~200 centistokes at 25°C. Applying 0.28 μL of this mixture to a 2.85 cm^2 skin area gave a chemical dose of 0.1 mg/cm^2 and a radioactive dose of 1.6 μCi.

Acetylcholinesterase Inhibition Assay[7]—Inhibition of acetylcholinesterase activity served as the basis for the enzymatic assay of the ^{14}C-labeled phosphonofluoridate. Enzyme activity was measured by the radiometric method of Siakotos *et al.* (2).

Acetylcholinesterase Stock Solution For Enzymatic Assay of the Phosphonofluoridate—Ten milligrams of eel acetylcholinesterase and 500 mg of bovine plasma albumin were dissolved in 500 mL of 10 mM potassium phosphate buffer, pH 7.0. Aliquots were stored at −20°C. Prior to use, an aliquot of enzyme solution was thawed, and $MgCl_2$ and NaCl were added to a final concentration of 10 mM and 100 mM, respectively.

Preparation of Dilutions and Determination of the Standard Curve—1,2,2-Trimethylpropyl methylphosphonofluoridate (20 mg) was dissolved in 100 mL of normal saline. The initial dilution was made by adding 100 μL of a 1.1 mM stock solution of the phosphonofluoridate to 0.90 g of ice-cold glass-distilled water in ~1.9-mL screw-top vials. Stock solutions (1.1×10^{-8} and 2.2×10^{-8} M) were prepared by serial dilution and kept on ice. Fresh

[7] [^{14}C]Acetyl-β-methylcholine and aqueous scintillation counting fluid (Aquasol) were purchased from New England Nuclear Corp., Boston, Mass. Eel AchE, type VI, was a product of Sigma Chemical Co., St. Louis, Mo. Amberlite CG-120 resin (sodium form, 200–400 mesh) was obtained from Mallinckrodt Co., St. Louis, Mo. Bovine plasma albumin was obtained from Armour Laboratory, Chicago, Ill.

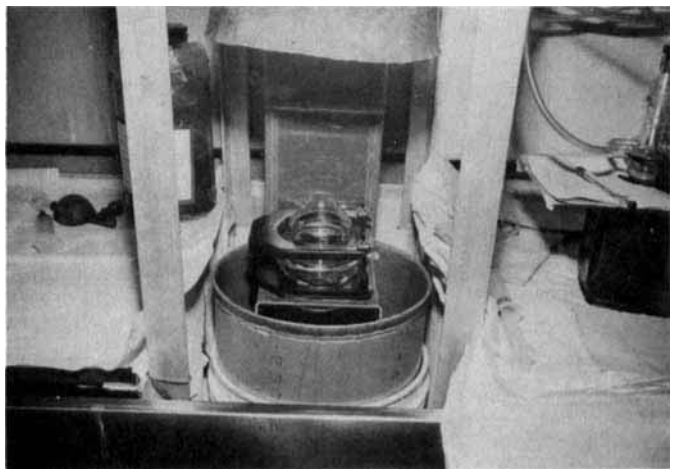

Figure 6—*Shower target assembly mounted in a hood.*

dilutions were prepared daily, and the standard curve was determined immediately after serial dilution. Assays were performed in 12-mL graduated centrifuge tubes. Four replicates were prepared for each concentration of the phosphonofluoridate. The reaction mixture contained 20 μL of 0.5 M potassium phosphate buffer (pH 7.4), 100 μL of eel acetylcholinesterase stock solution, 10 μL of 300 mM $MgCl_2$, the phosphonofluoridate solution, and enough glass-distilled water to make 210 μL. The mixture was incubated for 15 min at 37°C. To this mixture was added 100 μL of 3 mM [^{14}C]acetyl-β-methylcholine (0.1 μCi/100 μL), and the final mixture was incubated for 3 min at 37°C. The reaction was stopped by the addition of 5 mL of 20% (w/v) resin suspension in dioxane. The volume of each stopped-reaction mixture was adjusted to 10 mL with dioxane. After centrifugation, a 5-mL aliquot of dioxane supernatant (containing [^{14}C]acetate) was added to 10 mL of aqueous counting solution. Radioactivity was determined using a scintillation counter[8] which corrected for quenching. Radioactivity from controls, which were incubated with 100 μL of water in place of acetylcholinesterase, was subtracted from all assays to correct for nonenzymatic hydrolysis of the substrate. Inhibition of enzyme activity was expressed as the percentage of control which was not treated with the phosphonofluoridate.

Dilution of Radiolabeled Phosphonofluoridate Samples for Quantitative Enzyme Determination—Samples of solutions of the labeled phosphonofluoridate were kept on ice and diluted serially when necessary with ice-cold glass-distilled water so that appropriate aliquots inhibited the acetylcholinesterase at levels on the linear portion of the standard curve. Assays of the samples were carried out immediately. The procedures described above for the standard curve were followed for the label phosphonofluoridate samples. Stability of the radiolabeled compound was assessed before, during, and after the completion of the study by the enzymatic procedure. Initial and midpoint purities were essentially 100%. Purity was 70% when determined after the completion of the experiments.

Skin Samples—Skin was harvested from each of three female weanling Yorkshire pigs (~25 kg)[9]. After the pigs were sacrificed, hair was clipped from the animals with electric clippers[10]. An incision (~30 cm) was made down the midline of the back. At the 0-, 15-, and 30-cm points along the midline incision, perpendicular incisions (~15 cm) were made on the left side of the animal. A final incision was made parallel to the initial midline incision so that two square sections (15 cm × 15 cm) were formed. A notch was cut in the anterior edge of each section to preserve orientation. Whole-skin sections were removed from the animal and subcutaneous fat was removed by scraping. A small piece of skin from each animal was submitted for histopathological examination, which verified that the skin was normal tissue. The skin was cut into 3.2-cm diameter circles by using a punch. Each skin sample was coded by location. Skin was stored at −60°C for ~1 month prior to use.

Apparatus—Special glassware (Figs. 4 and 5) used in the study was custom-fabricated[11]. The bench-model decontamination unit was fabricated at the U.S. Army Medical Bioengineering R & D Laboratory, Fort Detrick, Frederick, Md. Details of the bench pump design can be found elsewhere (1). An assembly was constructed inside a hood (minimum linear air velocity of 45.8 m/min) to position the shower head of the bench model 30.5 cm above the skin surface when the skin was mounted on chamber A and inside chamber

[f] Radioactivity recovered by oxidation of the skin sample. [g] Radioactivity recovered from chamber A.

B (Fig. 6). The entire shower target assembly was surrounded by a movable shield to control water spray.

Shower Decontamination Trials—The skin disposition of diethyl malonate was compared with that of the phosphonofluoridate, and the skin disposition of thickened diethyl malonate was compared with that of the thickened phosphonofluoridate in shower decontamination trials. These experiments were compared with experiments where procedures remained the same except that no showering was done. Eight combinations of variables, which represented all possibilities, were compared on 6 separate days (48 total trials). The order in which the eight combinations were tested on a given day was randomized. Skin samples from the two sites on each of the three pigs were allocated to the experimental trials in a random fashion, with the restriction that an equal number of samples came from each of the three pigs.

Skin samples were removed from the −60°C freezer to a −8°C freezer the night before trials were made. The skin was placed in a glass vial in a 37°C water bath and allowed to thaw (15–20 min); the weight of the skin and location code were recorded. The thawed skin was attached to chamber A (Fig. 4) with a rubber O-ring. Chamber A was filled with Ringer's lactate, prewarmed to 37°C, and stoppered. Chamber A was placed inside chamber C, both within a water bath at 37°C. After the skin surface temperature reached 25–27°C, the skin surface was dosed with the appropriate chemical by streaking it across the skin surface (2.85 cm^2) with the blunt tip of a 1-μL syringe[12]. Immediately following application, the evaporation manifold was clamped to chamber C with chamber C remaining in the 37°C water bath. A peristaltic pump[13] was connected to the primary vapor trap (a tube containing 200 mg of absorbent powder[14]). The pump pulled air at 60 mL/min, causing air to flow into the inlet tubes of the evaporation manifold, over the skin surface, and into the primary vapor trap. Any radiolabeled chemical that evaporated from the skin surface was absorbed by the primary trap. A secondary safety bubbler trap was connected between the pump and the primary vapor trap.

After 14 min, chamber A was removed and mounted into chamber B (Fig. 5). Fifteen minutes after application of chemical, the skin was showered. The bench model was designed to shower the skin with a decontamination fluid followed by a water rinse. However, in a previous comparison (1) involving removal of thickened and unthickened diethyl malonate from skin, no difference was found between cycles with a 1% aqueous surfactant solution and with plain water. Therefore, distilled water was used in both shower cycles of this study. A total shower time of 2 s was used, 1 s/cycle. The water temperature was 20°C, and the pH was 6.8. After showering, chamber A was removed from chamber B. The sides of chamber A were rinsed into a tared beaker along with the contents and several rinses of chamber B. While tilting chamber A downward, the skin surface was scrubbed with a cotton ball containing 1% aqueous surfactant[15] and rinsed with 1 mL of the 1% aqueous surfactant (pH 6.7). The skin rinse and cotton ball were collected in a counting vial and assayed for radioactivity. The contents and rinses of the interior of chamber A were collected in a tared beaker and assayed for radioactivity (percutaneous penetration). The skin was removed from chamber A and cut into seven approximately equal portions. These were later assayed for radioactivity by combusting the samples[16], trapping the liberated $^{14}CO_2$[17], and counting the radioactivity on a scintillation counter. The primary vapor trap was removed from the evaporation mainfold and the contents (chemical trapped on absorbant powder) were flushed with aqueous (scintillation) counting fluid rinses (~15 mL each) into a counting vial. The content of this counting vial was then divided into six additional counting vials for more accurate counting. For each day, the volume of substance applied to the skin was placed in each of three volumetric flasks to serve as a control; an aliquot was taken from each for radioactivity assay.

When samples of the radiolabeled and thickened radiolabeled phosphonofluoridate were used, aliquots of residues recovered by scrubbing the skin surface, and from chamber A and chamber B, were subjected to the enzymatic assay.

RESULTS AND DISCUSSION

The disposition of radioactivity applied to the skin under the various conditions of the study is given in Table I. Overall recovery of the radioactive dose in these trials was ~70%, with the major portion recovered after evaporation from skin. The balance of the radioactive dose was probably lost by evaporation during the skin application process, before the evaporation manifold was in place. The amounts of evaporated diethyl malonate and 1,2,2-trimethylpropyl methylphosphonofluoridate, as measured by the amount of radioactivity recovered from the primary vapor trap, were very similar. This result was not changed by the presence of thickener.

A higher percentage of the radioactive dose of diethyl malonate than the phosphonofluoridate was recovered from the skin surface (by scrubbing) and from residues in the skin (by oxidation) at the end of 15 min following application without showering. However, showering removed a correspondingly larger percent of the applied radioactive dose of diethyl malonate than phosphonofluoridate so that residues left on the skin surface were similar (1–2%). Again, the presence of thickener did not change this outcome.

The efficiency of shower decontamination (calculated by dividing the percentage in the "Decontamination" column in Table I by the sum of percentages in the last four columns and multiplying by 100) showed little difference between the four test substances as evidenced by the following values (mean ± *SD*): diethyl malonate, 75 ± 7; phosphonofluoridate, 69 ± 14; thickened diethyl malonate, 72 ± 21; thickened phosphonofluoridate, 65 ± 13.

In a previous study (1), it was found that the force per unit area exerted by the shower on the surface of pig skin was the major variable responsible for differences in decontamination efficiency of diethyl malonate and thickened diethyl malonate. Varying the temperature of water from 23°C to 37°C or adding surfactant to the water had little effect on the decontamination efficiency (1). These results, together with the findings that all four test substances were decontaminated equally by the shower, suggest that the mechanism of shower cleaning is mechanical rather than chemical. Apparently, the shower cleans the skin by removing the upper layers of the stratum corneum so that contaminants residing in these upper layers are removed. The velocity of the water droplets in the shower could also contribute to mechanical removal of contaminants not in direct contact with the skin.

During the 15-min period immediately following application the percutaneous penetration of diethyl malonate, as measured by radioactivity appearing in chamber A, was significantly greater than the percutaneous penetration of the phosphonofluoridate (Table I). However, both were <0.1% of the applied dose. An analysis of variance revealed that showering or thickener had no significant influence on the percutaneous penetration of diethyl malonate or the phosphonofluoridate.

Enzymatic analysis showed inactivation of most of the phosphonofluoridate represented by carbon-14 removed from skin by showering or scrubbing (Table II). Any phosphonofluoridate that had penetrated through the skin was below the detection limit of the enzymatic analysis. The purity of the stock samples of the radiolabeled phosphonofluoridate was checked initially, during the

course of the study, and after the completion of the experiments. Purity was essentially 100% at the initial and midpoint, but fell to 70% after the completion of the experiments. However, no significant differences were found between results from initial and final samples.

The inactivation of 1,2,2-trimethylpropyl methylphosphonofluoridate in contact with skin is consistent with the observations of Fredricksson (3) who demonstrated the presence of organophosphate ester hydrolases in the skin of rats. Other investigators (4) who compared skin penetration of the phosphonofluoridate activity with radiolabel penetration reported that human skin decomposed at least 80% of the applied phosphonofluoridate as contrasted with 30% inactivation of its penetration of guinea pig skin.

Diethyl malonate was selected as a simulant for the phosphonofluoridate in skin-surface removal studies on the basis of similar physical properties. For both compounds, the majority of the applied dose evaporated. After 15 min, most of the radiolabel that remained (Table I) was recovered from the skin surface (by showering or scrubbing). The lack of agreement between radioactivity and enzyme inhibition assays of the shower and scrub water would suggest that some of the phosphonofluoridate hydrolyzed after it contacted the skin. In the case of diethyl malonate, hydrolysis on the skin is certainly possible. It is, therefore, possible that the shower removed a mixture of the original compounds as well as hydrolysis products, and it is no longer clear what is being compared. Presumably, the intact compound would have a different affinity for the skin than its hydrolysis products. The fact that similar skin decontamination efficiencies (as judged by the percent removal of radioactivity still on the skin after evaporation) were obtained by showering after application of the radiolabeled diethyl malonate and phosphonofluoridate may be fortuitous. However, if the shower removed the upper layers of skin, and thus removed contaminants in these layers indirectly, decontamination of surface residues would be independent of chemical structure, and similar decontamination efficiencies would be obtained as in this study.

Under the conditions of this study, skin penetration of 1,2,2-trimethylpropyl methylphosphonofluoridate and diethyl malonate was limited by the dose, short interval between application and decontamination, and the free evaporation of the chemicals during this interval. The skin penetration of the phosphonofluoridate is complicated by the possibilities of chemical degradation during its passage through the skin. Attempts to compare the percutaneous penetration of this phosphonofluoridate (and other highly toxic organophosphorous compounds) to analogues or simulants must await knowledge of the fate and distribution of these compounds in skin.

Stereospecific Fluorescence High-Performance Liquid Chromatographic Analysis of Warfarin and Its Metabolites in Plasma and Urine

CHRISTOPHER BANFIELD and MALCOLM ROWLAND ˣ

Received April 18, 1983, from the *Department of Pharmacy, University of Manchester, Manchester M13 9PL, England.* Accepted for publication August 19, 1983.

Abstract □ A stereospecific assay for the simultaneous determination of the enantiomers of warfarin and its major metabolites, 6- and 7-hydroxywarfarin and warfarin alcohols, in plasma and urine was developed. Involved in this determination was the formation of diastereoisomeric esters with carbobenzyloxy-L-proline, separation by normal-phase high-performance liquid chromatography, and detection by fluorescence after postcolumn aminolysis with *n*-butylamine. The determination limit for any enantiomer is in the order of 50–100 ng. The method was applied to the analysis of the enantiomers of warfarin and metabolites in plasma and urine of human subjects receiving racemic drug. The results for warfarin enantiomers are comparable with those obtained by an MS method, involving administration of a synthetic pseudoracemate [$^{12}C(R)$,$^{13}C(S)$]warfarin. In addition to all known metabolites, the detection of 7-*R*-hydroxywarfarin indicates that 7-hydroxylation is stereoselective rather than stereospecific.

course of the study, and after the completion of the experiments. Purity was essentially 100% at the initial and midpoint, but fell to 70% after the completion of the experiments. However, no significant differences were found between results from initial and final samples.

The inactivation of 1,2,2-trimethylpropyl methylphosphonofluoridate in contact with skin is consistent with the observations of Fredricksson (3) who demonstrated the presence of organophosphate ester hydrolases in the skin of rats. Other investigators (4) who compared skin penetration of the phosphonofluoridate activity with radiolabel penetration reported that human skin decomposed at least 80% of the applied phosphonofluoridate as contrasted with 30% inactivation of its penetration of guinea pig skin.

Diethyl malonate was selected as a simulant for the phosphonofluoridate in skin-surface removal studies on the basis of similar physical properties. For both compounds, the majority of the applied dose evaporated. After 15 min, most of the radiolabel that remained (Table I) was recovered from the skin surface (by showering or scrubbing). The lack of agreement between radioactivity and enzyme inhibition assays of the shower and scrub water would suggest that some of the phosphonofluoridate hydrolyzed after it contacted the skin. In the case of diethyl malonate, hydrolysis on the skin is certainly possible. It is, therefore, possible that the shower removed a mixture of the original compounds as well as hydrolysis products, and it is no longer clear what is being compared. Presumably, the intact compound would have a different affinity for the skin than its hydrolysis products. The fact that similar skin decontamination efficiencies (as judged by the percent removal of radioactivity still on the skin after evaporation) were obtained by showering after application of the radiolabeled diethyl malonate and phosphonofluoridate may be fortuitous. However, if the shower removed the upper layers of skin, and thus removed contaminants in these layers indirectly, decontamination of surface residues would be independent of chemical structure, and similar decontamination efficiencies would be obtained as in this study.

Under the conditions of this study, skin penetration of 1,2,2-trimethylpropyl methylphosphonofluoridate and diethyl malonate was limited by the dose, short interval between application and decontamination, and the free evaporation of the chemicals during this interval. The skin penetration of the phosphonofluoridate is complicated by the possibilities of chemical degradation during its passage through the skin. Attempts to compare the percutaneous penetration of this phosphonofluoridate (and other highly toxic organophosphorous compounds) to analogues or simulants must await knowledge of the fate and distribution of these compounds in skin.

of the *S*-isomer is decreased, whereas that of the *R*-isomer is, if anything, hastened (3, 5).

To explore the pharmacokinetics of the individual isomers and drug interactions with warfarin, several stereospecific assays were developed for the determination of warfarin enantiomers in plasma. One assay involved the synthesis of a stable isotope of one of the enantiomers, administration of a pseudoracemate, [^{12}C(*R*),^{13}C(*S*)]warfarin, and determination of the isomers in plasma by MS (6, 7). Another assay used was a stereospecific radioimmunoassay (8). Recently, we reported a high-performance liquid chromatographic (HPLC) technique involving UV detection (9). We now report an extension of the HPLC technique for determination of not only the enantiomers of warfarin, but also its enantiomeric metabolites in plasma and urine after administration of *RS*-warfarin to humans. The method is more sensitive and specific than the UV method.

EXPERIMENTAL SECTION

Reagents and Materials—Racemic warfarin was obtained from its sodium salt[1] by precipitation with 0.1 M HCl. The dried material was recrystallized from absolute ethanol. *R*(+)- and *S*(−)-warfarin[2]; warfarin metabolites[3] [6-hydroxywarfarin, 7-hydroxywarfarin, alcohol 1 (*RS* and *SR* alcohols)]; the selected internal standard[4], 3-α-[(4′-fluorophenyl)-β-acetylethyl]-4-hydroxycoumarin and 4′-fluorowarfarin; imidazole[5]; dicyclohexylcarbodiimide[6]; carbobenzyloxy-L-proline[6]; *n*-butylamine[6]; hexane (HPLC grade)[7]; methanol[8]; and ethyl acetate (HPLC grade)[7] were used as supplied. Peroxide-free ether[9] was prepared by passage through a column of activated alumina[10] (45 g).

Extraction from Plasma—To culture tubes[11] containing citrated plasma were added the internal standard (4′-fluorowarfarin), ranging from 0.85 to 6.8 μg/100 μL of water, sodium hydroxide (0.2 mL), and peroxide-free ether (4 mL). The mixture was shaken mechanically for 5 min and centrifuged[12] at 3000 rpm for 5 min; the organic phase was removed by aspiration. The aqueous phase was then acidified with 3 M HCl (0.5 mL), shaken with peroxide-free ether (8 mL) for 2 min, and centrifuged at 3000 rpm for 10 min; the ethereal layer was transferred to a clean culture tube. The ether was washed free of any citrate by shaking with pH 4 phosphate buffer (5 mL) for 5 min. (If the anticoagulant used is heparin, the pH 4 phosphate buffer

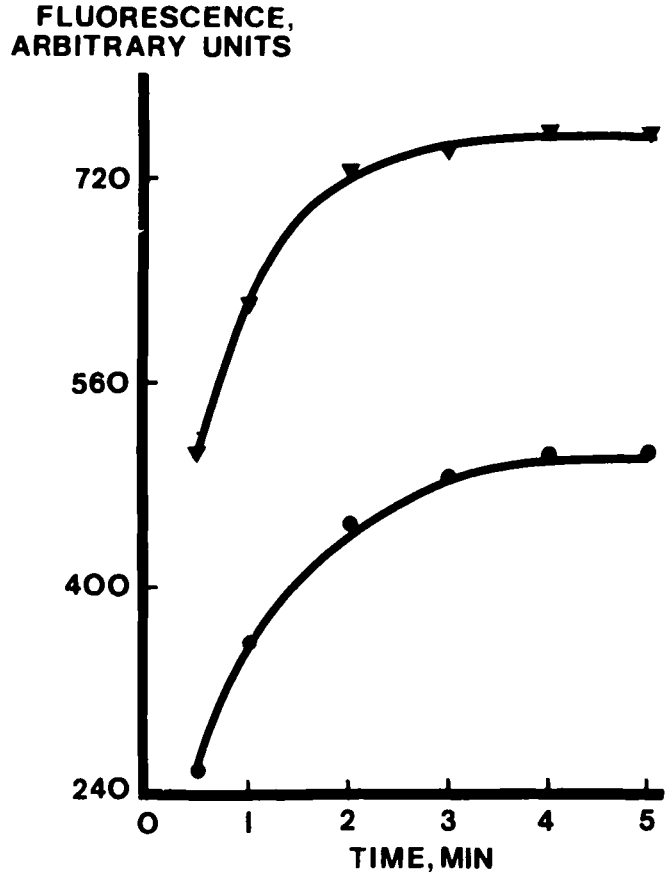

Figure 2—*Fluorescence intensity on incubation of the carbobenzyloxy-L-prolyldiastereoisomeric esters of* RS*-warfarin with* n*-butylamine (●) and 1,3-diaminopropane (▼).*

washing step can be omitted from the procedure.) After allowing the phases to separate, the ethereal layer was dried over calcium chloride (~1 g), centrifuged (3000 rpm for 3 min), and transferred to a culture tube, the tip of which was drawn out to a capacity of 0.2 mL. An antibumping granule was added to each tube, and the ether was evaporated on a heating block at 45°C under a stream of nitrogen. The tubes were washed three times with small volumes of ether, with evaporation of the ether carried out between each addition. Finally, a small volume of ether (100 μL) was added, vortexed, and evaporated to dryness.

Extraction from Urine—To silanized culture tubes containing internal standard (0.8–7 μg of 4′-fluorowarfarin in 100 μL of water) were added a urine sample (0.5 mL), 3 M HCl (0.5 mL), and chloroform (8 mL). The tubes were capped with screw-caps with polytef liners; the mixture was shaken for ~45 min by rotating gently and centrifuged at 3000 rpm for 10 min. The aqueous layer was removed by aspiration, and to the organic phase was added 0.1 M NaOH (1.7 mL). The process of extraction and phase separation was then repeated. The sodium hydroxide layer was transferred to a clean culture tube, acidified with 3 M HCl (0.5 mL), and shaken with chloroform (8 mL) for ~45 min. After centrifugation (10 min), the aqueous layer was removed by aspiration, and the chloroform layer was dried by vortexing for ~10 s over calcium chloride (~1 g/tube), followed by centrifugation at 3000 rpm for 5 min. As much as possible of the chloroform layer was then transferred to a culture tube, the tip of which was drawn out to a capacity of 0.2 mL and evaporated to dryness with a heating block at 65°C under a stream of nitrogen.

Derivatization—To the extracts in the tapered culture tubes were added carbobenzyloxy-L-proline (200 mg/mL of acetonitrile; 10 μL), imidazole (1 mg/ml of acetonitrile; 10 μL), and dicyclohexylcarbodiimine (200 mg/mL of acetonitrile; 10 μL), and the mixture was vortexed for ~10 s. After 2 h at ambient temperature a small volume of ethyl acetate (10 μL) was added to the mixture, and aliquots were analyzed by HPLC.

High-Performance Liquid Chromatography—A flow diagram of the HPLC system used for separation and fluorescence detection of the diastereoisomeric esters after aminolysis is shown in Fig. 1. The mobile phase [ethyl acetate-hexane-methanol-acetic acid (25:74.75:0.25:0.3)] was pumped[13] at a flow

rate of 0.8 mL/min through a stainless steel column (250 mm × 5 mm i.d.) packed with silica[14]. The analytical column outlet was fitted through the shortest possible length of polytef tubing (0.030 mm i.d.) to a stainless steel tee[15] (~0.16 cm i.d.), through which the postcolumn reagent [*n*-butylamine–methanol (1:1), pumped[16] at a flow rate 0.4 mL/min] was mixed with the mobile phase. The outlet of the tee was connected to a bed reactor (stainless steel column 3.0 mm i.d. × 25 cm) packed with glass beads[17] (40 μm). The entire system was at ambient temperature. The effluent from the bed reactor was analyzed fluorometrically with excitation at 313 nm, and the emission was measured in the presence of a filter[18] with a sensitivity setting of 6.16 and a time constant of 6 s. For the simultaneous determination of warfarin and metabolites, a range setting of 1 μA was used for between 5 and 1.0 μg per isomer of warfarin. When either the last internal standard ester or *SR*-alcohol had eluted, the range was switched to 0.2 μA to quantitate the other metabolites. At 0.2 μg per isomer of warfarin, the range setting was constant at 0.2 μA throughout the analysis.

The concentrations of enantiomers of warfarin and its oxidation products (6-hydroxywarfarin, 7-hydroxywarfarin) and reduction products (warfarin alcohols) in the unknown samples of plasma and urine were calculated by reference to appropriate calibration curves. These curves were constructed by taking known quantities of the reference materials in warfarin-free plasma and urine through the assay procedure and plotting the peak height ratios obtained, using either isomer of the internal standard, *versus* the known amount of isomeric material per sample.

Elution Order of Warfarin and Metabolites—The individual isomer elution order was established from the administration of either the *R*- or the *S*-warfarin in an isolated perfused rat liver system in a manner similar to that described by Pang and Rowland (10). *R*(+)- or *S*(−)-warfarin (20 μg/mL in Kreb's bicarbonate buffer) was added to the perfusate in a recirculating experiment. After 90 min, the experiment was stopped, and a sample of the reservoir was subjected to analysis for warfarin and metabolites as described above.

RESULTS AND DISCUSSION

Previously, we successfully developed a stereospecific HPLC method for the determination of *R*(+)- and *S*(−)-warfarin in plasma (9). The method involves the reaction of the 4-hydroxy group with carbobenzyloxy-L-proline with formation of diastereoisomeric esters, separation of the esters on silica as the stationary phase, and UV detection at 313 nm. The method has sufficient sensitivity (~0.1 μg per isomer) to measure the plasma concentrations of warfarin enantiomers after chronic maintenance therapy with racemic war-

farin and for up to 5 d after a large single oral dose (1.5 mg/kg) of the racemic drug. However, the method is insufficiently sensitive to measure in detail the pharmacokinetics after lower single doses and to measure the concentration of the warfarin metabolites (6-hydroxywarfarin, 7-hydroxywarfarin, warfarin alcohols), which are generally much lower than that of the parent drug (3). These limitations prompted us to develop a more sensitive stereospecific analytical procedure which was still based on the formation of diastereoisomeric esters with carbobenzyloxy-L-proline. Preliminary work showed that this reaction can readily be extended to warfarin metabolites. Use was made of the native fluorescence of warfarin and its metabolites (3).

Postcolumn Aminolysis—Fluorescence techniques often offer greater specificity, as well as enhanced sensitivity, over UV methods. However, by forming an ester at the 4-hydroxyl function, the fluorescent property of warfarin and its metabolites is lost, since only the ionized form of these species fluoresces (3). Therefore, to produce a fluorescent species, the chromatographed esters must be cleaved post column.

The optimal HPLC conditions for separation of the diastereoisomeric esters is the normal-phase mode, with silica used as the stationary phase. The mobile phase [ethylacetate–hexane–methanol–acetic acid (25:74.75:0.25:0.3)] is immiscible with water, so the frequently employed aqueous alkaline hydrolysis of esters could not be employed. The possibility of nonaqueous aminolysis of the carbobenzyloxy-L-proline esters of warfarin enantiomers with organic amines was explored by monitoring the liberated warfarin fluorometrically.

Successful nonaqueous aminolysis and development of a fluorescent species was achieved with *n*-butylamine and 1,3-diaminopropane in methanol. Triethylamine, *N*,*N*-dimethylaniline, and *N*,*N*,*N*′,*N*′-tetramethylethylenediamine were also investigated. However, not only did the warfarin carbobenzyloxy-L-prolyl esters aminolyze more slowly with these organic bases, but fluorescence of the liberated warfarin was also markedly reduced in the presence of these amines, as compared with that achieved in the presence of either *n*-butylamine or 1,3-diaminopropane. TLC analysis [ethyl acetate–hexane–acetic acid (30:70:0.2), silica gel] of the butylamine reaction mixture at the end of the reaction, as judged by the maximum fluorescence reading, confirmed that aminolysis was complete. In place of the two diastereoisomeric esters (R_f 0.27 and 0.32) there was now only one spot corresponding to warfarin (R_f 0.35). Phenyl acetate undergoes aminolysis by *n*-butylamine to form *n*-butylacetamide (11) and, probably, the warfarin esters react similarly. A factor favoring butylamine and 1,3-diaminopropane is that alone, neither reagent produces significant fluorescence.

The fluorescent intensity of a methanolic solution containing the warfarin esters, in the presence of 16.7% base, reached an asymptote within ~4 min (Fig. 2). The data could be described by the first-order expression:

$$\ln (F_{max} - F_t) = \ln F_{max} - kt$$

where F_{max} is the asymptotic value of the fluorescent intensity, F_t is the fluorescent intensity at time t, and k is the first-order rate constant. From such a plot of the data, rate constants of 1.0 ($r^2 > 0.99$) and 1.3 min^{-1} ($r^2 > 0.99$), corresponding to half-lives of 42 and 32 s were obtained for the *n*-butylamine- and 1,3-diaminopropane-catalyzed reactions, respectively. These very short half-lives indicate that the kinetics of aminolysis and production of a fluorescent species is sufficiently rapid for use in an analytical procedure involving a postcolumn reaction step.

Careful selection of the design of the postcolumn reactor is required if chromatographic resolution is to be maintained. Open tubes do not allow effective mixing of the mobile phase and reagent (12). For reaction times greater than 1 min, the long tube required to create sufficient residence time leads to considerable dispersion of sample (13) with resultant loss of resolution and sensitivity. In addition, open-tube reactors are sensitive to changes in flow rate [decreasing flow rate leads to increased residence time resulting in decreased peak height (12)]. In contrast, bed reactors (tubes packed with large-diameter glass beads) provide micromixing of sample and reagents by increasing radial dispersion (14); they are suitable for reactions of up to ~5 min and are less sensitive than open-tube reactors to changes in the flow rate (13). Therefore, based on the reported better performance of bed reactors over tube reactors and the relatively rapid kinetics of aminolysis and development of a fluorescent species, this system was employed in the fluorometric assay (Fig. 1). The residence time in the bed reactor was ~1.5 min (given by the difference in retention of the unretained solute in the presence and absence of the bed reactor). Although it is not critical that the reaction goes to completion, as long as it is reproducible, the less complete the reaction the lower is the overall sensitivity of the assay. Therefore, with the postcolumn reagent [*n*-butylamine–methanol (1:1)] in the HPLC system, which was used at an identical dilution to that in the kinetic study (16.7%), the estimate of half-life computed from the kinetic study was used in conjunction with the residence time in the bed reactor to estimate the percentage of maximum aminolysis

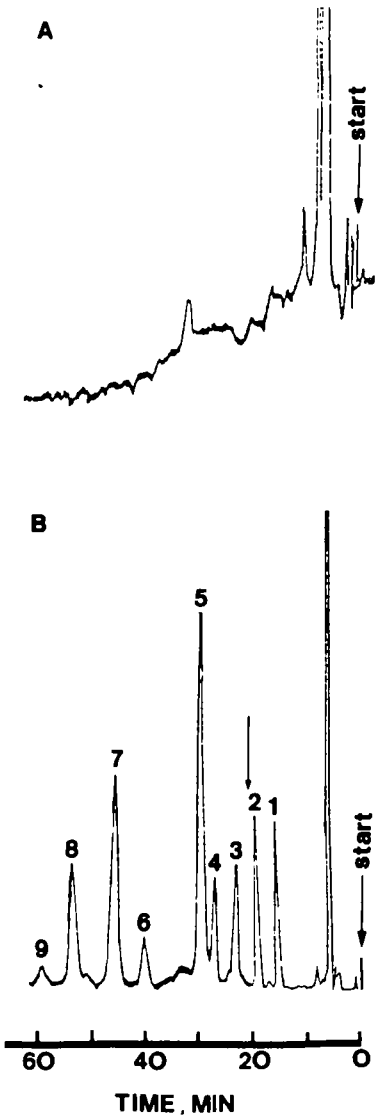

Figure 5—*Chromatogram resulting from extraction and derivatization with carbobenzyloxy-L-proline of a control urine sample (A) and a urine sample (0.5 mL) obtained from a subject between 4 and 5 d after oral administration of* RS-*warfarin (1.5 mg/kg) (B). Key: (1) first eluting peak of internal standard (0.42 μg); (2) second eluting peak of internal standard (0.42 μg); (3)* SR-*alcohol?; (4)* SS-*alcohol (not quantitated); (5)* RS-*alcohol (0.8 μg/mL); (6) 6-*S-*hydroxywarfarin (0.28 μg/mL); (7) 7-*S-*hydroxywarfarin (1.1 μg/mL); (8) 6-*R-*hydroxywarfarin (0.92 μg/mL); (9) 7-*R-*hydroxywarfarin (0.15 μg/mL). and fluorescence developed. Under these conditions, at least 78% of the maximum value is obtained. Although 1,3-diaminopropane gives superior results to those of *n*-butylamine, its choice for further investigation was rejected because of the greater toxicity of diamines.

The use of a racemic internal standard which forms diastereoisomeric esters requires a chromatographic system with high resolution to separate the internal standard esters from those of warfarin. Our situation was acute since under optimal chromatographic conditions, the ester of *S*(−)-warfarin elution was followed by the first eluting ester of the racemic internal standard, which preceded the ester of *R*(+)-warfarin. The lack of significant band broadening of the peaks when the postcolumn reactor was used (Fig. 1) is an important feature of the assay technique.

Elution Order of Warfarin and Metabolites—By using the isolated perfused rat liver preparation as a metabolite generator, in all cases, the metabolite derived from the parent molecule with the *S*(−)-configuration eluted first. Thus, 7-*S*-hydroxywarfarin eluted before 7-*R*-hydroxywarfarin, and 6-*S*-hydroxywarfarin eluted before the corresponding *R*-isomer. With the alcohols, the availability of (*R* and *S*)-alcohols (a mixture of all four alcohols), alcohol

1 (*SR* and *RS*), and pure *RS*-alcohol, permitted assignment of the order of elution as *SR*-, *SS*-, *RR*-, and *RS*-alcohol.

Analysis of Plasma—By varying both the concentration of the internal standard (0.85–6.8 μg) and the sensitivity setting on the fluorescence detector, warfarin and its major metabolites can be simultaneously quantitated from plasma (1 mL). The complete analysis time for warfarin and metabolites is 1 h. No major peaks occurred in the chromatogram of control citrated plasma obtained from a healthy volunteer. Similar results were observed for plasma obtained from other subjects. Warfarin and its metabolites had to be separated from citric acid with pH 4 phosphate buffer. In high concentration in citrated plasma, this acid consumes the activating reagent (*N,N*-dicyclohexylcarbodiimide) and also forms esters in place of carbobenzyloxy-L-proline with warfarin and metabolites, leading to nonreproducible results. There were no such problems with heparin, so the pH 4 phosphate buffer wash is not needed when this anticoagulant is used.

Calibration plots for racemic warfarin and the separate metabolites (*RS*-alcohol, 7-*S*- and 7-*R*-hydroxywarfarin, and 6-*S*- and 6-*R*-hydroxywarfarin) in plasma are linear ($r^2 > 0.99$), as are the corresponding plots when these species are analyzed as a multicomponent mixture. Once formed, the respective carbobenzyloxy-L-propyl esters are stable for at least 24 h. The *RSD* over the range 0.1 to 1.0 μg per isomer for the *S*- and *R*-warfarin isomers varied between 8.7 and 1.7% (first eluting esters of the internal standard). By using the second eluting peak of the internal standard, the *CV* ranged between 8.7 and 2.6%. By varying both the concentration of the internal standard (0.85–6.8 μg) and the sensitivity setting on the fluorescence detector, warfarin and its major metabolites could be simultaneously quantitated from plasma (1 mL). The determination limit (with a 10% *CV*) of the metabolites in plasma varied from 0.045 μg for 7-*R*-hydroxywarfarin to 0.15 μg for 6-*R*-hydroxywarfarin, when the first eluting ester of the internal standard was used to compute the peak height ratios. Similar results were obtained when the more slowly eluting ester of the internal standard was used. The noise level of the fluorescence detector was one of the major factors limiting sensitivity.

Analysis from Urine—Preliminary investigations of metabolite extraction from urine by the assay procedure for plasma and detection by the UV (313 nm) procedure were discouraging, because compounds present in metabolite-free urine were UV absorbent and chromatographed with retention times similar to those for the internal standard and the warfarin alcohols.

In contrast, fewer interferences were seen in chromatograms when the extraction procedure described above was used and when fluorescence was the mode of detection. Linear calibration plots were obtained for all the metabolites over their respective ranges (*RS*-alcohol, 0.106–0.85 μg; 7-*R*- and 7-*S*-hydroxywarfarin, 0.1–1.0 μg; 6-*R*- and 6-*S*-hydroxywarfarin, 0.14–1.1 μg). Owing to the lack of a good analytical standard for *SS*-alcohol (alcohol 2), no calibration plots were obtained. The determination limit (with a 10% *CV*) of the metabolites in urine were similar to those in plasma, ranging from 0.042 μg for the 7-*R*-hydroxywarfarin to 0.17 μg for 6-*S*-hydroxywarfarin.

Comparison with a Mass Spectroscopic Assay—As part of a collaborative program, plasma samples[19] from subjects who had participated in a phenylbutazone–warfarin study 2 years previously were received for analysis of *R*(+)- and *S*(−)-warfarin. In the study, subjects received a pseudoracemate of warfarin [^{12}C(*R*),^{13}C(*S*)]warfarin before and during administration of phenylbutazone, and the concentration of the individual enantiomers was determined by an MS method (15). The samples were stored frozen until they were analyzed by us, and the results of the previous analysis were not made available to the analyst until after the results by the present fluorescence method were obtained.

Rigorous statistical evaluation of the performance of the HPLC and the MS methods cannot be shown since both assays were not performed by the same laboratory. The concentrations of the isomers when *RS*-warfarin was administered alone or with phenylbutazone are presented in Fig. 3. The slopes of the warfarin concentrations in the absence or during phenylbutazone treatment are close to 1, suggesting that the two methods give comparable results. These graphs also illustrate both the good stability of warfarin in plasma, since these analyses were performed ~2 years apart, and the lack of interference of phenylbutazone and its metabolites in the analysis of warfarin. This lack of interference in the fluorescence assay was further demonstrated by the absence of interfering peaks and identity of the slopes of the calibration curves for the enantiomers of warfarin when assayed from plasma that was spiked with therapeutic concentrations of phenylbutazone and its major oxidation metabolites, oxyphenbutazone and γ-hydroxyphenylbutazone (16).

Presence of Other Drugs—Interference in the plasma or urine assay by other drug substances such as cimetidine and salicylate drugs that may be administered concomitantly with warfarin was also studied. Cimetidine produced no spurious peaks in the chromatograms in the presence or absence of *RS*-warfarin. As an imidazole, it is a base and presumably was extracted by the acid–base extraction step.

A large peak in the chromatogram, which interferes with the analysis of warfarin metabolites, was observed when urine spiked with salicylate was taken through the assay procedure. Salicylate fluoresces at the maximum wavelength of excitation of warfarin, is activated by dicyclohexylcarbodiimide, and forms an ester with warfarin or consumes the chiral reagent by formation of an ester at the phenolic group. Hence, the quantitation of the metabolites of warfarin in urine in the presence of salicylate is likely to be severely limited by some or all of the factors described above.

***In Vivo* Study**—Figure 4 shows a chromatogram of a plasma sample obtained 24 h after the administration of *RS*-warfarin (1.5 mg/kg) to a healthy volunteer. The metabolic pattern observed is consistent with the stereoselectivity of metabolism shown by other workers after the administration of the individual isomers (3, 4). In addition, a small quantity of 7-*R*-hydroxywarfarin was seen. A similar metabolic pattern can be seen in urine 123 h after ingestion of *RS*-warfarin (1.5 mg/kg) (Fig. 5). In addition, there is a peak which chromatographs with a retention time similar to that of the *SR*-alcohol. This peak is absent in a metabolite-free urine sample taken from the same subject. The presence of this peak suggests that the reduction of the *S*-isomer may not be stereospecific for the *S*-configuration.

Abstract □ The effect of different coadministered fluid (water) volumes on the consistency of digoxin absorption was studied in 16 male volunteers. Each volunteer received four single-dose treatments (two 0.25-mg digoxin tablets with 30- and 240-mL of water and two 0.2-mg digoxin capsules with 30- and 240-mL of water). Digoxin present in serum and urine samples collected for 48 h after dosing was quantified by RIA. Treatments were compared by evaluating the following model-independent pharmacokinetic parameters: maximum serum concentration (C_{max}); time of maximum serum concentration (t_{max}); area under the serum concentration-time curve for 0–12 h (AUC_{0-12}); cumulative urinary excretion for 0–48 h (CUE_{48}). No significant differences were found between dosage form (tablets *versus* capsules) and coadministered water volume (30 mL *versus* 240 mL) for any of the parameters. For both fluid volumes the AUC_{0-12} and C_{max} were significantly larger ($p < 0.01$) and the t_{max} significantly shorter ($p < 0.01$) for the capsules than for the tablets. The volume of coadministered water had no effect on the amount of digoxin absorbed from either dosage form.

Keyphrases □ Digoxin—bioavailability, coadministered fluid volume □ Fluid volume—bioavailability of digoxin

The bioavailability of orally administered drugs may be affected by a number of factors, including dosage form, physicochemical properties of the drug, first-pass extraction by the liver, interactions prior to absorption between the drug and substances in the GI tract, and certain diseases involving the GI tract. One factor which may affect oral bioavailability, that has received little attention, is the potential influence of coadministered fluid volume on drug absorption. In fact, a commonly accepted notion is that drugs are absorbed more rapidly from concentrated than from dilute solutions (1). However, some studies in experimental animals and humans dispute this point. Ferguson (2) studied the toxicity of a variety of organic and inorganic compounds following oral doses to fasted rats. Equal doses of dissolved compounds were given in increasing water volumes equivalent to 1.25, 2.5, and 5.0% of body weight. The toxicity of all compounds, expressed in terms of median lethal dose (LD_{50}), increased with increasing dilution, indicating that absorption was more rapid and/or more complete from dilute solutions. General mechanisms that have been suggested for increased drug absorption from dilute oral solutions are (*a*) more rapid stomach emptying due to the greater volume and (*b*) relative hypotonicity of the solutions, with consequent exposure of the solute to a greater intestinal surface area (3).

The influence of fluid volume on bioavailability of drugs in humans has been studied with erythromycin stearate (4), ampicillin trihydrate (5), amoxicillin trihydrate (5), theophylline (6), doxycycline hyclate (7), tetracycline hydrochloride (7), and propoxyphene hydrochloride (8). In general, these studies of passively absorbed drugs indicate that the volume of fluid coadministered with a drug of poor water solubility may significantly affect the rate and/or extent of its absorption. The bioavailability of drugs with good water solubility, on the other hand, is relatively unaffected by a change in fluid volume.

Digoxin is a compound that is poorly soluble in water [0.095 mg/mL (9)]. Because of this, concern has been expressed that absorption from a tablet may be affected by administration

with different fluid (water) volumes. If this concern was justified, differences in fluid volumes may have had a significant influence on the results of previously published bioavailability studies. Also, many patients take their medications with varying amounts of fluid, ranging from a small ("gulp") to a glassful of water. The difference in patterns of administration could be associated with inconsistency in the amount of digoxin absorbed from tablets during clinical use.

A solid dosage form (capsule) in which the digoxin is already in solution is now available. Theoretically, absorption from this capsule should not be affected by different water volumes and may be more consistent than tablet doses. Thus, a study was conducted to compare the influence of fluid volume on the consistency of digoxin absorption from these two dosage forms when given in bioequivalent doses[1]. This was accomplished by administering digoxin tablets and a digoxin formulation as a solution in soft gelatin capsules [90–100% absorbed (10–12)] with 30 mL and 240 mL of water to healthy volunteers in a crossover study.

EXPERIMENTAL SECTION

Clinical Study—Sixteen healthy male volunteers [23–33 years old (mean 25.1) and 61.2–83.0 kg (mean 72.2)] entered and completed the study. All volunteers were in good health (physical examination, clinical laboratory studies, and an electrocardiogram). Information about the purpose of the study and the procedures to be performed was provided to each volunteer. Each signed an informed consent form (approved by the Institutional Review Board) and participated in the study for approximately 8 weeks.

The volunteers fasted from midnight prior to dosing until 4 h following treatment administration. Volunteers were given 120 mL of water at least 1 h before dosing on the morning of each test day to provide adequate hydration after overnight fluid restriction.

Dosing for each treatment occurred at 8 a.m., and blood and urine collections were made over the next 48 h. Blood samples (5 mL) were obtained by standard venipuncture techniques in vacuum tubes without additives at the following times: just prior to dosing (0 h), 0.25, 0.5, 0.75, 1, 1.5, 2, 3, 4, 6, 8, 12, 24, and 48 h after dose administration. These samples were allowed to clot and immediately centrifuged; the serum was separated and stored at −20°C until the time of analysis.

Urine was collected prior to drug administration (blank specimen), 0–24 h, and 24–48 h after drug administration. At the end of each interval the samples were thoroughly mixed, the volumes measured and recorded, and aliquots were removed and frozen until analysis.

Following dose administration the volunteers were ambulatory; however, no strenuous or abnormal physical activity was permitted. A standardized light lunch was served 4 h after dosing.

[a] Incomplete urine collection.

Study Design—The treatments listed below were administered using an open, single-dose, four-way complete crossover (Latin square) design:

1. Two 0.25-mg digoxin tablets[2] with 30 mL of water (tablets + 30 mL).
2. Two 0.25-mg digoxin tablets[2] with 240 mL of water (tablets + 240 mL).
3. Two 0.2-mg capsules[3] of digoxin solution with 30 mL of water (capsules + 30 mL).
4. Two 0.2-mg capsules[3] of digoxin solution with 240 mL of water (capsules + 240 mL).

The sixteen volunteers were randomly assigned to four groups for treatment administration. A 2-week washout period followed each treatment.

Sample Analysis—Digoxin concentration in each serum sample was quantified in duplicate by RIA using a double-antibody slurry and ^{125}I-digoxin (available in kit form)[4]. The procedure was identical to that outlined[4] except that the order of double antibody and ^{125}I-digoxin was reversed. Urine samples were also determined in duplicate by RIA (13). The sensitivities of the serum and urine assays were both 0.1 ng/mL.

Pharmacokinetic and Statistical Analyses—The following parameters were determined from the serum concentration–time curves for each volunteer for each treatment: observed maximum serum concentration (C_{max}), time of observed maximum serum concentration (t_{max}), and the area under the serum concentration–time curve (AUC). Additionally, the cumulative urinary excretions of digoxin during the first 48 h after dose were determined (CUE_{48}). These parameters were analyzed using an ANOVA for a crossover design[5]. Individual contrasts were made using the least significant difference.

RESULTS

The doses of digoxin tablets and capsules used in this study are recognized as bioequivalent in both the official product labeling[1] and elsewhere (14, 15). Thus, all comparisons were made without adjusting for the actual differences in the doses administered (0.5 mg for tablets *versus* 0.4 mg for capsules).

Figure 1 graphically presents the serum digoxin concentration–time profiles (0–12 h) for the four treatments, and Fig. 2 presents the cumulative urinary excretions for the first 48 h after dose administration. For purposes of comparing relative bioavailability, the CUE_{48} was used. The AUC_{0-12}, C_{max}, and t_{max} were used for additional descriptive and clinical comparisons. AUC_{0-12} was used instead of AUC_{0-48} because the majority of the serum concentrations after 12 h following single-dose administration were below the level of assay sensitivity.

Tables I and II list the individual values for area under the serum concentration–time curves (ng · h/mL) and cumulative urinary digoxin excretions (μg/48 h). During the study, two urine collections were reported as incomplete by the respective volunteers. Table III gives the summary statistics for the pharmacokinetic parameters (*i.e.*, AUC_{0-12}, C_{max}, t_{max}, and CUE_{48}) determined in this study. Table IV summarizes the statistical analyses (ANOVA) of pharmacokinetic parameters based on the means of serum digoxin concentration and cumulative urinary excretion data.

[a] For drugs administered in previous studies that evaluated effect of coadministered fluid volume. [b] In water at room temperature. [c] Doses used in present study.

Based on CUE_{48}, there were no significant differences found between dosage form (tablets *versus* capsules) and coadministered water volume (30 mL *versus* 240 mL). Mean CUE_{48} values were 155.1 and 163.3 μg for the tablets with 30 mL and 240 mL of water, respectively. Mean CUE_{48} values for capsules with 30 mL and 240 mL of water were 161.8 and 166.9 μg, respectively. Both fluid volumes showed significantly larger ($p < 0.01$) AUC_{0-12}, and C_{max} values for capsules than tablets. The t_{max} was significantly shorter ($p < 0.01$) for the capsules than for the tablets. Also, capsules administered with 240 mL of water had a significantly shorter t_{max} ($p < 0.05$) than capsules administered with 30 mL of water (0.69 *versus* 0.95 h, respectively). There were no significant interactions between dosage form (tablets *versus* capsules) and coadministered water volume (30 mL *versus* 240 mL) for AUC_{0-12}, C_{max}, t_{max}, and CUE_{48}.

Figure 3 illustrates the between-subject variability in cumulative urinary excretion for the treatments. The *CV* values ranged from 9.5% for capsules administered with 240 mL of water to 17.0% for the tablets administered with 30 mL of water. The two other treatments (capsules + 30 mL and tablets + 240 mL) showed similar *CV* values of 13.9 and 13.7%, respectively.

DISCUSSION

Results of previous studies that evaluated the effect of coadministered fluid volume on bioavailability vary and depend largely on the compound tested. Erythromycin stearate was administered to fasting normal volunteers in single 500-mg doses with 20 mL or 250 mL of water. The results showed that reduction in fluid volume significantly decreased erythromycin serum levels, probably due to the low aqueous solubility of erythromycin stearate (4). Amoxicillin trihydrate (5) and theophylline (6) also show decreased serum levels when administered with smaller fluid volumes.

In some instances, the coadministered fluid volume has minimal or no effect on the bioavailability of the drug tested. Such was the case with doxycycline and tetracycline (water-soluble salts); little effect on the overall serum level-time profiles was seen when each preparation was administered with 25 mL or 250 mL of water (7). Ampicillin trihydrate bioavailability was slightly affected by changes in coadministered fluid volume (5). Although plasma propoxyphene levels have been shown to be lower with a 500 ml volume of water *versus* 250 ml when the drug is given as a capsule, the difference was significant only at the 6-h sampling time (8).

In this study, a comparison of mean CUE_{48} values across both coadministered fluid volume and dosage forms revealed no statistically significant differences. The power to detect a difference of 20% in means for these comparisons with $\alpha = 0.05$ was between 0.95 and 1.00. A comparison of the other pharmacokinetic parameters revealed no significant interactions between dosage form (tablets *versus* capsules) and volume (30 *versus* 240 mL of water). Capsules had significantly larger AUC_{0-12} and C_{max} values and a significantly shorter (earlier) t_{max} than tablets ($p < 0.01$). Interestingly, a significantly shorter t_{max} was observed when the capsules were administered with 240 mL of water than when they were taken with 30 mL of water ($p =$

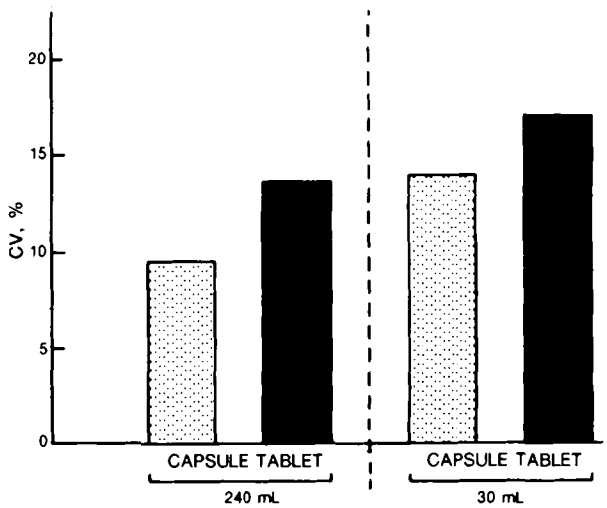

Figure 3—*Between-subject variability in cumulative urinary excretion of digoxin for capsules and tablets (expressed as* CV).

0.03). The larger C_{max} and shorter t_{max} with the capsules *versus* tablets indicate a more rapid absorption rate of the capsule dosage form. Our findings also confirm the results of previous comparative studies, which demonstrate the equivalence of bioavailability of the 0.2-mg capsule and 0.25-mg tablet doses (14, 15).

While no significant differences in the amount of digoxin absorbed were noted based on CUE_{48}, it is interesting to note from Fig. 3 that a smaller *CV* is seen with the capsule than the tablet for both the 240 mL (9.5 *versus* 13.7%) and the 30 mL (13.7 *versus* 17.0%) volumes of water.

Digoxin bioavailability studies (15–20) have used different coadministered volumes of water (100–240 mL). If the results of our study had indicated a difference in bioavailability with different volumes of water, some of the findings of these studies could be questioned. However, since we found no difference in bioavailability with a small *versus* a large amount of fluid, this variable does not have an important influence on digoxin absorption in normal individuals.

A review of drug solubility and volume-related variability in drug absorption is interesting. Table V presents a comparison of the solubilities and doses of drugs that have been administered in previous studies with designs similar to the present study. These data show that concerns over alterations in bioavailability of a drug due to coadministered fluids should not only take into account the solubility of the drug, but also the dose of the respective drug administered. A case in point is digoxin with a solubility of 0.095 mg/mL, one of the lowest values listed. However, because the therapeutic dose is small, only a small volume of water is theoretically required to solubilize the dose in the GI tract.

The results of this study indicate that, in normal volunteers, there are no differences in total digoxin absorption (for either the tablet or capsule forms), when digoxin is administered with relatively small or large volumes of fluid. Such pharmaceutical information is useful in identifying drugs or drug preparations which may or may not be influenced by differences in coadministered fluid volume.

Pharmacokinetics of Fostedil, a New Calcium Antagonist, in Beagle Dogs Following Oral and Intravenous Administration

ELIZABETH W. THOMAS ˣ and BARBARA A. BOPP

Received August 8, 1983, from the *Drug Metabolism Department, Pharmaceutical Products Division, Abbott Laboratories, North Chicago, IL 60064.* Accepted for publication November 28, 1983.

Abstract □ Twelve adult beagle dogs received both an oral and intravenous dose (12 mg/kg) of fostedil in a cross-over design. The plasma levels and urinary excretion of intact fostedil were measured, and the pharmacokinetic parameters of the drug were defined. The results indicate that fostedil was at least 68% bioavailable after an oral dose given as a suspension or solution. The terminal half-life was about 7–8 h. The *in vitro* protein binding, at concentrations of 0.1–100 μg/mL, ranged from 95 to 97%. The binding was not concentration dependent, and saturation of the binding sites was not apparent at concentrations up to 100 μg/mL. Excretion of unchanged drug from the kidneys accounted for only a small percentage of drug clearance.

Keyphrases □ Fostedil—pharmacokinetics, dogs □ Pharmacokinetics—fostedil, dogs □ Blocking agent—calcium entry, fostedil, pharmacokinetics, dogs

Fostedil (I) (diethyl{[4-(2-benzothiazolyl)phenyl]methyl}-phosphonate) is a new calcium entry blocking compound[1] (1–4). This study was designed to determine the pharmacokinetics of fostedil in beagle dogs after intravenous and oral administration.

[1] This compound is being studied under a joint license agreement between Abbott Laboratories, North Chicago, Ill., and Kanebo, Ltd., Japan, and has been reported in the literature as KB-944.

EXPERIMENTAL SECTION

Animals—Five male and seven female adult beagle dogs (8.5–13.0 kg) were randomly divided into three groups of four dogs per group. The groups were dosed at 12 mg/kg, once with an oral solution, an oral suspension, an oral

0.03). The larger C_{max} and shorter t_{max} with the capsules *versus* tablets indicate a more rapid absorption rate of the capsule dosage form. Our findings also confirm the results of previous comparative studies, which demonstrate the equivalence of bioavailability of the 0.2-mg capsule and 0.25-mg tablet doses (14, 15).

While no significant differences in the amount of digoxin absorbed were noted based on CUE_{48}, it is interesting to note from Fig. 3 that a smaller *CV* is seen with the capsule than the tablet for both the 240 mL (9.5 *versus* 13.7%) and the 30 mL (13.7 *versus* 17.0%) volumes of water.

Digoxin bioavailability studies (15–20) have used different coadministered volumes of water (100–240 mL). If the results of our study had indicated a difference in bioavailability with different volumes of water, some of the findings of these studies could be questioned. However, since we found no difference in bioavailability with a small *versus* a large amount of fluid, this variable does not have an important influence on digoxin absorption in normal individuals.

A review of drug solubility and volume-related variability in drug absorption is interesting. Table V presents a comparison of the solubilities and doses of drugs that have been administered in previous studies with designs similar to the present study. These data show that concerns over alterations in bioavailability of a drug due to coadministered fluids should not only take into account the solubility of the drug, but also the dose of the respective drug administered. A case in point is digoxin with a solubility of 0.095 mg/mL, one of the lowest values listed. However, because the therapeutic dose is small, only a small volume of water is theoretically required to solubilize the dose in the GI tract.

The results of this study indicate that, in normal volunteers, there are no differences in total digoxin absorption (for either the tablet or capsule forms), when digoxin is administered with relatively small or large volumes of fluid. Such pharmaceutical information is useful in identifying drugs or drug preparations which may or may not be influenced by differences in coadministered fluid volume.

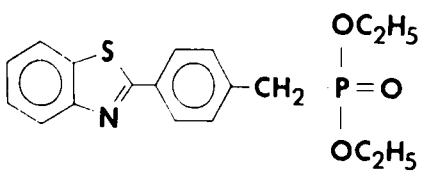
capsule, and an intravenous formulation. At ~2-week intervals, the three groups were crossed-over until each group had received each treatment once. The dogs were fasted for at least 12 h prior to dosing and for at least 5 h following dosing. They were housed individually in stainless steel metabolism cages and given water *ad libitum*.

Treatment—The oral and intravenous solution formulations were prepared as 24 mg of fostedil per mL in ethanol–propylene glycol–water (10:60:30, v/v/v). The suspension formulation was prepared as 24 mg/mL in 0.2% hydroxypropyl methylcellulose–water. The oral solution and suspension were administered by gavage, 0.5 mL/kg to each animal. The intravenous solution was administered intravenously as a bolus (0.5 mL/kg) into the right cephalic vein to provide a dose of 12 mg/kg. For the capsule dosing, the drug was weighed into clear gelatin capsules[2] and administered orally with 10 mL of water.

Heparinized blood samples (2–5 mL) were collected from the jugular vein at 0, 0.1 (intravenous route only), 0.25, 0.5, 1, 2, 3, 4, 6, 8, 10, 12, 24, 26, 28, and 32 h postdose. The plasma was harvested and stored frozen. If possible, urine was collected over the following intervals: 0–4, 4–8, 8–12, 12–24, 24–28, and 28–32 h postdose. The volumes were measured and recorded, and a 5-mL aliquot was stored frozen.

Assay of Fostedil in Plasma and Urine—Measurement of plasma and urine concentrations of fostedil was performed by using an HPLC fluorescence assay (5). The procedure was shown to be sensitive (5 ng/mL) and specific for the intact drug.



I

[2] No. 0.

Pharmacokinetic Analysis—The individual and mean plasma concentrations *versus* time data were subjected to sequential polyexponential regression analyses using STRIP, a slightly modified version of the computer program CSTRIP (6). Based on the criteria outlined by Sedman and Wagner (7), a triexponential model (*e.g.*, a two-compartment open model) was deemed more appropriate for the intravenous, suspension, and oral solution data. A biexponential model (*e.g.*, a one-compartment open model) was chosen for the capsule dosing data.

The data were fitted with NONLIN (8), using appropriate DFUNC subroutines. For the one-compartment model, the parameters on which iterations were performed included: K_a (apparent input rate constant), K_{net} (apparent net elimination rate constant), Vd (volume of distribution), and the absorption lag time. For the two-compartment model, the estimated preexponential and exponential terms were used to calculate the initial estimates of the microscopic rate constants by using the assumptions and equation described by Gibaldi and Perrier (9). Iterations by NONLIN were then performed on the following parameters: K_a, K_{net}, K_{12}, K_{21}, and Vd_1. During the fitting process, the data were weighted by reciprocal squared concentrations ($1/C^2$) (10).

Protein Binding—Fostedil, labeled with carbon-14 in the 2-position of the benzothiazolyl ring, was used in the *in vitro* protein binding studies. The binding of fostedil (concentrations, 0.1–100 μg/mL) was determined in the plasma of male and female beagle dogs by the ultrafiltration technique described by Rolinson and Sutherland (11). The ultrafiltrates and plasma were oxidized, assayed to determine levels of radioactivity, and corrected for quenching by automatic external standardization.

RESULTS AND DISCUSSION

Single-Dose Intravenous Study—A summary of the pharmacokinetic parameters as derived by NONLIN from the intravenous data is presented in Table I. The total body clearance ranged from 0.5 to 0.8 L/h/kg, with a mean value of 0.53 L/h/kg. The beta half-life ranged from 4.8 to 8.9 h, with a mean value of 6.4 h.

Single-Dose Oral Studies—The calculated pharmacokinetic parameters derived by NONLIN for the oral solution, suspension, and capsule dosing data

are listed Tables II–IV, respectively. Figure 1 is a semilogarithmic concentration-time plot of the mean data for each oral and intravenous formulation with the NONLIN generated best-fit curve. As expected for a compound with limited water solubility like fostedil, the absorption kinetics became more complex in progressing from an oral solution to a capsule formulation. Figure 1 illustrates this change, as the two-compartment model disposition kinetics, so distinct after intravenous administration, became less pronounced after oral administration. Indeed, following capsule dosing the data were best described by a one-compartment model, since the distribution phase was completely masked by the complex absorption phase. In the fits for some of the animals, the calculated apparent K_a value approached that of alpha as determined after intravenous administration. Thus, it was impossible to accurately determine the true absorption rate constant. Only an estimated apparent absorption half-life of ~15 min is reported.

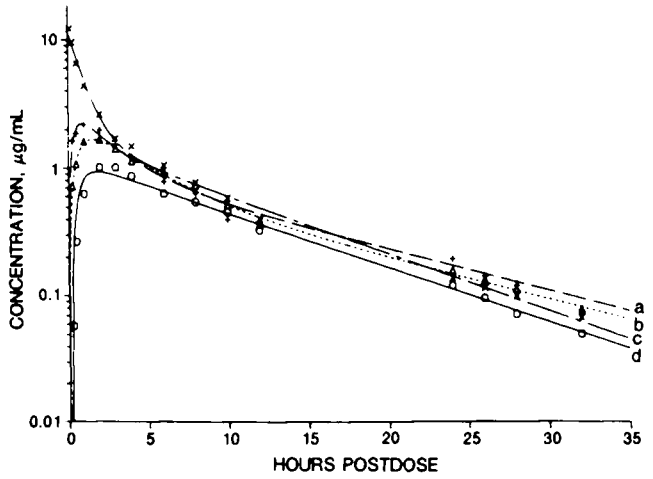

Figure 1—*Mean postdose fostedil concentration* versus *time. Key: (a) oral solution; (b) suspension; (c) intravenous administration; (d) capsule administration of fostedil (12 mg/kg) with NONLIN-generated best-fit curves.*

Studies with radiolabeled drug in rats and dogs have demonstrated the presence of extensive biliary secretion of fostedil and/or its metabolites, suggesting possible enterohepatic circulation[3]. Meal-related secondary peaks in the plasma profiles were observed for many animals in this study. This, in some cases, adversely affected the kinetic analyses. For two of the oral formulations, the mean elimination rate constants were found to be statistically significantly different ($p = 0.015$). However, these differences were considered to be of minor practical importance since the differences could be traced to data from animals displaying unusual plasma drug level profiles. In these cases, the model was inadequate to describe the possible enterohepatic circulation and the complex absorption phenomenon. Thus, the average beta half-life following oral dosing was 7.6 h.

The mean calculated C_{max} values for the oral formulations were: capsule, 0.78 μg/mL; suspension, 1.64 μg/mL, and oral solution, 2.33 μg/mL. An analysis of variance and the Duncan Multiple Range test showed all values to be significantly different from one another.

Since the same dose (12 mg/kg) was administered both orally and intravenously, the systemic availability (F) was calculated as the percent ratio of $(AUC_{0-\infty})$ oral/$(AUC_{0-\infty})$ intravenous (12). The individual F values for these animals following oral dosing are given in Tables II–IV. The mean F values were: oral solution, 71.4%; suspension, 63.6%; capsule, 42.2%. The $AUC_{0-\infty}$ values for the oral solution and suspension formulations were not statistically different ($p = 0.23$) but were greater than those for the capsule dosing. However, the results of another study in this laboratory have suggested that the low bioavailability might have been due to the type of capsule used[4].

Urinary excretion of unchanged drug for both the oral and intravenous dosings was less than 1% of the administered dose over the 32-h collection period.

Protein Binding Studies—The *in vitro* protein binding of [^{14}C]fostedil at

concentrations of 0.1–100 μg/mL ranged from 95–97% in dog plasma, and the binding appeared to be similar in the plasma from the male and the female dogs. The binding was not concentration dependent, and saturation of the binding sites was not apparent at concentrations up to 100 μg/mL.

Inhibition of Human Polymorphonuclear Leukocyte Cell Responses by Ibuprofen

EUFRONIO G. MADERAZO ˣ, STEVEN P. BREAUX, and CHARLES L. WORONICK

Received September 12, 1983, from the *Medical Research Laboratory, Department of Medicine, Hartford Hospital, Hartford, CT 06115.* Accepted for publication November 19, 1983.

Abstract □ The stimulation of cell swelling, cell aggregation, polymorphonuclear leukocyte locomotion, and lysosomal enzyme release in response to chemoattractant were all inhibited by ibuprofen, a nonsteroidal anti-inflammatory agent. The dosages needed to induce 50% inhibition (ID_{50}) were 5.9, 7.6, 60, and 95 μg/mL, respectively. Aside from the differences in ID_{50}, there was also a difference in the degree of maximum inhibition (I_{max}) of the complement C5a-stimulated responses observed, so that at achievable serum drug concentrations of 20–50 μg/mL, inhibition of 67–78% for cell swelling, 69–82% for cell aggregation, 20–35% for migration response, and 17–38% for lysosomal enzyme release were demonstrated. Also observed were a minor stimulatory effect on nitroblue tetrazolium reduction and an inhibitory effect on the ability to kill *Staphylococcus aureus*, but only at very high concentrations (~2 mg/mL).

Keyphrases □ Ibuprofen—inhibition of polymorphonuclear leukocyte cell responses □ Polymorphonuclear leukocytes—inhibition of response, ibuprofen □ Anti-inflammatory agents—ibuprofen, inhibition of polymorphonuclear leukocytes

Although the acute inflammatory reaction is usually the combined result of vascular, humoral, and cellular responses, there is considerable evidence that the contribution of the polymorphonuclear leukocyte[1] is indispensable (1). This is derived from studies showing inhibition of experimental inflammatory response in PMN-depleted animals, the presence of lysosomal enzymes in inflammatory exudates in humans, and the production of tissue damage in experimental animals by PMN lysosomal lysates. Moreover, one mechanism of action of the effects of a variety of anti-inflammatory drugs, which includes corticosteroids and colchicine, is their ability to inhibit the release of lysosomal enzymes from PMN. Consequently, it is important to determine whether nonsteroidal anti-inflammatory agents, in addition to their inhibitory activity on prostaglandin synthesis (2), also have direct inhibitory effects on PMN function. Although the inhibitory effect of these drugs on PMN migration has been shown previously (3–5), a systematic study to quantitate the effects on this and other PMN responses is lacking. Therefore, we studied and quantitated the effects of the anti-inflammatory drug ibuprofen on PMN responses.

EXPERIMENTAL SECTION

Preparation of Leukocytes and Serum—Blood for these studies was obtained from healthy male and female laboratory and hospital personnel. Polymorphonuclear cells were prepared from heparinized (50 U of preservative-free sodium heparin per mL of blood) whole blood by sedimenting erythrocytes with 6% hetastarch–whole blood at a ratio of 1:5. The leukocyte-rich plasma was washed once with a commercially obtained medium[2] at pH 7.4 and centrifuged at 500×*g*. The cell pellet was resuspended in the same medium, and the PMN concentration was adjusted to 5×10^6 PMNs/mL. This preparation was used for PMN locomotion and bactericidal assays. For leukocyte aggregation, swelling, and lysosomal enzyme release assays, the leukocyte pellet was prepared with Hank's balanced salt solution[1]. To lyse contaminating erythrocytes, the cells were resuspended in ice-cold 0.15 M NH_4Cl (pH 7.5) for 10 min, with five 2-min interval inversions, followed by another wash with HBSS. The final cell pellet was resuspended in HBSS to a cell concentration of 10^7 PMNs/mL. Serum was prepared from clotted whole blood.

Chemotactic Factor—The chemotactic factor used in PMN locomotion studies was derived from zymosan-activated serum prepared by incubation of 5 mg of zymosan with 1 mL of serum at 37°C for 30 min. A 3% solution of this material in the medium[2] was used in the lower compartment.

Partially purified complement C5a fragments were used as the chemotactic factor in leukocyte aggregation, swelling, and lysosomal enzyme release studies. C5a was derived by the activation of normal serum with zymosan in the presence of 1 M ε-aminocaproic acid[3] and purified by gel filtration[4] (6). Active fractions were identified by the lysosomal enzyme release assay, lyophilized, and then dialyzed against 0.1 M phosphate buffer (pH 7.4), and

Chemotaxis	3	60	78	20–35
Lysosomal enzyme release				
Glucosaminidase	3	94	110	19–38
Elastase	3	95	100	17–34

stored at −90°C in small aliquots until use. Each preparation was standardized by dose–response studies to calculate maximum enzyme release (V_{max}) and the concentration of C5a needed to induce 50% of the maximum response (K_m) in PMNs. Three times this value ($K_m \times 3$) was then used in the experiments.

Ibuprofen Preparation—Ibuprofen[5] was prepared by dissolving 16.7 mg of the drug in 1 mL of 0.1 M Tris-HCl buffer, pH 8 (high pH values allowed solubilization of ibuprofen). The mixture was readjusted to pH 7.5, mixed thoroughly, and diluted to 8.35 mL with Tris buffer. The ibuprofen concentration at this point was 2 mg/mL and had an absorbance of 0.176 at 280 nm.

Leukocyte Locomotion Assay—Assays were performed in duplicate by using modified transparent acrylic Boyden chambers[6] and 13-mm diameter, 5-μm pore-size cellulose nitrate filters[7]. The modifications of the Boyden technique, as well as the methods used for calculating the locomotion index (LI) have been previously reported in detail (7).

To test the effect of ibuprofen on PMN locomotion, various concentrations of the drug were added to 5×10^5 PMNs in the upper compartment (total volume of 0.7 mL in the medium[2]). The chemotactic attractant, 3% zymosan-activated normal serum, was introduced into the lower compartment. The prepared chambers were incubated at 37°C in a humidified, 5% CO_2 atmosphere for 90 min. After incubation, the filters were removed, fixed, stained, cleared, and mounted as described previously (7).

The effects of the drug on both the number of PMNs migrating and the locomotion index (distance migrated) were quantitated. To assess the total number of PMNs migrating into the filter, the number of cells was counted at a magnification of ×400. The counting was started at 20 μm below the cell monolayer (proximal filter surface) and continued at 10-μm intervals throughout the thickness of the filter. The locomotion index (LI_{20}), the average distance migrated by PMNs that migrated beyond the 20-μm level, was calculated as described previously (7). The chemotactic responses in the presence of ibuprofen were expressed as change from the control value measured in the absence of the drug.

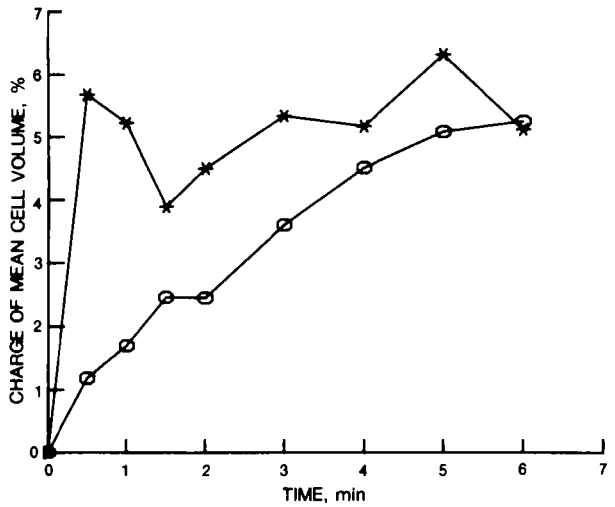

Figure 1—*Effect of ibuprofen on C5a-stimulated PMN swelling. For these experiments, 2×10^6 PMNs were exposed to 2.8 mg of ibuprofen per mL (total volume, 250 μL) for 2 min at 37°C, after which 100 μL of C5a solution ($K_m \times 3$) was added, and incubation was continued for an additional minute. An 80-μL aliquot was added to 20 mL of diluent, and the mean cell volume was determined at the times indicated. Key: (○) with ibuprofen; (✱) no ibuprofen.*

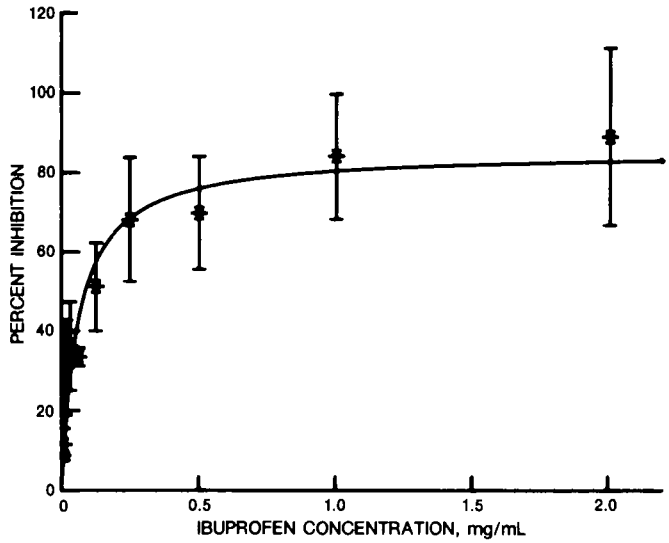

Figure 2—*Effect of ibuprofen on PMN locomotion (LI_{20}) toward activated normal serum as the chemoattractant. The results of three experiments are presented, with the bars representing* SD. *The ID_{50} was calculated to be 60 μg/mL, and the maximum inhibition was 78%.*

Lysosomal Enzyme Release Assay—Lysosomal enzyme release from PMNs was assessed by a method similar to that described by Fantone *et al.* (8). Reaction mixtures containing various concentrations of ibuprofen in the presence of cytochalasin B-treated PMNs (10^7 cells per mL) were preincubated at 37°C for 5 min. To these mixtures, 150 μL (K_m = 50 μL) of C5a was added. The mixtures were incubated at 37°C for 5 min and centrifuged at 200×*g* for 5 min at 4°C. The supernatant solutions were assayed for *N*-acetyl-β-D-glucosaminidase (8) and elastase (9).

Separation of C5a and Ibuprofen—In the study to determine whether ibuprofen has a direct effect on C5a, 2 mL of C5a was incubated with 2 mg of drug for 1 min at 37°C. The drug was then removed by using gel filtration columns[8]. An elution volume between 3.5 and 4.8 mL contained the highest concentration of C5a without the drug.

PMN Aggregation and Swelling—PMN aggregation and cell volume assays were performed by a technique described previously (6). We used a particle counter equipped with a size-distribution analyzer[9]. Reaction mixtures containing various concentrations of ibuprofen were incubated for 2 min at 37°C with 100 μL of PMNs (containing 2×10^6 PMNs). After incubation, 150 μL of C5a was added, and the mixtures were incubated for 60 s at 37°C. Aliquots of 80 μL from these reaction mixtures were added to 20 mL of isotonic solution[10] and immediately analyzed with a particle counter and size analyzer. The first determination of cell number and mean cell volume was obtained 15–30 s after contact of the PMNs with C5a. Subsequent readings were taken in the same vial which was intermittently shaken between readings. Cell number and mean cell volume were calculated for each drug concentration at all time intervals. A decrease in cell number was indicative of cell aggregation.

PMN Nitro Blue Tetrazolium Reduction and Bactericidal Assay—The methods of quantitating nitro blue tetrazolium reduction and bacterial killing by PMNs have been described previously (7). The only modification used for these assay procedures involved the preincubation of PMNs with various concentrations of ibuprofen for 30 min at 37°C.

Analysis of Results—To quantitate the inhibitory effects of ibuprofen, dose–response studies were performed to determine the degree of inhibition as a function of ibuprofen concentration. The percent inhibition (%I) was calculated from:

$$\%I = \left[\frac{R_D - R_{Neg}}{R_{C5a} - R_{Neg}} - 1\right]100$$

where the responses (R) are: R_D, in the presence of ibuprofen plus C5a fragments; R_{C5a}, in the presence of C5a fragments alone; R_{Neg}, in the presence

of neither. We found that the data conformed to a rectangular hyperbola of the form:

$$\%I = \frac{I_{max}\,[\text{ibuprofen}]}{ID_{50} + [\text{ibuprofen}]}$$

where I_{max} is the maximum reversal of chemoattractant effect expected when the ibuprofen concentration is extrapolated to infinite concentration, and ID_{50} is the concentration of ibuprofen that will produce $0.5 \times I_{max}$. The data were analyzed by nonlinear regression (10).

RESULTS

Ibuprofen inhibited all PMN responses to the chemoattractant. These included the locomotory chemotactic response (as measured by the micropore filter technique), lysosomal enzyme release, cell aggregation (as measured by a transient decrease in the number of PMN cells occurring within 30 s from contact with the chemoattractant), and cell swelling. These effects were directed against the cells and not against the chemoattractant, since treatment of C5a with ibuprofen and subsequent removal of the drug by gel filtration[8] did not impair subsequent C5a activity on release of the lysosomal enzyme elastase. The ID_{50} and I_{max} values with ibuprofen varied according to the response tested. A summary of these effects is shown in Table I. Cell swelling and cell aggregation had the lowest ID_{50} values, whereas these values were high for locomotory response and lysosomal enzyme release.

Of additional interest is the effect of ibuprofen on PMN cell swelling. Although it inhibited the rapid cell swelling that occurred 30 s after PMN contact with C5a, the drug itself produced a relatively slower swelling of cells (Fig. 1). The delayed swelling caused by ibuprofen, which eventually exceeded that produced by C5a, occurred with or without the presence of C5a. Six determinations of the effect of ibuprofen on PMN swelling and aggregation were made at an ibuprofen concentration of 1.75 mg/mL. We found that the inhibition of swelling was 90% (calculated value = 87%) and inhibition of aggregation was 96% (calculated value = 95%).

The locomotory index (distance migrated per cell) was inhibited, with an I_{max} value of 78% (Fig. 2), but the number of PMNs migrating did not diminish, except at very high concentrations (40% inhibition at 1.5–2.0 mg/mL) of the drug. Thus, the PMNs are affected in two distinctly different ways, depending on drug concentration. The reduced number of migrating PMNs at high concentrations of ibuprofen was not related to cell death or loss of viability since, in the trypan blue dye exclusion study, 98% of PMNs exposed to 2 mg of drug per mL excluded trypan blue dye, as compared with 94% of control cells. Also shown in the trypan blue dye study is that 55% of control cells had the triangular active morphology and were moving, whereas in the drug-treated PMNs only 12% assumed this active form. This is consistent with inhibition of locomotory response observed by the micropore filter assay.

Lysosomal enzyme release, particularly that of elastase, can be completely inhibited (I_{max} = 100%) by high concentrations of ibuprofen (Fig. 3). The reduced lysosomal enzyme activity observed in the presence of ibuprofen was due to reduced release of enzymes and not direct inhibition of the enzyme by the drug, since addition of ibuprofen after the enzyme release step of the assay, using control PMNs not previously treated with the drug, did not produce any change in the quantity of enzyme activity. There is a suggestion of individual variability in the ibuprofen response of PMNs. A donor with a low PMN locomotory response was found to have ID_{50} values of 191 μg/mL for glucosaminidase and 113 μg/mL for elastase release and I_{max} values of 111 and 113%.

Nitro blue tetrazolium reduction by PMNs was not affected, except at high concentrations of the drug. There was a linear increase ($p < 0.001$) in nitro blue tetrazolium reduction in the presence of 0.5–1.75 mg of the drug per mL and a sharp drop in activity thereafter (Fig. 4). Bactericidal activity against *Staphylococcus aureus* was also not affected by ibuprofen, except at a concentration of 2 mg/mL, at which a discernible inhibition was found (Fig. 5).

Perhaps of greater clinical relevance than the I_{max} values are the estimates of inhibition of the responses at drug concentrations of 20–50 μg/mL, since these are achievable in plasma. These estimates (Table I) indicate that PMN swelling and aggregation induced by C5a are most inhibited by these levels of ibuprofen. The chemotactic (locomotory) response to zymosan-activated normal serum is reduced by 20–35%, and the stimulation of lysosomal enzyme release by C5a is reduced by 17–38% (Table I).

DISCUSSION

The results of these studies indicate that ibuprofen may indeed exert its anti-inflammatory action on multiple sites. Besides its well-known effect on prostaglandin synthesis resulting from its potent inhibitory activity against the enzyme cyclo-oxygenase (11), it has easily demonstrable inhibitory effects on PMN responses to chemoattractant. By comparison, however, ibuprofen is much more active against cyclo-oxygenase than against PMN responses since the ID_{50} to platelet and endothelial cell prostaglandin synthesis was found to be 1 μg/mL [calculated from the data of Parks *et al.* (12)]. Relatively minimal effects on bactericidal function against *S. aureus* and on nitroblue tetrazolium reduction were also demonstrable at very high concentrations. Quantitative assessment of these effects indicates evidence of selectivity. For example, cell aggregation and swelling were inhibited by low concentrations of the drug that are easily achievable in serum with the usual oral doses, whereas lysosomal enzyme release and chemotactic (locomotory) responses required much higher concentrations. From these results, particularly with the effect of ibuprofen on chemotactic response, it is difficult to explain why the use of ibuprofen is not associated with a clinically obvious impairment of antimicrobial host defenses. It is likely that the combined effects on PMN responses and prostaglandin synthesis, but not separately, result in a predominantly anti-inflammatory effect. From these studies, it can be concluded that it is also likely that antimicrobial defenses may suffer at very high concentrations.

Because of its effect on PMN aggregation, it is possible that this drug and other nonsteroidal anti-inflammatory drugs may be useful in the prevention of disorders that result from vascular leukocytic stasis of intravascularly stimulated PMNs, such as adult respiratory distress syndrome related to open heart surgery, filtration leukapheresis, systemic infections, and hemodialysis

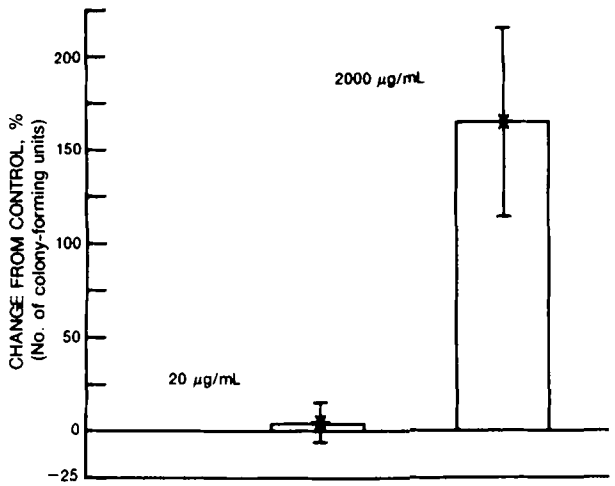

Figure 5—*Effect of ibuprofen on the bactericidal activity of PMNs against* S. aureus. *The percent change from the control is based on the number of colony-forming units remaining. Change in the positive direction indicates inhibition of the bactericidal activity of the cells.*

(13). Moreover, ibuprofen may be a useful agent to prevent the pulmonary complications of bleomycin, since new evidence indicates that this antineoplastic drug concentrates in PMNs and may be delivered at high concentrations to the lungs when conditions for the occurrence of pulmonary vascular leukocytic stasis are present (14).

The mechanism to explain the inhibitory effects of ibuprofen on PMNs is not known. Since aggregation, chemotaxis, and lysosomal enzyme release were inhibited almost to a similar degree by the drug, it is likely that the mechanism involves a pathway common to all three responses. These common pathways include the cell membranes and the cellular messengers, such as cell receptors, calcium, cyclic neucleotides, and arachidonic acid metabolites, particularly of the lipoxygenase pathway. Although the lysosomal membrane was "stabilized" by ibuprofen and other nonsteriodal anti-inflammatory drugs, as reported by this study and others (15), there is yet little direct evidence of cell membrane inhibitory effects by these drugs. Recent evidence points to a regulatory influence of prostaglandins on cyclic neucleotides and calcium (16). Although the effects of specific postaglandins on cyclic nucleotides may be known, it is not possible to predict what effects the inhibition of prostaglandin synthesis would have. This is because prostaglandin effects are concentration-dependent (a low concentration of PGE lowers, while a high cocentration raises, cAMP cellular levels), and also dependent upon the specific compound (*i.e.*, PGF_{2a} increases cGMP; PGE and PGD increases cAMP) (17, 18). Moreover, the effects of the early unstable metabolites (endoperoxides and thromboxane) differ from that of the stable prostaglandins (19).

Preparation of Spherically Agglomerated Crystals of Aminophylline

Y. KAWASHIMA ˣ, S. AOKI, H. TAKENAKA, and Y. MIYAKE *

Received April 21, 1983, from the *Gifu Pharmaceutical University, 5-6-1, Mitahora-higashi, Gifu 502, Japan* and **Eisai Co., Kawashimachyo, Hashimagun, Gifu 483, Japan.* Accepted for publication August 16, 1983.

Abstract □ The spherically agglomerated crystals of aminophylline (theophylline-ethylenediamine complex) can be compounded directly into pharmaceutical formulations without further processing, *e.g.*, granulation. Such crystals were prepared by mixing theophylline and ethylenediamine in a partially miscible solvent system, *i.e.*, organic solvent-ethanol-water. The organic solvents used were chloroform, 1-hexanol, isopropyl acetate, isobutyl acetate, isoamyl acetate, benzene, toluene, *n*-hexane, or *n*-heptane. Spherical crystallization depended upon the solubility of theophylline in the solvent mixture. The resultant agglomerated crystals were identical with the theophylline-ethylenediamine complex by IR, X-ray, and differential scanning calorimetry analyses, and was the α-, β-, or γ-form when the water of crystallization was ≤0.5, 1.0, and 2.5 mol, respectively. When the amount of ethylenediamine used was <1.1 mL (0.0165 mol), the resultant agglomerated crystals were converted to anhydrous theophylline by washing with ethanol. When water was added to the system (≥0.3 mL, *i.e.*, 0.0167 mol), water was occluded in the resultant agglomerates as water of crystallization. Ethylenediamine content in the agglomerated crystals could be controlled by changing the amount of ethylenediamine added in the crystallization solvent.

Keyphrases □ Aminophylline—preparation from spherically agglomerated crystals of theophylline and ethylenediamine □ Spherical crystallization—aminophylline, theophylline, ethylenediamine

In previous papers (1-3), we described a method for the direct agglomeration of crystals during the crystallization process. In this process, a partially miscible mixture, *e.g.*, water-ethanol-chloroform, was used as the crystallization solvent. By selecting the proper ratio, a small amount of water or chloroform was liberated which acted as the collecting liquid and preferentially wetted the resulting crystals and transformed them into a spherical shape. This technique was termed "spherical crystallization" (1) due to the spherical form of the resultant crystals. Sodium theophylline monohydrate crystals, produced by salting out, were directly agglomerated into spheres in a mixture of an ethylenediamine solution of theophylline, an aqueous sodium chloride solution, ethanol, and chloroform (2, 3). Needle-like salicylic acid crystals simultaneously formed and agglomerated into spheres in a mixture of water, ethanol, and chloroform (1).

The present study describes the preparation of spherically agglomerated crystals of the theophylline-ethylenediamine complex (aminophylline) by the spherical crystallization technique, and also describes the crystallization behavior and the physicochemical properties of the resultant agglomerated crystals.

EXPERIMENTAL SECTION

Spherical crystallization process—*Method 1*—A mixture of organic solvent (60 mL), ethanol (12 mL), and water (0.13-10 mL) was used as the crystallization solvent. The amount of water added to the solvent was adjusted so that the resulting spherically agglomerated crystals were ~1 mm in diameter. The organic solvents used were chloroform, 1-hexanol, isopropyl acetate, isobutyl acetate, isoamyl acetate, benzene, toluene, *n*-hexane, or *n*-heptane. All organic solvents were reagent grade and were used as received. Ethylenediamine[1] (3.0 mL) and theophylline[1] (6.0 g) were dissolved in the mixture and agitated at 500 rpm with a paddle type agitator with four blades. Fine white crystals formed and agglomerated simultaneously into spheres. After 2 h, the agglomerated crystals were separated and dried. When using 1-hexanol and isopropyl acetate, 6-7 h of agitation were required.

Method 2—Spherical crystallization was carried out using the crystallization solvent with various amounts of ethylenediamine (1.0-3.5 mL) and water (0.15-0.9 mL), added to alter the ethylenediamine content in the resultant agglomerated crystals. The crystallization solvent, without water, was also used. The aforementioned experimental procedure was followed.

For reference, the theophylline-ethylenediamine complex (aminophylline), without agglomeration, was prepared by a conventional method, referred to as JP(X) (4). To a solution of absolute ethanol (100 mL) and ethylenediamine (9.2 mL) was added theophylline (24.7 g). The mixture was stirred vigorously for 5-6 h, during which time white crystals formed. These were washed with ethanol and dried.

Liberation Test of the Aqueous Phase from the Crystallization Solvent—To a solution of *n*-hexane (10 mL) and ethanol (2 mL), ethylenediamine (0-6 mL) and water (0-0.9 mL) were added to give two phases.

Measurement of the Physicochemical Properties of the Agglomerated Crystals—The spherically agglomerated crystals and the aminophylline crystals, prepared by the conventional method, were photographed through an optical microscope[2] and a scanning electron microscope[3], respectively. The particle size of the agglomerated crystals was measured by sieve analysis, and the crystalline forms of the agglomerated crystals were analyzed by an X-ray diffractometer[4] and an infrared spectrophotometer[5]. The thermal degradation behavior of the agglomerated and conventional crystals was investigated with a differential scanning calorimeter with heating at a rate of 10°C/min. The contents of theophylline and ethylenediamine in the agglomerated crystals were measured spectrophotometrically at 275 nm and by a neutralization titration method with 0.1 M HCl, respectively. The water content was measured by the Karl Fischer method[6].

RESULTS AND DISCUSSION

Spherical Crystallization Behavior of Method 1—It was found that spherical crystallization was dependent upon the solubility of theophylline in the solvent mixture. When chloroform or 1-hexanol were used as the organic solvents, theophylline completely dissolved. When chloroform was used, the fine crystals changed into the spherically agglomerated crystals within a 1-2 h period. With 1-hexanol, 7 h were required to obtain acceptable spherically agglomerated crystals. The solubility of water in 1-hexanol (5) is relatively high when

compared with the solubility of chloroform and the other solvents (Table I). Therefore, the liberation of the aqueous solution, which acted as the collecting liquid for the crystals, appeared to occur less readily from 1-hexanol than chloroform. When a small amount of additional water (*e.g.*, 0.05 mL) was added to the 1-hexanol mixture during crystallization, (*e.g.*, at 2 h) the crystals agglomerated within several minutes.

When isopropyl acetate, isobutyl acetate, isoamyl acetate, benzene, or toluene were used, a part of the theophylline crystals remained undissolved. Since only dissolved theophylline presumably complexes with ethylenediamine, it is assumed that the undissolved theophylline dissolves as the complex precipitates. When using isopropyl acetate, 5 h were required.

When *n*-hexane or *n*-heptane were used, the spherically agglomerated crystals of theophylline formed immediately: the resultant crystals disintegrated into dispersed particles, and the spherically agglomerated crystals of the complex formed.

Physicochemical Properties of Spherically Agglomerated Crystals Prepared by Method 1—The representative photographs of the spherically agglomerated crystals and the theophylline-ethylenediamine complex (aminophylline) crystals, prepared in the conventional manner, are seen in Fig. 1.

The X-ray diffraction patterns of the agglomerated crystals, shown in Fig. 2, indicate that the agglomerates have three different crystalline forms, described here as the α-, β-, and γ-forms. The β-form was identical with aminophylline, while the patterns of the α- and γ-forms were different. The IR spectra of all the agglomerates were identical with that of aminophylline. The above IR and X-ray diffraction analyses suggested that the α- and γ-form of the agglomerated crystals were theophylline-ethylenediamine complexes with different crystalline forms.

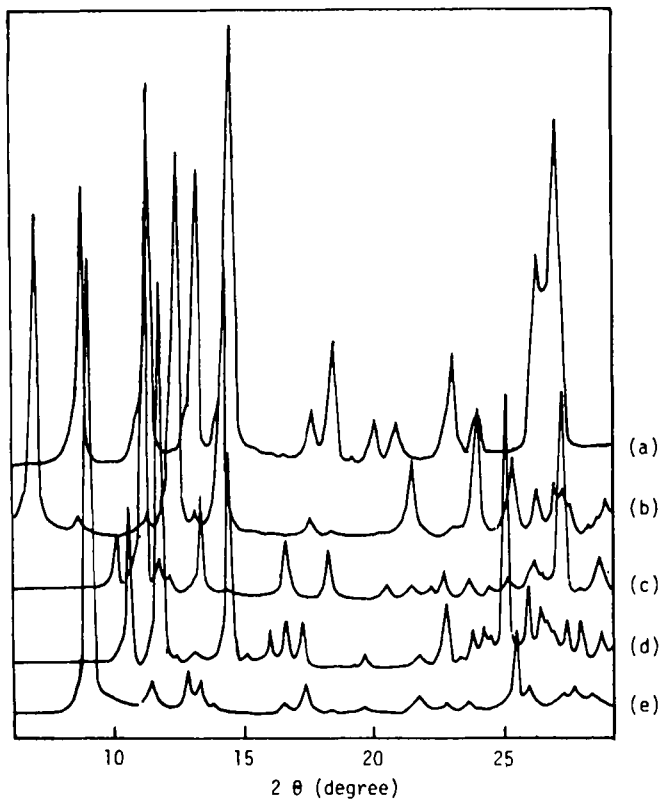

Figure 2—*X-ray powder diffraction patterns of agglomerates, anhydrous theophylline, theophylline monohydrate, and aminophylline. Key: (a) theophylline monohydrate; (b) anhydrous theophylline; (c) α-form of agglomerates; (d) β-form of agglomerates, aminophylline; (e) γ-form of agglomerates.*

The theophylline, ethylenediamine, and water content in the agglomerated crystals is tabulated in Table I. The water content in the agglomerates was classified in the following way: <0.5, 5-6, and 8-10%. Irrespective of the water content, the ratio of theophylline and ethylenediamine remained essentially the same. The water content of 4-6 and 8-10% correspond with ~1 and 2.5 mol of the water of crystallization, respectively, suggesting that the β- and γ-forms of the agglomerated crystals contained 1 and 2.5 mol of water of crystallization, respectively.

Differential scanning calorimetry (DSC) thermograms of the agglomerated crystals are shown in Fig. 3. The endothermic peak due to the release of 1 mol of ethylenediamine appeared at ~120°C and was detected by thermal gravimetry. The water of crystallization in the agglomerated crystals was released in a different way, depending on the crystalline form of the agglomerated crystals. In Table I, the amount of water required for obtaining the acceptable crystals having an average diameter of 0.81-1.55 mm are listed for the various organic solvents used. It was found that decreasing the solubility of water in the solvent decreased the amount of water required for the agglomeration, except for chloroform. This was explained by the fact that the agglomerates prepared using chloroform had higher amounts of water of crystallization (2.5 mol) than the other agglomerated crystals.

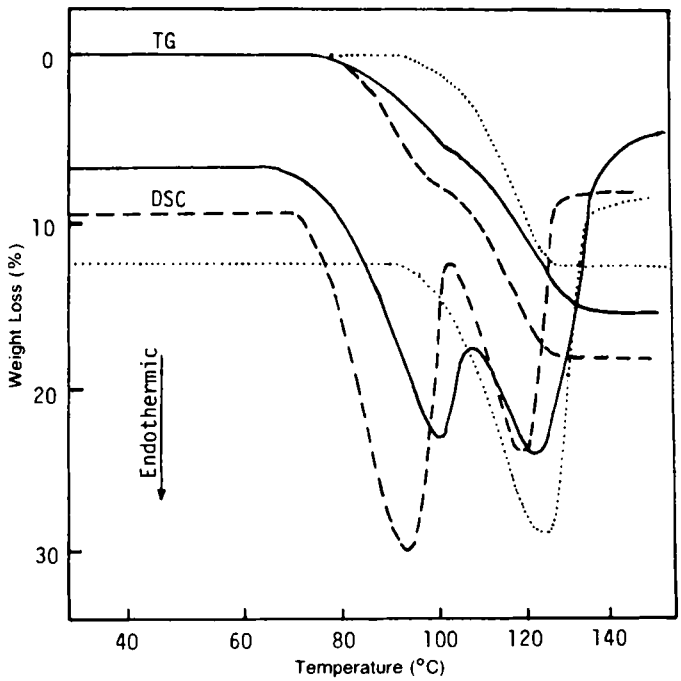

Figure 3—*DSC-TG thermograms of agglomerates and aminophylline. Key: (·····) α-form of agglomerates; (——) β-form of agglomerates, aminophylline; (- - -) γ-form of agglomerates.*

Table II—Effect of the Amounts of Ethylenediamine and Water on Theophylline and Ethylenediamine Contents in the Product

Ethylenediamine in the System, mL	Water in the System, mL	Drug and Water Contents in the Agglomerate, %			Average Diameter of Agglomerate, mm
		Theophylline	Ethylene-diamine	Water	
1.0	0.90	87.43	12.71	4.18	2.20
1.5	0.70	84.51	15.37	3.72	1.20
2.0	0.65	85.42	15.36	4.02	1.10
2.5	0.30	83.63	17.10	4.30	1.35
3.0	0.25	80.53	19.43	5.42	0.90
3.5	0.15	78.47	21.65	3.85	1.10

The theophylline and ethylenediamine content in the agglomerated crystals prepared using *n*-hexane, *n*-heptane, etc., in Table I, did not meet the specified values in JP(X), *i.e.*, 84–86% for theophylline and 14–15% for ethylenediamine. However, the theophylline and ethylenediamine contents in the resultant agglomerated crystals could be adjusted to the specified values in JP(X) by changing the amount of ethylenediamine used for the crystallization, as described below.

Spherical Crystallization Behavior of Method 2—To adjust the theophylline and ethylenediamine contents in the resultant agglomerated crystals to those specified in JP(X), the spherical crystallization was carried out by changing the amount of ethylenediamine (1.0–3.5 mL) and water (0.15–0.9 mL) in the mixture of *n*-hexane (60 mL) and ethanol (12 mL) used as the solvent. It was found that >1.1 mL (0.0165 mol) of ethylenediamine was required to obtain the theophylline-ethylenediamine complex. This critical amount of ethylenediamine corresponded to the amount required to obtain the molecular complex with 6 g of theophylline (0.0333 mol). When the amount of ethylenediamine used was <1.1 mL, the resultant agglomerated crystals were converted to anhydrous theophylline by washing with ethanol. This indicated that ethylenediamine was adsorbed physically on the theophylline crystals. When the ethylenediamine used was >1.1 mL, less water was required to obtain the spherically agglomerated crystals with a 1–2 mm diameter. The excess of ethylenediamine, >1.1 mL, was consumed as the collecting liquid for the crystals and was occluded physically in the agglomerates. The action of ethylenediamine as the collecting liquid was proved by the fact that the agglomerated crystals were prepared in the *n*-hexane (or *n*-heptane) and ethanol mixture with theophylline by adding ethylenediamine alone to the system without water. When the amount of water was <0.3 mL (0.0167 mol of water of crystallization) for 6 g theophylline (0.0333 mol), the water acted only as the collecting liquid for the crystals. When >0.3 mL of water was used, the water was occluded as water of crystallization (1 mol) and acted as the collecting liquid in the agglomerated crystals.

The amounts of ethylenediamine and water required to obtain the acceptable agglomerated crystals for practical use are plotted in Fig. 4. The straight line in Fig. 4 represents a phase separation line. In the region below the line, the solvents were miscible, and no agglomerates formed; whereas, in the region above the line, phase separation occurred and an aqueous solution of ethylenediamine was liberated, which collected the crystals to form the agglomerated crystals. The corrected points, obtained by subtracting the amount of ethylenediamine (1.1 mL, *i.e.*, 0.0165 mol) required to form the complex with theophylline (6 g, *i.e.*, 0.0333 mol) from that of ethylenediamine actually added to the system, lay on the phase separation line when the amount of water used was <0.3 mL. When the amount of water used was >0.3 mL, the corrected points deviated from the phase separation line. This indicated that the water was occluded as the collecting liquid as well as water of crystallization in the agglomerated crystals.

The ethylenediamine and theophylline contents in the agglomerated crystals, prepared using various amounts of ethylenediamine and water, are tabulated in Table II. The average diameter of the resultant agglomerates are also shown in Table II. The water contents in the agglomerates were almost constant, irrespective of the amount of water in the solvent mixture. The ethylenediamine content in the agglomerates increased with increases in the amount of ethylenediamine used. A linear relationship was found between the ethylenediamine content in the agglomerates and the amount of ethylenediamine used, as shown in Fig. 5. This indicated that the ethylenediamine contents in the agglomerated crystals could be adjusted to that of aminophylline specified in JP(X) by changing the amount of ethylenediamine used. The ethylenediamine >14.3% in the agglomerated crystals (corresponding to 1 mol of ethylenediamine included in aminophylline) was released by drastic desiccation, since it was adsorbed only physically.

Determination of the Ionization Constants of Compounds which Precipitate During Potentiometric Titration Using Extrapolation Techniques

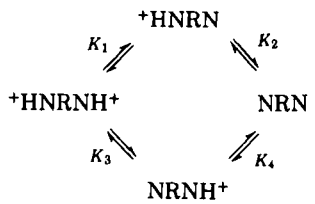
WILLIAM H. STRENG ˣ and M. A. ZOGLIO

Received December 12, 1982, from the *Merrell Dow Research Institute, Merrell Dow Pharmaceuticals, Inc., Subsidiary of The Dow Chemical Co., Cincinnati, OH 45215.* Accepted for publication October 11, 1983.

Abstract □ It is shown that the ionization constants of diacidic compounds can be determined by utilizing potentiometric titration data, even when a precipitate forms during the titration. The two methods presented are particularly useful for compounds for which the pK_a values are close together. A third method is presented which can be used with monoacidic compounds or compounds for which the pK_a values are far apart and form a precipitate during the titration. Four symmetrical diacidic compounds were studied which had similar pK_a values, and one compound was studied which had pK_a values that were far apart. Comparison of the second pK_a of the latter compound with that previously reported determined by a spectrophotometric procedure showed excellent correlation.

Keyphrases □ Ionization constants—determination, compounds which precipitate during potentiometric titration □ Potentiometric titration—determination of ionization constants

A method for determining the microionization constants of zwitterionic compounds is described in which potentiometric data are combined with spectrophotometric data (1). This method should be restricted, however, to well-behaved systems, *i.e.*, those which do not form precipitates or degrade during the course of the experiment. For sparingly soluble compounds, Maulding and Zoglio (2) and Levy and Rowland (3) have presented two techniques. Weak complexing agents were used by Maulding and Zoglio, whereas the method of Levy and Rowland required determining the solubility of the sparingly soluble component. In addition, these methods were only developed for monoprotic compounds or those polyprotic compounds for which pK_a values were sufficiently far apart (about 4 pK_a units) to be considered monoprotic. This study describes a method to determine the macroionization constants of compounds which precipitate during titration and which have similar pK_a values. The type of compounds considered form diacid salts, *i.e.*, there are two nitrogen atoms which can be protonated on each molecule and which undergo the equilibrium shown in Scheme I.



Scheme I

The microionization constants K_1, K_2, K_3, and K_4 are related to the macroionization constants by:

$$K_{13} = K_1 + K_3 \qquad \text{(Eq. 1)}$$

$$\frac{1}{K_{24}} = \frac{1}{K_2} + \frac{1}{K_4} \qquad \text{(Eq. 2)}$$

Utilizing potentiometric titration data, the macroionization constants K_{13} and K_{24} were determined for diprotic compounds in which species solubilities were exceeded and, therefore, which precipitated during the titration. This was accomplished by preparing the appropriate plots, as discussed below.

Measurements were made on four diacid salts in which the pK_a values were similar: 1,1′-(9*H*-fluorene-2,7-diyl)bis[2-diethylamino)ethanone]dihydrochloride (I); 1,1′-(2,8-dibenzofurandiyl)bis[2-(dimethylamino)-1-ethanone]dihydrochloride (II); 1,1′-(2,8-dibenzothiophendiyl)bis[2-(dimethylamino)-1-ethanone]dihydrochloride (III); 2,7-bis[2-(diethylamino)ethoxy]fluoren-9-one dihydrochloride (IV). Measurements were also made on one diacid salt for which the pK_a values were far apart: 10,11-dihydro-*N*-methyl-5*H*-dibenz[b,f]azepine-5-propanamine hydrochloride (V) (desipramine).

EXPERIMENTAL SECTION

Apparatus and Equipment—Potentiometric measurements were made with the apparatus previously described (1). For compounds I–IV, the apparatus was placed in a constant temperature bath and maintained at 25 ± 0.05°C, whereas the titration of V was done at room temperature (~24°C). Instead of the 50-mL buret used for I–IV, a syringe microburet was used for V.

Solution Preparation—Solutions of I–IV were prepared in the concentration range 3×10^{-4}–19×10^{-4} M. These solutions were titrated with 0.01 M potassium hydroxide, which was standardized with potassium acid phthalate. A solution of V with a concentration of 7×10^{-3} M was prepared, and an excess of 0.10 M hydrochloric acid standardized with potassium hydroxide was added to protonate both nitrogen atoms. This solution was titrated with 0.16 M potassium hydroxide standardized with potassium acid phthalate. All solutions were made with distilled water, boiled to remove oxygen and carbon dioxide, and saturated with nitrogen.

Table I—pK_{13} and pK_{24} Values for Compounds I–V

Compound	pK_{13}	pK_{24}
I[a]	8.16	8.89
II[b]	7.54	8.27
II[a]	7.54	8.24
III[a]	7.42	8.15
IV[a]	8.73	9.35
V[b,c]	1.51	10.24
V[c,d]	—	10.2

[a] Obtained by Method II. [b] Obtained by Method I. [c] The value of S_0 for compound V, obtained in this study was 60.8 μg/mL; the value obtained by Green (9) was 58.6 μg/mL. [d] Spectrophotometric method of Green (9).

THEORETICAL SECTION

In the following equations, { }, [ ], Y, and K represent activity, concentration, activity coefficient, and equilibrium constants on a molar scale, respectively. The total concentration of base added as titrant, halide, and acid being titrated are represented by $[B]$, $[X]$, and $[A]$, respectively.

The equilibria to be considered are not those for the microionization constants given by Scheme I, but rather the equilibria for the macroionization constants given by:

$$(NRN)H_2^{2+} \overset{K_{13}}{\rightleftharpoons} (NRN)H^+ + H^+ \qquad \text{(Eq. 3)}$$

$$(NRN)H^+ \overset{K_{24}}{\rightleftharpoons} NRN + H^+ \qquad \text{(Eq. 4)}$$

for which

$$K_{13} = \frac{\{(NRN)H^+\}\{H^+\}}{\{(NRN)H_2^{2+}\}} \qquad \text{(Eq. 5)}$$

$$K_{24} = \frac{\{NRN\}\{H^+\}}{\{(NRN)H^+\}} \qquad \text{(Eq. 6)}$$

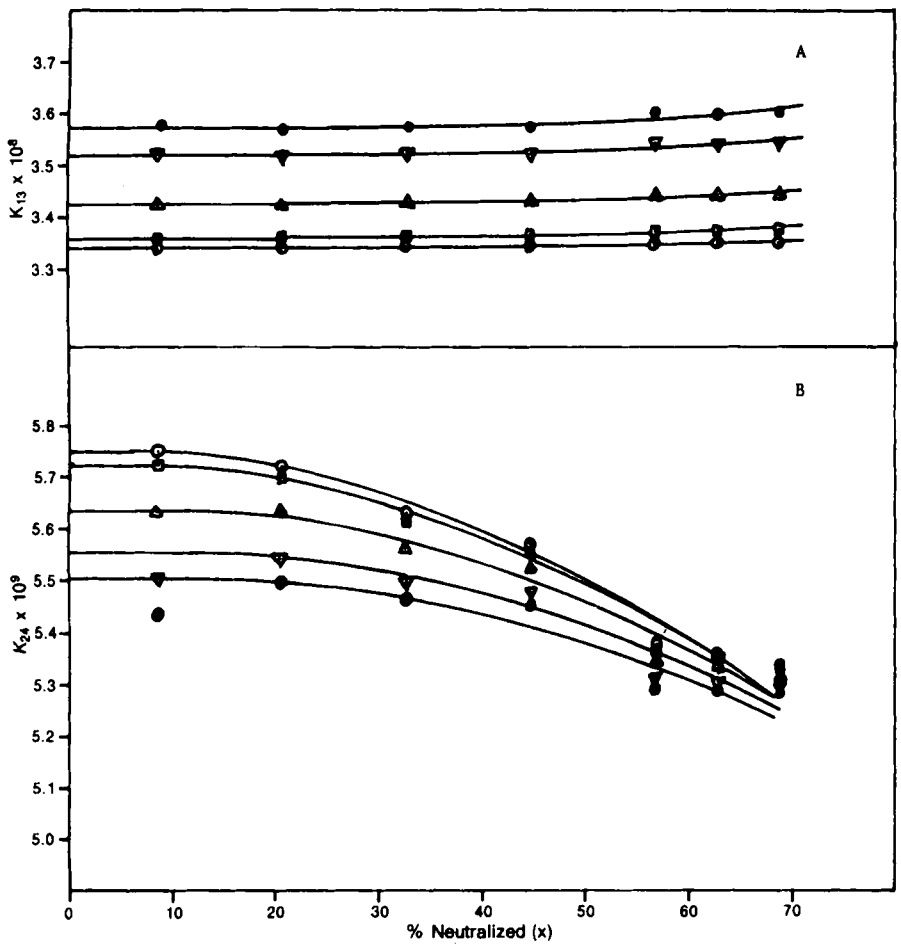

Figure 2—*(A)* K(*n,x*) versus *percent neutralized (x) for* K_{13} *of compound II. Key: the percent neutralized n is (⊙) 12; (⊡) 18; (▲) 24; (▼) 36; (●) 48. (B)* K(*n,x*) versus *percent neutralized (x) for* K_{24} *of compound II.*

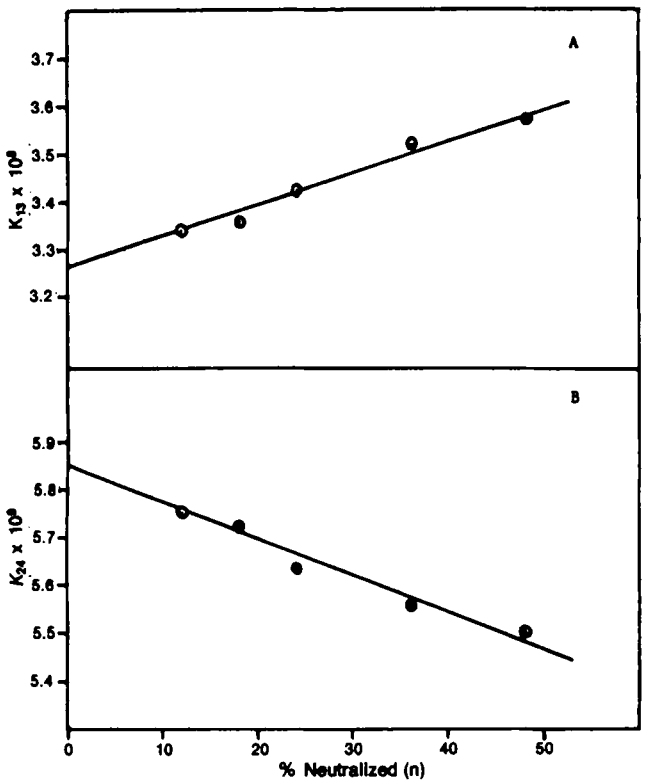

Figure 3—K(*n*,E) versus *percent neutralized (n) for* K_{13} *of compound II. (B)* K(*n*,E) versus *percent neutralized (n) for* K_{24} *of compound II.*

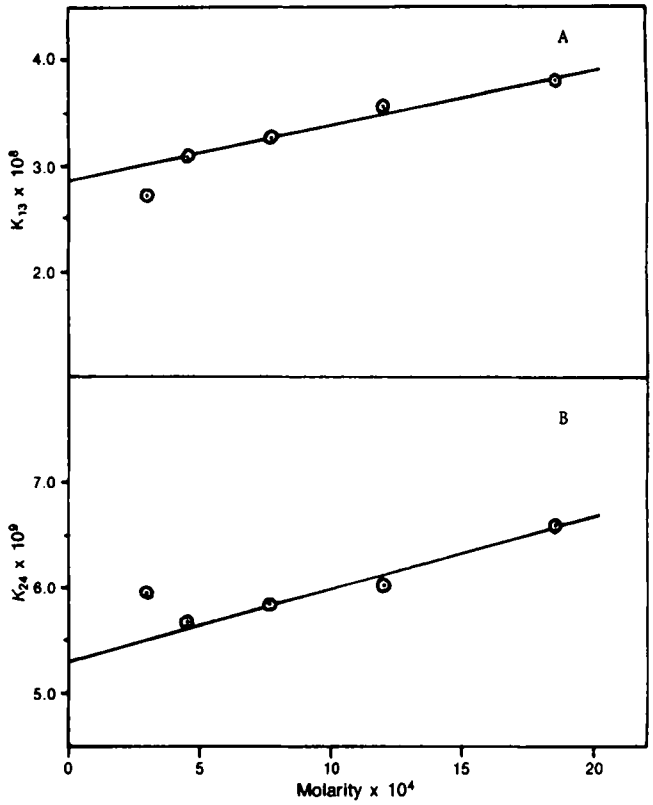

Figure 4—K(*0*,E) versus *molarity for* K_{13} *of compound II. (B)* K(*0*,E) versus *molarity for* K_{24} *of compound II.*

The equations used to determine the equilibrium constants in Eqs. 5 and 6 have been reported by many authors since the late 1800s (4–7) and will not be derived here. The derivation results in:

$$\alpha = \beta K_{13} + \gamma K_{13} K_{24} \qquad \text{(Eq. 7)}$$

where:

$$\alpha = [B]\{H^+\}^3 + \frac{\{H^+\}^4}{Y_{H^+}} - \frac{K_w\{H^+\}^2}{Y_{OH^-}} \qquad \text{(Eq. 8)}$$

$$\beta = \frac{Y_{(NRN)H^+}}{Y_{(NRN)H^+}}\left([A]\{H^+\}^2 - [B]\{H^+\}^2 - \frac{\{H^+\}^3}{Y_{H^+}} + \frac{K_w\{H^+\}}{Y_{OH^-}}\right) \qquad \text{(Eq. 9)}$$

$$\gamma = \frac{Y_{(NRN)H^+}}{Y_{NRN}}\left(2[A]\{H^+\} - [B]\{H^+\} - \frac{\{H^+\}^2}{Y_{H^+}} + \frac{K_w}{Y_{OH^-}}\right) \qquad \text{(Eq. 10)}$$

$$K_w = \{H^+\}\{OH^-\} \qquad \text{(Eq. 11)}$$

Conventional methods (4–7) can be used to determine K_{13} and K_{24} for well-behaved systems. Either of the two sets of experimental data can be combined according to Eqs. 12 and 13, or a plot of α/γ *versus* β/γ can be prepared, and the values for K_{13} and K_{24} determined from the slope and intercept:

$$K_{13} = \frac{\alpha_n\gamma_x - \alpha_x\gamma_n}{\beta_n\gamma_x - \beta_x\gamma_n} \qquad \text{(Eq. 12)}$$

$$K_{24} = \frac{\alpha_x\beta_n - \alpha_n\beta_x}{\alpha_n\gamma_x - \alpha_x\gamma_n} \qquad \text{(Eq. 13)}$$

where the subscripts n and x refer to two different sets of data. Modifications of these approaches can be made to determine the constants in systems in which precipitates are formed.

Method I—To use Eqs. 12 and 13, one set of data should be obtained before the first equivalence point and one should be obtained after. In well-behaved systems, the constants calculated will be independent of the sets of data used. For those systems that are not well behaved, *e.g.*, due to the formation of a precipitate, the values calculated for K_{13} and K_{24} will be incorrect. Those equilibrium constants calculated with data obtained after precipitation started will not be the same. They will, however, change in a systematic manner. Extrapolation of the calculated values to regions in which there is no precipitation should result in the correct value. This procedure can be expressed by:

$$K_T = \lim_{C\to 0}(\lim_{n\to 0}[\lim_{x\to E}[K_c(n,x)]]) \qquad \text{(Eq. 14)}$$

where K_c is the calculated equilibrium constant, C is the concentration, and K_T is the thermodynamic equilibrium constant. In this equation, n and x are two data sets: x is taken between the first and second equivalence points, and n is taken up to the first equivalence point. The limits used are E, the first equivalence point, for data set x; zero base addition for data set n; and infinite dilution for C. Each data set is comprised of a volume of base added and the measured pH. By knowing the concentration of strong base and the number of moles of weak acid initially, the volume of strong base can be expressed as a percentage of the weak acid neutralized.

Values for K_c are calculated by using two sets of data. For each n, there will be a set of K_c values determined with a different value for x. A plot is then prepared of the calculated K_c values *versus* the percentage of the second equivalent neutralized (x) for each n. Each value of n will result in a separate curve. The extrapolated values of K_c at x = 0 are then plotted *versus* the percentage of the first equivalent neutralized (n). The extrapolated value of K_c at n = 0 should equal the correct value, excluding activity effects. A third

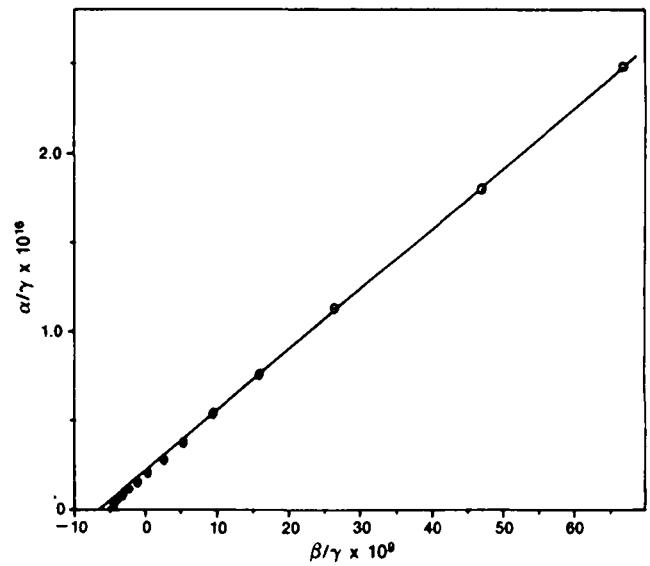

Figure 5—α/γ versus β/γ *for compound II.*

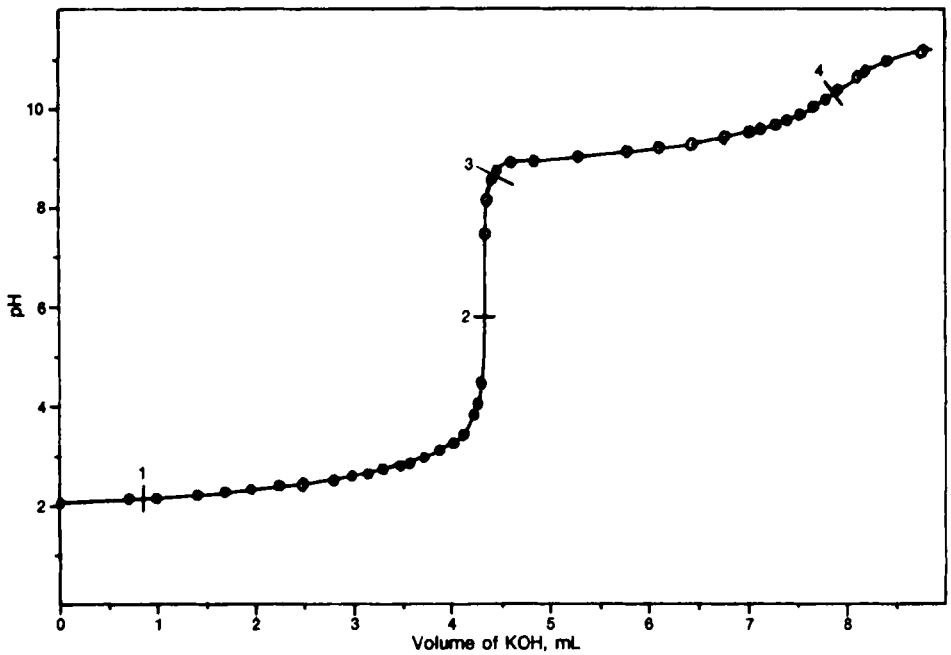

Figure 6—*Titration curve for compound V. Key: (1) starting point; (2) first equivalence point; (3) precipitate formed; (4) second equivalence point.*

plot of K_c *versus* concentration of weak acid will result in the thermodynamic value at infinite dilution.

Method II—A plot of α/γ *versus* β/γ from Eq. 7 will be linear until there is precipitation. Therefore, the determination of the slope of the linear segment and the linear extrapolation of this segment to the intercepts at α/γ and β/γ equal to zero enable the calculation of the equilibrium constants. The thermodynamic constants can be obtained from the infinite dilution value as described in method I.

RESULTS AND DISCUSSION

Figure 1 shows a typical titration curve for compounds I–IV. A precipitate formed during each titration, some of which formed prior to the first equivalence point. The data were treated by method I and/or method II. Approximations to the single ion activity coefficients were made by using the Davies equation (8):

$$-\log Y_i = AZ_i^2\left\{\frac{\sqrt{I}}{1+\sqrt{I}} - 0.2I\right\} \qquad \text{(Eq. 15)}$$

where Y_i is the single ion activity coefficient, A is a parameter for which the value at 25°C is 0.5092 on a molar scale, Z_i is the charge of ion i, and I is the molar ionic strength. The activity coefficients of the uncharged species were assumed to have a value of one.

According to method I, equilibrium constants were calculated with pairs of data; one set of data was from the region prior to the first equivalence point and the second set of data was from the region following the first equivalence point. These constants are written as K(n,x). For each data point designated by n, there was a set of equilibrium constants differentiated by the second data point used in the calculation and designated by x. The calculated values for K(n,x) can therefore be plotted *versus* x, and a separate curve can be obtained for each value of n. Typical plots of this type are shown in Figs. 2A and B for compound II. It can be seen that there is a separate curve for each data set n and that each curve approaches a constant value at x which corresponds to the first equivalence point. These values for K(n,E) are plotted *versus* n (Figs. 3A and B), and the curves obtained were extrapolated to an n value of zero. This value of n corresponds to zero base addition. There is a concentration dependency with these values of K(0,E) (Figs. 4A and B), and extrapolation of these curves to zero concentration will result in thermodynamic values. In Table I, the values obtained by this method for compound II are given.

By using method II, plots similar to those shown in Fig. 5 are obtained in which the deviation from linearity can be either negative or positive. This nonlinearity is due to either the formation of a precipitate during the titration and/or degradation. According to Eq. 7, the slope of the line from the linear segment will equal K_{13}, whereas the value of α/γ at the intercept at which

Table II—Microionization Constants for Compounds I–IV

Compound	$pK_1 = pK_3$	$pK_2 = pK_4$	K_{13}/K_{24}	K_1/K_2
I	8.46	8.59	5.37	1.35
II	7.84	7.94	5.01	1.26
III	7.72	7.85	5.37	1.35
IV	9.03	9.05	4.17	1.05

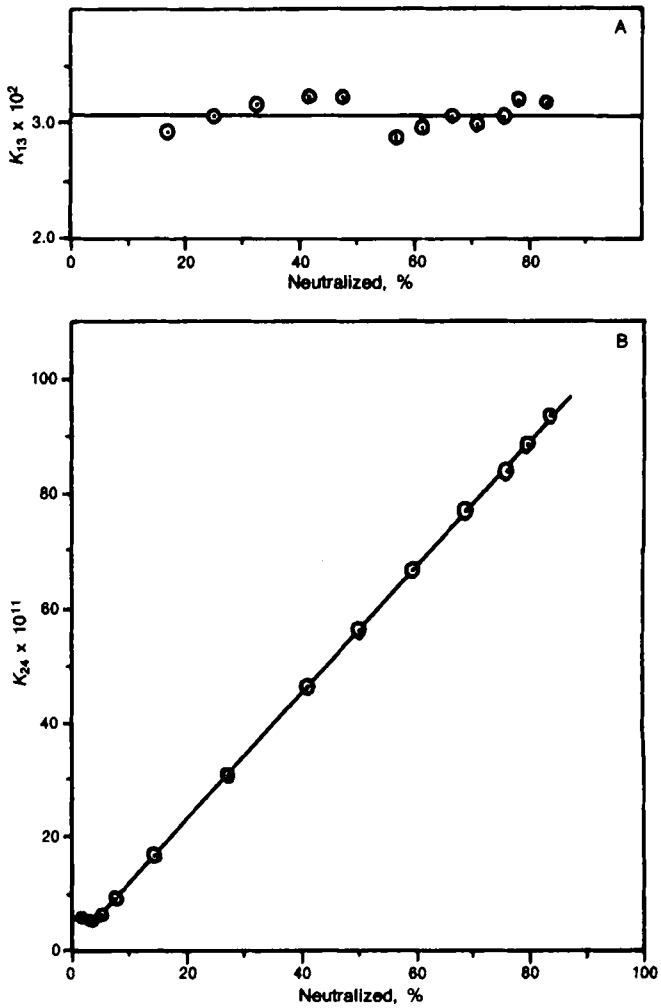

Figure 7—*(A)* K_{13} versus *percent neutralized for compound V. (B)* K_{24} versus *percent neutralized for compound V.*

$\beta/\gamma = 0$ is $K_{13}K_{24}$, and the value of β/γ at the intercept at which $\alpha/\gamma = 0$ is $-K_{24}$. These values of K_{13} and K_{24} have been found to be concentration dependent; therefore, plots similar to those shown in Figs. 4A and B were made to obtain the thermodynamic values. In Table I, the results of these calculations for compounds I–IV are given.

A modification of method I was used to obtain the values of K_{13} and K_{24} of compound V. Since the two pK_a values are far apart, the equilibria were assumed not to interact with each other; therefore, the equilibrium constants were determined by using the following expression for monoprotic compounds:

$$K_n = Z\frac{[H^+]([H^+] + [B] - [OH^-])}{[OH^-] + [A] - [H^+] - [B]} \qquad \text{(Eq. 16)}$$

where Z is the activity coefficient ratio $Y_{(NRN)H^+}/Y_{(NRN)H_2^{2+}}$ for K_{13} and $Y_{(NRN)}/Y_{(NRN)H^+}$ for K_{24}.

Figure 6 shows the titration curve obtained for compound V, and Figures 7A and B show the results of the calculated equilibrium constants *versus* percent neutralized. Precipitation was observed after the first equivalence point (Fig. 6), and therefore, consistent values should be obtained for K_{13} (Fig. 7A). Conversely, a change in the calculated value for K_{24} with respect to percent neutralized would be expected (Fig. 7B). The break in this latter curve at ~5% neutralization is due to the formation of a precipitate. The curve prior to precipitation should have a slope of zero (as in Fig. 7A), whereas the curve after precipitation will not necessarily be linear.

By knowing the value for K_{24} and the pH at which precipitation occurs, the solubility of the base (uncharged) species of compound V was determined by:

$$[NRN]_s = \frac{[A]K_{24}}{[H] + K_{24}} \qquad \text{(Eq. 17)}$$

In Table I, the results of the calculations for compound V are given, along with those values for K_{24} and $[NRN]_s$, as reported by Green (9) and determined by a spectrophotometric procedure. It can be seen there is excellent agreement among these data.

Since compounds I–IV are symmetrical molecules, it should be possible to calculate the microionization constants K_1, K_2, K_3, and K_4 of Scheme I. This is because K_1 should equal K_3, and K_2 should equal K_4. Furthermore, since the protonation sites are separated by large distances, it would be expected the K_2 and K_4 would be the same or only very slightly smaller than K_1 and K_3. The microionization constants were therefore calculated from Eqs. 1 and 2 and gave the results listed in Table II. It can be seen that there is very little difference in the calculated values, with K_2 and K_4 being slightly smaller.

For diprotic compounds with completely independent, equivalent sites of protonation, the ratio K_{13}/K_{24} will equal 4, and K_1/K_2 will equal 1. From these ratios (Table II), it can be seen that the values are very close to the theoretical values.

From these results, it can be concluded that the equilibrium constants of slightly soluble compounds can be determined potentiometrically by extrapolation procedures and give results which are consistent with those reported in the literature. It would be expected that method II would be better to use with those compounds that have equilibrium constants close together, whereas method I would be better to use with those compounds that have equilibrium constants farther apart.

Degradation of Fenprostalene in Polyethylene Glycol 400 Solution

DAVID M. JOHNSON ˣ **and WILLIAM F. TAYLOR**

Received March 14, 1983, from the *Institute of Pharmaceutical Sciences, Syntex Research, Palo Alto, CA 94304.* Accepted for publiction October 26, 1983.

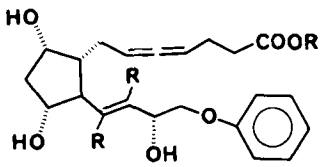
Abstract □ The kinetics of degradation of fenprostalene (I) in polyethylene glycol 400 solution was examined using HPLC. The degradation of I at 80°C was shown to depend on the presence of oxygen and a large number of polar products were produced, as evidenced by using ^3H-labeled I. Evidence that autoxidation of the polyethylene glycol 400 was concurrent with degradation of I was found from a drop in the apparent pH. Antioxidants were very effective in retarding the rate of degradation in the presence of oxygen. Degradation of I in polyethylene glycol 400 appears to arise from a reaction between the drug and reactive peroxide intermediates formed through air-oxidation of polyethylene glycol 400. This is supported by the finding that I reacts exclusively by a slow transesterification reaction in diethylene glycol, a solvent that is stable to autoxidation.

Keyphrases □ Degradation—fenprostalene in polyethylene glycol 400 □ Fenprostalene—autoxidation, degradation, kinetics □ Kinetics—fenprostalene in polyethylene glycol 400

Fenprostalene[1] (I), a PGF-type prostaglandin containing an aryloxy group at C-16 and an allene functionality at C-5 (1), is used as an abortifacient and for estrus synchronization in cattle (2). We have previously shown that in aqueous solution, I degrades exclusively through hydrolysis of the C-1 methyl ester under both acidic and basic conditions (3). No information is available, however, on the degradation of this family of prostaglandins in nonaqueous environments. Since an injectable formulation of fenprostalene (I) in polyethylene glycol 400 was chosen for development (4), we have investigated the chemical reactivity and degradation products of I in this solvent.

EXPERIMENTAL SECTION

Materials—The fenprostalene[1] (I) used was 99% pure (HPLC). The radiochemical purity of fenprostalene labeled with tritium at C-13 and C-14 was 98%. The acetonitrile used was glass-distilled HPLC-grade, and the water



I, R = H, R′ = CH_3
[^3H]I, R = ^3H, R′ = CH_3
II, R = H, R′ = $CH_2CH_2OCH_2CH_2OH$
III, R = R′ = H

[1] Fenprostalene is the generic name for methyl 7-[3,5-dihydroxy-2-(3-hydroxy-4-phenoxy-1-butenyl)cyclopentyl]-4,5-heptadienoate. Obtained from the Institute of Organic Chemistry, Syntex Research, Palo Alto, Calif. The synthesis of I is described in Ref. 1.

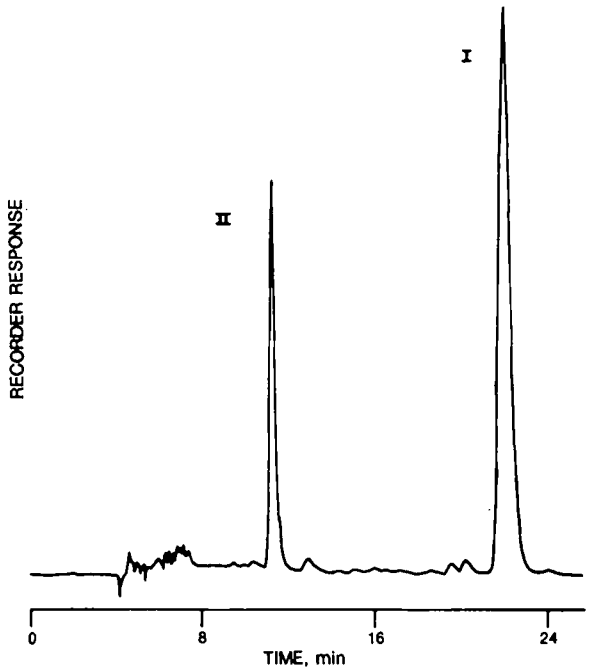

Figure 1—*Chromatogram of a solution of I after partial transesterification to II in diethylene glycol at 80°C.*

was purified through an ion-exchange and filtration system[2]. *dl*-α-Tocopherol was NF grade, propyl gallate and polyethylene glycol 400 were practical grade. All other chemicals were reagent grade.

Kinetic Methods—A mixture of 25 mg of I in 250 mL of polyethylene glycol 400 was stirred for 2 h and then filtered through a 0.7-μm glass membrane. This solution was used to prepare two other solutions, one containing 0.10% *dl*-α-tocopherol and another containing 0.006 M formic acid. The solutions were stored in either 10-mL ampules (5 mL of solution) or in 20-mL test tubes fitted with polytef-faced screw caps. These solutions were maintained at 80°C, 45°C, or 25°C. The samples stored in test tubes at 80°C were cooled, and the caps were removed for a few minutes each day to provide a relatively constant supply of oxygen to the solutions.

Solutions kept at 80°C were assayed by HPLC and compared with a control sample maintained at 4°C. The 45°C and 25°C samples were assayed by HPLC, and the chromatograms were compared to a freshly-prepared external standard of I. The polyethylene glycol 400 solutions of I were diluted 10-fold with water prior to HPLC analysis and 20-fold prior to pH measurements[3]. Diethylene glycol solutions of I were prepared and analyzed exactly as described above for the polyethylene glycol 400 solutions.

Hydrolysis of Degradation Products—A solution of I in polyethylene glycol 400 (100 μg/mL) was allowed to stand for 28 d at 80°C under air. After this period, HPLC assay showed 0.6% of I remaining. Concentrated HCl (41.5 μL) was added to a 5-mL aliquot of this solution and to a control solution of I. Both solutions were heated at 80°C for 3 h. Analysis of these solutions by HPLC showed that quantitative hydrolysis of I in the control solution occurred to give the free acid (III). None of this acid was found in the sample that had previously been degraded in polyethylene glycol 400.

Liquid Chromatographic Method—An HPLC system consisting of a pump[4], a variable-wavelength detector[5], and a 100-μL fixed-loop injector[6] was used. Separations were performed on columns packed with microparticulate bonded octyl material[7]. For analysis of I, a mobile phase of 35–45% acetonitrile in water was used. The eluant was monitored at 219 nm. Quantitation by integration of peak areas gave excellent linearity for I over the range of concentrations investigated in the kinetic studies. The presence of 10% polyethylene glycol 400 in the samples affected the quantitation of I when compared with an injection of a completely aqueous solution of I. The origin of this effect is unknown. To avoid this problem, standards of I were prepared in an aqueous solution containing 10% polyethylene glycol 400.

[2] Barnstead Nanopure System.

[3] Measurements of apparent pH were made on a Radiometer PHM 64 pH meter using a Radiometer combination electrode, type GK2401C. The polyethylene glycol 400 solutions were diluted with 0.01 M KCl solution.

[4] Altex model 110 A.

[5] Cecil model CE 212.

[6] Rheodyne model 70-10.

[7] For *analytical* use, an Ultrasphere 5-μm octyl 250 × 4.6-mm column by Altex was used. For semipreparative isolation of II, a 250 × 10-mm Ultrasphere 5-μm octyl column by Altex was used.

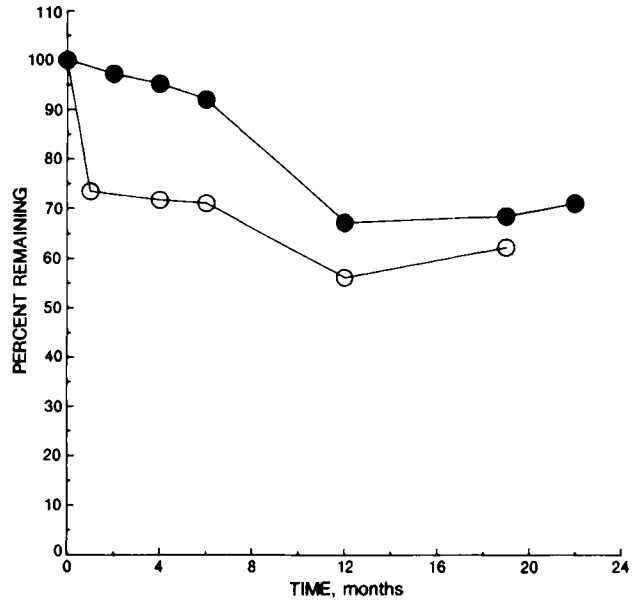

Figure 2—*Degradation rate of I in polyethylene glycol 400 at 25°C (●) and at 45°C (○). The solutions were sealed in ampules under air.*

Coincidentally, the diethylene glycol ester (II) and free acid (III) of fenprostalene (I) gave nearly the same retention time with the unbuffered mobile phase described above. Thus analysis of II in the presence of III was accomplished using a mobile phase of 35:65 acetonitrile–0.01 M aqueous phosphate buffer (pH 6). Under these conditions, III elutes near the solvent front while the retention of II is essentially unaffected by the pH change.

Formation of II in Diethylene Glycol—A solution containing 100 mg of I in 8 mL of diethylene glycol was prepared and sealed in a 10-mL ampule. The solution was allowed to stand at 80°C for 2 months and then was diluted fourfold with water and injected onto the semipreparative reverse-phase HPLC column. The fraction corresponding to the major degradation peak (Fig. 1) was collected and the mobile phase was removed by rotary evaporation to give a clear oil that was 98% pure (HPLC). ^{1}H-NMR ($CDCl_3$)[8]: δ 1.62 (m, 1, CH-8β), 1.79 (m, 1, CH-10α), 2.1–2.4 (m, 6, CH_2-3,7, CH-10β,12α), 2.48 (m, 2, CH_2-2), 3.60 (t, 2, J = 4.8 Hz, CH_2-4′), 3.74 (m, 3, CH-11β, CH_2-16), 4.28 (m, 3, CH-9β, CH_2-1′), 4.54 (m, 1, CH-15β), 5.1–5.2 (m, 2, allene CH),

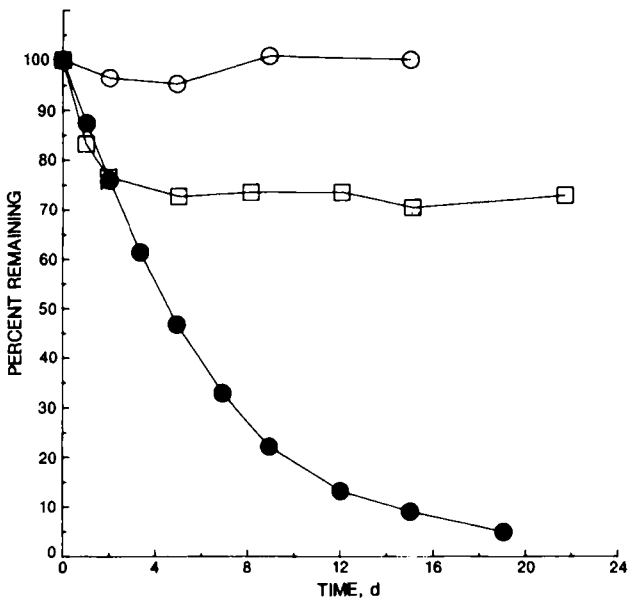

Figure 3—*Degradation rate of I in polyethylene glycol 400 at 80°C under various storage conditions. Key: (○) under nitrogen in a sealed ampule; (□) under air in a sealed ampule; (●) in a test tube exposed to air.*

[8] The NMR spectrum was determined at 300 MHz on a Bruker WM 300 FT spectrometer.

[9] The mass spectrum was obtained in the direct-inlet mode on a Varian MAT 112S system equipped with an SS-200 data system.

Table I—Apparent pH of Fenprostalene (I) Solutions

Solvent	Additive	Initial pH	Apparent pH[a]
Polyethylene Glycol 400	—	5.2	3.5
	N_2	5.2	5.0
	dl-α-tocopherol	5.2	4.5
	formic acid	3.9	3.5
Diethylene Glycol	—	5.8	5.2

[a] pH measured after a 20-fold dilution of the solution with 0.01 M KCl after 15 d at 80°C. [b] All solutions were stored in test tubes with a relatively constant supply of air except the sample stored under nitrogen, which was in a sealed ampule.

5.68 (m, 2, vinyl CH), and 6.9–7.3 ppm (m, 5, ArH). The mass spectrum was run at 90 eV in the CI mode with ammonia as the reagent gas[9]. The peak at *m/z* 476 was attributed to the $M\text{-}NH_4 - H_2O$ ion and a peak at *m/z* 459 to the $MH - H_2O$ ion. Other major peaks were at *m/z* 388, 259, and 241. The CI mass spectrum of the trimethylsilyl ether derivative gave an MNH_4^+ peak at *m/z* 782 with other prominent peaks at *m/z* 675, 581, 491, and 401.

Anal.—Calc. for $C_{26}H_{36}O_8$: C, 65.53; H, 7.62. Found: C, 65.70; H, 7.42.

Additional support for the structural assignment comes from observing that in 0.1 M HCl at 60°C, this diethylene glycol ester (II) hydrolyzes to give the free acid of I with a half-life of ~1 h. This rate is similar to that found for hydrolysis of fenprostalene under the same conditions (3).

Degradation of ^{3}H-Labeled I—A polyethylene glycol 400 solution (1 mL) was prepared containing 500 μg/mL of I with a specific activity of ~130 μCi/mg [^{3}H]I. After an aliquot was removed, the solution was sealed in a glass ampule and stored for 64 h at 80°C. The polyethylene glycol 400 solution containing [^{3}H]I was analyzed by collecting and counting fractions from the reverse-phase HPLC method described above. A 0.040-g sample was accurately weighed and diluted to 1 mL with water. On injection of 108 μL[10] of this solution, fractions of the eluant were collected. A 100-μL aliquot of each fraction was mixed with 15 mL of scintillation fluid[11] and counted in a liquid scintillation counter[12]. A volume of sample equal to the loop volume (108 μL) was also diluted with 15 mL of scintillation fluid and counted[13].

Incorporation of Tritium Into Polyethylene Glycol 400—A 0.4-mL aliquot of the degraded polyethylene glycol 400 solution of [^{3}H]I was added to 5 mL of methanol in a flask equipped with a serum cap containing a needle attached to a source of nitrogen. The other neck was connected to a pear-shaped receiving flask through a vacuum adapter. The round-bottom flask was warmed to 45°C, and a stream of nitrogen was used to transfer the methanol to the receiving flask which was cooled to −78°C. The stream of nitrogen leaving the apparatus was scrubbed with water prior to its escape into the environment. A second 5-mL portion of methanol was added to the residue in the flask, and the procedure was repeated. An aliquot of the resulting methanol solution was diluted with scintillation fluid and the counts per minute were compared with that of the degraded polyethylene glycol 400 solution prior to methanol exchange.

RESULTS AND DISCUSSION

The kinetics of the degradation of I in polyethylene glycol 400 in sealed ampules under air was followed by reverse-phase HPLC. Plots of percent remaining of I *versus* time for the degradation reactions at 25°C and 45°C are shown in Fig. 2. At 25°C a shelf-life of <8 months was observed. At 45°C the initial degradation rate is much faster than at 25°C, but surprisingly, the reaction abruptly stopped with ~60–70% of I remaining. The degradation at 25°C also shows a plateau in the rate profile, but more than 1 year is required for it to become apparent.

To evaluate the role oxygen plays in the above reaction, solutions of I in polyethylene glycol 400 were degraded at 80°C in sealed ampules containing either air or nitrogen in the head space and also in screw-capped test tubes that were opened each day to provide a relatively constant supply of oxygen. Figure 3 shows the dramatic differences observed under the three conditions. As was found at 25°C and 45°C, the degradation reaction at 80°C stopped with ~70% of I remaining unreacted in the ampules with air in the head space. When a constant supply of oxygen was permitted, however, the degradation reaction followed the first-order rate law[14] and nearly went to completion.

[10] The volume of the loop was calibrated using ^{3}H-labeled water.
[11] Oxifluor by New England Nuclear.
[12] Beckman model LS 8100.
[13] The slight difference in final solvent compositions after dilution of 100 μL of either mobile phase or the 4% polyethylene glycol 400–water solution into 15 mL of scintillation fluid had no significant effect on the counting efficiency of [^{3}H]I.
[14] When the data for samples exposed to air (solid circles shown in Fig. 3) is plotted as log percent remaining *versus* time, excellent linearity through >3 half-lives is obtained.

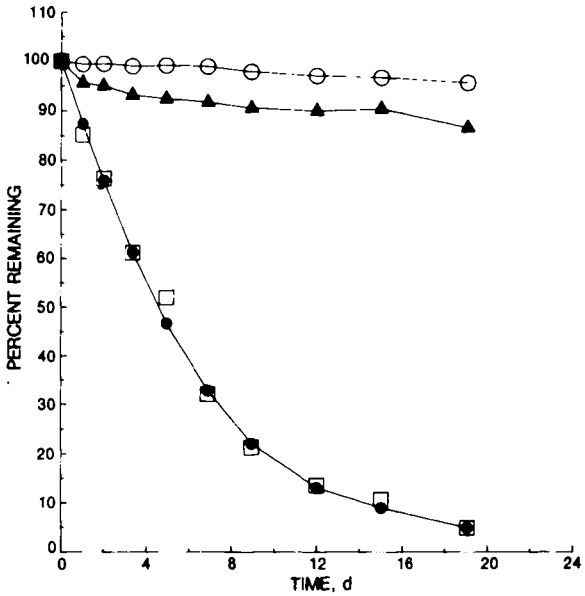

Figure 4—*Degradation rate of I at 80°C in diethylene glycol (▲) and in polyethylene glycol 400 solutions containing no additive (●), formic acid (□), and* dl*-α-tocopherol (○). All solutions were stored in test tubes exposed to air.*

Figure 3 also shows that no degradation of I was observed at 80°C when the solution was kept in an ampule containing nitrogen in the head space.

These results demonstrate that oxygen is required for the degradation of I in polyethylene glycol 400. The role oxygen plays in the degradation of I could be through direct reaction with the prostaglandin or through a reaction with the solvent, polyethylene glycol 400. The latter autoxidation reaction is known to produce peroxides and carboxylic acids (5–8). The highly reactive peroxide intermediates have been implicated in the degradation of several drugs in formulations containing polyethylene glycols (7, 8). Autoxidation of the solvent appears to occur during the degradation of I, which can be seen from the drop in apparent pH from 5.2 to 3.5 in the solution that contained a constant supply of air (Table I)[15]. The solution stored under nitrogen showed almost no pH change under the same conditions. When the initial pH of the solution exposed to air was lowered to 3.9 with formic acid, the rate of disappearance of I was identical to that of the pH 5.2 solution, as shown in Fig. 4. Thus, the pH drift in the solution has no apparent effect on the rate of degradation of I.

Autoxidation of the polyethylene glycol 400 provides a likely explanation for the incomplete reaction of I in sealed ampules containing air (Fig. 3). The autoxidation reaction consumes large amounts of oxygen resulting in the depletion of oxygen from solution; consequently, low peroxide levels are likely to occur as well.

The effect of 0.1% *dl*-α-tocopherol on the rate of degradation of I in polyethylene glycol 400 at 80°C is shown in Fig. 4. Although a constant supply of oxygen was present, the antioxidant prevented degradation of the prostaglandin under the reaction conditions[16]. The higher apparent pH of the solution after 15 d at 80°C compared with the solution without antioxidant (Table I) indicates that *dl*-α-tocopherol also appeared to prevent degradation of the solvent, thus reducing peroxide levels. Stabilization of fenprostalene (I) by the antioxidant is, in fact, likely to be a direct result of preventing peroxide accumulation in polyethylene glycol 400. One cannot, however, rule out the possibility that the antioxidant acts to inhibit reaction of I with oxygen directly.

The reverse-phase HPLC method used to follow the disappearance of I in polyethylene glycol 400 solutions under air did not provide any evidence of the formation of major degradation products. The only change noticed was an increase in the size of the already large solvent front. To unambiguously determine where the major degradation products of I eluted on reverse-phase HPLC, a solution of fenprostalene labeled with tritium at C-13 and C-14 in polyethylene glycol 400 was stored at 80°C for 64 h and analyzed. Fractions

[15] Addition of formic acid to polyethylene glycol 400 resulted in an apparent pH of 3.9 (Table I). This value is higher than that found for the degraded solution even though the concentration of formic acid (6×10^{-3} M) was 20-fold higher than the initial concentration of I (2.5×10^{-4} M). Thus, the pH drop in the degraded solution was due to formation of acidic decomposition products of polyethylene glycol 400, not fenprostalene (I).
[16] A similar effect was observed with 0.05% propyl gallate or 0.5% ascorbic acid as antioxidants.

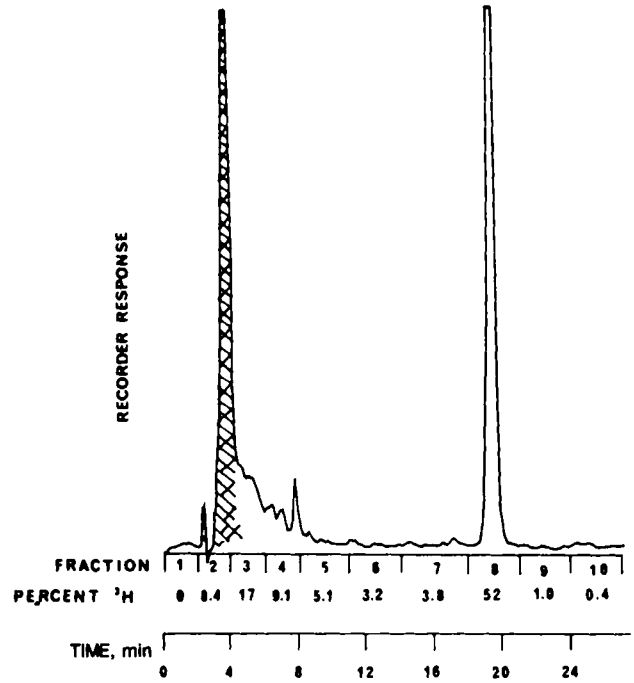

Figure 5—*Chromatogram of a partially degraded solution of [³H]I in polyethylene glycol 400. The percent of total radioactivity is shown for the 10 fractions collected. The hatched area in fraction 2 approximates the response due to the solvent front.*

of the HPLC eluant were collected and counted. The total cpm for all the fractions was 106% of the cpm determined directly by counting an aliquot of the degraded solution equal to the amount injected. Thus, no significant amount of radioactive material was bound to the column.

Both the analogue UV trace and the percent total radioactivity found in each fraction collected are presented in the chromatogram shown in Fig. 5. The peak area of each fraction appears to roughly correlate with the percent of total radioactivity found in that fraction, if the hatched area in fraction 2 is ignored. The large absorbance in fraction 2 is due predominantly to the solvent front. Most of the absorbance and counts in the chromatogram due to degradation products occurred near the solvent front, indicating that the products may be relatively polar compared with I[17]. Many peaks appear to be fused into aggregates, implying that many products are formed. The only evidence we have of their nature is that they are not due to transesterification with the solvent[18]. This was shown by treating a highly degraded (<1% of I remaining) solution of I in polyethylene glycol 400 with concentrated HCl at 80°C. No formation of the free acid (III) occurred under conditions which are known to completely hydrolyze fenprostalene.

The most likely reaction responsible for degradation of fenprostalene (I) in polyethylene glycol 400 is oxidation by reactive peroxides formed as a result of solvent autoxidation. However, the kinetic data described above does not exclude the possibility that oxygen reacts directly with the prostaglandin (as well as with the solvent) to account for at least part of the degradation reaction. Evidence that this pathway is not operating can be seen from the reaction of I in diethylene glycol under air at 80°C. Under conditions identical to those which result in rapid degradation of I in polyethylene glycol 400, the prostaglandin remains relatively stable in diethylene glycol (Fig. 4). The solvent also appears to be stable to autoxidation as evidenced by the small pH change after 15 d at 80°C (Table I)[19].

The slow degradation of I in diethylene glycol shown in Fig. 4 was not found to occur by oxidation, as suspected for the reaction of I in polyethylene glycol 400. Instead, the degradation product was identified as the diethylene glycol ester II of fenprostalene. Thus, while I undergoes a slow transesterification reaction in diethylene glycol, it undergoes a rapid oxidation reaction in polyethylene glycol 400[20]. This implies that fenprostalene (I) is intrinsically stable toward aerobic oxidation in nonaqueous solutions, but is susceptible to oxidation by peroxide intermediates formed during solvent decomposition. The success demonstrated by the use of antioxidants or nitrogen purging in stabilizing I in polyethylene glycol 400 is, therefore, due exclusively to the ability of these agents to prevent autoxidation of the solvent.

[17] A significant amount of the tritium detected in the chromatogram in Fig. 5 was in or near the solvent front. Since polyethylene glycol 400 is weakly retained, if at all, on reverse-phase HPLC, the question of tritium exchange of I with solvent was examined. A 50-fold molar excess of methanol was added to the degraded polyethylene glycol 400 solution. The methanol was then recovered by evaporation using a cold trap. Any tritium present in the polyethylene glycol 400 as —O³H would be incorporated into the methanol and detected by liquid scintillation counting. Only 1.5% of the total tritium present in the sample was found in the methanol recovered. The tritium detected in and near the solvent front in Fig. 5 must, therefore, be a prostaglandin degradation product and not ³H-labeled polyethylene glycol 400.

[18] Both aspirin (10) and indomethacin (11) are reported to undergo transesterification with polyethylene glycols.

[19] Although diethylene glycol is known to undergo autoxidation, long induction periods have been reported (12) and may explain the apparent lack of degradation observed here. Addition of the free radical initiator 2,2′-azobisisobutyronitrile to a solution of I in diethylene glycol resulted in apparent oxidation of both I and the solvent at 80°C. The reaction rate, however, was very slow compared with that in polyethylene glycol 400. Formation of II was not observed under these conditions.

[20] In the presence of *dl*-α-tocopherol (or nitrogen) a slow transesterification reaction of I with polyethylene glycol 400 might be expected; however, no degradation of I was observed (Fig. 4). Thus, transesterification of I in diethylene glycol, while a slow reaction, was faster than in polyethylene glycol 400.

Microbial Kinetics of β-Lactam Antibiotics against *Escherichia coli*

Abstract □ Microbial kinetics of *Escherichia coli* NIHJ JC-2 and *E. coli* B/r were investigated in the presence of β-lactam antibiotics. To maintain a constant drug concentration during the experiment, a novel technique, using a dialysis membrane tube containing the drug solution, was successfully employed. The drug-affected generation curves of *E. coli* exhibited common features. After the addition of drug, an apparent lag period was noted, followed by a first-order decrease of the sensitive organisms and, 6 h later, by a regrowth of resistant organisms, depending on the antibiotic concentration used. The relationship between the apparent generation rate constant, k_{app}, and the antibiotic concentration was found to be nonlinear. This phenomenon is consistent with a saturable receptor site model for the drug action. A good linear free energy relationship was observed between the microbial kinetic parameter, k_{max}, and the alkaline degradation rate constants, k_{OH}, of the cephalosporins studied.

Keyphrases □ Kinetics—microbial, β-lactam antibiotics against *Escherichia coli* □ β-Lactam antibiotics—microbial kinetics against *Escherichia coli*

In dosage regimens for infectious diseases, plasma levels of antibiotics based on the value of minimum inhibitory concentration (MIC) have been used as convenient indices of pharmacological effectiveness. The MIC is defined as the lowest concentration that results in complete inhibition of microbial generation during prolonged contact with an antimicrobial agent (~20 h). However, the quantitative meaning of the MIC is still obscure, and the value does not give any indication of the kinetic behavior of microbial generation in relation to the concentration of the drug remaining in the body at relatively short times after administration of an antibiotic. To evaluate the potency or efficacy of antibiotics more effectively and to establish more reasonable therapeutic guidelines and dosage regimens, it is necessary to investigate the microbial generation kinetics as a function of antibiotic concentration.

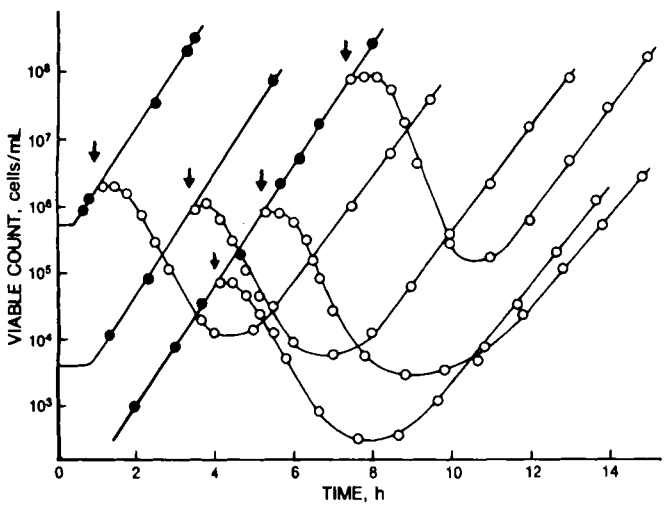

Figure 1—*Effect of organism population at the time of drug addition on the generation curves of* E. coli *B/r in the presence of 0.5 μg of ampicillin/mL and effect of inocula sizes on the generation curves of* E. coli *B/r in antibiotic medium[9] at pH 7.0 and 37°C. The time of drug addition is indicated by the arrow. Key: (●) control generation curves; (○) drug-affected generation curves.*

Several microbial kinetic studies in the presence of antibacterial agents have been reported (1–10); however, there are only a few reports on β-lactam antibiotics (4, 8). Elkhouly and Führer (8) have determined the apparent generation rate constants of *Escherichia coli* in the presence of various concentrations of ampicillin; however, it remains uncertain whether the apparent generation rate constants can be validly expressed as a function of drug concentration under their experimental conditions, because chemical and/or enzymatic degradation of ampicillin may occur under the conditions used in the study. To overcome this possible degradation, we introduced a novel method to keep the drug concentration constant.

The purposes of this study were to establish suitable experimental conditions for the microbial kinetic study of β-lactam antibiotics at constant drug concentrations and to elucidate the kinetic behavior of microbial generation in the presence of β-lactam antibiotics.

EXPERIMENTAL SECTION

Antibiotics—Penicillin G potassium[1] (1600 U/mg), ampicillin sodium[2] (955 μg/mg), methicillin sodium[3] (853 μg/mg), dicloxacillin sodium[2] (900 μg/mg), cefazolin sodium[4] (958 μg/mg), cephalexin monohydrate[5] (925 μg/mg), cefadroxil monohydrate[6] (947 μg/mg), and cephaloridine[5] (971 μg/mg) were used as received. All other chemicals, unless otherwise stated, were of reagent grade and were not further purified.

Organisms—Replicate slants of *E. coli* NIHJ JC-2[7] and *E. coli* B/r[8] [the same strains as used previously (4)] were used in the microbial kinetic study. The slants were prepared from single isolated colonies of the respective organisms and were stored at 4°C.

Culture Medium—Antibiotic medium[9] was rehydrated according to the specifications of the manufacturer and filtered twice through a 0.45-μm membrane filter[10]. This pH 7.0 medium was used for all experiments in the microbial generation studies. The medium was autoclaved at 120°C for 20 min.

Bacterial Generation—An aliquot (5 mL) of culture medium was inoculated from a fresh slant, and the culture was allowed to grow for 15 h at 37°C in an incubator. Samples of this culture were appropriately diluted in several steps to achieve an organism concentration of 10^4 cells/mL.

Two 0.5-mL portions of this culture were finally diluted into 49.5 mL of fresh medium for the control growth and 49.0 mL of fresh medium for the drug-affected growth, respectively. The cultures were maintained at 37°C in a constant-temperature water bath equipped with a shaker.

All pipets and media used were kept at 37°C to protect the organisms from temperature shock.

Cephaloridine	87.6	—	9.28	—	0.78	—

[a] At pH 7.0 and 37°C.

Viable Count Method—Samples (0.5 mL) were withdrawn from the cultures and serially diluted into sterilized 0.9% NaCl solution in accordance with a preplanned dilution scheme so that 50–150 colonies per plate would be obtained. From these dilutions, aliquots of 0.5 mL were transferred onto each of three replicate agar plates. The plates were incubated for 20 h at 37°C, and the resulting colonies were counted with an electronic colony counter.

Effect of Shaking Speed on Generation Rates—Four replicate, 49.5-mL volumes of the fresh medium were each inoculated with 0.5 mL of appropriately diluted *E. coli* NIHJ JC-2 culture in the logarithmic growth phase. They were cultured at 37°C and pH 7.0 under four different shaking conditions (0, 82, 130, and 190 strokes/min). The viable counts were determined in samples withdrawn at appropriate time intervals.

Effect of Dialysis Membrane Tube—Fresh solutions of ampicillin of two different concentrations were aseptically prepared for each experiment. They were diluted suitably so that aliquots of 0.5 mL added to replicate 49.5-mL volumes of the *E. coli* NIHJ JC-2 seeded culture yielded final concentrations of 4.0 and 1.25 μg/mL. The solutions were added to the cultures growing at 37°C in the logarithmic phase at an organism concentration of about 10^6 cells/mL. A cellulose tube[11] was knotted at both ends to form a bag (length, 10 cm). The bag, which contained 10 mL of ampicllin solution prepared with fresh culture medium to produce the same concentration as the experimental antibiotic concentration, was placed in the culture medium immediately after the drug was added. The dialysis membrane tube was replaced with a fresh tube every 3 h. At appropriate time intervals, aliquots of 0.5 mL were withdrawn, and the ampicillin concentration was assayed by the usual microbial paper disk method employing *Sarcina lutea*[12] as the test organism.

Effect of Organism Population on Drug-Affected Generation Rates—Three sets of the culture medium, with initial inoculum sizes of 6×10^4, 6×10^5, and 6×10^6 cells/mL, were prepared and used to determine generation curves of the *E. coli* B/r culture in the presence of 0.5 μg of ampicillin/mL at 37°C. The viable counts were obtained at appropriate time intervals.

Effect of Antibiotic Concentrations on Generation Rates—Aliquots (0.5

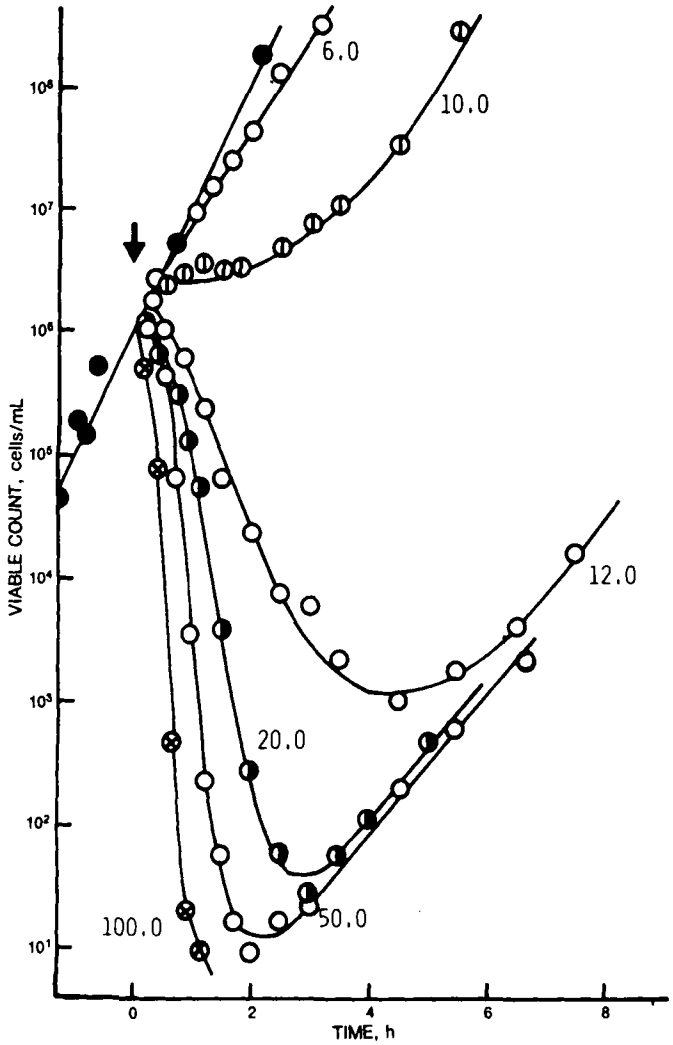

Figure 2—*Generation curves of* E. coli *NIHJ JC-2 in antibiotic medium[9] at pH 7.0 and 37°C in the absence (●) and presence (other symbols) of various concentrations of penicillin G. mL) of aqueous solutions of antibiotics were aseptically added to replicate 49.5-mL samples of *E. coli* cultures to yield the desired concentrations. The solutions were added to the cultures growing at 37°C in the logarithmic phase at an organism concentration of 10^6 cells/mL. As soon as the drug solution was added to the culture medium, a dialysis membrane bag containing the drug solution was put into the culture medium, as described above, to keep the drug concentration constant during the experimental period. Samples were withdrawn at appropriate time intervals, and the organism concentrations were determined by the viable count method.

The *E. coli* NIHJ JC-2 culture was carried out in the presence of selected concentrations of penicillin G, ampicillin, cephalexin, cefazolin, cefadroxil, and cephaloridine. The *E. coli* B/r culture was also carried out in the presence of various concentrations of penicillin G, ampicillin, dicloxacillin, and methicillin. As a control, one culture without any drug added was studied in each set of experiments.

RESULTS AND DISCUSSION

Effect of Shaking Speed on Generation Rates—To establish suitable experimental conditions for the kinetic study of antibiotic action on *E. coli*, the bacterial generation rates without antibiotics were determined from the generation time curves obtained at various shaking speeds. The culture of *E. coli* showed an exponential phase which could be expressed as:

$$\ln N = \ln N_0 + k_0 t \qquad \text{(Eq. 1)}$$

where N is the number of organisms per unit volume of broth medium at time t; N_0 is the number of organisms per unit volume of broth medium at the initial time, 0, in the logarithmic generation phase; and k_0 is the apparent generation rate constant for the drug-free culture. The mean generation time, tg, was calculated by:

$$tg = 0.693/k_0 \qquad \text{(Eq. 2)}$$

The generation rate constant, k_0, and the generation time, tg, were calculated by Eqs. 1 and 2. In the absence of agitation, the mean generation time was 22 min (slightly larger than the values obtained for cultures under agitation); however, very similar values of 17–18 min were obtained within the range of 82–190 strokes/min. Therefore, the shaking speed was fixed at 130 strokes/min in this microbial kinetic study.

Table II—Microbial Kinetic Parameter k_{max} of *E. coli* NIHJ JC-2 and Alkaline Degradation Rate, k_{OH}, of Cephalosporins

Cephalosporin	$10^4\ k_{max}, s^{-1}$	$10^2\ k_{OH}, M^{-1}\ s^{-1}$
Cephaloridine	87.6	108[a]
Cefazolin	47.7	31.7[a]
Cephalexin	16.9	7.33[a]
Cefadroxil	27.9	7.06[b]

[a] Reference 17. [b] Reference 18.

Effect of Dialysis Membrane Tube—Ampicillin concentrations in the *E. coli* NIHJ JC-2 culture in the absence or presence of a dialysis membrane tube containing drug solution of the same concentration as that of the culture medium was measured at suitable time intervals.

When the ampicillin concentration was 4.0 μg/mL, the drug concentrations remained nearly constant, both with and without a dialysis membrane tube. On the other hand, at the initial concentration of 1.25 μg/mL in the absence of a dialysis membrane tube, the concentration decreased significantly, with a half-life of ~7 h. However, with replacement of the dialysis membrane tube every 3 h, a constant ampicillin concentration was successfully maintained during the experimental period.

These results indicate the importance of keeping the drug concentration constant during the experiment and demonstrate that the method in which the dialysis membrane tube is utilized is suitable for this purpose. A membrane tube containing antibiotic solution of the appropriate concentration was, therefore, used in all microbial kinetic studies.

Effect of Organism Population on Drug-Affected Generation Rates—Semilogarithmic plots of the viable count *versus* time for *E. coli* B/r cultures treated with 0.5 μg of ampicillin/mL are illustrated in Fig. 1, in which the effects of different initial inoculum sizes and organism populations at the time of drug addition can be seen. No significant effects of the initial inoculum size and organism population at the time of drug addition are apparent.

Effect of Antibiotic Concentrations on Generation Rates—*Shape of Generation Curves*—Typical semilogarithmic plots of viable counts *versus* time for *E. coli* NIHJ JC-2 and *E. coli* B/r cultures in the presence of various concentrations of several β-lactam antibiotics are shown in Figs. 2 and 3 for penicillin G and cefadroxil, respectively.

All antibiotics studied gave very similar generation curves of *E. coli*. After the addition of a drug to the medium, a definite lag period was observed (Figs. 1–3) before the semilogarithmic plots of viable counts decreased linearly with time. As is apparent from the results shown in Figs. 2 and 3, these lag periods tend to become shorter at higher drug concentrations. These periods may depend on the time required for the antibiotic concentration on both sides of the bacterial membrane to reach steady state after drug addition to the broth medium. Garrett and Won (4) have reported similar lag periods in their study on the bactericidal effects of penicillin G, kanamycin, and rifampin against *E. coli* and have suggested that these intervals reflect the drug partitioning process into the bacterial membrane. In this study, however, we were not able to express the lag period as a function of drug concentration.

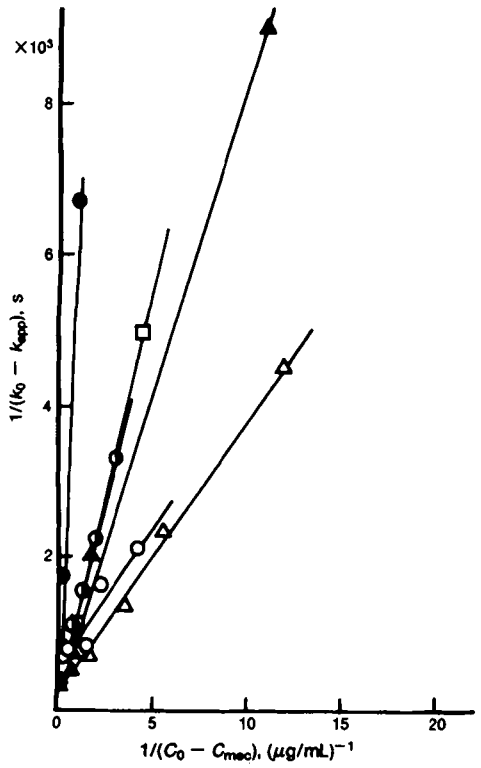

Figure 6—*Applicability of saturation kinetics to the dependency of apparent generation rate constants, k_{app}, of drug-affected* E. coli *NIHJ JC-2 on drug concentration at pH 7.0 and 37°C. Key: (●) penicillin G; (▲) ampicillin; (○) cephalexin; (△) cefazolin; (◑) cefadroxil; (□) cephaloridine.*

At higher drug concentrations, the number of viable cells decreased linearly in the semilogarithmic plots obtained immediately after drug addition. At lower drug concentrations, subsequent to the deviation from the curve of the drug-free culture, a new steady-state generation phase was established.

Apparent generation rate constants, k_{app} (in s^{-1}), of drug-affected cultures were obtained from the slopes of the linear portions of ln N *versus* t plots in accordance with the general rate expression:

$$\ln N = \ln N_0 + k_{app}t \qquad \text{(Eq. 3)}$$

Concentration Dependence of Generation Rate—The apparent generation rate constants, k_{app}, for the drug-affected *E. coli* NIHJ JC-2 and *E. coli* B/r cultures are plotted against antibiotic concentrations in Figs. 4 and 5, respectively. The plots for all antibiotics studied show a marked decrease of k_{app} with an increase in the drug concentration, C, and a tendency to reach maximum rate constants. These nonlinear plots indicate that the apparent generation rates of the drug-affected cultures obey the well-established kinetics of the saturable receptor site model proposed for other antibacterial agents (1, 2, 5–10) and can be expressed by:

$$k_{app} = k_0 - [k_{max} \times (C - C_{mec})]/[S_b + (C - C_{mec})] \qquad \text{(Eq. 4)}$$

where k_{max} and S_b are the proportionality constants relating to drug availability in the cell and drug affinity to receptor or binding sites, and C_{mec} is the minimum effective concentration manifesting antibacterial activity (defined as $C_{mec} = C$ when $k_{app} = k_0$). As suggested previously by Garrett and Won (4), C_{mec} may reflect the binding or removal of effective antibiotic by the components of the medium. The constants of k_{max}, S_b, and C_{mec} were determined by Eq. 4 using the nonlinear regression program NONLIN (11)[13] and are listed in Table I.

When the reciprocal values of the differences between the drug-free generation rate constant, k_0, and the drug-affected generation rate constant, k_{app}, are plotted against the reciprocal of the difference between the drug concentration, C, and the minimum effective concentration, C_{mec}, a good linearity is obtained by:

$$1/(k_0 - k_{max}) = S_b/k_{max}(C - C_{mec}) + 1/k_{max} \qquad \text{(Eq. 5)}$$

The plots are illustrated in Figs. 6 and 7 for *E. coli* NIHJ JC-2 and *E. coli* B/r,

[13] The computer analysis was performed with a FACOM-170F digital computer at the Data Processing Center, Kanazawa University.

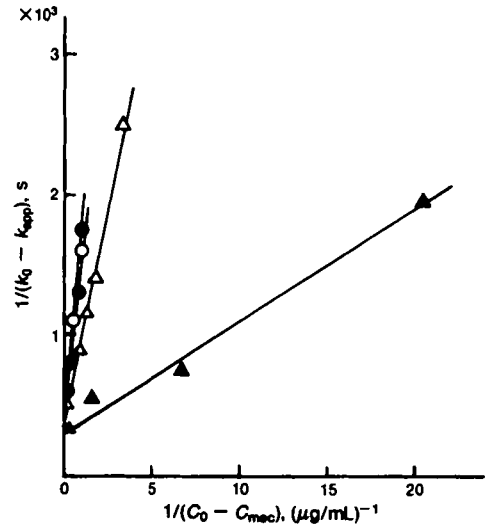

Figure 7—*Applicability of saturation kinetics to the dependency of apparent generation rate constants, k_{app}, of drug-affected* E. coli *B/r on drug concentration at pH 7.0 and 37°C. Key: (●) penicillin G; (▲) ampicillin; (○) dicloxacillin; (△) methicillin.*

respectively. The good agreement of data with Eq. 5 also substantiates the validity of the saturable receptor site model (1, 2, 5–10) for interpretation of the action of β-lactam antibiotics on microbial growth. It is likely that the receptor sites correspond to transpeptidase, which is known to interact with β-lactam antibiotics (12).

The quantitative meaning of the MIC is still unclear, and the magnitude does not always reflect the kinetic behavior of microbial generation in the presence of antibiotics. However, the parameter k_{max} corresponds to the V_{max} in enzyme kinetics and may reflect the intrinsic potency of the antibiotic better than does the MIC.

Structure–Activity Correlation of β-Lactam Antibiotics and Microbial Kinetics—Hermann (13) has suggested that the bactericidal activity of β-lactam antibiotics is parallel to the reactivity of the β-lactam ring, and Indelicato *et al.* (14, 15) and Yamana *et al.* (16, 17) have stated that the alkaline degradation rate, k_{OH}, of cephalosporin parallels antibacterial activity. The mechanism of hydroxide ion-catalyzed degradation of the β-lactam ring in alkaline solution is similar to the mechanism of the acylation of transpeptidase because both reactivities depend on the cleavage energy of the C—O bond of the β-lactam ring. Based on these considerations, a linear free energy relationship can be applied for k_{max} and k_{OH}:

$$G^{\neq}_{k_{max}} = \text{const} \cdot G^{\neq}_{k_{OH}} + \text{const} \qquad \text{(Eq. 6)}$$

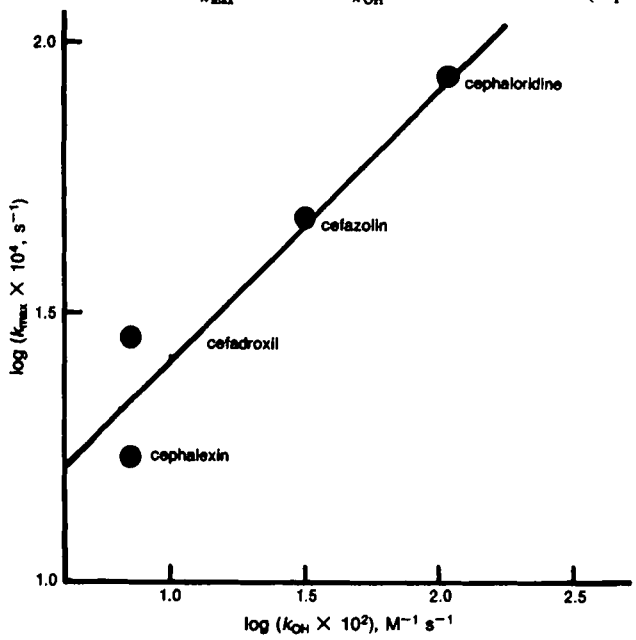

Figure 8—*Relationship between microbial kinetic parameter, k_{max}, of* E. coli *NIHJ JC-2 and alkaline degradation rates, k_{OH}, of cephalosporins.*

and:

$$k_{max} = \text{const} \cdot \exp(-G^{\neq}_{k_{max}}/RT) \quad \text{(Eq. 7)}$$

$$k_{OH} = \text{const} \cdot \exp(-G^{\neq}_{k_{OH}}/RT) \quad \text{(Eq. 8)}$$

where $G^{\neq}_{k_{max}}$ and $G^{\neq}_{k_{OH}}$ are free energies of activation for k_{max} and k_{OH}, respectively, const is a constant, R is the gas constant, and T is the absolute temperature. Taking the common logarithm of both sides of Eqs. 7 and 8 gives:

$$\log k_{max} = \text{const} - G^{\neq}_{k_{max}}/2.303RT \quad \text{(Eq. 9)}$$

$$\log k_{OH} = \text{const} - G^{\neq}_{k_{OH}}/2.303RT \quad \text{(Eq. 10)}$$

Substitution of Eqs. 9 and 10 for $G^{\neq}_{k_{max}}$ and $G^{\neq}_{k_{OH}}$ into Eq. 6, followed by rearrangement, yields:

$$\log k_{max} = \text{const} \cdot \log k_{OH} + \text{const} \quad \text{(Eq. 11)}$$

Equation 11 indicates a linear relationship between log k_{max} and log k_{OH}.

The k_{max} values for *E. coli* NIHJ JC-2 and k_{OH} values for cephalosporins are listed in Table II, and log k_{max} is plotted against log k_{OH} in Fig. 8 (good linearity was obtained). The regression equation obtained is:

$$\log k_{max} = 0.513 \cdot \log k_{OH} + 0.902 \quad \text{(Eq. 12)}$$

with a regression coefficient of 0.951. This relationship suggests that β-lactam antibiotics possessing high reactivity of the C—O bond in alkaline solution will show high bactericidal activity.

Organisms Resistant to Drug Action—Garrett and Won (4) have suggested the following possible explanations in connection with the regrowth of organisms after the first-order decrease of viable cells in drug-affected cultures (Figs. 1–3): (*a*) the consumption or degradation of the drug, (*b*) the production of an inhibitor or inactivator of antibiotic action, and (*c*) the presence of bacteria able to resist the drug action. This study on the microbial kinetics of various β-lactam antibiotics was conducted at constant drug concentrations (achieved by the dialysis membrane tube method); therefore, possibility *a* can be ruled out, but possibilities *b* and *c* still remain.

Kinetic Analysis and Characterization of the Bacterial Regrowth after Treatment of *Escherichia coli* with β-Lactam Antibiotics

SHOICHIRO HAMANO *[1], AKIRA TSUJI *[x], TETSUO ASANO *, IKUMI TAMAI *, EMI NAKASHIMA *, TSUKINAKA YAMANA [‡], and SUSUMU MITSUHASHI [§]

Received December 27, 1982, from the **Faculty of Pharmaceutical Sciences* and [‡]*Hospital Pharmacy, Kanazawa University, Takara-machi, Kanazawa 920, Japan* and the [§]*School of Medicine, Gunma University, Showa-machi, Maebashi 372, Japan.* Accepted for publication October 24, 1983. [1]Present address: Research Center, Taisho Pharmaceutical Co., Ltd., Yoshino-cho, Omiya 330, Japan.

Abstract □ The generation curves of *Escherichia coli* B/r and *E. coli* NIHJ JC-2 in the presence of several β-lactam antibiotics were studied from the kinetic point of view. Apparent first-order regrowth of resistant organisms was observed ~6 h after addition of these antibiotics. The time courses of apparent viable counts could be interpreted in terms of the sum of the viable counts of sensitive and resistant organisms. To clarify the nature of the regrowth, experiments involving a second addition of antibiotic, single colonization by subculture, and synchronous cell culture were carried out. Several possible explanations for the results are discussed, including β-lactamase production, selection in terms of membrane permeability, and mutation to acquire drug resistance. A selection process or a modification of membrane permeability caused by contact with the drug seems to be the most probable reason for the regrowth of the organisms.

Keyphrases □ Kinetics—microbial, analysis and characterization of bacterial regrowth after treatment of *Escherichia coli* with β-lactam antibiotics □ β-Lactam antibiotics—kinetic analysis and characterization of bacterial regrowth after treatment of *Escherichia coli*

In the previous paper (1), we described the microbial kinetics of *Escherichia coli* treated with several β-lactam antibiotics. We also mentioned that, once treated with β-lactam antibiotics, the organisms showed an apparent regrowth in spite of the maintenance of a constant drug concentration by the use of a dialysis membrane tube containing the antibiotic solution (1). This regrowth is a well-recognized phenomenon in drug-affected cultures (2–6). Much work has been done on

and:

$$k_{max} = \text{const} \cdot \exp(-G^{\neq}_{k_{max}}/RT) \quad \text{(Eq. 7)}$$

$$k_{OH} = \text{const} \cdot \exp(-G^{\neq}_{k_{OH}}/RT) \quad \text{(Eq. 8)}$$

where $G^{\neq}_{k_{max}}$ and $G^{\neq}_{k_{OH}}$ are free energies of activation for k_{max} and k_{OH}, respectively, const is a constant, R is the gas constant, and T is the absolute temperature. Taking the common logarithm of both sides of Eqs. 7 and 8 gives:

$$\log k_{max} = \text{const} - G^{\neq}_{k_{max}}/2.303RT \quad \text{(Eq. 9)}$$

$$\log k_{OH} = \text{const} - G^{\neq}_{k_{OH}}/2.303RT \quad \text{(Eq. 10)}$$

Substitution of Eqs. 9 and 10 for $G^{\neq}_{k_{max}}$ and $G^{\neq}_{k_{OH}}$ into Eq. 6, followed by rearrangement, yields:

$$\log k_{max} = \text{const} \cdot \log k_{OH} + \text{const} \quad \text{(Eq. 11)}$$

Equation 11 indicates a linear relationship between log k_{max} and log k_{OH}.

The k_{max} values for *E. coli* NIHJ JC-2 and k_{OH} values for cephalosporins are listed in Table II, and log k_{max} is plotted against log k_{OH} in Fig. 8 (good linearity was obtained). The regression equation obtained is:

$$\log k_{max} = 0.513 \cdot \log k_{OH} + 0.902 \quad \text{(Eq. 12)}$$

with a regression coefficient of 0.951. This relationship suggests that β-lactam antibiotics possessing high reactivity of the C—O bond in alkaline solution will show high bactericidal activity.

Organisms Resistant to Drug Action—Garrett and Won (4) have suggested the following possible explanations in connection with the regrowth of organisms after the first-order decrease of viable cells in drug-affected cultures (Figs. 1–3): (*a*) the consumption or degradation of the drug, (*b*) the production of an inhibitor or inactivator of antibiotic action, and (*c*) the presence of bacteria able to resist the drug action. This study on the microbial kinetics of various β-lactam antibiotics was conducted at constant drug concentrations (achieved by the dialysis membrane tube method); therefore, possibility *a* can be ruled out, but possibilities *b* and *c* still remain.

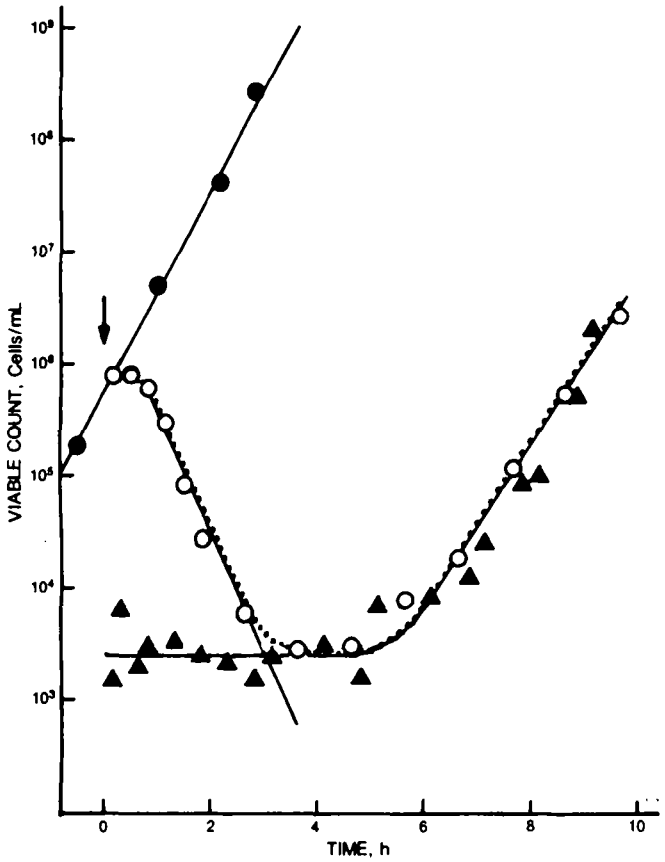

Figure 1—*Generation curves of* E. coli *B/r in antibiotic medium*[3] *at pH 7.0 and 37°C in the absence and presence of 0.5 μg of ampicillin/mL, based on viable counts. Key: (●) control generation curves; (○) drug-affected viable counts in drug-free agar plates; (▲) drug-affected viable counts in drug-containing agar plates. The dotted line was generated from Eqs. 1 and 2 by using the appropriate kinetic parameters (Table I.)*

drug-resistant mechanisms of organisms (7); however, very few reports (2, 6) have focused on the mechanism of regrowth after addition of antibacterial agents to the culture, even though it is very important to prevent the regrowth of organisms in chemotherapy.

The purposes of this study were to establish a mathematical model to describe the entire generation curve of organisms as a function of time and to clarify the nature of regrowth after the bactericidal action of β-lactam antibiotics.

EXPERIMENTAL SECTION

Microorganisms—Replicate slants of *E. coli* NIHJ JC-2[1] and *E. coli* B/r[2] [the same strains as used previously (2)] were used. The slants were prepared from a single isolated colony of the appropriate organism and stored at 4°C.

Culture Medium—Antibiotic medium[3] was rehydrated according to the specifications of the manufacturer and filtered twice through a 0.45-μm filter[4]. The medium was autoclaved at 120°C for 20 min. This pH 7.0 medium was used for all experiments.

Materials—Ampicillin sodium[5] (955 μg/mg), penicillin G potassium[6] (1600 U/mg), and cefazolin sodium[7] (958 μg/mg) were used as received. All other chemicals were of reagent grade and were used without further purification.

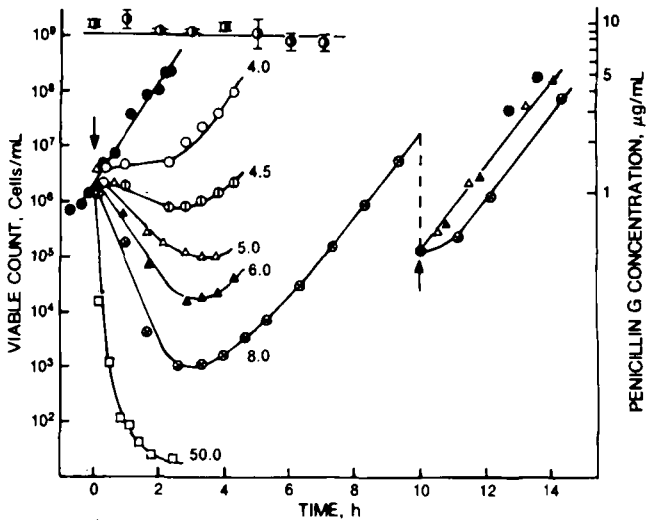

Figure 2—*Generation curves of* E. coli *B/r in antibiotic medium*[3] *at pH 7.0 and 37°C in the absence and presence of various concentrations of penicillin G. The numbers inside the figure are the drug concentrations in micrograms per milliliter. After the first addition (↓) of 8.0 μg of penicillin G/mL, the culture was diluted 100-fold with fresh medium at the second addition (↑). The observed drug concentrations are indicated (○) for 8 μg/mL (nominal) (right-hand axis).*

Bacterial Generation—An aliquot (5 mL) of culture medium was inoculated from a fresh slant and allowed to grow for 15 h at 37°C in an incubator. Samples of this culture were appropriately diluted in several steps to achieve the organism concentration of 10^4 cells/mL.

Two 0.5-mL portions of this cultture were finally diluted into 49.5 mL of fresh medium for control growth and 49.0 mL of fresh medium for drug-affected growth, respectively. The cultures were maintained at 37°C in a constant-temperature water bath equipped with a shaker set at 130 strokes/min. The drug solutions were added to the cultures in the logarithmic growth phase at 37°C. As soon as a drug was added to the cultures, a dialysis membrane tube[8] containing 10 mL of fresh culture medium with the same drug concentration as the organism culture medium was placed in the culture medium and replaced every 3 h with a new one (1). To keep the antibiotic concentration constant during the experiment, a membrane tube was used in all generation studies.

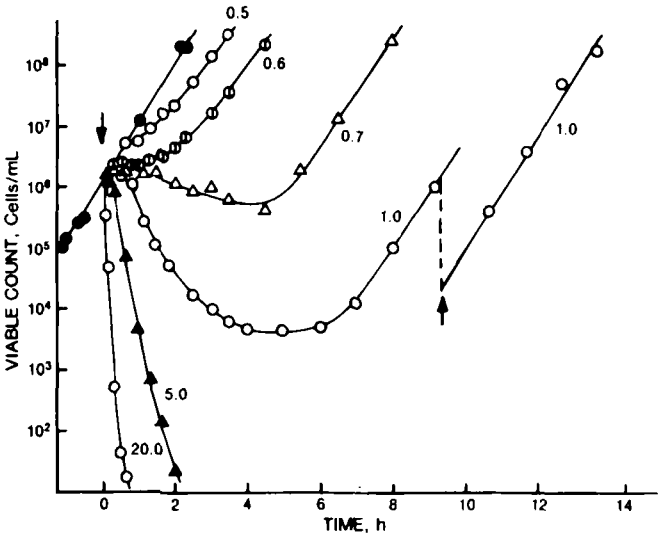

Figure 3—*Generation curves of* E. coli *NIHJ JC-2 in antibiotic medium*[3] *at pH 7.0 and 37°C in the absence and presence of various concentrations of cefazolin. The numbers inside the figure are drug concentrations in micrograms per milliliter. After the first addition (↓) of 1.0 μg of cefazolin/mL, the culture was diluted 100-fold with fresh medium at the second addition (↑).*

Table I—Microbial Kinetic Parameters of *E. coli* B/r and *E. coli* NIHJ JC-2 in Antibiotic Medium[3] [a]

Organism	Ns_0, cells/mL	Nr_0, cells/mL	k_{app}, s^{-1}	k_g, s^{-1}	L_1, min	L_2, min
E. coli B/r	8.0×10^5	3.2×10^3	-7.01×10^{-4}	4.67×10^{-4}	53	322
E. coli NIHJ JC-2	1.0×10^6	1.2×10^1	-1.04×10^{-3}	4.95×10^{-4}	55	326

[a] At pH 7.0 and 37°C in the presence of 0.5 and 1.5 μg of ampicillin/mL for *E. coli* B/r and *E. coli* NIHJ JC-2, respectively.

At appropriate time intervals, aliquots (0.5 mL) were withdrawn, and the penicillin G concentration was determined by the usual microbiological paper disk method, employing *Staphylococcus aureus* 209P[9] as the test organism.

Viable Count Method—Samples (0.5 mL) were withdrawn from the cultures and serially diluted into sterilized 0.9% NaCl solution in accordance with a preplanned dilution scheme so that 50–150 colonies per plate would result. From these dilutions, aliquots (0.2 mL) were transferred onto each of three replicate peptone agar plates. The plates were incubated for 20 h at 37°C, and the resulting colonies were counted with an electronic colony counter.

To obtain the viable count of drug-resistant organisms shown in Figs. 1–5, the procedure was the same as that described above, except for the use of peptone agar plates which contained the drug at the desired concentration.

Effect of Second Addition of Antibiotics—Aliquots (0.5 mL) of penicillin G and cefazolin solutions were added to *E. coli* B/r and *E. coli* NIHJ JC-2 cultures, respectively, in the logarithmic growth phase of the culture to give final concentrations of 8.0 μg/mL for penicillin G (culture A) and 1.0 μg/mL for cefazolin (culture B). The drug-affected cultures A and B were allowed to generate for ~10 h at 37°C in an incubator. Portions of these solutions were then diluted 100-fold with fresh medium. Aliquots of the *E. coli* B/r culture were then treated with penicillin G concentrations of 5.0, 6.0, and 8.0 μg/mL, and an aliquot of the *E. coli* NIHJ JC-2 culture was treated with 1.0 μg of cefazolin/mL. One colony of *E. coli* NIHJ JC-2 harvested from culture B in the logarithmic growth phase of regrowth was subcultured, and then the subcultured organism was used as a test organism. The effect of the second addition of cefazolin on this subcultured resistant organism was studied in the same manner as described above.

Population Distribution of Drug-Resistant Organisms—Replicate agar plates containing ampicillin concentrations of 0.1, 0.2, 0.3, 0.4, 0.5, 0.55, 0.6, 0.65, and 0.7 μg/mL were prepared. Samples (0.5 mL) were withdrawn from *E. coli* NIHJ JC-2 culture at an organism concentration of 2×10^6 cells/mL in the logarithmic growth phase and serially diluted. From these dilutions, samples (0.2 mL) were transferred onto the replicate agar plates containing drug. The plates were incubated for 20 h at 37°C, and the number of colonies was counted.

Single Colonization—*E. coli* NIHJ JC-2 obtained from a fresh slant was suspended in 2 mL of 0.9% NaCl. A portion of this solution was transferred onto peptone agar plates with a standard platinum loop and cultured for 20 h at 37°C. One colony from this agar plate was again treated in the same way; the colony that appeared the next day was used as the test organism.

Drug-Affected Growth and Effect of Second Addition—The experimental procedure for drug-affected growth and the effect of the second addition of antibiotic was the same as that described previously (1).

Minimal Inhibitory Concentration of Subcultured Drug-Resistant Organisms—The organism obtained from the regrowth of *E. coli* NIHJ JC-2 after ampicillin treatment (1.5 μg/mL) was purified by single colonization and subcultured up to 29 times on peptone agar plates. The minimal inhibitory concentration (MIC) was determined periodically.

The MIC values were determined by the agar dilution method. Overnight cultures of *E. coli* NIHJ JC-2 were diluted to final concentrations of ~10^6 and 10^8 cells/mL, and 5-μL aliquots of each culture were inoculated and incubated on antibiotic medium[3] agar plates containing serial twofold dilutions of ampicillin. The MIC values were recorded after 18 h of incubation at 37°C.

Effect of Ampicillin Concentrations on Regrowth Rates—Aliquots (0.5 mL) of aqueous solutions of ampicillin were aseptically added to replicate 49.5-mL volumes of *E. coli* NIHJ JC-2 cultures to yield concentrations of 0.55, 0.6, 0.7, and 1.1 μg/mL.

Preparation of Synchronous Cell Cultures—Aliquots (0.5 mL) of phenethyl alcohol solutions were aseptically added to replicate 49.5-mL volumes of *E. coli* NIHJ JC-2 culture in the logarithmic growth phase to yield desired concentrations. The cell concentration at the time of drug addition was ~10^5 cells/mL. A portion of the culture was diluted 1000-fold with fresh medium at 90 min so that the effect of phenethyl alcohol became negligible. A synchronized cell culture was generated from the medium containing 10^5 cells/mL. Aliquots (0.5 mL) of ampicillin solution were added to the synchronized cell culture at an organism concentration of ~2×10^5 cells/mL to achieve final concentrations of 1.25 and 1.5 μg/mL. The viable counts were monitored with an electronic colony counter.

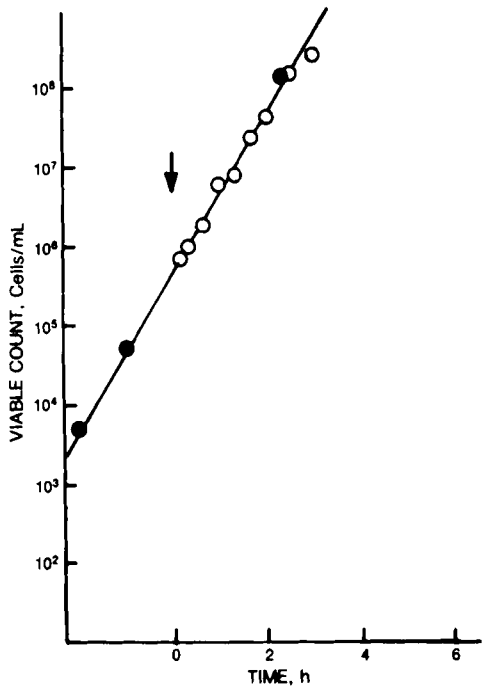

Figure 4—*Semilogarithmic plots of* E. coli *NIHJ JC-2 obtained from the logarithmic regrowth phase after the first addition of cefazolin (1.0 μg/mL) at pH 7.0 and 37°C. The experiment was effected 24 h after development and isolation of resistant organisms.*

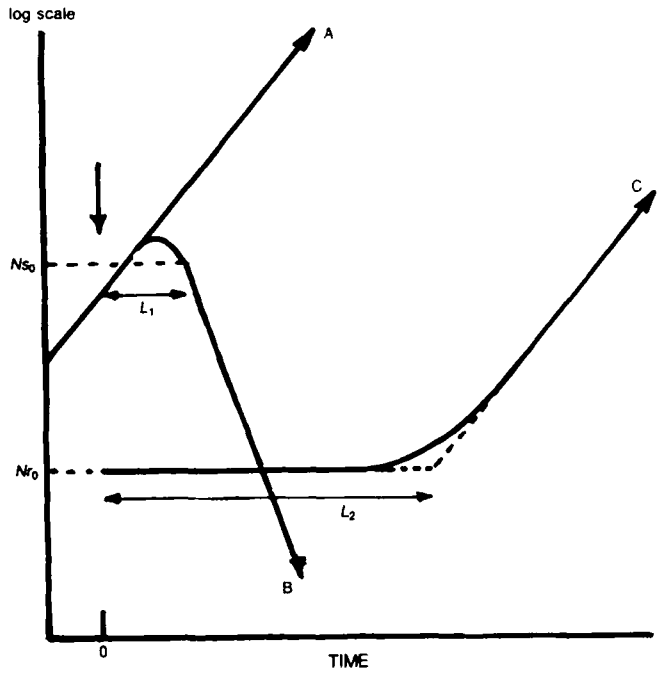

Figure 6—*Generation model for drug-affected organism. Key: (A) control generation curve; (B) generation curve of sensitive organisms; (C) generation curve of resistant organisms; (L_1 and L_2) lag times for sensitive and resistant organisms, respectively; (Ns_0 and Nr_0) initial organism concentrations for sensitive and resistant organisms, respectively; (time 0) time of drug addition.*

Assay of β-Lactamase—Antibiotic medium[3] in a 1.0-L flask was inoculated with 25 mL of an overnight culture of *E. coli* NIHJ JC-2 in the presence of 8 μg of penicillin G/mL at 37°C. After 4 h, the bacteria at a concentration of ~5 × 10^8 cells/mL in the logarithmic growth phase were harvested by centrifugation and washed once with 0.05 M phosphate buffer (pH 7.0). The packed cells were resuspended in 50 mL of 0.05 M phosphate buffer (pH 7.0), and the suspensions were intermittently treated in an ultrasonic disintegrator[10] for 3 min. The disrupted suspensions were centrifuged at 12,000 rpm for 30 min at 5°C to remove broken cells and cell debris; the cell-free extract was retained as the crude enzyme preparation. Activity of β-lactamase was then assayed spectrophotometrically (8) by measuring the decrease in the absorbance at the substrate-specific wavelengths of 233 and 260 nm for penicillin G and cephaloridine, respectively.

RESULTS

Development of Drug-Resistant Organisms—A typical semilogarithmic plot of the viable counts against time is shown (Fig. 1) for the action of 0.5 μg of ampicillin/mL on *E. coli* B/r. After a certain lag period following drug addition, the logarithm of the viable count against time decreased exponentially with time. After a definite period of organism killing, there is a subsequent generation of viable organisms. The slope of the regrowth phase in the presence of drug was found to be very similar to that for the plot in the absence of ampicillin. This result indicates a negligible drug effect in the terminal segments, even though the drug concentration was kept constant by the use of the dialysis membrane tube. A similar result was obtained for the *E. coli* NIHJ JC-2 culture treated with 1.5 μg of ampicillin/mL.

These observations indicate that the apparent generation curves in the presence of drugs (Fig. 1) consist of a first-order decrease of susceptible organisms and a first-order increase of resistant organisms, both of which occur after certain lag times. The lag time is the elapsed time from the time of drug addition to the time at which a decrease or an increase of the viable count begins. Therefore, the apparent generation curves may be expressed by the generation model depicted in Fig. 6, in which t is the time after addition of drug: Ns_0 is the number of susceptible organisms present at time L_1; Nr_0 is the number of resistant organisms at time L_2; L_1 and L_2 are the lag times for the appearances of the first-order decrease of susceptible organisms and the first-order increase of resistant organisms, respectively. This generation

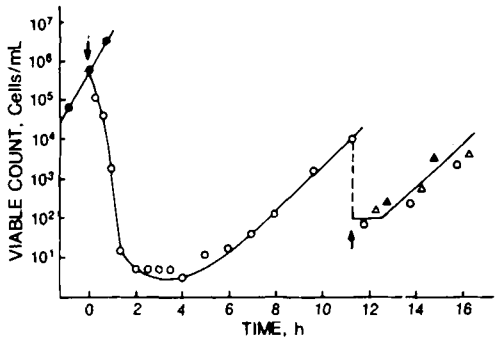

Figure 7—*Generation curves of the purified* E. coli NIHJ JC-2 *in antibiotic medium*[3] *at pH 7.0 and 37°C in the absence and presence of 1.5 μg of ampicillin/mL. After the first addition (↓) of ampicillin, the generating culture was diluted 100-fold with fresh medium at the second additions (▲) of various ampicillin concentrations. Key: (○) 1.5 μg/mL; (△) 1.2 μg/mL; (▲) 1.0 μg/mL.*

model leads to the following equations (see below for the derivation) after a lag period $t > L_1$ (when $L_1 \leqq t \leqq L_2$):

$$N_{app} = Ns_0 \cdot e^{k_{app}(t-L_1)} + Nr_0 \qquad \text{(Eq. 1)}$$

when $t > L_2$:

$$N_{app} = Ns_0 \cdot e^{k_{app}(t-L_1)} + Nr_0 \cdot e^{k_g(t-L_2)} \qquad \text{(Eq. 2)}$$

where N_{app} is the apparent number of organisms present at time t and k_{app} and k_g are the apparent generation rate constants for the susceptible and resistant organisms, respectively. The relationship between the observed number of viable counts and the simulation based on Eqs. 1 and 2 with the appropriate parameters listed in Table I seems to support the model depicted in Fig. 6.

Effect of Second Addition of Antibiotics—The effects of the second addition of penicillin G and cefazolin in the case of resistant organisms are shown in Figs. 2 and 3, respectively. In these experiments, the membrane tube containing the drug solution was used.

In a typical case shown in Fig. 2, a penicillin G concentration of 8 μg/mL

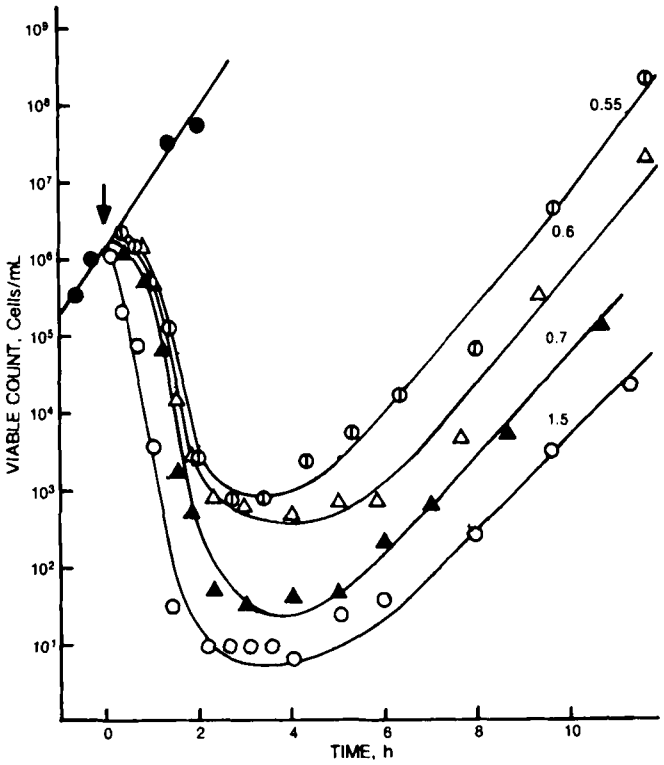

Figure 8—*Generation curves of the purified* E. coli *NIHJ JC-2 in antibiotic medium*[3] *at pH 7.0 and 37°C in the absence and presence of various concentrations of ampicillin. The curves are labeled according to drug concentrations in micrograms per milliliter.*

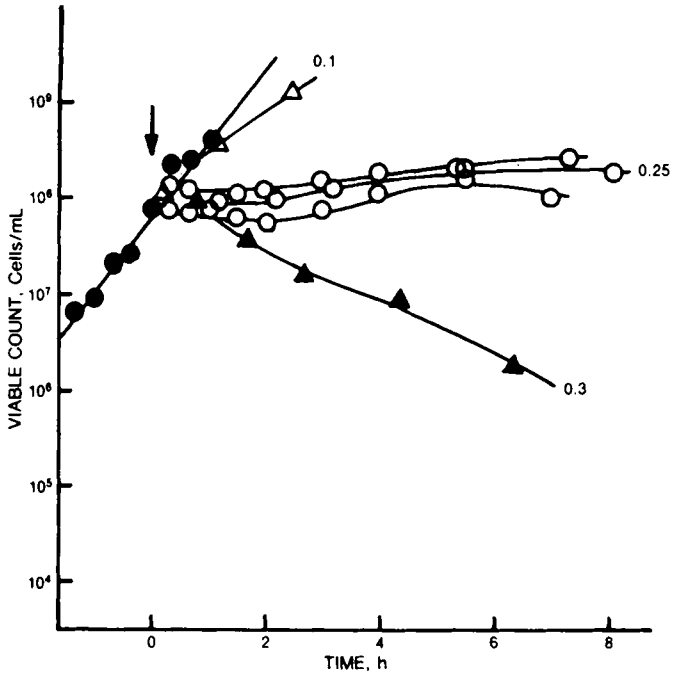

Figure 9—*Generation curves of* E. coli *NIHJ JC-2 in antibiotic medium*[3] *at pH 7.0 and 37°C in the absence and presence of phenethyl alcohol. The curves are labeled according to percent concentrations of phenethyl alcohol.*

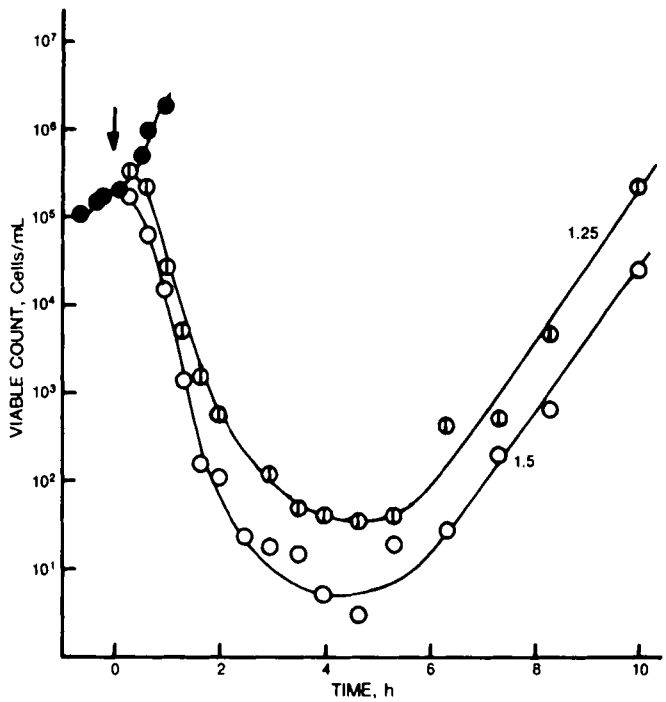

Figure 10—*Generation curves of the synchronized* E. coli *NIHJ JC-2 culture in antibiotic medium*[3] *at pH 7.0 and 37°C in the absence and presence of ampicillin. The curves are labeled according to ampicillin concentrations in micrograms per milliliter.*

was confirmed to be maintained essentially constant. At about 10 h after the first drug addition, when the drug-resistant organisms were in a logarithmic growth phase, the membrane tube was removed, and a 100-fold dilution was made with fresh medium to make the original drug action negligible. The second additions of penicillin G did not greatly affect the generation rate at the concentrations of 5.0 and 6.0 μg/mL (Fig. 2). Even though the first addition of penicillin G at these concentrations markedly reduced the viable counts, the generation rate constants for these concentrations were found to be similar to those of the drug-resistant organism at the first addition, although a slight lag time was observed at 8.0 μg/mL. The result indicates that once the organism has acquired resistance (after the first addition), it is resistant to all drug concentrations lower than that of the first addition. The same result was obtained for cefazolin with *E. coli* NIHJ JC-2 (Fig. 3).

The organism which was made resistant by the addition of 1.0 μg of cefazolin/ml was subcultured and again treated with cefazolin (1.0 μg/mL) on the next day. This drug-affected culture exhibited a generation rate similar to that of the drug-free culture (Fig. 4). This result shows that, once acquired, drug resistance is retained 48 h later.

Population Distribution of Drug-Resistant Organisms—To obtain a population diagram of ampicillin-resistant *E. coli* NIHJ JC-2, viable counts were performed in the agar plates with drug after isolation of organisms from drug-free culture. In Fig. 5 are plotted the resultant viable counts against ampicillin concentrations in the agar plates. A sharp decrease of viable counts was observed when the ampicillin concentration was increased from 0.4 to 0.5 μg/mL. This result suggests that the number of drug-resistant organisms depends on the drug concentration used.

Single Colony Subcultures—*Drug-Affected Generation Curve*—When the organism was purified by repeated subcultures of a single colony and then employed in the drug-affected generation experiment, the drug-resistant organisms increased again after about a 5-h lag period (Fig. 7). This result raises the possibility that some population among the presumably genetically identical organisms may have acquired drug resistance by contact with the drug. If some organisms such as these were originally insensitive to the ampicillin concentration of 1.5 μg/mL, they would not have shown a decrease of viable count after the first addition.

A second addition of antibiotic was also tested. Treatment with concentrations below that of the first addition also did not affect the generation rate of the resistant organisms.

Minimal Inhibitory Concentration for Subcultured Organisms—The MIC of ampicillin for the original strain of *E. coli* NIHJ JC-2 was 3.13 μg/mL at organism concentrations of both 10^6 and 10^8 cells/mL. The resistant organisms obtained after the first addition of ampicillin at 1.5 μg/mL were subcultured serially. The MIC values were in the ranges of 12.5–25 μg/mL at an organism concentration of 10^6 cells/mL and 25–50 μg/mL at 10^8 cells/mL. The MIC values remained essentially unchanged during 29 serial subcultures. This means that the resistance, once acquired, was persistent.

Effect of Drug Concentration on Generation Rate of the Purified Organism—Semilogarithmic plots of viable counts *versus* time for the *E. coli* NIHJ JC-2 culture treated with various concentrations of ampicillin are shown in Fig. 8. The generation curves are clearly concentration dependent, suggesting that the degree of resistance caused by contact with the drug might depend on the drug concentration.

Effect of Cell Cycle at the Time of Drug Addition—*Effect of Phenethyl Alcohol on Bacterial Generation*—The effect of phenethyl alcohol on the generation of *E. coli* NIHJ JC-2 was measured to ascertain the concentration which would effectively retard bacterial generation by the inhibition of DNA synthesis (9). The results (Fig. 9) indicate that 0.25% phenethyl alcohol treatment is suitable for the inhibition of DNA synthesis. Treatment with 0.1% phenethyl alcohol failed to inhibit DNA replication, whereas 0.3% phenethyl alcohol treatment killed the organisms.

Effect of Ampicillin Concentration on Generation Rate—The stationary-phase cells of *E. coli* NIHJ JC-2 were exposed to 0.25% phenethyl alcohol for 90 min. The inhibition was then released by 1000-fold dilution of the inhibitor with fresh medium, so that the effect of phenethyl alcohol became negligible. After this dilution, the synchronous culture started to grow again. Aliquots of ampicillin solution were added to yield concentrations of 1.25 and 1.5 μg/mL when the viable count had doubled. Generation curves similar to that of the nonsynchronous culture were observed (Fig. 10).

DISCUSSION

The apparent drug-affected generation curves for *E. coli* treated with β-lactam antibiotics seem to be the summation of the viable counts for drug-susceptible and drug-resistant organisms (Fig. 1). Based on this hypothesis, a mathematical model for the generation curve is presented in Fig. 6. The apparent number of viable counts can be expressed by:

$$N_{app} = Ns + Nr \qquad \text{(Eq. 3)}$$

where Ns and Nr are the numbers of susceptible and resistant organisms, respectively. When t is in the range of $L_1 \leqq t \leqq L_2$:

$$Ns = Ns_0 \cdot e^{k_{app}(t-L_1)} \qquad \text{(Eq. 4)}$$

$$Nr = Nr_0 \qquad \text{(Eq. 5)}$$

Here, $t = 0$ when the drug is added. Substitution of Eqs. 4 and 5 into Eq. 3 yields Eq. 1 (when t is $t > L_2$):

$$Ns = Ns_0 \cdot e^{k_{app}(t-L_1)} \quad \text{(Eq. 6)}$$

$$Nr = Nr_0 \cdot e^{k_g(t-L_2)} \quad \text{(Eq. 7)}$$

Replacement of Ns and Nr in Eq. 3 by Eqs. 6 and 7 gives Eq. 2.

Although the observed points were scattered around the simulation curve generated from Eq. 1 by incorporating the appropriate parameters (Table I), it appears that the apparent generation curves can be reasonably well described by the present mathematical model.

Garrett and Won (2) have reported the development of penicllin-resistant organisms and proposed the following possible explanation for the regrowth phenomenon: (*a*) the consumption or degradation of drugs, (*b*) production of an inhibitor or inactivator of antibiotic action, (*c*) preexistence of drug-resistant bacteria, and (*d*) acquisition of drug resistance through mutation and/or adaptation by exposure to the drug. Besides these factors, the cell cycle (*e*) may be an important factor in regrowth after the first addition of drug.

In the present study, the drug concentration was kept constant during the experiment by using a dialysis membrane tube containing drug solution. Therefore, possibility *a* is ruled out.

The regrowth pattern appears to depend on the drug concentration (Figs. 2 and 3). The organism, once it acquired resistance after the first drug addition, retained resistance to concentrations below that of the first addition (Figs. 2 and 3), and this persisted for at least 48 h during subculture (Fig. 4). These observations and the population diagram of the resistant organisms (Fig. 5) seem to support the preexistence of insensitive bacteria with different degrees of resistance, although possibilities *b*, *d*, and *e* cannot be excluded completely on the basis of the results shown in Figs. 2–4 and 7.

The subcultured organism from a single colony showed similar apparent regrowth (Fig. 8). The possibility of picking up an organism originally resistant to the ampicillin concentration of 1.5 μg/mL is very small, because the number of organisms which may manifest resistance to 1.5 μg of ampicillin/mL is expected to be <10, judging from the population diagram (Fig. 7).

The possibility of mutation and/or adaptation may be ruled out by the MIC determinations on subcultured organisms. If the resistance was acquired by mutation and/or adaptation, the MIC should increase gradually during repeated subcultures, but in fact it did not change. Furthermore, when the drug was added just at the doubling time (DNA synthesis stage) of the synchronous culture, a similar generation curve was obtained (Fig. 10); so, possibility *e* was ruled out.

The possibility of β-lactamase production still remains; therefore, we assayed β-lactamase activity by using resistant organisms generated with 8 μg of penicillin G/mL, but β-lactamase activity was not detected in the crude preparation. This result excludes the possibility that β-lactamase may have been induced by contact with the drug, leading to the acquisition of resistance.

The remaining and most probable explanation for the bacterial regrowth after the addition of the drug is a selection process and/or change of membrane permeability caused by contact with the drug at various concentrations.

Zimmermann (10) and Sawai *et al.* (11, 12) have reported an indirect method for measuring the outer membrane permeability of β-lactam antibiotics, but it is necessary to use β-lactamase-producing organisms. To confirm the difference in degree of permeability between sensitive and resistant organisms, a direct measurement of membrane permeability is desirable; however, a direct method for such measurement is not available at present.

Spectrofluorometric Determination of Captopril Plus Captopril Disulfide Metabolites in Plasma

EUGENE IVASHKIV

Received January 7, 1983, from *The Squibb Institute for Medical Research, New Brunswick, NJ 08903.* Accepted for publication October 31, 1983.

Abstract □ Captopril disulfides and the drug covalently bound to proteins were reduced with tri-*n*-butylphosphine. After sample purification on an XAD-2 column, captopril was treated with 1-(7-dimethylamino)-4-methyl-2-oxo-2*H*-1-benzopyran-3-yl)-1*H*-pyrrole-2,5-dione to form a fluorescent derivative. After acidification, the fluorescent derivative was extracted into toluene and purified on a C_{18} cartridge. The fluorescence of the dimethylformamide eluate was measured at an excitation wavelength of 380 nm and a fluorescence wavelength of 440 nm.

Keyphrases □ Captopril—spectrofluorometric analysis, plasma □ Angiotensin-converting enzyme inhibitors—captopril, spectrofluorometric analysis, plasma

Captopril (1-[(2*S*)-3-mercapto-2-methylpropionyl]-L-proline; I) a potent, specific, and orally active inhibitor of angiotensin-converting enzyme, has been shown (1) by *in vitro* and *in vivo* metabolism studies to exist in blood as unchanged drug, symmetrical disulfide, captopril–cysteine and captopril–glutathione mixed disulfides, and as captopril covalently bound to plasma albumin by S—S linkages. It has been reported that the plasma proteins and mixed disulfides with endogenous thiol compounds may act as a reservoir from which captopril is liberated over time to exert pharmacological effects (2, 3).

Several methods for determining captopril have been re-

ported, including GC–MS (4), GC (5), and HPLC (6–8). However, total captopril in plasma can be determined only after reduction of captopril disulfides and drug covalently bound to proteins. Tri-*n*-butylphosphine, used for reduction of captopril disulfides in urine (6), is also effective in plasma because it can penetrate the hydrophobic regions of proteins (9).

A rapid and simple analytical method is needed for measuring microgram levels of captopril plus disulfide metabolites in the plasma of patients during prolonged therapy (8), when the drug accumulates. Since all published methods for determination of captopril require expensive instrumentation not available to small hospital laboratories, a fluorometric method for measuring captopril plus disulfide metabolites in plasma has been developed.

EXPERIMENTAL SECTION

Apparatus—Fluorometric measurements were performed on a spectrofluorometer[1]. Samples were shaken on a heavy-duty shaker[2]. A centrifuge[3], 150- and 200-mm test tubes and plastic screw caps with polytef-faced rubber liners[2], 20-mL scintillation vials[2], C_{18} cartridges[4], 10-mL plastic syringes with 21-gauge needles, XAD-2 columns[5], and a water bath[6] set at 50°C were used.

Reagents—Acetone, toluene, hydrochloric acid, phosphoric acid, dimethylformamide, Tris buffer, urea, dibasic sodium phosphate heptahydrate, EDTA, and diethylenetriaminepentaacetic acid were reagent grade. 1-(7 - (Dimethylamino)-4-methyl-2-oxo- 2*H* -1-benzopyran-3-yl)-1*H*-pyrrole-2,5-dione reagent[7] (10 mg dissolved in 10 mL of acetone) was stable in a refrigerator for at least 1 year. A 20% v/v solution of tri-*n*-butylphosphine[8] was prepared in a fume hood by diluting 2 mL of the reagent with 8 mL of acetone.

A 0.1 M, pH 8.2, buffer was made by dissolving 12.1 g of Tris in 980 mL of distilled water; the pH was adjusted with phosphoric acid, and the buffer was diluted to 1 L with distilled water. Urea buffer, for reduction, was prepared daily by dissolving 20 g of urea in 0.1 M, pH 8.2, Tris buffer and diluting to 50 mL. HCl (0.1 M) with EDTA was prepared by adding 100 mg of the disodium salt per liter of acidic solution. A 0.05 M, pH 6.9, phosphate–dimethylformamide buffer was made by dissolving 20 g of dibasic sodium phosphate heptahydrate and 100 mg of diethylenetriaminepentaacetic acid in 650 mL of distilled water and adding 350 mL of dimethylformamide; the pH was adjusted with phosphoric acid. Column activator concentrate[5], 35 mL, was diluted to 500 mL with distilled water and kept in a refrigerator. Plasma was prepared from whole blood using citric acid as anticoagulant. A captopril disulfide[9] standard solution (20 μg/mL) was prepared in methanol and kept in a refrigerator no longer than 3 months.

	4.0	3.90	97.5
	2.0	1.93	96.5
Plasma Blank	0	0	—

Preparation of Columns—The protective cotton was removed from an XAD-2 column, and the column was placed on a 200-mm test tube. The diluted column activator (5 mL) was passed through the column, and the column was washed with 5 mL of 0.1 M HCl containing EDTA. Before use, a 21-gauge syringe needle was placed on the tip of the column. Columns were prepared on the day used.

Reduction—Plasma samples and one plasma blank were thawed, and 1.0 mL was transferred to a 20-mL scintillation vial. Urea buffer (5 mL) was added to each vial, followed by 0.1 mL of 20% tri-*n*-butylphosphine solution. Captopril disulfide standard solution (0.10 mL) was added to the plasma blank. The scintillation vials were covered with tin-lined plastic caps, and the samples were mixed on a vortex mixer. The vials were placed in a 50 ± 3°C water bath with the water level at half the height of the vials. The reduction was allowed to take place in the dark for 1 h.

Isolation, Purification, and Derivatization—The samples and standard were removed from the water bath and 5 mL of 0.66 M phosphoric acid was added immediately to each vial. The vials were capped and gently inverted four times to mix the acid. The solutions were decanted onto separate activated XAD-2 columns. Five milliliters of 0.1 M HCl containing EDTA was added to each vial, and the vials were then gently inverted four times.

After each sample passed through a column, the 0.1 M HCl wash was decanted onto the appropriate column. After all the wash had passed through the columns, the syringe needles were removed. The columns were washed with 10 mL and then 20 mL of 0.1 M HCl, placed on 150-mm screw-cap culture tubes, centrifuged at ~1000 rpm for 4 min, and then placed on clean 150-mm screw-cap culture tubes containing 0.1 mL of the reagent. To each column, 10.0 mL of 0.05 M pH 6.9 buffer was added. From time to time, the eluates were gently mixed with the reagent during elution[10]. The reagent blank was prepared in a 150-mm screw-cap culture tube by adding 10 μL of the reagent solution to 1.0 mL of 0.05 M pH 6.9 buffer and mixing.

Extraction of Captopril Derivative—After 10 min, 1.0 mL of each sample and the standard were transferred to 150-mm screw-cap culture tubes. One milliliter of 1.98 M phosphoric acid and 10.0 mL of toluene were added to each sample, standard, and blank. The tubes were shaken on a shaker for 5 min and centrifuged at ~1800 rpm for 5 min.

Purification on C_{18} Cartridges—A C_{18} cartridge was attached to a 10-mL syringe with the plunger removed. The syringe with the cartridge was placed on a 200-mm test tube, and 8.0 mL of toluene extract was transferred to it. The solution passed through the column by gravity; occasionally it was necessary to initiate flow through the cartridge with a plunger. After all the extract passed through the cartridge, 5 mL of toluene was added. At the end of the washing, the remaining toluene was forced out with the plunger and discarded. Each cartridge and syringe was placed on a fresh 200-mm test tube. Dimethylformamide (5.0 mL) was added to each syringe. The solvent was allowed to pass through the column by gravity, and at the end of the elution, the remaining solvent was forced out with the plunger. The eluates were mixed on the vortex mixer.

Fluorescence Measurement and Calculations—Fluorescence of the samples and standard was measured at an excitation wavelength of 380 nm and a fluorescence wavelength of 440 nm using the reagent blank to set the instru-

[10] Sometimes it is necessary to initiate flow through the columns by pressure from the palm of the hand or a rubber bulb.

ment to zero fluorescence. The concentration of captopril per milliliter of plasma was calculated from the concentration and fluorescence of a captopril disulfide standard with the same instrument settings used for the sample and standard measurements.

RESULTS AND DISCUSSION

Captopril has no native fluorescence and a very low absorbance in the UV region. Fluorescence can be obtained by reacting captopril with maleimide derivatives such as *N*-(*p*-2-benzimidazolyl)phenylmaleimide, *N*-(3-pyrene)-maleimide, *N*-[*p*-(2-benzoxozolyl)phenylmaleimide, and 1-(7-(dimethylamino)-4-methyl-2-oxo-2*H*-1-benzopyran-3-yl)-1*H*-pyrrole-2,5-dione which react with the sulfhydryl group. Because of low water solubility, none of these reagents can be used for reaction of captopril in blood.

Among fluorescent-labeling sulfhydryl reagents, 1-(7-(dimethylamino)-4-methyl-2-oxo-2*H*-1-benzopyran-3-yl)-1*H*-pyrrole-2,5-dione was selected for analysis of captopril in serum. It provides good sensitivity and is stable during all steps of the procedure. The synthesis of this reagent was described by Machida *et al.* (10).

Captopril reacts with the reagent on a mole per mole basis. Excess reagent was used to speed up the reaction and to account for some impurities in column eluates, which can consume the reagent. The reaction of captopril with the reagent under the assay conditions was complete in ~15 min. The reaction product is stable in the mixture for at least 1 h. When solutions are acidified and stored in a refrigerator, the product is stable for at least 24 h.

The fluorescent adduct can be extracted from acidified solutions with many water-immiscible solvents such as ethyl acetate, toluene, and dichloromethane. Toluene was chosen because of its selectivity; it extracts very few impurities from aqueous reaction solutions. The captopril–reagent derivative is stable in toluene for at least 24 h, and the adduct can be absorbed quantitatively from toluene onto C_{18} cartridges. The excitation and fluorescence maximum wavelengths of the captopril–reagent adduct vary with the solvent. In dimethylformamide it is 380/440 nm.

Standard curves were prepared in the ranges of 0–1 μg and 0–10 μg of captopril/mL of plasma. Concentrations in the ranges tested produced straight lines that passed through the origin. Data for the standard curves are given in Table I.

The sulfhydryl group of captopril is very reactive. It can react with blood components or be oxidized to captopril disulfide and mixed disulfides. If the sulfhydryl group is not protected immediately after blood is drawn from the patient, the free captopril is oxidized to disulfides. A considerable amount of captopril is covalently bound to plasma proteins.

In vitro experiments show that when ^{14}C-labeled captopril, symmetrical disulfide, and captopril–cysteine mixed disulfide were added to plasma, after 1 week of storage at 5°C, 32% of captopril was covalently bound to plasma proteins and 68% remained as disulfides. In samples stored at −20°C, 68% of the captopril was bound to plasma proteins and 32% remained as disulfides. After 4 weeks of storage, 62% of captopril was bound to plasma proteins at 5°C and 87% at −20°C.

Interchange between the —SH groups of plasma proteins and captopril disulfides can occur. After 4 weeks of storage at 5°C and −20°C, a complete interchange between captopril and captopril–cysteine occurred; 43% of captopril was interchanged for symmetrical captopril disulfide. The *S*-methyl metabolite of captopril is stable in plasma.

To determine total captopril in plasma with the reagent, samples have to be reduced. Tri-*n*-butylphosphine was chosen as the reducing agent because it is a potent agent for the cleavage of captopril disulfide, captopril mixed disulfides, and drug covalently bound to proteins. One mole of tri-*n*-butylphosphine reduces 1 mol of disulfide, and the reaction is relatively rapid and quantitative.

The reduction of disulfides with tri-*n*-butylphosphine is pH and temperature dependent. Almost complete reduction of captopril disulfide is obtained in solutions at pH >8. It takes ~30 min to reduce captopril disulfide with 20 mg of tri-*n*-butylphosphine/mL of plasma at 50°C and ~45 min to reduce captopril bound to proteins. About 96% of the drug is reduced at this concentration. With 2 mg of tri-*n*-butylphosphine/mL of plasma, only 50% reduction is obtained. At room temperature, only ~85% of the plasma sample is reduced. Increasing the temperature to 70°C does not have any effect on the reaction. The volume of urea–Tris buffer up to 10 mL has no effect on the reduction efficiency. However, volumes of plasma >1 mL cause incomplete reduction of captopril disulfides.

Captopril was isolated from the tri-*n*-butylphosphine mixture and purified on XAD-2 resin before it was treated with the reagent. Captopril was retained on XAD-2 resin, while other compounds containing the sulfhydryl group passed through the column. The optimum pH for adsorption of captopril on XAD-2 resin is 0.5–2.5. The adsorptive power of the resin is optimized by the incorporation of a column prewash using an activator solution.

The unimpeded flow rate of the diluted sample through the column would be ~5 mL/min. This is too fast for complete retention of the drug on the resin. The flow rate is reduced to ~1 mL/min with a 21-gauge syringe needle.

Captopril can be quantitatively eluted from XAD resin with dioxane, methanol, ethanol, ethyl acetate, acetonitrile, acetone, isopropyl alcohol, tetrahydrofuran, dichloromethane, chloroform, and other solvents. Some of them elute interfering compounds. However, captopril does not react with fluorescent labels in any of these solvents; it reacts only in aqueous solutions. Removal of organic solvents by evaporation, even under controlled conditions, results in the oxidation of captopril. A 0.05 M phosphate buffer containing dimethylformamide proved to be a suitable eluant. It elutes captopril quantitatively from XAD-2 resin and provides a proper pH and medium for the reaction with the reagent. Up to 35% dimethylformamide does not interfere with the reaction. About 10 mL of dimethylformamide–phosphate buffer, pH 6.9, is needed for complete elution of captopril; ~2 mL of solvent is retained by the column. Therefore, before and after elution, columns must be centrifuged. Captopril is eluted from columns into tubes containing ~100 μg of reagent to prevent reoxidation of the drug. However, if needed, samples can be first eluted, gently mixed by four inversions, and 1 mL of eluate treated with 10 μg of the reagent.

Samples have to be further purified by extraction of the captopril–reagent derivative from the acidic solution with toluene. For complete extraction of the adduct, the ratio of aqueous solution to toluene should be 1:10. Excess reagent and some remaining impurities are removed with C_{18} cartridges. The

Table IV—Total Captopril in Human Plasma Measured by Fluorometric and GC–MS Methods [a]

Patient	Total Captopril, ng/ml		Δ (GC–MS − Fluorometry)	$\frac{\Delta}{\text{Mean}} \times 100$, %

[a] Patients received 100 mg of captopril orally.

captopril-reagent derivative adsorbs onto the cartridge packing from toluene and can be eluted with dimethylformamide.

A plasma sample with standard captopril disulfide (2 μg/mL) is run along with samples to compensate for incomplete reduction. If high (off scale) fluorescence readings from the sample are obtained, eluates from the cartridges can be diluted to proper concentration with dimethylformamide.

Recovery experiments were carried out by addition of various concentrations of captopril, captopril disulfide, captopril-cysteine disulfide, or captopril-glutathione disulfide to plasma. These were kept at room temperature for 4 h then stored at 5°C overnight. Results are shown in Table II. Recoveries ranged from 95 to 104%.

Reproducibility was checked by performing six assays of a plasma sample spiked with captopril disulfide at 2 μg/mL (Table III). Precision at this concentration is 1.7% (*CV*).

Results obtained by the fluorometric method were compared with those obtained by the GC–MS method (Table IV). The data were correlated by linear regression analysis, which yielded an intercept of 5.6, a slope of 0.9914, and a correlation coefficient of 0.9949. Agreement between the methods is acceptable.

Although the fluorometric method is very sensitive (because as little as 2 ng of a pure captopril standard/mL of dimethylformamide solution can be accurately measured in a 1-cm cell, without HPLC separation), the method can be used for measuring captopril in plasma containing >200 ng of the drug/mL. Therefore, it is suitable for patients who accumulate captopril during extended therapy and have microgram per milliliter levels of captopril plus disulfide metabolites in plasma. It can be especially useful to the small hospital laboratory which does not have expensive instrumentation (such as GC–MS) available.

Reverse-Phase High-Performance Liquid Chromatographic Determination of Halogenated 8-Hydroxyquinoline Compounds in Pharmaceuticals and Bulk Drugs

EDWARD J. WOJTOWICZ

Received August 23, 1983, from the *Food and Drug Administration, 599 Delaware Avenue, Buffalo, NY 14202.* Accepted for publication December 6, 1983.

Abstract □ A reverse-phase high-performance liquid chromatographic (HPLC) method was developed for determining iodochlorhydroxyquin, 5,7-dichloro-8-hydroxyquinoline, and 5,7-diiodo-8-hydroxyquinoline in creams, ointments, shampoos, tablets, and bulk drugs. A column packed with 10-μm phenyl-silica and a mobile phase of 0.001 M $NiCl_2$ in acetonitrile–methanol–water (30:20:50) was used to separate the nickel complexes of the three drugs, with detection at 273 nm. Analysis of creams, ointments, shampoos, and tablets gave results close to the label declarations. Recovery of standard material added to samples was ≥98%. Linearity of response was shown over a range of 30–150% of label claim for standards of the three drug substances. Multiple analyses of iodochlorhydroxyquin and diiodohydroxyquinoline bulk drugs showed purities of 99.96 and 98.77% with *CV* of 1.17 and 0.73%, respectively. The HPLC method offers an alternative to current USP procedures, which lack stability-indicating and specificity characteristics.

Keyphrases □ HPLC—Halogenated 8-hydroxyquinoline compounds □ 8-Hydroxyquinoline—halogenated, HPLC

The current USP XX IR spectrophotometric procedure (1) for determining iodochlorhydroxyquin (I) in creams and ointments has many deficiencies, as reported by Gruber *et al.* (2), who used GC to determine trimethylsilyl ether derivatives of related halogenated 8-hydroxyquinolines. A colorimetric procedure (3) complexed I with nickel ion. However, other 8-hydroxyquinolines, present as impurities, would interfere to give high results. A normal-phase high-performance liquid chromatographic (HPLC) procedure (4) involved esterification of I using a mixture of pyridine–acetic anhydride, an evaporation step, and a reconstitution of the residue in the mobile phase. Procedures using anion-exchange HPLC (5, 6) and reverse-phase HPLC (7, 8) failed to adequately separate I from other 8-hydroxyquinolines.

In this study, a simple and specific reverse-phase HPLC method was developed to separate and quantitate iodochlorhydroxyquin (I), 5,7-dichloro-8-hydroxyquinoline (II), and 5,7-diiodo-8-hydroxyquinoline (III) as their nickel complexes

in bulk drug form and in pharmaceuticals. The HPLC system also resolved I, II, and III from 5-chloro-8-hydroxyquinoline (IV) and 8-hydroxyquinoline (V), which are precursors in the syntheses of bulk forms of the drugs.

EXPERIMENTAL SECTION

Materials—Nickel chloride hexahydrate[1], iodochlorhydroxyquin[2], 5,7-dichloro-8-hydroxyquinoline[3], 5,7-diiodo-8-quinolinol[2], 5-chloro-8-hydroxyquinoline[4], 8-hydroxyquinoline[4], and diphenylamine[5] were used as received. Methanol[6], acetonitrile[6], and tetrahydrofuran[6] were distilled in glass.

Chromatographic System—The liquid chromatographic system consisted of a high-pressure pump[7], a variable-wavelength UV detector[8], an integrator-recorder[9], and a phenyl column (10 μm, 30 cm × 3.9 mm)[10]. The mobile phase, 0.001 M $NiCl_2$, was prepared in acetonitrile–methanol–water (30:20:50) and filtered before use. The flow rate of the mobile phase was 1.2 mL/min. The detector was set at 273 nm and at a range of 0.1 AUFS. The integrator-recorder was used at an attenuation setting equal to 8 mV, a threshold value of 3, and a peak width setting of 0.16 in the peak height measuring mode.

Quantitative Procedure for Iodochlorhydroxyquin (I)—Ointment or cream samples containing an equivalent of 30 mg of I were dissolved with heating in 40–50 mL of tetrahydrofuran. The solutions were quantitatively transferred to 100-mL volumetric flasks and diluted to volume with tetrahydrofuran. An accurately weighed 30-mg portion of USP standard I was transferred to a 100-mL volumetric flask and diluted to volume with tetrahydrofuran. Five-milliliter aliquots of sample and standard preparations were transferred to separate 50-mL volumetric flasks. One milliliter of a 10-mg/mL methanolic solution of nickel chloride was added to each flask, and the flasks were shaken to disperse the reagent.

The complex formed between nickel and I produced a yellow solution. An internal standard solution of 80 mg of diphenylamine in 200 mL of methnol was prepared, and 5.0-mL portions were transferred into each 50-mL flask. The petrolatum base in ointments or creams precipitated when the internal standard solution was added. The flasks were diluted to volume with methanol. Injections were made from the final standard and filtered sample solutions. Peak height response relative to the internal standard was used to calculate the amount of I in the samples.

Quantitative Procedure for II—An accurately weighed portion of a shampoo, containing an equivalent of 30 mg of II, was dissolved with heating in 40–50 mL of methanol. The solution was quantitatively transferred to a 100-mL volumetric flask and diluted to volume with methanol. A standard of 30 mg of II was accurately weighed into a 100-mL volumetric flask and diluted to volume with methanol. Two-milliliter aliquots of the sample and standard preparations were transferred into separate 50-mL volumetric flasks. One milliliter of the methanolic nickel chloride reagent and 3.0 mL of the internal standard solution were added to the sample and standard flasks. The solutions were diluted to volume with methanol, and the samples were filtered before HPLC. Peak height response relative to the internal standard was used to quantitate II.

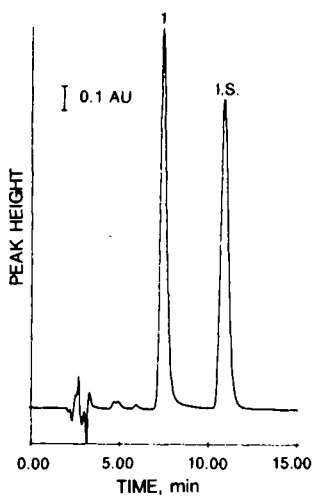

Figure 2—*Chromatogram of ointment preparation of iodochlorohydroxyquin (1) and diphenylamine (I.S.), at a detector setting of 0.1 AU and 273 nm.*

Quantitative Procedure for III—An accurately weighed portion of cream equivalent to 20 mg of III was dissolved with heating in 40–50 mL of tetrahydrofuran. The solution was quantitatively transferred to a 100-mL volumetric flask and diluted to volume with tetrahydrofuran. For the tablet form, 20 tablets were accurately weighed and finely powdered. An accurately weighed portion of the ground composite equivalent to 200 mg of III was transferred to a 250-mL volumetric flask with ~150 mL of tetrahydrofuran. The flask was heated on a steam bath for a few minutes and then shaken for 30 min on a mechanical shaker. After dilution to volume with tetrahydrofuran, a 25-mL aliquot was diluted to volume with tetrahydrofuran in a 100-mL volumetric flask. An accurately weighed 20-mg portion of standard III was diluted to volume with tetrahydrofuran in a 100-mL volumetric flask. Five-milliliter aliquots of the sample and standard preparations were transferred into separate 50-mL volumetric flasks, and 1 mL of the methanolic nickel chloride reagent and 3.0 mL of the internal standard solution were added to each flask. After dilution to volume with methanol, the standard preparation and filtered samples were chromatographed. Peak height response relative to the internal standard was used to quantitate III in the samples.

samples were diluted to volume with tetrahydrofuran in 100-mL volumetric flasks and treated similarly to the cream and ointment samples after appropriate dilution.

System Suitability—The HPLC system in this study was suitable when a resolution factor of at least 1.5 was obtained between the sample and internal standard peaks, and a relative *SD* of ≤2% was achieved for the response ratio of the two peaks after five replicate injections.

RESULTS AND DISCUSSION

Early in this study, it was evident that iodochlorhydroxyquin (I) needed to be chemically modified to obtain a satisfactory reverse-phase high-performance liquid chromatogram. This modification had to be quantitative and easy to accomplish for analytical method application.

The formation of chelate complexes of 8-hydroxyquinolates with bivalent inorganic ions was explored. Salts of zinc and bivalent nickel, copper, and cobalt were used as complexing agents for I. Reverse-phase HPLC of methanolic solutions of these complexes, through octadecylsilane columns of 5- and 10-μm particle sizes with mobile phase composed of combinations of methanol, water, acetic acid, and various ion-pairing chemicals, was unsuccessful.

Reverse-phase HPLC has been used with a mobile solvent system containing nickel acetate to determine aniline and its metabolites (9). The use of bivalent metal ion salts in the mobile phase was investigated for the chromatography of chelate complexes of I. When a mobile solvent system of 0.01 M $NiCl_2$ in

[a] HC = hydrocortisone.

methanol–water (75:25) was used, I eluted from a C_{18} column with some tailing.

Substitution of a phenyl-bonded column, addition of acetonitrile to the mobile phase, increase of the water content in the mobile phase to 50%, and reduction of the nickel salt concentration to 0.001 M yielded an HPLC system which separated the nickel complexes of five related standard hydroxyquinolates. This chromatographic system was used to quantitate I, II, and III in pharmaceuticals. Diphenylamine was chosen as the internal standard because it absorbed in the same UV region as the complexes and was adequately separated from the Ni–III complex, which was the last to elute from the column (Fig. 1).

Tetrahydrofuran was chosen as the solvent for petrolatum-based creams or ointments and tablet formulations of I and III. Methanol was used with a shampoo containing II. Warming the samples in the appropriate solvent on a steam bath aided in dispersing the samples and dissolving the active ingredients. Warming the initial standard preparations ensured their complete dissolution.

Addition of the methanolic nickel chloride solution to aliquots of the sample and standard preparations resulted in the immediate formation of the yellow organometallic complex. The metal salt was added in ≥10-fold excess for complete complexation. Addition of the methanolic solution of the internal standard, and dilution with methanol to volume, caused precipitation of the petrolatum in ointment or cream samples and necessitated filtration of these samples before chromatography.

The absorbance maximum for the Ni–I complex was 273 nm; this wavelength was also used in determining the nickel complexes of II and III. The presence of hydrocortisone or formulation excipients in ointments and creams did not interfere with sample analysis. Hydrocortisone eluted in ~4.8 min from the column and had a low absorbance at 273 nm. Figures 2 and 3 are typical chromatograms obtained from ointment and cream preparations of I and III formulated with hydrocortisone. Figure 4 is a chromatogram of a shampoo containing II.

Table I gives the results of duplicate analyses of different lots of preparations containing I, II, and III. Close agreement with label claim is evident. Recoveries for standards added to the prepared samples are listed in Table II. Recoveries of ≥98% were obtained for each added standard.

Linearity of response was tested by preparing a standard curve for five different concentrations of standards of I, II, and III. A correlation coefficient of 0.999 was obtained for each standard over a range of ~30–150% of the label claim, based on sample preparation using the proposed procedure.

Bulk drug samples of I and III were analyzed five times. An average purity of 99.96% with a 1.17% *CV* was obtained for I, while the bulk sample of III had an average purity of 98.77% and a *CV* of 0.73%.

The high selectivity and efficiency achieved by the use of metal ions in mobile solvents for reverse-phase HPLC have been attributed to secondary chemical equilibria (10). These secondary chemical equilibria control retention time and peak symmetry, and, if chromophoric counterions are used, detection will be enhanced. When nickel ion was absent from the mobile phase used in this study, no peaks were detected when a mixture of nickel complexes was injected into the column. Addition of the metal ion and adjustment of acetonitrile content resulted in a well-resolved chromatogram. The solvation effect of the acetonitrile in the mobile phase gave the eluting peaks a symmetry that was lacking in systems of water–methanol solutions of the nickel salt.

The use of metal ion salts in reverse-phase HPLC should find increasing application in research involving biochemical and pharmaceutical substances. The method presented here is stability indicating because possible decomposition products and impurities are separated from the parent compound, and the method is an alternative for the current official USP procedures (1,

11) for assaying and identifying I and III in bulk drug form or pharmaceutical preparations.

Distribution and Elimination of Coated Polymethyl [2-^{14}C]Methacrylate Nanoparticles After Intravenous Injection in Rats

DANIEL LEU *§, BARBARA MANTHEY ‡, JORG KREUTER §, PETER SPEISER §, and PATRICK P. DeLUCA *x

Received March 11, 1983, from **The University of Kentucky College of Pharmacy, Lexington, KY 40536* and the §*School of Pharmacy, Swiss Federal Institute of Technology, CH-8603 Schwerzenbach, Switzerland.* Accepted for publication October 28, 1983. ‡Present address: Institute of Toxicology, Swiss Federal Institute of Technology, CH-8092 Zurich, Switzerland.

Abstract □ Surfactant-coated polymethyl [2-^{14}C]methacrylate nanoparticles had significantly different time-course distribution patterns in rats than noncoated and albumin-coated particles. Blood concentrations of poloxamer 188-coated particles were 70-fold higher after 30 min, and the particles persisted at higher levels in the circulation for up to 2 h. The initial and final liver levels were significantly lower (38% after 30 min, 51% after 7 d) and spleen levels were significantly higher (21% after 30 min, 23% after 7 d) than noncoated particles (74% in the liver and 5% in the spleen after 7 d) and the albumin-coated particles (84% in the liver and 5% in the spleen after 7 d). Specific activity was somewhat higher for the surfactant-coated particles in other organs such as the lungs, kidneys, testicles, ovaries, and lymph nodes. The bovine serum albumin sorption behavior of polymethyl methacrylate nanoparticles was followed under various conditions, and adsorption was found to increase with increasing protein concentration and increasing temperature, reaching a maximum at the isoelectric point of pH 4.9 after ~12 h of incubation. The zeta potential of the particles decreased with increasing pH, and the change was more pronounced with the albumin-coated particles.

Keyphrases □ Polymethyl methacrylate—^{14}C-labeled nanoparticles, distribution and elimination in rats, intravenous injection □ Distribution—^{14}C-labeled polymethyl methacrylate nanoparticles, intravenous injection, rats □ Elimination—^{14}C-labeled polymethyl methacrylate nanoparticles, intravenous injection, rats

There is growing interest in polymeric drug-delivery systems for parenteral administration to provide sustained release and action, and to increase the stability of easily metabolized drugs (1, 2). Nanoparticles (10 nm–1 μm) have been suggested as new drug-delivery systems (3–6). The goal is to develop a system to direct potent drug molecules to specific organs or cells, thereby limiting the systemic levels and potential toxicity to healthy or normal tissues and cells.

Polymethyl methacrylate has been used in surgery for over 30 years as a material for artificial bones (7). Implanted methyl methacrylate polymers appear to be well tolerated if the implants are monomer-free and under a certain threshold size (8). However, little is known about the biodegradability and the elimination of polymethyl methacrylate particles from the body. Nanometer-size particles exhibit a much larger surface area than the implants used in previous studies (9, 10) and are expected to degrade much faster. Information on the long-term effects of acrylic polymer particles on the living cell, however, is scarce (11).

It is generally accepted that polymers in the form of nanometer-size particles are mainly taken up by the cells of the reticuloendothelial system, predominantly in the liver and spleen. It was found that 70% of polymethyl [2-^{14}C]methacrylate nanoparticle radioactivity localized in the liver of rats 7 d after intravenous administration in phosphate-buffered saline (12). The clearance of labeled polystyrene divinylbenzene microspheres (3–25 μm) from the blood was size-dependent in beagle dogs (13, 14). Microspheres of ≥8 μm were mechanically filtered and retained in the lungs, while smaller spheres cleared the lungs and localized in the liver and spleen. Although the effect of physicochemical surface properties on distribution has been recently reported (15), the possible long-term effects associated with retention of particulate matter in the body tissues have not been studied.

Emulsifying agents have been found to affect the fractional removal rate of lipid emulsions from the blood stream (16, 17). Since emulsifying agents appear to play a major role in the removal of lipid substances from the blood stream, it was anticipated that adsorbed surfactants also influence the clearance of polymethyl methacrylate nanoparticles from the blood. Other workers have demonstrated the significance of plasma components with respect to the uptake of particulate polymeric matter by cells of the reticuloendothelial system and, accordingly, in the clearance from the blood and subsequent organ distribution (18, 19). Distribution in various organs has been reported to be influenced by the surface charge of the particles. Microspheres with adsorbed positively charged proteins (18) and nonionic surfactant (15) show a decreased uptake by the liver.

22 h	24.0 ± 8.6%	

[a] Mean of four determinations. The statistical dispersion is given as the *SD* in percent of the mean value. The values are percent of albumin adsorbed from solution, except particle concentration (mg of albumin/mg of particles).

In a previous study, polymethyl methacrylate nanoparticles of ~150 nm were found to accumulate in the lungs in relatively high concentrations 30 min following intravenous administration (12), presumably due to agglomeration of the particles. This paper presents information on the fate of surface-coated polymethyl [2-^{14}C]methacrylate nanoparticles after intravenous injection in rats. Before the animal experiments, the adsorption of the nanoparticles to bovine serum albumin and the resulting surface charge (zeta potential) were determined.

EXPERIMENTAL SECTION

Preparation of ^{14}C-Labeled Nanoparticles—The nanoparticles were prepared as previously described (12) and freeze-dried from a suspension in 0.15 M phosphate-buffered saline. The polymer had a specific activity of 4 mCi/g[1]. The freeze-dried powder contained 56.3% of buffer salts (dibasic sodium phosphate dihydrate-monobasic potassium phosphate-sodium chloride (7.6:1.45:4.8, w/w/w) and 43.7% of polymethyl [2-^{14}C]methacrylate. Particle size determination by photon correlation spectrometry[2] (20) revealed an average diameter of 131 ± 30 nm.

***Preparation of the* Suspension**—*Reference Group*—Nanoparticle-buffer preparation (220 mg) was suspended in 11 mL of distilled water and 33 mL of phosphate-buffered saline, to give a suspension of 2.185 mg of nanoparticles/mL and ultrasonicated for 5 min at 20 kHz in a sonicator cell disrupter with a micro tip[3].

Surfactant Group—The nanoparticle preparation (220 mg) was suspended in 11 mL of 0.5% (w/v) poloxamer 188[4] in water and 33 mL of 0.5% (w/v) poloxamer 188 in phosphate-buffered saline and ultrasonicated.

Protein Group—The nanoparticle preparation (220 mg) was suspended in 76 mL of a 3% (w/v) solution of rat serum albumin[5] in 0.145 M phosphate buffer (pH 4.9), incubated in an end-over-end shaker (22 rpm) at 37°C for 12 h, and then centrifuged at 30,000×g_{ave}[6]. The protein-coated particles were washed twice with 0.145 M phosphate buffer (pH 4.9) and then suspended in 44 mL of phosphate-buffered saline and sonicated. The protein adsorbed was 8.2% from the solution, measured by UV absorbance at 280 nm. This corresponds to 1.92 mg of albumin/mg of nanoparticles. The adsorption of protein was irreversible since protein was not detected in the washings or phosphate-buffered saline suspensions.

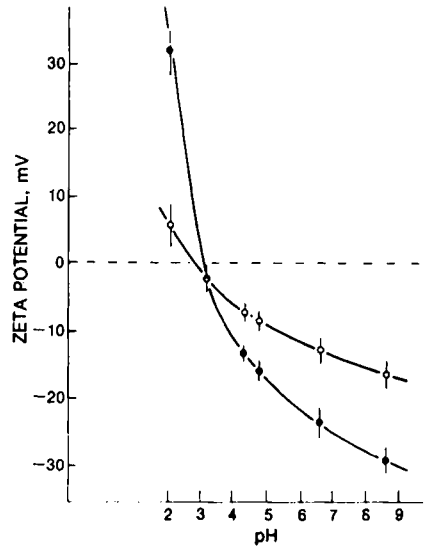

Figure 1—*The influence of pH on the zeta potential of noncoated (○) and protein-coated (●) polymethyl methacrylate nanoparticles. Each value is the mean of 10 measurements; the vertical lines represent* SD.

Specific Activity of the Suspensions—Five 1:1000 dilutions of each suspension and 0.175 mL of a combustion aid[7] were combusted in an oxidizer[8]. The resulting carbon dioxide was absorbed in 7 mL of an absorption medium[9]. This medium was then mixed with 15 mL of scintillation cocktail[10] and the ^{14}C-radioactivity was measured in a liquid scintillation counter[11]. The specific activities of the suspensions were calculated using a quench curve (19) and the following values were obtained: (*a*) reference group: 7.76 ± 0.39 μCi/mL; (*b*) surfactant group: 8.59 ± 0.48 μCi/mL; (*c*) protein group: 6.85 ± 0.16 μCi/mL.

Protein Binding Studies—Experiments were conducted to determine suitable conditions for the adsorption of albumin to the nanoparticles. The parameters assessed were particle concentration, protein concentration, temperature, time of incubation, and pH of the incubation solution. The nanoparticle suspensions were incubated in a solution of bovine serum albumin[12] in 0.145 M phosphate-buffered saline at a constant temperature in glass tubes which were rotated end over end. The suspensions were centrifuged, and the protein concentration in the supernatant was determined by measuring the absorbance at 280 nm. This method was verified by the Lowry test (21).

Surface Charge—The zeta potential of nanoparticle suspensions at different pH values (before and after the adsorption of bovine serum albumin) was calculated after measuring the microelectrophoretic mobility of small particle-agglomerations in a phosphate buffer (ionic strength 0.01 M) with a zeta meter[13]. An optimal particle concentration for tracking in the electrophoretic cell was 25 ppm. Ten particles (or small particle-agglomerations) were counted for each value at a voltage of 100 V. Measurements were not made of particles suspended in different solutions of two surfactants, poloxamer 188 and polysorbate 80[14], because these preparations did not show any agglomerations in a zeta-meter-suitable microscope and, therefore, were not detectable.

Injection—Groups of four (two male and two female) randomly-selected Wistar rats (203–335 g) were used for each suspension and for each time point (0.5, 2, 24 h, and 7 d). The rats were anesthetized with ether and then restrained in a supine position on a hard board. After exposing the femoral vein with sterile instruments, the animal was injected with the nanoparticle suspension using a 26-gauge needle attached to a plastic syringe at a rate of 1 mL/min. Immediately before injection the suspensions were ultrasonicated at 20 kHz for 20 s. The injection dose was 60 μCi/kg of bodyweight (~2

[a] Mean ± *RSD* percent of the administered dose; $n = 4$. The specific activity is the percent of administered dose per gram of tissue (wet weight) or milliliter of blood. The blood volume was assumed to be 64.1 ± 9 mL/kg (24). The 24-h and 7-d values include the elimination by urine and feces (see Table IV). [b] Key: (Ref) untreated particles; (Sur) particles treated with surfactant; (RSA) particles coated with rat serum albumin. [c] Without bronchia. [d] Without tubes. [e] One gram (wet weight).

mL/animal). The incision was sealed with aluminum wound clips and rinsed with an iodine solution.

Organ Distribution and Elimination of ^{14}C-Radioactivity—The animals were anesthetized with ether and injected with an overdose of sodium pentobarbital [100 mg/kg ip of a 2% aqueous solution (22)]. After ~5 min, the abdomen and chest were opened and a blood sample was taken from the vena cava. The vena cava was then cut, and the blood was drained. The liver, lungs, spleen, kidneys, testicles or ovaries, and lymph nodes (from the mesenterium and cervix) were removed. The organs were washed with distilled water, and the connective tissue and fat was removed. The organs were weighed and stored at −20°C for further examination.

After injection, a corresponding group of animals was housed in metabolism cages for 7 d (food and water *ad libitum*). Urine and feces were collected in separate containers and removed every 24 h. Weighed urine and freeze-dried fecal samples were stored at −20°C for further examination.

The organs were homogenized with water (1:10) and an aliquot (0.001–0.5 of an organ, depending on the expected radioactivity) was combusted in an oxidizer. The resulting $^{14}CO_2$ was absorbed in 7 mL of absorption medium, mixed with 15 mL of scintillation cocktail, and analyzed in the liquid scintillation counter. Urine (0.5 mL) was mixed with 15 mL of scintillation cocktail[15] and analyzed in the scintillation counter. Freeze-dried feces was homogenized with water, and a sample of 100 mg was combusted with several drops of a combustion aid. The resulting $^{14}CO_2$ was analyzed in the manner described above for the organs. The percentages of the administered dose of nanoparticles in the organs, blood, and excreta were calculated using the standard values and quench curves (23).

RESULTS

Protein Binding Studies—The adsorption of bovine serum albumin to polymethyl methacrylate nanoparticles as a function of the parameters studied is shown in Table I. From these experiments, the following conditions were selected for protein-coating prior to the zeta potential measurements and the animal studies: concentration of serum albumin, 3.0%; particle concentration, 0.1%; time of incubation, 12 h; buffer, 0.145 M potassium phosphate (pH 4.9); temperature of incubation, 37°C.

Surface Charge—The influence of pH on the zeta potential of noncoated and protein-coated nanoparticles is shown in Fig. 1. The zeta potential decreased with increasing pH for both particle types, but the influence was greater on the coated nanoparticles.

Organ Distribution of ^{14}C-Radioactivity—Table II shows the distribution of ^{14}C-radioactivity in several organs [selected using the findings of Kreuter *et al.* (12)] after intravenous administration of the nanoparticles. The distribution behavior in the reference and protein-coated groups was similar, but, in most of the organs examined, the surfactant group showed a very different accumulation of particles. One fifth of the administered dose of the surfactant

[a] All values are mean ± *RSD* percent of the administered dose. [b] Key: (Ref) noncoated particles; (Sur) particles treated with surfactant; (RSA) particles coated with rat serum albumin.

group remained in the blood after 0.5 h. This was ~60 times more than that of the other groups. After 2 h, however, the blood level of the surfactant group was of the same order as that of the other groups.

After 0.5 h, 85% of the radioactivity was found in the liver in the reference and the protein groups. This value decreased to ~74% in the reference group but remained constant in the protein group. In the surfactant group, only ~38% was found in the liver after 0.5 h. This value increased to ~60% after 24 h and dropped to 51% after 7 d.

In the lungs, the accumulation after 0.5 h was 1.4% of the administered dose for the reference group. About three times as much was detected in the surfactant group; the value for the protein group was intermediate. The lung radioactivity remained constant for 24 h in the protein group, but it increased almost twofold in the other groups. In all groups, the clearance was essentially complete after 7 d.

In the spleen, the accumulation for the reference and the protein groups showed a similar value of ~4% after 0.5 h, which increased slightly to ~5% after 7 d. In the surfactant group, 21% of the injected dose was localized in the spleen after 0.5 h. This value increased to ~31% after 2 h and dropped to ~23% after 7 d.

In the other organs (kidneys, ovaries, testicles, and lymph nodes) the amount of radioactivity was <1% after 0.5 h, and the values decreased with time. The surfactant group showed a higher accumulation than the reference and protein groups for most values (Tables II and III). Although the absolute quantity in the testicles and ovaries was < 0.1% of the administered dose, higher concentrations of all particle suspensions were found in the ovaries. This higher affinity can be clearly demonstrated using the nanoparticle concentration, given in terms of specific activity, *i.e.*, percent of the dose per gram of organ (wet weight) (Table II). The spleen also showed a very high affinity for the surfactant-treated nanoparticles (3–15 times higher than in the other groups), whereas the affinity of the liver for surfactant-treated particles was significantly lower than the other groups. In all other organs (except the blood after 0.5 h), the specific activity was of the same order of magnitude for all preparations.

Elimination of ^{14}C-Radioactivity—The ^{14}C-elimination in urine and feces was followed for 7 d (Tables IV and V). In all groups, ~1% of the administered dose was excreted in the urine and 2–4% in the feces within 7 d. The majority of the ^{14}C-excretion was found after the first day.

DISCUSSION

It has been suggested that colloidal materials interact with blood components after injection into systemic circulation (13, 25–28). This interaction and coating with blood proteins may influence the subsequent organ distribution of these particles (28, 29). In investigating the sorption behavior of the nanoparticles in aqueous bovine serum albumin solutions, the amount of adsorbed protein was found to be higher with low particle concentrations and with high protein concentrations, as expected. The pH of the incubation medium influenced the adsorption; maximum adsorption was at pH 4.9, the isoelectric point of bovine serum albumin. This finding seems to be a general characteristic of proteinaceous solutions (30). The temperature, in the examined range of 4–37°C, showed only a small influence on the adsorption. Protein adsorption increased with incubation time up to 12 h, when equilibrium apparently occurred.

The greater influence of the pH on the zeta potential of the albumin-coated particles, compared to the noncoated particles, is probably caused by the protonation/deprotonation of the albumin amino groups, but the potential of the noncoated particles is influenced only by surface adsorption of protons or hydroxyl ions. Although a 10-mV difference in zeta potential was observed at pH 7.4, it is not possible to infer that this seemingly insignificant difference would influence body distribution. The effect of charge on distribution warrants further study.

While differences in the organ distribution among the three preparations were observed, the reference group and the protein group show generally the same distribution pattern. The albumin-coating procedure was conducted because albumin has been shown to prevent platelet adhesion and to enhance the biocompatibility of diverse materials (31, 32) and, therefore, was expected to lead to a significant change in the distribution of the particles. However, albumin coating did not alter the organ distribution significantly when compared to the noncoated particles. This suggests that injected noncoated particles soon become coated with serum proteins. Almost 90% of the administered dose in the reference and the protein groups accumulated in the liver and spleen. Since both organs are part of the reticuloendothelial system, this finding suggests that nanoparticles with incorporated or adsorbed antigens hold promise as adjuvants (3, 12). The only difference in the distribution behavior between the reference group and the protein group is that accumulation in the liver remained constant at ~85% in the protein group; in the reference group it decreased from 85% after 30 min to 74% after 7 d.

A distinctively different distribution pattern was obtained in the surfactant group. Only 38% of the administered dose was found in the liver after 30 min, and the accumulation was only 51% after 7 d. This is similar to results reported with poloxamer-coated polystyrene microspheres (15). The apparent loss from the liver between 1 and 7 d indicates some clearance and/or degradation phenomenon. Accumulation was significantly greater in the spleen for the surfactant group (21%) than in the other groups (<4%). After 2 h, the spleen levels increased to 31%, ~12 times higher than the noncoated group and 8 times higher than the protein group. As in the liver, the level of particles in the spleen decreased after 24 h to 13% and increased again to 23% within 7 d. No satisfactory explanation can be given for this oscillation in spleen levels.

Another distinct difference of the surfactant group is an apparent slower

blood clearance. About 21% of the administered dose still remained in the blood after 30 min, *versus* 0.3% for the other groups. Since nanoparticles may be preferentially taken up by tissues exhibiting enhanced endocytotic activity, such as tumor tissue (33, 34), a longer persistence of the particles in the circulatory system may enhance their potential for accumulation in cancerous tissue. Therefore, surface-treated nanoparticles may possibly be useful as carriers for toxic anticancer drugs.

The accumulation of nanoparticles in the lung was lower than that reported previously (12), in which particles similar to the reference group were used. In that study ~22% of the particles were localized in the lungs after 30 min, a value that decreased continuously to ~13% after 7 d, in this study only 1.4% was detected in the lungs after 30 min. After 24 h and 7 d, 3.3 and 0.2%, respectively, of the administered dose was found in the lungs. The surfactant and the protein groups showed similar lung accumulations of 3.8 and 2.3% after 30 min, respectively, and both values decreased to <1% within 7 d. This finding confirms that if agglomeration occurred, the clusters were small enough to pass through the capillary network in the lungs.

Coagulated particle clusters have been reported to be mechanically trapped by the lung capillaries (13, 14). However, these were clusters of microspheres >3μm in diameter. According to a recent review by Kreuter (28), particles in the submicron range, *i.e.*, 125 nm–1 μm, do not show any major differences in body distribution. It has also been shown that gentle mixing of polymethyl methacrylate nanoparticles with plasma will cause disintegration of particle clusters (20). It is, therefore, believed that the difference in the distribution behavior between surfactant-coated and noncoated particles was due to a difference in surface properties. The difference in the distribution behavior between the noncoated particles in this study and those used previously (12) can be attributed to certain refinements in methodology which minimized agglomeration tendencies. These refinements include sonication by means of a microtip immediately before each injection, as opposed to sonication of the total suspension in a bath-type sonicator ~20 min before the experiment. Additionally, in this study the particles were suspended in 2 mL of phosphate-buffered saline and injected over a period of 2 min into the femoral vein of animals anesthetized with ether; in the earlier experiment the particles were suspended in 0.5 mL and injected over 5–10 s into the tail vein without anesthetization.

The results of this study clearly demonstrate that surfactant-coated nanoparticles result in a slower blood clearance and a significantly different organ distribution after intravenous administration. The targeting of incorporated or adsorbed drugs to specific organs may, therefore, be influenced by pretreatment of the carrier particles with surface-active agents. More experiments with other surfactants are required to gain systematic information about factors that influence the distribution behavior of nanoparticles after intravenous injection. These factors include the surface charge as well as the chemical nature of the surface and, consequently, the agglomeration tendency of the particles. Although scanning electron micrographs of the coated particles did not reveal aggregation, they were not discernibly different from micrographs of noncoated particles. This study has revealed extended residence in the blood and differences in organ distribution patterns with coated nanoparticles. Therefore, physicochemical characterization of the particles, including particle size distribution, is essential to further organ distribution studies.

Oral and Intravenous Pharmacokinetics of Milrinone in Human Volunteers

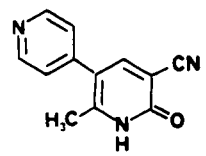
RONALD M. STROSHANE, RAYMOND F. KOSS, CHARLES E. BIDDLECOME, CAROL LUCZKOWEC, and JEROME EDELSON ˣ

Received May 19, 1983, from the *Department of Drug Metabolism and Disposition, Sterling-Winthrop Research Institute, Rensselaer, NY 12144.* Accepted for publication November 29, 1983.

Abstract □ Thirty-nine healthy men received milrinone either orally or intravenously in two separate double-blind, placebo-controlled studies. The mean bioavailability, based on the area under the plasma concentration *versus* time curves, was 0.92. The plasma data for those subjects in the intravenous study were described by an open two-compartment model with a mean (±*SD*) apparent first-order terminal elimination rate constant (β) of 0.86 (± 0.23) h^{-1}, which corresponds to a half-life of 0.8 h. In the intravenous study, the renal clearance and total body clearance were 21.1 and 25.9 L/h, respectively. The corresponding values in the oral study were 23.8 and 29.7 L/h. Between 79.9 and 84.5% of the total doses were recovered in the urine samples taken at 0–24 h.

Keyphrases □ Milrinone—blood plasma levels, human volunteers, oral and intravenous administration, bioavailability □ Pharmacokinetics—milrinone, an open two-compartment body model □ Cardiotonic agents—milrinone, pharmacokinetics, bioavailability

Milrinone[1] (1,6-dihydro-2-methyl-6-oxo[3,4′-bipyridine]-5-carbonitrile; I), is an experimental cardiotonic agent that is chemically related to amrinone (1). Both compounds, which are neither glycosides nor catechols, have demonstrated positive inotropic effects in animal models (2). In dogs, an intravenous bolus injection of milrinone (0.01–1.0 mg/kg) caused an increase in cardiac contractile force within 1 min, with a duration of action of up to 2 h. The effects could be maintained by intravenous infusion (0.3–10 μg/kg/min) for several hours. Oral activity (0.1–1.0 mg/kg) in dogs was also demonstrated, with an onset of activity within 30 min and a duration of more than 6 h (3).



I

Milrinone has been given to patients with severe chronic heart failure (4, 5). Intravenous bolus administration (25–150 μg/kg) resulted in significant increases in the cardiac index. Hemodynamic improvements were maintained with intravenous infusion (0.25–1.0 μg/kg/min) over periods of 24–48 h (5). Thus far, preliminary data disclosed that after intravenous treatment, the oral administration of milrinone (10–20 mg/d divided into three or four doses) maintained the improvement in cardiac function without reported adverse effects (4).

The analytical method for analysis of milrinone in human plasma and urine and the pharmacokinetic parameters following intravenous administration in dogs have been described previously (6). In this report, the results of our investigations into the pharmacokinetics of milrinone in humans following intravenous medication are described, and plasma levels following oral and intravenous administration are compared.

EXPERIMENTAL SECTION

Human Subjects—As part of the safety and pharmacokinetic evaluation of milrinone, 21 normal male volunteers between the ages of 19 and 40 years (mean, 28.5 years) and 18 normal male volunteers between the ages of 18 and 41 years (mean, 28.9 years) were selected to receive milrinone in an intravenous study and an oral study, respectively. Prior to acceptance in a study, each volunteer was examined to ensure that there were no clinical findings indicative of renal, hepatic, or cardiac dysfunction. Appropriate institutional review and approval were obtained prior to initiation of the study, and each volunteer gave informed consent. Subjects were admitted to the clinic the evening before initiation of the study, and all subjects remained in the clinic at least 24 h after receiving medication or placebo.

Study Design—The intravenous and oral studies consisted of six or seven groups of three volunteers each. In the intravenous study, subjects received single injections of 10, 30, 45, 60, 75, 100, or 125 μg of milrinone/kg. Three subjects received each of the seven doses. In the oral study, volunteers received single doses of 1.0, 2.5, 5.0, 7.5, 10.0, or 12.5 mg of either milrinone or placebo; three subjects received each of the six doses. Blood samples (10 mL) were collected in evacuated tubes containing oxalate anticoagulant before medication and at ~2, 5, 10, 15, 30, and 45 min and 1.0, 2.0, 3.0, 4.0, 6.0, 8.0, 12.0, 16.0, and 24.0 h after medication. The blood was centrifuged; plasma was separated and frozen until it was analyzed.

In both studies, urine was collected and measured for total volume, and an aliquot was removed for analysis. Collection times included the following intervals: premedication and 0–4, 4–8, 8–12, and 12–24 h after medication.

Assay Procedure—The analysis of plasma and urine for milrinone concentration followed that described previously (6). The method required extraction of milrinone from plasma or urine with ethyl acetate and back-extraction into acid; the samples were then neutralized and subjected to reverse-phase HPLC. Plasma and urine standards, which were freshly prepared in normal human plasma and urine, were extracted and analyzed with each set of samples from the study subjects. The concentrations of milrinone in plasma were determined by comparison with the regression line of the peak height ratios (drug–internal standard) *versus* milrinone concentration in the standards; the mean (±*SE*) correlation coefficients were 0.9967 (±0.0012) for plasma (n = 19) and 0.9997 (±0.0002) for urine (n = 9). The minimum quantifiable level of milrinone was estimated as that concentration at which the lower 80% confidence limit just encompassed zero (7) and was ~1.9 ng/mL for plasma samples and 19.6 ng/mL for urine samples. The HPLC system used consisted of an automatic injector[2], a pump[3], a precolumn[4], a column[5], and a UV detector[6] which monitored the column effluent at 340 nm. The detector was interfaced with a data processing system[7] for data collection and processing.

Pharmacokinetic Calculations—The data obtained from the analysis of the human plasma samples from the intravenous study were described by an open two-compartment model by a nonlinear regression (NLIN) procedure (8). The concentrations were weighted as the square of their reciprocals. An attempt was made to describe the plasma concentration data obtained from the oral study by either an open one- or two-compartment model with first-order absorption.

The plasma concentration data were also analyzed with respect to the following regression-independent parameters: the maximum observed plasma concentration (C_{max}, oral study only); the time at which C_{max} was observed (t_{max}, oral study only); and the area under the plasma concentration *versus* time curve (AUC_0^∞), which was calculated by using the trapezoidal rule plus

[a] Incomplete urine collection. [b] Excluding incomplete collection data.

terminal plasma concentration divided by the terminal elimination rate constant (to correct to infinite time). Total body clearance was determined by dividing the dose by the AUC_0^∞. Other pharmacokinetic parameters were estimated by classical techniques (9).

The data obtained from urine were used to calculate the renal clearance of milrinone by dividing the amount of unchanged milrinone excreted in the urine over a given period by the AUC for that period. The relative bioavailability was determined by dividing the mean normalized AUC_0^∞ for the oral dose by the mean normalized AUC_0^∞ for the intravenous dose.

RESULTS AND DISCUSSION

The concentrations of milrinone in the plasma samples from each volunteer were determined. After intravenous medication, the plasma concentrations declined biexponentially with time, suggesting that a two-compartment model would be appropriate. Pharmacokinetic parameters for each subject in the intravenous study were estimated after computer fitting the data obtained from plasma by an iterative nonlinear least-squares regression technique (8) (Table I).

The mean apparent first-order terminal elimination half-life for milrinone following intravenous medication was ~50 min. The mean apparent volume of distribution at steady state Vd_{ss} was 23.0 L or, dividing by body weight, 0.32 L/kg. The mean value for α (8.52 h^{-1}) corresponded to a distributive-phase half-life of <5 min. The mean regression-independent total body clearance (dose/AUC_0^∞) was 25.9 L/h, whereas the mean regression-independent renal clearance (total intact drug in urine/AUC_0^∞) was 21.1 L/h, which exceeds the glomerular filtration rate and suggests an active excretion mechanism. The values obtained by the trapezoidal rule for the regression-independent AUC_0^∞ were consistently higher than the corresponding regression-dependent AUC_0^∞ ($A/\alpha + B/\beta$). Since the Vd_{ss} values are inversely related to the square of the AUC_0^∞, the regression-independent Vd_{ss} values are consistently lower than the corresponding regression-dependent values. Although there is almost a threefold difference between the highest (subject 4) and lowest (subject 21) clearances, the observed concentration data from the intravenous study were adequately described by the model for both of these subjects; a comparison of the observed and predicted concentrations is shown in Fig. 1. The agreement between the observed values and those predicted by the open two-compartment body model is apparent. The amount of intact milrinone present in the urine over the 24-h period following drug administration was similar in both studies: 84.5% of the dose following intravenous administration and 79.9% of the dose following oral administration. The dosage ratio, oral-intravenous, suggests that the fraction of the oral dose that is bioavailable is ~0.95 (see below).

The plasma concentration data obtained in the oral study were not adequately described by either the open one- or two-compartment model with first-order absorption, although several weighting schemes were tried. Regression-independent parameters were determined for the oral study (Table II). The mean time of maximum plasma concentration was 1.13 h after medication. The renal clearance (23.8 ± 6.4 L/h) was comparable to that found in the intravenous study, as was the total body clearance (29.7 ± 6.7 L/h). The terminal elimination half-life was ~55 min.

Although the same subjects were not used in a crossover manner in the intravenous and oral investigations, an estimate of the absolute bioavailability was obtained by comparing the data from the two independent studies. The mean absolute bioavailability or oral-parenteral ratio, defined as the ratio of the AUC_0^∞/dose for the tablet to the regression-independent AUC_0^∞/dose for the intravenous solution, was 0.92, which is consistent with the urinary excretion data. Analysis of variance indicated that the AUC_0^∞/dose values for medication administered either by the intravenous or oral routes were not significantly different ($p = 0.21$). Furthermore, a statistical analysis of AUC_0^∞/dose against administered dose showed that the AUC_0^∞/dose was not dose dependent ($p = 0.94$).

The mean terminal elimination half-life of milrinone obtained in these human volunteers varied substantially from the value of 3.6-h obtained in dogs at intravenous doses of 5 mg/kg (6). This difference is surprising in light of the relatively good correlation in the amrinone studies between the mean terminal elimination half-life in dogs receiving doses of 5 mg/kg iv (2.37 h) (10) and human volunteers receiving doses of 75 mg iv (3.6 h) (1). Following

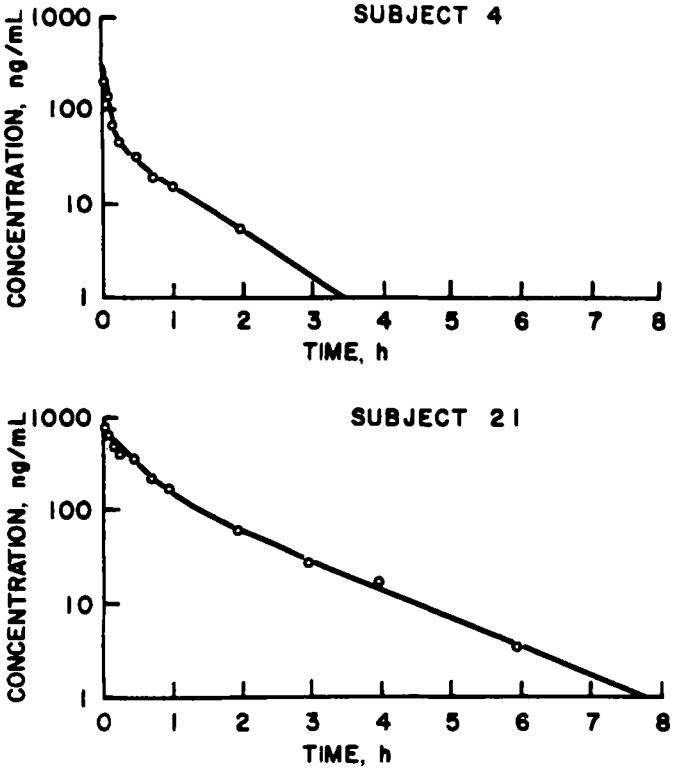

Figure 1—*Plasma concentration of milrinone in human volunteers after intravenous administration. Data points are plasma concentrations observed in two subjects with widely divergent clearance rates and concentrations predicted by the open two-compartment model (solid line).*

oral administration of 75 mg to volunteers, the mean terminal elimination half-life of amrinone was 4.33 h (1).

The mean half-life of amrinone in patients with congestive heart failure was 8.3 h (11), which is more than twice that seen in volunteers with normal cardiac function. We anticipate a similar increase in the terminal elimination half-life of milrinone in patients with congestive heart failure. The decrease in renal and hepatic blood flow in patients with severe cardiac impairment may be responsible for this increase in the duration of the drug in plasma. We are currently studying the pharmacokinetics of milrinone in patients with congestive heart failure as part of clinical efficacy trials. Attempts will be made to correlate the effects of dose on the terminal elimination half-life of milrinone.

Crystallinity and Dissolution Rate of Tolbutamide Solid Dispersions Prepared by the Melt Method

JAMES W. McGINITY *x, PHILIPPE MAINCENT *, and HUGO STEINFINK ‡

Received October 24, 1983, from the **Drug Dynamics Institute, College of Pharmacy and* ‡*Department of Chemical Engineering, University of Texas at Austin, Austin, TX 78712.* Accepted for publication December 21, 1983.

Abstract □ The influence of cooling rate of solid dispersions prepared by the melt method was studied by X-ray diffraction and scanning electron microscopy. Tolbutamide was the model drug investigated, and the carriers included urea and polyethylene glycol 6000. Slow-cooled urea dispersions of tolbutamide demonstrated a complete lack of crystallinity suggesting the formation of an amorphous material. The rapidly cooled dispersion showed peaks for urea and an absence of drug in the X-ray pattern, suggesting that a true molecular dispersion was formed. The X-ray patterns of rapid- and slow-cooled dispersions of tolbutamide and polyethylene glycol 6000 demonstrated that a physical mixture of drug and carrier resulted from both methods of dispersion preparation.

Keyphrases □ Solid dispersions—melt method of preparation, cooling rates and physicochemical properties □ Tolbutamide—solid dispersions with urea and polyethylene glycol 6000 □ X-ray diffraction—tolbutamide, solid dispersions, carriers □ Scanning electron microscopy—solid dispersions □ Dissolution rates—tolbutamide, solid dispersions

The rate-determining step in the absorption process for drugs of low solubility is generally the dissolution rate of such drugs in the GI fluids rather than the rapidity of their diffusion across the gut wall. The formation of solid dispersions of the drug with a water-soluble carrier is one of several techniques that can be used to improve the dissolution properties of poorly soluble or hydrophobic drugs. In 1961, Sekiguchi and Obi (1) became the first researchers to propose the use of solid dis-

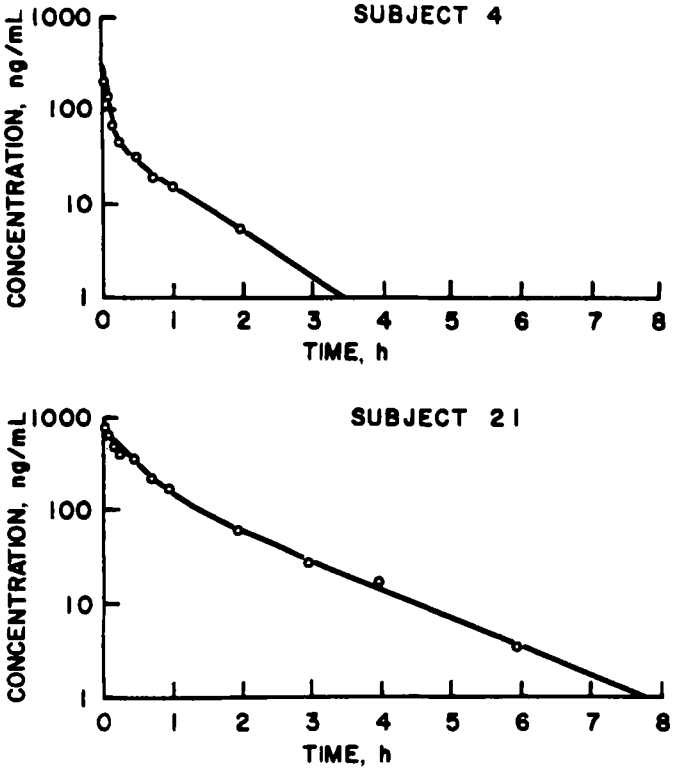

Figure 1—*Plasma concentration of milrinone in human volunteers after intravenous administration. Data points are plasma concentrations observed in two subjects with widely divergent clearance rates and concentrations predicted by the open two-compartment model (solid line).*

oral administration of 75 mg to volunteers, the mean terminal elimination half-life of amrinone was 4.33 h (1).

The mean half-life of amrinone in patients with congestive heart failure was 8.3 h (11), which is more than twice that seen in volunteers with normal cardiac function. We anticipate a similar increase in the terminal elimination half-life of milrinone in patients with congestive heart failure. The decrease in renal and hepatic blood flow in patients with severe cardiac impairment may be responsible for this increase in the duration of the drug in plasma. We are currently studying the pharmacokinetics of milrinone in patients with congestive heart failure as part of clinical efficacy trials. Attempts will be made to correlate the effects of dose on the terminal elimination half-life of milrinone.

persions to increase the dissolution rate and oral absorption of drugs. In recent reports, (2–6), the great variety of drug molecules and water-soluble carriers used to prepare solid dispersions have been reviewed.

Although in previous reports the technology of solid dispersions has been extensively examined, systems in which this technique is utilized have been fraught with problems; thus, few systems have been marketed (3). Since solid dispersions are dynamic systems, further research into the physicochemical properties of these systems is certainly warranted. In recent studies, it has been shown that soluble complexes between drug and carrier may form (7). Kaur and co-workers (5) have studied the phase equilibrium phenomena of solid dispersion systems, whereas Ravis and Chen (4) have compared, by X-ray analysis, the difference in crystallinity between solid dispersions and physical mixtures of drug and carrier. Significant contributions have been made by Ford and Rubinstein (8), who have studied the effect of aging on the dissolution properties of an indomethacin–polyethylene glycol 6000 solid dispersion.

One aspect of solid dispersion technology that has received little attention has been the method of sample preparation. A brief survey of the literature has indicated that there is no uniform method presently used to prepare solid dispersions by the melt method. In several cases, the temperatures to which the carrier and drug were subjected were not reported. Dispersions have been solidified by cooling the melt to room temperature (9, 10). Kaur and co-workers (5, 6) cooled their samples to 4°C, Chiou and Niazi poured the melts onto a stainless steel plate (11), whereas Allen and co-workers (12) rapidly solidified their samples by pouring the melt into an aluminum dish that was placed in a block of dry ice. Other investigators have employed metal pans (2), ice baths (7), and dry ice–acetone baths (13).

The objective of this study was to investigate the influence of cooling conditions on the physicochemical properties of solid dispersions prepared by the melt method. Urea and polyethylene glycol 6000 were the carriers studied, and tolbutamide (1-butyl-3-(*p*-tolylsulfonyl)urea) was the model drug investigated. Some preliminary results were also obtained with salicylic acid and sulfathiazole.

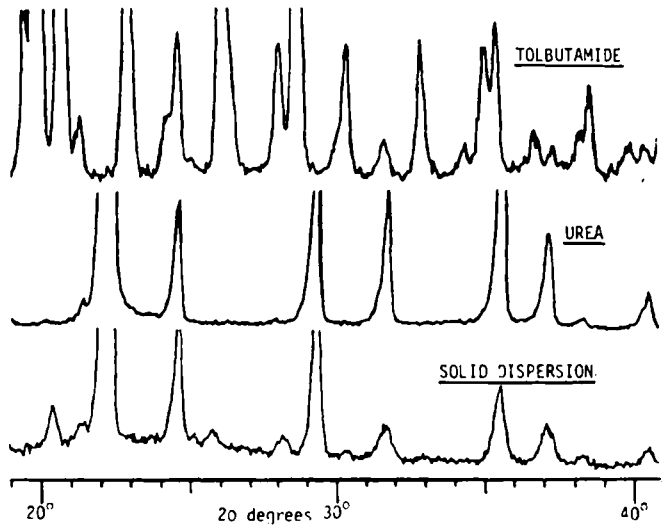

Figure 2—*X-ray patterns of drug, carrier, and rapid-cooled dispersion.*

EXPERIMENTAL SECTION

Materials—Urea[1] (mp 139.7°C), polyethylene glycol 6000[2] (mp 56°C), tolbutamide[3] (mp 125.5°C), salicylic acid[4] (mp 158°C), and sulfathiazole[2] (mp 202°C) were used.

Methods—X-ray diffraction patterns were obtained with an X-ray diffractometer[5] with $CuK_{\alpha 1}$ radiation (0.15405 nm) over a 2θ range of 6–50°. The scanning electron micrographs were recorded on a microscope[6]. Dissolution profiles of drug from dispersion samples were determined with the USP paddle apparatus. For the tolbutamide samples, 900 mL of pH 6.0 buffer were stirred at 50 rpm and maintained at 37°C. The melts were prepared by first heating the carrier in an aluminum dish over an oil bath to 5°C above the melting point of the carrier. The drug was then dissolved into the molten carrier and stirred for 2 min to ensure a homogeneous dispersion. Two methods of cooling were employed. Process A involved the flash cooling of the dispersion by immersion of the aluminum dish containing the molten dispersion in a bath of dry ice and acetone. The preparation of the dispersion by Process B involved the gradual cooling of the oil bath under ambient conditions over a period of several hours. Dispersions from both processes were then passed through a 20-mesh screen, and the 20- to 40-mesh fraction was retained for the dissolution study. Ground samples of the dispersion were employed for the scanning electron microscopic evaluation of the surface crystalline properties. Dispersions in the 60–100 mesh range were used for X-ray analysis. Ratios of carrier to drug, 2:1 w/w, were used for all samples with the exception of the polyethylene glycol 6000–sulfathiazole system, in which a 4:1 ratio was employed. For all these systems, full solution dispersions were obtained prior to the cooling step.

RESULTS AND DISCUSSION

Powder X-ray diffraction patterns of tolbutamide, urea, and polyethylene glycol 6000 were taken of samples that were both slow and flash cooled. For each material alone, the rate of cooling did not influence the crystallinity since the peak widths of the diffraction profiles remained constant. No additional new diffraction lines were detected, indicating that no degradation or new compound formation had occurred. Minor changes in the intensity of some peaks were seen with samples prepared by either process. However, this was probably due to changes in preferred orientation rather than any alteration in the physicochemical properties of the material. The multitude of peaks obtained with urea and tolbutamide verified the crystalline properties of these solids. The two most intense peaks in the X-ray pattern for polyethylene glycol 6000 were found at 19.2 and 23.4°.

A study of the physical mixture of tolbutamide–urea produced a pattern which was due to the combination of the drug and carrier. Markedly different results were evident with the urea–tolbutamide dispersions prepared by the rapid- and slow-cooled methods. The X-ray patterns for the slow-cooled dispersions demonstrated a complete lack of crystallinity, suggesting the formation of an amorphous material. A scanning electron micrograph of this dispersion is shown in Fig. 1. The X-ray patterns shown in Fig. 2 are those of tolbutamide, urea, and the dispersion prepared by process A (rapid cooled). The complete absence of peaks for the tolbutamide in the dispersion is readily evident. All peaks present from the dispersion sample are those of the carrier. This phenomenon could be due to the formation of a true molecular dispersion of the tolbutamide within the urea matrix, or alternatively, it could mean that tolbutamide is present on the surface of the urea crystals as an amorphous coating.

A similar phenomenon has been reported by Chiou (14) with the griseofulvin–polyethylene glycol 6000 system. Since the peaks for the drug were absent in the X-ray diffraction pattern, Chiou has proposed that an amorphous form of griseofulvin was present in the melt after cooling. However, when X-ray diffraction studies were repeated several days later, major diffraction peaks of griseofulvin were present, indicating crystal formation in the dispersion. This result was obtained for all samples studied with the exception of the 5% drug sample. An examination of the tolbutamide–urea dispersion prepared by process A after storage at 25°C for 45 d indicated that no tolbutamide peaks were present in the X-ray diffraction pattern. These preliminary stability data suggest that some form of molecular interaction may be present between tolbutamide and urea to maintain the drug in the amorphous state. Storage of the slow-cooled dispersion (Fig. 1) at 25°C for 5 months resulted in crystal growth (Fig. 3). The X-ray pattern of this sample was identical to that of the solid dispersion (Fig. 2), indicating that the crystals consisted of urea rather than tolbutamide. X-ray examination of physical mixtures of tolbutamide–urea verified that samples containing as little as 2% drug yield peaks for tolbutamide.

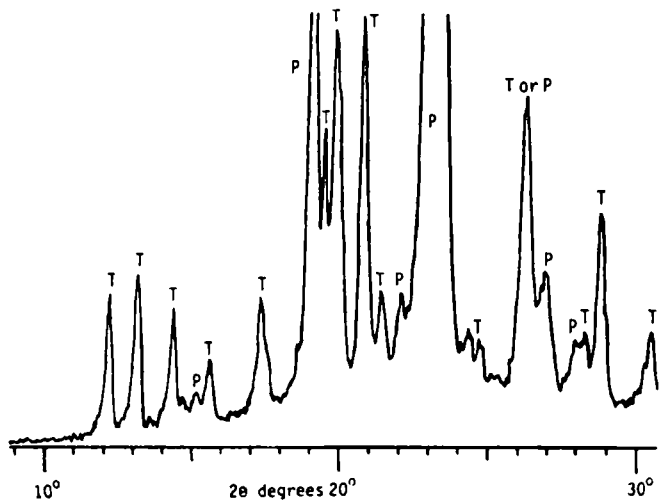

Figure 5—*X-ray pattern of polyethylene glycol 6000–tolbutamide dispersion prepared by process B.*

Table I—Dissolution Characteristics of Polyethylene Glycol 6000–Tolbutamide (2:1) Dispersions [a]

Time, min	Percent Drug Released [b]		
	Rapid Cooled (Process A)	Slow Cooled (Process B)	Physical Mixture
6	36.9 ± 5.3	29.7 ± 2.6	27.8 ± 4.0
10	60.4 ± 3.5	45.8 ± 3.5	44.4 ± 4.2
15	72.3 ± 4.4	57.9 ± 3.5	60.1 ± 1.9
20	78.3 ± 5.4	64.4 ± 1.6	64.2 ± 2.5
25	86.7 ± 4.7	71.5 ± 2.9	70.8 ± 3.4
40	91.0 ± 4.3	75.6 ± 3.5	80.0 ± 2.4
60	96.3 ± 3.0	84.6 ± 1.9	82.8 ± 1.5
100	100.6 ± 1.2	90.5 ± 1.0	87.5 ± 1.8

[a] In 900 mL of pH 6.0 buffer maintained at 37°C and agitated at 50 rpm by the USP paddle method. [b] Mean ± *SD*.

The X-ray patterns of tolbutamide, polyethylene glycol 6000, and the solid dispersion prepared by process A are shown in Fig. 4. Comparison of these patterns indicates that the dispersion is present as a physical mixture of the drug and carrier. The slow-cooled dispersion shown in Fig. 5 had a very similar pattern to the dispersion shown in Fig. 4. The higher intensity of peaks shown in Fig. 5 suggested a greater degree of crystallinity from the slow-cooled samples. This phenomenon was verified by scanning electron microscopy.

The dissolution properties of tolbutamide–polyethylene glycol 6000 dispersions prepared by process A and process B were compared with the dissolution properties of tolbutamide from the physical mixture of the drug and polyethylene glycol 6000 (Table I). Insignificant differences were seen in the dissolution properties of drug from the slow-cooled dispersion and the physical mixture. However, ~15% more drug passed into solution at most time intervals for the dispersion prepared by process A. This phenomenon was probably due to a particle size effect since a smaller drug particle was expected from the flash-cooled dispersion. The lower degree of crystallinity for this dispersion was verified by the X-ray diffraction patterns (Figs. 4 and 5). The greater dissolution rate of dispersions prepared by process A may also be attributed to a greater energy of the drug particles in these dispersions. Less crystalline or more amorphous forms generally possess greater thermodynamic activities than more crystalline forms of the same substance (15).

The peaks for sulfathiazole in the X-ray diffraction patterns of sulfathiazole–urea dispersions were absent for both the slow- and flash-cooled dispersions. This result was similar to that for the tolbutamide–urea dispersions prepared by process A. A physical mixture of both drug and carrier was found with the sulfathiazole–polyethylene glycol 6000 samples. Salicylic acid in urea dispersions produced new peaks in the X-ray diffraction patterns, suggesting that either an interaction occurred or a polymorphic change in either the drug or carrier took place to form a new phase.

In summary, the applications of X-ray diffraction to study the physicochemical properties of solid dispersions have been demonstrated. The rate of cooling of melt dispersions will, in many cases, influence the physical state of both drug and carrier. Other techniques are presently being evaluated for use in conjunction with X-ray diffraction to differentiate and identify polymorphic transitions, degradation product or complex formation, molecular dispersion formation, physical mixtures, and the determination of degrees of crystallinity in the melt dispersions. Future studies will also employ X-ray diffraction to examine changes in the microcrystalline properties of these dispersions as a function of time and temperature.

A High-Performance Liquid Chromatographic Method for The Simultaneous Determination of Nicardipine and Its Pyridine Metabolite II in Plasma

ANNE T. WU ˣ, IAN J. MASSEY, and STANLEY KUSHINSKY

Received September 29, 1983, from the *Department of Analytical and Metabolic Chemistry, Syntex Research, Palo Alto, CA 94304.* Accepted for publication December 5, 1983.

Abstract □ A rapid and specific method in which reverse-phase high-performance liquid chromatography (HPLC) with UV detection was used for the simultaneous determination of nicardipine and its pyridine metabolite II in human plasma is described. Nicardipine, its pyridine metabolite II, and the internal standard were extracted from plasma and partially purified by acid–base partitioning. Final purification and quantitation were achieved by HPLC by using a reverse-phase column and a UV detector (254 nm). The extraction efficiencies for nicardipine and its pyridine metabolite II from 1 mL of plasma were 77.4 and 81.1%, respectively. The sensitivity of the assay was 5 ng/mL for both nicardipine and its pyridine metabolite II, and the linear concentration range of the assay was 5–150 ng/mL for both compounds. The low coefficients of variation (≤5%) for samples spiked with nicardipine and its pyridine metabolite II in this concentration range demonstrate good reliability and reproducibility of the assay. The HPLC procedure has been validated by comparison with a GC–electron-capture detection (ECD) procedure, which gives the combined concentration of nicardipine–its pyridine metabolite II (total) and with an HPLC/GC–ECD procedure, which gives the concentration of its pyridine metabolite II. All three methods, which were developed in our laboratory, were used to analyze nicardipine and its pyridine metabolite II in specimens of plasma from subjects treated with nicardipine hydrochloride. Good correlations were found for concentrations of nicardipine, its pyridine metabolite II, and nicardipine plus the metabolite determined by these three procedures. The HPLC procedure is suitable for use in pharmacokinetic studies following administration of nicardipine hydrochloride to humans.

Keyphrases □ Nicardipine—simultaneous determination with its pyridine metabolite II, reverse-phase HPLC □ HPLC—reverse-phase simultaneous determination of nicardipine and its pyridine metabolite II in human plasma

Nicardipine hydrochloride, 2-(*N*-benzyl-*N*-methylamino)ethyl methyl 1,4-dihydro-2,6-dimethyl-4-(*m*-nitrophenyl)-3,5-pyridinedicarboxylate monohydrochloride (I), is a new calcium entry-blocking agent with potent oral vasodilating activity. The therapeutic efficacy of this compound for the treatment of angina, hypertension, and cerebrovascular disease is under investigation.

Nicardipine hydrochloride, which is effective at relatively low doses, undergoes extensive first-pass metabolism to produce several metabolites (1). Therefore, a sensitive and specific method is required for its determination in human plasma. Various methods have been reported for the determination of nicardipine in plasma. These include gas chromatography (GC) with either electron-capture detection (GC–ECD) (2) or with mass spectrometric detection (GC–MS) (3). However, these methods are relatively nonspecific because they require oxidation of nicardipine prior to GC analysis. Since the product of this oxidation is the pyridine metabolite II of nicardipine, these methods measure the combined concentration of nicardipine plus its pyridine metabolite II (total). Pharmacokinetic analyses of data generated by these methods can be misleading in view of the fact that the vasodilative activity of the pyridine metabolite II is only $^1/_{300}$ that of the parent drug (4). The individual concentrations of nicardipine and its metabolite in human plasma have been investigated recently using a TLC–GC–MS method (5), in which nicardipine was separated from its pyridine metabolite II by TLC prior to analysis by GC–MS. These investigators have found that in healthy volunteers and hypertensive patients, the concentration of nicardipine relative to that of the combined concentrations of nicardipine plus its pyridine metabolite II ranged from 74% to 99% (5). Recently, we developed a method using high-performance liquid chromatography (HPLC) in conjunction with GC–ECD which allowed the individual concentrations of nicardipine and its pyridine metabolite II to be determined[1]. In this HPLC/GC–ECD method, which was developed prior to the availability in our laboratory of a high-sensitivity HPLC detector, HPLC was used to separate nicardipine from the pyridine metabolite II prior to analysis of the latter by GC–ECD. The concentration of nicardipine in a sample of plasma was obtained by subtracting the concentration of the pyridine metabolite II as determined by the HPLC/GC–ECD assay from the combined concentration of nicardipine plus the pyridine metabolite II as determined by the GC–ECD method

The HPLC procedure is suitable for use in pharmacokinetic studies following administration of nicardipine hydrochloride to humans.

Keyphrases □ Nicardipine—simultaneous determination with its pyridine metabolite II, reverse-phase HPLC □ HPLC—reverse-phase simultaneous determination of nicardipine and its pyridine metabolite II in human plasma

Nicardipine hydrochloride, 2-(*N*-benzyl-*N*-methylamino)ethyl methyl 1,4-dihydro-2,6-dimethyl-4-(*m*-nitrophenyl)-3,5-pyridinedicarboxylate monohydrochloride (I), is a new calcium entry-blocking agent with potent oral vasodilating activity. The therapeutic efficacy of this compound for the treatment of angina, hypertension, and cerebrovascular disease is under investigation.

Nicardipine hydrochloride, which is effective at relatively low doses, undergoes extensive first-pass metabolism to produce several metabolites (1). Therefore, a sensitive and specific method is required for its determination in human plasma. Various methods have been reported for the determination of nicardipine in plasma. These include gas chromatography (GC) with either electron-capture detection (GC–ECD) (2) or with mass spectrometric detection (GC–MS) (3). However, these methods are relatively nonspecific because they require oxidation of nicardipine prior to GC analysis. Since the product of this oxidation is the pyridine metabolite II of nicardipine, these methods measure the combined concentration of nicardipine plus its pyridine metabolite II (total). Pharmacokinetic analyses of data generated by these methods can be misleading in view of the fact that the vasodilative activity of the pyridine metabolite II is only $^1/_{300}$ that of the parent drug (4). The individual concentrations of nicardipine and its metabolite in human plasma have been investigated recently using a TLC–GC–MS method (5), in which nicardipine was separated from its pyridine metabolite II by TLC prior to analysis by GC–MS. These investigators have found that in healthy volunteers and hypertensive patients, the concentration of nicardipine relative to that of the combined concentrations of nicardipine plus its pyridine metabolite II ranged from 74% to 99% (5). Recently, we developed a method using high-performance liquid chromatography (HPLC) in conjunction with GC–ECD which allowed the individual concentrations of nicardipine and its pyridine metabolite II to be determined[1]. In this HPLC/GC–ECD method, which was developed prior to the availability in our laboratory of a high-sensitivity HPLC detector, HPLC was used to separate nicardipine from the pyridine metabolite II prior to analysis of the latter by GC–ECD. The concentration of nicardipine in a sample of plasma was obtained by subtracting the concentration of the pyridine metabolite II as determined by the HPLC/GC–ECD assay from the combined concentration of nicardipine plus the pyridine metabolite II as determined by the GC–ECD method

[1] Unpublished results (a brief description of this method is given in the text).

(2). Based on our HPLC/GC-ECD assay, the pyridine metabolite II accounted for 28.58 ± 8.73% (n = 36) of the combined concentration of nicardipine plus the pyridine metabolite II in plasma from subjects treated orally with nicardipine hydrochloride. In view of the presence of varying proportions of nicardipine and its pyridine metabolite II in plasma, a specific method for the determination of the concentrations of nicardipine should be used to provide data for pharmacokinetic analysis. Although the TLC-GC-MS and HPLC/GC-ECD methods have this specificity, they are relatively laborious and do not provide a practical means for the specific determination of nicardipine and its pyridine metabolite II in plasma on a routine basis.

The method described here is a simple HPLC method which allows the simultaneous determination of the individual concentrations of nicardipine and its pyridine metabolite II in human plasma. The assay, which has a sensitivity of 5 ng/mL for nicardipine and the pyridine metabolite II is suitable for the analysis of these compounds in plasma collected from subjects treated orally with nicardipine hydrochloride at doses as low as 20 mg.

CV, %	4.9	0.0	1.4	3.7	0.5	2.8

[a] Total of four assays.

The aqueous 2.0 M NaOH solution was washed once with an equal volume of acetonitrile and once with an equal volume of ether before use. Acid buffer was prepared by mixing equal volumes of 0.1 M sodium acetate solution and 0.1 M hydrochloric acid.

Chromatographic Conditions—HPLC was performed by using a mobile phase of acetonitrile–0.02 M KH_2PO_4 (pH 4.8; 53:47 v/v) with a flow rate of 1.5 mL/min (2000 psi).

Standard Solutions—Stock solutions of the internal standard III, nicardipine hydrochloride (I), and the monohydrochloride of its pyridine metabolite II at a concentration of 1 mg/mL were prepared in ethanol. The working solution of internal standard III contained 75 ng/500 μL of 2% ethanolic acid buffer. Spiking solutions, containing 5, 10, 20, 50, 100, and 150 ng of the hydrochloride salts of nicardipine (I) or its pyridine metabolite II per 500 μL of 4% ethanolic acid buffer, were prepared by serial dilution of the stock solutions.

Sample Preparation for the Determination of Nicardipine and Its Pyridine Metabolite II—Human plasma (0.1–1.0 mL) was transferred into a 15-mL culture tube (16 × 125 mm) fitted with a polytef-lined screw cap. The volume was adjusted to 1 mL by the addition of blank human plasma[13]. Ethanolic acid buffer (4%, 1 mL), 500 μL of internal standard solution (III, 75 ng), and 500 μL of 2.0 M NaOH were added to the sample. The mixture was agitated on a vortex mixer for 15 s. The mixture was extracted with 4 mL of ether by shaking on a mechanical shaker for 5 min and centrifuging for 5 min at 5000 rpm. The organic layer was transferred to another 15-mL tube. To the organic phase was added 2 mL of 0.1 M HCl, and the mixture was shaken for 5 min. The mixture was centrifuged, and the organic layer was removed and discarded by using a vacuum aspirator. The aqueous fraction was made alkaline by the addition of 500 μL of 2.0 M NaOH. The mixture was extracted with 4 mL of ether as described previously. After centrifugation, the organic layer was transferred to another 15-mL culture tube, and the solution was evaporated to dryness under a stream of nitrogen in a water bath (45°C). The residue was immediately dissolved in 70 μL of HPLC mobile phase, and the solution was transferred to an autosampler vial[14]. Of this final solution, 20–55 μL was injected onto the liquid chromatograph for analysis.

Quantitation—Concentrations of nicardipine and the pyridine metabolite II in unknown samples were calculated with reference to their corresponding calibration curves, which were generated by using a 1-mL sample of blank plasma spiked with nicardipine hydrochloride and the monohydrochloride of the pyridine metabolite II at levels of 5, 10, 20, 50, 100, and 150 ng/mL. The samples of spiked plasma were processed as described above.

Calibration curves were obtained by plotting the ratio of the peak height for the analyte to that of the internal standard against the amount of analyte added.

HPLC/GC-ECD Assay for the Pyridine Metabolite II—This assay employed as the internal standard the pyridine form[1] of the internal standard III used for the direct HPLC assay described here. Preparation of the samples for HPLC was as described above. HPLC was performed as described above,

[13] Venous blood from four untreated volunteers was drawn into heparinized containers and centrifuged to generate a plasma pool.

[a] Total = Nicardipine plus its pyridine metabolite II.

except that a mobile phase of acetonitrile–0.01 M KH_2PO_4 (pH 4.8; 1:1) was employed. Under these conditions, the pyridine metabolite II and the internal standard coeluted and were well separated from nicardipine. The HPLC effluent containing the pyridine metabolite II and the internal standard was collected, made alkaline by the addition of 0.5 mL of 2.0 M NaOH, and extracted with ether (4 mL). The ether extract was evaporated to dryness, and the residue was reconstituted in 50 μL of toluene. A portion of the extract was subjected to GC-ECD analysis (2). The concentration of the pyridine metabolite II in plasma was determined by reference to suitable calibration curves which were constructed by using a procedure analogous to that described above.

RESULTS AND DISCUSSION

The UV absorption maximum of nicardipine was at 237 nm. However, in this assay, the absorption at 254 nm was used for quantitation. Although the use of 254 nm reduces the theoretical sensitivity to some extent, it has the advantage of providing a cleaner chromatogram for blank plasma. A typical chromatogram for 1 mL of blank human plasma processed by this method is shown in Fig. 1. There were no components which eluted with nicardipine, the pyridine metabolite II, or the internal standard. To achieve a clean chromatogram of this type, we found that it was necessary to perform the acid–base partitioning step prior to the HPLC analysis. In addition, we found that the 2.0 M NaOH used in this procedure must be washed once with acetonitrile and once with ether prior to use. If unwashed 2.0 M NaOH is used, potentially interfering components appear in the chromatogram. By using the extraction procedure described above, the extraction efficiencies for nicardipine and its pyridine metabolite II from 1 mL of plasma were 81.1 and 79.6%, respectively.

Representative chromatograms for 1 mL of blank human plasma spiked with nicardipine hydrochloride and the monohydrochloride of the pyridine metabolite II, each at levels of 5 or 50 ng and processed by this procedure, are shown in Figs. 2 and 3, respectively. A typical chromatogram for 1 mL of plasma taken from a subject who received nicardipine hydrochloride is shown in Fig. 4.

A good separation of nicardipine, the pyridine metabolite II, and the internal standard from each other and from other components was obtained. During the HPLC separation, an acidic mobile phase (pH 4.8) with a relatively high buffer concentration (0.02 M KH_2PO_4) was used. The acidic mobile phase causes nicardipine, the pyridine metabolite II, and the internal standard to exist as the corresponding protonated species during chromatography, thereby leading to improved chromatographic peak shapes and reduced retention times. The high buffer concentration was found to be necessary to ensure a good separation between the pyridine metabolite II and the internal standard. At a lower buffer concentration (0.01 M KH_2PO_4), the separation of these three compounds and even their order of elution was found to vary as the column aged. Even with the higher buffer concentration, as the column aged, it was necessary to add a small quantity of methanol to the solvent system [*e.g.*, acetonitrile–0.02 M KH_2PO_4–methanol (43:49:8 v/v/v)], to maintain the elution order and the quality of the separation.

Calibration curves for nicardipine hydrochloride and the monohydrochloride of the pyridine metabolite II showed good linearity. Data for the recovery of nicardipine and the pyridine metabolite II from samples of plasma fortified with these compounds in the range of 5–150 ng/mL are shown in Tables I and II, respectively. The low coefficients of variation (≤5% at all levels) provide evidence of the reproducibility of the method.

The HPLC method was validated against a GC-ECD method which gave the combined concentration of nicardipine plus the pyridine metabolite II and against an HPLC/GC-ECD method, which gave the concentration of the pyridine metabolite II. All three methods were applied to samples of plasma obtained from subjects treated orally with nicardipine hydrochloride (Table III). A comparison of the levels of nicardipine, the pyridine metabolite II, and nicardipine–the pyridine metabolite II determined by the three methods is shown in Table III. The overall agreement between the results obtained by all three methods is good.

A plasma concentration–time profile for nicardipine and the pyridine metabolite II obtained for one subject on day 4 of a multiple-dose study (20 mg, three times per day) is presented in Fig. 5 as evidence of the usefulness of this method for pharmacokinetic analyses.

Analysis of *N*-(4-Hydroxyphenyl)retinamide Polymorphic Forms by X-ray Powder Diffraction

F. A. CHRZANOWSKI ˣ, B. J. FEGELY, W. R. SISCO, and M. P. NEWTON

Received December 6, 1982, from the *Department of Chemical and Pharmaceutical Development, McNeil Pharmaceutical, Spring House, PA 19477.* Accepted for publication November 16, 1983.

Abstract □ A quantitative X-ray diffraction method, with zinc oxide used as the internal standard, was developed for the analysis of polymorphic forms I and II of *N*-(4-hydroxyphenyl)retinamide. The standard curve relating peak height ratio to the percentage of form I was linear. The method was precise and accurate to within ±6%.

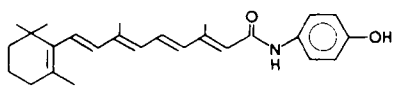
Keyphrases □ *N*-(4-Hydroxyphenyl)retinamide—X-ray powder diffraction analysis of polymorphic forms □ X-ray powder diffraction—analysis of polymorphic forms of *N*-(4-hydroxyphenyl)retinamide □ Polymorphs—*N*-(4-hydroxyphenyl)retinamide, analysis by X-ray powder diffraction

N-(4-Hydroxyphenyl)retinamide (fenretinide; III), an analogue of vitamin A which was first synthesized by Gander and co-workers (1), has a demonstrated prophylactic effect against mammary tumors in rats. Two polymorphic forms of *N*-(4-hydroxyphenyl)retinamide which occur alone or in combination after recrystallization have been identified by X-ray powder diffraction (Fig. 1).

The polymorphic form of a drug may affect its efficacy. The bioavailability of both chloramphenicol (2) and sulfameter (3) after oral administration in humans is dependent on their polymorphic forms. Studies in animals with polymorphs of indomethacin (4), amobarbital (5), and phenobarbital (6) have demonstrated the nonequivalence of polymorphic forms. To monitor the polymorphic character of *N*-(4-hydroxyphenyl)-retinamide drug substance used in preclinical animal testing and to evaluate the physicochemical properties of the two forms, a quantitative analytical procedure was developed.

X-ray powder diffraction and IR spectroscopy have been used for quantitative analysis of mixtures of polymorphs. Walkling *et al.* (7) have developed an IR spectroscopic method to quantitate difenoxin hydrochloride polymorph mixtures. Aguiar *et al.* (2) have used X-ray powder diffraction to determine the composition of chloramphenicol palmitate polymorph mixtures by calculating the peak height ratio of two peaks, with each peak characteristic of one of the two forms. The calibration line they obtained was curvilinear rather than straight. They found that the amorphous form did not interfere and that they could correct for the amount of a third crystalline form occasionally present. Papariello *et al.* (8) have successfully used X-ray powder diffraction as a nondestructive analytical method for measuring the amount of glutethimide in intact tablets. Black and Lovering (9) have used X-ray powder diffraction to quantitate the crystalline polymorphs in digoxin. X-ray diffraction studies of vitamin A analogues appear to have been limited to single-crystal studies to elucidate their chemical structures (10–14).

In this report is described a quantitative X-ray powder diffraction method which determines the amounts of the polymorphic forms I and II of *N*-(4-hydroxyphenyl)retinamide in samples of *N*-(4-hydroxyphenyl)retinamide drug substance. Zinc oxide was selected as the internal standard since all of its diffraction peaks (Fig. 1) occur at higher reflection angles than those of the two polymorphic forms of *N*-(4-hydroxyphenyl)-retinamide.



N-(4-hydroxyphenyl)retinamide

EXPERIMENTAL SECTION

Reagents and Materials—Zinc oxide[1] (internal standard), analytical reagent grade, was obtained commercially and was passed through an 80-mesh sieve prior to use. *N*-(4-Hydroxyphenyl)retinamide was ≥99% pure, as determined by an HPLC method in which the 13-*cis* isomer was separated from the all-*trans* isomer, *N*-(4-hydroxyphenyl)retinamide. There was <0.5% 13-*cis* isomer in the test materials. Mixtures of forms I and II gave the same HPLC peak and TLC spot. There were qualitative differences in the IR spectra of forms I and II that were suggestive of polymorphism. The solution NMR spectra were identical, indicating that the two forms were not isomers of each other. The two forms do not interconvert under the conditions described in this report.

Standards—Authentic samples of *N*-(4-hydroxyphenyl)retinamide forms I and II were passed through an 80-mesh sieve. When *N*-(4-hydroxyphenyl)-retinamide was passed through a 200-mesh sieve, the sample could not be used due to the induction of a static electrical charge. The 80-mesh powder samples were used as the 100 and 0% form I standards. The 25, 50, and 75% form I standards were prepared by mixing forms I and II in a mortar.

Assay—A sample (200 mg) of *N*-(4-hydroxyphenyl)retinamide or standard was mixed with 40 mg of zinc oxide in a glass mortar. The *N*-(4-hydroxyphenyl)retinamide–zinc oxide mixture (5:1) was placed into a sample holder, and the powder was pressed into place with a glass slide by moving the slide from side to side, thereby leaving a smooth, lightly compacted surface. The samples were scanned over the 5–37° 2θ range. The peak heights of the sample and internal standard were measured at 19.1° and 31.8° 2θ from a baseline drawn from 11° to 33° 2θ. The ratio $I_{19.1}/I_{31.8}$ was calculated, and the amount of form I was obtained from a standard curve relating $I_{19.1}/I_{31.8}$ *versus* the percentage of form I.

Apparatus—An X-ray diffractometer[2] containing a long fine-focus copper tube X-ray source, diffracted-beam monochromater, theta-compensating slit, and scintillation counter was used. The X-ray tube was operated at 40 kV and 30 mA. The scan speed was 1°/min; range, 5 kcps; time constant, 1. The takeoff angle was 6°.

Reproducibility and Accuracy—A 2.5-g mixture was prepared, as described above, containing 75% form I and 25% form II. The mixture was mixed with zinc oxide (5:1) and analyzed 10 times using a different aliquot for each assay. Nine other mixtures were prepared in which the amount of form I ranged from 19 to 100%. The concentrations of form I were determined for the 10 samples and compared with the known concentrations.

RESULTS AND DISCUSSION

The X-ray powder diffraction patterns for polymorphic forms I and II are shown in Fig. 1. The *d*-spacings and relative intensities of the two polymorphs are tabulated in Table I. It appears that a number of peaks such as 2θ = 19.1°, 25.1°, and 19.8° could be used quantitatively to measure the amounts of forms I and II in samples of drug substance. Since the peaks are sharp and have about the same width at half-height, peak height is a reasonable approximation of the area of the peak. Several peak height and peak height ratio combinations were evaluated. None were sufficiently accurate for determining the composition of known mixtures. The low angle peaks below 11° 2θ, at which

overlap was reduced, would appear to be good candidates for quantitation. Unfortunately, the intensities of the peak heights of each component were not always proportional to the amounts present.

Zinc oxide was selected as the internal standard because of the proximity of its major peak at $2\theta = 31.8°$ (100), 34.5° (002), and 36.3° (101) to the major peaks of the two polymorphic forms of *N*-(4-hydroxyphenyl)retinamide, and a complete absence of zinc oxide peaks in the region below $2\theta = 30°$. Form I has a small peak at $2\theta = 31.5°$ which did not interfere with the measurement of the zinc oxide peak, as evidenced by the good correlation and linearity of the calibration curve. The peak widths at $2\theta = 19.1°$ and 31.8° were between 0.2° and 0.4° when measured at half-height in all tested samples.

The calibration curve, relating the peak height ratio $I_{19.1}/I_{31.8}$ *versus* the percentage form I, was linear ($y = 0.0143 + 0.00259x$; $r = 0.9997$). A *y*-intercept occurred as a result of the method used to establish the baseline and the slight amount of background noise observed at $2\theta = 19.1°$ with 0% form I (100% form II) standards. The excellent correlation and linearity of the calibration curve indicate that the selection of zinc oxide as the internal standard was appropriate. An organic internal standard is usually preferred for the analysis of organic compounds; however, the number of peaks in the X-ray diffraction patterns of the two forms of *N*-(4-hydroxyphenyl)retinamide (Fig. 1) make it unlikely that an organic internal standard would have been suitable.

In Table II are summarized the results obtained from the repetitive testing

Table II—Precision of Analysis of *N*-(4-Hydroxyphenyl)retinamide in a Mixture of Known Composition [a]

I	40	0.113	38	−2

[a] Mean difference, 2.3%.

of the 75% form I sample. Ten aliquots of this sample were packed and scanned over the range 2θ = 5–37°. The calculated mean was 76.7% form I. All 10 assays were within the 74–79% range. The mean difference was 2.1%, and the *SD* and *CV* were 1.8 and 2.3%, respectively. When zinc oxide was not used as an internal standard and the peak height ratio, $I_{25.1}/I_{19.8}$, was used, the calculated mean percentage of form I for these samples was 55%, and the range was 49–61%. Incorporation of zinc oxide as the internal standard substantially increased the accuracy and precision of the assay method. The uncertainty in the ratios in Table II is ~5%. This value is higher than the *SD* obtained from the repetitive testing of the 75% form I sample (Table II), 1.8%, and may be only a statistical anomaly.

In Table III are summarized the data obtained from the analysis of nine different mixtures of *N*-(4-hydroxyphenyl)retinamide. The mean difference for all nine mixtures was 2.3%. The largest differences between the known and calculated amounts of form I were −3 and +6%.

In summary, this method represents a precise and accurate method, within ±6%, for quantitation of the amount of *N*-(4-hydroxyphenyl)retinamide polymorph I present in samples of drug substance. The amount of form II can be calculated by difference. It appears that zinc oxide merits consideration for use as an internal standard in quantitative X-ray diffraction methods for other organic compounds.

Absolute Intramuscular, Oral, and Rectal Bioavailability of Alizapride

G. HOUIN, J. BARRE, and J. P. TILLEMENT ˣ

Received June 29, 1983, from the *Laboratoire de Biochimie I et de Pharmacologie, Centre Hospitalier Intercommunal de Créteil, 94000 Creteil, France.* Accepted for publication October 24, 1983.

Abstract □ A study was designed to estimate the absolute bioavailability of alizapride after intramuscular injection, oral administration as a solution or a tablet, and rectal administration as a suppository compared with that after intravenous injection. A balanced incomplete block-design trial was adopted. The intramuscular injection and the tablet administration showed identical results with those of the intravenous injection. On the contrary, the oral solution and the rectal suppository dosage forms gave lower absorption values, *i.e.*, 75 and 61% of the dose administered was absorbed, respectively.

Keyphrases □ Alizapride—bioavailability, intravenous, intramuscular, oral tablet, oral solution, rectal suppository □ Bioavailability—alizapride, intravenous, intramuscular, oral tablet, oral solution, rectal suppository □ Pharmacokinetics—alizapride, intravenous, intramuscular, oral tablet, oral solution, rectal suppository

Alizapride[1], *N*-[(1-allyl-2-pyrrolidinyl)methyl]-6-methoxy-1*H*-benzotriazole-5-carboxamide (I), is a new drug with antiemetic properties (1–3). It is used mainly in emergencies and is given intravenously in cancer patients (4), the pediatric population (5), and for internal medicine purposes (6). Chronic administration can be continued by intravenous, rectal, or even the oral routes of drug administration if patients are monitored well. For all these pharmaceutical forms, bioavailability results must be known to choose the appropriate dosage regimen for each route of drug administration.

In a previous study (7), it has been shown that the pharmacokinetics of alizapride were independent of the dose administered, in the dosage range of 50–200 mg, either by the intravenous or oral routes. In this report are described the pharmacokinetic results obtained after intramuscular, oral solution or tablets, and rectal administrations compared with those after intravenous injection.

EXPERIMENTAL SECTION

Materials—Alizapride was obtained commercially and showed no impurities in two different TLC systems. All reagents for alizapride analysis in biological materials were of commercially available analytical grade and were used without further purification.

Alizapride Analysis—Alizapride was measured in plasma and urine by using a previously described HPLC method (7).

HPLC involved a single-step extraction, a reverse-phase chromatographic

[a] Numbers refer to the order of the forms administered separated by weekly intervals.

separation[2], and fluorometric detection[3]. Under the described conditions, the assay sensitivity was 5 ng/mL in plasma and 0.1 mg/L in urine, with a mean coefficient of variation of 3.9% between 25 and 2000 ng/mL. No endogenous interfering peaks appeared during the assays.

Alizapride Administrations—Because of the five alizapride dosage forms to be tested, a balanced incomplete block design (8) was adopted to avoid a complete block design, which would have led to a very cumbersome protocol. Ten subjects gave informed consent to participate in the study. They were free from cardiac, renal, hepatic, and respiratory diseases and allergies by clinical and biological examinations. None of the subjects received any drugs for at least 15 d prior to the study. Each subject received the same dose of 100 mg in three different forms at intervals separated by 1 week. The order of the pharmaceutical form of drug administration was done in a random, balanced fashion so that each form could be administered at least once. The experimental design for the drug administrations is indicated in Table I, with the numbers indicating the order of drug administration. All drugs were administered after an overnight fast, and oral tablets were administered with 200 mL of water. Subjects were allowed to have a light meal 4 h after drug administration.

Sampling—A 7-mL heparinized blood sample was withdrawn at 0, 5, 10, 15, 20, 30, 45, 60, 90, and 120 min and 3, 4, 6, 8, 10, 12, and 24 h after drug administration. Urine samples were collected every 2 h during the first 12 h, once during the next 12 h, and every 24 h during the next 4 d.

Calculations—Statistical and pharmacokinetic calculations were performed with a table microcomputer[4]. Pharmacokinetic parameters were obtained with previously developed programs (7, 9). The interpretation of drug concentrations as a function of time was systematically performed according to three different pharmacokinetic models, *i.e.*, one-, two-, or three-compartment open models by a Gauss–Newton algorithmic method. At each step, a statistical Fischer test with the least-squares criterion was used to evaluate the benefit of increasing the number of compartments. Pharmacokinetic parameters were then calculated by the equations of Wagner (10). Results were compared for the different pharmaceutical forms using an analysis of variance (ANOVA) adapted to the trial design (11, 12). Furthermore, the symmetrical confidence intervals were estimated for the comparisons of the area under the curves and the amounts excreted unchanged in the urine after each administered form (8, 13).

RESULTS AND DISCUSSIONS

Intravenous Administration—The mean alizapride concentrations obtained from the six subjects receiving the intravenous form are shown in Figs. 1 and 2. The corresponding mean pharmacokinetic parameters estimated from in-

dividual results are presented in Table II. The results show a rapid distribution phase corresponding to a half-life of 0.10 ± 0.05 h (range, 0.062–0.15 h) and an elimination phase with a mean half-life of 2.75 ± 0.78 h (range, 1.75–3.99 h). The volumes of distribution were large [36.3 ± 22.6 L (range, 14–68 L) for the central compartment and 61.4 ± 11.3 L (range, 44.1–72.8 L) for the peripheral compartment]. The total clearance of elimination was moderate [461.8 ± 57.3 mL/min (range, 405.5–533 mL/min)]. The mean unchanged drug urinary elimination curves of the six subjects are shown in Fig. 3. The overall urinary elimination of unchanged alizapride (80.51 ± 5.4%) of the dose administered (range, 73.2–88.7%) indicates that urinary excretion is the main route of alizapride elimination. About 20% of the injected dose was not recovered in this study. This cannot be explained by an insufficient amount of urine collected (Fig. 3). So the difference must be accounted for by metabolism or another route of elimination of unchanged drug or its metabolites, such as biliary excretion. It is noteworthy that in a previous study (7) it was shown that the chromatographic method was specific for the unchanged drug, both in urine and plasma, and no extra peak appeared in the chromatograms. Therefore, from the data of alizapride urinary elimination, the renal clearance can be calculated to be 372.0 ± 58.0 mL/min, indicating an active tubular process of alizapride excretion.

Intramuscular Administration—The plot of mean plasma concentrations of alizapride *versus* time is shown in Fig. 1, and the corresponding pharmacokinetic parameters are presented in Table II. The appearance of the drug in plasma is very rapid, corresponding to a rate constant of 7.13 ± 5.56 h^{-1}. Maximum concentrations were 848 ± 193 ng/mL and occurred within 20 min after injection. The calculated parameters were very close to those observed after intravenous injection. It is noteworthy that the area under the plasma concentration curves (AUC) and the amount excreted unchanged in the urine are identical.

Oral Administration—The plot of the mean plasma concentrations of alizapride *versus* time obtained after the oral administration of tablets and solutions are shown in Fig. 2. The corresponding mean pharmacokinetic parameters are listed in Table II. The maximum plasma concentrations were higher after solution administration than after tablet administration (mean, 930 ± 350 ng/mL *versus* 740 ± 90 ng/mL) and occurred slightly sooner after solution administration (0.57 ± 0.34 h *versus* 0.69 ± 0.47 h). Similarly, the lag time observed with the solution dosage form was two times lower than that of the tablet. Compared with the parameters obtained after the intravenous injection, the AUC values were lower (mean, 3.53 ± 1.08 and 2.86 ± 1.24 mg·h/L, respectively, for the tablet and the solution), and the amount excreted unchanged in the urine decreased to 78.3 ± 7.3 and 69.7 ± 7.1 mg for the tablets and solutions, respectively. With these dosage forms, therefore, the bioavailability seemed to decrease, resulting in increased apparent volumes of distribution and total clearances, since these parameters were estimated on the assumption of total absorption. On the contrary, the elimination half-lives and the renal clearances, which are independent of the percentage of the dose administered that was absorbed, are identical with those obtained after intravenous injection.

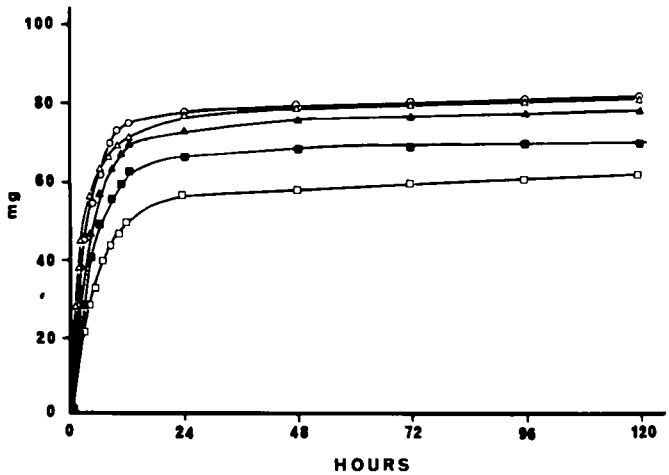

Figure 3—*Mean unchanged alizapride urinary elimination curves obtained from six subjects after each of the different forms was administered. Key: (○) intravenous; (△) intramuscular; (▲) tablet; (■) oral solution; (□) rectal.*

Rectal Administration—The plots of the mean plasma and urine concentrations *versus* time are shown in Figs. 2 and 3, respectively. The corresponding pharmacokinetic parameters are listed in Table II. The maximum plasma concentrations obtained with suppositories were the lowest (630 ± 210 ng/mL) and were seen last at 1.26 ± 1.02 h after administration. The amounts absorbed from this form seemed to be low since the AUC was 2.32 ± 0.69 mg·h/L and the mean urinary elimination was 61.8 ± 9.8 mg. The mean elimination half-lives and renal clearances were identical with those observed after intravenous injection.

Bioavailability Study—The absolute bioavailability of the four dosage forms was estimated from the AUC and the overall amounts of unchanged excreted drug. The ANOVA analyses corresponding to the trial design showed no statistical differences at the 0.05 levels between subjects or time of drug administration for both parameters.

The AUC ANOVA failed to show an overall difference between the dosage forms ($^4_{16}F$ = 2.996, but was very close to the significant value at the 0.05 level, ($^4_{16}F$ = 3.01). However, for the urinary excretion studies, ANOVA showed a significant difference in the tested form at the 0.01 level ($^4_{16}F$ = 5.47). The protected multiple Student t test (11), applied for comparisons of each dosage form against intravenous injections, showed that intramuscular and oral tablet administrations were not significantly different from the intravenous administration (t = 0.9 and 2.25, respectively). However, the oral solution and the rectal suppositories both differed significantly from the intravenous injection at the 0.01 level (t = 10.8 and 18.7, respectively).

The difference observed between the two parameters can be explained by the greater variability observed with the AUC. This is shown by the estimation of the symmetrical confidence interval according to Westlake (8, 13) which yielded 36.9 and 31.2% intervals for the tablet and the intramuscular forms when estimated from AUC and only 13.0 and 13.9% for the same forms, respectively, when estimated from amounts excreted in the urine. Due to this greater variability, the ANOVA was unable to show any difference, although it seemed to occur.

It was surprising to find that the oral solution showed significantly lower bioavailability than did the tablet forms since, in most cases, solutions yielded higher bioavailabilities than did the solid forms. Such an observation has been made with two barbiturates, namely, cyclobarbital (14) and heptabarbital (15). Physiological explanations for such a phenomenen are difficult. Either a precipitation in the stomach and/or the intestinal tract or a delay in the transfer of the drug from the stomach to the intestine can occur (10). The latter was unlikely to have occurred with alizapride since it appeared very rapidly in the blood stream with both oral forms, and the maximum plasma concentrations were obtained very rapidly.

Differences in the rate of absorption of the drug with the extravascular forms were tested by using the nonparametric Kruskal–Wallis test (11) for

the observed plasma maximum concentrations and the time at which they occurred. This test failed to show any difference between the four tested forms with the two chosen parameters. Therefore, the study of the bioavailability of intramuscular, oral solution, tablet, and rectal suppository administration compared with intravenous administration showed that the intramuscular dosage form and oral tablets gave results similar to those obtained by intravenous injection, but the oral solution and the suppositories showed a mean lower bioavailability of 75 and 61%, respectively.

Kinetic Study of the Polymorphic Transformations of Phenylbutazone

YOSHIHISA MATSUDA ˣ, ETSUKO TATSUMI, ETSUKO CHIBA, and YUKIE MIWA

Received June 15, 1983, from the *Kobe Women's College of Pharmacy, Higashinada, Kobe 658, Japan.* Accepted for publication December 5, 1983.

Abstract □ The polymorphic transformations of phenylbutazone from metastable forms α and β to stable form δ were studied quantitatively at four temperature and five humidity levels by X-ray powder diffractometry. The transformation of form α conformed with the Avrami-Erofe'ev kinetic model and form β conformed with apparent first-order kinetics. In the two transformation systems, the induction periods depended on the storage conditions and were prolonged with lowering of temperature and humidity. The transformation rate of form α was not affected by humidity, whereas that of form β increased according to a rise in humidity. The temperature dependency of the transformation rate constant was remarkable. The Arrhenius treatment was applicable to the $\beta \rightarrow \delta$ transformation at low temperatures. The overall half-life, including induction period, revealed that form α was more stable than form β under any storage condition. A good linear relationship existed between the induction period and the transformation rate constant, irrespective of the storage conditions. The scanning electron photomicrographs of forms α and β demonstrated that acicular crystals of form δ grew as the transformation progressed. This could be confirmed as the change in particle diameter of the samples.

Keyphrases □ Phenylbutazone—polymorphic transformation, physicochemical stability under different storage conditions □ Polymorphic transformation—phenylbutazone, physicochemical stability under different storage conditions □ Physicochemical stability—phenylbutazone, different storage conditions, polymorphic transformation

The method for improving the bioavailability of a slightly soluble drug is an important problem in the preformulation study of solid dosage forms. Polymorphic transformation is often effective as a technique for increasing solubility. Since the solubility and dissolution rate of a metastable polymorph are usually higher than those of the stable form, the former is more desirable clinically than the latter; however, the former is not always preferable in physicochemical stability. It is well known that, irrespective of temperature, only one crystal form is thermodynamically stable and all other forms convert eventually to the stable one. A metastable form nevertheless may occasionally exhibit sufficient stability to ensure a reasonable shelf life. If a metastable form is used in a formulation because of its excellent dissolution properties, it is prerequisite to demonstrate that the metastable form is never transformed to a more stable form under usual storage conditions.

Although some difficulties are involved in establishing a quantitative method for polymorphic transformation, there are several previous reports on the method (1–8). Due to the complexity of solid-state reaction, the stability-indicating kinetic interpretation has been fully discussed in only a few reports (1, 7, 8). The techniques described here are divided into three groups: IR spectrophotometry based on the quantitative Nujol mull technique (1–3, 6), differential scanning calorimetry (4, 5), and X-ray powder diffractometry (7, 8). Among these, X-ray diffractometry may be the most useful method because heat and liquid relating closely to polymorphic transformation are not involved in the measurement.

In the present investigation, the stability profiles between the two metastable forms of phenylbutazone are comparatively evaluated. The preparation and characterization of the phenylbutazone polymorphism have been described previously (9–16). The polymorphic system has been reported to consist of a stable form (form δ), four metastable forms (forms α, β, γ, and ϵ), and two pseudopolymorphs, among which form ϵ has the highest solubility. For the reasons of high yield and simplicity of preparation, forms α and β were chosen as polymorphic models in this study. The transformations of these forms were measured quantitatively by X-ray powder diffractometry and thoroughly studied over long periods of time under different storage conditions.

EXPERIMENTAL SECTION

Preparation and Characterization of Polymorphs—*Form δ*—A single batch of commercial phenylbutazone[1] was used as received. The drug was confirmed to be form δ by X-ray powder diffraction analysis, differential scanning calorimetry (DSC), and IR spectroscopy.

Form α—An acetone solution (20% w/v) of the drug was evaporated to dryness under reduced pressure at 0°C by using a rotary evaporator.

Form β—The same solution as that used for form α was poured into 10 volumes of distilled water and stirred vigorously at room temperature. The separated crystals were removed by filtration through a sintered-glass funnel and dried under reduced pressure. These modifications were also characterized as forms α and β, respectively, according to a previously described method (16).

To expose the maximum surface area to ambient moisture, all modifications were micronized with a pin mill[2] at 26,960 rpm. The specific surface area diameters of the milled forms α and β, measured by an air permeability method (17), were 3.2 and 2.8 μm, respectively. The particle densities of forms α, β, and δ were determined with an air comparison pycnometer[3]. The X-ray powder diffraction patterns and the DSC data of the samples before and after milling indicated that no polymorphic transformation occurred during the milling operation (Figs. 1 and 2).

Determination of Transformation Rate—*Preparation of Calibration Curves by X-ray Powder Diffractometry*—Known quantities of form α or β were thoroughly mixed with form δ in various proportions in a mortar. The mixtures (250 mg each) were subjected to X-ray powder diffraction analysis. The X-ray diffraction pattern was recorded according to a previously described method (16). The instrument was set as follows: (*a*) 35 kV, 7 mA; (*b*) 1° beam slit and 0.2° detector slit; (*c*) count range, 1000 cps; (*d*) time constant, 1 s; (*e*) range of diffraction angle 2θ = 30–5°; (*f*) scanning speed, 4°/min; and (*g*) chart speed, 40 mm/min.

Although the X-ray diffraction pattern of form δ obviously differed from that of forms α and β (16), most of the peaks characterized by these forms in the mixture were not fully separated due to the close vicinity of the diffraction angles. Figure 3 represents the typical X-ray diffraction patterns of various proportions for α–δ and β–δ binary mixtures by weight basis. The changes in peaks (arrows) accompanying various mixing ratios were especially remarkable at the diffraction angles of 6.6°, 7.1°, 19.1°, and 20.1° for the α–δ system and at 15.6°, 16.4°, 20.1°, and 21.0° for the β–δ system. These

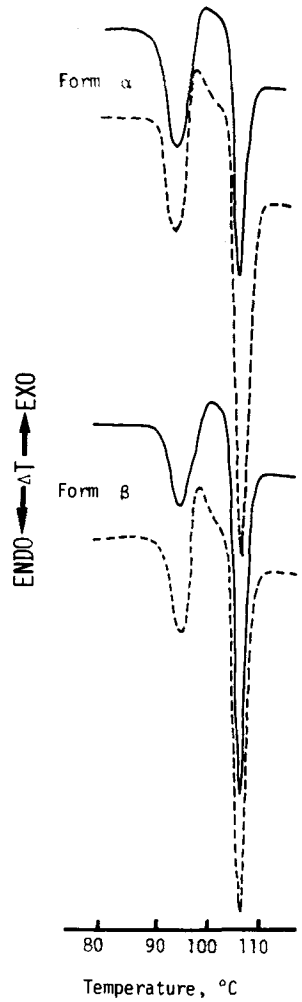

Figure 2—*DSC curves for forms α and β before (—) and after (- - -) milling. Sample weights: 7.30, 9.21, 8.19, and 8.01 mg (from top to bottom); heating rate, 10°C/min; sensitivity, ±20 mJ/s.*

peaks consisted of the individual peak characterizing each form. Thus, the diffraction intensity ratios of the two adjacent diffraction angles were plotted against the weight fraction of each component (Fig. 4). Despite the fluctuation of the individual diffraction intensity, these plots were always reproducible to give a smooth curve for any of the mixing ratios. Since curve a (Fig. 4) for the α–δ system approached infinity at the lower weight fraction of form δ, the reciprocal values of intensity ratios were regressed with curve b (Fig. 4), and their terminal regions were made up for each other (thick line of the left panel, Fig. 4). Although the calibration data for the α–δ and β–δ systems could be obtained as straight lines on the middle part of log-probability and semi-logarithmic scales, respectively, they deviated from these lines on the terminal regions. Therefore, the original calibration curves were used. The conversion rates for the two systems were expressed by the mean of values estimated from the two calibration curves.

The changes in diffraction intensity at these angles are shown for the actual transformation system in Fig. 5. The time course change in relative diffraction intensity was clearly observed, indicating the validity of this method.

Preparation of Calibration Curves by Differential Scanning Calorimetry—For purposes of comparison with the X-ray powder diffractometry method, DSC was employed for determining the conversion rate. Similarly to X-ray powder diffractometry, preparation of an exactly equal amount of mixed samples of varying weight ratios was attempted to accomplish the plotting of DSC data. This was almost impossible from a technical point of view; therefore, the following method was alternatively employed. Different amounts of form α or β were accurately weighed and thermograms of these pure samples were recorded in a closed pan system. The DSC[4] operation conditions were: (*a*) heating rate, 5°C/min; (*b*) sensitivity, ±5 mJ/s; (*c*) chart speed, 40 mm/min; (*d*) flow rate of nitrogen gas, 30 mL/min. Forms α and β exhibited endothermic peaks at 91.0–92.0°C and 95.0–96.5°C, respectively,

[4] DSC-30; Shimadzu Co., Kyoto, Japan.

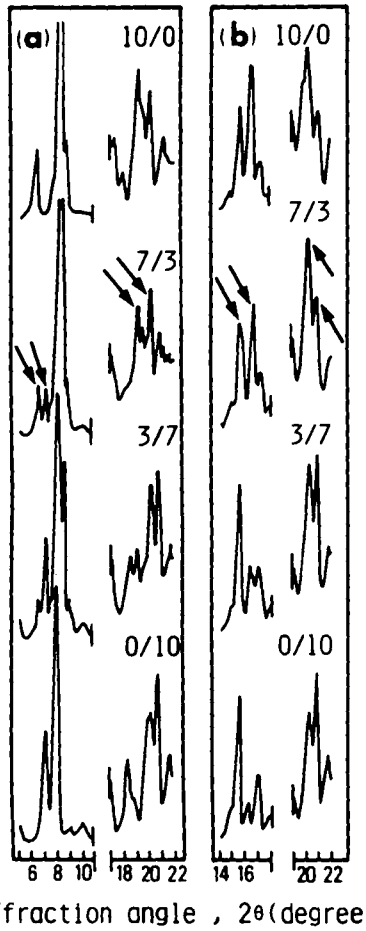

Figure 3—*X-ray diffraction patterns of α–δ and β–δ binary mixtures in various ratios. Key: (a) α–δ system; (b) β–δ system. The fraction in the graph represents the form α (form β)/form δ weight ratio.*

which subsequently underwent polymorphic transformations to show exothermic peaks at 93.0–94.0°C and 96.5–98.0°C, respectively. Two areas consisting of an area surrounded by both an endothermic peak curve and a line connecting the starting point of the endothermic peak with the top of the exothermic peak and another area surrounded by the same curve and the line connecting the same point with the terminal point of the exothermic peak were regarded as areas A and B, respectively (Fig. 6). The areas were measured by a gravimetric technique and were plotted against sample weight. Good straight lines were obtained between both parameters for the two systems. The conversion rate was expressed as the ratio of the mean of the two values estimated with lines A and B to the weight of sample on an aluminum pan.

Storage Conditions and Sampling of Polymorphs—About 1.2 g of a sample was placed in a vial as lightly as possible and stored over saturated solutions of various salts placed in laboratory desiccators. The desiccators were kept in a thermostated cabinet. The samples for thermal analysis were placed on an aluminum pan and stored in the same desiccators. The temperatures and humidities used were 25, 40, 50, and 60°C and 0, 30, 50, 70, and 80% relative humidity, respectively. Phosphorus pentoxide was used to provide a limiting humidity of 0% relative humidity at 60°C. The stored sample was withdrawn from each vial at various time intervals for X-ray powder diffractometry. After the measurement, the sample was returned to the vial for further storage.

Scanning Electron Microscopy—The scanning electron photomicrographs of the samples stored at 60°C and 80% relative humidity were taken with a microscope[5] at magnifications ranging from 600× to 2000×.

RESULTS AND DISCUSSION

Kinetic Interpretation of Transformation Processes—Since the solid-state reaction is essentially a surface phenomenon, the solid–solid transformation of a metastable polymorph may require a long period of time under mild stress condition. The residual percentage was determined by the X-ray powder

[5] Model JSM-U3; JEOL Co. Ltd., Tokyo, Japan.

	60	0.988 (7)	—	1.000 (4)	0.990 (4)	0.999 (4)

[a] Experiment was not carried out. [b] Not calculated; coefficient of correlation could not be calculated because the transformation did not proceed at all or proceeded only to a small extent. [c] Number of plots are indicated in parentheses.

for form α were all sigmoidal in shape, whereas those for form β were exponential. Similar profiles were obtained for the samples stored under other conditions of temperature and humidity. A common feature was the presence of an induction period similar to that obtained by Moustafa *et al.* (1, 2), which varied depending on the storage condition.

Figure 8 shows the comparison of the residual percentage determined by X-ray diffractometry with that determined by the DSC for the same sample as shown in Fig. 7. Irrespective of the humidity level, a good correspondence was obtained after the middle stage of the $\alpha \rightarrow \delta$ transformation. However, in the earlier stage of the $\alpha \rightarrow \delta$ transformation and throughout the entire process of $\beta \rightarrow \delta$ transformation, such a correspondence could not be established; the DSC resulted in an overestimation of the conversion rate. These results indicate that during the course of heating some further transformation occurred before the transition peak was observed. The DSC thus proved to be inadequate for determining the conversion rate in the present transformation systems; therefore, the subsequent determinations were carried out by the X-ray powder diffractometry method alone.

To confirm the conformance of isothermal kinetic data to theoretical kinetic equations, an interpretation method by Hancock and Sharp (18) was applied to the accompanying Avrami-Erofe'ev equation (19):

$$\ln [-\ln (1 - \alpha)] = m \cdot \ln t + \ln B \qquad \text{(Eq. 1)}$$

where α and t represent a conversion rate of polymorph and storage time, respectively, B is a constant, and m is the constant relating to the mechanism of transformation. In the present transformation systems, Eq. 1 should be modified as:

$$\ln [-\ln (1 - \alpha)] = m \cdot \ln (t - t_i) + \ln B \qquad \text{(Eq. 2)}$$

where t_i is the induction period. Equation 2 indicates that a linear relationship of a gradient m exists between the values of $-\ln (1 - \alpha)$ and $t - t_i$ on the double logarithmic scale. The best-fitting values for m and t_i, which should give the maximum coefficient of correlation, were calculated from the conversion rates to be <80% by the computer-aided least-squares method. The values for m and the correlation coefficients are given in Tables I and II, respectively.

Although several values were somewhat abnormal due to the paucity of data, the integer m values for $\alpha \rightarrow \delta$ and $\beta \rightarrow \delta$ transformations were rounded up to 2 and 1 from their mean values of 1.95 and 0.96, respectively. Equations 3 and 4 are, consequently, derived from Eq. 2:

$$[-\ln (1 - \alpha)]^{1/2} = k_1 (t - t_i) \; (\alpha \rightarrow \delta \text{ transformation}) \qquad \text{(Eq. 3)}$$

$$\ln (1 - \alpha) = -k_2 (t - t_i) \; (\beta \rightarrow \delta \text{ transformation}) \qquad \text{(Eq. 4)}$$

where k_1 and k_2 are transformation rate constants. The values for both transformation systems in Fig. 7 were plotted according to Eqs. 3 and 4 (Fig. 9). All values gave straight lines under all storage conditions; hence, the regression analyses were repeated by using Eqs. 3 and 4 to calculate the values of t_i, k_1, and k_2 (Table III).

The m value of 2 suggests that $\alpha \rightarrow \delta$ transformation is controlled by a nucleation-and-growth reaction and that the growth of the stable form may take place by a one- or two-dimensional mechanism (20). According to a reaction model (21) conforming to this kinetic expression (Eq. 3), which described the first formation followed by growth of potential nuclei on the surface of the drug, the nucleation was rapid and complete. Therefore, the growth appeared to be two-dimensional. On the contrary, the result of the $\beta \rightarrow \delta$ transformation conforming to the first-order kinetics suggests that the rate of transformation is controlled by random nucleation (*cf.* instantaneous nucleation for $\alpha \rightarrow \delta$ transformation) in an assemblage of an identical reactant fragment (21).

Effects of Temperature and Humidity on the Induction Period and Transformation Rate Constant—Since the induction period and transformation rate depend on the mobility of constituent atoms or molecules of the solid, they must vary considerably with temperature. The effects of temperature and humidity on the induction period on semilogarithmic scales are illustrated in Fig. 10, in which the relative humidity is converted to absolute humidity to provide a thorough understanding of the water contents. The right terminal point of each regression line represents the limiting absolute humidity corresponding to 100% relative humidity at the designated temperature. Temperature affected the induction period more markedly than did humidity. The two transformation systems showed a common tendency to prolong the induction period with a lowering in temperature and humidity, suggesting the delayed initiation of nucleation of the stable form. It should be emphasized that even under the extreme humidity condition of 0% relative humidity at 60°C the induction period was always a finite value for the two transformation systems. The micronization of samples by milling may cause generation of a large number of point defects or dislocations on the crystal surfaces, resulting in selective heterogeneous nucleation. Judging from the water-absorbing power of phosphorus pentoxide[6], as well as the environmental temperature and atmospheric pressure, complete desorption of water molecules on the sites of potential nuclei formation seems to be difficult under these conditions. Therefore, even though the amount of water is very small, it may serve as a nucleation catalyst.

Moustafa *et al.* (1) interpreted the induction period as the time required for equilibration of the crystal surfaces with water vapor. However, the results that the induction period was a finite value at 0% relative humidity and was prolonged at lower temperatures indicate reasonably that the induction period is defined as the time at which the embryo of a stable form grows to the critical nuclei at the nuclei formation sites.

Figure 11 illustrates the effects of temperature and humidity on the

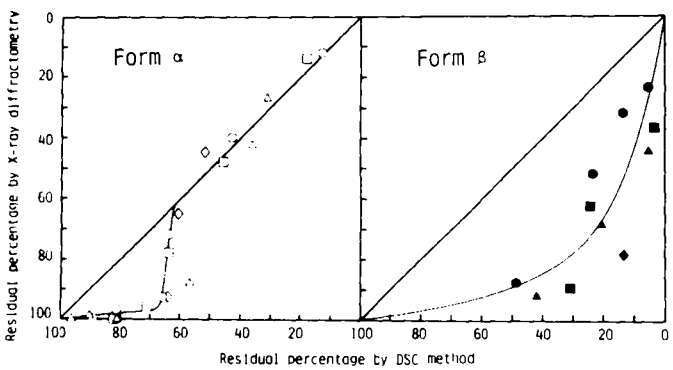

Figure 8—*Relationship between residual percentages of forms α and β at 60°C determined by X-ray diffractometry and those determined by differential scanning calorimetry. Key: (◇ ◆) 0%; (△ ▲) 50%; (□ ■) 70%; (○ ●) 80% relative humidity.*

[6] The water content remaining in dried air over phosphorus pentoxide in a desiccator is 2.5×10^{-5} mg/L (*cf.* Ref. 22).

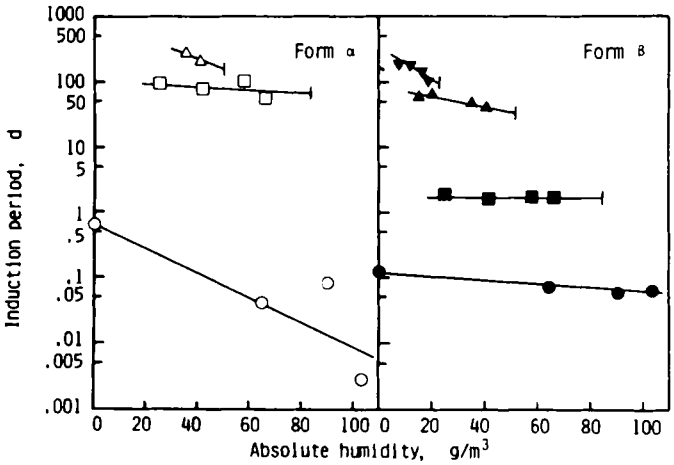

Figure 10—*Effect of absolute humidity on induction periods at different temperatures. Key: (▼) 25°C; (△▲) 40°C; (□■) 50°C; (○●) 60°C. The induction periods for α → δ transformation at 25°C could not be obtained within the time course of this investigation.*

transformation rate constant. The rate constants for forms α and β showed the same dimension of day^{-1}. It was, however, meaningless to use these values for comparison with the rate of transformation, because the mechanisms of transformation differed. The rate constant and the induction period were remarkably affected by temperature, and the rate was increased with a rise in temperature. The difference between the two transformations was distinct: the transformation of form α was not affected by humidity, whereas form β underwent transformation by a complex action of temperature and humidity. Furthermore, the higher the temperature, except for 60°C in the form β transformation, the stronger the dependence on humidity. These data indicate that storage at lower temperature and humidity is essential to inhibit polymorphic transformation.

The estimated half-life, including induction period, was much smaller in form β than in form α under any storage condition, indicating that form β is less stable (Table IV). The order of the thermodynamic instabilities of forms α and β corresponds well to that of superiority in dissolution properties (16).

Figure 12 shows the elevated temperature transformation data plotted by the Arrhenius procedure, in which the logarithmic values for the rate constants obtained by interpolating or extrapolating each regression line of Fig. 11 to the designated absolute humidity are plotted against the reciprocal of absolute temperature. Only one plot was obtainable at each temperature for form α, because the rate constant was not humidity dependent. The rate constant at 25°C was not obtained, because no transformation occurred within the time course of the present investigation. Good linear relationships existed for the β → δ transformation at lower humidities at temperature levels ranging from 25°C to 50°C, indicating that the higher the humidity, the steeper the slope

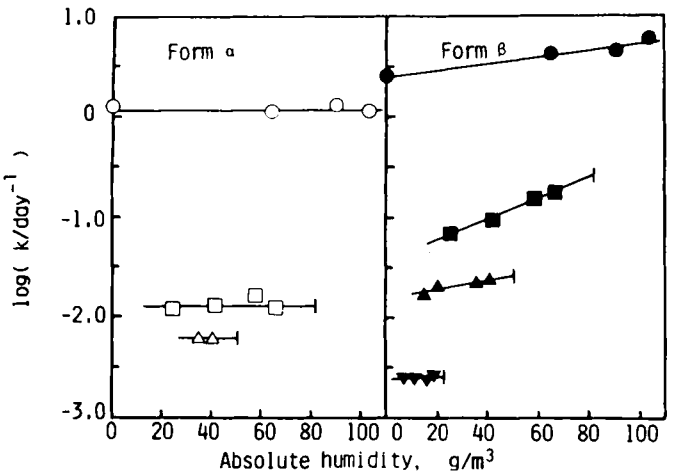

Figure 11—*Effect of absolute humidity on the transformation rate constant at different temperatures. Key: (▼) 25°C; (△▲) 40°C; (□■) 50°C; (○●) 60°C. The transformation rate constants for α → δ transformation at 25°C could not be obtained, because no transformation started within the time course of this investigation.*

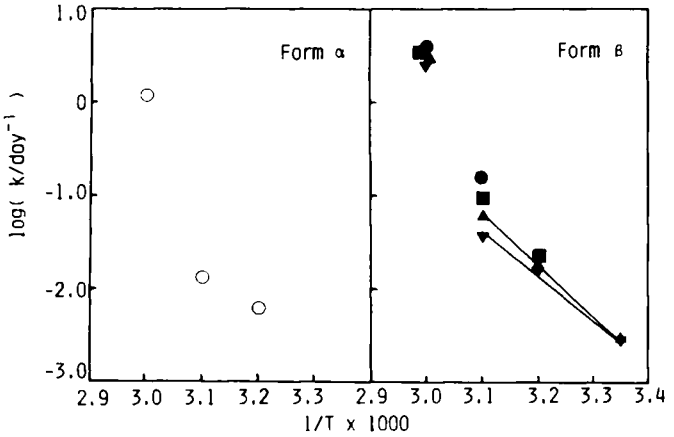

Figure 12—*Arrhenius plot for α → δ and β → δ transformations at different absolute humidities. Key: (○) 0, 20, 40, and 60 g/cm³ for α → δ transformation; (▼) 0 g/cm³, (▲) 20 g/cm³, (■) 40 g/cm³, (●) and 60 g/cm³ for β → δ transformation.*

of the straight line. Although the linearity and/or temperature dependency of the slope at higher humidities were blurry due to insufficient data, the activation energy for transformation was found to increase gradually with an increase in humidity. The dehydration processes from crystals entrapping water of crystallization were also affected by temperature and water vapor pressure (23, 24), *e.g.*, the activation energy for dehydration increases with a rise in water vapor pressure (24). However, the role of water in the present transformation systems fundamentally differed from that in the dehydration reaction. Since the transformation rate is a function of several variables possessing different temperature coefficients, this result is not easily explained.

The activation energies thus determined at absolute humidities of 0 and 20 g/m³ were ~21.7 and 25.1 kcal/mol, respectively. These values were much smaller than the activation energy of ~203 kcal/mol (11) that was determined by the method of Kissinger (25). Weaker intermolecular actions such as van der Waals forces or hydrogen bonds are predominant in polymorphs; therefore, the transformation must not require a higher activation energy. The validity of this suggestion may be supported by the facts that the activation energy for the polymorphic transformation in binaphthyl is ~60 kcal/mol and that for *p*-dichlorobenzene is much smaller (17 kcal/mol) (26). It is also interesting to note that the activation energy for loss of water from cytosine monohydrate is ~25 kcal/mol (26).

The rate constants at 60°C in the two transformation systems were abnormally higher than those estimated by extrapolating the regression lines, suggesting that the activation energies became high at ~60°C. Additional information on other transformation systems is needed to understand why a change in activation energy accompanies a rise in temperature. It has been reported that since not all solid-state reactions conform to the Arrhenius treatment, the activation energy is not necessarily constant with temperature (27, 28).

The kinetic behavior during the induction period and in the transformation rate constant suggest the close relationship between them. The double-logarithmic plotting of both factors gave a good straight line, irrespective of the storage conditions for the two transformation systems (Fig. 13). It was verified

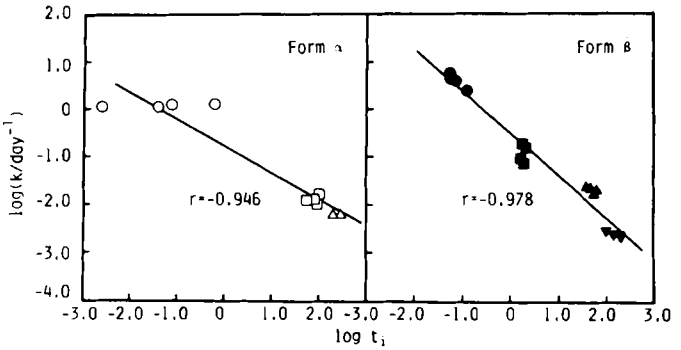

Figure 13—*Relationships between induction period and transformation rate constant for α → δ and β → δ transformations. Key: (▼) 25°C; (△▲) 40°C; (□■) 50°C; (○●) 60°C. The plots for α → δ transformation at 25°C could not be obtained within the time course of this investigation.*

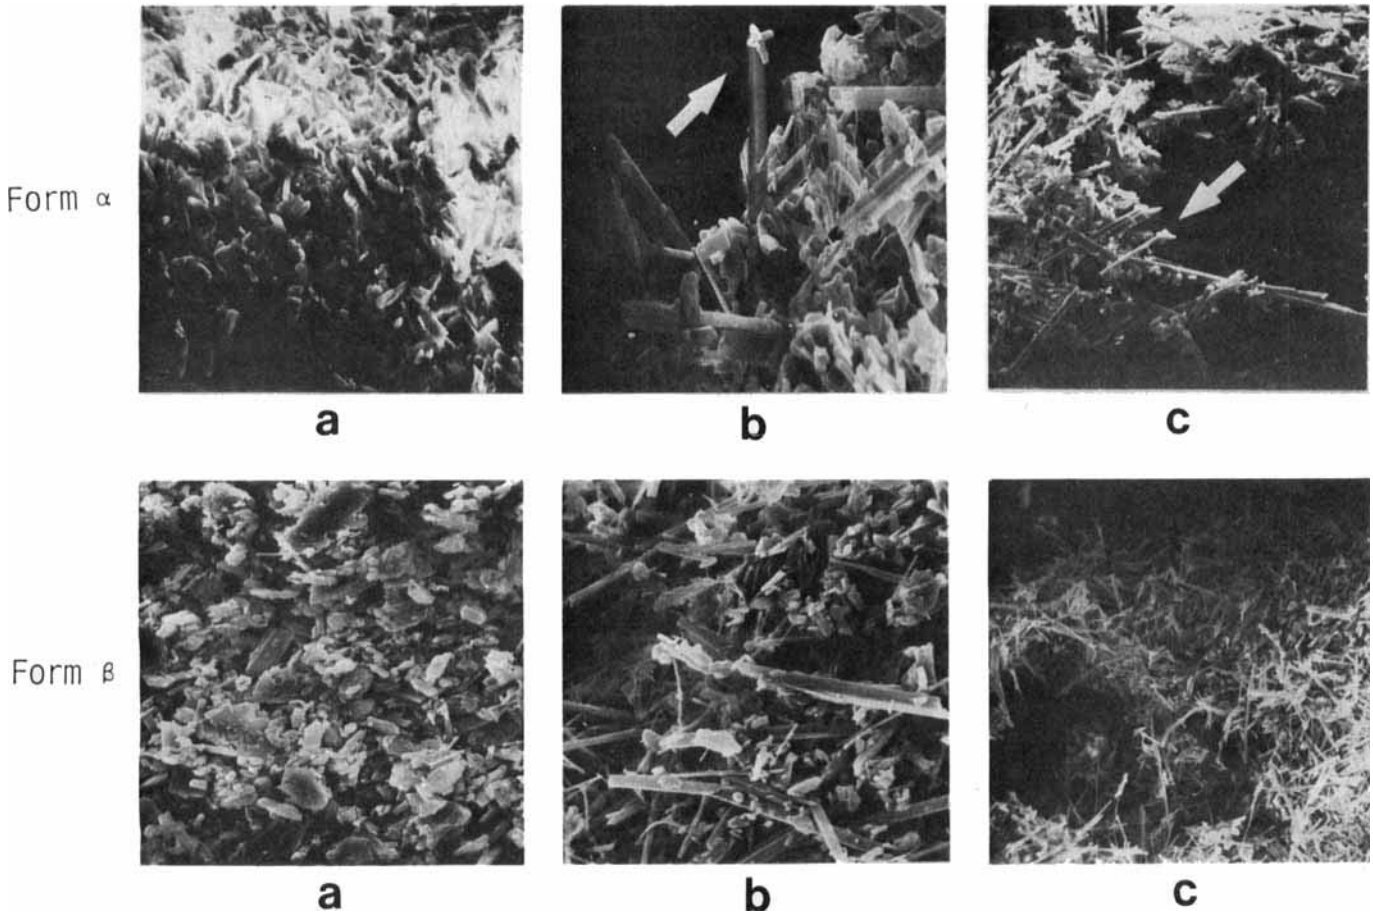

Figure 14—*Scanning electron photomicrographs representing various stages in crystal growth accompanying α → δ and β → δ transformations at 60°C and 80% relative humidity. Key: (a) initial, 2000×, (b) 50% transformed, 2000×; (c) 80% transformed, 600×.*

that prolongation of the induction period led to the subsequent lowering of the rate constant, resulting in further stability. These results indicate that the induction stage is a process that induces control of transformation. The regression analyses showed that these factors were closely correlated with each other at a 5% level of significance. Hence, the following regression equations were obtained:

$$k_1 \times t_i^{0.56} = 0.167 \ (\alpha \rightarrow \delta \text{ transformation}) \qquad \text{(Eq. 5)}$$

$$k_2 \times t_i^{0.88} = 0.319 \ (\beta \rightarrow \delta \text{ transformation}) \qquad \text{(Eq. 6)}$$

It is possible to estimate an approximate induction period for the $\beta \rightarrow \delta$ transformation by substituting the rate constant under a given storage condition (obtained from Fig. 12) into Eq. 6. Assuming that the Arrhenius treatment of the $\alpha \rightarrow \delta$ transformation was applicable in the same temperature range as that of the $\beta \rightarrow \delta$ transformation, the induction period should require not less than ~8.8 years at 25°C.

Microscopic Characterization of Transformation Processes—The morphological changes of the crystal surface in the course of transformation were traced by scanning electron photomicroscopy. Figure 14 shows the photomicrographs of forms α and β which were transformed by 50 and 80% at 60°C and 80% relative humidity in intact samples. Due to minute sizes, any newly born crystal nuclei could not be discriminated in the early stage of transformation. The occurrence and growth of whiskers characterizing form δ were clearly observed during mid and late transformations. The whiskers were thicker and longer in the $\alpha \rightarrow \delta$ transformation than in the $\beta \rightarrow \delta$ transformation. This result may be explained by the fact that the transformation of form α is slower than that of form β, as shown above. Since the transformation rate of form α is independent of moisture, the interface must advance from the nuclei surface into the crystal entity accompanying the growth of the stable form. This view is not contradictory to the previous statement that the growth of the stable phase may be two-dimensional. The knots (arrows in the photos) of sesame seed-sized form α crystals, which are distributed over the surface of acicular crystals of form δ, became thin as the transformation progressed, suggesting their uptake into the crystal entity.

The particle densities of forms α, β, and δ were almost identical, with the measured values being 1.21, 1.21, and 1.19 g/cm^3, respectively. Therefore, it is believed that no visible change in the volume of one crystal occurs during transformation. The fact that acicular crystals much larger than intact crystals in volume are nevertheless growing suggests strongly the sintering of crystals at the potential nuclei formation sites. In this sense, the mechanism of the

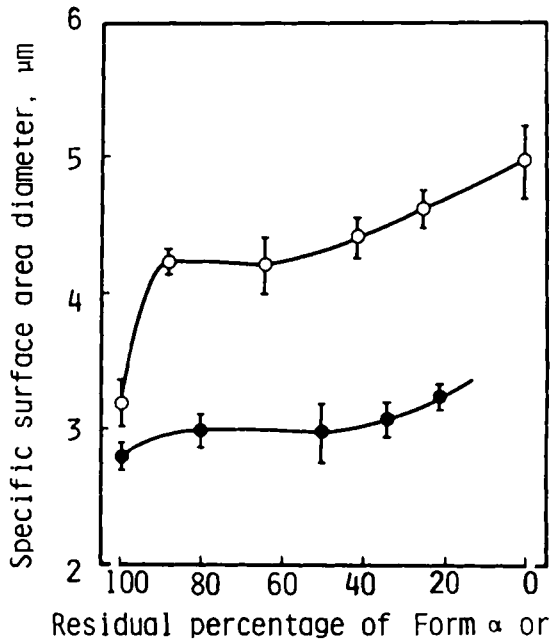

Figure 15—*Changes in particle diameter of samples under transformation. Key: (○) α → δ transformation; (●) β → δ transformation. Each point represents mean ± SD (n = 15).*

present whisker growth is quite different from that of whisker growth on an ethenzamide tablet which is liable to sublimation (29).

The morphological changes were quantitatively confirmed in Fig. 15, in which the specific surface area diameter of the sample was plotted against the percent conversion of form α or β. The growth curves of forms α and β showed a quite similar pattern to the BET-type adsorption isotherm and consisted of three stages: (*a*) a rapidly growing stage up to an ~10% conversion rate; (*b*) a cessation stage without evident increase in particle diameter; (*c*) a regrowing stage of whiskers. The increasing rate of particle diameter of form α at an 80% conversion rate was ~2.8 times as high as that of form β, indicating that a higher increasing rate of the diameter was induced by slower transformation.

In addition to showing the fundamental guideline for solution of a stability problem of polymorphic forms, the practical significance of controlling ambient factors which can maintain the integrity of the selected form has been suggested. A more detailed explanation of the relationship between crystal growth and mechanism of transformation is not available at the present time, and further studies are required to draw definite conclusions.

This study was presented in part before the 102nd Annual Meeting of the Pharmaceutical Society of Japan, Osaka, April 1982.

The bulk sample of phenylbutazone was generously supplied by Ciba-Geigy (Japan) Ltd. Thanks are also tendered to Dr. H. Nakamachi, Takeda Chemical Industries Ltd., Osaka, for preparation of the scanning electron photomicrographs.

Intravaginal Controlled Administration of Flurogestone Acetate I: Development of a Stability-Indicating Liquid Chromatographic Method and Stability Kinetics of Flurogestone Acetate

MOHAN B. KABADI, KIRTI H. VALIA*, and YIE W. CHIEN ˣ

Received October 3,1983, from the *Controlled Drug Delivery Research Center, College of Pharmacy, Rutgers-The State University of New Jersey, Piscataway, N.J. 08854.* Accepted for publication November 30, 1983. * Present address: Lilly Research Laboratories, Eli Lilly & Co., Indianapolis, IN 46206.

Abstract □ Flurogestone acetate is a synthetic progestin useful for estrus synchronization in sheep. The estrus synchronization is achieved by inserting the drug-impregnated vaginal sponge in the sheep for up to 15 d, during which time flurogestone acetate is administered continuously by intravaginal absorption to suppress estrus and ovulation. The sponge is then withdrawn to regain estrus within 2–4 d. A review of the literature suggests that the analytical methods currently available are not specific, sensitive, and rapid enough. A stability-indicating high-performance liquid chromatographic method was developed, which is capable of characterizing the stability kinetics of flurogestone acetate under various environmental conditions and quantifying the release and absorption profiles of the drug from the vaginal sponges.

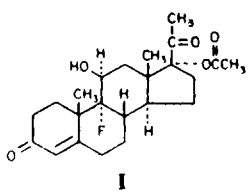
Keyphrases □ Flurogestone acetate—stability-indicating HPLC method, stability kinetics □ HPLC—stability-indicating method, flurogestone acetate □ Stability kinetics—flurogestone acetate

Flurogestone acetate (I) is a synthetic progestin used in sheep for estrus synchronization (1). The objective for developing an effective treatment for estrus synchronization is to establish a stage at which estrus can be induced to make the females fertile in a desired season. Estrus synchronization is achieved by prolonged continuous administration of flurogestone acetate-releasing vaginal sponges to the sheep for 15 d; 2–4 d after withdrawal of the sponges most sheep regain their estrus.

Over the years, flurogestone acetate has been assayed by GC (2), gravimetric analysis (2), and radioactive tracers (3). However, these methods lack assay specificity, speed, sensitivity, and/or convenience; therefore, a high-performance liquid chromatographic (HPLC) method was developed to provide a rapid, quantitative, and specific assay for this drug in the presence of its degradation products. This assay was used to study several stability characteristics of flurogestone acetate, including the effects of acid, base, and temperature.

EXPERIMENTAL SECTION

Materials—A high-performance liquid chromatograph equipped with a reciprocating-piston pump[1], injector[2], UV detector (254 nm)[3], and a strip-chart recorder[4] was employed in conjunction with a 10-μm (3.9 mm × 30 cm) C_{18} column[5] for separation.



I

All chemicals and reagents were analytical grade unless indicated. Flurogestone acetate[6], testosterone[7], anhydrous dibasic sodium phosphate[8], anhydrous citric acid[8], dibasic potassium phosphate[8], monobasic potassium phosphate[8], and glass-distilled methanol[9] were used as received. Deionized water[10] was freshly prepared and used throughout the study.

Analytical Procedure—A fixed quantity of testosterone was added to each sample as an internal standard to assure injection-to-injection reproducibility. Aliquots were injected into the HPLC column and the peak height ratios of flurogestone acetate to testosterone were then determined and compared with the standard curve for calculation of the flurogestone acetate concentration. Methanol–water (50:50) was used as the mobile phase. The column and the solvent were at ambient temperature. At a solvent flow rate of 2 mL/min, the retention times for flurogestone acetate and testosterone were ~21 and ~32 min, respectively.

Standard Calibration Curve—The standard stock solution of flurogestone acetate and testosterone (internal standard) were prepared in methanol and stored at 4°C. The flurogestone acetate stock solution was diluted as necessary. The standard calibration curves were constructed by plotting peak height ratio *versus* flurogestone acetate concentration. A straight-line fit of the data was made by linear regression analysis, and the correlation coefficient was determined.

Stability Studies—*Effect of pH*—Three methanolic stock solutions (which contained 1.00–1.49 mg/mL of flurogestone acetate) were prepared and then diluted to 71.5, 39.8, and 5.03 μg/mL with 0.1 M HCl (pH 1.0), 0.1 M NaOH (pH 13), and simulated vaginal fluid (pH 7.3), respectively. The simulated vaginal fluid was prepared from 870 mL of 0.4 M Na_2HPO_4 and 130 mL of 0.2 M citric acid made up to 2 L with water. The diluted acidic, basic, and simulated vaginal fluid solutions were placed in well-sealed glass containers and stored at 94°C (by reflux), 30°C, and 38°C (shaken in a water bath[8]), respectively, until the completion of the study. Aliquots (1 mL of the acidic solution or 2 mL of either basic or simulated vaginal fluid solutions) were withdrawn periodically from each flask and assayed for flurogestone acetate

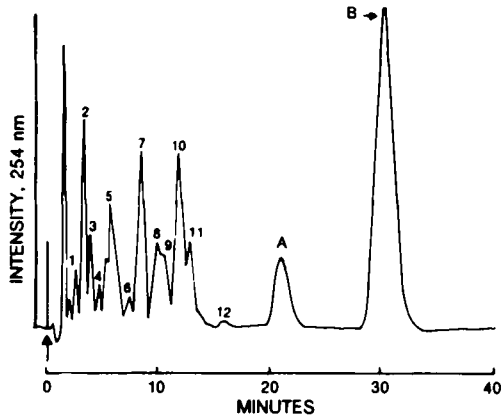

Figure 2—*Chromatogram of flurogestone acetate (A) after 95 h in 0.1 M HCl (pH 1.0) at 94°C. Key: (1–12) degradation products with retention times at 2.02, 3.19, 3.74, 4.71, 5.82, 7.73, 8.81, 9.56, 11.15, 12.61, 13.23, and 15.28 min; (B) testosterone (internal standard).*

and its degradation products. However, the acidic and basic solutions were first neutralized to pH 5.5 and 6.59, respectively, with 1 mL of 0.1 M K_2HPO_4 (pH 9.3) or 2 mL of 0.2 M KH_2PO_4 (pH 4.46); after vortexing, 50 μL of testosterone (0.61 or 0.13 mg/mL) was added to each sample. An aliquot (~100 μL) of each sample was assayed by the HPLC method.

Effect of Temperature—Flurogestone acetate stock solution prepared in simulated vaginal fluid (5.75 μg/mL) was placed in well-sealed glass containers and stored in a shaking water bath at 38°C, 70°C, 80°C, and 90°C. Each experiment was performed in triplicate. An aliquot (2 mL) was withdrawn periodically from each flask and, after cooling, 50 μL of testosterone (0.113 mg/mL) was added. The sample (100 μL) was then assayed by the HPLC method for flurogestone acetate and degradation products.

Treatment of Data—Semilogarithmic plots of the flurogestone acetate concentration as a function of time were constructed to evaluate the kinetics and rates of drug degradation. An Arrhenius plot (4) was then constructed from the kinetic data obtained from the studies with different temperatures. The line of best fit was determined by linear regression analysis.

RESULTS AND DISCUSSION

Chromatographic Data—A typical chromatogram for flurogestone acetate in the presence of testosterone (the internal standard) is shown in Fig. 1. Peaks for flurogestone acetate and testosterone are observed at retention times of 21.2 and 31.5 min, respectively. No interfering peaks were detected in the 40-min run time. The standard curve constructed for flurogestone acetate was linear over the concentration ranges of 0–10 and 10–40 μg/mL ($r > 0.99$) when the peak height ratio of flurogestone acetate to testosterone was used.

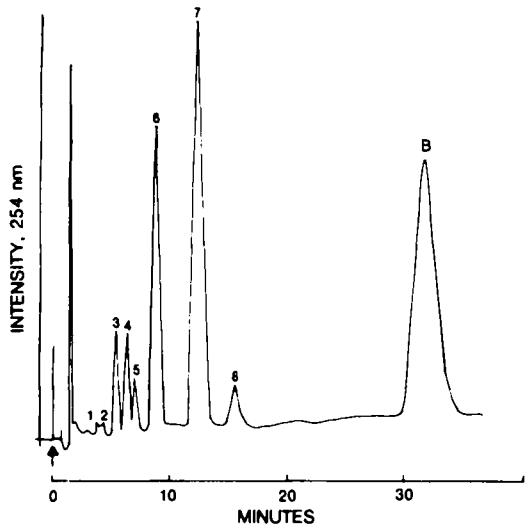

Figure 3—*Chromatogram of flurogestone acetate after 24 h in 0.1 M NaOH (pH 13) at 30°C. Key: (1–8) degradation products with retention times at 3.65, 4.16, 5.08, 6.00, 6.88, 8.34, 11.69, and 14.75 min; (B) testosterone (internal standard).*

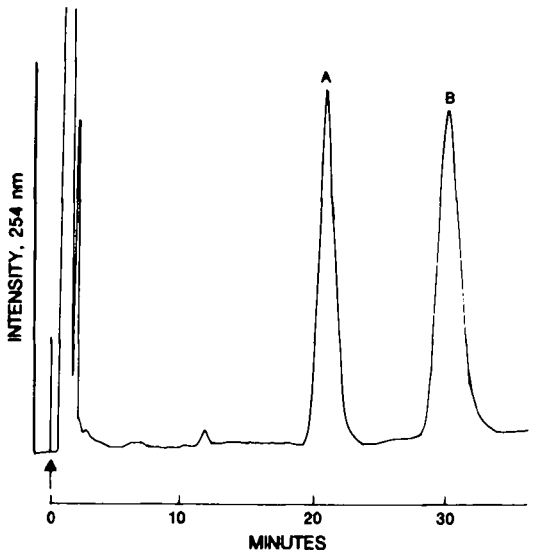

Figure 4—*Chromatogram of flurogestone acetate (A) after 22 d in simulated vaginal fluid (pH 7.3) at 38°C, with testosterone (B) as internal standard. Very little degradation was observed.*

The retention time varied slightly from day to day and with the pH of the injected solution.

The sensitivity of detection for flurogestone acetate at an injection volume of 50 μL was ~ 0.65 μg/mL (at 0.005 AUFS), which was equivalent to the injection of 28 ng of drug into the column. The assay sensitivity can be improved substantially by increasing the injection volume, by using a less-polar mobile phase (by increasing the ratio of methanol to water, *e.g.*, from 50:50 to 70:30), or by changing the detector wavelength from the conventional 254 nm to 236–238 nm, which is the maximum absorbance for flurogestone acetate (ϵ = 17,520) (5).

Solution Stability and Effect of Acid and Base—The HPLC method was used to study the solution stability of flurogestone acetate and to detect the degradation products, if any, under various conditions. Flurogestone acetate solutions in 0.1 M HCl (pH 1), 0.1 M NaOH (pH 13), or simulated vaginal fluid (pH 7.3) were stored at various elevated temperatures for different intervals; samples were taken periodically for chromatographic assay. The samples from 0.1 M HCl solutions at 94°C yielded 12 well-defined peaks of degradation products (Fig. 2); 8 degradation-product peaks formed under alkaline conditions at 30°C (Fig. 3). Under the chromatographic conditions all the degradation peaks appear before 18 min and none interfered with the primary peaks of flurogestone acetate (at 21.2 min) or testosterone (at 31.5 min). The samples from the simulated vaginal fluid (pH 7.3) at 38°C (the vaginal temperature of the sheep) yielded only a very small degradation peak after 22 d (Fig. 4).

A semilogarithmic plot of flurogestone acetate concentrations as a function

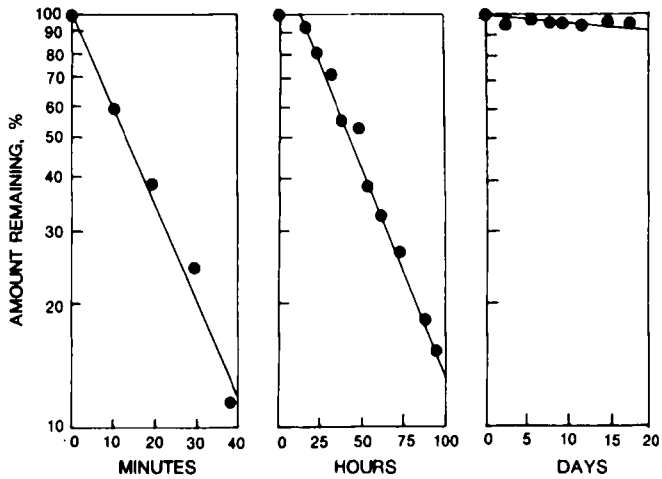

Figure 5—*Degradation profiles of flurogestone acetate in basic (a), acidic (b), and simulated vaginal fluid (c) solutions. Key: (a) pH 13 (30°C), k = 0.053 min^{-1}; (b) pH 1 (94°C), k = 0.023 h^{-1}; (c) pH 7.3 (38°C), k = 0.0018 d^{-1}.*

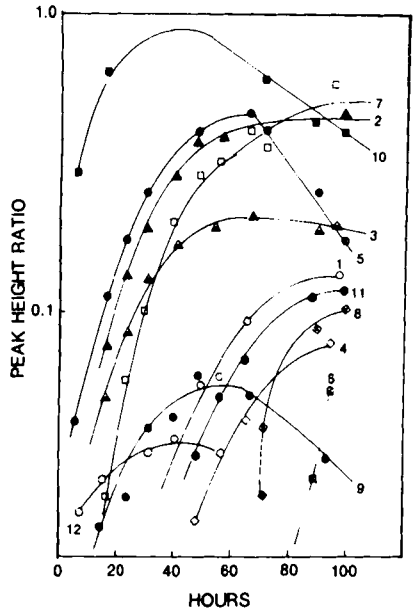

Figure 6—*Time course for the appearance of various degradation products of flurogestone acetate in 0.1 M HCl (pH 1) at 94°C. Key: (1-12) degradation product peaks in Fig. 2.*

of time yields a linear relationship, indicating that the degradation could follow first-order kinetics (Fig. 5). The data in Fig. 5 indicate that the degradation of flurogestone acetate is most rapid at pH 13, intermediate at pH 1, and slowest at pH 7.3. The apparent first-order half-life determined from these first-order kinetic plots is 13 min at pH 13, 30.1 h at pH 1, and ~370 d at pH 7.3, respectively.

Flurogestone acetate degradation, subject to both acid and base catalysis, is minimized at pH 7.3 (the vaginal pH of the sheep). The drug degradation profiles (Figs. 6 and 7) illustrate the time course for the appearance and disappearance of degradation products in acidic (pH 1) and alkaline (pH 13) solutions.

Thermal Stability in Simulated Vaginal Fluid—The thermal stability of flurogestone acetate in simulated vaginal fluid was studied at 70°C, 80°C, and 90°C. The semilogarithmic plot of drug concentration as a function of time was linear at various temperatures (Fig. 8), indicating first-order degradation kinetics. The apparent first-order degradation kinetic constants determined from the slope of these linear plots are 0.0490, 0.1303, and 0.3941 d^{-1} at 70°C, 80°C, and 90°C, respectively. The results suggest that the

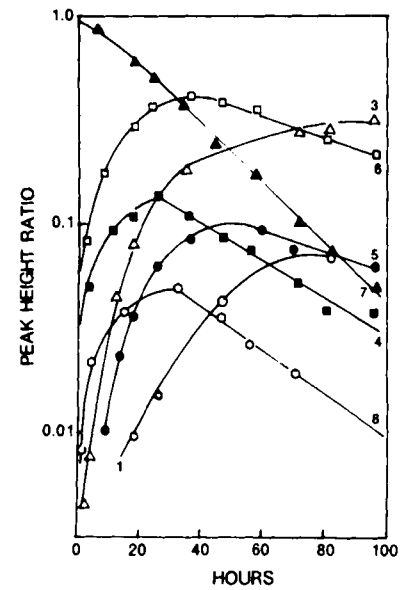

Figure 7—*Time course for the appearance of various degradation products of flurogestone acetate in 0.1 M NaOH (pH 13) at 30°C. Key: (1-8) degradation product peaks in chromatogram in Fig. 3.*

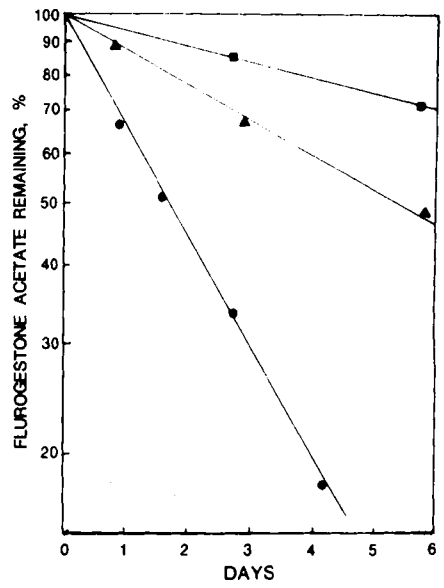

Figure 8—*Thermal stability of flurogestone acetate in the simulated vaginal fluid (pH 7.3) at 70°C (■), 80°C (▲), and 90°C (●). The first-order degradation constants were calculated to be 0.0490 d^{-1} (70°C), 0.1303 d^{-1} (80°C), and 0.3941 d^{-1} (90°C).*

thermal degradation of flurogestone acetate could follow the Arrhenius relationship (4) of:

$$\log k = \log A - \frac{E_a}{2.303R} \cdot \frac{1}{T}$$

where k is the apparent rate constant of degradation obtained from the kinetic plots in Fig. 8, R is the gas constant (1.98 cal/mol·K), T is the absolute temperature (K), E_a is the energy of activation, and A is the frequency factor. The exponential relationship between the apparent first-order rate constants (k) obtained and the reciprocal of the absolute temperature is shown in Fig. 9. Extrapolation of the data obtained at elevated temperatures to the vaginal temperature (38°C) results in a predicted first-order rate of 0.0010 d^{-1}, which compares favorably (95% confidence limit) with the rate constant of 0.0018 d^{-1} obtained experimentally at 38°C. E_a and A values, derived from the slope and intercept, are 25.55 kcal/mol and 9.27×10^{14} d^{-1}, respectively.

The potential utility of the temperature-dependent relationship is determined by the controlling mechanism of degradation (6). Since the E_a value

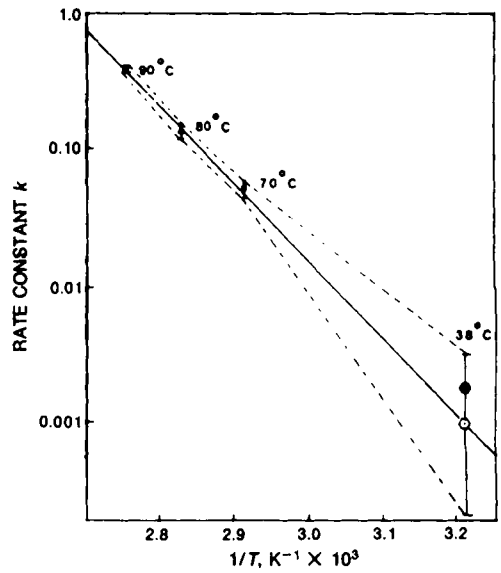

Figure 9—*Arrhenius plot (—) of the thermal degradation rate constants of flurogestone acetate in the simulated vaginal fluid (pH 7.3) with 95% confidence limits (- - -) (7, 8). The filled data points are actual data obtained experimentally; the open data point is the calculated value extrapolated from the Arrhenius plot of the data at elevated temperatures; E_a = 25.55 kcal/mol.*

(25.55 kcal/mol) is rather high, the degradation of flurogestone acetate (in vaginal fluid) could be the result of a solvolytic process, which generally has an energy of activation in the range of 10–30 kcal/mol (6). The higher the value of E_a, the greater the thermal stability of the drug.

CONCLUSIONS

The HPLC method developed is specific and allows a good separation of flurogestone acetate from its degradation products. The degradation is both acid- and base-catalyzed, but is much slower in the simulated vaginal fluid (pH 7.3). Thermodynamic studies indicate that the degradation in simulated vaginal fluid is very slow, as it requires a fairly high energy of activation (25.55 kcal/mol).

This assay should be suitable for determination of the release kinetics of flurogestone acetate from the vaginal sponges and its absorption rate through the vaginal wall. Since it is also a stability-indicating method, the metabolism of flurogestone acetate, if any, in the simulated vaginal fluid or vaginal mucosa could be detected (9).

Intravaginal Controlled Administration of Flurogestone Acetate II: Development of an *In Vitro* System for Studying the Intravaginal Release and Permeation of Flurogestone Acetate

MOHAN B. KABADI and YIE W. CHIEN ˣ

Received October 3, 1983, from the *Controlled Drug Delivery Research Center, College of Pharmacy, Rutgers–The State University of New Jersey, Piscataway, NJ 08854.* Accepted for publication November 30, 1983.

Abstract □ A relatively simple and easily constructed *in vitro* system was developed for studying the mechanism of release and intravaginal absorption of flurogestone acetate from vaginal sponges. The stability-indicating high-performance liquid chromatographic method developed earlier was used to provide a rapid, reproducible, and sensitive assay. The *in vitro* intravaginal release/permeation system developed was capable of determining the rate of flurogestone acetate release from vaginal sponges and, simultaneously, the rate of absorption through the vaginal wall. The design, calibration, and applicability of the system, and the release and absorption profiles of the drug from vaginal sponges in this system are discussed.

Keyphrases □ Drug release—flurogestone acetate, intravaginal, sheep □ Flurogestone acetate—intravaginal release and permeation measurement *in vitro* □ Intravaginal administration—flurogestone acetate, sheep

In 1975, the use of flurogestone acetate-releasing vaginal sponges (Fig. 1) to replace the conventional daily injection of progesterone for estrus synchronization in sheep was introduced (1). On intravaginal administration, the polyurethane sponges release the drug continuously for 15 d, this suppresses estrus and ovulation. Two to four days after removal of the sponges, the sheep reenter estrus and ovulate. During this period, artificial insemination can be performed at a predetermined schedule to promote a specific breeding program (2).

Knowledge of the pattern and rate of drug release is essential for an understanding of the action of flurogestone acetate-impregnated sponges in the vagina (3). Development of a suitable *in vitro* drug release/permeation system is essential to understand the mechanisms of drug release and permeation under *in vivo* conditions (4). Currently, the release profiles are determined by extracting the residual drug content in the vaginal sponges and then assaying it by GC (2) or by radioactivity count (5). However, these *in situ* experiments require the use of large numbers of animals over an extended period of time. Also, the lack of assay sensitivity can jeopardize the

accurate determination of the kinetics of the drug-release profile. One prime concern in making release/permeability measurements is determining the rates reliably and in as short a time as possible. The development of such a technique could also make possible the direct measurement of the drug-release flux (6).

With these considerations in mind, a relatively simple and easily constructed *in vitro* intravaginal drug release/permeation system was designed. In conjunction with the HPLC method (7), a reproducible technique for determining the drug release kinetics was developed. The release rates of flurogestone acetate from the vaginal sponges and the permeation rates of the drug through the vaginal mucosa were investigated.

EXPERIMENTAL SECTION

Materials—All chemicals and reagents were analytical grade unless otherwise indicated. Flurogestone acetate[2], testosterone[3], anhydrous dibasic sodium phosphate[4], anhydrous citric acid[4], polyethylene glycol 400 (laboratory grade)[4], and glass-distilled methanol[5] were used as received. Freshly prepared deionized water[6] was used throughout the study.

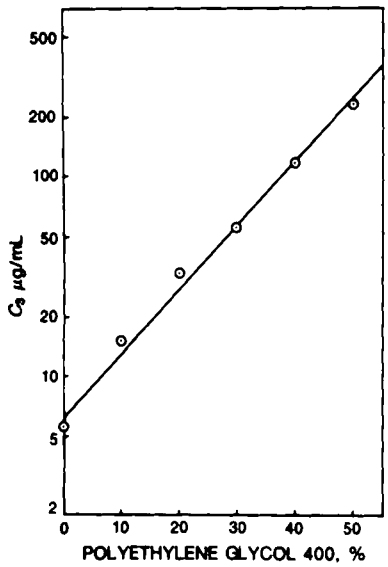

Figure 3—*Exponential relationship between solution solubility (C_s) and the volume fraction (% v/v) of the polyethylene glycol 400 in the simulated vaginal fluid at 38°C.*

Table I—Composition of Elution Media [a] Containing Various Volume Fractions of Polyethylene Glycol 400 in Simulated Vaginal Fluid

Polyethylene Glycol 400 Conc., % v/v	0.02 M Citric Acid, mL	0.04 M Na_2HPO_4, mL	Polyethylene Glycol 400 Volume, mL
0	95	405	0
10	100	400	100
20	135	365	200
30	170	330	300
40	200	300	400
50	235	265	500

[a] The final volume was made up to 1000 mL with distilled water; pH = 7.3.

Drug Release/Permeation System—The system[7] developed for studying the pattern of drug release/permeation is shown schematically in Fig. 2. Each of the donor and receptor cells holds up to 1 L of elution medium which is thermostated at 38°C (the vaginal temperature of the sheep) by a circulating water bath[8]. The impeller assembly can be rotated at a constant speed (30–400 rpm) by a six-station heavy-duty magnetic stirrer (42 × 44 × 12 cm). All six diffusion cells (three pairs) are operated simultaneously at the same speed by a single control.

High-Performance Liquid Chromatography—A chromatograph equipped with a reciprocating-piston pump[9], injector[10], UV detector (at 254 nm)[11], and a strip-chart recorder[12] (1–10 mV) was employed in conjunction with a 5-µm (3.9 mm × 15 cm) C_{18} column[13] for separation. The operating conditions of the HPLC method (7) were slightly modified. A less-polar mobile phase of the methanol–water (65:35) was used. The column and solvent were maintained at ambient temperature. At a solvent flow rate of 1 mL/min, the retention times for flurogestone acetate and testosterone (internal standard) were reduced to ~4 and ~8 min, respectively, to facilitate the assay procedure.

Drug Delivery Device—The vaginal sponges, each containing 40 mg of flurogestone acetate, were commercially available[14]. Each polyurethane sponge was loaded (with hypodermic syringes) with 2 mL of solution containing 20 mg/mL of the drug in acetone–absolute ethanol (1:4). The sponges

[a] Sherwood number (see text). [b] Calculated from Eq. 2.

were then placed, thread up (Fig. 1), on polyethylene over a wire grid and allowed to dry overnight (8).

Elution Medium—The elution medium was prepared by mixing a given volume of polyethylene glycol 400 with a concentrated solution of simulated vaginal fluid and then diluted to 1 L with distilled water (Table I). The concentrated simulated vaginal fluid was prepared by mixing various quantities of 0.04 M Na_2HPO_4 and 0.02 M citric acid. After the addition of polyethylene glycol 400, the water was added. The pH of the elution medium was 7.3 ± 0.5 (the vaginal pH of sheep).

Determination of Drug Solubility—The solubility of flurogestone acetate at the study temperatures was determined by vigorously mixing an excess of drug particles in 10 mL of elution medium containing various volume fractions of polyethylene glycol 400. At equilibrium (24 h), samples were rapidly filtered through preheated syringes equipped with a filter holder. The clear filtrate was then assayed by HPLC. An exponential relationship between the solubility of the drug and the volume fraction of polyethylene glycol 400 was found (Fig. 3), as expected (9), from the following:

$$\log C_s = \log C_{SVF} + e \cdot f \qquad \text{(Eq. 1)}$$

where, C_s and C_{SVF} denote the solubilities of flurogestone acetate in the polyethylene glycol 400–simulated vaginal fluid and in pure simulated vaginal fluid, respectively; e is the slope of the log solubility *versus* volume fraction profile; and f is the volume fraction of polyethylene glycol 400 (v/v) added. The solubility of the drug (C_{SVF} = 5.4 μg/mL) was enhanced remarkably by the addition of polyethylene glycol 400; the perfect sink condition was thus maintained.

Calibration of the System—*Time to Reach 38°C*—The donor and receptor compartments were maintained at 38°C, and then 600 or 1000 mL of simulated vaginal fluid (at room temperature) was poured into each compartment

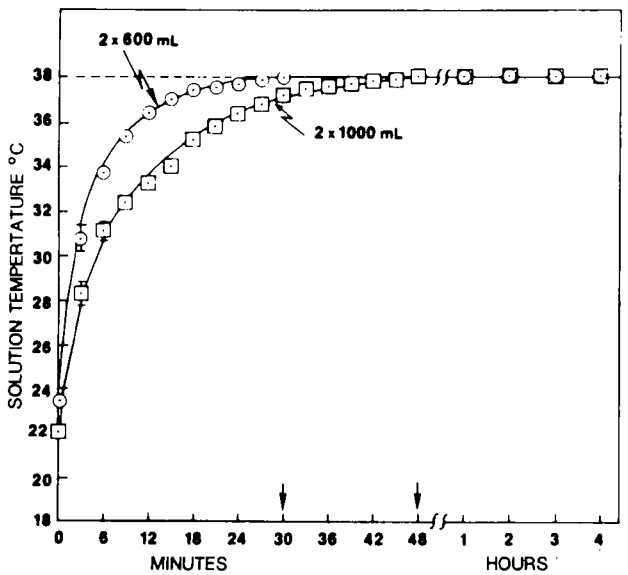

Figure 5—*Time required for the solution temperature in the donor and receptor compartments to reach the equilibrium temperature of 38°C (vaginal temperature of the sheep) from room temperature (n = 3); stirring speed 360 rpm.*

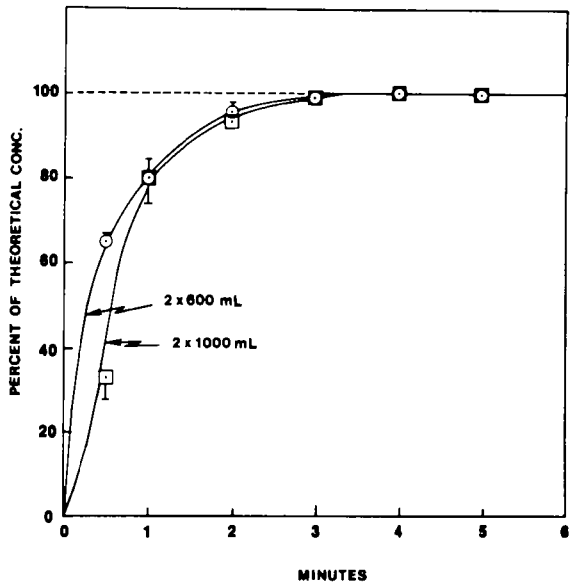

Figure 6—*Time required for the solution in the receptor compartment to reach a theoretical concentration after addition of a known concentration of flurogestone acetate stock solution to the donor solution (n = 3).*

while the stirrer rotated at 330 rpm. Temperature of the elution medium in the receptor compartment was measured[15] every 3 min until the equilibrium temperature of 38°C was reached.

Hydrodynamics of Mixing—After the simulated vaginal fluid solution in each compartment reached 38°C, known concentrations of flurogestone acetate (0.5–1.0 mL) was added to the donor solution, while the stirrer rotated at 330 rpm. Samples were removed from the receptor solution every 30–60 s until the theoretical concentration was reached. Samples were then assayed for the drug by HPLC.

Drug Release Study—A vaginal sponge containing 40 mg of flurogestone acetate was inserted into the flange opening of the donor compartment and an impermeable barrier was sandwiched between the two compartments (Fig. 2). The magnetic stirrer was turned on and adjusted to 330 rpm. Then, 1000 mL of the elution medium containing various volume fractions of polyethylene glycol 400 (preheated to 38°C) was poured into each of the compartments. At scheduled intervals, a 2-mL aliquot of elution medium was withdrawn, but not replaced, from each compartment and assayed for the drug by HPLC.

Drug Permeation Study—The sheep's vagina[16] was cut open vertically (10, 11) and the mucosa was separated from the wall (Fig. 4). The vaginal mucosa was sandwiched between the donor and receptor compartments and clamped. Six hundred milliliters of saturated or unsaturated flurogestone acetate solution (40% polyethylene glycol 400 in simulated vaginal fluid) and 600 mL of drug-free solution (20% polyethylene glycol 400 in simulated vaginal fluid) were added to the donor and receptor compartments, respectively. Samples were removed from the receptor compartment at scheduled intervals for the duration of the experiment. Aliquots were assayed for the drug by HPLC.

Analytical Procedure—The HPLC assay procedure developed earlier (7) was utilized here. A fixed quantity of testosterone was added to each sample as an internal standard to ensure the injection-to-injection reproducibility required. Aliquots were injected into the HPLC column, and the peak height ratios of flurogestone acetate to testosterone were determined and compared with the standard curve for the calculation of flurogestone acetate concentrations.

RESULTS AND DISCUSSION

After assembly, the entire *in vitro* intravaginal release/permeation system (Fig. 2) is totally enclosed so that solvent loss is minimized during a long-term experiment. When a sponge is inserted into the flange opening, the drug-release profile from the sponge can be studied. When the vaginal mucosa is present, permeation can be evaluated. When both are present, release and permeation can be investigated simultaneously.

The impeller assembly of the intravaginal release/permeation system provides excellent stirring (up to 400 rpm), which significantly reduces the thickness of the hydrodynamic diffusion layer on the surface of sponge and

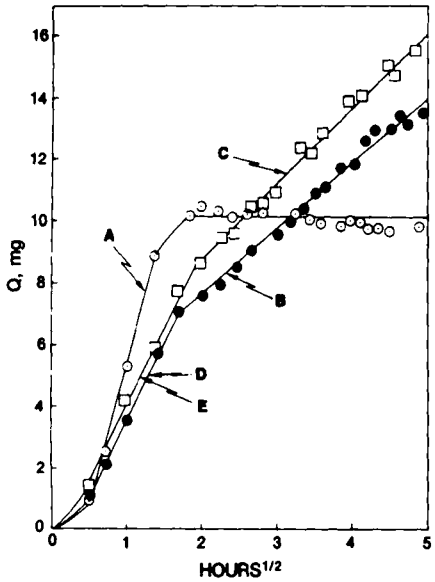

Figure 7—*Linear relationship between the cumulative amount of flurogestone acetate (Q) released from the vaginal sponge (containing 40 mg of the drug) into 1000 mL of elution medium (at nonsink conditions) and the square root of time ($t^{1/2}$). Note the change in the slopes at ~3 h. Key: (A) 0% polyethylene glycol 400, 8.64 mg/h$^{1/2}$; (B) 20% polyethylene glycol 400, 2.14 mg/h$^{1/2}$; (C) 30% polyethylene glycol 400, 2.40 mg/h$^{1/2}$; (D) 4.95 mg/h$^{1/2}$; (E) 4.89 mg/h$^{1/2}$.*

mucosa (Table II). The thickness of the hydrodynamic diffusion layer (δ_D) is related to the Sherwood number (Sh) (12) by the following:

$$\delta_D = \gamma\epsilon/Sh_r = D/k \qquad \text{(Eq. 2)}$$

where γ is the radius of the sponge, ϵ is the porosity of the sponge, Sh_r is the Sherwood number around the radian of the sponge, D is the diffusion coefficient, and k is the mass transfer coefficient. When the Sherwood number is >200, the thickness of the diffusion layer is very small (12); therefore, the effect of solution hydrodynamics on the release of drug from the sponge is negligibly small. This is consistent with the experimental results (Table II).

It is critically important that the magnitude of δ_D be held constant (and as small as possible) so the real mechanisms of drug release and permeation can be obtained and a meaningful comparison between experimental observations can be made. A rotation speed of 330 rpm was used, which maintains a constant thickness of hydrodynamic diffusion layer of $<14 \times 10^{-4}$ cm on the immediate surface of the sponge, and also provides a homogenous drug concentration in the elution medium. Additionally, a drug-stable and water-miscible polymer, *i.e.* polyethylene glycol, was added to the simulated vaginal fluid (elution medium) to enhance the solubility of the drug and to simulate the biological sink. Under these conditions, the cell sensitivity is fairly high, so that hourly measurements of drug release/permeation flux is feasible. The drug release/permeation profile is followed closely by directly assaying the drug concentration in the elution medium. Although the construction of this system is relatively simple, the rate of drug release/permeation can be determined reliably in a short period of time.

The results indicate that it requires 30 and 48 min, respectively, for the elution media (2 × 600 mL and 2 × 1000 mL) to reach the equilibrium temperature of 38°C from room temperature (22°C) (Fig. 5). Therefore, the solutions were always preheated to 38°C before each experiment. For both volumes of solutions (*i.e.*, 2 × 600 mL and 2 × 1000 mL), it took only 3 min

Table III—Effect of Polyethylene Glycol 400 Concentration on Rate of Drug Release from Vaginal Sponges [a]

Note that there is no change in slope. Key: (A) 50% polyethylene glycol 400, 2.55 mg/h$^{1/2}$; (B) 40% polyethylene glycol 400, 2.67 mg/h$^{1/2}$.*

to reach the theoretical concentration when a rotation speed of 330 rpm was applied (Fig. 6), indicating very rapid mixing even in large volumes.

The release profiles of flurogestone acetate from vaginal sponges into simulated vaginal fluid containing various volume fractions of polyethylene glycol 400 were evaluated. The quantity of drug released was initially high and then decreased. This pattern of a nonlinear drug-release profile was also observed earlier in both *in vitro* (13-17) and *in vivo* (18, 19) studies of matrix-type drug dispersing devices.

Theoretically, when the matrix diffusion is the rate-controlling factor for the drug-release process, the release of drug from an insoluble, inert, polymeric matrix (like the polyurethane sponge in this study) is best described by the following (16):

$$Q = \left[\frac{D\epsilon}{\tau}(2A - \epsilon C_s)C_s t\right]^{1/2} \qquad \text{(Eq. 3)}$$

where Q is the cumulative amount of drug released, D is the diffusivity, ϵ is

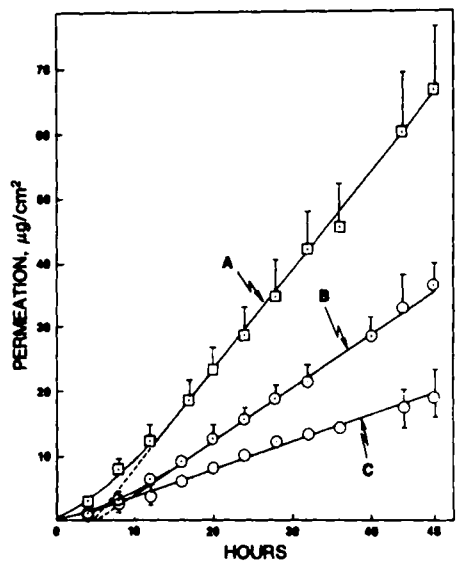

Figure 9—*Linear relationship between the cumulative amount of flurogestone acetate permeating the vaginal mucosa into 600 mL of elution medium and time (t). Note that a zero-order absorption pattern was obtained. The donor solution contained 40% polyethylene glycol 400; the receptor solution contained 20% polyethylene glycol 400. Bars represent* SE. *Key: (A) C_D^s = 116.2 µg/mL (36.48 µg/cm^2/d); (B) $^1/_2C_D^s$ = 66.3 µg/mL (20.68 µg/cm^2/d); (C) $^1/_4C_D^s$ = 30.96 µg/mL (9.98 µg/cm^2/d).*

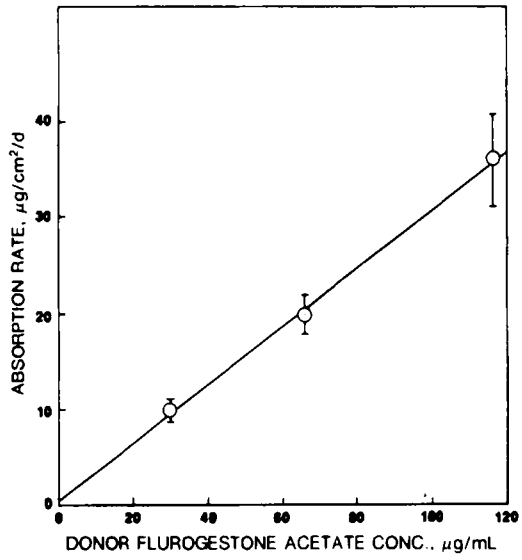

Figure 10—*Linear dependence of the steady-state intravaginal rate of absorption across an isolated vaginal mucosa on the concentration of flurogestone acetate in the donor solution (mucosa side). A P_v value of 0.311 cm/d is obtained from the slope.*

the porosity, and τ is the tortuosity in the sponge matrix; A is the initial loading dose of drug in the sponge; C_s is the solubility of the drug in the elution medium; and t is time. The theoretical model described in Eq. 3 indicates that the cumulative amount of drug released should be a linear function of the square root of time ($t^{1/2}$). Experimentally, this Q *versus* $t^{1/2}$ linearity was achieved (Figs. 7 and 8). There was, however, a break in the slope of the Q *versus* $t^{1/2}$ line when the elution medium was at non-sink conditions (0–30% polyethylene glycol 400–simulated vaginal fluid) (Fig. 7). On the other hand, perfect Q *versus* $t^{1/2}$ linearity was achieved when the elution medium was at sink conditions (40–50% polyethylene glycol 400–simulated vaginal fluid) (Fig. 8).

The results clearly indicate that the release of drug from the vaginal sponge can be divided into two steps: the initial release, which is controlled by the dissolution process of solid drug from the surface of the vaginal sponge, and the steady-state release (which prevails after complete dissolution of the surface drug), in which the drug dispersed inside the sponge matrix is released by the matrix diffusion-controlled mechanism. This is illustrated by comparing the $Q/t^{1/2}$ values generated in various combinations of polyethylene glycol 400 and simulated vaginal fluid (Table III). It has been reported that the initial release rates are remarkably affected by the solution hydrodynamics on the surface of the sponge, depending on both the fluid viscosity and the impeller rotation speed (12). As viscosity of the solution increases (from 0 to 50% polyethylene glycol 400), the initial rate of drug release decreases. On the other hand, the effect of solution hydrodynamics on the steady-state release rates is rather negligible and, therefore, the rates become fairly independent of polyethylene glycol 400 concentration. As polyethylene glycol 400 concentration goes beyond 30%, the steady-state rate of release stays at essentially the same level (2.54 ± 0.14 mg/h$^{1/2}$).

The permeation profiles of flurogestone acetate from the 40% polyethylene glycol 400–simulated vaginal fluid solution (which contains various drug concentrations) through the vaginal mucosa were investigated (Fig. 9). The cumulative amount of drug absorbed (Q) was a linear function of time. As the concentration of flurogestone acetate in the donor compartment decreases (from a 100% to a 25% saturated solution), the rate of drug permeation, $(Q/t)_v$, through the vaginal mucosa was observed to decrease proportionally (Fig. 10). The steady-state permeation rate, $(Q/t)_v$, across the vaginal mucosal barrier is defined by:

$$(Q/t)_v = P_v \cdot \Delta C_v \qquad \text{(Eq. 4)}$$

where P_v and ΔC_v are the permeability coefficient and the concentration gradient across the vaginal barrier, respectively. From the slope of the regression line of $(Q/t)_v$ *versus* ΔC_v, a permeability coefficient of 0.311 cm/d was determined for the intravaginal permeation of flurogestone acetate through the vaginal mucosa of sheep.

CONCLUSIONS

A relatively simple drug release/permeation system was designed for the measurement of *in vitro* drug release and permeation profiles. The system developed is capable of maintaining sink conditions by the use of water-miscible polyethylene glycol 400, which tends to simulate the biological sink. By doing so, it is expected to achieve a better *in vitro–in vivo* correlation. The effect of the diffusion boundary layer on the release and permeation of the drug is minimized by maintaining a thin, but constant, thickness of the hydrodynamic diffusion layer on the surface of the sponge and vaginal mucosa. This was accomplished by constant stirring and maintaining a fixed temperature throughout the experiments. The release of flurogestone acetate from the vaginal sponge followed a surface dissolution-matrix diffusion-type consecutive release. The initial rate was apparently influenced by both the fluid viscosity and impeller rotation speed. The steady-state release, which is described by a linear Q *versus* $t^{1/2}$ profile, was then established. The intravaginal absorption rate of the drug from the solution was observed to be constant and was proportional to the flurogestone acetate concentration in the donor solution. An intravaginal permeability coefficient of 0.311 cm/d was determined. It is surprising to note that the release rate of flurogestone acetate from the sponge is much faster than the rate of absorption (compare Fig. 8 with Fig. 9). An ideal device should deliver the drug at a rate equal to the rate of absorption. This could be achieved by making the device release the drug in zero-order fashion. Since the dose of flurogestone acetate required for estrus synchronization in sheep is only 0.3–0.4 mg/d, a slower release rate than that of the present sponge would be desired. It is apparent that an intravaginal drug delivery system which releases the drug at a slower, but constant, rate should be developed.

Quantitation of Flecainide Acetate, A New Antiarrhythmic Agent, in Biological Fluids by Gas Chromatography with Electron-Capture Detection

J. D. JOHNSON, G. L. CARLSON, J. M. FOX, A. M. MILLER, S. F. CHANG ˣ, and G. J. CONARD

Received February 3, 1983, from the *Drug Metabolism Department, Riker Laboratories, Inc., a Subsidiary of 3M, 3M Center, St. Paul, MN 55144.* Accepted for publication November 29, 1983.

Abstract □ A sensitive and selective gas chromatographic (GC) method for the quantitation of flecainide acetate, a new antiarrhythmic agent, was developed. The unchanged drug and internal standard were separated from biological fluids by a sequence of solvent extractions and then the drug was derivatized. The pentafluorobenzamide derivatives were chromatographed on a 3% SP-2250 glass column and detected with a nickel-63 electron-capture detector. By this method, ≥12.5 ng of flecainide/mL can be quantitated in a 1-mL sample of plasma, saliva, or urine. The intraday precision, expressed as the *RSD*, at plasma levels of 12.5, 25, 50, 100, 200, 300, 400, and 600 ng/mL was 3.4, 6.2, 5.3, 6.4, 1.0, 1.6, 2.0, and 0.5%, respectively; the accuracy, expressed as relative error at these levels was −24.6, −6.9, −6.0, +0.6, +3.8, −0.3, +2.4, and −1.4%, respectively. The interday precision at these levels was 13.8, 13.0, 5.7, 7.6, 8.3, 6.1, 9.0, and 5.4%, respectively. Several other antiarrhythmic agents and one β-blocker, which might be administered concurrently with flecainide acetate, do not interfere with the assay.

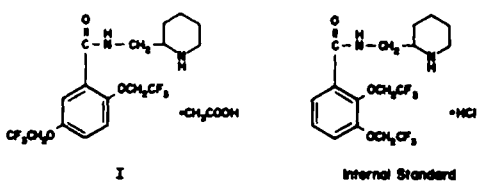
Keyphrases □ Flecainide acetate—quantitation in biological fluids, GC-ECD □ GC—quantitation of flecainide acetate in biological fluids □ Antiarrythmic agents—flecainide acetate, quantitation in biological fluids, GC-ECD

Flecainide acetate [*N*-(2-piperidylmethyl)-2,5-bis(2,2,2-trifluoroethoxy)benzamide monoacetate] (I) is a new antiarrhythmic agent currently undergoing clinical evaluation worldwide. Pharmacological, pharmacokinetic, and efficacy information have been reported previously (1–9). Sensitive fluorometric methods (10, 11) have also been reported but have suffered from a lack of adequate specificity due to interference. Recently, HPLC methods have been reported (12, 13). In this report, we describe a highly selective and sensitive gas chromatographic (GC) method for the quantitation of the drug in plasma, urine, or saliva following the administration of single or multiple doses.

EXPERIMENTAL SECTION

Reagents—All reagents were analytical reagent grade. Ether was distilled in glass[1]; all other solvents were nanograde[2]. Fresh 0.2 M trimethylamine in benzene was made daily by dilution from a concentrated stock solution stored at −10°C. The derivatization reagent, pentafluorobenzoyl chloride (PFBC)[3], was stored at 4°C. Aqueous solutions of 0.1 M NaOH, 1.0 M NaOH, and 0.5 M HCl were prepared fresh daily in distilled water.

Blank Plasma, Urine, and Saliva—Human plasma, urine, and saliva samples were obtained from volunteers who had not taken any medication during the previous week. Donors were asked to fast for 12 h prior to giving blood. Human saliva was obtained by paraffin stimulation followed by expectoration into a disposable sputum collecting cup.



I Internal Standard

Gas Chromatography—A gas chromatograph[4] equipped with an electron-capture detector (15 mCi of nickel-63) and an automatic liquid sampler[5] was used. The glass column (180 cm × 2 mm i.d.) was silanized, packed with 3% SP-2250 on 100–120 mesh Supelcoport[6], and conditioned for 48 h at 275°C. The operating conditions were as follows: injection port temperature, 275°C; detector temperature, 310°C; oven temperature, 268°C (isothermal); carrier gas (5% methane in argon) flow rate, 20 mL/min.

Standard Solutions—All stock solutions of the drug and the internal standard, a positional isomer of flecainide [*N*-(2-piperidylmethyl)-2,3-bis(2,2,2-trifluoroethoxy)benzamide hydrochloride] (14), were made in distilled water. Standard solutions containing 800, 600, 400, 300, 200, 100, 50, 25, and 12.5 ng of flecainide acetate per 0.5 mL were made by diluting a 10-μg/mL primary standard solution. The 10-μg/mL primary standard solution of the internal standard was diluted to give a concentration of 100 ng/0.5 mL. The primary standard solutions of the drug and the internal standard were stored at 4°C.

Extraction—*Plasma*—To glass culture tubes (16 × 150 mm) with polyethylene-lined screw caps, 1-mL aliquots of unknown samples of human plasma and 0.5 mL of distilled water were added. Along with each set of unknown samples, 10 standards in blank human plasma were prepared by adding 0, 12.5, 25, 50, 100, 200, 300, 400, 600, and 800 ng of flecainide acetate in 0.5 mL of distilled water to 1-mL aliquots of blank human plasma. Next, 0.5 mL of internal standard (100 ng) solution, 0.2 mL of 0.2 M trimethylamine (TMA) in benzene, 1 mL of 1 M NaOH, and 10 mL of diethyl ether were added, in that order, to all tubes. The tubes were capped and shaken in a horizontal position for 30 min on a reciprocal mechanical shaker and then centrifuged for 5 min at 700×*g*. Then, 9.0 mL of the organic layer was transferred to a glass tube containing 2 mL of 0.5 M HCl. All tubes were shaken for 15 min and then centrifuged for 3 min. The ether was aspirated and discarded. The remaining aqueous layer was decanted into a 12-mL conical glass centrifuge tube for subsequent derivatization.

Urine—Because of the relatively high concentrations of flecainide in the urine samples, usually less than 1 mL of urine was analyzed. When less than

Table II—Interday Precision for Determination of Flecainide (I) in Human Plasma [a]

Sample Concentration, ng/mL	Response Ratio (Mean ± *SD*)	*RSD*, %
12.5	0.32 ± 0.04	13.8
25	0.49 ± 0.06	13.0
50	0.76 ± 0.04	5.7
100	1.32 ± 0.10	7.6
200	2.57 ± 0.21	8.3
300	3.62 ± 0.22	6.1
400	4.93 ± 0.44	9.0
600	6.95 ± 0.37	5.4

[a] $n = 6$.

1 mL of a urine sample was used, blank urine was added to bring the total sample volume to 1 mL. The extraction, derivatization, and analysis procedures were the same as described above for plasma.

Saliva—A saliva sample of 1 mL or less was analyzed in the same manner as described above for plasma; when less than 1 mL was used, distilled water was added to bring the total volume to 1 mL. It was shown that a standard curve (12.5–800 ng/mL) in saliva was the same as that in distilled water; thus, in all subsequent saliva analyses, a flecainide standard curve in distilled water was used for the determination of flecainide concentrations in saliva samples.

Derivatization—For derivatization of both the drug and the internal standard, 2 μL of neat pentafluorobenzoyl chloride was added to each aqueous extract with a 10-μL syringe[7]. Immediately after the addition of pentafluorobenzoyl chloride, the tube was vortexed for 5 s to disperse and suspend the derivatizing reagent. Next, 1 mL of 1 M NaOH was added, and the tube was vortexed for 15 s. Finally, 1 mL of hexane was added and the tube was again vortexed for 15 s. The derivatization sequence was carried out with pairs of tubes.

After the derivatization procedure was completed for all samples, the tubes were capped and centrifuged for 3 min at 700×*g*. Then, ~0.8 mL of each hexane phase was transferred to a clean conical glass tube containing 3 mL of 0.1 M NaOH. The tubes were vortexed for 15 s and centrifuged for 3 min. The hexane phase was then transferred to the glass autosampler vial, and a 5-μL aliquot of each sample was injected into the glass chromatograph.

Calculation—The area ratios (the drug–internal standard) were calculated with an integrating GC terminal[8]. The slope and intercept from the least-squares line of the concentrations of the drug standards *versus* the area ratios of the drug were used to calculate the concentrations in unknown samples.

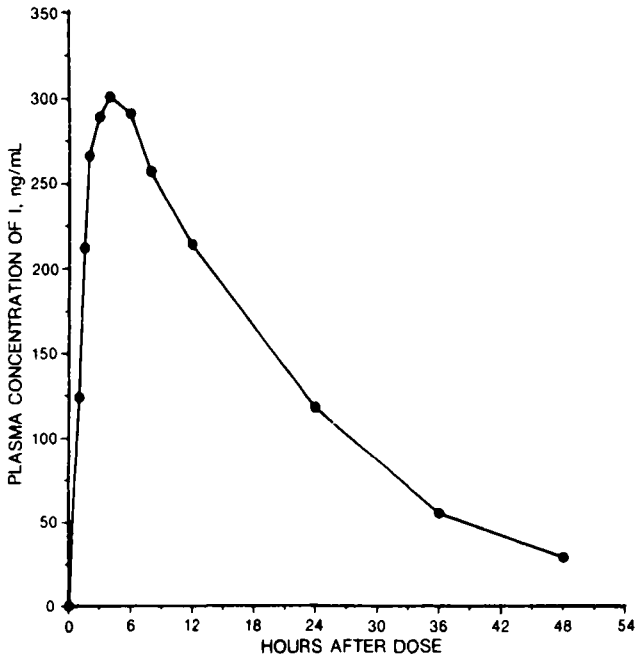

Figure 2—*Plasma concentrations of flecainide (I) in a healthy human subject following a single oral 200-mg dose of I.*

[7] Hamilton.
[8] Model 18850A; Hewlett-Packard.

Radiometric Analysis of Carbon-14—For the extraction recovery, an aqueous solution of ^{14}C-labeled drug (15) was used (9.2 μCi/mg, 10 ng/μL). Aliquots of 0, 5, 10, 40, and 60 μL were added to 1-mL blank human plasma samples in triplicate, and these samples were extracted by standard procedures. After the drug was extracted again into 0.5 M HCl, 1 mL of the aqueous phase was mixed with 0.4 mL of 1 M NaOH and counted in 15 mL of liquid scintillation solution[9]. Triplicate aliquots of the standard solution in 0, 5, 10, 40, and 60 μL were also directly counted in 15 mL of the same liquid scintillation solution. After cold and dark adaptation, carbon-14 was measured in a liquid scintillation counter[10]. Counting data were converted to disintegrations per minute by computer using the BIOAES program[11]. The percent extraction was calculated from the total disintegrations per minute in the aqueous extract compared with the disintegrations per minute in the spiked sample.

Tests for Other Drugs—A 500-ng/0.5 mL deionized water solution was prepared for propranolol hydrochloride, procainamide hydrochloride, disopyramide phosphate, quinidine sulfate, mexiletine hydrochloride, and lidocaine. Of each of these solutions, 0.5 mL was added to 1 mL of human plasma; the mixture was then extracted and derivatized by the procedure described above for flecainide. A positive control, a 600-ng flecainide standard with internal standard added, was run in parallel with the samples described above.

Gas Chromatographic–Mass Spectrometric Analysis—GC–MS analysis was performed on a gas chromatograph–mass spectrometer system which was comprised of a gas chromatograph[12], a magnetic double-focusing mass spectrometer[13], and a data system[14]. A stainless steel column (180 cm × 3.2 mm o.d.) packed with the same material as that for the glass column was used. The operating conditions were as follows: for the gas chromatograph, oven temperature, 245°C; injection port temperature, 230°C; carrier gas flow rate, 25 mL/min (He); for the mass spectrometer, resolving power, 500; source temperature, 250°C; for the data system, acquisition rate, 6 kHz, scan time, 2 s/decade. Unknown samples were extracted and derivatized by standard procedures. Aliquots of the final hexane extract were injected into the GC–MS system. Unknown samples were compared qualitatively with the synthetic pentafluorobenzamide of the drug at *m/z* 195, 278, 301, and 331, which are characteristic of the pentafluorobenzamide derivative of the drug.

RESULTS AND DISCUSSION

Derivatization—Based on the results from earlier studies[15] of ^{14}C-labeled flecainide in animals, it was anticipated that the plasma levels of the drug in humans would be in the low nanogram per milliliter range. Thus, it was decided at the outset that a GC–electron capture detector (GC–ECD) approach would be investigated. Flecainide contains six fluorine atoms which should provide enough ECD sensitivity; however, the material proved to be relatively difficult to chromatograph at the picogram to low nanogram amounts, possibly due to the presence of the piperidyl group. Thus, the piperidyl group was derivatized with pentafluorobenzoyl chloride. Although the perfluorobenzamide derivative, in comparison with its corresponding perfluorobutyramide, has a relatively low vapor pressure, thus requiring a higher column temperature for elution, this disadvantage is counterbalanced by the greater ECD sensitivity of the perfluorobenzamide derivative (16, 17) and the lack of any noticeable interferences.

Chromatography and Peak Separation—Although the drug and the internal

standard differ only in the position of the trifluoroethoxy group on the aromatic ring, sufficient separation was achieved by using a 3% SP-2250 column. Under the chromatographic conditions used, there was no interference with the drug or the internal standard by any extractable endogenous materials present in plasma, urine, or saliva. Typical GC tracings of derivatized extracts from blank human plasma, from human plasma of a subject dosed with the drug, and reference flecainide acetate and internal standard derivatives are shown in Fig. 1. The retention times of the pentaflurobenzoyl derivatives of I and internal standard under these experimental conditions are 16.2 and 13.7 min, respectively.

Interference due to excess pentafluorobenzoyl chloride was eliminated by more accurate addition of the 2 μL of this reagent and/or by increasing the amount of NaOH added (from 1.0 to 1.5 mL of 1 M NaOH) to hydrolyze any excess derivatizing reagent. Care must also be taken when transferring the 0.8-mL hexane phase to the tube containing 3 mL of 0.1 M NaOH for the washing step. If any of the aqueous phase is transferred with the hexane, the chromatogram will show a large interfering solvent front.

Adsorption sites on a new column must be saturated by repeated injections of the synthetic derivatives of flecainide and the internal standard. Saturation is adequate when approximately equal peak areas are obtained for several successive injections. Extensive use of a column results in the deterioration of the resolution of flecainide from the internal standard. Repacking the front ~5 cm of the column was found to be necessary after ~800 sample injections.

Extraction Recovery—The extraction recovery of the drug from plasma was determined by carrying ^{14}C-labeled flecainide through the extraction to the derivatization steps and then measuring the total radioactivity recovered. The extraction recovery over the concentration range of 50 to 600 ng/mL was 86 to 91%, with a mean $\pm SD$ of 88 ± 2%.

Selectivity—GC-MS (electron impact) studies of plasma samples from human subjects who received the drug, in comparison with the synthetic pentafluorobenzoyl derivative of the drug, showed identical fragmentation patterns; thus, the pentafluorobenzoyl derivative of the drug is the species actually measured in human plasma samples.

Lidocaine, mexiletine, procainamide, disopyramide, propranolol, and quinidine, drugs which may be present together with flecainide in specimens obtained from patients, were tested for interference under the extraction and derivatization conditions used for the drug and the internal standard. Lidocaine, mexiletine, procainamide, and disopyramide showed no response, whereas propranolol and quinidine showed longer retention times than the pentafluorobenzoyl derivatives of the drug and the internal standard.

Linearity—A total of 9 or 10 single standards (0–800 ng) were run daily with each set of unknown samples. The mathematical expression of the least-squares line from a typical standard curve (0–800 ng) is $y = 0.0096x - 0.0662$. The correlation coefficient is 0.9998, and the coefficient of determination is 0.9996, indicating good linear proportionality between the concentration of flecainide and the detector response. The concentration-response relationship has also been shown to be linear up to a concentration of 1400 ng/mL. However, in most cases a shorter standard curve is used; *e.g.*, for routine analysis of samples after a single dose of flecainide, a 0–600 ng/mL range is used.

Sensitivity—By this method, concentrations as low as 12.5 ng of flecainide/mL of plasma, saliva, or urine can routinely be quantitated. Although not done routinely, under ideal chromatographic conditions, samples containing ≥6 ng of flecainide/mL can be quantitated.

Precision and Accuracy—The intraday precision and accuracy of this method was assessed by carrying five replicate samples at eight concentrations (12.5, 25, 50,100, 200, 300, 400, and 600 ng/mL) through the entire procedure on one analysis day. The intraday precision, expressed as the *RSD*, was 3.4, 6.2, 5.3, 6.4, 1.0, 1.6, 2.0, and 0.5% for the eight concentrations listed above, respectively (Table I). The accuracy of this method, expressed as relative error, at these levels was −24.6, −6.9, −6.0, +0.6, +3.8, −0.3, +2.4, and −1.4%, respectively.

The interday precision, at the concentrations described above, was established by analyzing these standards on 6 separate days over a 1-month period (Table II). The response ratios from 6 separate days for each standard concentration were pooled, and the mean ± *SD* values were calculated. The *RSD* values were 13.8, 13.0, 5.7, 7.6, 8.3, 6.1, 9.0, and 5.4% for concentrations of 12.5, 25, 50, 100, 200, 300, 400, and 600 ng/mL, respectively.

Application—The method has been used to measure plasma, urinary, and salivary levels of flecainide from various metabolic, pharmacological, and therapeutic studies in humans. More than 10,000 samples have been successfully analyzed by this procedure in our laboratory, as well as in several other laboratories worldwide. A typical curve of the plasma concentration of the drug *versus* time following a single oral 200-mg dose of the drug in a healthy human volunteer is shown in Fig. 2.

Received June 27, 1983, from the *Department of Chemistry, Virginia Polytechnic Institute and State University, Blacksburg, VA 24061 and ‡Philip Morris Research Center, Richmond, VA 23261. Accepted for publication January 19, 1984.

Abstract □ In this study the relationships between previously reported connectivity indices described by Kier and Hall and steric contributions to the rate constants for several series of reactions are examined. Rate data were examined for four different series of reactions, which were chosen to represent a range of different reaction mechanisms and transition-state structures. For sterically controlled reactions, the relative rates of series of substrates can be correlated either with the connectivity indices of the substrates themselves or with the changes in the indices that accompany formation of transition states. As expected, the significant indices in the correlations are of the cluster and path-cluster types. The connectivity indices should be useful descriptors in helping relate equilibrium properties, chemical reactivities, and pharmacological data to one another.

Keyphrases □ Connectivity indices—relationship with steric contributions to rate constants □ Kinetic steric factors—relationship with connectivity indices to rate constants

The development of structure–activity relationships (SAR) in pharmacology (1, 2) has relied heavily on the use of physicochemical parameters which are based on chemical reactivity relationships, such as Hammett σ-ρ constants and Taft E_s values. Many of the more recent studies, including those in which pattern recognition methods are employed, also make use of other descriptors which reflect substructural information like molecular connectivity and branching characteristics (3). The connectivity indices described by Kier and Hall (4), which were introduced as a generalization of the Randic' branching index (5), have proved to be extremely useful in this regard.

Kier and co-workers and others have been quite successful in obtaining correlations (4, 6–8) of physical, thermodynamic, and pharmacological properties with the connectivity indices, but there has been only one report to date concerned with the relationship between connectivity indices and chemical reactivity (9). There obviously are very close relationships between physicochemical parameters, chemical reactivities, and pharmacological properties, and it is important that these relationships be understood. We have therefore undertaken the present study of correlations between molecular connectivity and chemical reactivity.

It is clear that the connectivity indices described by Kier and Hall carry information about the nature and number of atoms in the molecule, as well as the degree of branching and the amount of folding. The dependence of kinetic steric factors on molecular branching has been well established by the detailed studies of Charton (10), Dubois *et al.* (11), and Ruchardt and Beckhaus (12), among others; therefore, kinetic steric factors may be correlated with connectivity indices. In fact, the link between the two has already been made by Murray (9), who succeeded in finding correlations between the Taft E_s parameters (13) and effective connectivity indices for a series of substituted alkanes.

The connectivity indices are based on hyrogen-suppressed graphs and are defined by:

$$ {}^{m}\chi_t = \sum_{j=1}^{n_m} \left[\prod_{i=1}^{m+1} (\delta_i)^{-1/2} \right]_j \qquad \text{(Eq. 1)} $$

where m is the number of connected edges in the subgraph defined by the atoms whose valencies are denoted by δ_i. The summation is over the entire set of all n_m possible subgraphs of the given order and type. The different types which can occur for $m \geq 3$ are differentiated by t; the designation used is $t = P$ for path, C for cluster, PC for path-cluster, and CH for chain (cycle).

The approach taken by Murray was to correlate kinetic steric factors with χ values for a series of substrates in a particular reaction. This implies that steric factors simply reflect structural features of the ground-state substrate molecules. Although many kinetic data have been successfully correlated with ground-state properties of substrate molecules in the past, it seems that a better approach would be based on the transition-state theory. This would correlate kinetic data with parameters which measure the changes that take place during the activation process for a reaction. In particular, we suggest that a convenient set of parameters can be defined as:

$$ \Delta({}^{m}\chi_t) = {}^{m}\chi_t^{\ddagger} - {}^{m}\chi_t \qquad \text{(Eq. 2)} $$

where ${}^{m}\chi_t^{\ddagger}$ is the connectivity index for transition states and ${}^{m}\chi_t$ is the corresponding quantity for reactant molecules. The utility of $\Delta{}^{m}\chi_t$ to measure kinetic steric factors is suggested by the striking success that Kier and co-workers achieved in correlating molar heats of formation with ${}^{m}\chi_t$. If similar relations hold in the transition state, then it would be expected that the enthalpy of activation and the activation energy will be related to $\Delta{}^{m}\chi_t$.

Our goal was to determine whether correlations could be found between chemical reactivity and connectivity indices (either ${}^{m}\chi_t$ or $\Delta{}^{m}\chi_t$). We considered four different chemical reactions: quaternization of substituted pyridines, bromide exchange reaction of branched alkanes, acid-catalyzed hydrolysis of alkanoic esters, and a nucleophilic substitution process on chlorodinitrobenzene, all of which will be discussed below. In all cases, we have found that both sets of indices do generally correlate with the reactivity data.

Our calculations differed from those of Murray in two respects. First, we calculated ${}^{m}\chi_t$ for the actual full substrate molecules rather than replacing the reactive center with an effective atom that has some arbitrary valence. Second, we treated subgraphs of different types separately, since we expected the cluster or path-cluster terms to be most important. All of our indices were calculated with a FORTRAN program developed along the lines of the algorithm suggested by Kier and Hall (4). We simply employed the list of atomic valencies (δ_i) which they provided, including the empirical values they had found appropriate for halogen atoms[1].

[1] Values of δ used in this study were: $-CH_3$, 1; $-CH_2-$, 2; $-\overset{|}{C}H-$, 3; $-\overset{|}{\underset{|}{C}}-$, 4; $-NH_2$, 3; $\equiv N$, 5; $-N=$(pyridine), 5; $-\overset{|}{\underset{|}{N}}-$ (quaternary), 6; OH, 5; $-O-$, 6; $=O$, 6; $-Br$, 0.254.

RESULTS AND DISCUSSION

Substituted Pyridines and Their Quaternization Rates—The alkylation of substituted pyridines is one of the most studied reactions from a structure–reactivity point of view (14–16). Because the steric and branching effects of pyridine alkylation are so well understood, this reaction seemed to be an ideal first candidate for a connectivity index study. Since some of the most striking correlations described by Kier and Hall are for molar heats of formation, we decided to first look at the available data of that type for the alkylpyridines. The only data available were those listed by Cox and Pilcher (17) for the 10 compounds listed in Table I. We found that these values could be described by the simple expression:

$$\Delta H_f^\circ(g)/(\text{kcal}\cdot\text{mol}^{-1}) = -21.80(^1\chi) + 74.27 \qquad \text{(Eq. 3)}$$

where $r = 0.9897$, $RSD = 0.98$, and $n = 10$. The correlation coefficient can be increased to 0.9922 by any of the following:

$$\Delta H_f^\circ(g)/(\text{kcal}\cdot\text{mol}^{-1}) = -32.97(^1\chi) + 10.05(^2\chi) + 84.49 \qquad \text{(Eq. 4)}$$

$$= -24.02(^1\chi) + 4.49(^4\chi_{PC}) + 78.47 \qquad \text{(Eq. 5)}$$

$$= -27.84(^1\chi) + 18.00(^3\chi_C) + 85.28 \qquad \text{(Eq. 6)}$$

Although these findings are not as impressive as the results of Kier and Hall for alkanes, they are significant. The size of the current data set is appreciably smaller than that of Kier and Hall, and the uncertainties in the experimental data are larger. In Fig. 1 are shown the types of subgraphs that contribute to the indices $^2\chi$, $^3\chi_C$, and $^4\chi_{PC}$. It is appropriate that these enter the correlations Eqs. 4–6 since they measure the degree of methylation of the pyridine nucleus; $^4\chi_{PC}$ also contains a measure of the degree of substitution at adjacent pyridine sites.

If one examines the series of rate constants previously reported (14–16) for the methylation of alkylpyridines, it appears that the relative rates are dominated by steric effects and have only subordinate electronic contributions. We have recently published (14, 16) some theoretical studies of this reaction based on the model transition state (TS) corresponding to the activation process shown in Scheme I. We used this model to calculate a set of ($^m\chi_t^\ddagger$) and $\Delta(^m\chi_t)$ for a series of 37 alkyl-substituted pyridines (Table II). The valency of nitrogen in the model transition states was taken to be 6, which is the value suggested by Kier and Hall for quaternized nitrogen (4). This corresponds to the assumption to a fully formed N—CH_3 bond in the TS; in subsequent studies, it may be desirable to use intermediate valencies which correspond to partially formed bonds. For the set of 37 alkylpyridines, in which the relative reaction rates cover four orders of magnitude, the best linear correlation we found was:

$$\ln(k_{rel}) = -10.7\,\Delta^5\chi_{PC} + 2.75 \qquad \text{(Eq. 7)}$$

where $r = 0.8786$, $RSD = 1.28$, $n = 37$, and k_{rel} is the second-order rate constant relative to that of pyridine.

Other powers of the parameters were investigated, and the best correlation obtained was:

$$\ln(k_{rel}) = -10.4(\Delta^5\chi_{PC})^2 - 7.24(\Delta^4\chi_{PC})^2 + 1.30 \qquad \text{(Eq. 8)}$$

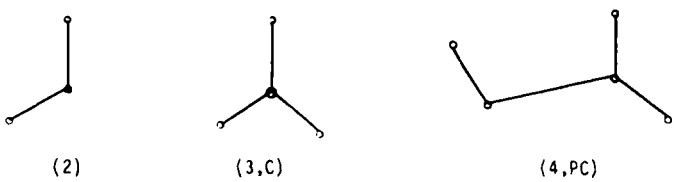

Figure 1—*Illustrative subgraphs of types* $^2\chi$, $^3\chi_C$, $^4\chi_{PC}$.

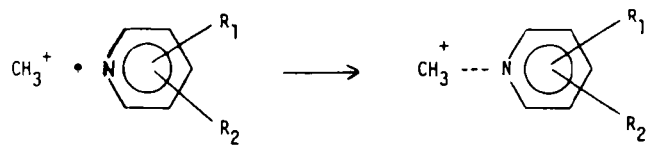

Scheme I

where $r = 0.9092$, $RSD = 1.13$, and $n = 37$. The results of Eq. 8 are compared with the observed values of [ln (k_{rel})] in Table II. In Figure 2 are shown some illustrative subgraphs that contribute to $\Delta^5\chi_{PC}$ and $\Delta^4\chi_{PC}$ for the model transition states. It is easy to see that these terms should constitute measures of steric hindrance in the reaction.

In the case of Eq. 8, as well as for all succeeding correlations involving multiple parameters, statistical tests were applied regarding the utility of the added parameters. Parameters were not added to the correlations unless they were significant at the 90% confidence interval, as indicated by the *F*-test.

Although Eqs. 7 and 8 are quite reasonable, better results might have been expected. Further consideration indicates that there may be a good reason for this discrepancy; although this reaction is dominated by steric factors, there are apparently sizeable electronic contributions in some cases. In fact, Berg *et al.* (18) have studied the iodomethylation of a series of 2-substituted pyridines, using heteroatom substituents as well as alkyl groups, and have arrived at a separation of electronic and steric contributions to the relative rates of reaction. They separated log (k_{rel}) into steric (S°) and electronic (E°) components:

$$\log(k_{rel}) = S^\circ + E^\circ \qquad \text{(Eq. 9)}$$

and, using a Brønsted relation to estimate E°, were able to determine S° and E° for the series of molecules. For the series of 2-alkylpyridines with alkyl groups being methyl, ethyl, isopropyl, and *tert*-butyl, they found values of E°/S° to be −0.59, −0.33, −0.24, and −0.061, respectively. Whether or not their values of S° and E° are precisely correct, it must be concluded that electronic effects are not insignificant in the above series of alkylpyridines and, furthermore, that their fractional contributions vary considerably through the series.

[a] From Ref. 18. [b] See Table IX for values of ${}^m\chi_t$ and $\Delta^m\chi_t$.

For the whole set of molecules studied, Berg *et al.* (18) found that the ratio of $E°/S°$ varies from −0.68 to +2.03, so the data cover the range from predominant steric control to predominant electronic control. The values of $S°$ which they obtained for the 2-substituents —CHO and —$COCH_3$ seemed out of line with the rest of their data, so we dropped those compounds from further consideration, leaving a total of 13 compounds to be considered (Table III). No significant correlations could be found for log (k_{rel}); this is consistent with the conclusion that both electronic and steric factors are important in this series (18). The situation was dramatically different when the values of $S°$ were examined. The best single-parameter linear correlation was:

$$S° = -4.43\Delta^6\chi_{PC} + 0.26 \qquad \text{(Eq. 10)}$$

where $r = 0.8739$, $RSD = 0.46$, and $n = 13$. The situation improved dramatically when multiple parameters were permitted. The best linear relation obtained was:

$$S° = -4.11(\Delta^6\chi_{PC}) - 70.1(\Delta^3\chi_C) + 3.00(\Delta^4\chi_P) + 7.27 \qquad \text{(Eq. 11)}$$

where $r = 0.9430$, $RSD = 0.35$, and $n = 13$. When other powers of the parameters were examined, slightly better agreement was found by:

$$S° = -0.584(\Delta^4\chi_{PC})^{-1} - 0.117(\Delta^4\chi_P)^{-1} + 0.338(\Delta^6\chi_{PC})^{-1} + 0.460 \qquad \text{(Eq. 12)}$$

where $r = 0.9585$, $RSD = 0.30$, and $n = 13$. The values of $S°$ calculated from Eqs. 11 and 12 are compared with the experimentally derived values of Berg *et al.* (18) in Table III. These investigators did a credible job of identifying steric contributions to these relative rates. Furthermore, as we expected, Eqs. 10–12 are dominated by path-cluster- and cluster-type terms.

If we correlate $S°$ with the indices of the substrate molecules themselves, the best single-parameter equation is somewhat better than Eq. 10:

$$S° = -3.41({}^5\chi_{PC}) - 0.35 \qquad \text{(Eq. 13)}$$

where $r = 0.9127$, $RSD = 0.47$, and $n = 13$. However, the best multiple-parameter equation is not quite as good as Eqs. 11 or 12:

$$S° = -13.69({}^5\chi_C) - 0.93({}^4\chi_P) - 0.38 \qquad \text{(Eq. 14)}$$

where $r = 0.9270$, $RSD = 0.44$, and $n = 13$. If the calculated values of $S°$ in Table III are examined it is hard to decide whether Eq. 11, 12, or 14 is preferable to the others. The single-parameter correlations behave as expected in that the index occurring in Eq. 10 (${}^6\chi_{PC}$) is of a higher order than that in Eq. 13 (${}^5\chi_{PC}$).

The success of Eqs. 10 and 13 indicates that there should exist a linear relationship between the activation indices ($\Delta^6\chi_{PC}$) and the substrate indices (${}^5\chi_{PC}$). The relation was found to be:

$$\Delta^6\chi_{PC} = 0.712({}^5\chi_{PC}) + 0.154 \qquad \text{(Eq. 15)}$$

where $r = 0.9660$, $RSD = 0.0483$, and $n = 13$. The existence of this relationship is consistent with results of a previous study on the Menschutkin reaction, which has established that relative reactivities of substituted pyridines can be interpreted either in terms of TS calculations or in terms of substrate equilibrium structures with essentially equal success (14–16).

Bromide Exchange Reaction—Another reaction which is generally accepted as being largely sterically controlled is the bromide exchange reaction of alkyl groups:

$$Br^- + RBr \rightarrow BrR + Br^- \qquad \text{(Eq. 16)}$$

which was studied experimentally by de la Mare *et al.* (19). For these reactions, Abraham and co-workers have estimated the nonbonded interactions in a model transition state (Fig. 3) and concluded that steric effects are highly dominant (20). More recently, deTar *et al.* (21) have applied molecular mechanics to the same transition state; they concluded that although steric effects apparently predominate, polar effects must be invoked to interpret the rate constants for the α series of alkyl groups (methyl, ethyl, isopropyl, *tert*-butyl).

We examined the rate constants at 25°C (Table IV) which were listed by deTar *et al.* (21). As before, transition-state valencies were assigned on the basis of fully formed bonds. This included use of the empirical value of 0.254 for bromine.

The best single-parameter correlation was rather poor:

$$\ln(k) = -2.73(\Delta^5\chi_C) - 7.50 \qquad \text{(Eq. 17)}$$

where $r = 0.7269$, $RSD = 3.70$, $n = 7$, and k is in $s^{-1}\ M^{-1}$. With two parameters the results were much better:

$$\ln(k) = -3.70(\Delta^5\chi_C) - 1.30(\Delta^3\chi_C) - 3.44 \qquad \text{(Eq. 18)}$$

where $r = 0.9763$, $RSD = 1.30$, $n = 7$, and k is in $s^{-1}\cdot M^{-1}$.

In this case, the substrate connectivity indices do a slightly better job than do the $\Delta\chi$. In comparison with Eq. 17, we have:

$$\ln(k) = -2.87({}^2\chi) - 2.87 \qquad \text{(Eq. 19)}$$

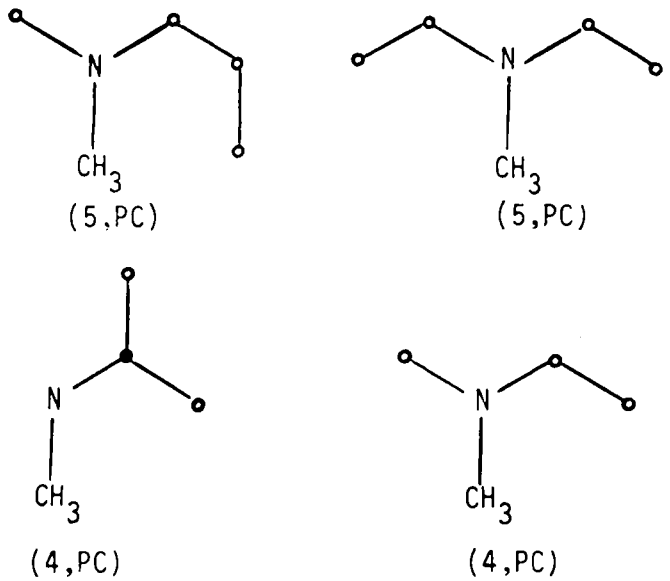

Figure 2—*Illustrative subgraphs contribution to terms in Eq. 8.*

Table IV—Second-Order Rate Constants and Steric Contributions to Activation Energies for Br^- Exchange Reactions [a]

R	ln (k)			$\Delta E^{\ddagger}_{ST}$		
	Observed [b]	Eq. 18 [c]	Eq. 20 [c]	Calc [d]	Eq. 22 [c]	Eq. 23 [c]
Methyl	−2.00	−3.44	−2.81	7.41	7.20	7.50
Ethyl	−6.41	−6.39	−6.08	13.61	12.55	12.95
n-Propyl	−6.81	−5.52	−6.29	13.65	14.40	13.30
Isopropyl	−10.96	−9.63	−9.50	17.77	18.44	18.65
Isobutyl	−9.74	−9.90	−10.42	15.48	16.79	16.07
tert-Butyl	−12.17	−13.27	−13.24	25.38	25.04	24.90
Neopentyl	−17.35	−17.28	−17.08	20.64	19.52	20.57

[a] Rate constants are in seconds^{-1}·Molar^{-1}, activation energies are in kilocalories·moles^{-1}, and the exchange reaction is depicted in Eq. 16. [b] From Ref. 19. [c] See Table X for values of $^{m}\chi_t$ and $\Delta^{m}\chi_t$. [d] From Ref. 21.

where $r = 0.8606$, $RSD = 2.73$, $n = 7$, and k is in $s^{-1}\cdot M^{-1}$. The counterpart of Eq. 18 is:

$$\ln(k) = -2.33(^{2}\chi) - 3.06(^{4}\chi_{PC}) - 2.87 \qquad \text{(Eq. 20)}$$

where $r = 0.9829$, $RSD = 1.10$, $n = 7$, and k is in $s^{-1}\cdot M^{-1}$. Note that Eqs. 19 and 20 contain lower-order indices than do Eqs. 17 and 18. The values of ln (k), as calculated from Eqs. 18 and 20 are compared with the experimental values in Table IV.

We also examined the steric contributions to the activation energies, $\Delta E^{\ddagger}_{st}$, which deTar *et al.* calculated *via* molecular mechanics (21). Correlation of these numbers with the $\Delta\chi$ values yielded the best single- and multiple-parameter correlations:

$$\Delta E^{\ddagger}_{st} = 1.64(\Delta^{3}\chi_C) + 11.96 \qquad \text{(Eq. 21)}$$

where $r = 0.7575$, $RSD = 4.11$, $n = 7$, and $\Delta E^{\ddagger}_{st}$ is in kcal·mol^{-1}, and:

$$\Delta E^{\ddagger}_{st} = 2.35(\Delta^{3}\chi_C) + 2.13(\Delta^{4}\chi_C) + 7.20 \qquad \text{(Eq. 22)}$$

where $r = 0.9865$, $RSD = 1.15$, $n = 7$, and $\Delta E^{\ddagger}_{st}$ is in kcal·mol^{-1}. These are slightly better than Eqs. 17 and 18 involving the rate constants.

When the substrate indices were used, we obtained:

$$\Delta E^{\ddagger}_{st} = 3.89(^{2}\chi) + 7.50 \qquad \text{(Eq. 23)}$$

where $r = 0.9951$, $RSD = 0.62$, $n = 7$, and $\Delta E^{\ddagger}_{st}$ is in kcal·mol^{-1}. In this case no statistically significant second parameter could be added to the correlation. However, Eq. 23 is already superior to Eq. 22. Equations 22 and 23 are compared with the molecular mechanics values of deTar *et al.* in Table IV.

Linear regression of the best single activation index ($\Delta^{3}\chi_C$) against the best single substrate index ($^{2}\chi$), yielded a correlation coefficient of only 0.752. This low value is to be expected in view of the small r associated with Eq. 21.

Whether the substrate connectivity indices ($^{m}\chi_t$) or the changes that occur in them during activation ($\Delta^{m}\chi_t$) are employed, we had slightly better correlations with the steric portion of the activation energy than we did with the rate constants. This tends to support the conclusion of deTar *et al.* (21) that polar effects are not negligible in these reactions.

E_s Values of Taft—The E_s values described by Taft (13) for alkyl groups were derived as steric contributions to the relative rates of hydrolysis reactions:

$$RCOOC_2H_5 + H_3O^+ \rightarrow RCOOH + C_2H_5OH + H^+ \qquad \text{(Eq. 24)}$$

Murray (9) correlated the E_s values with effective connectivity indices obtained for RX molecules, and assigned X an effective valency of 2. We examined these reactions using the model transition state shown in Fig. 4.

By using the $\Delta\chi$ values, the best one-parameter equation obtained was:

$$E_s = -2.48(\Delta^{6}\chi_{PC}) - 0.31 \qquad \text{(Eq. 25)}$$

where $r = 0.9181$, $RSD = 0.58$, and $n = 19$. The use of multiple parameters improved this to:

$$E_s = -2.25(\Delta^{6}\chi_{PC}) - 1.58(\Delta^{4}\chi_{PC}) + 0.08 \qquad \text{(Eq. 26)}$$

where $r = 0.9372$, $RSD = 0.53$, and $n = 19$. When the substrate indices were used for the ethyl esters, we obtained:

$$E_s = -1.57(^{3}\chi_P) + 0.69 \qquad \text{(Eq. 27)}$$

[a] E_s values described by Taft (13). [b] From Ref. 13. [c] See Table XI for values of $^{m}\chi_t$ and $\Delta^{m}\chi_t$.

where $r = 0.9317$, $RSD = 0.53$, and $n = 19$.

In Table V is shown a comparison between Eqs. 26 and 27 with the E_s values given by Taft (13). Equations 25 and 27 are better than the single-parameter correlations described by Murray (9), and Eq. 26 is better than his two-parameter relation.

Here, again, there is a significant correlation between the indices used in Eqs. 25 and 27, *viz.*:

$$\Delta^{6}\chi_{PC} = 0.567(^{3}\chi_P) - 0.303 \qquad \text{(Eq. 28)}$$

where $r = 0.9106$, $RSD = 0.225$, and $n = 19$.

Nucleophilic Substitution of 1-Chloro-2,4-Dinitrobenzene by Alkylamines—As a final example, we chose the nucleophilic substitution of 1-chloro-2,4-dinitrobenzene by an aliphatic amine by the activation process shown in Scheme II. The relative rate constant data were obtained from the experiments of Brady and Cropper (22) (Table VI).

[a] Equations 7 and 8.

An excellent correlation of ln (k_{rel}) was obtained with activation indices:

$$\ln(k_{rel}) = -4.506(\Delta^{5}\chi_{PC}) - 1.087(\Delta^{5}\chi_{P}) + 10.800 \quad \text{(Eq. 29)}$$

where $r = 0.9984$, $RSD = 0.134$, and $n = 8$. The only relation found between ln (k_{rel}) and the substrate alkylamine indices was not nearly as good:

$$\ln(k_{rel}) = -3.929(^{3}\chi_C) + 2.106 \quad \text{(Eq. 30)}$$

where $r = 0.9177$, $RSD = 0.848$, and $n = 8$. The results of Eqs. 29 and 30 were compared with the experimental data (Table VI).

In addition, there is a reasonable linear relation between the indices of Eqs. 29 and 30:

$$^{3}\chi_C = 0.959(\Delta^{5}\chi_{PC}) - 1.559 \quad \text{(Eq. 31)}$$

where $r = 0.9248$, $RSD = 0.191$, and $n = 8$.

CONCLUSIONS

The correlations presented here indicate that the connectivity indices can serve as useful steric parameters in reactivity studies. It appears that they are capable of distinguishing between cases of steric control and electronic control. Either the connectivity indices in the substrate molecules or the changes that occur in formation of the transition state can apparently be used. This ambiguity is consistent with the fact that it is often possible to interpret relative reaction rates for a series of molecules either in terms of transition-state calculations or in terms of substrate-molecule equilibrium properties. For any particular reaction, the activation indices which appear in the correlations are always of higher order than the corresponding substrate indices, and the two sets are generally correlated with one another. We strongly feel that any empirically derived steric parameters must correlate with these indices if they

are at all reasonable. Charton (10) has recently concluded that no one set of steric parameters is suitable for all reactions. Since they take into account the TS structure, the $\Delta^m\chi_t$ values may have sufficient flexibility to be generally useful. This is illustrated by the fact that different indices are important for different reactions.

Within the last year Edward has published two studies in which the molecular basis for the relationship of a number of physical properties and connectivity indices is beginning to be unraveled (7). The inclusion of connectivity indices in recent pattern recognition investigations of pharmacological activities suggests that this type of descriptor variable encodes structural features which influence *in vivo* tests. Our present findings bring together connectivity indices as a descriptor for structural effects in both chemical reactivity and pharmacological activities.

APPENDIX

Tables VII–XII contain the values of $^m\chi_t$ and $\Delta^m\chi_t$ that were employed in all correlations. There is one table for each table in the text. Table VII gives the values employed in Table I, *etc.*

Relationship between Refractive Index and Dry-Substance Content for Lactulose Syrups

A. DE REIJKE ˣ, P. VAN BEMMEL, and H. W. GELUK

Received November 29, 1982, from the *Duphar B.V., Research Laboratories, 1380 AA Weesp, The Netherlands.* Accepted for publication October 24, 1983.

Abstract □ The relationship between the refractive index and the dry substance content of lactulose syrups of different compositions was investigated. It was found that, for a concentration range of 55–75% of dissolved carbohydrates, the sucrose tables can be used after correction by a factor of 0.97.

Keyphrases □ Lactulose—determination of dry substance, refractive index-dry-substance content relationship □ Refractive index-dry-substance content, lactulose syrups

Lactulose (4-*O*-β-D-galactopyranosyl-D-fructofuranose) is a synthetic disaccharide which is primarily used for the treatment of constipation (1), portal systemic encephalopathy, and hepatic coma (2). The drug, prepared by a base-catalyzed isomerization of lactose, known as the Lobry de Bruyn–Alberda van Ekenstein rearrangement, is commonly marketed as an aqueous syrup. This syrup also contains small amounts of lactose and other carbohydrates formed during the isomerization process (3).

Lactulose, lactose, and galactose can be analyzed by specific chromatographic (4, 5) or enzymatic methods (6); however, suitable methods are not available to determine each of the other sugars. The total weight of the other sugars can be determined from the difference between the amount of the analyzed compounds and the total weight of solid material dissolved in the syrup. Our problem, therefore, was to find a method to determine the amount of carbohydrates present in the lactulose syrup.

Several methods for dry-substance determination of sugars are known and have recently been critically discussed (7). Drying procedures at temperatures of >100°C are not reliable for lactulose syrup because of the possible decomposition of labile carbohydrates and the loss of water by dehydration reactions. Freeze-drying procedures are also unsatisfactory because water is not completely removed from the amorphous or syrupy residue and the remaining water must be determined by a different method. An indirect method for the determination of the dry substance content is by measuring the water content using the Karl Fischer method (8). This method, however, requires special equipment and is time consuming. The dry-substance content of sugar solutions is frequently determined by means of refractometry (9) or densimetry (10). Refractive index measurements, in particular, are easily and accurately accomplished and would be the method of choice provided that the relationship between dry-substance content and refractive index is known. For aqueous sucrose solutions, correlation tables (Brix values) are readily available (9, 11, 12) and are included in the refractive index measuring scale. Refractive index data have also been published for aqueous solutions of other common sugars such as glucose (12), fructose (11), lactose (13, 14), and maltose (9) and for different types of syrups (12, 15–17); however, no data were available for lactulose. Therefore, we have investigated the refractive index-dry-substance relationship for lactulose syrups with different compositions.

61.95	63.78	0.971
67.47	69.38	0.972
74.55	76.60	0.973
Mean		0.972

[a] The amount of real dry substance/dry substance from refraction.

EXPERIMENTAL SECTION

Apparatus—Refractive indices were measured on a refractometer[1] thermostated at 20 ± 0.1°C[2]. The water content in the dry substance was determined automatically[3]. For freeze-drying procedures, a self-made laboratory freeze-drier was used. The condenser was cooled with solid carbon dioxide in acetone.

Chemicals—Lactulose, the analytical reference standard, had a purity >99.5% and a water content of 0.23% (recrystalized from methanol). The α-D-lactose monohydrate[4] had a purity of >99.5% and the α-D-galactose[5] had a purity of >99%.

Preparation of Sugar Solutions—Eight solutions of pure lactulose in water were made by weight in the range of 55–75% (Table I). Then, an artificial mixture containing lactulose (89.9%), lactose (4.5%), and galactose (5.6%) was prepared. Four solutions were made by weight in the range of 55–75% by dilution of this mixture with water (Table II).

Another set of sugar solutions was prepared with four samples of lactulose syrup which were freeze-dried. The amorphous residue was kept at 70°C for 2 h. From the residue of each batch, four solutions in water were made by weight in the range of 55–75%. Since it was not possible to obtain a water-free residue, a correction was made for the remaining water determined with the Karl Fischer titration (in the four batches these values were 0.93, 0.98, 0.21, and 0.20%, respectively) (Table III).

Samples of 26 production batches of lactulose syrup and 61 batches of formulated product[6] were analyzed for dry substance using the Karl Fischer titration and the refractive index (Table IV).

RESULTS AND DISCUSSION

The relationship between the real dry-substance content of lactulose solutions and the dry substance obtained from the refraction and sucrose index (°Brix), is expressed as: real dry substance/dry substance from refraction. From the refractive index-dry-substance relationship, as given for various sugars in the literature, correction factors can be calculated for sucrose dry-substance values.

Table V gives the results for solutions of some common carbohydrates and syrups at three different concentrations. It appears that the factor for the aqueous sugar solutions varies between 0.969 for lactose and 1.021 for glucose and fructose. The mean factor we found in all our experiments was within this range.

It may be concluded from Tables I and II that the factor for pure lactulose, or for lactulose mixed with lactose and galactose, will be ~0.97 for solutions of 55-75% of dry-substance content. Almost the same values were found for lactulose syrups of different compositions. Thus, the presence of other carbohydrates in lactulose syrup does not significantly influence the refractive index. The dry-substance content of lactulose syrups can, therefore, be determined easily and accurately by refractometry using sucrose-dry-substance or Brix values after correction by a factor of 0.97.

[6] Duphalac; the lactulose content is 667 g/L according to the label claim.

Bare Silica as a Reverse-Phase Stationary Phase: Liquid Chromatographic Separation of Antihistamines with Buffered Aqueous Organic Mobile Phases

HAROLD RICHARDSON ˣ **and BRIAN A. BIDLINGMEYER**

Received October 26, 1982, from *Waters Associates, Milford, MA 01757.* Accepted for publication October 5, 1983.

Abstract □ Unbonded silica gel is an effective support for reverse-phase liquid chromatographic separations of lipophilic amines. Simple buffered aqueous-organic mobile phases provide rapid isocratic separations of antihistamines. Phenylpropanolamine hydrochloride, chlorpheniramine maleate, and dextromethorphan hydrobromide are separated in 8 min on bare silica with a mobile phase of 75% methanol and 25% water which is 0.01 M in $(NH_4)_2HPO_4$. Quantitation is reproducible. A wide variety of additional compounds may be separated using the same mobile phase.

Keyphrases □ Bare silica—reverse-phase stationary phase, liquid chromatography □ Antihistamines—buffered aqueous organic liquid chromatographic mobile phases

The object of this work is to demonstrate that the use of silica in the reverse-phase mode is practical for the liquid chromatographic separation of lipophilic amines. The group of amines used as antihistamines, antitussives, and decongestants are frequently formulated together. When using C_{18}-bonded phase columns, it is necessary to use amine mobile-phase modifiers to ensure good retention and peak shape (1) in the ion-suppression mode. While C_{18}-bonded phases have been reported most often for the separation of these lipophilic amines, recent work (2) suggests that unbonded silica gel, with the maximum concentration of surface silanol groups, is a preferable stationary phase for these compounds.

Using unbonded silica as the stationary phase permits the analyst to separate a wide variety of amine compounds with a simple mobile phase of organic solvent and an aqueous phosphate buffer for pH control. The retention volumes are lower and the peaks are more symmetrical when silica, rather than a C_{18}-bonded support, is used as the stationary phase. However, because this use for unbonded silica is new, it is necessary to demonstrate long-term performance in routine operation.

Table I—Formulations

	Components	Concentration
Syrup		
A	Acetaminophen	625 mg/30 mL
	Phenylpropanolamine hydrochloride	25 mg/30 mL
	Chlorpheniramine maleate	2 mg/30 mL
	Dextromethorphan hydrobromide	20 mg/30 mL
B	Potassium guaiacolsulfonate	100 mg/5 mL
	Pseudoephedrine hydrochloride	30 mg/5 mL
	Chlorpheniramine maleate	2 mg/5 mL
	Dextromethorphan hydrobromide	10 mg/5 mL
E	Phenylpropanolamine hydrochloride	12.5 mg/5 mL
	Chlorpheniramine maleate	2 mg/5 mL
F	Guaifenesin	100 mg/5 mL
	Pseudoephedrine hydrochloride	30 mg/5 mL
	Dextromethorphan hydrobromide	10 mg/5 mL
Tablet		
C	Acetaminophen	325 mg
	Phenylpropanolamine hydrochloride	12.5 mg
	Dextromethorphan hydrobromide	10 mg
D	Pyrilamine maleate	25 mg
G	Theophylline	130 mg
	Ephedrine hydrochloride	24 mg
	Pyrilamine maleate	16.6 mg

This paper demonstrates that practical separations of commercial antihistamine formulations on unbonded silica in the reverse-phase mode result in reproducible analyses and good column life. In addition, the sample preparation is straightforward so that high throughput of samples is attained.

EXPERIMENTAL SECTION[1]

The salts[2], ammonium hydroxide[3], sodium hydroxide[3], hydrochloric acid[3], and phosphoric acid[3] used in this study were obtained commercially. Purified water[4], chromatographic-grade acetonitrile[5], and methanol[5] were used for mobile phase preparation. The mobile phases were filtered through 0.45-μm cellulose acetate filters[6] and deaerated under vacuum in an ultrasonic bath before use.

Seven different over-the-counter pharmaceutical formulations (tablets or syrups) were purchased in a local pharmacy and prepared as samples by dissolving 10 mL, or 1 tablet, in 100 mL of mobile phase and filtering through a 0.5-μm filter[7]. The composition of the various formulations is shown in Table I. A standard solution of formulation A was prepared from pharmaceutical grade materials obtained from a variety of sources. The concentrations of standards were designed to duplicate a 10:1 dilution of label concentration.

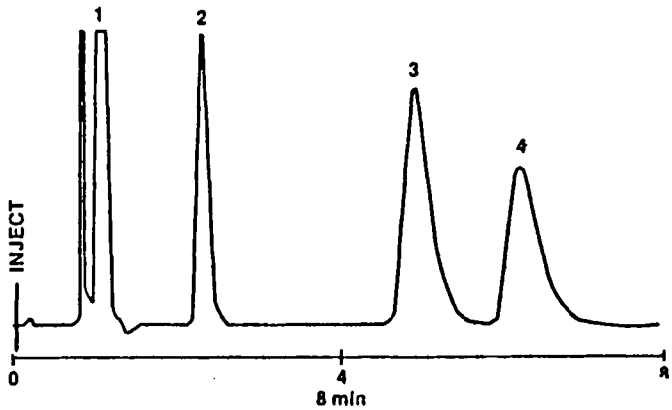

Figure 1—*Separation of a 1:10 solution of syrup A. Operating conditions were: solvent: 75% methanol, 25% H_2O, 0.01 M $(NH_4)_2HPO_4$, pH = 7.8; flow rate: 4 mL/min; 50-μL injection; detection at 254 nm; 0.05 AUFS. Key: (1) acetaminophen; (2) phenylpropanolamine; (3) chlorpheniramine; (4) dextromethorphan.*

[1] The chromatographic system was a Waters Associates, Inc., (Milford, Mass.) Model 244 ALC which included a Model 6000A Solvent Delivery System, Model U6K Injector, Model 480 Variable Wavelength Spectrophotometric Detector, and a Model R401 Refractometer. The column was Radial-PAK μPorasil Silica (8 mm × 10 cm) cartridges which were maintained under radial compression in the Z-Module Radial Compression Separation System (Waters). If excessive back pressure developed, the cartridge was reversed and the tubing to the detector was detached and sent to waste; the cartridge was flushed with mobile phase. When the pressure returned to the original value, the cartridge was returned to the original orientation and the module was reattached to the detector. The analog output of the absorbance (UV) was recorded with a Model 730 Data Module (printer, plotter, and integrator) (Waters) and the quantitation was done at 214 nm. Retention times were converted to retention volumes using the flow rate. Samples were injected automatically using the Model 710B Waters Intelligent Sample Processor (WISP). Automatic control of flow rate, injection, and data documentation was accomplished using the Model 720 System Controller.

RESULTS AND DISCUSSION

Development of the Separation—Formulation A, which had one nonionic component (acetaminophen) and three amines, was chosen as a demonstration case. The first separations were done with the acetonitrile–aqueous salt eluant described in a previous report (2). This separation resulted in inadequate resolution of chlorpheniramine (10.33 min) and dextromethorphan (11.10 min). Since methanol frequently exhibits different selectivity than acetonitrile (increased α) and weaker solvent strength (increased k'), it was evaluated at various aqueous salt concentrations. Using the organic content of 75% methanol and a salt concentration of 10 mM resulted in the optimized chromatogram shown in Fig. 1. The retention volumes were adequate and the resolution was more than baseline for chlorpheniramine and dextromethorphan. The relationship between the fraction of organic modifier (methanol) and the log retention volume was linear, as shown in a previous report (2).

Determination of Optimum Wavelength of Detection—For the separation shown in Fig. 1, detection was at 254 nm. The absorbance of acetaminophen (molar absorptivity = 13,200 at 248 nm) saturated the detector amplifier and gave a nonlinear response when a sufficient mass of the amines was injected for convenient detection; the amine components are present in much lower concentrations than acetaminophen. Inspection of the UV spectra of the various components indicated that acetaminophen has a minimum absorbance at 217 nm and that a significant improvement of signal strength occurs for phenylpropanolamine at 214 nm. Evaluation at 214 nm indicated that sensitive, reliable quantitation of the lipophilic amines was possible (Fig. 2). At 254 nm, sensitivity for phenylpropanolamine and chlorpheniramine was excellent, while sensitivity for dextromethorphan was not as good. At 214 nm, the relative sensitivity of chlorpheniramine is reduced compared with dextromethorphan and phenylpropanolamine. The quantification is better for all components at 214 nm. Even so, the absorbance of acetaminophen was still too high (from 26 to 350 times as much as the amines) for quantitation. When it was desirable to quantitate acetaminophen, it was necessary to decrease the sample size such that detection of dextromethorphan (254 nm) or chlorpheniramine (214 nm) was very difficult. A different method with greater retention is preferable for acetaminophen.

Table II—Reproducibility of Quantitation with Standard Solution [a]

Compound	Conc., mg/mL	*RSD*, %
Phenylpropanolamine hydrochloride	0.0847	±0.65
Chlorpheniramine maleate	0.00672	±4.53
Dextromethorphan hydrobromide	0.0669	±1.45

[a] n = 30; run completed overnight.

Table III—Linearity of Response with Sample Load

Compound	Slope	Intercept	Coefficient of Correlation
Phenylpropanolamine hydrochloride	0.01952	0.00223	0.9980
Chlorpheniramine maleate	0.02217	0.000038	0.9980
Dextromethorphan hydrobromide	0.01913	0.00239	0.9980

Table IV—Quantitative Analysis of Syrup A

Compound	Conc., mg/mL Found	Label Claim	% of Label Claim
Phenylpropanolamine hydrochloride	0.08008	0.08333	96.1
Chlorpheneramine maleate	0.00629	0.00667	94.3
Dextromethorphan hydrobromide	0.0632	0.06667	94.8

Determination of Reproducibility and Linearity—A standard solution was prepared from pharmaceutical grade materials which duplicated a 10:1 dilution of the label concentrations in Syrup A of phenylpropanolamine, chlorpheniramine, and dextromethorphan. Table II shows that the quantitation of the three bases in the standard solution is excellent: two components had <2% *SD* for a series of 30 injections, and the component present in lowest concentration had a <5% *SD*. The linearity of the system with sample load was evaluated. When plots of sample load in μg *versus* detector response in mg/mL were evaluated, the lines reported in Table III were obtained. The system was linear from 0.002 mg/mL to 0.022 mg/mL. The assay results of a 10:1 dilution of syrup A is shown in Table IV. The concentrations found were ~95% of label for all three components. This method was developed on a single column and several hundred injections were completed with comparable

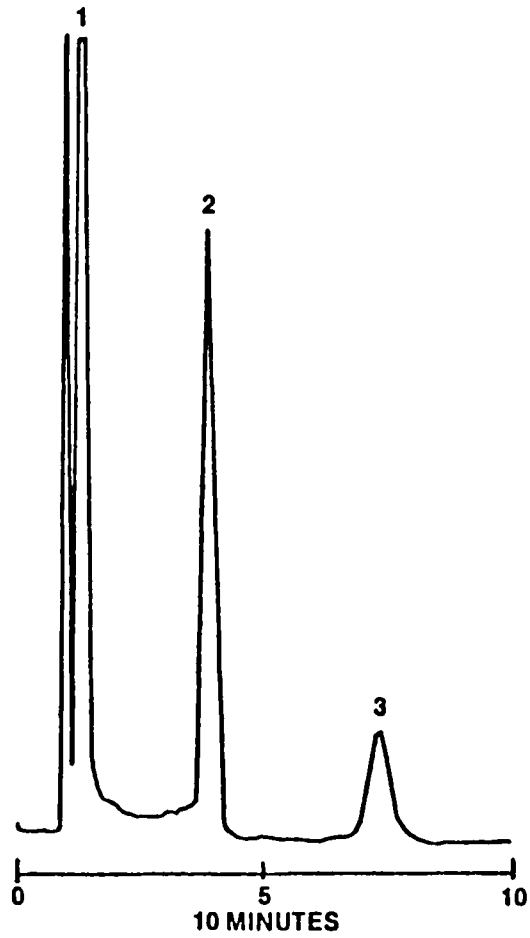

Figure 3—*Chromatogram of over-the-counter cough syrup F. Conditions as in Fig. 2. Key: (1) guaifenesin; (2) pseudoephedrine; (3) dextromethorphan.*

resolution: More than 800 injections were completed on a second column with no change in the separation.

Analysis of Additional Over-the-Counter Pharmaceutical Formulations—The six additional preparations, shown in Table I, were examined to determine whether the silica adsorbent was appropriate for other basic drugs. Chromatograms were obtained using the same mobile phase and detector wavelength as for quantitation of syrup A, and no attempt was made to optimize the separations. For example, Fig. 3 illustrates that other basic drugs are also eluted in this mobile phase system.

CONCLUSIONS

The separation of lipophilic bases on unbonded silica stationary phases in the reverse-phase mode is rapid and convenient. No amine modifiers or gradients are necessary for the separation; only simple buffers are required for pH control. Separations of several samples indicated that a variety of compounds may be separated with this system. Assay of a single sample indicated that linearity, reproducibility, and length of column life are excellent.

Hypolipidemic Activity of Phthalimide Derivatives V: Reduced and Hydrolytic Products of Simple Cyclic Imides

JAMES M. CHAPMAN, JR., STEVEN D. WYRICK, P. JOSÉE VOORSTAD, JAMES H. MAGUIRE, GEORGE H. COCOLAS, and IRIS H. HALL ˣ

Received February 24, 1983 from the *School of Pharmacy, University of North Carolina at Chapel Hill, Chapel Hill, North Carolina* 27514. Accepted for publication September 8, 1983.

Abstract □ A series of cyclic imides and related compounds have previously been shown to possess hypolipidemic activity at the low dose level of 20 mg/kg/d. Hydrolytic and reduced products of the cyclic imides were synthesized and examined to discern if possible metabolic products were the active chemical species of these hypolipidemic agents. Phthalimide proved to be the most active cyclic imide tested. Unfortunately, the new products did not, in general, improve hypolipidemic activity in rodents. The exceptions were piperidine which demonstrated improved hypotriglyceridemic activity, and 3,4,5,6-dibenzohomopiperidin-2-one, which demonstrated improved hypocholesterolemic activity compared to phthalimide.

Keyphrases □ Cyclic imides—phthalimide derivatives, reduced and hydrolytic products, hypolipidemic activity □ Phthalimide derivatives—cyclic imides, hypolipidemic activity, reduced and hydrolytic products □ Hypolipidemic activity—phthalimide derivatives, cyclic imides, reduced and hydrolytic products

A series of cyclic imides including phthalimide (I), succinimide, 1,8-naphthalimide, and saccharin have been shown to be potent hypolipidemic agents in rodents (1). After conducting dose response studies on these compounds, the optimum dose appears to be 20 mg/kg/d ip when tested in mice. Thus, we have selected that dose for this structure-activity relationship study. The mode of action of these derivatives is different from standard therapeutic agents on the market in that they do not inhibit the regulating enzyme of cholesterol synthesis, HMG CoA reductase; rather, they regulate mitochondrial citrate exchange and the availability of acetyl CoA, the key intermediate required in the synthesis of fatty acids and cholesterol (1). These agents also decreased cholesterol absorption in the intestine and accelerated cholesterol excretion by the biliary route. The agents had no effect on appetite, organ weights, or body weight, and there was no evidence of organ toxicity or deleterious systemic effects (1). Since these are potentially hypolipidemic agents, we expanded the types of imide rings and examined a series of their reduced and hydrolytic products, which may be potential metabolic products of the parent imide yet retain pharmacological activity.

EXPERIMENTAL SECTION

All chemicals used as synthetic intermediates were purchased and used as obtained from the manufacturers[1]. Melting points were obtained on a capillary melting point apparatus[2] and are uncorrected. Column chromatography was performed on silica gel 60 (70–230 mesh)[2]. TLC was performed using precoated silica gel plates with fluorescent indicators[3]. ^{1}H-NMR spectra were obtained on a 60-mHz Fourier transform spectrometer[4]. Elemental analyses for prepared compounds are correct within ±0.4% of theoretical values.

Phthalimidine (II)—Preparation of this compound has been reported previously (1). The yield is 47%; mp 150–152°C.

Isoindoline (III)—The procedure of Bornstein and Shields (2) was used to prepare this compound in 43% yield, bp 98°C/10 mm Hg [lit. (bp) 120°C/30 mmHg]; ^{1}H-NMR ($CDCl_3$): δ 7.2 [s, 4, ArH_4] and 4.19 ppm [s, 4, $(CH_2)_2$].

Phthalamic Acid (IV)—Utilizing the process of Chapman and Stephen (3) 8.0 g (0.0054 mol) of phthalic anhydride was added to 40 mL of concentrated ammonium hydroxide, and the reaction mixture was stirred for 1 h at room temperature. The water was removed under reduced pressure, and the colorless solid residue was dissolved in 80 mL of water. Concentrated hydrochloric acid was added and the mixture was cooled on ice to afford a precipitate, which was removed by filtration to give 1.2 g (13%) of a colorless solid, mp 149–152°C; IR (KBr): 3180 (N—H), 1675, and 1645 (C=O) cm^{-1}.

Anal.—Calc. for $C_8H_7NO_3$ for C, 72.17; H, 5.30. Found: C, 72.38, H, 5.28.

Glutaramic Acid (XIV)—The synthesis of this compound has been reported previously (4).

Diphenimide (XVI)—Utilizing the procedure of Underwood and Kochmann (5), diphenamic acid (25.0 g, 0.10 mol) was added to a solution containing 30 mL of glacial acetic acid and 37 mL of acetic anhydride; the mixture was then stirred under reflux for 7.5 h. On cooling, the crude product which precipitated was removed by filtration and recrystallized from ethanol to afford 10.0 g (43%) of a colorless solid, mp 217–219°C.

Anal.—Calc. for $C_{14}H_9NO_2$: C, 75.33; H, 4.06; N, 6.27. Found: 75.53; H, 4.18; N, 6.28.

3,4,5,6-Dibenzohomopiperidin-2-one (XVIII)—The procedure of Chapman, *et al.* (6) was used to reduce XVI to the lactam. Powdered zinc (5.5 g, 0.085 mol) was stirred for 5 min in a solution of 450 mg of mercuric chloride in 1.5 mL of concentrated hydrochloric acid and 13 mL of water. The supernatant was decanted, and the zinc amalgam was washed with 20 mL of water. Diphenimide (XVI) (1.9 g, 0.0085 mol) was added, followed by 10 mL of water and 15 mL of concentrated hydrochloric acid. The mixture was stirred under reflux for 6 h, and was then filtered hot. The cooled filtrate was extracted with dichloromethane. The organic phase was dried (sodium sulfate) and the solvent evaporated under reduced pressure to afford 2.0 g of crude solid, which was purified by column chromatography[5] to afford 250 mg (13%) of a yellow solid, mp 167–169°C: ^{1}H-NMR ($CDCl_3$): δ 7.04–8.18 [m, 8, $(ArH_4)_2$] and 4.12 ppm (m, 2, CH_2).

Anal.—Calc. for: $C_{14}H_{11}NO$: C, 79.68; H, 4.89; N, 6.22. Found: C, 79.35; H, 5.26; N, 6.49.

3,4,5,6-Dibenzohomopiperidine (XVIII)—The procedure of Uffer and Schletterl (7) for reduction of imides to amines was used. To a 766-mg (0.02-mol) suspension of lithium aluminum hydride in 25 mL of ether was added, in a dropwise manner, a solution of 0.5 g (0.0067 mol) of XVI in 30 mL of dry tetrahydrofuran. The mixture was stirred under reflux for 16 h and the excess hydride was decomposed by dropwise addition of water. The resulting suspension was filtered and the filtrate was extracted with 1.0 M HCl. The aqueous extracts were combined and extracted with ether, made alkaline with sodium hydroxide, and extracted again with ether. The organic extracts were dried (sodium sulfate) and evaporated under reduced pressure to afford 400 mg of a viscous oil which was purified by column chromatography[6] to afford 375 mg (29%) of XVIII as a viscous oil. ^{1}H-NMR ($CDCl_3$): δ 7.42 [m, 8, $(ArH_4)_2$] and 3.64 ppm [s, 4, $(CH_2)_2$].

Anal.—Calc. for $C_{14}H_{13}N$: C, 86.16; H, 6.66; N, 7.17. Found: C, 86.03; H, 6.73; N, 6.97.

Diphenamic Acid (XIX)—Utilizing the procedure of Underwood, *et al.* (5), a 93% yield of product was obtained, mp 189–191°C [lit. (5) mp 187.0–187.5°C].

Adipamic Acid (XXIV)—The synthesis of this compound has been reported previously (4).

RESULTS AND DISCUSSION

Examination of the individual imides, I, VI, XI, XVI, and XXI, for hypolipidemic activity showed that the phthalimide moiety was more active than succinimide, glutarimide, diphenimide, and adipimide (Table I). However, all these imides were more active at 20 mg/kg/d than clofibrate, which is inactive at this dose. Clofibrate requires doses of 150–200 mg/kg to observe a 15% reduction of serum cholesterol levels and a 25% reduction of triglyceride levels. Succinimide, for example, reduced serum triglyceride levels 32% and glutarimide reduced the levels 23%.

Examination of derivatives where the carbonyl groups were reduced demonstrated mixed results. In the phthalimide series, reduced compounds were

less active than I in both the cholesterol and triglyceride screens; interestingly, the completely reduced compound isoindoline (III) was more active than the partially reduced phthalimidine (II) in both screens. In the succinimide series, the reduced compounds VII and VIII demonstrated less hypotriglyceridemic activity; the partially reduced compound 2-pyrolidinone (VII) demonstrated less hypocholesterolemic activity, but the totally reduced compound, pyrrolidine (VIII) was more active than succinimide in the cholesterol screen, causing 31% reduction. In the glutarimide series, the partially reduced compound, valerolactam (XII), demonstrated approximately the same activity in the cholesterol screen as glutarimide, but it demonstrated less hypotriglyceridemic activity than glutarimide. The fully reduced compound, piperidine (XIII) was more effective in both screens, with a marked reduction, 66%, of serum triglyceride levels. The reduction of diphenimide led to improved hypocholesterolemic activity for both derivatives, lowering serum cholesterol levels 51–49% and the fully reduced derivative serum triglyceride levels 48%. In the adipimide series, the reduction of the carbonyl groups led to little change in hypolipidemic effects in either screen.

Examination of the hydrolytic products of the phthalimide series showed that the half amide, phthalamic acid (IV), afforded approximately the same hypocholesterolemic activity as phthalimide; however, IV produced less effect on lowering triglyceride levels than I. The phthalic acid (V) demonstrated less activity in both screens compared to I. The hydrolytic products of the succinimide series (IX and X), the glutarimide series (XIV and XV), and the adipimide series (X, XXIV, and XXV) demonstrated no improvement in hypolipidemic activity over the parent derivatives. In the diphenimide series, the hydrolytic products XIX and XX demonstrated approximately the same hypocholesterolemic activity as XVI.

In conclusion, there did not appear to be a trend among all of the reduced products of imide analogues with respect to improvement or loss of activity in the hypolipidemic screens in mice. In general, the new compounds examined in this study did not extensively improve the hypocholesterolemic and hypotriglyceridemic activity of the lead compound, phthalimide (I). Piperidine produced improved hypotriglyceridemic activity compared to I, and XVII demonstrated improved hypocholesterolemic activity compared to I. The compound which demonstrated the best activity in both screens, other than I, was XVIII, which was slightly more potent than I in the cholesterolemic screen (6%) and slightly less active in the triglyceridemic screen (8%) in mice (Table II). These differences are probably not significant. Thus, I and XVIII are very similar in hypolipidemic activity. A dose response study with XVIII from 10–60 mg/kg showed that a 20 mg/kg/d dose was optimum for reducing serum cholesterol levels, and a 40 mg/kg/d dose lowered serum triglyceride levels to the level observed for I at 20 mg/kg. Further investigation of these derivatives is warranted since they are more active than commercially available agents, *e.g.*, clofibrate.

Liquid Crystals as a Potential Ointment Vehicle

SVEN WAHLGREN *, ANNA L. LINDSTROM ‡, and STIG E. FRIBERG §x

Received May 2, 1983, from **The National Corporation of Swedish Pharmacies, Stockholm, Sweden*, ‡*Aco Company, Solna, Sweden*, and the §*Chemistry Department, University of Missouri-Rolla, Rolla, MO 65401.* Accepted for publication October 28, 1983.

Abstract □ A lecithin–water lyotropic liquid crystal was used as an ointment vehicle for a hydrocortisone formulation. The hydrocortisone was soluble in the liquid crystalline phase up to 5% by weight. The diffusion coefficient determined for the hydrocortisone in the liquid crystalline phase was 5.5×10^{-9} $cm \cdot s^{-1}$, which is four magnitudes higher than the corresponding value for skin.

Keyphrases □ Ointments—vehicles, liquid crystals, lecithin–water □ Lecithin—liquid crystals as potential ointment vehicle □ Hydrocortisone—lecithin–water liquid crystals as potential ointment vehicle

The total therapeutic effect of percutaneous preparations depends not only on the action of the drug itself, but also on other factors related to the structure of the vehicle (1, 2). These latter factors may be divided into two main groups.

The first group contains vehicle–barrier interactions, mostly involving changes in the structure of the stratum corneum caused by the vehicle. These interactions may be evaluated *in toto* by use of standardized tests such as the blanching test (3, 4). Stratum corneum structural changes may facilitate or retard the diffusion of the active substance through this layer, as found for the absorption of solvents through skin (5). It has been claimed that some substances enhance penetration of pharmacological agents when topically applied (6).

The second group includes vehicle–drug interactions. Of these, the capacity of the structure to dissolve (solubilize) the active substance, the related chemical potential difference of the drug in the vehicle and in the stratum corneum, and the diffusion rate of the drug through the vehicle are the most important (7). The vehicle is usually a liquid that is immobilized by the presence of polymers or solid particles (1). The factors mentioned above are, therefore, related to the properties of the liquid phase; the immobilization of the bulk has little importance for the drug diffusion.

vehicles in a systematic manner have not been utilized in preparations so far, in spite of the interesting solubility properties of these structures (8). This report describes the properties of a lamellar liquid crystal for use as the basic vehicle for an ointment preparation.

The preparation appears to have a series of advantages. It is thermodynamically stable, the solubility in hydrocortisone is considerably higher than in a liquid, and the diffusion of the active substance is higher than is the case for a suspension of solid hydrocortisone, the common preparation form.

EXPERIMENTAL SECTION

Materials—Micronized hydrocortisone[1], and a soy lecithin[2] with 95% phosphatidylcholine were obtained commercially. The purity was checked by TLC. The water was twice distilled.

Preparation—The liquid crystals were prepared by the general technique introduced by Loomis *et al.* (9). The hydrocortisone was dissolved to 1.5% by weight in absolute alcohol, and the lecithin was dissolved to 10% in chloroform. Different volumes of the two solutions to give required hydrocortisone–lecithin ratios were mixed, and the solvent was evaporated at ambient temperature and reduced pressure. The range of volumes were 1–1.95 to give 5% by weight of hydrocortisone in the liquid crystal. Water in a 3:7 weight ratio was added to the hydrocortisone–lecithin mixture and homogenized by a combination of heating to 50°C and vibrational stirring.

The maximum solubility of hydrocortisone was directly detected by visual observation in a microscope with polarized light against the liquid crystalline background. A series of samples with a different percentage of hydrocortisone were examined, and the solubility limit was determined to be the highest hydrocortisone concentration at which no crystals could be observed. The hydrocortisone crystals are a conspicuous feature and easily detected. The presence of crystals was verified from their X-ray diffraction patterns with a camera[3].

Structure Determinations—The liquid crystalline structure was identified from its optical pattern in polarized light, and the spacing ratios in the low-angle X-ray diffraction pattern were obtained with a camera[4].

Diffusion Coefficient—The diffusion rate was determined in the following manner. A glass cylinder (23 mm i.d.) was filled with liquid crystal-containing hydrocortisone. An identical cylinder with the liquid crystal without hydrocortisone was placed on top of the first one with the free surfaces in complete contact. The cylinders were dismantled at different times, and the liquid crystal was pressed from the cylinders, scraped off, and weighed to enable exact calculations of the thickness of removed layers. The cortisone concentration was determined photometrically according to Pharm. Nord. (see *Appendix*).

[3] Debye-Scherrer; Seifert & Co., Hamburg, Federal Republic of Germany.
[4] Kiessig; Seifert & Co.

RESULTS

Solubility of Cortisone—The maximum solubility of hydrocortisone in the liquid crystal with 70% lecithin–30% water was 5.0% by weight. This meant a molecular ratio of 1:6 for hydrocortisone–lecithin.

Low-Angle Diffraction—The repeat fraction distance showed a 1:2 spacing ratio, confirming the optical patterns which indicated a lamellar structure. The interlayer spacing for the sample without hydrocortisone was calculated to be 5.3 nm, which is in good agreement with previously reported values (10). A sample with 3% hydrocortisone gave exactly the same interlayer spacing.

Diffusion Rate—The concentration of hydrocortisone *versus* the distance at 96 and 192 h is shown in Fig. 1. The curves show excellent symmetry across the separating surface, which is marked as distance zero on the diagram.

Calculation of Diffusion Coefficient—The second equation of Fick states that:

$$\frac{\partial C}{\partial t} = D\frac{\partial^2 C}{dx^2} \qquad \text{(Eq. 1)}$$

where C is the concentration of diffusing substance, t is time, D is the diffusion coefficient, which is assumed to be constant, and x is the distance along the diffusion axis. From this relation, an explicit expression can be given for the relation between concentration, time, and coordinate for the system in question:

$$C = \frac{C_0^1}{2}[1 - \psi(x/2\sqrt{Dt})] \qquad \text{(Eq. 2)}$$

where $\psi(x/2\sqrt{Dt})$ is the probability integral. The diffusion coefficient is obtained by:

$$D = \frac{x^2}{4t}\left[\frac{1}{\psi^*\left(1 - \frac{2C}{C_0^1}\right)}\right]^2 \qquad \text{(Eq. 3)}$$

where $\psi^*(1 - 2C/C_0^1)$ is the inverse function of the probability integral.

The calculations were made by using the values shown in Fig. 1. The parameter $1 - 2C/C_0^1$ was calculated for a series of points along the curves, and numerical integration was used to obtain $\psi^*(1 - 2C/C_0^1)$. The values obtained gave an average of $D = 5.0 \times 10^{-9} \pm 0.1 \times 10^{-9}$ cm·s^{-1} with a 95% confidence interval.

DISCUSSION

The results of this study show two features of importance for the use of a liquid crystal as an ointment vehicle for percutaneous hydrocortisone preparations. The first feature is the high solubility of hydrocortisone in the lamellar liquid crystalline phase. The value is about four times greater than the corresponding solubility of hydrocortisone in the commonly used ethylene glycol. The reason for this high solubility is not the subject of this report, but the qualitative information may be useful for other applications. According to Israelachvili *et al.* (11), the free energy of a planar layer in a liquid crystal may not be the lowest energy level of an amphiphile–water system. A vesicle with a certain radius may be a more stable configuration for a certain volume of the hydrocarbon chains and a certain cross-sectional area of the polar group. The ratio between the two free energies is $(1 - \alpha)$, in which α depends on the factors mentioned above.

This condition means that the addition of a solute to the structure may in some cases lower the structure-dependent part of the free energy and hence give a higher solubility than can be achieved in an isotropic liquid with a similar chemical composition.

The second feature of importance is the large value of the diffusion coefficient. Its value is distinctly in excess of the one determined for passage through skin. This fact implies a full benefit of the high concentration in the liquid crystal during percutaneous treatment with hydrocortisone. The barrier giving rise to slow release in the commonly used dispersion does not exist in a liquid crystal vehicle. This high diffusion coefficient is related to the location of the hydrocortisone in the structure of the lamellar liquid crystal, and a discussion of the site of the hydrocortisone molecules may be of interest.

The low-angle X-ray diffraction studies showed identical values for the liquid crystal with and without hydrocortisone. This indicates that the hydrocortisone molecules are located between the lecithin molecules in the liquid crystalline structure. A location between the layers would have given a proportional increase of the interlayer spacing. A location between the molecules would facilitate the diffusion of the hydrocortisone molecules.

Such a location and the structure of hydrocortisone make a comparison meaningful with the lecithin–cholesterol–water system (12), which has been

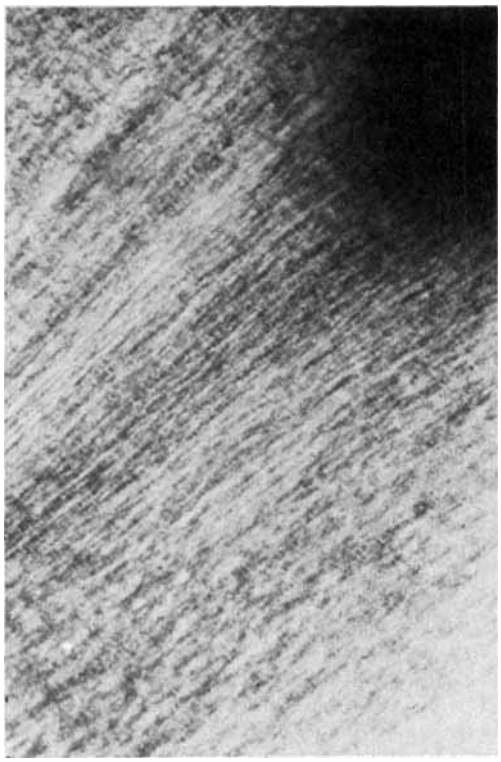

Figure 2—*The optical pattern in polarized light typical of a lamellar structure.*

carefully investigated with regard to its importance for atherosclerotic lesions (13). The influence on the chain order by the presence of cholesterol has been evaluated by McIntosh (14) for the gel state. In all cases the cholesterol molecule is located between the lecithin molecules, and its influence on the interlayer spacing is ascribed to change in tilt and/or order of the hydrocarbon chains. It appears reasonable to assume that the location of the hydrocortisone molecule is between the lecithin molecules and that its diffusion mainly takes place within the constraints of the hydrophobic parts of the lamellar structure.

Diffusion coefficients for the lecithin molecules in liquid crystals with cholesterol have recently been determined by pulsed-spin echo NMR (15). The presence of cholesterol up to 33 mol % counted on lecithin increased the diffusion coefficient for the lecithin by 33%. The amounts of hydrocortisone present in the liquid crystal investigated were less than half the value in the case of cholesterol, and it appears that the presence of hydrocortisone has a relatively minor influence on the diffusion conditions.

The value found for the diffusion coefficient of hydrocortisone was ~10 times less than the one determined previously for lecithin (15) in a lamellar liquid crystal. Two factors contribute to the difference. The values found for lecithin are for the local diffusion parallel to the layers. The values reported for hydrocortisone are bulk volumes for a body of the liquid crystal in which layers have orientations varying in all directions.

A completely statistical distribution of diffusion directions in space would reduce the diffusion coefficient. By assuming equal distribution in all directions and neglecting diffusing perpendicular to the layer plane, the ratio between diffusion as measured by NMR (D_{NMR}) and the total diffusion coefficient measured in this investigation (D_{tot}) would be the average over all angles:

$$D_{tot}/D_{NMR} = \frac{2}{\pi}\int_0^{\pi/2} \sin\theta d\theta = 2/\pi \qquad \text{(Eq. 4)}$$

The ratio between measured values is obviously larger than this, and additional factors must be found to explain the difference.

One such factor originates from the dislocation pattern in a lamellar phase (16). The dislocations are mainly of the focal-conical type or other closed figures. Any part of the total space in the sample in which the layers form a closed figure adds to the total diffusion only to an insignificant amount. A superficial observation of a typical dislocation pattern of a lamellar liquid crystal in this concentration range (Fig. 2) does not rule out a considerable part of the structure consisting of closed figures. The overall diffusion coefficient found in this manner appears to be of reasonable magnitude for a system in which the hydrocortisone molecules are located between the lecithin molecules that diffuse in the hydrophobic layers only. The diffusion coefficient for hydrocortisone in a lamellar liquid crystal was considerably higher than the one for passage through skin; this is a factor of importance for some topical dosage forms.

APPENDIX

Reagents—The following reagents were used for hydrocortisone analysis: absolute ethanol; concentrated acetic acid; a 10% solution of tetramethyl ammonium hydroxide (TMAH)[5], which was kept refrigerated in the dark; 1% TMAH by dilution of 10% TMAH with 9 parts ethanol; 2,3,5-triphenyl tetrazolium chloride (TPTC)[6], which was kept in the refrigerator and dark; 0.5% of TPTC in ethanol, which was prepared immediately before use and protected against light; hydrocortisone standard (50 mg of hydrocortisone standard was dissolved in 100 ml of ethanol; 10.00 mL of this solution was diluted to 100.00 mL with ethanol).

Procedure—Ointment (0.2500 g) was weighed in a 50-mL flask. Ethanol (40 mL) was added, and the mixture was heated to boiling on a water bath with careful stirring. The flask was removed from the water bath and shaken vigorously.

After cooling to room temperature, alcohol was added to 50 mL and the solution was filtered; 5 mL of filtrate and 13 mL of ethanol were added to a 25-mL flask with 2.0 mL of 1% TMAH, and after careful shaking with 2.0 mL of TPTC, 0.5% TPTC was carefully added.

The solution was stored in the dark for 60 min and after 0.05 mL of concentrated acetic acid and ethanol to 25 mL were added, the extinction was determined at 485 nm in a 1-cm cell. As the reference solution was used, 18 mL of ethanol was treated analogously. Calibration was made by using an identical procedure on 5 mL of the hydrocortisone standard and 13 mL of ethanol.

Determination of Ibuprofen in Capillary and Venous Plasma by High-Performance Liquid Chromatography with Ultraviolet Detection

K. S. ALBERT*[x], A. RAABE[‡], M. GARRY[‡], E. J. ANTAL*, and W. R. GILLESPIE*

Received May 9, 1983, from the *The Upjohn Company, Kalamazoo, MI 49001 and [‡]Hazleton Laboratories America, Inc., Madison, Wis. Accepted for publication October 21, 1983.

Abstract □ A high-performance liquid chromatographic (HPLC) method is described which determines ibuprofen in human capillary or venous plasma. Ibuprofen plus the internal standard, flurbiprofen, were extracted from acidified plasma with pentane–ether, back-extracted into base, and then extracted into the pentane–ether solution after acidification of the aqueous phase. A reverse-phase octadecylsilane column with acetonitrile–water–phosphoric acid as mobile phase and UV detection provided a quantifiable peak for 1 μg/mL of ibuprofen in 0.1 mL of plasma. Capillary and venous plasma level curves were virtually superimposable after administration of 400 mg of ibuprofen to four normal volunteers. No ibuprofen was detected in the saliva of the subjects.

Keyphrases □ Ibuprofen—HPLC, small volumes, human plasma and saliva □ Anti-inflammatory agents—ibuprofen, HPLC, capillary and venous plasma, saliva, humans

Ibuprofen, a nonsteroidal phenylpropionic acid derivative possessing potent anti-inflammatory, antipyretic, and analgesic properties (1–3), is used extensively to treat adult rheumatoid arthritis (4–6). In addition, the drug has been shown to be an effective pediatric antipyretic (7). A variety of GC (8–13) and high-performance liquid chromatographic (HPLC) (14–16) methods suitable for measuring ibuprofen in plasma or serum have been reported. With the exception of the electron-capture GC procedure (8), which detects ≥1 μg/mL in 0.1 mL of sample, all methods require >0.5 mL of plasma or serum which limits their use in juvenile or pediatric populations and in multiple-dose studies requiring small sample volumes. The electron-capture procedure (8) is tedious because it involves a TLC step prior to derivatization.

We describe a rapid, specific, and sensitive HPLC method with UV detection for measuring ≥1 μg/mL of ibuprofen in 0.1 mL of plasma or serum. Application of this method to human capillary venous plasma and to saliva is described.

EXPERIMENTAL SECTION

Instrumentation—The high-pressure liquid chromatograph[1] was equipped with a variable-wavelength UV detector[2], an octadecylsilane column[3] (15 cm × 4.6 mm), an automatic injector[4], and a recorder[5]. The flow rate was maintained at 1.5 mL/min (1250 psi) at ambient temperature. The UV detector was set at 195 nm with an attenuation of 0.2 AUFS. The mobile phase was acetonitrile–water–phosphoric acid (550:450:0.5), filtered through a membrane[6] and deaerated before use.

Chemicals and Reagents—Reagents were analytical grade or better. Acetonitrile was distilled in glass[7]. Anhydrous ether was monitored daily for peroxide formation. Stock solutions of ibuprofen[8] (1 mg/mL) and flurbiprofen[8] (1 mg/mL) were prepared in acetonitrile. Appropriate spiking solutions of ibuprofen in acetonitrile and a 10-μg/mL spiking solution of flurbiprofen internal standard in acetonitrile were prepared from the respective stock solutions. The water was deionized[9].

Analytical Method—Standards ranging from 0 to 100 μg/mL were prepared in culture tubes by combining 100 μL each of an appropriate ibuprofen spiking solution, internal standard, and drug-free matrix with 900 μL of deionized water. Samples were prepared by combining 100 μL each of acetonitrile, internal standard, and sample with 900 μL of deionized water. All tubes were vortex-mixed briefly, 0.5 mL of 1 M HCl was added to each, and the tubes were mixed again. The samples were extracted with 10 mL of pentane–ether (80:20, v/v). The upper organic layers were transferred to clean

60.0	60.5	1.43	2.36
100.0	99.5	2.82	2.83

[a] Mean of 14 determinations except for nominal concentration of 60.0 μg/mL, which was the mean of 13 determinations.

culture tubes and extracted with 1.0 mL of 1 M NaOH. After aspirating off the upper organic layer, the pH was adjusted with 2.0 mL of 1 M HCl and the samples were extracted with 10 mL of pentane–ether. The upper organic layer was transferred to clean culture tubes and evaporated to dryness[10]. The residue was dissolved in 0.4 mL of acetonitrile–water (55:45), transferred to vials, and 25 μL was injected onto the HPLC.

Calculations—Calculations were made using baseline-corrected peak height values[11]. Standards were fit to the linear equation, $y = a + bx$, where x corresponds to the concentration of ibuprofen (μg/mL) and y corresponds to the ratio of ibuprofen-to-internal standard peak heights. A split curve was used to calculate the data. The two curves consisted of standards from 1 to 10 μg/mL and from 10 to 100 μg/mL. This was done to prevent negative bias on low-end values caused by variation in the high-end standards. A correlation coefficient was calculated to judge if an adequate curve fit was obtained. Slope and intercept values were also checked to note day-to-day consistencies. Control and sample values were calculated from the appropriate standard curves.

Validation Study—A standard curve with seven data points, a blank plasma control, and two positive plasma controls were assayed in duplicate on each of 3 d. On the fourth day a saliva standard curve, a blank saliva control, and two positive saliva controls were analyzed in duplicate.

To estimate recovery, 100 μL of 10-μg/mL flurbiprofen and ibuprofen spiking solutions were either added to 0.1 mL of plasma and analyzed (matrix standard) or diluted to 0.4 mL with mobile phase and injected directly into the chromatograph (injection standard). Runs were made on four separate occasions and recoveries were determined by comparing matrix-standard peak heights with injection-standard peak heights.

Validation samples were generated by administering ibuprofen to four non-obese volunteers[12] whose average age was 39.5 years (range, 31–47 years) and whose average weight was 69.2 kg (range, 59–77 kg). Each subject fasted

[a] Degrees of freedom. [b] Adjusted for missing day 3, a 60-μg/mL value.

9 h prior to drug administration, then received a 400-mg dose of ibuprofen[13] with 180 mL of water. Food was withheld for an additional 4 h after dosing.

Blood specimens (venous and capillary) were withdrawn at predetermined times over a 10-h period after dosing. Seven milliliters of venous blood was collected at each interval from a forearm vein into evacuated tubes containing sodium heparin[14]. Approximately 0.5 mL of capillary blood was simultaneously collected by fingertip puncture with a sterile blood lancet into heparinized capillary collection tubes[15]. The plasma was harvested and stored frozen until the time of assay.

Saliva samples also were collected at each sampling time and frozen immediately. The production and collection of saliva was facilitated by allowing the subjects to chew on a piece of flexible thermoplastic sheeting[16]. Plasma and saliva samples were assayed using a seven-point standard curve, a blank plasma control, and 5.0- and 50.0-μg/mL positive plasma controls.

RESULTS AND DISCUSSION

A typical chromatogram (Fig. 1) of a plasma extract with and without ibuprofen and the internal standard, flurbiprofen, shows well-resolved sharp peaks free from endogenous interferences. The precision of the assay was assessed by evaluating 14 sets of calibration curve data. Six sets were generated from duplicate curves run on three consecutive days, and eight sets were generated during the analysis of plasma levels of ibuprofen from the four subjects who were administered a 400-mg dose of ibuprofen tablets. The *RSD* ranged from 1.91 to 11.6% (Table I). Excluding the 1-μg/mL concentration, the mean *RSD* was 3.7%. Assay sensitivity was 1 μg/mL for a 0.1-mL sample. The mean correlation coefficient for the low curve was 0.9987, while that for the high curve was 0.9992.

An estimate of within-day *versus* between-day variability was obtained by statistically evaluating the duplicate calibration curve data using a two-way ANOVA with nominal concentrations and days as blocking variables. In this analysis, the mean square associated with days represents between-day variation, while that for the error term represents within-day variation. No significant differences were observed for either the low or high calibration curves (Table II) indicating that between- *versus* within-day variabilities were comparable.

The accuracy of the method was estimated by assaying the two positive plasma controls on 14 separate occasions. The results show that excellent accuracy was obtained at both low and high concentrations; the mean *RSD* was 5.1%. Recoveries were 59.2 and 57.2% for the internal standard and ibuprofen, respectively.

Results from the measurement of ibuprofen in capillary and venous plasma in four normal human volunteers after a single oral 400-mg dose of ibuprofen (tablets) are shown in Fig. 2. Capillary and venous plasma level curves were superimposable. No significant differences between capillary and venous concentrations were observed using the nonparametric Wilcoxon signed-rank test.

In Table III the pharmacokinetic parameters obtained from capillary and venous plasma for the four subjects are compared. Values from the two sampling techniques were virtually identical, demonstrating the utility of capillary sampling for bioavailability/pharmacokinetic studies where small volumes of blood are prerequisites.

Saliva samples were also assayed for ibuprofen; calibration curves, positive controls, and blank (negative) controls were prepared in drug-free saliva rather

A New Method for High-Performance Liquid Chromatographic Determination of Drotaverine in Plasma

J. MEZEI ˣ, S. KÜTTEL, P. SZENTMIKLÓSI, S. MARTON, and I. RÁCZ

Received December 7, 1982, from the *Institute of Pharmacy, Semmelweis University of Medicine, Högyes E. 7., 1092. Budapest, Hungary.* Accepted for publication August 30, 1983.

Abstract □ A sensitive, specific high-performance liquid chromatographic procedure was developed for the determination of plasma drotaverine levels. Basic plasma samples were adjusted to pH 1.5 and extracted with chloroform. HPLC [*n*-heptane–dichloromethane–diethylamine (50:25:2)] on a microporous silica column, with a variable-wavelength UV detector set at 302 nm allowed the measurement of drotaverine at the 50-ng/mL level. The utility of this method for determination of drotaverine in dog and rat plasma was demonstrated.

Keyphrases □ Drotaverine—liquid chromatography, plasma □ Liquid chromatography—determination of plasma drotaverine levels

Drotaverine, [1-(3,4-diethoxybenzylidene)-6,7-diethoxy-1,2,3,4-tetrahydroisoquinoline] (I), an effective spasmolytic drug (1), is also marketed as a salt developed with theophylline-7-acetic acid (2).

There are only a few reports in the literature describing the measurement of drotaverine in plasma. ^{14}C-Labeled drotaverine was used to study the pharmacokinetics of the drug in mice (3) and humans (4). The spectrophotometric method (5) and the procedure suggested for the assay of papaverine (6) was found to be neither specific nor sensitive. This paper describes a modification of the high-performance liquid chromatographic method (HPLC) which has been reported for the measurement of papaverine in plasma (7).

EXPERIMENTAL SECTION

Reagents—Drotaverine[1], papaverine hydrochloride[1], drotaveraldine[1] (II), chloroform[2], hydrochloric acid[3], *n*-heptane[4], diethylamine[3], dichloromethane[3], glacial acetic acid[5], and anhydrous sodium sulfate[3] were used without any further purification.

Apparatus—The liquid chromatograph[6] was fitted with a stopped-flow injector[6], a variable-wavelength UV detector[7] (set at 302 nm), and a microporous silica column[8]. The flow rate of the mobile phase was 1.6 mL/min. Chromatograms were recorded[9] at 1 cm/min chart speed.

Basic plasma samples were adjusted to pH 1.5 and extracted with chloroform. HPLC [*n*-heptane–dichloromethane–diethylamine (50:25:2)] on a microporous silica column, with a variable-wavelength UV detector set at 302 nm allowed the measurement of drotaverine at the 50-ng/mL level. The utility of this method for determination of drotaverine in dog and rat plasma was demonstrated.

Keyphrases □ Drotaverine—liquid chromatography, plasma □ Liquid chromatography—determination of plasma drotaverine levels

Drotaverine, [1-(3,4-diethoxybenzylidene)-6,7-diethoxy-1,2,3,4-tetrahydroisoquinoline] (I), an effective spasmolytic drug (1), is also marketed as a salt developed with theophylline-7-acetic acid (2).

There are only a few reports in the literature describing the measurement of drotaverine in plasma. ^{14}C-Labeled drotaverine was used to study the pharmacokinetics of the drug in mice (3) and humans (4). The spectrophotometric method (5) and the procedure suggested for the assay of papaverine (6) was found to be neither specific nor sensitive. This paper describes a modification of the high-performance liquid chromatographic method (HPLC) which has been reported for the measurement of papaverine in plasma (7).

EXPERIMENTAL SECTION

Reagents—Drotaverine[1], papaverine hydrochloride[1], drotaveraldine[1] (II), chloroform[2], hydrochloric acid[3], *n*-heptane[4], diethylamine[3], dichloromethane[3], glacial acetic acid[5], and anhydrous sodium sulfate[3] were used without any further purification.

Apparatus—The liquid chromatograph[6] was fitted with a stopped-flow injector[6], a variable-wavelength UV detector[7] (set at 302 nm), and a microporous silica column[8]. The flow rate of the mobile phase was 1.6 mL/min. Chromatograms were recorded[9] at 1 cm/min chart speed.

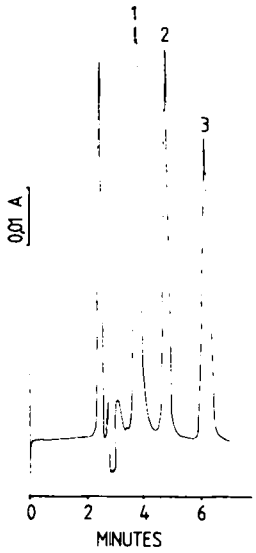

Figure 1—*Chromatograms of a mixed sample of drotaveraldine (0.5 μg), drotaverine (1.0 μg), and papaverine (2.5 μg). Key: (1) drotaveraldine; (2) drotaverine; (3) papaverine.*

A solution containing *n*-heptane–dichloromethane–diethylamine (50:25:2) was filtered[10] and deaerated by refluxing in a water bath. Elution was performed at room temperature. The mobile phase was prepared fresh daily.

Standard Solutions—Solutions of drotaverine hydrochloride in water (25, 50, 100, 150, and 200 μg/mL) were used to spike plasma samples. Papaverine hydrochloride dissolved in chloroform (1000 μg/mL) was used as the internal standard.

Quantitation—Control plasma from rat and dog whole blood was drawn into heparinized tubes, and 10 μL of each standard solution was added to 1.00 mL of the plasma. The spiked plasma samples were adjusted to pH 1.5 using a few drops of 1 M hydrochloric acid. Following the addition of 10.0 mL of chloroform to each tube, the tubes were capped and then shaken on a shaker[11] for 30 min. The mixtures were centrifuged[12] for 10 min, at 4000×*g*. The separated chloroform layers were acidified with 40 μL of glacial acetic acid and then dried with anhydrous sodium sulfate. Eight milliliters of the solution was evaporated to dryness under reduced pressure. Each residue was redissolved in a mixture of 70 μL of chloroform and 10 μL of the internal standard solution. Twenty microliters of the solution was injected onto the column and chromatographed.

Table I—Linearity of the Assay Method[a]

Drotaverine Concentration, μg/mL	Peak Height of Drotaverine, mm	Peak Height of Papaverine, mm
0.25	8.3 ± 0.8	103 ± 2.1
0.50	15.0 ± 1.1	108 ± 4.3
1.00	31.3 ± 3.0	103 ± 4.3
1.50	47.5 ± 3.7	108 ± 5.7
2.00	63.1 ± 5.9	108 ± 2.7

[a] Mean ± *SD*; $n = 8$.

A standard curve was prepared by plotting the ratios of peak heights (drotaverine from the extracted plasma samples–internal standard) *versus* the drotaverine concentrations expressed as micrograms per milliliter of plasma. Plasma drotaverine recovery levels were determined by comparing the peak heights of the spiked plasma standards with those of unextracted drotaverine standards (taking into consideration that only 8.0 mL of the original 10.0 mL of chloroform was analyzed).

Sample Preparation and Assay—Drotaverine was orally administered as an aqueous solution of 1.2% to Long Evans rats (200 g) through a gastric tube in doses of 60 mg/kg, and to beagle dogs (10–11 kg) in capsules containing 300 mg of the active substance. Before drug administration, the animals had been fasted overnight with water *ad libitum*. Blood samples were taken prior to dosing and at specified times (0.5, 1, 2, 4, 6, 8, and 24 h) postdose. In the case of rats, three animals at each sampling time were exsanguinated by aortal puncture, and the blood samples were collected separately. For the three beagle dogs, blood samples (2.0 mL) were withdrawn at different time intervals through the saphenous vein. The samples were collected in heparinized, evacuated tubes and centrifuged. One milliliter of each plasma sample was assayed immediately, using the procedure described above for drotaverine-spiked plasma.

Having measured the peak-heights, the ratios (extracted drug–internal standard) were calculated, and the plasma drotaverine levels were read from the calibration curve.

RESULTS AND DISCUSSION

Under the described chromatographic conditions, drotaverine was eluted from the column in 4.7 min and it could be separated from its metabolite, drotaveraldine, which appeared at 3.6 min. The retention time of the internal standard was 6 min (Fig. 1).

After 20–30 samples, the retention time of drotaverine changed gradually to ~4.3 min, due to the decreased retention capacity of the column. To remove impurities from the plasma, the column was washed with methanol[3]; thereafter, the retention capacity was controlled by injecting standard solutions of drotaverine and papaverine onto the column.

Representative chromatograms of blank and spiked plasma extracts and

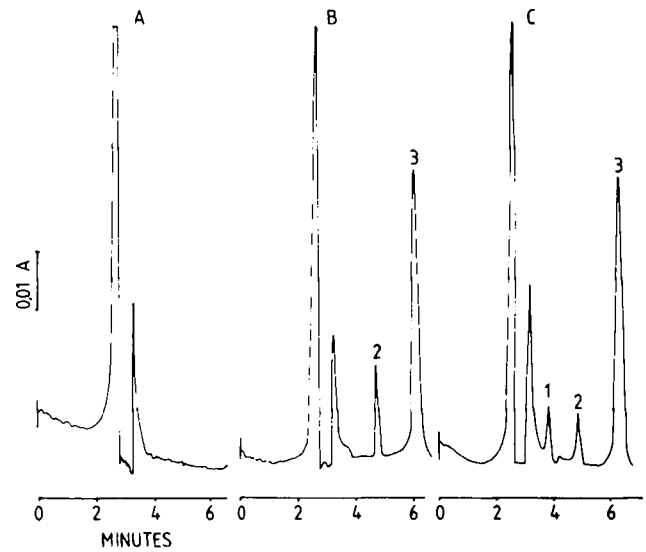

Figure 3—*Chromatograms of extracts from a plasma blank (A), spiked plasma (1.0 μg/mL) (B), and plasma from a dog administered drotaverine (C). Key: (1) drotaveraldine; (2) drotaverine; (3) papaverine, internal standard.*

Table II—Recoveries of Drotaverine from Spiked Rat and Dog Plasma [a]

Drotaverine Concentration, μg/mL	Recovery from Rat Plasma, %	Recovery from Dog Plasma, %
0.25	83.2 ± 4.7	82.8 ± 6.8
0.50	77.0 ± 9.1	84.4 ± 5.2
1.00	82.3 ± 6.5	85.8 ± 8.8
1.50	89.8 ± 6.0	87.9 ± 4.9
2.00	94.3 ± 7.3	88.7 ± 7.1

[a] Mean ± *SD*; $n = 8$.

plasma extracts from a rat given 60 mg/kg of drotaverine, and from a dog given 30 mg/kg of drotaverine, are shown in Figs. 2 and 3.

The drotaverine ultraviolet spectrum has maxima at 242, 302, and 350 nm wavelengths. A variable-wavelength UV detector set at 302 nm was used to eliminate background contributions to the drotaverine peak at 242 nm in blank plasma extracts. The intensity of the maximum at 350 nm is lower than that of the maximum at 302 nm. The detection limit was found to be 50 ng of drotaverine/mL of plasma.

Data in Table I show the linearity of the assay method. A linear regression analysis was performed for the calibration curve prepared from drotaverine-spiked plasma samples. It resulted in the equation $y = 0.2912x + 0.0038$, where y is the ratio of the peak height of the drug divided by the peak height of the internal standard, and x is the drug concentration in the plasma. As evidenced by the experimental data, peak heights were proportional to the drotaverine concentrations for the range examined (from 0.25 to 2 μg of drotaverine/mL of plasma).

Recoveries of drotaverine were nearly quantitative at plasma concentrations of 0.25–2.0 μg/mL, with average recoveries ranging from 77.0 to 94.3% and coefficients of variation ranging from 4.7 to 9.1% (Table II).

Influence of α- and β-Adrenergic Antagonists on Dopamine-Induced Responses in the Isolated Heart of *Mercenaria mercenaria*

DAVID E. MANN, JR. [x] **and RONALD F. GAUTIERI**

Received December 6, 1982, from the *Department of Pharmacology, School of Pharmacy, Temple University, Philadelphia, PA 19140* Accepted for publication September 8, 1983.

Abstract □ Agents with predominantly adrenergic antagonistic properties (the α-blockers, phentolamine and tolazoline, and the β-blocker propranolol), and those with suspected α-blocking capabilities [hydralazine and 3,3′-(4,4′-biphenylene)bis(2,5-diphenyl-2*H*-tetrazolium chloride) (neotetrazolium chloride); I] were added individually to a bath containing an isolated *Mercenaria mercenaria* heart. Two and one-half minutes later, dopamine was added to the bath as the second drug and cardiac responses were noted. Pretreatment with saline controls, followed by dopamine 2.5 min later, produced results that were identical with those which occurred after the administration of dopamine alone, *i.e.*, marked stimulation and cardiac arrest. Pretreatment with phentolamine and I were the only procedures that prevented dopamine-induced cardiac arrest. Phentolamine, tolazoline, and hydralazine generally produced positive inotropic responses when initially added to the bath, whereas propranolol mimicked the effects caused by the addition of dopamine alone or after saline pretreatment. The *M. mercenaria* heart appears to possess an adrenergic receptor of an α-configuration.

Keyphrases □ α- and β-Adrenergic antagonists—dopamine-induced response, heart of *Mercenaria mercenaria* □ Dopamine—α- and β-adrenergic antagonists, effect on heart of *M. mercenaria*, pretreatment controls.

A number of studies have suggested the presence of an adrenergic receptor in the smooth muscle of the heart of *Mercenaria mercenaria*, the hard-shelled clam or quahog. Welsh and Taub (1) administered various drugs to the isolated heart of *M. mercenaria* and noted that epinephrine evoked negative inotropic responses and tachyphylaxis. Fujita and Mann (2) reported similar responses with norepinephrine under comparable experimental conditions. Ciuchta and Mann (3) examined the relative effectiveness of ephedrine isomers in preventing the onset of norepinephrine-induced tachyphylaxis in the *M. mercenaria* heart and found that the *l*-isomer was the most potent, the racemate less potent, and the *d*-isomer least potent. Orzechowski and Mann (4) performed a similar experiment with amphetamine isomers and observed that norepinephrine-induced tachyphylaxis was blocked most effectively by the *d*-isomer, while the *d,l*- and *l*-isomers were equal but less potent. When higher doses of amphetamine isomers were given, norepinephrine elicited positive inotropic responses, suggesting that these agents act upon common receptor sites. It was further speculated that amphetamine, like ephedrine, may block cardiac inhibitory sites on which norepinephrine acts, thus allowing ephedrine to cause stimulation.

Dopamine, which is present in *M. mercenaria* nervous tissue (5), appears to activate excitatory receptors in the clam heart in contrast to epinephrine and norepinephrine, which affect inhibitory receptors. Tachyphylaxis also occurs in the *M. mercenaria* heart after successive, equal doses of dopamine[1].

The purpose of this study was twofold:

1. To determine whether the α-blockers (tolazoline, phentolamine, and hydralazine) and the β-blocker (propranolol) could prevent the excitatory effects of dopamine on the isolated *M. mercenaria* heart, thereby elucidating the nature of its adrenergic receptor;

2. To ascertain whether the hypotensive agent, 3,3′(4,4′-biphenylene)bis(2,5-diphenyl-2*H*-tetrazolium chloride) (neotetrazolium chloride; I), which has both adrenergic α-blocking and gangliolytic actions (6–8), could antagonize

the effects of dopamine on the *M. mercenaria* heart. Positive results obtained with I and the other adrenergic α-blockers would presume an adrenergic α-receptor as the site upon which dopamine acts, because the *M. mercenaria* heart is devoid of autonomic ganglia.

EXPERIMENTAL SECTION

Animals—*M. mercenaria*[2] were maintained in a 378.4-L aquarium filled with artificial sea water[3] for at least 2 d prior to use.

Apparatus—The heart was isolated according to the methods of Welsh and Taub (1) and Wait (9). After cracking the shell with a hammer, the heart was removed and attached to a hook embedded in a plastic rod. The rod was then lowered into an aerated[4] glass bathing chamber containing 40 mL of sea water. A thread extending from the apex of the ventricle to a detecting head[5] activated a transducer[6] and physiograph[7] to record contractility.

Materials—When contractions were normal, a glass syringe[8] delivered either 0.8 mL of neotetrazolium chloride[9], 0.8 mL of the vehicle control[9], 2.5 mL of the test drug, or 2.5 mL of a saline control[10], followed 2.5 min later by the addition, using a second syringe[8], of 4 mg (0.1 mL) of dopamine hydrochloride[11]. The test drugs were prepared in the following concentrations: phentolamine mesylate[12], tolazoline hydrochloride[13], and propranolol hydrochloride[14] at 0.6%; hydralazine hydrochloride[15] and I[9] at 1.0%.

Pretreatment Dose Regimen—A 15-mg dose of each agent was administered 2.5 min prior to dopamine challenge (except for I, the dose of which was 8 mg). A 2.5-mL aliquot of the saline control was added to the bath; this volume was equivalent to that of each test drug, except for I. Because the latter compound utilized a vehicle control (5% ethyl alcohol and 20% propylene glycol in distilled water) and a lower dosage than the rest, it has a control volume of only 0.8 mL.

RESULTS AND DISCUSSION

The typical response elicited by dopamine (4 mg) on the isolated *M. mercenaria* heart bathed in 40 mL of artificial sea water is shown in Fig. 1. The heart stopped contracting at once when dopamine was added to the bath, but recovered its contractility within 6 min. When I (8 mg) was added to the bath, 2.5 min before dopamine challenge, it not only prevented cardiac arrest due to dopamine, but also produced a negative inotropic response that was mimicked by the subsequent addition of dopamine (Fig. 2). By contrast, preadministration of the vehicle control for I, in a volume comparable to that of the test drug (0.8 mL), failed to prevent cardiac arrest caused by dopamine; however, the recovery time for the return of contractility was shortened over that induced by dopamine administration alone (Fig. 3).

The average percent of cardiac inhibition attributed to the test drugs and to dopamine challenge is presented in Table I. The number of animals used in each group ranged from 6 to 15. The percent inhibition was calculated by measuring the amplitude of the peak at the moment of test drug challenge and dopamine challenge, and the lowest amplitude within 1 min after administering each agent; *i.e.*, the response recorded in Fig. 1 after the addition to the bath of dopamine alone represents 100% inhibition.

Although each agent, except the solvent control, caused some degree of cardiac inhibition within 1 min of its administration (Table I), propranolol produced the most dramatic and consistent inhibitory responses. Immediately after the addition of the β-blocker to the bath, the heart lost contractility and became spastic, an excitatory response that was identical with that observed after the administration of dopamine alone (Fig. 1). Two and one-half minutes later, the addition of dopamine produced an even greater response.

Initial administrations of phentolamine, tolazoline, and hydralazine yielded consistently positive inotropic responses during the 2.5-min period prior to the addition of dopamine, whereas I caused variable effects (*i.e.*, positive, negative, or no alteration of the inotropic response) prior to the addition of dopamine. Phentolamine mesylate, an α-adrenergic blocker, and I, an experimental hypotensive agent with presumed α-adrenergic blocking activity, appear to act on an adrenergic receptor of an α-configuration within the *M. mercenaria* heart to block the stimulatory effects of dopamine. Of the two compounds, I is the more potent in this respect.

Identification and Determination of the *S*-Methyl Metabolite of Captopril in Human Plasma by Selected-Ion Monitoring Gas Chromatography–Mass Spectrometry

ALLEN I. COHEN *x, EUGENE IVASHKIV *, TERRENCE McCORMICK *, and DORIS N. McKINSTRY ‡

Received April 14, 1983, from the **Department of Analytical Research, The Squibb Institute for Medical Research, New Brunswick, NJ 08903* and ‡*Department of Clinical Pharmacology, The Squibb Institute for Medical Research, Princeton, NJ 08540.* Accepted for publication November 29, 1983.

Abstract □ The *S*-methyl metabolite of captopril was identified and determined in human plasma by positive chemical ionization selected-ion monitoring gas chromatography–mass spectrometry. After oral administration of 100 mg of captopril to healthy subjects, the maximum plasma level was 60–114 ng/mL. These data for the *S*-methyl metabolite of captopril were correlated to total and unchanged captopril levels.

Keyphrases □ Captopril—identification and determination of the *S*-methyl metabolite in human plasma, gas chromatography-selected-ion monitoring mass spectrometry □ Gas chromatography-selected-ion monitoring mass sepectrometry—determination of the *S*-methyl metabolite of captopril in human plasma after oral administration

Captopril (1-[(2*S*)-3-mercapto-2-methylpropronyl]-L-proline; I) (1, 2) has received considerable attention as an orally active angiotensin-converting inhibitor (3) that is effective in lowering arterial blood pressure (4). The absolute bioavailability and pharmacokinetics of [^{14}C]captopril given orally and intravenously have been reported previously (5). Analysis of the kinetic data suggested that captopril is extensively partitioned into tissue. The interconversion of protein-bound captopril with non-protein-bound mixed disulfides has been suggested as a biotransformation pathway that may extend the pharmacological effects of captopril (5, 6).

Gas chromatography–mass spectrometry (GC–MS) selected-ion monitoring (SIM) methods have been reported for the determination of unchanged captopril in whole blood (7) and total captopril in plasma (8). Total captopril includes unchanged drug, the disulfide dimer of the parent drug, and mixed disulfides with endogenous thiol-containing compounds, *e.g.*, glutathione and cysteine. Recently, the *S*-methyl metabolite of captopril (II) has been identified as a urinary metabolite in humans (9) and rats (6). A GC–MS SIM method was developed to measure the plasma level of the *S*-methyl metabolite (II) after oral administration of captopril. The plasma levels of the metabolite II from samples collected from healthy human subjects after the administration of a single 100-mg tablet of captopril were compared with the free captopril blood levels and total captopril plasma levels determined as IV by GC–MS SIM methods previously reported (7, 8).

RESULTS AND DISCUSSION

The typical response elicited by dopamine (4 mg) on the isolated *M. mercenaria* heart bathed in 40 mL of artificial sea water is shown in Fig. 1. The heart stopped contracting at once when dopamine was added to the bath, but recovered its contractility within 6 min. When I (8 mg) was added to the bath, 2.5 min before dopamine challenge, it not only prevented cardiac arrest due to dopamine, but also produced a negative inotropic response that was mimicked by the subsequent addition of dopamine (Fig. 2). By contrast, preadministration of the vehicle control for I, in a volume comparable to that of the test drug (0.8 mL), failed to prevent cardiac arrest caused by dopamine; however, the recovery time for the return of contractility was shortened over that induced by dopamine administration alone (Fig. 3).

The average percent of cardiac inhibition attributed to the test drugs and to dopamine challenge is presented in Table I. The number of animals used in each group ranged from 6 to 15. The percent inhibition was calculated by measuring the amplitude of the peak at the moment of test drug challenge and dopamine challenge, and the lowest amplitude within 1 min after administering each agent; *i.e.*, the response recorded in Fig. 1 after the addition to the bath of dopamine alone represents 100% inhibition.

Although each agent, except the solvent control, caused some degree of cardiac inhibition within 1 min of its administration (Table I), propranolol produced the most dramatic and consistent inhibitory responses. Immediately after the addition of the β-blocker to the bath, the heart lost contractility and became spastic, an excitatory response that was identical with that observed after the administration of dopamine alone (Fig. 1). Two and one-half minutes later, the addition of dopamine produced an even greater response.

Initial administrations of phentolamine, tolazoline, and hydralazine yielded consistently positive inotropic responses during the 2.5-min period prior to the addition of dopamine, whereas I caused variable effects (*i.e.*, positive, negative, or no alteration of the inotropic response) prior to the addition of dopamine. Phentolamine mesylate, an α-adrenergic blocker, and I, an experimental hypotensive agent with presumed α-adrenergic blocking activity, appear to act on an adrenergic receptor of an α-configuration within the *M. mercenaria* heart to block the stimulatory effects of dopamine. Of the two compounds, I is the more potent in this respect.

EXPERIMENTAL SECTION

Apparatus—A mass spectrometer[1] with a data acquisition system and a GC and interface (7) as well as other equipment and apparatus have been described previously (7, 8).

Reagents—The *S*-methyl metabolite II and its 4-fluoro analogue (III) were pharmaceutical grade materials[2] and were used without additional purification. Redistilled petroleum ether (bp 30–60°C) was first washed with small portions of concentrated sulfuric acid until the discarded sulfuric acid was colorless and then with distilled water prior to distillation. Ammonium hydroxide (3%) was prepared by diluting ammonium hydroxide with distilled water. All other reagents have been previously described; this includes the columns, ethyl acetate, phosphoric acid, methanolic HCl kits, and hydrochloric acid (10).

Extraction of Plasma Samples—The internal reference standard (II) (500 ng) was added to 5 mL of plasma[3] and acidified with 2 mL of 6 M phosphoric acid. The sample was transferred to a 1-g preactivated XAD-2 column (8) by decantation and subsequent rinsing with 0.1 M hydrochloric acid. The washed, vacuum-dried column was eluted with 25 mL of purified ethyl acetate at a rate of 3 mL/min. To the ethyl acetate eluate, collected in a screw-capped tube, (250 × 150 mm), 10 mL of purified petroleum ether and 2 mL of 3% ammonium hydroxide solution were added. The drugs were extracted by shaking into the alkaline aqueous solution. After separation of the layers, the organic phase was removed by aspiration, and 1 mL of 6 M phosphoric acid and 3 g of sodium chloride were added. The solution was washed twice by shaking with 5 mL of ethyl acetate for 5 min and by centrifuging for 5 min. The retained ethyl acetate portions were combined and evaporated to dryness. Compounds II and III were determined as their respective methyl esters, V and VI, by treating the residue with 0.1 mL of 0.8 M methanolic hydrochloric acid solution in a sealed vial at 60°C for 10 min. The solution was evaporated, and the residue was dried in a vacuum desiccator for 1 h. The sample was reconstituted with 20 μL of acetone (10).

Preparation of Standard Curves—Various amounts (0–200 ng of II/mL and 500 ng of III/mL) were added to 5 mL of plasma. A freshly prepared control sample, containing 200 ng of II and 100 ng of III/mL of plasma, was extracted along with each set of samples. These samples were processed by the general scheme described above.

Instrumental Procedure—The combined GC–MS with data system was operated under the SIM mode. In the electron-impact (EI) mode, the unit was tuned from 69 to 502 Da with 1,1,2,2,3,3,4,4,4-nonafluoro-*N*,*N*-bis(nonafluorobutyl)-1-butanamine at an ionization voltage of 70 eV and an emission of 300 μA. The ion source was controlled at a constant temperature of 200°C. Helium was used as the carrier gas at a flow rate of 30 mL/min. For the chromatography in the EI mode, the column was connected through a single-stage jet separator to remove helium from the effluent. Helium, otherwise diverted, was allowed to flow into the ion source from 0.5 min to the end of the acquisition. In positive chemical ionization GC–MS, methane was used as the GC carrier gas and reagent at a flow rate of 15 mL/min. Under these conditions, the source pressure was ~80 Pa. The respective emission and electron energy were 250 μA and 240 V, optimized for the abundance of the *m/z* 219, 414, and 614 ions of 1,1,2,2,3,3,4,4,4-nonafluoro-*N*,*N*-bis(nonafluorobutyl)-1-butanamine.

In both detection modes, the multiplier and electron voltages were only applied during the data collection period. The separator and transfer lines were kept at 275°C, the ion source was maintained at 250°C, and the injector was kept at 290°C. The silanized glass column (80 cm × 2 mm), packed with 3% OV-101[4], was kept at an isothermal temperature of 190°C for 2.5 min until the analytical components were eluted (~1.5 min) and then temperature programmed to 240°C at a rate of 30°C/min to drive off other components.

About 1–2 μL of solution was evaporated on a GC solids injector. Depending on the mode of ionization, the appropriate ion profiles were obtained by SIM. The procedure for measuring the maximum peak heights and processing the data have been reported previously (7).

RESULTS AND DISCUSSION

Although the extraction procedure for the metabolite II was patterned after the method developed for the extraction of IV (7), there were several significant differences. The isolation was accomplished by direct adsorption of II from acidified plasma samples onto XAD-2. The back-extraction was performed with 3% ammonium hydroxide. The solubility of II in ethyl acetate was suppressed by the addition of petroleum ether, which resulted in better phase separation. The compounds were then quantitatively extracted into ethyl acetate from aqueous solutions saturated with sodium chloride to remove additional potentially interfering components. Because significantly lower *S*-methyl metabolite II levels were expected, 5 mL of plasma was processed, with a total of 500 ng of III added as the internal reference standard. It was not practical to isolate and measure total captopril and II concurrently because of the great disparity in their levels. It was decided to process individual samples for the metabolite II in plasma, unchanged captopril in whole blood treated with *N*-ethylmaleimide at the time of sampling, and total captopril in plasma (7, 8). The *S*-methyl metabolite II may be stored for at least 4 weeks at either 5°C or −20°C in plasma without decomposition (Table I).

Methylation of the proline carboxylic acid group was chosen because it forms a low-molecular-weight derivative suitable for GC–MS. Both EI and chemical ionization (CI) MS were explored as potential methods, but the greatest sensitivity and specificity was obtained by CI with the MH^+ of esters V and VI. Under these conditions, a linear calibration curve was obtained with a slope of 1.5 and an intercept of 0.001, as determined by linear regression analysis. A correlation coefficient of 0.9981 was obtained from the calibration data. With each set of extracts, a freshly extracted control was measured as a validation of the method. The 26 replicate measurements of the 100-ng/mL extracted control samples showed a mean *SD* of 2.25 ng/mL and an absolute difference of 0.6 ng/mL from the added amount (Table II). A difference of 0.4 ng/mL was found for the four 12.5-ng/mL spiked samples. The *m/z* 128–*m/z* 146 ions, although producing intense EI ions, also had significant interferences from the coeluting background components.

The levels of the *S*-methyl metabolite II were low (Table III) relative to both unchanged and total captopril levels for the same subjects (Table IV). For the comparison, the unchanged captopril blood values were multiplied by two to approximate the plasma levels. The parameter *D* is defined as the

[a] Seven subjects. [b] Assumes plasma is one-half the volume of whole blood. [c] Difference $D = T - 2F$ = disulfide metabolites derived from captopril. [d] Taken from the mean values shown in Table III. [e] $R = S/T$. The mean from samples taken at 0.5–12 h was 0.024; (σ/mean) × 100 = 11. [f] Excluded from determination of the means.

difference between the total captopril level and twice the free captopril level as an expression of the disulfide levels. Uniformly, the individual values followed exactly the mean values (Table IV). Whereas the unchanged captopril levels predominate during the first hour, the disulfides derived from captopril were the significant components after that. Levels of the metabolite II followed most closely the total drug concentrations. The mean ratio between the metabolite II and total captopril, R, was 0.024 for samples taken at 0.5–12 h (Table IV). No zero values of metabolite II were observed in any of the samples taken during the first 12 h, and more than half of the samples collected over 24 h had values of ≥1 ng/mL.

In recent reports, various discussions have been concerned with the concept of interconversion of protein-bound drug to "free" captopril (5) and of a subsequent conversion of captopril or its disulfides to the *S*-methyl metabolite by *S*-methyltransferase (6). The role of *S*-methylation, other than as a metabolic pathway, is not well understood. The discussion following a recent presentation highlights this point (9). This analytical method, combined with the previously reported methods for determining unchanged (7) and total (8) captopril, allows profiling to study the role of *S*-methylation in renal function. Future steady-state studies, combined with pulsed deuterated analogue administration, might help in establishing the role of protein-bound captopril in deep compartments *versus* circulating protein-bound blood components.

Relationship of Morphine-Induced Miosis to Plasma Concentration in Normal Subjects

IRA L. FEDDER *, PETER H. VLASSES *, PARVIZ MOJAVERIAN *, MARIO L. ROCCI, JR. ‡, HESCHI H. ROTMENSCH *, BRIAN N. SWANSON *, and ROGER K. FERGUSON *x

Received June 27, 1983, from the *Division of Clinical Pharmacology, Department of Medicine, Jefferson Medical College of Thomas Jefferson University, Philadelphia PA 19107, and the ‡Department of Pharmacy Practice, Philadelphia College of Pharmacy and Science, Philadelphia, PA 19104. Accepted for publication December 6, 1983.

Abstract □ The relationship between morphine plasma concentration and pupil diameter was evaluated 2–10 h following intravenous administration of morphine sulfate (10 mg). Seven healthy male volunteers received 10 mg of morphine intravenously following pretreatment for 4 d with either cimetidine (300 mg po four times a day) or placebo in a single blind, balanced crossover study. Pupil diameters were measured directly from contact prints using calipers and a photographed millimeter scale. Cimetidine pretreatment had no significant effect on pupil size either before or after morphine administration or on morphine pharmacokinetics. The relationship between morphine plasma concentration (2–10 h postdose) and pupil diameter was evaluated from the pooled data from both morphine treatment periods by perpendicular least-squares regression. In each individual, a strong relationship existed between morphine plasma concentrations and pupil diameter ($r = -0.76$ to -0.91; $p < 0.05$). Weaker correlations for both pupil diameter ($r = -0.65$; $p < 0.0001$) and the absolute change in pupil diameter from baseline ($r = 0.72$; $p < 0.0001$) for the grouped data probably reflect intersubject variation in morphine sensitivity. Thus, the miotic response to an intravenous dose of morphine varies in proportion to morphine plasma concentration.

Keyphrases □ Morphine—relationship of morphine-induced miosis and plasma concentration in normal subjects □ Miosis—morphine-induced, relationship to plasma concentration

In the initial 2 h following an intravenous dose of heroin, pupil diameter is directly related to plasma concentration of morphine equivalents in both naive and dependent subjects (1). After oral methadone administration, decreases in pupil diameter appear to follow the same time course as methadone plasma concentration (2). While investigating the effects of oral cimetidine on the disposition of intravenous morphine (3), serial measurements of the extent and duration of morphine-induced miosis were made. In this report are described the relationships observed in individuals between plasma morphine concentrations after an intravenous morphine dose and pupil diameter.

EXPERIMENTAL SECTION

Seven healthy male volunteers (weight, 65–98 kg; age, 20–38 years) participated in a single blind crossover study and were randomly assigned to receive either oral cimetidine (300 mg once every 6 h) or placebo for 4 d. On day four of each treatment period, the volunteers reported for testing after an overnight fast. Each subject received either cimetidine or placebo orally. One hour later, morphine sulfate (10 mg; 8.5 mg of free base) was administered intravenously over 2 min. Plasma was obtained at a series of times postinjection to determine the pharmacokinetics of morphine. Morphine concentrations were determined by radioimmunoassay (4). A 7-d interval separated morphine treatments.

Pupil diameters were measured prior to and at 2, 5, 7, and 10 h after each morphine dose by a photographic technique (5–8). Subjects were placed in a dimly lit room (4 foot candles) and allowed to sit quietly. Black and white photographs of the left eye of each subject were taken with a 35-mm single lens reflex camera[1] with ASA-125 film[2]. The camera was equipped with an electronic flash and a fixed-focus, close-up lens which produced a life size, (*i.e.*, 1:1 magnification) image on the negative. A millimeter scale was photographed under the same magnification. Pupil diameters were measured on the contact prints with calipers and the millimeter scale. A representative example of pupil measurements taken before and after morphine administration is depicted in Fig. 1.

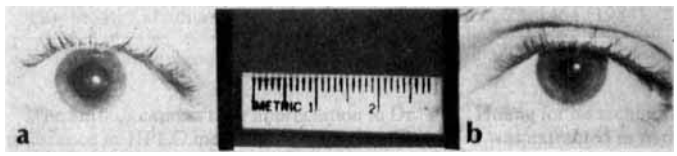

Figure 1—*Pupillary response to intravenously administered morphine sulfate (10 mg) in subject 4. Pupil diameter (5.9 mm) prior to morphine administration (a) is contrasted with pupil diameter 2 h following morphine administration (3.3 mm) (b).*

The relationships within and among individuals between morphine plasma concentration and pupil diameter were evaluated by perpendicular least-squares regression (9). Statistical comparison of pupil diameters as well as the slopes of the regression lines were done by using a paired Student's *t* test (9). All results are expressed as the mean ± *SD*.

RESULTS

Cimetidine pretreatment had no effect on baseline (premorphine) mean pupil diameter (placebo *versus* cimetidine, 6.4 ± 0.7 *versus* 6.3 ± 0.9 mm). A significant correlation existed between morphine plasma concentration and pupil diameter for each treatment period (placebo, $r = -0.69$, $p < 0.0001$; cimetidine, $r = -0.60$, $p < 0.001$). In addition, the mean of the slopes of the regression lines for each individual were not significantly different (placebo = −0.098, cimetidine = −0.110; $p < 0.05$).

Since cimetidine pretreatment appeared to have no effect on morphine pharmacokinetics (3) or on the relationship between morphine plasma concentration and pupil diameter, additional analysis of the combined data was performed. For the combined data, significant correlations were observed between pupil diameter and morphine plasma concentration at corresponding times. A significant correlation existed between the absolute change in pupil diameter from baseline (premorphine) and morphine plasma concentration ($r = 0.72$; $p < 0.0001$). The correlation coefficient for the grouped data (all observations) was −0.65 ($p < 0.0001$), whereas the correlation coefficients for the data from each subject, independent of pretreatment, ranged from −0.76 to −0.91 (Table I). The relationships between pupil diameter (in millimeters) and morphine plasma concentration for the subjects with the highest and lowest correlation coefficients (*i.e.*, subjects 4 and 6, respectively) are shown in Fig. 2.

Table I—Correlation Between Pupil Diameters and Plasma Morphine Concentrations in Healthy Volunteers [a]

Subject	Correlation Coefficient	Slope
1[b]	−0.86[c]	−0.120
2	−0.85[c]	−0.094
3	−0.77[c]	−0.065
4	−0.91[c]	−0.071
5	−0.78[c]	−0.089
6	−0.76[d]	−0.050
7	−0.82[c]	−0.066
Mean ± *SD*	−0.82 ± 0.06	−0.079 ± 0.02

[a] Pupil diameters are in millimeters, and plasma morphine concentrations are in nanograms per milliliter; $n = 10$ after a 10-mg iv infusion of morphine sulfate; data were collected before and at 2, 5, 7, and 10 h after morphine injection and were combined for placebo and cimetidine treatment periods (see text). [b] $n = 9$. [c] $p < 0.01$. [d] $p < 0.05$.

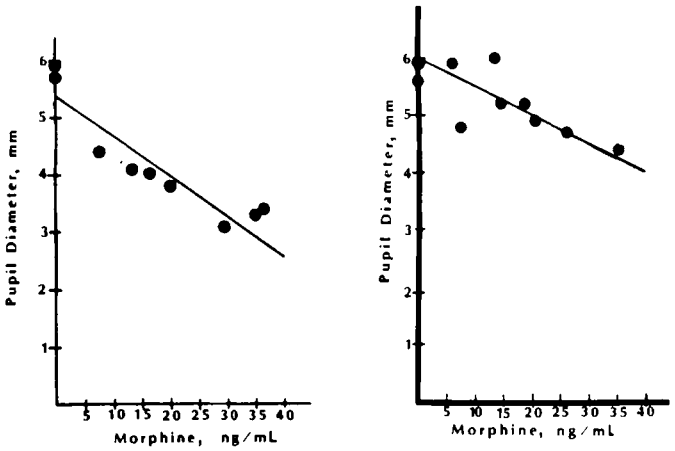

Figure 2—*Regression line derived from the data for subjects 4 and 6. These represent the subjects with the highest and lowest correlation coefficients. For subject 4 (left),* $y = -0.07x + 5.4$, $r = -0.91$, $p < 0.01$; *for subject 6 (right),* $y = -0.05x + 6.0$, $r = -0.76$, $p < 0.05$.

DISCUSSION

Recently, greater emphasis has been placed on evaluating the nature of the relationship between the pharmacokinetics and pharmacodynamics of an agent (10). The data from the present study establish the relationship between the miotic response to morphine and its plasma concentrations in the postdistributive phase. A difference in the magnitude of the correlation coefficients for individuals *versus* the group was observed. This is most probably accounted for by individual variation in pretreatment pupil diameter and sensitivity to morphine; evidence for the latter is the wide range of slopes described in Table I. Cimetidine exhibited no demonstrable effect on pupil diameter prior to or following morphine administration. These findings suggest that H_2-receptors have little role in the regulation of pupil size and are consistent with the lack of effect of cimetidine on morphine pharmacokinetics (3).

These data confirm and extend the previous observations of a relationship between plasma concentration of morphine equivalents following an intravenous dose of heroin and pupil diameter (1, 11). However, correlation coefficients were not reported in those studies, making comparison with the results obtained in this study impossible. Similarly, the time course of methadone-induced miosis appears to parallel methadone plasma concentrations (2).

Photographic pupillometry is an easily performed, readily quantifiable test which may have experimental and clinical utility for monitoring opiate activity. For example, tolerance to the miotic response to morphine has been demonstrated and used in the assessment of opiate dependency (7, 11). Further investigations are warranted to clarify the relationships between the serum concentrations of other opiate analgesics or other ocularly active agents and pupil diameter.

Evidence Favoring the Venous Equilibrium Model for Hepatic Clearance of (*S*)-(−)-Propranolol

Keyphrases □ Propranolol—hepatic clearance, venous equilibrium model □ Hepatic clearance—propranolol, venous equilibrium model

To the Editor:

Drug clearance is an important pharmacokinetic parameter since it most closely reflects the ability of the body to rid itself of drug. Because the liver is a major site of drug elimination, there is considerable interest in understanding the processes by which drugs are cleared as they pass through this organ. Two physical models for hepatic drug clearance have been proposed. The venous equilibrium or "well-stirred" model assumes that the liver can be viewed as a single homogeneous compartment with the free or unbound drug concentration in hepatic venous blood in equilibrium with that in the liver (1). The sinusoidal model assumes that the liver is composed of a number of parallel tubes with drug-metabolizing enzymes evenly distributed throughout (2). In this model, drug concentration declines continuously as blood traverses the sinusoid. Although the determinants of drug clearance are the same in both models (liver blood flow, unbound fraction of drug in blood, and intrinsic clearance of unbound drug), the equations relating these variables to hepatic clearance differ. For the venous equilibrium model:

$$CL = Q \cdot f_u \cdot CL_{u,int}/(Q + f_u \cdot CL_{u,int}) \quad \text{(Eq. 1)}$$

while for the sinusoidal model:

$$CL = Q(1 - e^{-f_u \cdot CL_{u,int}/Q}) \quad \text{(Eq. 2)}$$

where Q is the liver blood flow, f_u is the fraction of unbound drug in blood, $CL_{u,int}$ is the intrinsic clearance of unbound drug, and CL is the liver clearance.

Despite the difference between these equations, both predict quantitatively similar values for drug clearance under most conditions of varying blood flow, free fraction, or intrinsic clearance. However, an extensive theoretical analysis of the models has suggested that major differences exist in predictions of area under the concentration-time curve (AUC) and systemic availability (F) when highly extracted drugs are administered orally (3). In the venous equilibrium model:

$$F = Q/(Q + f_u \cdot CL_{u,int}) \quad \text{(Eq. 3)}$$

and:

$$\text{AUC} = \text{Dose}/f_u \cdot CL_{u,int} \quad \text{(Eq. 4)}$$

while in the sinusoidal model:

$$F = e^{-f_u \cdot CL_{u,int}/Q} \quad \text{(Eq. 5)}$$

and:

$$\text{AUC} = \text{Dose}(e^{-f_u CL_{u,int}/Q})/Q(1 - e^{-f_u CL_{u,int}/Q}) \quad \text{(Eq. 6)}$$

It is readily appreciated from these equations that changes in blood flow or drug binding will result in approximately linear changes in F and AUC for a highly extracted drug according to the venous equilibrium model, while the sinusoidal model predicts exponential changes.

The venous equilibrium model appears to be much more commonly employed in pharmacokinetic analysis today. However, there is little physiological or experimental evidence to suggest that this model is preferable. Using the isolated perfused rat liver preparation, Pang and Rowland (4) found that the clearance of highly extracted lidocaine was best described by the "well-stirred" model. The hepatic elimination of galactose, however, has been observed to be more consistent with the predictions of the sinusoidal model (5). Both of these investigations were conducted under conditions of perturbed blood flow. Such studies could also be carried out by varying the degree of protein binding (3). Jones *et al.* (6) have recently reported that a sevenfold change in the free fraction of propranolol does not alter effluent unbound propranolol concentration in the perfused rat liver, a finding consistent with venous equilibrium theory. The discovery over the past several years that many highly extracted basic drugs are highly bound to α_1-acid glycoprotein (7) makes this approach feasible not only *in situ* but also in the intact animal, since the concentration of α_1-acid glycoprotein and degree of protein binding may change dramatically and rapidly in a number of conditions and disease states (8–10).

The recently published data of Terao and Shen (11) provides an excellent opportunity to evaluate the relative merits of the proposed models based on *in vivo* observations. These investigators administered oral and intravenous (*S*)-(−)-propranolol to rats 1 and 7 d following implantation of an indwelling jugular venous catheter. The free fraction of (*S*)-(−)-propranolol decreased from an average of 0.169 1 d following catheter insertion to 0.074 7 d later, presumably due to a catheter-stimulated increase in α_1-acid glycoprotein concentration. Bioavailability and AUC were measured following the administration of oral drug on both occasions and are listed in Table I. F was found to increase from 4.1 to 7.8%, while AUC increased from 3.45 to 6.95 μg·min/mL as protein binding increased.

The predicted effect of such a change in binding on these parameters was calculated for both models using Eqs. 3–6. These predictions assume complete absorption of (*S*)-(−)-propranolol, that liver blood flow and intrinsic clearance of unbound drug are the same on both study days and that

Table I—Observed and Predicted Changes in *F* and AUC Secondary to Increased Protein Binding

	$f_u = 0.169$	$f_u = 0.074$	Ratio[b]
Observed F (%)[a]	4.1	7.8	1.90

(*S*)-(−)-propranolol is entirely cleared by the liver. The value of $CL_{u,int}$ for each model was estimated from Eqs. 1 and 2 using the (*S*)-(−)-propranolol clearance of 6.61 mL/min/100 g observed following intravenous administration 1 d after catheter insertion. Q was calculated using this value for clearance and an extraction ratio of 0.959. Table I lists the predictions and compares the ratio of predicted or observed values at the time of increased binding to the original observation. As expected, significant differences between the models were observed with the venous equilibrium equations predicting 2.17- and 2.28-fold increases in F and AUC, respectively, given the observed binding change, while the sinusoidal model predicted 6.00- and 7.63-fold increases in these parameters. Clearly, the predictions of the venous equilibrium model more closely approximate the values observed by Terao and Shen (11). In fact, there is remarkably good agreement with only 14.1 and 13.4% error in the predictions of F and AUC, respectively, using this model.

Although this data is limited to observations in one species with a single substrate, it does provide *in vivo* evidence in support of the venous equilibrium model for hepatic clearance. This is important information since there are many clinical situations in which liver blood flow, protein binding, or intrinsic drug clearance may be altered. Knowledge of the appropriate physical model for hepatic clearance allows one to predict with reasonable accuracy the effect of changes in these factors on important pharmacokinetic parameters such as F and AUC. This is particularly crucial when highly extracted compounds are administered orally. Prospective studies examining this issue further with other highly extracted drugs are needed in order to confirm that the venous equilibrium model is indeed the preferred physical model for hepatic drug clearance.

Method for Determination of First-Pass Metabolism in Human Skin

Keyphrases □ Metabolism, first-pass—transdermal formulations, human skin □ Transdermal formulations—percutaneous first-pass metabolism, human skin □ Viprostol—transdermal formulations, first-pass metabolism

To the Editor:

The technological advances in drug-delivery systems have allowed increased utilization of transdermal formulations for therapeutic purposes. This route of administration is most suitable for potent drugs possessing short biological half-lives, extensive first-pass metabolism after oral administration, and narrow therapeutic indices. By controlling the rate of delivery and absorption through the skin, it is possible to maintain therapeutic drug concentrations in the blood and/or at the site of action. The systemic blood concentrations of such compounds after transdermal administration in humans is very low and often below the sensitivity levels of specific assay procedures. Nitroglycerin, which undergoes extensive first-pass metabolism when given orally, is one of the most widely used drugs in transdermal systems. To circumvent the assay sensitivity problem and allow for a comparison of dosage forms, Karim (1) has proposed, and effectively implemented, blood sampling from the ipsilateral antecubital forearm veins after application of the topical formulation on the volar surface of the wrist. The purpose of this communication is to describe a similar procedure that can also estimate the percutaneous first-pass metabolism of topically applied compounds, even when extensive biotransformation takes place in the skin.

Drug and/or drug and metabolite (*i.e.*, total) concentrations in samples from the contralateral antecubital forearm will be low and represent the systemic blood concentrations (C_c). The ipsilateral samples will contain higher blood concentrations (C_i), and represent the concentration of the drug absorbed plus C_c at any given time. After correction for C_c, the ipsilateral concentrations will directly reflect the flux of the drug (C_j) through the skin; *i.e.*,

$$C_j = C_i - C_c \qquad \text{(Eq. 1)}$$

where $C_i = C_{p,j} + C_{m,j} + C_{p,c} + C_{m,c}$, $C_c = C_{p,c} + C_{m,c}$, and $C_j = C_{p,j} + C_{m,j}$. In this case C_p is the concentration of the unchanged drug and C_m is the total concentration of metabolites.

In the absence of any metabolism and/or degradation of the drug during the percutaneous absorption process, C_j will consist of the intact drug only, *i.e.*, $C_j = C_{p,j}$. If during the absorption processes the drug undergoes metabolism, C_j will consist of the concentrations of the drug ($C_{p,j}$) and metabolite(s) ($C_{m,j}$) in the ipsilateral samples at any time. In such a situation the magnitude of the first-pass metabolism can be estimated by calculating the fractions of unchanged drug and metabolite(s). Biotransformation and/or binding in the vein from the absorption site (the skin) up to the point of blood sampling would be accounted for but not differentiated from metabolism in the skin. The same is true if degradation processes other than biotransformation were involved.

When the rate of absorption through the skin is constant, and C_j reaches steady-state level, the fraction metabolized in the skin (f_s) can be estimated by:

$$f_s = \frac{C_{m,j}}{C_{p,j} + C_{m,j}} \qquad \text{(Eq. 2)}$$

12	0.52	27.8	9.8	18.0	0.65	0.57	14.8	3.2	11.6	0.78
16	—	6.7	2.7	4.0	0.60	—	10.8	2.7	8.1	0.75
Mean					0.65					0.70
CV					6.2%					10%

[a] $f_s = C_{m,j}/C_j$, where $C_j = C_i - C_c$ and $C_{m,j} = C_j - C_{p,j}$. Because $C_{p,i} = C_{p,j} + C_{p,c}$ and the values of $C_{p,c}$ are below the detectable level of 0.05 ng/mL, $C_{p,j}$ was assumed to be essentially the same as $C_{p,i}$ as presented in this table. [b] Interpolated values.

where $C_{p,j}$ and $C_{m,j}$ are concentrations of the drug absorbed either unchanged or as a metabolite(s), respectively. Assuming that (*a*) skin metabolism is much higher than the metabolism in other tissue up to the point of ipsilateral sampling and (*b*) there is no preferential tissue binding of the drug or metabolites, the areas under the plasma concentrations *versus* time profiles of the drug ($AUC_{p,j}$) and metabolite ($AUC_{m,j}$) will be independent of the distribution volume, and the summation of the two values will represent the area under the C_j *versus* time profile (AUC_j). Therefore, f_s can also be calculated by:

$$f_s = \frac{AUC_{m,j}}{AUC_{p,j} + AUC_{m,j}} \quad \text{(Eq. 3)}$$

or:

$$f_s = \frac{AUC_{m,j}}{AUC_j} \quad \text{(Eq. 4)}$$

as by definition $AUC_j = AUC_{p,j} + AUC_{m,j}$.

Methyl (±)-(11α,5*Z*(and 5*E*),13*E*,16*R*(and 16*S*)-16-ethenyl-11,16-dihydroxy-9-oxoprosta-5,13-dien-1-oate (viprostol; I), a prostaglandin analogue, is a topically effective antihypertensive agent (2). In the blood and body it apparently undergoes instantaneous and complete ester hydrolysis to give an equally effective compound, (±)-(11α,5*Z*(and 5*E*), 13*E*,16*R*(and 16*S*))-16-ethenyl-11,16-dihydroxy-9-oxoprosta-5,13-dien-1-oic acid (II). The transdermal administration of [^{14}C]I has shown good absorption in various animal models, as measured by total concentrations of carbon-14 (3). The low systemic concentrations (contralateral) of I or II, require a sophisticated GC–MS technique for quantitation (4). In humans, effective doses of I result in low concentrations of II (not I) in the systemic circulation, often below the sensitivity limit of the GC–MS procedure (76 pg/mL). To study the transdermal absorption, 1.5 mg (specific activity 18.99 μCi/mg) of [^{14}C]I in petrolatum bandages[1] (10 cm^2) was applied to the volar surface of the forearm of normal male subjects, and serial ipsilateral and contralateral blood samples were collected into heparinized tubes. Following centrifugation, the plasma was removed and then stored at −40°C until assay. Total radioactivity in each sample was determined by scintillation counting. The concentration of the unchanged drug (II) in the ipsilateral plasma samples were determined by the specific GC–MS assay procedure (4). Because of the rapid hydrolysis of I to II, it was only possible to measure the concentrations of II by GC–MS, and II is considered to be the unchanged active drug ($C_{p,i}$). Therefore, all calculations were done for II.

[1] Formulation Research Section, Medical Research Division, American Cyanamid Co., Pearl River, N.Y.

Table I summarizes the concentrations of II ($C_{p,i}$) and total radioactivity in the ipsilateral ($C_i = C_{p,i} + C_{m,i}$) and contralateral (C_c) plasma samples after application of a 1.5-mg dose on the forearm of two subjects, randomly selected for this report. In general, C_c was relatively low, <1 ng/mL of which, on the average, <10% (~0.05 ng/mL) was in the form of unchanged II and would not be readily measurable by the GC–MS procedure. C_i, of which 35 and 30% was in the form of unchanged II in subjects 1 and 2, respectively, was quite high. These data indicate that about two-thirds of the dose underwent metabolism during absorption from the topical application site and/or in transit to the point of blood sampling in the same arm. As part of a pharmacokinetic study of topical and intravenous [^{14}C]nitroglycerin, Wester *et al.* were able to measure the absolute bioavailability (57%) and estimate the percutaneous first-pass metabolism (16–21%) in monkeys (5). Basically, the procedure is the same as that used for determination of first-pass metabolism after oral administration, *i.e.*, utilizing the difference between the total radioactivity and unchanged nitroglycerin which reached the systemic circulation. The ipsilateral–contralateral method offers the possibility of determining the percutaneous metabolism after one application in the same subject at the same time.

In summary, the results of this study suggests that this simple procedure may be used for the estimation of percutaneous first-pass metabolism of drugs which are administered transdermally and where the skin is a significant site of biotransformation. It would also be of interest to examine this procedure for percutaneous metabolism of other potent drugs which undergo metabolism in the skin.

Area Under Blood Level versus *Time Curves at Steady State for Daily Dosing at Unequal Dosing Intervals*

Most problems that deal with steady-state drug blood levels for multiple dosing assume that doses are administered at equal intervals during a 24-h period, *e.g.*, four tablets every 6 h or three tablets every 8 h. For the one-compartment model, for example, under these circumstances, it is well known that at steady state, the area under the blood level *versus* time curve (AUC) during a 24-h period is (Total Daily Dose)/k_e, where k_e is the first-order elimination rate constant. A question of interest is the value of the AUC at steady state when the doses are not given at equal intervals but where the dosage regimen is regular over some period, in particular, 24 h. This is the more realistic situation, *e.g.*, one tablet at 8 a.m., noon, 4 p.m. and 8 p.m. The following simple proof shows that for the above conditions, at a constant total daily dosage, the AUC at steady state is independent of the dosage time intervals for any input function. The following differential equation describes a one-compartment model, in general:

$$dX_c/dt = f[X(t)] - k_e X_c \qquad \text{(Eq. 1)}$$

where $f[X(t)]$ is in the input function (absorption) and $k_e X_c$ represents first-order elimination.

If $X(t)$ is periodic, so is $f[X(t)]$. (Note that the 24-h dosing schedule does not change.) At steady state, X_c will be periodic with the same period. Here, the period is 24 h for a regular 24-h dosing regimen. Integrating Eq. 1 from t_0 to $t_0 + T$:

$$\int_{t_0}^{t_0+T} (dX_c/dt)dt = \int_{t_0}^{t_0+T} f[X(t)]dt - k_e \int_{t_0}^{t_0+T} X_c dt \qquad \text{(Eq. 2)}$$

$X_c(t_0 + T) - X_c(t_0)$ = (Total dose from t_0 to $t_0 + T$) $- k_e$(AUC) from t_0 to $t_0 + T$. If T is the period (24 h in this example): $X_c(t_0 + T) = X_c(t_0)$, and (Total 24-h dose) = $X_{24} = k_e(\text{AUC})_{24}$, or AUC = $(X_{24})/k_e$. Therefore, the AUC over a 24-h period is dependent on the total dose given during the 24 h, and independent of how it is administered providing that the regimen is periodic.

Using a similar argument, it can be shown that this conclusion holds also for higher-compartment models with any input function, if dosing is periodic during a specific interval.

Secret Formulations from the Industry's Perspective

As an individual who has worked in industry some 10 years now, I was most disturbed at some of the comments and implications in Dr. Feldmann's editorial[1] "Putting an End to Secret Formulations." First of all, I take strong exception to his assertion that the reason for industry's reluctance to disclose our formulations is simply to create an illusion of mystery. Those of us in the formulation development end of the business feel very strongly that protection of our formulations is indeed an important issue with respect to competition. While it may be true that another firm could "crack" our formulas if they were willing to invest enough analytical effort (although I question whether it is only a "moderate challenge" for the analyst to completely quantitate any given formula), the very fact that such an effort would have to be made presents a significant barrier to our competition. We have no obligation or desire to give away the substantial investment we have made in developing our formulas without compelling justification. To do otherwise makes no more sense than for GM to provide blueprints of their latest design innovations to Ford and Chrysler on request.

Dr. Feldmann alludes several times to the possibility that (perish the thought!) industry's primary motivation might be to make a profit. Obviously, it *is* the goal of industry as well as the rest of the drug distribution system to make a profit (without which there would be no industry as we know it in the free world, no viable private sector, no pharmaceutical research, and, very likely, no funding for APhA, APS, or this Journal) and we have nothing to apologize for this. A profit is not at all necessarily inconsistent with high ethical standards and a genuine concern for mankind, both of which the U.S. pharmaceutical industry has repeatedly demonstrated. Dr. Feldmann provides no basis for his emotional accusation that somehow industry has been trading "human lives" for profits by not labeling our products with the entire listing of ingredients. Although I am personally unaware of any documented evidence that formulation excipients are causing significant medical problems, there may indeed be a persuasive justification for this information being made available due to substantive safety issues. However, such arguments should be factually presented and weighed against legitimate commercial concerns, not couched in emotional tirades based on highly questionable assumptions.

Beyond these specific concerns, I am disturbed at the hostile tone of this editorial towards industry. I would hope that the Association has matured beyond the simplistic big-business-always-wears-black-hats mentality that was so prevalent in our society in the late 60's and early 70's. The pharmaceutical industry is certainly not above criticism, but the consistently negative portrayals of industry practices and ethics in such editorials are not only inaccurate in my opinion but can hardly be called objective. Such apparent bias and the inevitable polarization it encourages seems highly inappropriate for an organization which claims to represent all of pharmacy.

[1] E. G. Feldmann, *J. Pharm. Sci.*, **73**, 577 (1984).

Author's Response

I wish to assure Dr. Mendenhall, as well as all our readers, that no "hostile tone" toward industry was intended in my editorial that he cited. Certainly, we can disagree regarding specific policies and still maintain cordial working relationships and feelings of mutual respect.

In fact, the matter of maintaining secrecy regarding drug product ingredients has been an issue of considerable difference of opinion *within* the pharmaceutical industry. In my discussions with industry colleagues over the past several years, many of them have favored full ingredient disclosure for precisely the reasons mentioned in the editorial. And, at the same time, many other industry colleagues felt contrary-minded.

Indeed, it is my understanding that such differences in viewpoint existed not only among industry scientists, but also between various firms. This had prevented PMA as an organization from supporting the concept of complete ingredient disclosure. However, we were happy to learn that 2 months following our editorial, at its meeting on July 9, the PMA Board of Directors voted that its member companies will voluntarily list inactive ingredients in product labeling. According to the PMA announcement, this action "is intended to provide added safety for persons sensitive to an inactive ingredient."

As to the two "specific concerns" voiced by Dr. Mendenhall: (*a*) our readers can make their own judgments as to the relative difficulty that a qualified analytical laboratory would currently encounter in determining the qualitative composition of a typical drug product, and (*b*) each of us in his or her own conscience needs to reconcile the degree that our profit motives will be balanced against our humanitarian and societal concerns.

Total Synthesis of Natural Products: The 'Chiron' Approach. (Organic Chemistry Series, Vol. 3). By STEPHEN HANESSIAN. Pergamon Press, Inc. Maxwell House, Fairview Park, Elmsford, NY 10523. 1983. 291 pp. 15 × 23 cm. Price: $20.00.

The present generation of organic chemists considers no total synthesis of a natural product to be truly satisfactory unless it also yields an optically pure product. One of the ways of achieving this objective is to begin the synthesis with a substrate drawn from the chiral pool so bountifully provided by nature: amino and hydroxy acids, terpenes, and carbohydrates, many of which are readily available and relatively cheap. In this book, Professor Hanessian, one of the leading practitioners of the art of using carbohydrates as precursors in asymmetric total synthesis, presents both a personal approach to this field and a thorough review, with much informative commentary, of successful syntheses employing carbohydrates as starting materials.

Part 1 of the book describes those features of compounds from the chiral pool—variety in carbon framework, sense of chirality, number of asymmetric centers, functional group sequences—that make them versatile springboards from which to launch asymmetric syntheses. All important, of course, is the designer's perception of the structural and stereochemical relationships between these "chiral templates" and the target structure. Parts 2 and 3 of the book, entitled "Design" and "Discovery" respectively, present guidelines on how to establish the appropriate "visual dialogue" (a functional, if not particularly felicitous, phrase). The central feature of the approach is the identification and selection of "chirons"—suitably functionalized, defunctionalized, or otherwise modified versions of the chiral templates which, after activation, may be assembled to give the target product.

The rest of the book, and by far the largest part, is devoted to "Execution," a detailed discussion of selected carbohydrate-based asymmetric syntheses. These syntheses fall into three main groups: those in which the targets contain reasonably obvious carbohydrate-type symmetry; those in which such symmetry is partially hidden; and those in which only the most hardened fans of the approach would have looked for a carbohydrate precursor in the first place. Each section is further subdivided into chapters according to the types of molecules being synthesized. The relatively straightforward chiral targets (acyclic compounds, tetrahydrofurans, tetrahydropyrans and the like) predominate the earlier chapters and more complex products (*i.e.* prostaglandins, heterocyclic antibiotics, macrolides, and ansa compounds) dominate the later sections. In almost all cases, the syntheses chosen for illustration are of compounds with substantial pharmaceutical significance. The book ends with a brief discussion of a possible role for computers in the visual recognition of chiral templates within target structures.

Not the least virtue of this book is the abundance of flow-sheets (more than 150) for the syntheses discussed. In most cases, the flow sheets show both a retrosynthetic analysis from target via chiron to chiral template, as well as the forward steps, with reagents, of the completed synthesis. It appears that every reference of importance in the field has been included, and the index is reasonably comprehensive. There appear to be very few errors. Those whose chief fascination is the art and philosophy of organic synthesis will certainly read this book with avidity, even if they remain unconvinced that carbohydrates necessarily provide the ideal solution to the problem of introducing asymmetry into a synthetic scheme.

Molecular Aspects of Anti-Cancer Drug Action. (Topics in Molecular and Structural Biology. 3). Edited by STEPHEN NEIDLE and MICHAEL J. WARING. Verlag Chemie International Inc., 303 N.W. 12th Ave., Deerfield Beach, FL 33441. 1983. 404 pp. 16 × 24 cm. Price: $97.50.

This book, the third in a series on *Topics in Molecular and Structural Biology*, contains eleven chapters dealing largely with Drug-DNA interactions of a number of cancer chemotherapeutic agents currently of high interest. Literature is covered through 1981 with the occasional appearance of a few later citations. Based on a random survey, the book is remarkably free from typographical errors. The text is printed in small (but clear) type. In most cases chemical structures, figures, and tables are easily read; however, in some cases the codes to structural formulae were difficult to read. The selection of topics includes: acridines, three chapters on topics related to anthracycline drugs, quinoxaline antibiotics, bleomycin, platinum compounds, alkylating agents, and methotrexate and analogues. In addition, there are reviews of the chemical and biological damage by certain antitumor drugs.

The chapter on acridines by Denny, Boyuley, Cain, and Waring is an excellent review of the enormous work of the group that was headed by the late Bruce Cain. It culminates in amsacrine and describes the studies (largely by Polish workers) on nitracrine—an active but toxic 1-nitro-acridine derivative—and of the bifunctional acridines. The interactions of daunomycin and adriamycin with nucleic acids is covered in a brief but useful chapter by Neidle and Sanderson; however, this subject has been covered in greater detail in earlier reviews. J. R. Brown presents a timely chapter with much new material on synthetic anthracycline drugs that will be of particular interest to medicinal chemists seeking a rational basis for the synthesis of new agents in this class.

Bifunctional intercalation is again reviewed by Waring and Fox in a chapter dealing with quinoxaline antibiotics. Although this group has not attained clinical significance, the techniques discussed in the study of molecular interactions may be of general use. Another review by Roberts and Pera dealing with the action of platinum antitumor drugs is presented in an authoritative manner. Lown briefly surveys the chemistry of DNA damage by a large number of antitumor agents. This chapter should be of particular value to medicinal chemists.

Molecular Aspects of Anti-Cancer Drug Action will be useful to medicinal chemists seeking rational approaches to the synthesis of antitumor agents. Unfortunately, the high cost of this volume ($97.50) may restrict purchases to technical libraries.

A Guide to the Chemical Basis of Drug Design. By ALFRED BURGER. John Wiley & Sons, Inc., One Wiley Drive, Somerset, NJ 08873. 1983. 300 pp. 16.5 × 23.5 cm. Price: $45.00.

The contributions of Professor Alfred Burger to the discipline of medicinal chemistry, particularly the literature of medicinal chemistry, have long been noted and acknowledged. His current effort attempts to recount those experiences of the medicinal chemist which, in cooperation with biologists and pharmacologists, have resulted in the chemical design of therapeutically useful drug substances. It is the broad scope of this endeavor which accounts for both the success and failure of this latest effort. The success of this overview of drug design resides mainly in those areas in which Professor Burger provides personal insight. This guide, afterall, recounts many ideas and examples which "are results of a lifetime in medicinal chemistry." After a brief introduction in which he traces his early interest in the chemistry of medicinally useful agents, and thus traces the development of medicinal chemistry, the book discusses drug design from three distinct, but oftentimes redundant, viewpoints. Chapter 1 begins as a fascinating discussion of the history of medicinal chemistry but develops into a chapter which lacks direction and depth. Chapter 2 presents areas of research interest with particular emphasis on antihypertensive agents, anti-inflammatory agents, antiviral and antitumor agents, antihistaminics, analgetics and antihyperglycemic agents. It is in this chapter that general aspects of drug design, molecular modifications and quantitative structure-activity relationships are presented. The discussion in each of these areas represents a general overview of the subject and precludes any discussion in depth. For example, in the discussion of recent research in the area of antihypertensive agents the role of presynaptic α_2-adrenoceptors in the action of newer agents such as clonidine is neglected. On the other hand, the discussion of the development of analgetic research is particularly interesting. Chapter 3 is intended as a discussion of selected examples of drug design. Many aspects of drug design of analgetic, anti-inflammatory, anticholinergics and antihistaminic agents discussed in Chapter 2 are repeated in the early part

The interactions of daunomycin and adriamycin with nucleic acids is covered in a brief but useful chapter by Neidle and Sanderson; however, this subject has been covered in greater detail in earlier reviews. J. R. Brown presents a timely chapter with much new material on synthetic anthracycline drugs that will be of particular interest to medicinal chemists seeking a rational basis for the synthesis of new agents in this class.

Bifunctional intercalation is again reviewed by Waring and Fox in a chapter dealing with quinoxaline antibiotics. Although this group has not attained clinical significance, the techniques discussed in the study of molecular interactions may be of general use. Another review by Roberts and Pera dealing with the action of platinum antitumor drugs is presented in an authoritative manner. Lown briefly surveys the chemistry of DNA damage by a large number of antitumor agents. This chapter should be of particular value to medicinal chemists.

Molecular Aspects of Anti-Cancer Drug Action will be useful to medicinal chemists seeking rational approaches to the synthesis of antitumor agents. Unfortunately, the high cost of this volume ($97.50) may restrict purchases to technical libraries.

A Guide to the Chemical Basis of Drug Design. By ALFRED BURGER. John Wiley & Sons, Inc., One Wiley Drive, Somerset, NJ 08873. 1983. 300 pp. 16.5 × 23.5 cm. Price: $45.00.

The contributions of Professor Alfred Burger to the discipline of medicinal chemistry, particularly the literature of medicinal chemistry, have long been noted and acknowledged. His current effort attempts to recount those experiences of the medicinal chemist which, in cooperation with biologists and pharmacologists, have resulted in the chemical design of therapeutically useful drug substances. It is the broad scope of this endeavor which accounts for both the success and failure of this latest effort. The success of this overview of drug design resides mainly in those areas in which Professor Burger provides personal insight. This guide, afterall, recounts many ideas and examples which "are results of a lifetime in medicinal chemistry." After a brief introduction in which he traces his early interest in the chemistry of medicinally useful agents, and thus traces the development of medicinal chemistry, the book discusses drug design from three distinct, but oftentimes redundant, viewpoints. Chapter 1 begins as a fascinating discussion of the history of medicinal chemistry but develops into a chapter which lacks direction and depth. Chapter 2 presents areas of research interest with particular emphasis on antihypertensive agents, anti-inflammatory agents, antiviral and antitumor agents, antihistaminics, analgetics and antihyperglycemic agents. It is in this chapter that general aspects of drug design, molecular modifications and quantitative structure-activity relationships are presented. The discussion in each of these areas represents a general overview of the subject and precludes any discussion in depth. For example, in the discussion of recent research in the area of antihypertensive agents the role of presynaptic α_2-adrenoceptors in the action of newer agents such as clonidine is neglected. On the other hand, the discussion of the development of analgetic research is particularly interesting. Chapter 3 is intended as a discussion of selected examples of drug design. Many aspects of drug design of analgetic, anti-inflammatory, anticholinergics and antihistaminic agents discussed in Chapter 2 are repeated in the early part

Total Synthesis of Natural Products: The 'Chiron' Approach. (Organic Chemistry Series, Vol. 3). By STEPHEN HANESSIAN. Pergamon Press, Inc. Maxwell House, Fairview Park, Elmsford, NY 10523. 1983. 291 pp. 15 × 23 cm. Price: $20.00.

The present generation of organic chemists considers no total synthesis of a natural product to be truly satisfactory unless it also yields an optically pure product. One of the ways of achieving this objective is to begin the synthesis with a substrate drawn from the chiral pool so bountifully provided by nature: amino and hydroxy acids, terpenes, and carbohydrates, many of which are readily available and relatively cheap. In this book, Professor Hanessian, one of the leading practitioners of the art of using carbohydrates as precursors in asymmetric total synthesis, presents both a personal approach to this field and a thorough review, with much informative commentary, of successful syntheses employing carbohydrates as starting materials.

Part 1 of the book describes those features of compounds from the chiral pool—variety in carbon framework, sense of chirality, number of asymmetric centers, functional group sequences—that make them versatile springboards from which to launch asymmetric syntheses. All important, of course, is the designer's perception of the structural and stereochemical relationships between these "chiral templates" and the target structure. Parts 2 and 3 of the book, entitled "Design" and "Discovery" respectively, present guidelines on how to establish the appropriate "visual dialogue" (a functional, if not particularly felicitous, phrase). The central feature of the approach is the identification and selection of "chirons"—suitably functionalized, defunctionalized, or otherwise modified versions of the chiral templates which, after activation, may be assembled to give the target product.

The rest of the book, and by far the largest part, is devoted to "Execution," a detailed discussion of selected carbohydrate-based asymmetric syntheses. These syntheses fall into three main groups: those in which the targets contain reasonably obvious carbohydrate-type symmetry; those in which such symmetry is partially hidden; and those in which only the most hardened fans of the approach would have looked for a carbohydrate precursor in the first place. Each section is further subdivided into chapters according to the types of molecules being synthesized. The relatively straightforward chiral targets (acyclic compounds, tetrahydrofurans, tetrahydropyrans and the like) predominate the earlier chapters and more complex products (*i.e.* prostaglandins, heterocyclic antibiotics, macrolides, and ansa compounds) dominate the later sections. In almost all cases, the syntheses chosen for illustration are of compounds with substantial pharmaceutical significance. The book ends with a brief discussion of a possible role for computers in the visual recognition of chiral templates within target structures.

Not the least virtue of this book is the abundance of flow-sheets (more than 150) for the syntheses discussed. In most cases, the flow sheets show both a retrosynthetic analysis from target via chiron to chiral template, as well as the forward steps, with reagents, of the completed synthesis. It appears that every reference of importance in the field has been included, and the index is reasonably comprehensive. There appear to be very few errors. Those whose chief fascination is the art and philosophy of organic synthesis will certainly read this book with avidity, even if they remain unconvinced that carbohydrates necessarily provide the ideal solution to the problem of introducing asymmetry into a synthetic scheme.

Molecular Aspects of Anti-Cancer Drug Action. (Topics in Molecular and Structural Biology. 3). Edited by STEPHEN NEIDLE and MICHAEL J. WARING. Verlag Chemie International Inc., 303 N.W. 12th Ave., Deerfield Beach, FL 33441. 1983. 404 pp. 16 × 24 cm. Price: $97.50.

This book, the third in a series on *Topics in Molecular and Structural Biology*, contains eleven chapters dealing largely with Drug-DNA interactions of a number of cancer chemotherapeutic agents currently of high interest. Literature is covered through 1981 with the occasional appearance of a few later citations. Based on a random survey, the book is remarkably free from typographical errors. The text is printed in small (but clear) type. In most cases chemical structures, figures, and tables are easily read; however, in some cases the codes to structural formulae were difficult to read. The selection of topics includes: acridines, three chapters on topics related to anthracycline drugs, quinoxaline antibiotics, bleomycin, platinum compounds, alkylating agents, and methotrexate and analogues. In addition, there are reviews of the chemical and biological damage by certain antitumor drugs.

The chapter on acridines by Denny, Boyuley, Cain, and Waring is an excellent review of the enormous work of the group that was headed by the late Bruce Cain. It culminates in amsacrine and describes the studies (largely by Polish workers) on nitracrine—an active but toxic 1-nitro-acridine derivative—and of the bifunctional acridines. The interactions of daunomycin and adriamycin with nucleic acids is covered in a brief but useful chapter by Neidle and Sanderson; however, this subject has been covered in greater detail in earlier reviews. J. R. Brown presents a timely chapter with much new material on synthetic anthracycline drugs that will be of particular interest to medicinal chemists seeking a rational basis for the synthesis of new agents in this class.

The contributions of Professor Alfred Burger to the discipline of medicinal chemistry, particularly the literature of medicinal chemistry, have long been noted and acknowledged. His current effort attempts to recount those experiences of the medicinal chemist which, in cooperation with biologists and pharmacologists, have resulted in the chemical design of therapeutically useful drug substances. It is the broad scope of this endeavor which accounts for both the success and failure of this latest effort. The success of this overview of drug design resides mainly in those areas in which Professor Burger provides personal insight. This guide, afterall, recounts many ideas and examples which "are results of a lifetime in medicinal chemistry." After a brief introduction in which he traces his early interest in the chemistry of medicinally useful agents, and thus traces the development of medicinal chemistry, the book discusses drug design from three distinct, but oftentimes redundant, viewpoints. Chapter 1 begins as a fascinating discussion of the history of medicinal chemistry but develops into a chapter which lacks direction and depth. Chapter 2 presents areas of research interest with particular emphasis on antihypertensive agents, anti-inflammatory agents, antiviral and antitumor agents, antihistaminics, analgetics and antihyperglycemic agents. It is in this chapter that general aspects of drug design, molecular modifications and quantitative structure-activity relationships are presented. The discussion in each of these areas represents a general overview of the subject and precludes any discussion in depth. For example, in the discussion of recent research in the area of antihypertensive agents the role of presynaptic α_2-adrenoceptors in the action of newer agents such as clonidine is neglected. On the other hand, the discussion of the development of analgetic research is particularly interesting. Chapter 3 is intended as a discussion of selected examples of drug design. Many aspects of drug design of analgetic, anti-inflammatory, anticholinergics and antihistaminic agents discussed in Chapter 2 are repeated in the early part

of this chapter. The bulk of the chapter is devoted to a discussion of the development and design of chemotherapeutic agents. Again, the major drawback to this chapter, for the most part, is a lack of in-depth discussion of many key areas as exemplified by the brief discussion of antitumor agents.

To offset the problems associated with attempts to cover these broad areas in 300 pages, Professor Burger has extensively documented this coverage by citing 1512 references. Most of these are up to 1980, but several key post-1980 references are included. Unfortunately, several errors appear. For example, isoproterenol is described as the *N*-isopropyl homologue of epinephrine possessing "maximal α-adrenergic properties" (p. 20). Several structures are incorrectly drawn and other seemingly minor, but important, errors occur. For example, chlorisondamine is described as a drug lacking quaternary ammonium groups when, in fact, the opposite is true (p. 33).

Overall, while this project may have been somewhat too ambitious, it does represent another important contribution to the literature of medicinal chemistry by Professor Burger. The book should be of particular interest as background preparation for the organic chemist preparing for a research career in medicinal chemistry.

Sending Unapproved Drugs Abroad

As this column is being written, legislation is being debated in Congress that would allow United States pharmaceutical manufacturers to export drugs that have not been approved for use in this country.

The issue is a highly controversial one with very vocal opponents, as well as proponents, each stirring up considerable public interest in the issue and support for their respective positions. As just one example, several prominent lay newspapers, including the *New York Times* and the *Washington Post*, have published editorials opposing such legislation.

Those opposed generally make the argument that Americans would create "a double standard"; namely, drugs that have not been shown to be sufficiently safe and effective for marketing in the United States and for use by Americans would be sanctioned for export and use by people living in other lands.

Admittedly, that argument appears appealing and persuasive on purely moral or ethical grounds. Political foes who would wish to cast the United States in a bad light undoubtedly could have a field day playing it to their best advantage. Moreover, there is some unfortunate past history—many, many years ago—when unscrupulous manufacturers did use the export market to "dump" substandard batches of deteriorated or otherwise unsuitable drug products.

However, the legislation that is presently under consideration does seem to have provisions that would adequately safeguard foreign consumers from products of inferior quality. Hence, the basic difference today is not one of manufacturing quality, but rather the degree of proof of safety and effectiveness. Put another way, it revolves around the inherent features of the drug entity rather than characteristics of the dosage form or the drug product. And again even in this regard, the present legislation would only permit export to (*a*) countries having a well-regarded drug regulatory agency that could make a valid judgement as to the suitability of the imported drug for that country's population given the specific circumstances involved or (*b*) other countries only if at least one country having a well-regarded drug regulatory agency has approved the drug. No export would be allowed if any agency throughout the world that is comparable to the U.S. Food and Drug Administration had banned or withdrawn the drug on the grounds of its safety or efficacy.

Unfortunately, in presenting their arguments, the major proponents of the legislation have consistently emphasized only the economic considerations involved. They point out, and correctly so, that under current law American manufacturers can establish plants abroad to produce, sell, and distribute the very drugs that they now are prohibited from producing in their U.S. plants to export for exactly the same purpose. The proponents further note that this serves to send abroad investment capital, jobs, and income that otherwise would benefit the U.S. and its citizens. Jobs are lost, the balance of trade is upset, and technology is drained away.

Editor's Note: Dr. Feldmann's editorials are an expression of personal opinion and do not necessarily reflect views or policies of APhA. The editorials are intended to be provocative and to stimulate thinking. Readers having reactions, either pro or con, are invited to submit them for publication in the *Open Forum* section.

These points are all quite valid. However, they neglect to address what is, in our opinion, the most persuasive argument. Specifically, many drugs needed in other parts of the world are intended to treat conditions for which there is virtually no American market and, hence, there is no reason whatsoever for the drug company to expend the time, effort, and expense of seeking U.S. approval.

For example, in late September, a prominent American pharmaceutical firm presented the results of three clinical studies at a session of the XI International Congress for Tropical Medicine and Malaria in Calgary, Canada. The studies involved clinical investigations that were conducted in close collaboration with the World Health Organization.

Based simply on the news releases prepared for the professional press announcing those reports, the results were dramatic and represent a potential public health breakthrough that would greatly benefit a very significant portion of the world's population—virtually none of whom reside in the U.S.

Specifically, a single oral dose of a new antiparasitic drug (identified as "ivermectin") was found to be a highly promising agent for the treatment of the tropical disease known as onchocerciasis or "river blindness."

An estimated 40 million people in Africa, Central and South America, and Yemen in the Middle East are currently afflicted with this disease. Its victims not only suffer blindness, but a whole host of other seriously debilitating conditions. A tiny blackfly which breeds in fast-moving streams carries the developing larvae of the worm that causes onchocerciasis and is the reason why the disease is referred to as "river blindness."

But, according to all three of the studies reported at the International Congress, a single oral dose of ivermectin reduced to near zero in skin snip samples the numbers of microfilariae or tiny worm larvae which cause the disease. And the drug's side effects or toxicity was nominal at most.

It strikes us as not only ironic, but virtually a social injustice, that current American law prevents the American drug manufacturer—that discovered and developed this drug in its U.S. laboratories—from producing and exporting the drug from its U.S. plants for foreign markets. It is now prohibited from doing so because the drug is not approved in the U.S. and, with no incidence of "river blindness" in the U.S., it is a safe assumption that the drug will not be subjected to the very costly and time-consuming process involved in seeking such approval.

Consequently, recognizing the surface arguments that can be cited in opposing the present legislation to relax the prohibition on exporting of American produced drugs not approved in the U.S., it is our belief that the greater good would be served by passage of such legislation.

RESEARCH ARTICLES

Characterization of Polyacryl Starch Microparticles as Carriers for Proteins and Drugs

PER ARTURSSON, PETER EDMAN, TIMO LAAKSO, and INGVAR SJÖHOLM ˣ

Received July 20, 1983, from the *Division of Pharmacy, Department of Drugs, National Board of Health and Welfare, S-751 25 Uppsala, Sweden* and the *Department of Pharmaceutical Biochemistry, Biomedical Center, University of Uppsala, Uppsala, Sweden.* Accepted for publication December 2, 1983.

Abstract □ Biodegradable microparticles of cross-linked starch (maltodextrin) have been designed as carriers of proteins and low molecular weight drugs *in vivo*. Methods are presented for the synthesis of acryloyl starch and its polymerization to microparticles. Macromolecules were immobilized in the microparticles in high yields, *i.e.*, up to 40% of the dry weight consisted of the immobilized protein. The optimal conditions of immobilization were investigated by varying the concentration of starch (D), the concentration of acryloyl groups (T), and the amount of additional cross-linking agent (C). Exclusion of the cross-linking agent gave maximal immobilization of the macromolecules. Enzyme kinetics, release profiles, surface localization, and heat stability of the immobilized macromolecules are also presented. Microparticles based on starch with small amounts of acryloyl groups were completely degraded after incubation with amyloglucosidase. The degradation of microparticles in serum and in the target organelle, the lysosome, was investigated *in vitro*. The polyacrylic starch microspheres (mean diameter, 0.5 μm) constitute an attractive alternative to other drug and enzyme carriers.

Keyphrases □ Drug carrier systems—biodegradable, starch microparticles, lysosomal degradation □ Microspheres—drug carrier system, lysosomal degradation, polyacryl starch

Enzymes have hitherto had relatively limited applications *in vivo* and have essentially been used only for the treatment of blood coagulation disorders. Several problems are associated with the use of enzymes *in vivo*, *e.g.*, the targets of the enzymes are often strictly compartmentalized to specific tissues and cell compartments and administered enzymes cannot readily pass the membranes of these compartments. Furthermore, free enzymes available from human sources are rapidly degraded by proteolytic enzymes. Foreign enzymes, when injected, will induce the formation of antibodies and other immunologic reactions. Systems that will protect the enzymes from degradation and direct them to their specific targets are not yet available. Similarly, suitable carrier systems for low molecular weight drugs are still unavailable for targeting *in vivo*, although several different carriers have been extensively tested (1–4).

Spherical microparticles (<1 μm) made of polyacrylamide or polyacrylic dextran can be used for the immobilization of proteins (5, 6). When the particles are injected intravenously in rats and mice, they are rapidly cleared from the circulatory system by macrophages in the reticuloendothelial system (RES). After uptake, the particles are localized in the lysosomal vacuome (7, 8). This "passive targeting" of microspheres to the RES has been used successfully to treat an artificially induced storage disease in mice (9). However, any system used as an *in vivo* drug carrier must fulfill certain requirements: it must be biocompatible and not induce toxic reactions; it must be biodegradable to avoid accumulation in the tissues; it should be small to avoid respiratory distress after intravenous injection; it must be compartmentalized in such a way that the therapeutic index of the drug or enzyme carried is improved.

This paper describes the preparation and characteristics of biodegradable starch microparticles. The biodegradability of the spheres is investigated *in vitro* with hydrolytic enzymes and an isolated lysosome-enriched rat liver fraction.

EXPERIMENTAL SECTION

Materials—Human serum albumin[1], immunoglobulin G[1], carbonic anhydrase[2], α-amylase[3], amyloglucosidase[2], *N*-acetyl-β-glucoseamidase[2], and lysosyme[4] were used without further purification. *N,N'*-Methylenebisacrylamide[5], 4-methylumbelliferyl-*N*-acetyl-β-D-glucoseamidine[2], *p*-nitrophenyl acetate[2], and the other chemicals used were analytical grade. Hydroxyethyl starch[6] (mol. wt., 400,000; degree of derivatization, 0.7), maltodextrin[7] (mol. wt. 5000), [^{14}C]paraformaldehyde[8], and [^{14}C]starch (prepared from *Nico-*

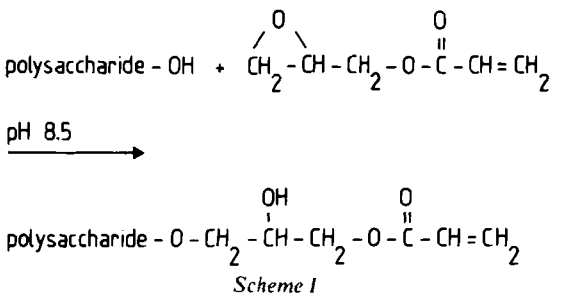

Scheme I

tiana tabacum[9]; mol. wt., 7000–8000) were used without further purification.

Acryloylation of Polysaccharides—Chemical modification of the polysaccharides (Scheme I) with acrylic acid glycidyl ester followed the procedure outlined by Edman *et al.* (7). Maltodextrin or hydroxyethyl starch (10 g) was dissolved in 0.2 M phosphate buffer (pH 8.5) to give a solution of appropriate concentration. Acrylic acid glycidyl ester[10] (10 mL) was added, and the two-phase system was magnetically stirred for up to 15 d. Samples (10 mL) were withdrawn on days 1, 3, 5, 7, 10, and 15 and centrifuged for 15 min at 3000×*g*. Unreacted acrylic acid glycidyl ester was discarded, and the aqueous solution with the derivatized polysaccharide was extracted with 10 parts of toluene to remove remaining unreacted glycidyl ester.

Determination of the Degree of Derivatization of Polysaccharides—The degree of derivatization (acrylic groups/glucose residue) was analyzed by ^{1}H-FT-NMR according to the method of Lepistö *et al.* (10). The measurements were made at 100 MHz on a spectrometer[11] using the water-elimination Fourier transform method. After phase correction of the region containing the acrylic and anomeric proton resonances (δ 4.8–6.7 ppm) the region was integrated. The signals of the anomeric proton (δ 4.8–5.8 ppm) were used as internal standard.

Preparation of Polyacryl Starch Microparticles—Microparticles with or without protein were prepared as described previously (5, 6). Protein and, when applicable, bisacrylamide were dissolved in a solution of acryloylated maltodextrin or in acryloylated hydroxyethyl starch in 0.2 M sodium phosphate buffer, pH 8.5. EDTA (1×10^{-3} M) and ammonium peroxodisulfate were added to the deoxygenated mixture. The water solution (5–10 mL) was homogenized with poloxamer 188[12] in 600 mL of chloroform–toluene (1:4) to produce a water-in-oil emulsion. On addition of *N,N,N′,N′*-tetramethylethylenediamine the water phase droplets were polymerized to microparticles. The microparticles were freed from the organic phase and nonimmobilized protein by repeated washings with buffer.

The microparticle composition is characterized by the D-T-C nomenclature suggested by Hjertén (11), as modified by Edman *et al.* (6). The D-T-C values denote the amounts of the components in the monomer solution used for particle formation: D denotes the concentration of derivatized macromolecules (*i.e.*, acryloylated starch, g/100 mL); T denotes the total concentration of acryloyl groups (g/100 mL); C is the relative amount of the cross-linking agent, bisacrylamide, expressed as the percentage (w/w) of the total amount of acrylic monomers.

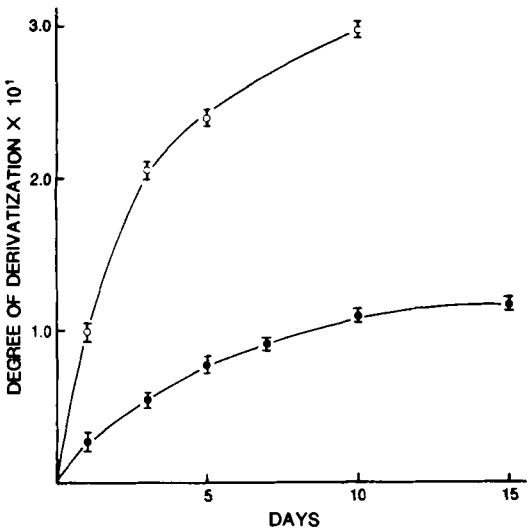

Figure 1—*Derivatization of the polysaccharides. The degree of derivatization (acrylic groups per glucose residue) of maltodextrin (●) and hydroxyethyl starch (○) are expressed as mean values ± SD (n = 5 and 3, respectively).*

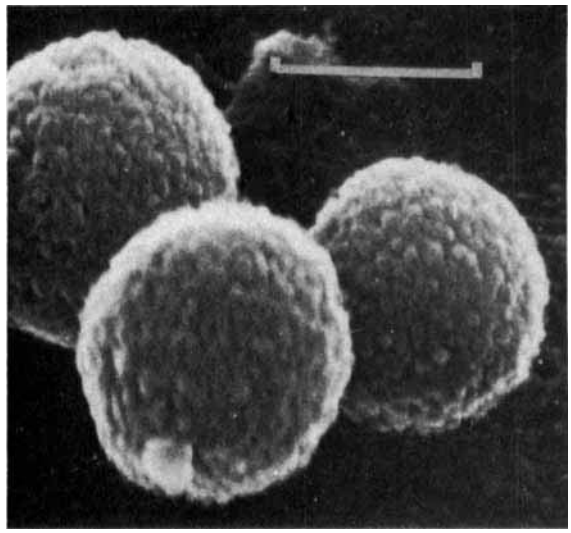

Figure 2—*Scanning electron micrograph (30,000×) of polyacryl starch microparticles (D-T-C 10-0.2-0). The bar indicates 1 μm.*

Radioactive Labeling of Polyacryl Starch Microparticles—Two types of radioactive labels were used. The label was introduced with ^{14}C-labeled *N,N′*-methylenebisacrylamide as the cross-linking agent or with [^{14}C]starch as part of the monomers. In the former case, the labeled derivative was prepared from [^{14}C]paraformaldehyde and acrylamide according to Feuer and Lynch (12) as described by Sjöholm and Edman (7). The radioactive starch was derivatized with acrylic acid glycidyl ester together with the polysaccharides used in the particle preparation.

Protein Determination—The amount of protein incorporated in the microparticles was determined with an automatic amino acid analyzer after hydrolysis in 6 M HCl at 105°C for 20 h. The amount of protein leaking from the microspheres was measured by the method of Lowry *et al.* (13). In each case, the protein studied was used as a standard. In some experiments, ^{125}I-human serum albumin was used to determine the protein content of the microparticles and to follow the leakage of the albumin from the particles.

Determination of Carbonic Anhydrase Activity—The activity of carbonic anhydrase was determined with the chromogenic substrate *p*-nitrophenyl acetate (14). The assay mixture consisted of 4.7 mL of 0.05 M Tris buffer (pH 7.4), 0.25 mL of substrate solution in absolute ethanol at the appropriate concentration, and 0.05 mL of the enzyme (immobilized or in free form) in Tris buffer. The formation of the hydrolysis products was followed spectrophotometrically at 400 nm at room temperature. The velocity of the reaction is the initial increase in absorbance during 1 min. Correction was made for the spontaneous hydrolysis of the substrate in samples that did not contain the enzyme; the particle matrix did not affect the reaction rate (results of control experiments). Furthermore, the particles did not cause light scattering at this wavelength, and no sedimentation was detectable during the time of measurement.

Determination of the Functional Capacity of Immobilized Human Serum Albumin—The functional capacity of immobilized albumin was determined by the method of Kober *et al.* (15). Microparticles containing albumin were incubated with a fixed concentration of [^{14}C]salicylic acid. After centrifugation, the concentration of the free drug was determined by measuring the radioactivity in the supernatant. The amount of salicylic acid bound to albumin was calculated from the percent binding and from a standard curve derived by equilibrium dialysis with different albumin concentrations.

Iodination of Human Serum Albumin—Human serum albumin (10 mg) in 0.5 mL of 0.05 M phosphate buffer (pH 7.3) containing 0.15 M NaCl was labeled with [^{125}I]NaI (1 mCi) in the presence of lactoperoxidase (20 μg) and hydrogen peroxide (0.03% v/v, 20 μL added 3 times at 3-min intervals) according to the method of Phillips and Morrison (16). The reaction was terminated after 10 min by diluting the sample with chilled buffer. The ^{125}I-labeled human serum albumin was isolated from the reaction mixture by gel filtration on a Sephadex G-25 column.

[a] The study was carried out with 100 mg of ^{125}I-labeled human serum albumin/mL of aqueous buffer. The protein content of the particles was determined in a gamma counter. The amount of functionally active protein in the particles was determined by estimating the capacity of the albumin to bind [^{14}C]salicylic acid (15). [b] Not determined. [c] Determined after 50 d.

Determination of Radioactivity, Particle Size, and Density—β-Emitting isotopes were determined in a scintillation counter[13]; the counting efficiency was calculated with an external standard. Iodine-125 was measured in a gamma scintillation counter[14].

The size of the particles was determined from photographs taken with a scanning electron microscope (7). Using this technique, 85% of the microparticles had a diameter of 0.2–1.0 μm; 15% were 1.0–1.6 μm in diameter.

The densities of the microparticles were determined by density gradient centrifugation in colloidal silica coated with polyvinylpyrrolidone[15] (17) utilizing a gradient ranging from 1.02 to 1.10 g/cm^3, obtained with a dual-chamber gradient maker. Density marker beads[16] were used to monitor the gradient according to the manufacturer's specification. The gradient volume was 10 mL. Microparticles (0.5–2.5 mg) in 300 μL of physiological saline were applied to the top of the gradients, which were centrifuged at 400×g for 25 min using a swing-out rotor.

Isolation of a Lysosomal Fraction from Rat Liver Homogenate—The isolation of the lysosomal fraction followed the technique outlined by Beaufay (18). Livers from male Sprague–Dawley rats, which were fasted for 12 h, were removed rapidly and immersed in a beaker containing ice-cold 0.25 M sucrose (pH 5.5). After weighing, the tissue was cut into pieces and homogenized with 3 volumes of the medium in a Potter–Elvehjelm homogenizer. The homogenate was centrifuged at 4°C and 750×g for 10 min. The sediment was redispersed three times and centrifuged. The resulting supernatants were pooled and centrifuged at 12,000×g for 10 min. The supernatant was discarded and the pellet was dissolved in 0.25 M sucrose and centrifuged for 10 min at 6500×g. This step was repeated three times and the supernatants were combined and centrifuged for 15 min at 12,000×g. The resulting sediment was dispersed in water (pH 4.5) and made up to a final volume equal to that of the original tissue. The suspension was frozen and thawed twice before use. The isolated lysosome-enriched fraction was usually preserved with penicillin G. The partition of lysosomes in the different fractions during the preparation was followed by assay of the lysosomal enzyme, N-acetyl-β-glucoseamidase. The enzyme was determined by using 4-methylumbelliferyl-N-acetyl-β-D-glucoseamidine as substrate in 0.15 M acetate buffer, pH 4.2 (19).

Enzymatic Solubilization of Microparticles—α-Amylase (10 U/mL in 0.1 M phosphate buffer, pH 5.5) or amyloglucosidase (0.1–10 U/mL in 0.1 M citrate buffer, pH 4.5) was added to 0.5 mg of radioactive microparticles in the same buffer to give a final volume of 2.0 mL. In other experiments, 1.0 mL of pooled human serum or 1.0 mL of the lysosomal fraction was added to 1.0 mL of radioactive microparticles (0.5 mg dry weight). After incubation at 37°C for 0.5–6 h the particles were centrifuged (3000×g) and the radioactivity in 1.0 mL of the supernatant was measured before or after filtration through a 0.45-μm membrane filter. In some of the experiments, the radioactive degradation products were separated on a Sephadex G-150 column. The degradation products (5 mL) were applied on a 2.6 × 100-cm column. The separation was performed with 0.01 M phosphate buffer (pH 7.4) containing 0.15 M NaCl as the elution medium.

Size Determination of Microparticle Aggregates—Microparticles (100 μL, 50 μg) were suspended in 150 mL of particle-free buffer[17]. The suspensions were used in a particle counter[18], which simultaneously counts particles in 14 size classes. The instrument was fitted with a 50-μm orifice tube. During all measurements the speed and stirrer position were constant. The mean diameters of each size class of suspended microparticles were calculated[19] from the particle distribution.

In some experiments, microparticles containing human serum albumin were incubated with a specific antiserum (*i.e.*, 50 μL of rabbit anti-human serum containing 3.6 mg of immunoglobulin G/mL) in an end-over-end mixer for 45 min prior to the estimation of the mean diameter. In control experiments, the microparticles containing human serum albumin were incubated with 0.15 M NaCl, or empty microparticles were incubated with the corresponding antiserum.

RESULTS

Derivatization of Polysaccharides—The introduction of acryloyl groups into hydroxyethyl starch and maltodextrin with acrylic acid glycidyl ester was followed by NMR for 10 and 15 d, respectively. Hydroxyethyl starch reacted more rapidly and more extensively than maltodextrin (Fig. 1); every 3rd glucose residue was substituted after 10 d compared with every 10th glucose unit for maltodextrin. The higher reaction rate with hydroxyethyl starch can most probably be ascribed to the presence of the hydroxyethyl groups. With maltodextrin, a plateau was reached after ~10 d.

Immobilization of Proteins in Microparticles of Different Composition—Table I summarizes results from the incorporation of ^{125}I-labeled human

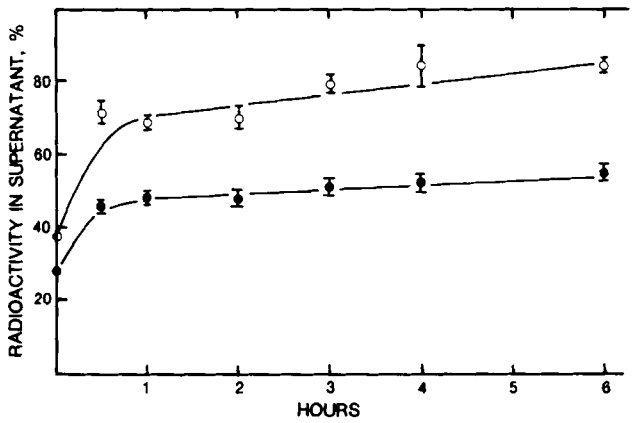

Figure 3—In vitro *digestion of ^{14}C-labeled microparticles in a lysosome-enriched fraction. Maltodextrin particles with D-T-C of 10-0.2-0 (○) and 10-0.4-0 (●) were preincubated in pooled human serum for 1 h prior to incubation with the lysosomal fraction. Mean values* ± SD (n = 3–6).

serum albumin in polyacryl starch microparticles. Three series of experiments were run, varying total concentration of starch (D), total concentration of acrylic groups (T), and degree of cross-linking (C). A decrease of acryloylated starch (D) in the particles decreases the total yield of immobilized protein as well as the yield of particles.

Increase of the concentration of acrylic groups (T) (acryloylated maltodextrin or hydroxyethyl starch) in the aqueous phase resulted in an increase in the amount of albumin immobilized in the particles. The maximal amount of albumin which could be incorporated corresponded to 37% of the dry weight (particles based on maltodextrin and a D-T-C value of 10-0.4-0). The relative amount of cross-linking agent (C) also had an influence on the total protein yield; particle yield and protein content decreased when the cross-linking agent bisacrylamide was introduced into maltodextrin microparticles. The functional capacity of immobilized albumin to bind salicylic acid varied between ~40 and 95%. No systematic trend could be detected; high C values possibly improve the functional capacity.

Microparticle Density, Surface Structure, and Protein Leakage—The density of polysaccharide microparticles was 1.04–1.07 g/mL, which is somewhat lower than that obtained with polyacrylamide particles (5). The density essentially followed the content of acryloyl groups, when both maltodextrin and hydroxyethyl starch were studied. Thus, when T was increased from 0.2 to 0.4, the density of maltodextrin particles increased from 1.04 to 1.06 g/mL. The density was the same when the particles contained up to 30% human serum albumin.

Microparticles based on maltodextrin or hydroxyethyl starch have a surface structure quite different from that of highly cross-linked polyacrylamide particles. The particles have a relatively smooth surface structure with smaller pores (Fig. 2) than polyacrylamide particles with a T-C value of 8-25 (5).

The leakage of ^{125}I-human serum albumin from the microparticles (Table I) was investigated to study the influence of the microparticle composition on the protein fixation within the polymer. Variations in leakage were observed with T and C changes. The maltodextrin microparticles with few acryloyl groups leaked more than particles with higher T values. The hydroxyethyl starch microparticles were generally not as leaky as the maltodextrin spheres; no systematic change was found when T was varied.

When the cross-linking agent *N,N'*-methylenebisacrylamide was added to the maltodextrin microparticles, the leakage of ^{125}I-human serum albumin was accelerated. This is consistent with previous findings that microparticle pore radius increases with the addition of a cross-linking agent (5).

Storage of the microparticles at −20°C was also studied. Maltodextrin microparticles with compositions of 10-0.2-0, 10-0.4-0, and 10-0.4-25 and a batch of hydroxyethyl starch microparticles (10-0.8-0) lost no particle-bound protein when stored at −20°C for 8 weeks.

Table III—Degradation of Maltodextrin Microparticles in Serum and in a Lysosome-Enriched Fraction[a]

Microparticle Composition, D-T-C	Solubilized Radioactivity, %[b] Incubation in Serum, 1 h	Incubation in Lysosomal Fraction, 1 h	Incubation in Lysosomal Fraction, 6 h
	Empty Microparticles		
10-0.2-0	21.8 ± 1.8	44.4 ± 3.2	51.1 ± 3.2
10-0.4-0	12.6 ± 0.8	30.8 ± 1.4	36.4 ± 3.2
10-0.4-20	10.8 ± 2.3	29.2 ± 3.3	53.5 ± 7.8
	Protein-Containing Microparticles[c]		
10-0.2-0	38.0 ± 0.9	68.3 ± 1.4	83.5 ± 2.4
10-0.4-0	28.5 ± 2.3	47.9 ± 3.2	54.3 ± 3.4
10-0.4-20	40.6 ± 1.5	66.5 ± 2.1	73.8 ± 2.4

[a] The [^{14}C]starch-labeled particles were preincubated for 1 h in serum before further incubation in the lysosomal fraction. Mean values ± *SD* for incubation in lysosomes ($n = 3$–6) and incubation in serum ($n = 18$). [b] Cumulative values. [c] Human serum albumin, 100 mg/mL of the aqueous phase.

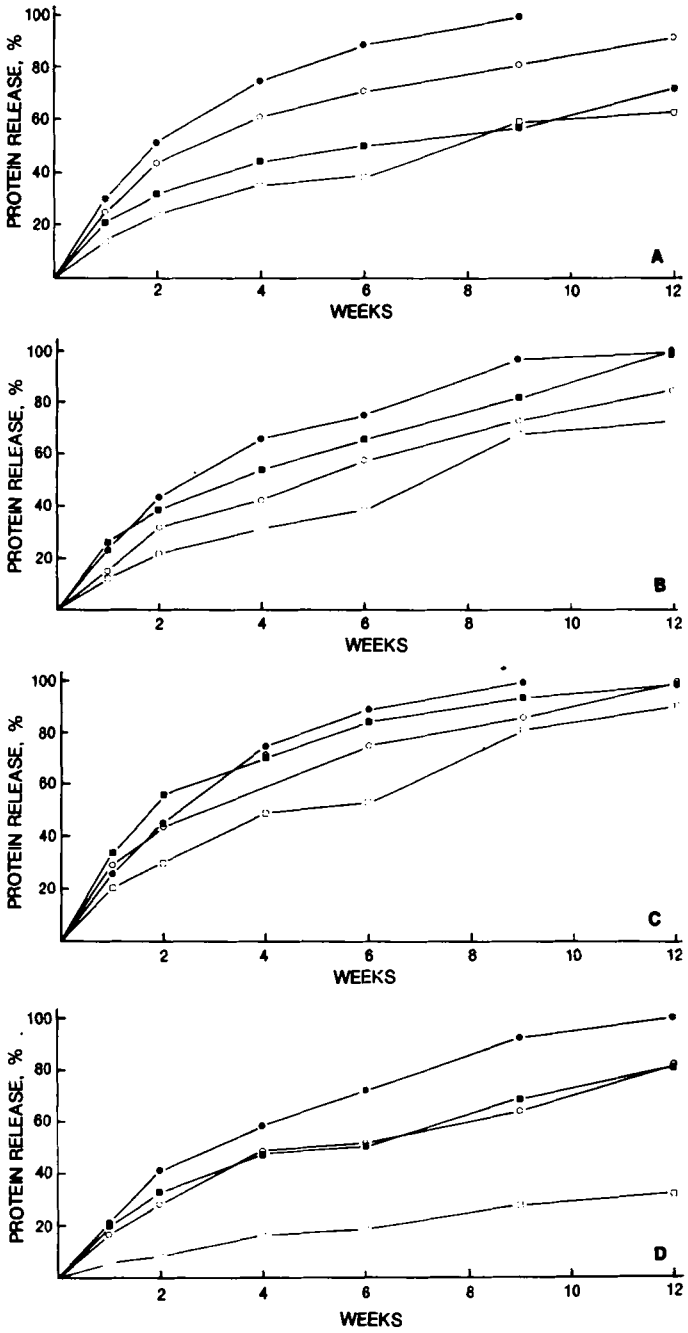

Figure 4—*Release of immobilized proteins during storage at room temperature from microparticles of maltodextrin with D-T-C of 10-0.2-0 (A), 10-0.4-0 (B), and 10-0.4-25 (C) and hydroxyethyl starch with D-T-C of 10-0.8-0 (D). The immobilized proteins were lysozyme (●), human serum albumin (○), carbonic anhydrase (■), and immunoglobulin G (□).*

Enzymatic Degradation of Polyacryl Starch Microparticles—The particles in Table I (0.5 mg dry weight) were incubated with α-amylase, and the release of ^{125}I-human serum albumin was compared with the controls. Maltodextrin microspheres with the D-T-C compositions of 10-0.2-0, 10-0.3-0, and 10-0.4-0 released 27, 24, and 26% of the entrapped radioactivity in 1 h, respectively. Spheres containing bisacrylamide had a lower release, *e.g.*, 15% (D-T-C 10-1.2-60). No significant increase in radioactivity was found in the supernatants when hydroxyethyl starch microspheres were incubated with α-amylase.

The degradation of the starch matrix by amyloglucosidase was investigated for maltodextrin microparticles of different compositions (D-T-C 10-0.2-0, 10-0.4-0, and 10-0.4-25) containing acryloylated ^{14}C-labeled starch and albumin (Table II). The particles were incubated with amyloglucosidase (10 IU/mL) for 3 h at 37°C. Particles with few acrylic groups (D-T-C, 10-0.2-0) were totally solubilized, and all radioactivity was regained in the supernatant

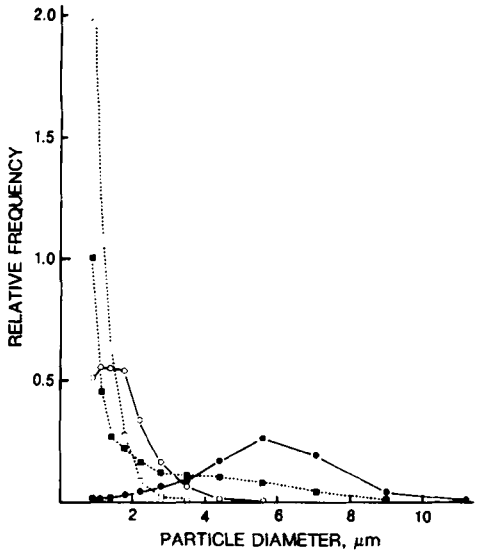

Figure 5—*Size distribution of maltodextrin microparticles (D-T-C 10-0.4-25), including the frequency by weight before (○) and after (●) incubation with specific antiserum and the frequency by number before (□) and after (■) antiserum addition. The relative frequency was obtained by division of the frequency values by the class width.*

after 3 h. When the degradation mixture was gel-filtered on a Sephadex G-150 column, 30% of the radioactivity was obtained in the void volume and 70% in the low molecular weight region. Identical results were obtained when particles with the same composition containing ^{125}I-human serum albumin were incubated with amyloglucosidase. The ^{125}I-albumin-containing microparticles were completely dissolved in 3 h. Spheres containing 0.4% (w/w) acrylic groups (D-T-C 10-0.4-0) or a cross-linking agent (D-T-C 10-0.4-25) were more stable, and 59 and 69%, respectively, of the radioactivity was detected in the supernatant after incubation for 3 h.

The microparticles were also affected by fresh human serum (Table III). Incubation of 0.5 mg of ^{14}C-labeled particles in serum for 1 h at 37°C gave a release of 11-41% of the radioactivity, depending on the particle composition and immobilized protein content. "Empty" spheres and spheres with a high amount of acrylic groups (high T value) were relatively stable in serum, *e.g.*, particles with a D-T-C of 10-0.2-0 containing no protein were 22% digested compared with 38% when albumin was present. Microparticles (D-T-C, 10-0.4-0) containing albumin were solubilized 28% after a 1-h incubation, compared with 38% when spheres with D-T-C 10-0.2-0 were used. However, the rate of degradation was increased when the particles contained protein and a cross-linking agent. The increased rate probably depends on a better penetration of the particles by the enzymes, as both the proteins and increased C may increase the pore radius of the particles. No further degradation was seen when the incubation time was increased to 6 h.

In an attempt to simulate the biological conditions of particles after intravenous injection, the spheres were preincubated in fresh serum for 1 h prior to incubation with isolated rat liver lysosomes for 1 and 6 h (Table III, Fig. 3). Particles with a D-T-C of 10-0.2-0 were highly affected, and ~84% of the radioactivity in the spheres was regained in the supernatant after incubation for 6 h. Particles with larger T, (D-T-C, 10-0.4-0) were more stable; 54% of the spheres were metabolized after 6 h. Corresponding "empty" microspheres were more inert under these conditions. Empty spheres with a D-T-C of 10-0.2-0 were degraded 51% as compared with 84% when the particles contained albumin (Table III).

When the microparticles were incubated directly in the lysosomal fraction, *i.e.*, without preincubation in serum, the amount of solubilized radioactivity after a 6-h incubation was the same as with preincubation. Thus, the metabolism of polyacryl starch microparticles is related to the protein content and the composition of the particle.

Immobilized Proteins in Polyacryl Starch Microparticles—Further studies were performed with three different batches of maltodextrin microparticles and one batch made of hydroxyethyl starch. The maltodextrin microparticles had compositions 10-0.2-0 (I), 10-0.4-0 (II), and 10-0.4-25 (III). The hydroxyethyl starch microspheres (IV) had a composition of 10-0.8-0.

Release Profiles—Microparticles were prepared with proteins of various sizes: lysozyme [mol. wt. 14,400 (20)], carbonic anhydrase [mol. wt. 31,000 (21)], human serum albumin [mol. wt. 66,500 (22)], and human immunoglobulin G [mol. wt. 150,000 (23)]. The spheres were suspended in buffered physiological saline, pH 7.4 with sodium azide (0.1%) added as a preservative.

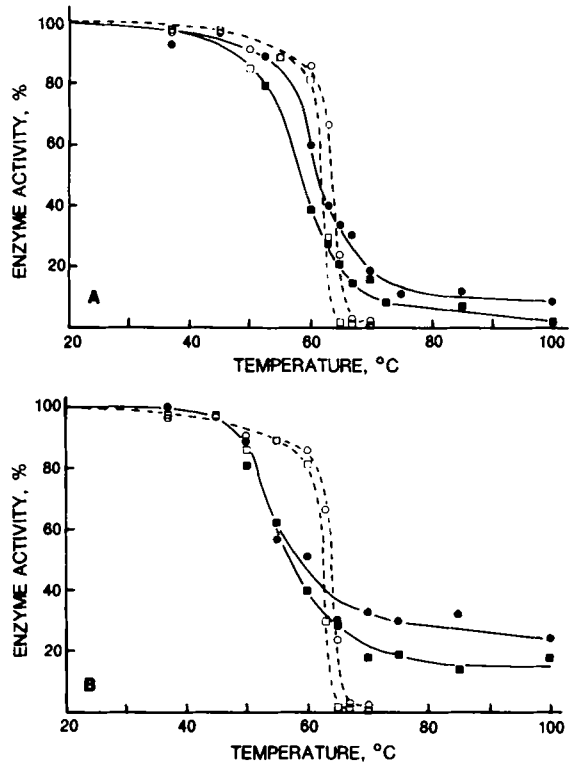

Figure 6—*Thermostability of carbonic anhydrase immobilized in maltodextrin microparticles with D-T-C of 10-0.2-0 (A) and 10-0.4-0 (B) compared with that of the free enzyme. The remaining activity was measured after heating the enzyme for 5 (○, ●) and 30 (□, ■) min. The open symbols represent free enzyme; the solid symbols represent particle-bound enzyme.*

The samples were left at room temperature (22°C) for 1, 2, 4, 6, 9, and 12 weeks. The protein released from the spheres after centrifugation (Fig. 4) was determined by the method of Lowry *et al.* (13).

The most pronounced release, irrespective of particle composition, was obtained when lysozyme was used (Fig. 4A): 100% of the lysozyme was released in 9-12 weeks, depending on the gel composition. Also, release rates generally decrease with increasing molecular weight independent of particle composition. Microparticles containing bisacrylamide as a cross-linking agent (III) (Fig. 4C) released the proteins most rapidly; ~90-100% of the incorporated protein was lost after 12 weeks, irrespective of molecular weight.

Surface Localization—The localization of proteins on the surface of the microparticles can be studied conveniently by adding specific antiserum and following particle aggregation with a Coulter Counter equipped with a computer program. The Coulter Counter cannot detect particles <0.8 μm with the 50-μm orifice tube and does not give an exact measure of the true mean diameter of the microparticles. The results, therefore, cannot be compared with those obtained with the electron microscope, but the method does give a relative measure of the changed size distribution (by number and volume) when the antiserum is added to the microparticles. The mean diameter, based on volume, increased from 2.04 ± 0.82 μm to 5.66 ± 1.65 μm when III microparticles with immobilized human serum albumin were incubated with rabbit anti-albumin serum (Fig. 5). The mean diameter, by number, was also calculated, and a similar increase was noted (Fig. 5). Increases in diameters were also detected for microparticles of other compositions. Empty microparticles did not aggregate after addition of the antiserum.

To further investigate the nature of the surface-localized albumin, the study was repeated after 8 weeks with the same batch of particles. At that time ~50% of the protein had leaked from the spheres (Fig. 4). No significant changes in the aggregation patterns of the washed microparticles could be detected with the Coulter Counter. Obviously, a significant fraction of the immobilized albumin is stably bound on the surface and available for interaction with the antibodies.

Heat Stability—To investigate the effect of immobilization in polyacryl starch microparticles on the stability of proteins, carbonic anhydrase was incorporated into the microparticles. The spheres were exposed to elevated temperatures for 5 or 30 min. After treatment, the spheres were immediately cooled in an ice bath for 5 min. The samples were then incubated at room temperature for 30 min, and the remaining activity was determined. It is apparent that the microspheres protect the enzyme against heat denaturation

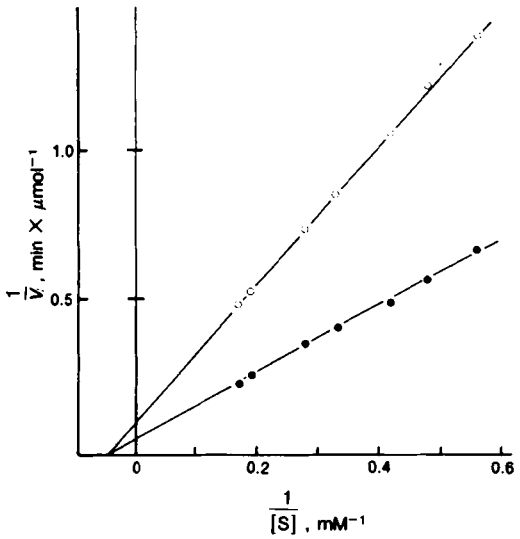

Figure 7—*Lineweaver-Burk plots for the enzymatic activity of carbonic anhydrase in maltodextrin microparticles (D-T-C 10-0.2-0) (○) and free (●) form.*

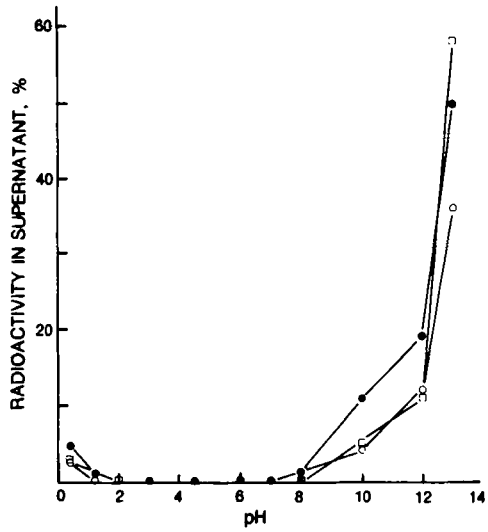

Figure 8—*Stability of ^{14}C-labeled maltodextrin microparticles at different pH. The particles were incubated at 37°C for 12 h. Key to D-T-C values: (●) 10-0.2-0; (○) 10-0.4-0; (□) 10-0.4-25.*

(Fig. 6). Depending on the composition of the spheres, the enzymatic activity after 30 min at 100°C varied between <5 and 20%. Microparticles containing 0.4% acrylic groups (w/w), *i.e.*, II (Fig. 6B), gave better protection against heat than spheres with T = 0.2 (I) (Fig. 6A). The use of a cross-linking agent (III) or hydroxyethyl starch (IV) did not improve the thermal stability of carbonic anhydrase.

Enzymatic Properties of Immobilized Carbonic Anhydrase—To assess the effect of entrapment on the function of the immobilized enzymes, the Michaelis-Menten constant (K_m) of carbonic anhydrase was determined. Regression analysis showed that the Lineweaver-Burk plots for immobilized and soluble enzyme were linear over the entire range of concentrations studied. The calculated K_m for native carbonic anhydrase was 18 mM; for immobilized enzyme, it was 18-24 mM. The increase in K_m by immobilization (irrespective of microsphere composition) is probably due to a limited diffusion rate of substrate and/or reaction products, as observed in other immobilized enzyme systems (24-26).

The maximal reaction rate (v_{max}) of the immobilized enzyme, in I particles, was compared with that of the native enzyme (Fig. 7). The v_{max} of the immobilized enzyme, as calculated from the ordinate intercept, was 58% of that of the free enzyme. Based on amino acid analysis, the amount of enzyme in the two experiments was the same. The enzymatic activity, therefore, is more inhibited in the polyacryl starch particles than in macroporous polyacrylamide microparticles (27).

pH Stability of Polyacryl Starch Microparticles—The pH stability of the polymer matrix was investigated with ^{14}C-labeled starch. The hydroxyethyl starch particles (IV) could not be studied because labeled hydroxyethyl starch is not available and incorporation of ^{14}C-acryloylated starch in these particles would result in inadequate labeling of the particle matrix. The maltodextrin microspheres were incubated at pH 0.4-13 for 12 h at 37°C. Aliquots were withdrawn from the supernatants after centrifugation, and the radioactivity was measured (Fig. 8). The microparticles were stable at pH 2-8. At pH 12, ≤19% of the particles were solubilized; at pH 12.8, ≤58% of the radioactivity was lost from the microparticles. Acidic pH (≥1.2) did not significantly affect the microparticles; at pH 0.5, 5% (at most) was solubilized in 12 h.

DISCUSSION

In our earlier work, small particles were prepared for protein immobilization by polymerization of either acrylic groups in acrylamide and *N,N'*-methylenebisacrylamide to form polyacrylamide microparticles (5) or acrylic groups of acryloyldextran and *N,N'*-methylenebisacrylamide to form polyacryldextran particles (6). These two types of microparticles are only slowly metabolized *in vivo*, with $t_{1/2}$ values of 10-20 weeks (7, 28). The half-life is directly related to the amount of hydrocarbon chains formed during the polymerization (and to some extent to the presence of dextran, which is slowly degraded in the lysosomes). These particles will probably find only limited applications *in vivo*.

In the present paper, a low molecular weight fraction of starch (maltodextrin; mol. wt. 5000) and a preparation of hydroxyethyl starch (mol. wt. 400,000), which are water soluble, were used. The starch compounds were modified with acrylic acid glycidyl ester and polymerized in a water-in-oil emulsion to form small particles; the particle size is essentially determined by the dispersion degree of the emulsion. The cross-links in the microparticles, the hydrocarbon chains, are formed by the acryloyl groups, but their contribution to the matrix structure can be much lower (0.3-0.4% in the polymerization mixture) than in polyacrylamide and polyacryldextran particles. This means that the main part (>95%) of the matrix is composed of maltodextrin or hydroxyethyl starch and will be easily degraded by lysosomal enzymes (maltodextrin particles). The degradation of the maltodextrin microparticles has been followed with ^{14}C-labeled starch from *Nicotiana tabacum* (about the same molecular weight as maltodextrin) included in the microparticles and treated as described for maltodextrin. Unfortunately, no labeled hydroxyethyl starch could be obtained, and consequently, no reliable studies to follow the degradation of hydroxyethyl starch particles have been possible. However, information is available on the metabolism of underivatized hydroxyethyl starch, which is extensively used as a plasma expander in humans. The half-life of hydroxyethyl starch (mol. wt. 450,000; degree of derivatization 0.70) in the spleen and liver of the rat is ~64 and 132 d, respectively (29). It may therefore be concluded that hydroxyethyl starch microparticles are more slowly metabolized than maltodextrin microparticles. Such microparticles are, therefore, the carrier of choice when a prolonged protection of the immobilized material is more essential than a rapid degradation of the particle matrix.

The degradation of the starch particles has been followed *in vitro* in a lysosome-enriched fraction from rat liver prepared by differential centrifugation, in serum, and with isolated enzymes. Maltodextrin particles were relatively rapidly degraded by the lysosomal enzymes; >80% of the radioactivity (originating from the starch matrix) was found in the supernatant after 6 h from particles with a D-T-C of 10-0.2-0, and ~50% from particles with a D-T-C of 10-0.4-0. In serum, with α-amylase, or with amyloglucosidase, the solubilization was faster with the less-modified maltodextrin. When the cross-linking degree was increased by adding *N,N'*-methylenebisacrylamide (yielding particles with a D-T-C of 10-0.4-25) the rate of degradation consistently increased. An increased rate of degradation was also seen when the particles contained immobilized protein. In both of these situations the enzymes could better penetrate the particles and hydrolyze the starch, since both proteins and increased C increase the pore radius (5).

In addition to ^{14}C-labeled starch, the degradation of the different particles was studied with immobilized ^{125}I-human serum albumin or ^{14}C-labeled *N,N'*-methylenebisacrylamide, which gave consistent results. As expected, hydroxyethyl starch particles were resistant to α-amylase and amyloglucosidase treatment. On the other hand, maltodextrin particles (D-T-C 10-0.2-0) were totally solubilized by amyloglucosidase in 3 h, and gel filtration revealed that ~70% of the radioactively labeled starch was regained in the low molecular weight fraction. We thus conclude that the derivatization of starch with acrylic acid glycidyl ester has not profoundly changed the biodegradability; enzymes normally found in animal tissues can dissolve maltodextrin microparticles *in vitro*. Whether the same extensive metabolism of these microparticles can happen *in vivo* and the degradation products can be completely eliminated from the macrophages of the reticuloendothelial system

remains to be seen. Preliminary results[20] indicate that maltodextrin microparticles are metabolized and eliminated *in vivo*, which means that degradation products can also pass the lysosomal membrane.

It is obvious that T (specified essentially by the derivatization degree of the starch) and C (the fraction of added *N,N'*-methylenebisacrylamide) are important factors in the microparticle matrix structure and, therefore, also in biodegradation. The structure will determine the amount of proteins immobilized, their leakage, and the stability of the immobilized proteins towards heat denaturation. The macrostructure of maltodextrin particles, as seen in the electron microscope, is obviously smoother than that of polyacrylamide (T-C 8-25) which exhibits a macroporous structure (5). In the polyacrylamide microparticles, thick bundles of polymer threads are formed, in which the proteins are fixed. The proteins are partly exposed on the surface and can interact with cells (30). Even if biodegradable starch microparticles are not cross-linked to the same extent, proteins obviously can be stably bound on the surface in such a way that they interact with antibodies and form large aggregates.

The pores of polyacryl starch particles are thus smaller than those of highly cross-linked polyacrylamide particles. This means that the initial yield of immobilized proteins will be significantly larger because a larger fraction will be entrapped inside the formed network; the larger the Stokes radius of the protein, the more will be immobilized. Under standard conditions (100 mg of protein/mL of aqueous phase), 35-40% of the dry weight is protein, as shown with human serum albumin. The functional capacity, however, is generally not >40-60%, and ~50% of the protein is released from the particles in 6 weeks. These figures indicate that the fraction of protein trapped inside the particles, and not physically fixed in the polymeric network, is much larger than in the polyacrylamide particles. Moreover, the diffusion of low molecular weight ligands or substrates becomes restricted as the functional binding capacity of human serum albumin is decreased, and the enzymatic activity (K_m, v_{max}) of carbonic anhydrase is impaired. The polymer concentration (T) in the microparticles also influences the thermal stability, which is not greatly increased when T = 0.2%. It is important to note that the polymer concentration in the particles is high enough to guarantee that molecules are localized on the surface and that antibodies can form aggregates with the microparticles. This means that polyacryl starch microparticles could be used for specific targeting within the central compartment *in vivo*. In such a system, specific antibodies may be the instrument to target the microparticles to pathological cells in the circulation (*e.g.*, leukemia cells) or to eliminate circulating macromolecules (*e.g.*, antibodies or immune complexes).

Any drug carrier system designed for injection must be degradable. The metabolism of the polyacryl starch microparticles can be varied within wide limits, and the bulk of the matrix (the maltodextrin fraction) can be completely broken down by endogenous enzymes. The metabolism of the remaining part (the hydrocarbon chains from the acryloyl groups) must be further studied, but in the present system the fraction is small. However, the hydrocarbon chains are the decisive factor in the rate of degradation *in vivo*, which must be chosen according to need in the specific situation. As has been clearly demonstrated, polyacryl starch particles (D-T-C 10-0.4-0 or 10-0.2-0) are degraded in normal serum, and 30-40% of the starch is solubilized in 1 h. The half-life of microparticles in the circulatory system after intravenous injection is also ~1 h (7, 24). It is thus obvious that the derivatization of the starch must be high enough to give a reasonable stability in the circulation to ensure transport of the immobilized material to the target. Our experiments have shown that the leakage of immobilized proteins largely follows the degradation of the microparticles. The composition of the carrier system is thus a compromise: it must persist long enough in the circulatory system and yet must be metabolized rather quickly within the target organ. This principle is valid when the carrier is used for the immobilization of low molecular weight substances (*e.g.*, drugs) or proteins (*e.g.*, enzymes). Moreover, in some situations it is essential to control the release of active material from the carrier within the target cells, *e.g.*, to correlate the rate of release and the rate of denaturation of an enzyme. In such situations, it is important that the metabolism of the carrier can be anticipated and controlled. This is true for the polyacryl starch microparticles.

Adsorption of Pepsin by Aluminum Hydroxide I: Adsorption Mechanism

ROBERT J. SEPELYAK *, JOSEPH R. FELDKAMP ‡, TIMOTHY E. MOODY ‡, JOE L. WHITE ‡, and STANLEY L. HEM *x

Received July 18, 1983 from the *Departments of *Industrial and Physical Pharmacy and ‡Agronomy, Purdue University, West Lafayette, IN 47907.* Accepted for publication February 9, 1984.

Abstract □ Adsorption of pepsin by gibbsite and boehmite, non-acid-reactive forms of aluminum hydroxide, was observed and related to the surface area of the adsorbent. Adsorption was pH dependent, with maximum adsorption occurring between pH 2.7–3.3 for gibbsite and pH 2.7–4.3 for boehmite. Electrostatic attraction was an important adsorption mechanism at the pH conditions encountered in the GI tract; the isoelectric point of pepsin was ~1, giving it a negative charge, and the point of zero charge for the adsorbents was >9, giving them a positive charge. However, the pH–adsorption profile can not be fully explained by electrostatic considerations. Desorption studies indicate the importance of specific adsorption because pepsin was not desorbed by washing with acidified water, but was partly desorbed by exchange with phosphate. The IR spectrum of adsorbed pepsin also suggested that specific adsorption of pepsin occurred through anionic ligand exchange involving carboxylate groups of pepsin and surface aluminum ions.

Keyphrases □ Aluminum hydroxide—adsorption, pepsin □ Pepsin—adsorption by aluminum hydroxide □ Adsorption—pepsin by aluminum hydroxide

Aluminum hydroxide is widely used in peptic ulcer therapy. Recent clinical studies, which have shown that aluminum hydroxide-containing antacid products are effective in healing ulcers (1–3), have stimulated interest in the mechanism by which antacids act to heal ulcers. The Food and Drug Administration's OTC Panel on Antacids suggested that the neutralization of gastric acid was the only mechanism of action (4). Because the activity of pepsin is pH dependent, the neutralization of gastric acid will affect the activity of pepsin. Piper and Fenton (5) concluded that one mechanism by which aluminum hydroxide reduced pepsin activity was to raise the pH of the gastric fluid. Kuruvilla (6) concluded that antacids in general reduce pepsin activity by raising the gastric pH. Piper and Fenton (7) also stated that antacids which raise the gastric pH to 4–5, *i.e.*, aluminum hydroxide, only temporarily inhibit pepsin activity while antacids such as sodium bicarbonate, which raise the pH above 8, will denature pepsin and permanently inhibit its activity.

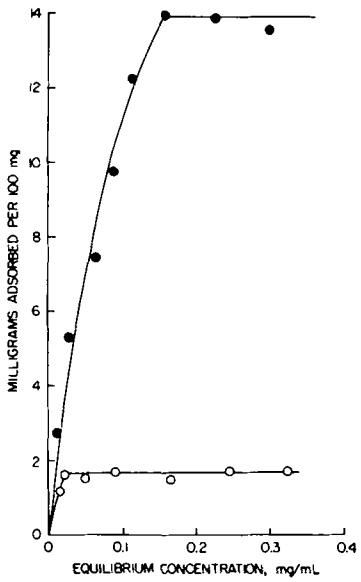

Figure 1—*Adsorption isotherms of pepsin on gibbsite (○) or boehmite (●).*

Other reports have speculated that antacids reduce pepsin activity by precipitating pepsin from solution (8, 9) or by adsorbing pepsin (5, 10–16). The adsorption of bile acids is believed to aid in ulcer therapy (17–19). Earlier studies suggested that antacids act by coating the mucosal lining and protecting it from the digestive action of gastric acid and pepsin (20–22). The reports of ulcer coating by antacids have been contradicted (23, 24), and the recent trend in formulating antacid products has been to incorporate only acid-reactive antacid materials.

This study was undertaken to investigate the interaction of aluminum hydroxide and pepsin with special emphasis on any specific mechanism by which aluminum hydroxide reduces the proteolytic effect of pepsin on the gastrointestinal mucosa.

BACKGROUND

Pepsin, a globular proteolytic enzyme, is secreted by the chief cells of the gastric mucosa as its zymogen, pepsinogen. At ≤pH 5, pepsinogen is converted to pepsin by the cleavage of six peptide segments from the *N*-terminal end of pepsinogen. Pepsin and pepsinogen have molecular weights of ~35,000 and 42,000, respectively (25).

The primary structure of pepsin consists of 327 amino acids including 43 acidic amino acids and 4 basic amino acids (26). The isoelectric point of pepsin is ~1, so pepsin is a negatively charged protein in the GI tract (27). Pepsin is composed of a single polypeptide chain which has folded and packed to form a globular protein. The calculated molecular diameter of pepsin is 4.38 nm (28). The three-dimensional structure is stabilized by three disulfide bonds. Pepsin has only one active site which is believed to include the carboxyl groups from two aspartic acids (29).

The role of pepsin in the body is to digest proteins, and it is most active in hydrolyzing bonds involving phenylalanine, tyrosine, and leucine (30). Bonds involving glutamic acid are hydrolyzed, but to a lesser extent (30). The proteolytic activity of pepsin is dependent on pH. Pepsin A, which has also been termed pepsin III, is the predominant pepsin and exhibits an optimal pH range for activity between 1.5 and 3.0 (31).

The adsorption of pepsin by aluminum hydroxide is well documented, but the mechanism of adsorption has not been elucidated. Pawelczak determined the extent of pepsin adsorption by a number of antacid preparations (32). Wenger and Sundy determined the adsorption of pepsin by various colloidal materials at different pH conditions and suggested that the extent of adsorption was dependent on particle size and the chemical nature of the colloidal material (13). Piper and Fenton determined that aluminum hydroxide and charcoal were the best adsorbers of pepsin among a group of materials (5). Anderson and Harthill found pepsin to be completely adsorbed by an acid-reactive aluminum hydroxide gel as well as by an acid-insoluble aluminum hydroxide gel (14). Liebman also found that pepsin was adsorbed by aluminum hydroxide (15).

EXPERIMENTAL SECTION

Materials—Porcine pepsin[1], gibbsite[2], and boehmite[2] were obtained commercially. The surface area of gibbsite and boehmite was determined by

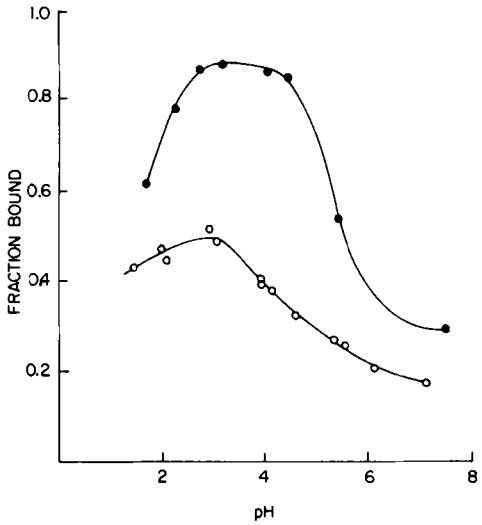

Figure 2—*pH profile of the percent pepsin bound on gibbsite (○) or boehmite (●).*

the triple-point gas adsorption method[3]. The point of zero charge was determined using a continuous titration procedure (33).

Adsorption Isotherms—Adsorption isotherms for pepsin on gibbsite or boehmite were determined at pH 2.3. Pepsin stock solutions were prepared at 2 and 3 mg/mL in 0.01 M HCl for gibbsite and boehmite, respectively. Gibbsite and boehmite stock suspensions (1%) were prepared and sonicated to break up aggregates. Ten milliliters of the stock suspension was transferred into a 25-mL volumetric flask. The suspension was adjusted to pH 2.3 by adding a total of 0.26 or 0.27 mmol of HCl to the gibbsite or boehmite suspensions, respectively. The actual amount of 0.1 M HCl added depended on the amount of pepsin required, since 1 mL of the pepsin solution provided 0.01 mmol of HCl. After the addition of the appropriate amount of 0.1 M HCl, the required amount of pepsin was added. The final volume of the suspension was brought to 25 mL by the addition of distilled water. The suspensions were shaken for a 5-min adsorption period, after which the pH was recorded. The suspensions were centrifuged at 10,000 rpm for 30 min and the supernatants were filtered through a 0.45-μm filter. The absorbance of the supernatants was read at 280 nm (34, 35); the equilibrium pepsin concentration was determined by use of a Beer's law plot, and the amount adsorbed was calculated by difference.

Fraction Bound Study—The percentages of pepsin bound on gibbsite and boehmite were determined at various pH conditions. Pepsin solutions (1 and 2 mg/mL for gibbsite and boehmite, respectively) were prepared in 0.001 M HCl. Gibbsite or boehmite stock suspensions (1%) were prepared and sonicated to break up aggregates. Ten milliliters of the stock suspension was transferred into 25-mL volumetric flasks and adjusted to the desired pH with appropriate quantities of HCl or NaOH. Five milliliters of the appropriate pepsin solution was added, and the final volume was adjusted to 25 mL with distilled water. The suspensions were shaken for 5 min, and the pH was recorded. The suspensions were centrifuged at 10,000 rpm for 25 min, and the supernatants were filtered through a 0.45-μm filter. The absorbance of the supernatants was read at 280 nm. Blanks were prepared and treated in the same manner except that 0.001 M HCl was used instead of the pepsin solution. Also, another pepsin solution was prepared in the absence of gibbsite or boehmite. The percent pepsin bound was calculated by:

$$B = \frac{A_0 - (A_s - A_b)}{A_0} \times 100$$

where B is the percent pepsin bound; A_0 is the absorbance of the pepsin solution without gibbsite or boehmite; A_s is the absorbance of the supernatant from the pepsin-adsorbent suspension; and A_b is the absorbance of the supernatant of the blank.

Desorption by Acid Wash—Pepsin solutions in 0.001 M HCl having a concentration of 1 and 2.5 mg/mL were prepared for gibbsite and boehmite, respectively. Gibbsite and boehmite stock suspensions (1%) were prepared and sonicated to break up aggregates. Ten milliliters of the stock suspension was transferred into 25-mL volumetric flasks and adjusted to pH 2.4 with 0.1 M HCl. The appropriate pepsin solution (5 and 8 mL, respectively) was added to the gibbsite or boehmite suspensions. The suspensions were adjusted to 25 mL with distilled water. A blank was prepared in the same manner, except

Table I—Desorption of Pepsin by Washing Pepsin–Adsorbent Complex with Acidified Water (pH 2.4)

Wash	Pepsin Adsorbed, mg/100 mg of Gibbsite	Cumulative Percent Desorbed	Pepsin Adsorbed, mg/100 mg of Boehmite	Cumulative Percent Desorbed
0	1.938		14.413	
1	1.884	2.8	13.137	8.8
2	1.811	6.6	12.977	10.0
3	1.810	6.6	12.926	10.3
4	—		12.861	10.8
5	—		12.829	10.9

0.001 M HCl replaced the pepsin solution. The suspensions were shaken for 5 min, and the pH was recorded. The suspensions were centrifuged at 10,000 rpm for 15 min. The supernatant was decanted, and its volume was recorded. The absorbance of the supernatant was read at 280 nm, and the pepsin concentration determined by use of a Beer's law plot. If the absorbance of the supernatant was >0.001, the solids were washed with acidified water at pH 2.4. The volume of the acidified water added to the solids was the same as the volume of the supernatant that was decanted. The suspension was shaken for 5 min, the pH was recorded, and the procedure was repeated until the absorbance of the supernatant was ≤0.001. The solid phase was resuspended in 25 mL of water at pH 2.4 and lyophilized. The carbon content of the solid phase was determined by microanalysis[4]. The amount of pepsin adsorbed was calculated from the carbon content of pepsin.

Desorption by Exchange with Phosphate—Pepsin solutions having concentrations of 0.5 mg/mL and 2.5 mg/mL in 0.01 M HCl were prepared for gibbsite and boehmite, respectively. Gibbsite and boehmite stock suspensions (1%) were prepared and sonicated to break up aggregates. Ten milliliters of the stock suspension was adjusted to pH 2.4 with 0.01 M HCl. Five milliliters of the appropriate pepsin solution was added, and the volume was adjusted to 20 mL. The suspensions were shaken for 20 min (control). Similar suspensions were prepared, and 5 mL of a 0.12-g/mL phosphate solution was added to 20 mL of suspension after the 20-min shaking period. The control and phosphate-containing suspensions were centrifuged at 10,000 rpm for 15 min, and the supernatants were filtered through a 0.45-μm filter. The absorbance of the supernatants was read at 280 nm; the equilibrium pepsin concentration was determined by use of a Beer's law plot, and the amount adsorbed was calculated by difference.

Infrared Spectroscopy—Samples were lyophilized and prepared as potassium bromide pellets (1 mg of lyophilized sample/300 mg of KBr). The IR spectrum was recorded between 1800–1000 cm^{-1}. The IR spectrophotometer[5] was interfaced with a computer to provide subtraction of different spectra.

RESULTS AND DISCUSSION

Acid-reactive aluminum hydroxide gels, which are known as carbonate-containing aluminum hydroxide or aluminum hydroxycarbonate (36) and which are used in antacid products, usually react completely within 15–20 min at the pH and temperature of the stomach. Although the adsorption of pepsin by acid-reactive aluminum hydroxide has been demonstrated (5, 12–15), elucidation of the mechanism of adsorption requires a stable surface. To obtain a stable aluminum hydroxide surface, gibbsite and boehmite were used as models because they are closely related structurally to acid-reactive aluminum hydroxide, but they react very slowly with acid, *i.e.*, <2% reacts in 90 min at pH 3 and 37°C. Gibbsite is the most stable polymorph of aluminum hydroxide and has the molecular formula $Al(OH)_3$ (37). Boehmite is an aluminum oxyhydroxide which has the molecular formula AlO(OH) (37). Hydroxyl is the only surface group of gibbsite, while hydroxyl and oxide surface groups are present in boehmite. The samples of gibbsite and boehmite had surface areas of 5 and 250 m^2/g, respectively.

The adsorption isotherms of pepsin on gibbsite and boehmite were determined at pH 2.3, the pH of maximum proteolytic activity (31). As seen in Fig. 1, the adsorptive capacity was 1.7 mg of pepsin/100 mg of gibbsite and 13.9 mg of pepsin/100 mg of boehmite. Thus, the adsorptive capacity was related to the surface area of the adsorbent.

The percent pepsin bound by gibbsite and boehmite was determined at various pH values (Fig. 2). Adsorption of pepsin by both gibbsite and boehmite was observed over the pH range of the GI tract. The greater adsorptive capacity of boehmite was again apparent. Maximum pepsin adsorption occurred at pH 2.7–3.3 for gibbsite, while the range was pH 2.7–4.3 for boehmite. The broader range of maximum adsorption observed for boehmite may be due to

a difference in the pH of maximum adsorption for hydroxyl surface groups when compared with oxide surface groups.

The adsorption of pepsin by gibbsite and boehmite can be partially explained on the basis of electrostatic attraction; the isoelectric point of pepsin was ~1 (38), and the points of zero charge of gibbsite and boehmite were 9.2 and 9.1, respectively. Thus, in the pH region studied, *i.e.*, pH <8, the adsorbent will have a positive surface charge while pepsin will have a negative charge which will decrease as the pH approaches 1. The decreased adsorption at very acidic conditions seen in Fig. 2 may be related to a reduced electrostatic attraction. However, the adsorbent should retain a strong positive charge until the pH was within 1 unit of the point of zero charge, *i.e.*, pH ~8 (39). Thus, the decreased adsorption above pH 3.3 or 4.3 for gibbsite or boehmite, respectively, was not expected based solely on electrostatic attraction.

The pH-adsorption profile seen in Fig. 2 suggests that specific adsorption was also important. Hingston *et al.* (40) and Bowden *et al.* (41) found that anions of incompletely dissociated acids, such as phosphate, are specifically adsorbed by metal oxides and that maximum adsorption occurs when the pH equals the pK_a of the weak acid. The pK_a values of the acidic amino acids in pepsin, such as aspartic acid and glutamic acid, are 3.86 and 4.25, respectively (42), and are in the pH region where maximum adsorption occurred. In addition, the general shape of the pH-adsorption profile is similar to that observed for specific adsorption of anions by metal oxides (40, 41, 43). Bowden *et al.* (41) indicated that the increase in specific adsorption as the pH increases toward the pK_a is due to a more rapid increase in the number of adsorbing species than in the rate of decrease of the positive charge of the surface. The extent of specific adsorption decreases as the pH increases above the pK_a because the surface becomes less positive at a rate greater than the rate of dissociation.

A study of pepsin desorption from gibbsite or boehmite was performed to determine if specific adsorption was an important mechanism. Once pepsin was adsorbed by gibbsite or boehmite at pH 2.4, the pepsin-adsorbent complexes were washed repeatedly with acidified water at pH 2.4. Analysis of the supernatant (Table I) following each wash showed that little pepsin was desorbed by acidic washing. The amount of pepsin adsorbed following five washes was also determined by carbon analysis of the solid phase. The analysis of duplicate samples yielded the following results: 1.80 and 1.74 mg of pepsin adsorbed/100 mg of gibbsite and 12.7 and 13.2 mg of pepsin adsorbed/100 mg of boehmite. It is interesting to note that the adsorptive capacity determined from the plateau of the adsorption isotherm (Fig. 1) also agrees with the results of the desorption experiment. Desorption was expected if the only mechanism of adsorption was electrostatic attraction, as a chloride anion would replace pepsin, or protons would neutralize the negative charge of pepsin, and facilitate pepsin desorption.

Phosphate is specifically adsorbed by aluminum hydroxide by anionic ligand exchange (40, 44). Therefore, washing with phosphate should desorb pepsin if pepsin is also adsorbed by specific adsorption through anionic ligand exchange. The pepsin-gibbsite or pepsin-boehmite complexes were washed with a phosphate solution at 8 times the phosphate concentration of intestinal fluid at pH 2.4. Analysis of the supernatant showed that 95 and 79% of the adsorbed pepsin was desorbed from gibbsite and boehmite, respectively. Since phosphate desorbed pepsin, it was concluded that pepsin was also specifically adsorbed by anion ligand exchange. Phosphate is known to complex with gibbsite by a mono- or bidentate ligand mechanism (40, 44). Desorption studies of monodentate ligands show that binding is reversible, whereas multidentate ligands favor irreversible binding (44). Since phosphate did not totally desorb pepsin, pepsin is believed to form multidentate ligands with gibbsite and boehmite.

The mechanism of adsorption was further investigated by IR spectroscopy. The IR spectrum of pepsin in the 1800–1300-cm^{-1} region is shown in Fig. 3 (line B). The major absorption bands occur at 1530 and 1650 cm^{-1}. The band at 1530 cm^{-1}, known as the amide II band, is due to the N–H deformation vibrations of the main chain of pepsin (45). The band at 1650 cm^{-1}, termed the amide I band, results from the C=O stretching vibrations of the main chain (45). A shoulder present at 1730 cm^{-1} is believed to be due to the C=O stretching vibrations from the undissociated carboxylic acid groups of glutamic and aspartic acids (46).

The IR spectrum of pepsin adsorbed on gibbsite could not be determined because the small amount of adsorbed pepsin could not be detected. However, the degree of adsorption of pepsin on boehmite was sufficient to permit measurement of the IR spectrum of adsorbed pepsin. Boehmite has minimal absorbance in the 1800–1300-cm^{-1} region of the IR spectrum (Fig. 3A). However, to eliminate the contribution of boehmite, the spectrum of the adsorbent was subtracted by computer from the pepsin-boehmite spectrum to produce the IR spectrum of adsorbed pepsin (Fig. 3, line C). The subtraction was performed based on a boehmite band at 1070 cm^{-1}. Before subtracting, a multiplication factor was used on the pepsin-boehmite spectrum to cancel the 1070 cm^{-1} band, *i.e.*, the contribution of boehmite to the spectrum. A multiplication factor of 2.2 was used on the spectrum to produce the same relative absorbance of the amide I band as in pepsin.

As seen in Fig. 3 line C, the amide II band of pepsin at 1530 cm^{-1} was unaffected by adsorption, but the amide I band was shifted to a slightly higher frequency. A slight deformation of structure of pepsin due to adsorption might cause this frequency shift (47). The shoulder at 1730 cm^{-1} was not present in the IR spectrum of adsorbed pepsin, indicating that the carboxyl groups are ionized. The absence of the band at 1730 cm^{-1} supports the ligand exchange adsorption mechanism, since the carboxylic acid groups involved in ligand exchange would have to be in their ionized form to interact by ligand exchange with surface aluminum ions. Thus, ligand exchange would be expected to cause the decrease in absorbance at 1730 cm^{-1} observed for adsorbed pepsin.

Pepsin is adsorbed by aluminum hydroxide in the pH range of the GI tract by specific adsorption involving anionic ligand exchange as well as by electrostatic attraction. Some carboxylate groups of pepsin will displace hydroxyl or water groups from the surface of aluminum hydroxide and covalently bond with surface aluminum. Other carboxylate groups of pepsin which are not physically able to specifically adsorb will interact with the positive surface of aluminum hydroxide by electrostatic attraction. This combination of mechanisms results in strong adsorption which is not reversed by simple washing.

Adsorption of Pepsin by Aluminum Hydroxide II: Pepsin Inactivation

ROBERT J. SEPELYAK *, JOSEPH R. FELDKAMP ‡, FRED E. REGNIER §, JOE L. WHITE ‡ and STANLEY L. HEM *x

Received July 18, 1983, from the *Departments of *Industrial and Physical Pharmacy, ‡Agronomy, and §Biochemistry, Purdue University, West Lafayette, IN 47907.* Accepted for publication February 9, 1984.

Abstract □ Pepsin adsorbed on gibbsite or boehmite, non-acid-reactive forms of aluminum hydroxide, had a significantly lower activity than pepsin in solution. IR and desorbed pepsin activity studies showed that the reduced activity of adsorbed pepsin was not due to denaturation of pepsin on adsorption. Steric occlusion of the active site, following pepsin adsorption, was responsible for the lower activity of pepsin adsorbed on gibbsite. The porous morphology of boehmite caused diffusional resistance and steric exclusion, contributing to the decreased activity of adsorbed pepsin. The specific inactivation of pepsin by adsorption on aluminum hydroxide may be important in ulcer therapy.

Keyphrases □ Aluminum hydroxide—adsorption of pepsin, pepsin inactivation □ Pepsin—adsorption by aluminum hydroxide, inactivation □ Adsorption—pepsin adsorption by aluminum hydroxide, pepsin inactivation

The first phase of this study demonstrated that aluminum hydroxide adsorbs pepsin by anionic ligand exchange and electrostatic attractive forces (1). The effect of adsorption on the activity of pepsin and the elucidation of the mechanism responsible for any specific antipepsin effect is the focus of this study.

BACKGROUND

The reduction of pepsin activity by colloidal antacid materials was initially hypothesized to be due to the precipitation of pepsin (2, 3). Berstad (4) has recently concluded that aluminum hydroxide has powerful adsorbent and precipitation effects on pepsin in human gastric juice. Aluminum hydroxide was reported to precipitate pepsin in an inactive form (2). Mutch (5) indicated that pepsin was adsorbed on kaolin, silica gel, calcium phosphate, and magnesium phosphate. Pepsin adsorbed on kaolin or silica gel remained active, but pepsin adsorbed on calcium phosphate or magnesium phosphate was inactive due to denaturation by the high local pH of the surface. Bismuth aluminate, magnesium oxide, and magnesium carbonate were effective in inhibiting pepsin following adsorption (6). Berstad *et al.* (7) assumed that pepsin adsorbed by aluminum hydroxide was inactive. Piper and Fenton (8) stated that the effect of adsorption on pepsin activity was just as important as the pH effect for aluminum hydroxide. Anderson and Harthill (9) found that pepsin adsorbed on an acid-reactive aluminum hydroxide exhibited only 21% of the theoretical activity. Liebman (10) reported that the activity of pepsin was 22% of the control following adsorption on aluminum hydroxide, 29% of the control following adsorption by magnesium hydroxide, and 46% of the control following adsorption by cholestyramine. It was concluded that pepsin was still active while adsorbed because pepsin activity, following dissolution of the three adsorbents, was 88-91% of the control.

EXPERIMENTAL SECTION

Gibbsite[1], boehmite[1], aluminum hydroxycarbonate gel[2], aluminum chlorohydrate[3], porcine pepsin[4], and bovine hemoglobin[4] were obtained commercially. The proteolytic activity of pepsin was determined by either the Anson method (11, 12), using hemoglobin as the substrate, or the dipeptide method (13), which uses the dipeptide *N*-acetyl-L-phenylalanyl-L-3,5-diiodotyrosine as the substrate. The activity of pepsin in the presence of a series of soluble cations was determined using a pepsin solution (20 μg/mL) which was 0.14 mM with respect to the appropriate cation. Likewise, the activity of pepsin in the presence of gibbsite or boehmite was determined using a pepsin solution (20 μg/mL) which contained 0.5 mg/mL of gibbsite or boehmite.

Pepsin solutions (20 μg/mL), or pepsin (20 μg/mL) and gibbsite (0.5 mg/mL) or boehmite (0.5 mg/mL) suspensions, were lyophilized and pre-

pared as potassium bromide disks (1 mg of lyophilized sample/300 mg of KBr) for IR analysis. The pepsin solution was denatured by either adding 1 M NaOH to adjust the pH to 9 (base-denatured pepsin) or by heating the pepsin solution at 90°C for 1 h (heat-denatured pepsin). The denatured pepsin solutions were lyophilized and prepared for IR analysis as above. The IR spectrum was recorded using a spectrophotometer[5] interfaced with a computer. The spectrum of adsorbed pepsin was obtained by subtracting the spectrum of boehmite from the spectrum of pepsin-boehmite based on the 1070 cm^{-1} band of boehmite (1).

Desorbed-pepsin studies were performed by initially interacting pepsin (25 μg/mL) and aluminum hydroxycarbonate gel (1.7 mg equivalent of aluminum oxide/mL) at pH 2.3 in a pH-stat titrator[6]. Preliminary studies indicated immediate adsorption under these conditions. The aluminum hydroxycarbonate was dissolved under pH-stat[6] conditions at pH 2.3 and 5°C. After complete dissolution of the aluminum hydroxycarbonate gel, the activity of pepsin was determined by the modified Anson method.

The activity of desorbed pepsin was also determined by adsorbing pepsin (20 μg/mL) on gibbsite (0.5 mg/mL) or boehmite (0.5 mg/mL) at pH 2.3. After adsorption, a 0.12-g/mL phosphate solution (pH 2.3) was added. The supernatant was analyzed at 280 nm to monitor the desorption of pepsin. The activity of the desorbed pepsin was determined by the modified Anson method.

Samples of gibbsite and boehmite were prepared for scanning electron microscopy[7] by air-drying a sonicated 0.2% suspension. The samples were coated with gold and platinum[8]. A microdrop of a 0.2% sonicated gibbsite or boehmite suspension was placed on a 300-mesh copper grid which was coated with polyvinyl formal[9] and stabilized with evaporated carbon. After air-drying, the sample was examined by transmission electron microscopy[10] at 80 keV.

RESULTS AND DISCUSSION

To improve the precision of the Anson method, which has a *CV* of ~5% (14), five replicates were run rather than three. Pepsin activity tended to decrease with each replicate (Table I). The decrease appeared to be related to time and is believed to be due to the autodigestion of pepsin in the pepsin stock solution. The autodigestion of pepsin was slowed by maintaining the pepsin stock solution at 5°C, but a variation in pepsin activity (a) with time was still observed. A plot of pepsin activity *versus* time for the data in Table I showed that time accounts for the major part of the variation in activity. Equation 1 was used to correct for time to obtain the mean corrected pepsin activity, $\bar{A}$:

$$\bar{A} = r^2 y + (1 - r^2)\bar{a} \qquad \text{(Eq. 1)}$$

where r^2 is obtained from the linear regression analysis and y represents the intercept of the optimal straight line. The experimental mean pepsin activity, $\bar{a}$, is influenced by the time dependence of the replicates. Thus, $\bar{A}$ represents the mean activity that would be observed if autodigestion did not occur. However, if $r^2 = \sim 0$ (indicating only slight time dependence), then $\bar{A} \approx \bar{a}$. If a_p represents the predicted activity at time t, obtained from the optimal straight line, then each individual activity, a, may be corrected to give a corrected pepsin activity, A:

$$A = a + (\bar{A} - a_p) \qquad \text{(Eq. 2)}$$

Thus, the procedure to correct for the effect of time adjusted the mean pepsin activity from 2950 to 3152 activity units and decreased the *SD* from 228 to 39 activity units. The correction for autodigestion of the stock pepsin solution reduced the *CV* ~1%. Perhaps some of the conflicting reports on pepsin inactivation are due to the large *CV* associated with the unmodified Anson method. All results in this study were obtained using the aforementioned modificiation of the Anson method.

The pH-activity profile of pepsin obtained by the modified Anson method is shown in Fig. 1, line A and is similar to previously reported profiles (15, 16). The optimal pH range for pepsin activity is pH 2.2-2.6. Pepsin activity approaches zero at pH 4, which supports one of the goals of peptic ulcer therapy, *i.e.*, to raise the gastric pH to minimize pepsin activity.

The activity of pepsin in the presence of soluble forms of aluminum was determined because numerous investigators have reported an inhibitory effect by aluminum (3, 8, 17, 18). However, Anderson and Harthill (9) reported that aluminum ions had no effect on pepsin activity. Two forms of soluble aluminum (aluminum chloride and aluminum chlorohydrate) were tested for an antipepsin effect at pH 2.4 by the modified Anson method. Aluminum chlorohydrate was chosen because it is an aluminum complex with a +7 charge (19). A concentration ratio of 250 ions per pepsin molecule was chosen to provide a substantial excess of aluminum ions, because pepsin contains ~43 carboxylate groups on the surface. The results (Table II) indicate a slight enhancement of pepsin activity (~4%) by aluminum cation and a slight inhibition (~4%) by aluminum chlorohydrate. These differences are statistically significant at an α level of 0.05. Even though statistically significant differences in pepsin activity were observed in the presence of aluminum ion and aluminum chlorohydrate, these differences are not believed to be large enough to produce any significant *in vivo* effects. Furthermore, aluminum cation did not alter the pH-activity profile of pepsin (Fig. 1, line B).

The first part of this series demonstrated that pepsin was specifically adsorbed by aluminum hydroxide through anionic ligand exchange, involving carboxylate groups of pepsin and surface aluminum ions, and electrostatic attraction (1). Therefore, the effect of adsorption on pepsin activity was examined by determining pepsin activity in the presence of gibbsite or boehmite, non-acid-reactive forms of aluminum hydroxide. Under normal physiological conditions, a 600-mg dose of aluminum hydroxide will produce a pepsin to aluminum hydroxide ratio in the stomach of 0.02:1 to 0.16:1 (20). Thus, a ratio of pepsin to aluminum hydroxide of 0.04:1 was used. The activity of pepsin in the presence of either gibbsite or boehmite was lower than the control (Table

III). However, the observed activity of pepsin in the aluminum hydroxide suspensions was not due to adsorbed pepsin alone since not all of the enzyme was adsorbed. Activity due to adsorbed pepsin will be termed immobilized pepsin activity. To calculate the immobilized pepsin activity, the extent of adsorption had to be determined. Also, it was assumed that free pepsin in the aluminum hydroxide suspension had the same activity as pepsin in the control solution. For example, UV analysis of the supernatant from the pepsin–boehmite suspensions indicated that 26% of the pepsin was in solution. Thus, the activity contributed by the free pepsin was calculated to be 716 AU, *i.e.*, 26% of the activity of the control. Since the total activity of the pepsin–boehmite suspension was 1571 AU, the adsorbed pepsin (which comprised 74% of the pepsin in the suspension) had an activity of 855 AU. However, 74% of the activity of the control is 2037 AU. Thus, the adsorbed pepsin exhibited 42% as much activity as unadsorbed pepsin. The adsorbed pepsin in the pepsin–gibbsite suspension was only 68% as active as free pepsin.

The decreased antiproteolytic activity of adsorbed pepsin was directly measured by adsorbing pepsin on gibbsite or boehmite, washing, and separating the solid phase to obtain only immobilized pepsin. Adsorption was strong enough that desorption did not occur when the immobilized pepsin was resuspended (1). Pepsin immobilized on gibbsite was 59–67% as active as free pepsin while pepsin adsorbed on boehmite was only 31–39% as active as the control, as determined by the modified Anson method (Table IV). These results agree with the 68 and 42% activity calculated for pepsin adsorbed on gibbsite and boehmite, respectively, based on the activity of the unwashed suspension (Table III).

Three factors may be involved in the decreased immobilized pepsin activity. A structural change in pepsin may result from adsorption on the aluminum hydroxide surface. The properties of the active site of an enzyme depend on the tertiary structure and any modification of the three-dimensional structure could have an effect on activity. A second factor might involve steric occlusion of the active site due to adsorption. Depending on the orientation of the adsorbed pepsin molecule, the accessibility of the active site may be reduced or blocked altogether. This effect would reduce the rate of proteolysis. A third possible mechanism is the development of a substrate concentration gradient between the bulk solution and the microenvironment of the adsorbed pepsin. The substrate concentration gradient can be due to diffusional resistance of the substrate or steric exclusion of the substrate from reaching the adsorbed pepsin.

The possibility that adsorption produces a structural change in pepsin was investigated by IR spectroscopy and by determining the activity of pepsin which had been desorbed from gibbsite or boehmite. The IR spectra of pepsin, base-denatured pepsin, and heat-denatured pepsin are compared in Fig. 2. The major bands for pepsin occur at 1530 cm^{-1} (amide II) and 1650 cm^{-1} (amide I) (21). The shoulder at 1730 cm^{-1} is due to the C=O stretching vibrations from the carboxylic acid groups of glutamic and aspartic acids (22). The spectra of the base-denatured and heat-denatured pepsin also had bands at 1530 and 1650 cm^{-1}. The base-denatured pepsin had a band at ~1600 cm^{-1} which was due to the strong asymmetric stretching vibrations from the ionized carboxylic acid groups of glutamic and aspartic acids. Since the carboxylic acid groups will be ionized at the pH required for base denaturation, the shoulder at 1730 cm^{-1} was not present in the spectrum of the base-denatured pepsin. Both the base-denatured and the heat-denatured pepsin possess a unique band at 1400 cm^{-1}. This band has not been assigned but is believed to be associated with the denaturation of pepsin.

The IR spectrum of pepsin adsorbed on boehmite was obtained by computer subtraction of the boehmite spectrum from the pepsin–boehmite spectrum and is shown as Fig. 2, line D. The amount of pepsin adsorbed by gibbsite was too low to obtain an IR spectrum. The absence of the band at 1400 cm^{-1} suggests that pepsin was not denatured by adsorption. The amide I band at 1650 cm^{-1} shifted to a slightly higher frequency, possibly due to a slight deformation of the structure of pepsin as a consequence of adsorption. The similarity of the spectra of pepsin and pepsin adsorbed on boehmite suggests that pepsin was still active even when adsorbed on aluminum hydroxide.

Pepsin activity following desorption was determined to further establish whether pepsin was denatured due to adsorption. A dissolution method and an exchange method were used to desorb pepsin. Aluminum hydroxycarbonate gel, the acid-reactive form of aluminum hydroxide, was used as the adsorbent for the dissolution method. A low ratio of pepsin to aluminum hydroxide was used so that the majority of pepsin would be adsorbed. Following dissolution of the aluminum hydroxycarbonate gel, the activity of the desorbed pepsin

Immobilized pepsin activity, %	59.3	—	66.5	—	30.8	—	38.9	—

was determined by the modified Anson method (Table V). The desorbed pepsin was 96% as active as the control indicating that adsorption by aluminum hydroxide did not affect the structure of pepsin enough to alter its activity. This result corresponds well with an earlier study which reported a 94% recovery of activity following dissolution of the adsorbent, aluminum hydroxide (9).

Pepsin was also desorbed from gibbsite or boehmite by exchange with phosphate. As seen in Table VI, almost all of the adsorbed pepsin was desorbed from either gibbsite or boehmite by exchange with phosphate. The activity of the desorbed pepsin, as determined by the modified Anson method, was virtually identical to the controls. However, the mean corrected activity after phosphate exchange includes both desorbed pepsin and pepsin which had not been adsorbed. When Eq. 3 was applied to calculate the activity of only desorbed pepsin, the pepsin desorbed from gibbsite and boehmite was 91 and 96% as active as the control, respectively.

$$D = \frac{\bar{A}_t - \left(\bar{A}_c \frac{F_f}{F_r}\right)}{\bar{A}_c - \left(\bar{A}_c \frac{F_f}{F_r}\right)} \times 100 \qquad \text{(Eq. 3)}$$

where D is the activity of desorbed pepsin, %; $\bar{A}_t$ is the mean corrected activity after phosphate exchange; $\bar{A}_c$ is the mean corrected activity of control; F_f is the fraction of pepsin in the supernatant initially; and F_r is the fraction of pepsin in the supernatant after phosphate exchange. Thus, IR and desorption studies indicate that adsorption of pepsin by aluminum hydroxide does not denature pepsin.

To determine whether steric effects were involved in reducing the activity of adsorbed pepsin, the activity of pepsin against a smaller substrate was studied. Hemoglobin (Hb), the substrate used in the Anson method, is a macromolecule with a mol. wt. of ~35,000 (23). The low-molecular-weight substrate selected was *N*-acetyl-L-phenylalanyl-L-3,5-diiodotyrosine, a dipeptide with a mol. wt. of ~600. The smaller size of the dipeptide should enable it to reach the active site of adsorbed pepsin more easily, and increased activity against the dipeptide should be observed if steric effects are important. The autodigestion of pepsin was observed using the dipeptide, and the mathematical procedure used to correct for the autodigestion of pepsin during the Anson method was also used for the dipeptide method. This method is reported to have a *CV* of 6% (13). When the modifications developed for the Anson method were applied to the dipeptide method, the *CV* was reduced to 2%. The pH–activity profile of pepsin using the dipeptide (Fig. 1, line C) was similar to the pH–activity profile using hemoglobin (Fig. 1, line A).

The activity of pepsin adsorbed on gibbsite or boehmite was determined in two separate studies using the modified Anson and the modified dipeptide methods. As seen in Table VII, pepsin adsorbed on gibbsite was less active than the control, but the Student's t test, at an α level of 0.05, showed that the immobilized pepsin activity was statistically the same for both substrates. Thus, both the dipeptide and hemoglobin interacted with the active site of pepsin to the same extent, indicating that both hemoglobin and the dipeptide experienced the same inhibitory steric effect. This steric effect is probably due to steric occlusion of the active site of pepsin resulting from adsorption. Anderson and Harthill (9) also suggested that some active site occlusion occurs when pepsin is adsorbed by aluminum hydroxide.

The immobilized pepsin activity depended on the substrate when pepsin was adsorbed on boehmite (Table VII). Pepsin adsorbed on boehmite was less active than the control, but greater activity occurred with the dipeptide substrate. The t test indicated that the difference in activity against hemoglobin and the dipeptide was statistically significant at an α level of 0.05. These results suggest that a steric factor related to the adsorbent is important, in addition to steric occlusion.

It is possible that the substrate may interact directly with the adsorbent and that the degree of adsorption may differ between hemoglobin and the dipeptide. An adsorption effect occurring between the dipeptide and boehmite can be considered negligible, since the activity of pepsin adsorbed on either boehmite or gibbsite was similar when the dipeptide was used as the substrate. However, hemoglobin may be adsorbed by boehmite since the activity of pepsin adsorbed on boehmite decreased when compared with pepsin adsorbed on gibbsite with hemoglobin as the substrate. This lower activity may be caused by a decrease in hemoglobin concentration in the microenvironment of the adsorbed pepsin due to adsorption of hemoglobin on boehmite. This possibility was discounted when calculation showed that the hemoglobin could form a monomolecular layer 400 times as great as the surface area of the boehmite used in the test. Thus, even if adsorption of a hemoglobin bilayer occurred, the concentration of hemoglobin in solution would not be substantially reduced.

Adsorption of hemoglobin could also affect the activity of adsorbed pepsin if the adsorbed pepsin was "buried" by the adsorption of hemoglobin on the adsorbed pepsin. This mechanism was also discounted because both hemoglobin and the dipeptide were affected equally by pepsin adsorbed on gibbsite.

Diffusional resistance may be partially responsible for the reduced activity of adsorbed pepsin. Hemoglobin has a diffusion coefficient of $6.3\text{–}6.7 \times 10^{-7}$ cm^2/s (24). The diffusion coefficient of the dipeptide has not been determined, but it is expected to be at least 10 times larger than hemoglobin since there is a 58-fold difference in molecular weight. Thus, the dipeptide would be more likely to maintain an equal concentration between the bulk and the mi-

[a] Treatment. [b] Control.

croenvironment of the adsorbed pepsin. In addition to the size of the diffusing species, the morphology of the surface may be an important factor in diffusional resistance. Scanning electron micrographs of gibbsite and boehmite at 30,000× magnification are shown in Fig. 3. Gibbsite is platy with smooth faces and sharp edges, while boehmite is porous. Because the boehmite particles did not have the well-defined edges of gibbsite, the scanning electron micrographs are not as well resolved.

Transmission electron micrographs (Fig. 4) provide more information on the morphology of the adsorbents. Gibbsite particles again appear to have a well-defined structure with distinct edges. The material is platy which can be seen by close examination of the edges of the hexagonal units. The darker particles are a collection of stacked plates. The individual boehmite particles are shown to be smooth flat plates. The plates tend to roll up and form an aggregate of interpenetrating scrolls. The tubular nature of the boehmite particles was deduced because the cores appear to be less dense. Gibbsite particles and boehmite aggregates are approximately the same size, but the porous nature of the boehmite aggregate results in a larger surface area.

The lower activity against hemoglobin of pepsin adsorbed on boehmite when compared with gibbsite can be explained by the porous nature of the boehmite aggregate. Pepsin adsorbed on gibbsite is similar to adsorption on a smooth flat plate, whereas adsorption on boehmite is similar to adsorption in a long narrow channel (Fig. 5). In the case of pepsin adsorbed on gibbsite, the substrate only has to diffuse to the surface. In this situation, the size of the substrate would not be expected to be a factor. Thus, the observation that pepsin adsorbed on gibbsite was equally active against either hemoglobin or the dipeptide is consistent with the morphology of the gibbsite particle.

The porous boehmite morphology requires that the substrate must diffuse through channels in the porous structure to reach adsorbed pepsin. The dipeptide has a diffusion coefficient high enough to maintain the same concentration throughout the channels as in the bulk solution. The dipeptide is also more likely to reach all of the adsorbed pepsin due to its small size. Thus, the lower activity against hemoglobin of pepsin adsorbed on boehmite can also be related to the morphology of boehmite. The lower diffusion coefficient of hemoglobin would make it difficult to maintain the same concentration of hemoglobin in the channels as in the bulk solution. The continuous digestion of hemoglobin as it diffuses through the channels will also lower the concentration of hemoglobin in the microenvironment of the adsorbed pepsin. Thus, pepsin adsorbed at the opening of a channel will have a faster rate of proteolysis than pepsin adsorbed in the interior of a channel. The large size of hemoglobin may even sterically exclude hemoglobin from narrow pores.

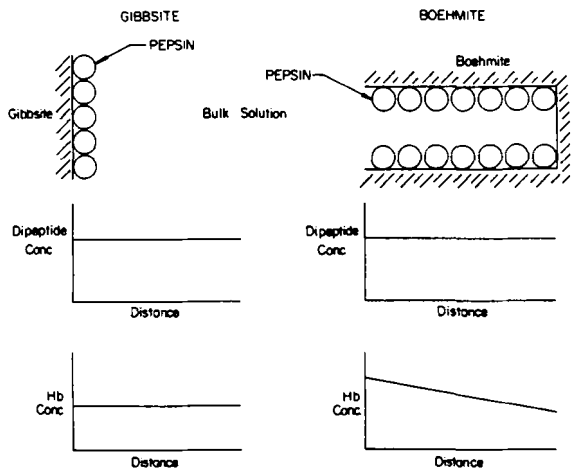

Figure 5—*Schematic diagram of pepsin adsorbed on gibbsite and boehmite.*

The conclusions regarding the importance of the morphology of the adsorbent are consistent with reported differences in activity between low- and high-molecular-weight substrates when an enzyme was adsorbed on a porous material. Immobilized papain on a copolymer had a lower activity using casein than benzoyl-L-arginine ethyl ester as the substrate (25). Pronase adsorbed on a diazotized copolymer had different activities, depending on the molecular weight of the substrate (26). The results were explained on the basis of impedance of substrate access to the catalytic site by the supporting solid matrix. The activity of trypsin adsorbed on aminoethylcellulose also depended on the molecular weight of the substrate (27, 28). It was concluded that the lower activity against the larger substrate was due to the inaccessibility of the adsorbed enzyme.

Thus, pepsin is not denaturerd by adsorption on boehmite or gibbsite. However, the orientation of the adsorbed pepsin results in steric occlusion of the active site, thereby reducing the activity of adsorbed pepsin. In addition to steric occlusion, the activity of pepsin adsorbed on boehmite is also reduced by diffusional resistance and steric exclusion due to the porous morphology of boehmite.

Antacids such as sodium bicarbonate, calcium carbonate, and magnesium hydroxide react very rapidly with acid. pH-Stat titration of these antacid compounds at pH 3 and 37°C showed that the time required to neutralize 50% of the theoretical acid, t_{50}, is <1 min. Therefore, these antacid compounds are expected to be present in the gastric fluid as their soluble ions soon after ingestion. To determine if these antacid compounds exhibit a specific antipepsin effect in addition to the general pH effect, the activity of pepsin in the presence of sodium, calcium, and magnesium ions was determined. Concentrations of ions and pepsin were selected to provide 250 ions per pepsin molecule. As seen in Table VIII, no statistically significant ($\alpha = 0.05$) change in pepsin activity was observed in the presence of sodium, calcium, or magnesium ions.

Aluminum hydroxide reacts more slowly with acid; even amorphous aluminum hydroxycarbonate gel, the acid-reactive form of aluminum hydroxide, does not react as quickly as sodium bicarbonate, calcium carbonate, or magnesium hydroxide. A recent survey of antacid suspensions containing aluminum hydroxide gel and magnesium hydroxide gel showed that the most rapidly reacting product neutralized 96% of the theoretical amount of acid in 15 min at pH 3 and 37°C, while the slowest reacting product neutralized only 31%

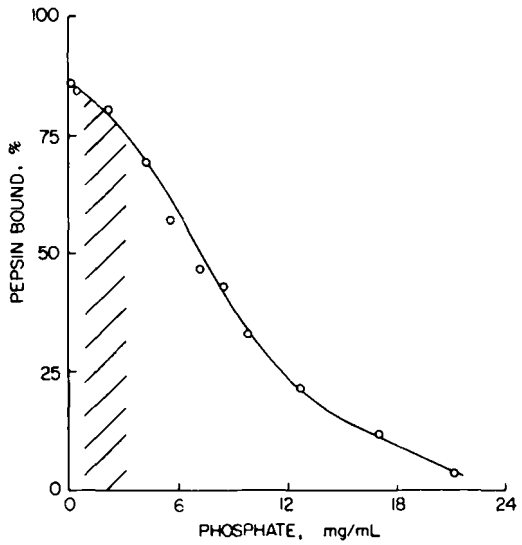

Figure 6—*Effect of phosphate on the fraction of pepsin adsorbed by boehmite. The shaded area indicates the phosphate concentration of gastric fluid.*

Table VIII—Effect of Sodium, Calcium, and Magnesium Ions on Pepsin Activity

	Sodium		Calcium		Magnesium	
	Treatment	Control	Treatment	Control	Treatment	Control
Mean corrected activity, AU	3099	3114	2921	3003	2929	2965
SD	±86	±63	±67	±173	±42	±155
pH	2.43	2.43	2.41	2.41	2.43	2.43

under the same conditions (29). Thus, a solid phase, which can adsorb and inactivate pepsin, will be present in the gastric fluid for a longer time when aluminum hydroxide is used as an antacid in comparison with sodium bicarbonate, calcium carbonate, or magnesium hydroxide.

Before the adsorption and inactivation of pepsin by aluminum hydroxide can be extrapolated to *in vivo* conditions, the possibility that solutes in the gastric fluid (such as phosphate) will compete with pepsin for adsorption by aluminum hydroxide must be considered. Phosphate is also specifically adsorbed by aluminum hydroxide (30, 31). The extent of pepsin adsorption in the presence of phosphate is shown in Fig. 6. The shaded area of the curve indicates the phosphate concentration which is found in gastric fluid (32). Pepsin was 85% bound in the absence of phosphate. The extent of pepsin adsorption gradually decreased with increasing phosphate concentration. Pepsin was 75% bound at the phosphate concentration of the gastric fluid. Therefore, even in the presence of other solutes which are strongly adsorbed by aluminum hydroxide, a major fraction of pepsin would be expected to be adsorbed by aluminum hydroxide.

Non-acid-reactive forms of aluminum hydroxide have been used in ulcer therapy. In 1941 it was reported that non-acid-reactive alumina produced nearly the same symptomatic relief as acid-reactive alumina (33). The effect of non-acid-reactive alumina was attributed to the coating of the gastric mucosa, which provides a physical barrier to gastric acid. Antacid products were marketed that contained a non-acid-reactive aluminum hydroxide. Two gastroscopic studies concluded that non-acid-reactive aluminum hydroxide coated ulcers and acted as an inert physical barrier (34, 35). The results of these studies were contradicted by Hoon (36) who observed no coating, and by Morrissey *et al.* (37) who found approximately one-third of the ulcers completely coated, but the coatings remained for only a short time. Thus, recent thinking has been that acid neutralization is the chief function of antacids. Accordingly, the recent trend in formulating antacid products has been to incorporate only acid-reactive materials. The results of the present study of the adsorption and inactivation of pepsin by gibbsite and boehmite suggest that earlier antacid products containing non-acid-reactive aluminum hydroxide may have promoted ulcer healing by adsorbing and temporarily inactivating pepsin, rather than by coating the ulcers.

Based on this study, it is hypothesized that acid reactive aluminum hydroxycarbonate promotes ulcer healing by neutralizing gastric acid, inactivating pepsin by raising the pH of the gastric contents, and specifically adsorbing and inactivating pepsin. The specific adsorption and inactivation of pepsin by aluminum hydroxide may be responsible for the wide use of aluminum hydroxide in ulcer therapy. The specific adsorption and inactivation of pepsin in ulcer therapy may be enhanced by the use of a non-acid-reactive form of aluminum hydroxide that has a high surface area, such as boehmite.

Possible Mechanism Behind the Adjuvant Action of Phosphate Derivatives on Rectal Absorption of Cefoxitin in Rats and Dogs

TOSHIAKI NISHIHATA ˣ, CHIA-SHUN LEE, BA THU NGHIEM, and TAKERU HIGUCHI

Received July 18, 1983, from the *Department of Pharmaceutical Chemistry, The University of Kansas, Lawrence, KS 66045.* Accepted for publication January 19, 1984.

Abstract □ The mechanism underlying the ability of phosphate derivatives to act as adjuvants and coadjuvants was examined in *in vivo* and *in situ* preparations in rats and dogs. The adjuvant effect of DL-α-glycerophosphate on the rectal absorption of sodium cefoxitin was greatly augmented by the presence of either sodium phytate or sodium tripolyphosphate. These coadjuvants only slightly enhanced cefoxitin rectal absorption when administered alone. Therefore, enhancement of the permeation of tripolyphosphate and phytate by α-glycerophosphate may be necessary before the coadjuvants can significantly affect cefoxitin absorption. The inhibitory effect of disodium 4,4′-diisothiocyano-2,2′-disulfonate stilbene, which is known to interact with the amino group in the protein fraction, on enhanced cefoxitin absorption suggests the involvement of the protein fraction in transport of cefoxitin across the rectal membrane.

Keyphrases □ Absorption—rectal, cefoxitin, rats and dogs □ Phosphate derivatives—adjuvant or coadjuvant action □ Adjuvants—α-glycerophosphate, enhancement of rectal absorption □ Coadjuvants—phytate, tripolyphosphate, adjuvant action in the presence of α-glycerophosphate □ Bioavailability—cefoxitin, dogs □ Inhibitors—disodium 4,4′-diisothiocyano-2,2′-disulfonate stilbene and calcium chloride

Rectal administration of drugs is becoming more popular due to the convenience of the suppository dosage form. Some anti-inflammatory drugs such as indomethacin (1–3) are currently administered as suppositories in clinical therapy. It has also been suggested (4, 5) that certain drugs which are metabolized by the liver (first-pass effect) after oral administration may have a higher systemic bioavailability when administered rectally.

In our attempt to find novel adjuvants which enhance rectal absorption of drugs poorly absorbed from the rectal compartment due to their high water solubility, we initially examined compounds with chelating activity. The potential link between chelation and adjuvant action was first recognized when the weak chelating agent acetoacetic acid was found to enhance the uptake of sulfadimethoxine into erythrocytes (6). We have since reported that other weak chelating agents such as salicylate analogues (7–9), enamine derivatives of β-diketones (10, 11), and glyceryl derivatives of acetoacetate (12) also effectively enhance drug absorption.

In the present study, we examine the absorption-promoting ability of phosphate derivatives since phosphate is generally known to have chelating ability. Sodium cefoxitin was used as a model water-soluble drug. The adjuvant action of disodium DL-α-glycerophosphate (I), sodium tripolyphosphate, and sodium phytate on the rectal absorption of cefoxitin in rats and dogs is reported. The adjuvant action of glycerol, sodium chloride, and disodium phosphate on rectal absorption of sodium cefoxitin in rats is also described. The ability of several of the compounds described above to act as coadjuvants, agents which promote drug absorption only when their own permeation through the membrane is enhanced by the presence of another absorption-promoting compound, was examined, and speculations concerning the mechanism of adjuvant and coadjuvant action were made.

EXPERIMENTAL SECTION

Materials—Disodium DL-α-glycerophosphate (I)[1], sodium tripolyphosphate[1], and sodium phytate[1] were analytical grade. Sodium cefoxitin[2] was used as obtained from the manufacturer.

Procedures—Sprague-Dawley male rats (weight, 200–225 g) were fasted, with water available, for 16 h prior to experimentation. During the experiments, rats were anesthetized with sodium pentobarbital (60 mg/kg) by intraperitoneal injection and kept on a 38°C surface. Drugs were administered rectally in microenema formulations with dosage volumes of ~ 100 μL/100 g of body weight. The initial pH of the microenema was adjusted to 5.8–6.3 with hydrochloric acid when necessary. To avoid leakage of the solution after administration, the rat anus was ligated with thread. Blood samples were taken from the jugular vein at designated time intervals with a syringe treated with 3% sodium citrate. Plasma samples were collected by centrifugation.

In experiments in which an *in situ* loop was used, the rat rectum was ligated with thread ~4 cm from the anus before administration of a microenema. The *in situ* loop was excised at 1.5 h after microenema administration (wet weight of tissue was 438.4 ± 41.3 mg measured after the experiments). The loop was rinsed with 8 mL of distilled water, and the total volume of the collected rinse solution was adjusted to 10 mL with distilled water. The amount of cefoxitin present in the solution was determined.

Ten male beagle dogs (weight, 9.5–12.0 kg) were also fasted, with water available, for 16 h prior to the experiments (crossover design). Drugs with particle sizes ranging from 72 to 144 μm were administered as 1-g suppositories, prepared with triglyceride suppository base[3] as described previously (12). Blood samples were taken from the jugular vein at designated time intervals.

An *in vitro* study of cefoxitin release from suppositories was carried out at 37°C. One-gram suppositories containing 0.45 mM cefoxitin with I, tripolyphosphate, and/or phytate (see Table II for formulations) were placed in 3 mL of a stirred saline solution. Samples were drawn from the beaker at designated intervals to determine the amount released.

Assays—Assays of cefoxitin were performed by the HPLC method described by Nishihata *et al.* (13).

RESULTS AND DISCUSSION

In a previous study (13), we found that sodium cefoxitin was poorly absorbed by the rat rectum. Plasma cefoxitin levels were undetectable (<0.22 μM) or very low (0.22–0.88 μM) after rectal administration of a microenema containing 44 mM cefoxitin prepared with distilled water. Coadministration of disodium DL-α-glycerophosphate (I) with cefoxitin increased the plasma cefoxitin levels significantly (Table I). A dose-response relationship was apparent since an increase in the concentration of I in the microenema caused an increase in plasma cefoxitin levels.

Glycerol was not as effective in promoting rectal cefoxitin absorption as did I (Table I). For example, 1.09 mmol of glycerol per kg of rat body weight had a similar effect on plasma cefoxitin levels as 103 μmol of I, a 10-fold difference. The sodium ion and phosphate moiety in I may, therefore, be actively involved in the adjuvant effect of the compound.

To investigate the adjuvant activity of the phosphate moiety, the adjuvant action of disodium phosphate, sodium tripolyphosphate, and sodium phytate was studied. Sodium tripolyphosphate and sodium phytate (dose, 0.026

mmol/mL/kg, each contributing 0.27 mmol of sodium to the microenema) weakly enhanced the cefoxitin plasma levels, whereas the presence of disodium phosphate (0.138 mmol/mL/kg; contributing 0.27 mmol of sodium to the microenema) did not enhance cefoxitin absorption (Table I). In a sequential study in which I was coadministered with either sodium tripolyphosphate or sodium phytate in a cefoxitin microenema, the cefoxitin plasma levels were enhanced to a much greater degree than when I was administered alone (Table I). Although the coadministration of disodium phosphate with I only slightly enhanced the plasma cefoxitin level above that obtained with I alone (Table I), this enhancement is worth noticing since disodium phosphate itself had no effect on drug absorption. These results therefore suggest that once the transport of disodium phosphate and particularly sodium tripolyphosphate and sodium phytate through rectal epithelial cells is increased by the presence of I, the adjuvant ability of these phosphate derivatives can be realized.

In male beagle dogs, results were obtained which exhibited a similar trend as observed in the rat studies. The relative bioavailability of cefoxitin [measured by comparing the area under the curve from 0 to 240 min (AUC_{0-240}) of cefoxitin plasma levels after rectal administration to that after intravenous injection] in the absence of any adjuvant in the suppository was <5% (Table II). The presence of I in the suppositories administered to the dogs enhanced the plasma cefoxitin levels (Table II). Administration of either tripolyphosphate or phytate in a suppository containing cefoxitin only slightly enhanced the plasma cefoxitin levels. However, coadministration of I with either tripolyphosphate or phytate in a cefoxitin suppository produced substantially higher cefoxitin plasma levels than when either I or the coadjuvants was administered alone (Table II). Since >95% of the cefoxitin was released from each suppository within 20 min, it is unlikely that the release process was an important factor in this absorption study.

To determine what effect the sodium moiety had in the absorption-promoting ability of I, the adjuvant action of I and sodium chloride was compared in rats. The presence of 0.52 mmol of sodium chloride in a cefoxitin microenema did not have as great an effect on cefoxitin rectal absorption as did 0.258 mmol of I (also contributing 0.52 mmol of sodium/mL) (Table I). The strong adjuvant action of I is therefore not due solely to the sodium content. It is interesting to note that coadministration of sodium chloride with 0.258 mmol of I produced greater cefoxitin plasma levels than those obtained when only 0.258 mmol of I without sodium chloride was administered (Table I). Sodium chloride may, therefore, be effectively acting as a coadjuvant. Studies in which the effect of sodium ion on drug absorption are investigated are currently ongoing in our laboratory.

The exact physicochemical interactions that take place between I and the rectal membrane and that are involved in the enhancement of membrane permeability to cefoxitin and phosphate coadjuvants are not clearly understood. However, the inhibitory effect of disodium 4,4′-diisothiocyano-2,2′-disulfonate stilbene (II) on the enhancing action of I possibly suggests involvement of the membrane protein fraction. Compound II is known to inhibit anion transport through the erythrocyte membrane (14) by interacting with the amino group in the protein fraction (15). The disodium DL-α-glycerophosphate-enhanced disappearance of cefoxitin from the rectal *in situ* loop was suppressed when II was present in the microenema (Table III). Therefore, an interaction may occur between the adjuvant phosphate moiety and the membrane protein fraction, causing a conformational change in the protein. This change in protein structure ensuing from the interaction with I most probably does not result in membrane damage caused by chelation since the adjuvant effect of I on cefoxitin disappearance from a rectal *in situ* loop was only slightly suppressed by calcium chloride (Table III).

When calcium chloride was administered with either sodium tripolyphosphate or sodium phytate without I into a rectal *in situ* loop, the ability of both coadjuvants to enhance the disappearance of cefoxitin was significantly inhibited (Table III). The adjuvant action of these coadjuvants was not affected by coadministration of II (Table III). From these findings, we can speculate that the apparent adjuvant activity of sodium tripolyphosphate and sodium phytate when administered without I may depend primarily on chelating activity. In this study, the enhancing action of phytate was found to be similar to that of EDTA (16). EDTA, a strong chelating agent which has been shown to enhance drug absorption from the small intestine (17) and rectum (16) in rats, has also been found to cause solubilization of protein from erythrocyte ghosts (18). Consequently, the ability of tripolyphosphate and phytate to enhance rectal cefoxitin absorption when administered without I may be a result of membrane damage.

In a previous report by Nishihata *et al.* (12), the difference in the adjuvant action of glyceryl esters of acetoacetate was found to be due, partly, to the

difference in their ability to permeate the rat rectal tissue. In the present study, we found that the coadjuvants tripolyphosphate and phytate substantially enhanced the absorption of cefoxitin only after their own permeation of the membrane was apparently enhanced by I. Thus, we speculate that adjuvant permeation of the mucosal membrane may be mechanistically necessary before enhanced compound absorption across the rectal membrane can occur.

In conclusion, the enhancing action of I on rectal cefoxitin absorption appears to depend on the affinity of I to the protein fraction in the mucosal membrane. The weak enhancing ability of the phosphate coadjuvants when administered with cefoxitin alone may involve chelating activity and possible damage to the rectal mucosa. However, the large increase in drug absorption after coadministration of I with either chelating agent, tripolyphosphate or phytate, is not just a consequence of the added effect of the enhancing action of I and chelation. These phosphate derivatives apparently have a strong adjuvant efficacy which can be realized only when their own permeation of the mucosal membrane is enhanced by adjuvants such as I.

Abstract □ A physiological flow model was developed for the distribution of sulfathiazole residues in various tissues in swine. The approach was compartmental, in which the compartments and equilibrium constants had physiological meaning. Differential equations were developed, and appropriate parameter values and initial conditions were substituted and solved by a fourth-order Runga-Kutta technique. Simulation values corresponded with the experimentally determined concentration values in plasma and kidney, liver, muscle, fat, and heart tissues.

Keyphrases □ Sulfathiazole—physiological flow model, distribution, swine □ Physiological flow model—sulfathiazole, swine, distribution □ Distribution—physiological model, sulfathiazole, swine

Allergic reaction and increasing bacterial resistance are possible side effects resulting from human consumption of meat derived from animals given antibiotics (1). Consequently, regulations have been promulgated by the Food and Drug Administration setting tolerance levels for antibiotics and other drugs in slaughtered animals (2). Mathematical models which predict the residual amounts of a given drug in various organs at various times after administration are therefore important

[a] Microenemas contained 15 mg of cefoxitin/mL and had a dosage volume of 100 μL/100 g of rat body weight; $n \geq 3$. [b] $p < 0.001$ *versus* adjuvant without additive.

difference in their ability to permeate the rat rectal tissue. In the present study, we found that the coadjuvants tripolyphosphate and phytate substantially enhanced the absorption of cefoxitin only after their own permeation of the membrane was apparently enhanced by I. Thus, we speculate that adjuvant permeation of the mucosal membrane may be mechanistically necessary before enhanced compound absorption across the rectal membrane can occur.

In conclusion, the enhancing action of I on rectal cefoxitin absorption appears to depend on the affinity of I to the protein fraction in the mucosal membrane. The weak enhancing ability of the phosphate coadjuvants when administered with cefoxitin alone may involve chelating activity and possible damage to the rectal mucosa. However, the large increase in drug absorption after coadministration of I with either chelating agent, tripolyphosphate or phytate, is not just a consequence of the added effect of the enhancing action of I and chelation. These phosphate derivatives apparently have a strong adjuvant efficacy which can be realized only when their own permeation of the mucosal membrane is enhanced by adjuvants such as I.

Abstract □ A physiological flow model was developed for the distribution of sulfathiazole residues in various tissues in swine. The approach was compartmental, in which the compartments and equilibrium constants had physiological meaning. Differential equations were developed, and appropriate parameter values and initial conditions were substituted and solved by a fourth-order Runga-Kutta technique. Simulation values corresponded with the experimentally determined concentration values in plasma and kidney, liver, muscle, fat, and heart tissues.

Keyphrases □ Sulfathiazole—physiological flow model, distribution, swine □ Physiological flow model—sulfathiazole, swine, distribution □ Distribution—physiological model, sulfathiazole, swine

Allergic reaction and increasing bacterial resistance are possible side effects resulting from human consumption of meat derived from animals given antibiotics (1). Consequently, regulations have been promulgated by the Food and Drug Administration setting tolerance levels for antibiotics and other drugs in slaughtered animals (2). Mathematical models which predict the residual amounts of a given drug in various organs at various times after administration are therefore important

in setting the minimum time until slaughter after administration of the drug. The model must be sensitive to a number of factors, including the characteristic properties of the drug, the species of the animals, and the weight of the animal.

In this report, a model developed for the distribution of sulfathiazole residues in a number of organs in swine is described. Previously, a two-compartment model was used to describe these data (3). This work has been extended by development of a physiologically based model. The additional information obtained and the accuracy of physiological models for drug tissue concentrations has been well recognized in human pharmacokinetic modeling, especially with chemotherapeutic agents. In general, data from a number of organs and knowledge of several physiological parameters are needed. This allows the more detailed physiological model to yield more information than the usual compartmental model, in which the parameters are not directly related to the physiology of the animal. The model developed in this report closely follows the basic ideas developed previously (4, 5) (the Bischoff-Dedrick model). This approach has been applied to pharmacokinetic models in humans for thiopental (5, 6), methotrexate (4, 7, 8), cytarabine (9), and salicylate (10).

Table I—Parameters for Sulfathiazole Distribution in Swine (34 kg)

E_l	76.8

EXPERIMENTAL SECTION

Theoretical Basis—Like the Bischoff-Dedrick model, the approach described here is a compartmental approach in which the compartments and equilibrium constants have physiological meaning. Scheme I displays the pattern of blood flow through the animal. Since the drug is administered by rapid injection, it was assumed that at the initial time $t = 0$ h the total dose of the drug was homogeneously distributed throughout the plasma compartment.

Compartments corresponding to plasma, kidney, liver, muscle, fat, and heart have been included. Data were available for all of these tissues. In particular,

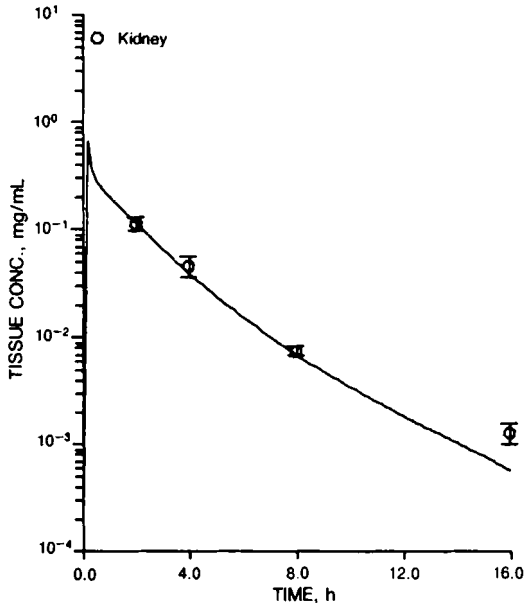

Figure 2—*Semilogarithmic plot of kidney concentration of sulfathiazole (O) versus time after intravenous administration to swine. The points were experimentally determined (SD as error bars), and the line was calculated according to Scheme I with the parameter values from Table I.*

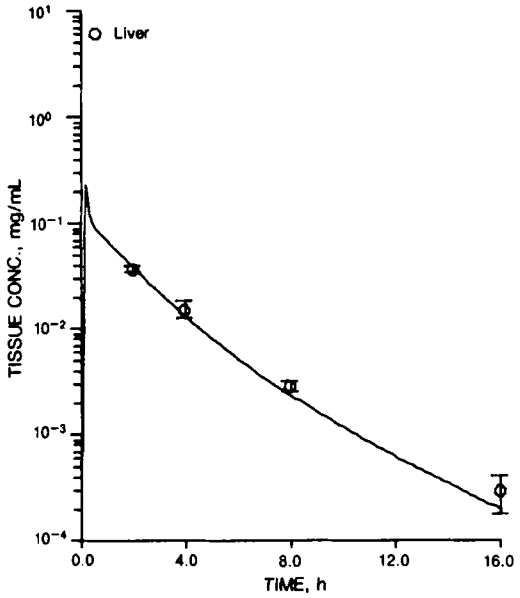

Figure 3—*Semilogarithmic plot of liver concentration of sulfathiazole (O) versus time after intravenous administration to swine. The points were experimentally determined (SD as error bars), and the line was calculated according to Scheme I with the parameter values from Table I.*

small amounts of drug were located in the heart, but it was included in the model as additional verification of the accuracy of the simulation.

From Scheme I a system of ordinary differential equations was derived by using the mass balance approach developed for physiological models (4, 5):

$$Vp \cdot \frac{dC_p}{dt} = \frac{Q_k}{R_k} \cdot C_k + \frac{Q_l}{R_l} \cdot C_l + \frac{Q_f}{R_f} \cdot C_f + \frac{Q_m}{R_m} \cdot C_m + \frac{Q_h}{R_h} \cdot C_h - (Q_k + Q_l + Q_f + Q_m + Q_h) \cdot C_p \quad \text{(Eq. 1)}$$

$$V_k \cdot \frac{dC_k}{dt} = Q_k \cdot C_p - \frac{Q_k}{R_k} \cdot C_k - \frac{E_k}{R_k} \cdot C_k \quad \text{(Eq. 2)}$$

$$V_l \cdot \frac{dC_l}{dt} = Q_l \cdot C_p - \frac{Q_l}{R_l} \cdot C_l - \frac{E_l}{R_l} \cdot C_l \quad \text{(Eq. 3)}$$

$$V_f \cdot \frac{dC_f}{dt} = Q_f \cdot C_p - \frac{Q_f}{R_f} \cdot C_f \quad \text{(Eq. 4)}$$

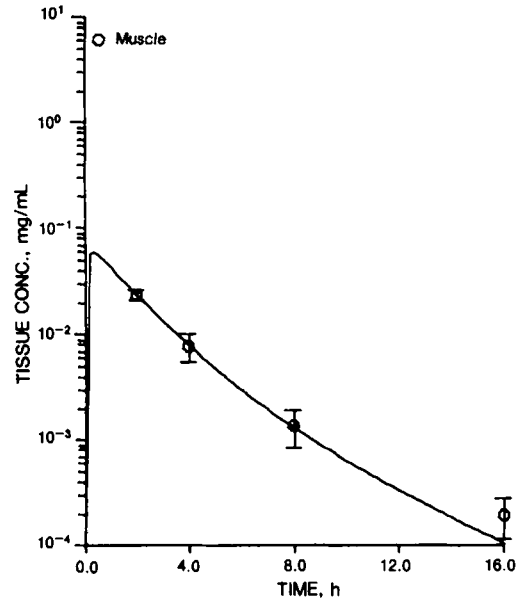

Figure 4—*Semilogarithmic plot of muscle concentration of sulfathiazole (O) versus time after intravenous administration to swine. The points were experimentally determined (SD as error bars), and the line was calculated according to Scheme I with the parameter values from Table I.*

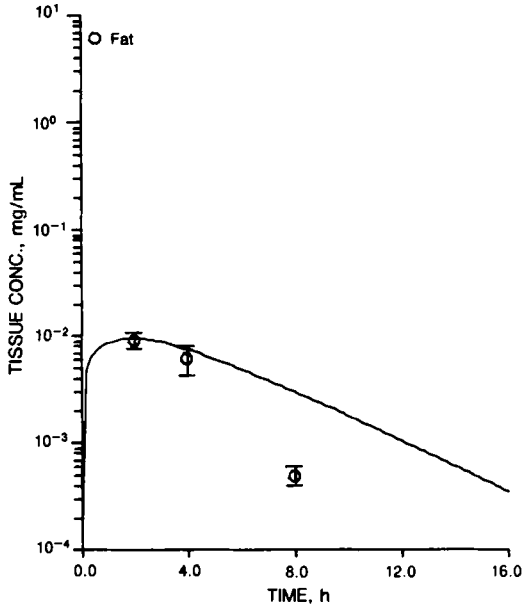

Figure 5—*Semilogarithmic plot of fat concentration of sulfathiazole (O) versus time after intravenous administration to swine. The points were experimentally determined (SD as error bars), and the line was calculated according to Scheme I with the parameter values from Table I.*

$$V_m \cdot \frac{dC_m}{dt} = Q_m \cdot C_p - \frac{Q_m}{R_m} \cdot C_m \quad \text{(Eq. 5)}$$

$$V_h \cdot \frac{dC_h}{dt} = Q_h \cdot C_p - \frac{Q_h}{R_h} \cdot C_h \quad \text{(Eq. 6)}$$

where V is volume, C is concentration, t is time, Q is plasma flow rate, R is the tissue to plasma equilibrium constant, E is the plasma clearance of the organ, and the subscripts represent the various organs: p for plasma, k for kidney, l for liver, f for fat, m for muscle, and h for heart. Hence, Q_m represents the plasma flow rate to the muscle.

The dose of the drug (D) was administered by rapid injection. By assuming it is instantly distributed through the plasma, the following initial conditions apply:

$$C_p(0) = D/V_p \quad \text{(Eq. 7)}$$

$$C_k(0) = C_l(0) = C_f(0) = C_m(0) = C_h(0) = 0 \quad \text{(Eq. 8)}$$

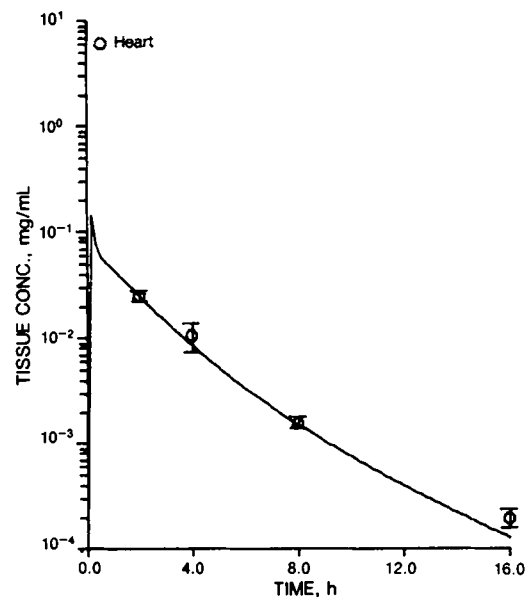

Figure 6—*Semilogarithmic plot of heart concentration of sulfathiazole (O) versus time after intravenous administration to swine. The points were experimentally determined (SD as error bars), and the line was calculated according to Scheme I with the parameter values from Table I.*

On substitution of appropriate parameter values and the initial conditions of Eqs. 7 and 8, Eqs. 1–6 were solved numerically by the fourth-order Runga-Kutta technique.

Parameters—Table I gives the parameters used in the simulation. The volumes for the blood, liver, kidney, and heart were obtained by first computing the organ weight by the method of Adolf (11) and then assuming a tissue density of 1 g/mL. Muscle and fat volumes were calculated from the percentages of body weight found in swine (12) and converted to the corresponding weight in the swine used. The average weight of the experimental swine was 34 kg. The plasma volume was computed as 60% of the whole blood volume. Bischoff *et al.* (13) have indicated that the method of Adolf of calculating blood volume produced a value lower than that reported in humans. Bischoff *et al.* have corrected for this difference by adjusting the Adolf values upward by a factor of 1.43. This adjustment was also made in this study.

Plasma flow rates for kidney, liver, and muscle were obtained from the relationship between plasma flow and body weight reported by Bischoff *et al.* (13). As fat is poorly perfused, it was assumed to have a very low flow rate. The actual value used was determined by perturbation. The heart plasma flow rate (adjusted for weight) was assumed to be the same as that for humans (14).

The total body clearance and renal clearance values were calculated from the data of Bourne *et al.* (3) as $k_{el} \cdot Vd$ and $k_e \cdot Vd$ respectively, where k_{el} is the elimination rate constant, k_e is the excretion into urine rate constant, and Vd is the apparent volume of distribution for a one-compartment pharmacokinetic model. The hepatic clearance term was calculated as the difference between the total body clearance and renal clearance values and represents the formation of an acetyl metabolite and sulfathiazole not recovered in urine.

The initial values for the equilibrium constants (R) were obtained from human autopsy (15) and were perturbed to obtain the simulation values. The dose of sodium sulfathiazole given to each animal was 72 mg/kg of body weight. In the simulation, the dose used was 2290.5 mg/kg of body weight, which was the average amount of sulfathiazole administered.

Experimental Data—The experimental data from Bourne *et al.* (3) were obtained by averaging the concentration of drug in the tissue of the three swine sacrificed at each time point. Sulfathiazole was extracted from tissues, as described by Bevill *et al.* (16), and quantitated by a modified Bratton-Marshall colorimetric method (17). The plasma concentrations (Fig. 1) were calculated as the average of the values obtained from the remaining swine at each time point. Plasma concentrations of sulfathiazole were measured by the modified Bratton-Marshall method of Annino (18).

RESULTS

The experimental data and the simulation for the plasma, kidney, liver, muscle, fat, and heart are shown in Figs. 1–6. The simulation parameters were chosen so that the graphs closely followed the trends indicated by the data. The values of those parameters which were obtained by experimentation or from the literature were not adjusted. The simulation results show a good correlation with the experimental data in all tissues except, possibly, fat. Data were collected from the muscle of the shoulder, loin, and leg. In Fig. 4, the experimental data are the average of these three concentrations in muscle tissue. The results obtained for fat tissue are shown in Fig. 5 (the simulation corresponds with the first two points, whereas the third point may indicate a factor not accountable by the model). The fat tissue included in the simulation is probably more diffuse than the samples taken for the experimental values.

DISCUSSION

A general physiological model has been presented for sulfathiazole in swine. The physiological meaning of each compartment allows the prediction of drug concentrations in those organs. The ability of the model to predict residue levels with reasonable accuracy in many different compartments suggests that the physiological approach is valuable. With this more complete model it should be possible to extrapolate or interpolate tissue concentrations of sulfathiazole in the various important food-providing tissues down to the regulated tolerance levels with more confidence than is possible with the linear compartmental approach. Given suitable estimates of the required parameters, drugs which are likely to give significant residue problems may be identified. Greater reliance on the model can be achieved with parameters specific for the species rather than parameters determined by extrapolation from other species.

Neutron Activation of Iron Tablets to Evaluate the Effects of Glycine on Iron Absorption

JOHN M. CHRISTENSEN ˣ, MUSA GHANNAM, and JAMES W. AYRES

Received May 2, 1983, from the *School of Pharmacy, Oregon State University, Corvallis, OR 97331.* Accepted for publication December 19, 1983.

Abstract □ Neutron bombardment (neutron flux, 3×10^{12} neutrons/cm^2/s) of prepared iron tablets containing glycine-iron or iron alone was performed to prepare radioactive tablets to assess the effects of glycine on iron absorption from tableted formulations. No interfering isotopes of sufficient quantity were generated during neutron activation of the iron tablets. Cobalt-60 was the major trace mineral detected and accounted for only 1.3% of the total activity. There may have been trace amounts of zinc-65 or chromium-51 present, but they were not detectable above background radioactivity in the final tablet produced. Iron-59 represented >98% of the radioactivity present in the tablets used in the study. Glycine-containing iron tablets produced dramatically higher amounts of iron in blood and tissues of rabbits ($p < 0.05$) than did the same tablet formulations without glycine. The area under the iron blood concentration time curve over 4 h increased by 67% with glycine added to the formulation over control iron tablets. Iron concentrations in tissues 4 h after iron administration was in the order of blood > liver > heart > kidney > muscle.

Keyphrases □ Absorption—iron, effects of glycine, neutron activation of iron tablets □ Neutron activation—iron tablets, effects of glycine on iron absorption □ Formulations—tablets, neutron activation to evaluate the effects of glycine on iron absorption

Several investigators have noted that amino acids may increase iron absorption from the GI tract (1–7). It was proposed that amino acids facilitate increased iron absorption by (*a*) buffering the intestine and delaying the rise in pH toward neutralization at sites where iron is oxidized to insoluble salt forms, (*b*) forming iron-amine chelates that act to enhance iron absorption, and (*c*) stimulating iron transport systems within the animal (6).

In previous studies, it has been shown that glycine enhances iron absorption (6, 7). Also, it has been shown that administration of diets containing glycine compared with diets lacking glycine result in a greater amount of iron absorbed (8). It was the purpose of this study to determine whether glycine added to iron (at a ratio of 2:1, respectively) in a tablet dosage form could increase iron absorption.

To prepare radioactive iron tablets, neutron activation was tested to determine whether this technique offers a viable method of preparing intact tableted dosage forms that can conveniently be made radioactive after formulation. By preparing tableted dosage forms first and then making them radioactive by neutron activation, there is less of a potential for contamination of facilities and there are unique opportunities to use radiolabeled compounds to test some qualities of solid dosage forms.

Table I—Radionuclides Expected To Be Activated in Tablets from Neutron Flux [a]

Element Produced During Neutron Activation	Element Half-Life
^{24}Na	15 h
^{42}K	12.4 h
^{27}Mg	9.5 min
^{56}Mn	2.6 h
^{60}Co	5.26 years
^{51}Cr	27.8 d
^{38}Cl	37.3 min
^{65}Zn	243.6 d
^{59}Fe	45.1 d

[a] Neutron flux, 3×10^{12} neutrons/cm^2/s.

EXPERIMENTAL SECTION

Production of Tablets—Direct compression was used to produce tablets[1]. Two types of tablets were prepared. The first type contained glycine and ferrous chloride. The control tablets did not contain glycine.

Type 1 Tablet—The average weight of each tablet was 0.42 g. The formula for one tablet of type 1 is (in milligrams/percent): granulated sucrose[2] (296.6/71.4), magnesium stearate (29.7/7.1), glycine (39.5/9.5), and ferrous chloride (49.4/11.9).

Type 2 Tablet—The average weight of each tablet was 0.41 g. The formula for one tablet of type 2 is (in milligrams/percent): granulated sucrose[2] (328.1/81), magnesium stearate (28.9/7.1), and ferrous chloride (48.2/11.9).

Disintegration tests were done for both tablet types by using a USP tablet and disintegration tester[3] (9).

Neutron Activation of Tablets—Tablets were put into small scintillation bags[4]. Each bag was sealed by heating and placed in a polyvial[5]. The polyvials were then sealed by heating. Tablet samples were then put in the Oregon State University (OSU) Triga reactor in the Lazy Susan and activated with a neutron flux of 3×10^{12} neutrons/cm^2/s generated by 1 MW of power from the reactor. The irradiation time was 4 h. The tablets were allowed to stand for 1 week after irradiation to allow short-half-life radionuclides to decay.

Neutron Activation Equation—For neutron activation analysis, the following was used:

$$A = N\phi\sigma(1 - e^{-\lambda T})e^{-\lambda t} \qquad \text{(Eq. 1)}$$

where A is the activity at end of irradiation (disintegrations/s), N is the number of atoms, ϕ is the flux (neutrons/cm^2 s), σ is the cross-section (cm^2), λ is the decay constant (s^{-1}), T is the length of irradiation (s), and t is the time elapsed between activation and measurement.

The activity at the time of measurement of radiation depends on the half-life of the isotope of interest and the time that has elapsed between activation and measurements (10, 11). Activation analysis is subject to a variety of errors. These include errors due to flux gradients, self-shielding, and interfering nuclear reactions (10).

The errors due to neutron flux gradients within the reactor can be minimized by rotating or spinning the sample during irradiation (12). The OSU Triga reactor is a circulator reactor, and the samples were rotated around the reactor core during irradiation in the Lazy Susan. For other reactors, the use of an internal standard to determine the flux and to ensure that future samples have the exact orientation and position of irradiation as those of previous samples reduces the necessity to vary flux gradients (12, 13).

The effects of self-shielding can be shown to be a function of the sample mass and length (12). More self-shielding occurs when each of the parameters is larger. With samples of <4 g in mass, very little self-shielding occurs (12, 13). Also, self-shielding is reduced when the sample is homogeneously spread in an inert material (*e.g.*, sucrose) (12). Tablets produced for this study were small (0.41–0.42 g), and the major ingredient in 71–81% of the tablets is granulated sucrose. Both of these factors minimize self-shielding.

Interference in counting iron-59 may occur from cobalt-60 and zinc-65 when counting with a sodium iodide detector in a solid scintillation counting chamber[6]. The 1.099- and 1.292-MeV gamma rays of iron-59 with the 1.173-

Table II—Sources of Radioactivity in Tablets Used in Animal Study 1 Week after Activation

Sample	^{60}Co, ppm ± 16	^{51}Cr, ppm ± 16	^{65}Zn Upper Limit, %[a]	^{59}Fe, cpm	^{60}Co, cpm
Tablet	0.72 ± 0.04	ND[b]	>0.013	30,176	392
$FeCl_3$	6.8 ± 0.1	11.0 ± 3.0	ND	287,750[c]	3700[c]
Glycine	ND	1.1 ± 0.2	ND	ND	ND
Magnesium stearate	ND	ND	ND	ND	ND
Granulated sucrose[2]	ND	ND	ND	ND	ND

[a] Value represents the upper limit plus 3 standard deviations of the percentage of zinc activity that may be contained in the tablet that was being hidden by background counts. [b] Not detectable. [c] Ratio of count of ^{60}Co-^{59}Fe was equivalent to that of the tablet.

and 1.332-MeV gamma rays of cobalt-60 and the 1.115-MeV gamma rays of zinc-65 would appear as a single peak in a sodium iodide detector. Other radionuclides that produce gamma rays in this range, *i.e.*, nickel, aluminum, copper, manganese, *etc.*, are either not generated to a sufficient extent on bombardment by slow thermal neutrons due to their low cross sections or have half-lives too short to be active at the end of 1 week of storage.

To ensure that the tablets contained only trace amounts of cobalt-60 after activation, all components of the tablet, the powders used for tablet formulations, and the tablets were activated and counted for 100 min in a germanium-lithium [Ge(Li)] detector[7] with a multichannel analyzer. This detector was calibrated at 1 KeV per channel, with the screen having 2048 channels. The samples were analyzed for radioactivity having gamma energys in the range of 80 keV-2.04 MeV, to make certain that the samples to be collected later in the animal study could be reliably counted by the NaI detector as iron-59 counts.

Procedure with Rabbits—The iron-glycine activated tablets, as well as the control activated tablets, were each tested on groups of four rabbits. The tablets were administered to each rabbit before 2 weeks had elapsed from the neutron activation of the tablets. Female rabbits were used (weight, 2.0–3.0 kg each). The ears of each rabbit were shaved with an electric shaver and commercial ointment[8]. The rabbit was then put in a rabbit restrainer with its head out and given orally four tablets with a total activity of 1.1 μCi.

At time periods of 5, 10, 15, 20, 30, 45, 60, 90, 120, 150, 180, 210, and 240 min after tablet administration, 100-μL blood samples were collected from the ears with capillary tubes. Bleeding was initiated by pricking the vein of the ears with a 20-gauge needle. Procaine was used as a local anesthetic. Blood samples were placed into counting vials. The 1.099- and 1.292-MeV gamma rays of 44.6-d iron-59 of each sample were counted for 4000 s in a solid scintillation counter chamber.

At the end of 4 h, the animals were sacrificed by ether administration, and liver, kidney, muscle, and heart samples were taken from the animals, weighed, and then counted as reported previously (7).

RESULTS AND DISCUSSION

When samples are exposed to neutron activation, all elements with atomic numbers greater than 10 are activated. The abundance of the different isotopes of the elements that are to be generated depends on the neutron flux to which they are exposed and whether the isotope of the element has a high or low cross section to the neutron flux to which it is exposed. For example, iron that is subjected to a neutron flux of 3×10^{12} neutrons/cm^2/s produces only iron-59. The other isotopes of iron are not produced to any detectable level because of their low cross sections when exposed to the neutron flux employed.

After the tablets and powders were activated by the OSU Triga reactor in the Lazy Susan, there was too much radioactivity emanating from them to be easily quantitated. The tablets and powders were thus sealed in a lead storage area and kept for 1 week. In Table I is a list of elements that were expected to be generated and suspected to be the cause of the initially high radioactive emissions of the tablets and powders. All elements except iron-59, cobalt-60, zinc-65, and chromium-51 have very short half-lives and would become nonradioactive after 1 week of storage. The tablets and powders were counted in the Ge(Li) detector after 1 week of storage (Table II). Iron-59 accounted for >98% of the radioactivity counted. Cobalt-60 accounted for ~1.3% of the radioactivity present. Only a trace amount of zinc-65 was observed, and no detectable levels of chromium-51 were present in the tablets to be used in the animal study. The ratio of counts of cobalt-60 in the tablet was obtained as:

$$\text{Ratio} = \frac{^{60}\text{Co}_{(\text{cpm})} \times 100}{^{59}\text{Fe}_{(\text{cpm})} + {}^{60}\text{Co}_{(\text{cpm})}} \qquad \text{(Eq. 2)}$$

The majority of the radioactivity contained in the tablets (>98%) originated from one isotope, iron-59. For this reason, the NaI detector could be used to count the samples obtained from the animal study.

The tablets prepared by neutron activation for use in this study were administered to the rabbits before 2 weeks had elapsed from initial activation. Allowing the tablets to stand for longer periods would have caused the cobalt-60/iron-59 ratio to change in the tablets. After 2 months, the cobalt-60 would contribute to >3% of the tablet radioactivity instead of the 1.3% of tablet radioactivity that was measured. The percentage of radioactivity in the tablets due to cobalt-60 would increase the longer the tablets were stored, since iron-59 has a half-life much shorter than that of cobalt-60.

Ferrous chloride was used rather than the more commonly prescribed ferrous sulfate because the tablets were to be activated, and the less radioactive the tablets, the more convenient they are for handling. Sulfur-35, with a half-life of 88 d, is produced when ferrous sulfate is activated. Chlorine-38, with a half-life of 37.3 min, is produced when ferrous chloride is activated (14). Since, chlorine-38 decayed very quickly after the end of bombardment, it was more convenient to use to count the 45-d iron-59.

After the tablets were prepared and before neutron activation, disintegration tests were conducted by using a tablet disintegration apparatus[3]. Tablet hardness averaged 15 kg/in^2 when tested with a tablet hardness tester[9]. Eighteen tablets of each type were tested. Seventeen glycine-iron tablets disintegrated within 18 min, whereas the 18th tablet disintegrated in 23 min. On the other hand, 16 control tablets disintegrated within 15 min, whereas the two others disintegrated within 19 min. Thus, any difference in iron absorption should not be due to differences in tablet disintegration after administration. Dissolution studies, which often correlate more closely with bioavailability, were not conducted.

In Figs. 1 and 2 are shown, respectively, the iron concentration in blood and different tissues following oral administration of glycine-iron and iron control neutron-activated tablets to rabbits. It is evident from these experiments that iron appears more quickly and in greater amounts in blood when the tablets contained glycine. The area under the iron concentration curve for the time during which data were collected increased by 67% when the tablets contained glycine (Fig. 1). From an assessment of the total amount of iron absorbed, the iron-glycine tablets showed a statistically significant increase in the amount of iron absorbed during the first 4 h postdose ($p \leq 0.05$) based on the

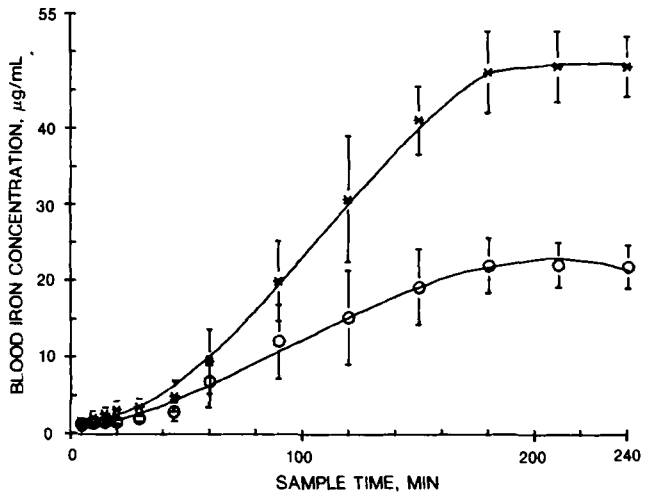

Figure 1—*Blood iron concentration (±SD) versus time curve in rabbits following oral administration of four tablets containing 192.92 mg of ferrous chloride (○) and four tablets containing 197.64 mg of ferrous chloride and 158.12 mg of glycine (*).*

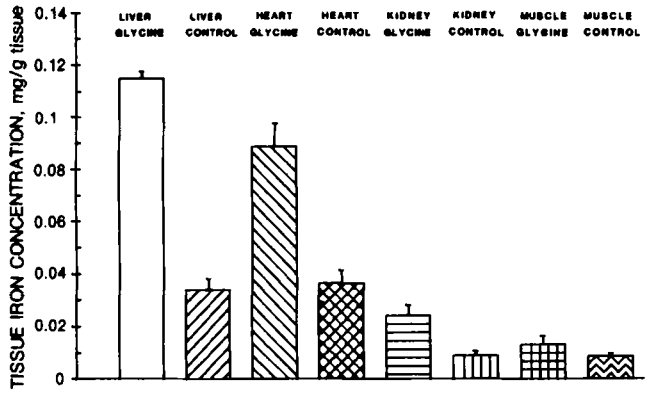

Figure 2—*Iron concentration (±SD) in body tissues 4 h after oral administration of four tablets containing 192.92 mg of ferrous chloride (control) and four tablets containing 197.12 mg of ferrous chloride and 158.12 mg of glycine.*

assumption that the area under the iron concentration–time curve (0–4 h) is an indicator of absorption.

The amount of iron in the different tissues was also consistent with iron levels in the blood. Iron concentration was highest in the tissues of the rabbits that received the glycine–iron tablets (Fig. 2). Iron–glycine tablets generated iron concentrations in tissue that were statistically significantly different from those of control iron tablets ($p < 0.001$ for the tissues of the liver, heart, and kidney; $p < 0.05$ for muscle).

All data were consistent with those from a previous report (7) from our laboratory indicating that glycine increases iron absorption into both blood and tissues. Neutron activation analysis is known to be very useful in analytical problems in which high sensitivity is required (sensitivity can reach 10^{-9} g). It is safe, economical, fast, practical in elemental analysis, and nondestructive (15). Also, thermal neutrons do not activate isotopes with atomic numbers of less than 10; therefore, carbon, hydrogen, oxygen, and nitrogen are not activated.

The data show that neutron activation analysis of final tableted dosage forms of iron can be utilized to investigate the effects of variable formulation factors on the absorption of iron. Further work is needed in the area utilizing multiple dosing, mixed protein hydrolysate, and pure defined amino acid mixtures to optimize tablet formulations for iron absorption. The technique of neutron-activation analysis can be employed for other minerals such as zinc or magnesium and may be used for comparing the rate and extent of absorption of minerals from commercially available vitamin-mineral mixtures (tablets or capsules). This application is currently under investigation in our laboratories.

Potential Inhibitors of Tyrosine Hydroxylase and Dopamine-β-Hydroxylase

K. R. SCOTT ˣ, CALVIN J. ALT, MURRAY KEMP, ELISE HAYES, and VASANT G. TELANG

Received June 28, 1983, from *Howard University, College of Pharmacy and Pharmacal Sciences, Department of Medicinal Chemistry, Washington, DC 20059.* Accepted for publication September 26, 1983.

Abstract □ A series of methyl-substituted 1,2,3,4-tetrahydrocarbazoles was synthesized and screened for *in vitro* activity against tyrosine hydroxylase and dopamine-β-hydroxylase. The most potent compounds were evaluated for inhibition of norepinephrine biosynthesis in rats. The results indicated no significant decrease in norepinephrine levels at three dosage levels.

Keyphrases □ Tyrosine hydroxylase—*in vitro* activity, effect of methyl-substituted 1,2,3,4-tetrahydrocarbazoles □ Dopamine-β-hydroxylase—*in vitro* activity, effect of methyl-substituted 1,2,3,4-tetrahydrocarbazoles □ Methyl-substituted 1,2,3,4-tetrahydrocarbazoles—effect on tyrosine hydroxylase and dopamine-β-hydroxylase, *in vitro*

It has been shown that the 1,2,3,4-tetrahydrocarbazole nucleus is an active pharmacophore. Previous studies have shown that the various carbazoles exhibit anti-inflammatory (1–6), antidepressant (7–12), hypoglycemic (13), analgetic (14), cardiotonic (15), anti-infective (16), and anticancer activities (17). It was of interest to extend the initial work of

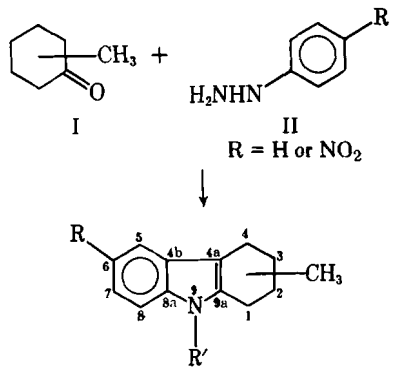
Mooradian *et al.* (15) and to systematically evaluate the following structural modifications of the 1,2,3,4-tetrahydrocarbazole nucleus: the effect of substitution on the aromatic ring; the effect of removal of the proton on the indole nitrogen; and the effect of the addition of an alkyl group to the tetrahydro ring. Representative analogues were evaluated in two *in vitro* systems, tyrosine hydroxylase (18) and dopamine-β-hydroxylase (19) for potential use as antihypertensive agents. The reaction sequence for the synthesis of the methyl-substituted 1,2,3,4-tetrahydrocarbazoles is shown in Scheme I.



I; II (R = H or NO_2)

III: R′ = H
IV: R′ = CH_3, dialkylaminoalkyl, cycloaminoalkyl, $(CH_2)_2CN$, or $(CH_2)_2COOH$

Scheme I

The methyl-substituted cyclohexanone (I) was treated with the appropriate phenylhydrazine (II) (20, 21) using acetic acid (R = H) or acetic acid and hydrochloric acid (R = NO_2) to give the methyl-1,2,3,4-tetrahydrocarbazoles (III). Treatment of III with the appropriate base, followed either by the addition of methyl iodide, a dialkylaminoalkyl chloride, a cycloaminoalkyl chloride, or acrylonitrile, produced the 9-methyl, 9-dialkylaminoalkyl, 9-cycloaminoalkyl, or 9-(3-cyanopropyl) derivative (IV), respectively. The latter compound was hydrolyzed to the propionic acid derivative with either acid or base. It was shown (22) that 2-methylcyclohexanone undergoes the reactions shown in Scheme II.

These products, 1-methyl-1,2,3,4-tetrahydrocarbazole (V) and 2,3,4,4a-tetrahydro-4a-methyl-1*H*-carbazole (VI), were

of interest in view of varying reports (22–24) on the yields as well as investigating a new and related series, 2,3,4,4a,9,9a-hexahydro-4a-methyl-1*H*-carbazole (VII), which occurs on reduction of VI.

Selected compounds from each group were tested for *in vitro* activity against tyrosine hydroxylase and dopamine-β-hydroxylase. The most active compound, X, was tested at three dosage levels for inhibition of norepinephrine biosynthesis in rats.

EXPERIMENTAL SECTION

Instruments—Melting points were obtained using a melting point apparatus[1] and are uncorrected. Observed boiling points were also uncorrected. IR spectra were obtained on a spectrophotometer[2] as KBr pellets or neat. NMR spectra were obtained on a 60-MHz spectrometer[3] with tetramethylsilane as the internal reference. Elemental analyses were also performed[4]. Tritium was assayed on a liquid scintillation counter[5].

Reagents—All ketones[6] and phenylhydrazine[7] were distilled before use. *p*-Nitrophenylhydrazine[8] was recrystallized. L-[3,5-^{3}H]Tyrosine, L-[^{3}H]-epinephrine, [^{3}H]tyramine, *S*-[C^{3}H$_3$]adenosyl-L-methionine, and scintillation fluids[9] were used without further purification. 1,4-Dithiothreitol[10], dopamine, norepinephrine, epinephrine, and *S*-adenosyl-L-methionine[11] were used without further purification. Tyrosine hydroxylase was prepared (25), purified (26), and assayed (27); the protein content was also determined (28). Dopamine-β-hydroxylase (EC 1.14.17.1)[12] was assayed (29); phenylethanolamine-*N*-methyltransferase (EC 2.1.1.28)[12] was also assayed (30).

General Procedure for the Preparation of Methyl-Substituted 1,2,3,4-Tetrahydrocarbazoles (III, R = NO$_2$)—The previous method (21) was modified as follows. One-half mole of 4-methylcyclohexanone and *p*-nitrophenylhydrazine were dissolved in 180 g of glacial acetic acid. The mixture was heated at reflux for 4 h, chilled to 5°C, and filtered. The dried hydrazone was dissolved in 1 L of hydrochloric acid and was heated at reflux for 1 h. The product separated as yellow needles (78% yield), mp 166.5–167.5°C [lit. (31) 165–166°C].

General Procedure for Alkylation of Methyl-Substituted 1,2,3,4-Tetrahydrocarbazoles—*Method A* (*IV*, *R′* = *CH$_3$*)—The previous method (17) was employed using 0.05 mol of 3-methyl-1,2,3,4-tetrahydrocarbazole (VIII) and 0.05 mol of methyl iodide with 3 g of sodium hydride (51%, freed from mineral oil) in 25 mL of dimethylformamide. Chromatography on silica gel afforded 9.2 g (92% yield) of 3,9-dimethyl-1,2,3,4-tetrahydrocarbazole (XIII) as white crystals, mp 74–75°C; ^{1}H-NMR (CDCl$_3$): δ 1.90 (3, d, *J* = 4 Hz, CH$_3$), 3.10 (6, m, CH$_2$), 3.40 (1, m, CH), 3.80 (3, s, CH$_3$—N), and 7.30 ppm (4, m, ArH).

Anal.—Calc. for $C_{14}H_{17}N$: C, 84.23; H, 8.61; N, 7.06. Found: C, 84.46; H, 8.63; N, 7.01.

Table III—1,2,3,4-Tetrahydrocarbazoles and 2,3,4,4a,9,9a-Hexahydrocarbazoles as Inhibitors of Tyrosine Hydroxylase[a]

[a] Data from Ref. 35. [b] Data from Ref. 36.

Method B [*IV*, $R' = (CH_2)_3N(CH_3)_2$]—The previous method (17) was employed using 0.05 mol of 3-methyl-1,2,3,4-tetrahydrocarbazole (VIII) and 0.05 mol of 3-dimethylaminopropyl chloride (17) in dimethylformamide with 3 g of the aforementioned sodium hydride to give 16.7 g (75% yield) of IX, bp 154–155°C (0.35 mm Hg), as a light-yellow oil. ^{1}H-NMR (acetone-d_6): δ 1.82 (3, d, J = 4 Hz, CH_3), 2.05–2.55 (m, CH_2), 2.25 (3, s, CH_3—N), 3.20 (6, m, CH_2), 3.45 (1, m, CH), and 7.22 ppm (4, m, ArH).

Anal.—Calc. for $C_{18}H_{26}N_2$: C, 79.88, H, 9.70, N, 10.41. Found: C, 80.00; H, 9.87; N, 10.46.

Method C [*IV*, $R' = (CH_2)_2CN$]—The previous method (17) was employed using 0.05 mol of 3-methyl-1,2,3,4-tetrahydrocarbazole (VIII) and 0.10 mol of acrylonitrile in benzene containing 1.5 mL of trimethylbenzylammonium hydroxide to give 9.59 g (80% yield) of XI as a white amorphous powder, bp 188–191°C (0.7 mm Hg), mp 99–100°C. IR (KBr): 2250 cm^{-1} (s, C≡N); ^{1}H-NMR (acetone-d_6): δ 1.80 (3, d, J = 4 Hz, CH_3), 2.40 (1, d, J = 17 Hz, CHCN), 2.80 (1, d, J = 17 Hz, CHCN), 2.90 (2, m, —CH_2N), 3.05 (6, m, CH_2), 3.50 (1, m, CH), and 7.20 ppm (4, m, ArH).

Anal.—Calc. for $C_{16}H_{18}N_2$: C, 80.62; H, 7.63; N, 11.76. Found: C, 80.59; H, 7.77; N, 11.55.

3-Methyl-1,2,3,4-tetrahydrocarbazole-9-propionic acid (XII)—Compound XI (0.03 mol) was dissolved in 400 mL of 90% ethanol containing 0.50 mol of potassium hydroxide. The mixture was refluxed for 18 h and then the solvent was evaporated under reduced pressure. The residue was dissolved in water, decolorized, and acidified with hydrochloric acid. The product was extracted with ether, and the organic phase was washed with water and dried (Na_2SO_4). Evaporation of the solvent and distillation of the residue afforded XII, as white crystals, bp 195–197°C (0.55 mm Hg), mp 104–105°C. IR (KBr): 1740 cm^{-1} (s, C=O); ^{1}H-NMR (acetone-d_6): δ 1.75 (3, d, J = 4 Hz, CH_3), 3.00 (6, m, CH_2), 3.45 (1, m, CH), 4.45 (3, t, J = 7 Hz, $NCHCH_2C$), 6.95–7.50 (4, m, ArH), and 10.45 ppm (1, s, COOH).

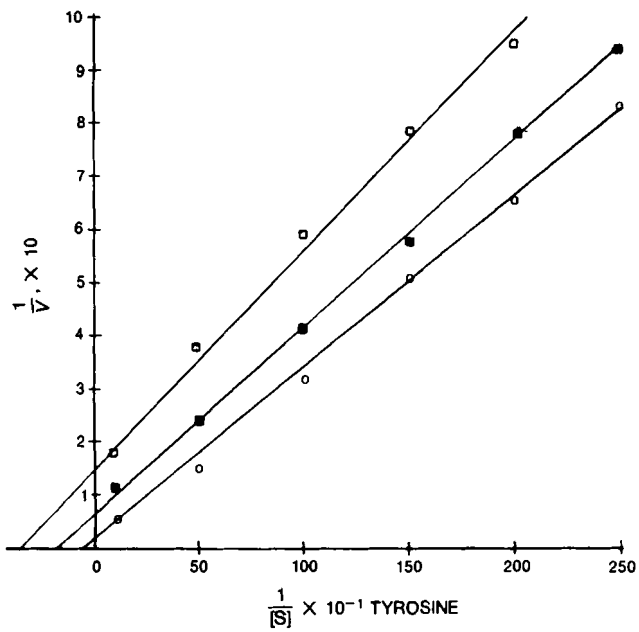

Figure 1—*Effect of X (■) and XIV (□) on the hydroxylation of L-tyrosine. Concentrations of L-tyrosine (substrate) varied from 1 × 10^{-4} to 4 × 10^{-6} M; (○) control.*

Anal.—Calc. for $C_{16}H_{19}NO_2$: C, 74.66; H, 7.46; N, 5.44. Found: C, 74.83; H, 7.62; N, 5.16.

In all alkylation methods when R = NO_2, additional solvent was required.

1-Methyl-1,2,3,4-tetrahydrocarbazole (V)—The previous method for the preparation of III (R = NO_2) was employed. Cyclization was accomplished using dilute sulfuric acid (32). The product was isolated and distilled, bp 121–129°C (0.4 mm Hg), mp 67–68°C as tan crystals [lit. (22) bp 142–146°C (0.3 mm Hg), mp 69°C].

2,3,4,4a-Tetrahydro-4a-methyl-1*H*-carbazole (VI)—The aforementioned hydrazone was cyclized using glacial acetic acid (32) to give a liquid, bp 98–106°C (0.9 mm Hg), picrate 170–171°C as yellow crystals [lit. (33) bp 98–100°C (0.3 mm Hg), picrate 169–171°C]. ^{1}H-NMR ($CDCl_3$): δ 1.26 ppm (3, s, CH_3).

2,3,4,4a,9,9a-Hexahydro-4a-methyl-1*H*-carbazole (VII)—Catalytic hydrogenation of V (0.1 mol) employing platinum oxide in a mixture of hydrochloric acid and alcohol (34) for 8 h gave VII in 82% yield, bp 105–112°C (0.6 mm Hg), mp 52–53°C as white crystals. IR (KBr): 3425 cm^{-1} (s, NH); ^{1}H-NMR ($CDCl_3$): δ 10.2 ppm (1, s, NH).

Anal.—Calc. for $C_{13}H_{17}N$: C, 83.35; H, 9.17; N, 7.48. Found: C, 83.66; H, 9.08; N, 7.48.

Analytical data for the compounds prepared by the above methods are shown in Tables I and II.

Enzyme Inhibition—*Tyrosine Hydroxylase*—Tyrosine hydroxylase inhibitors were screened as previously indicated (27) with the substrate concentration varied from 1 × 10^{-5} to 5 × 10^{-5} M and each potential inhibitor tested at concentrations of 2 × 10^{-4} M and 4 × 10^{-4} M. DL-α-Methyltyrosine[8] was used as a standard inhibitor for this phase. The results are listed in Table III.

Dopamine-β-Hydroxylase—Dopamine-β-hydroxylase inhibitors were screened as previously reported (29). The substrate concentration was 5 × 10^{-4} M. *O*-Benzylhydroxylamine[8] was used as a standard inhibitor in this study. The data are listed in Table IV.

***In Vivo* Determinations**—Thirty male Sprague-Dawley rats, weighing ~200 g, were divided into five groups of six rats each. Each group received an injection of either 1 mg/kg of X, 10 mg/kg of X, or 400 mg/kg of α-methyltyrosine or saline. The intraperitoneal doses were in a volume of 1 mL. After 4 h, the initial dose was repeated and, after an additional 4 h, the animals were sacrificed. The brains, hearts, and blood were taken for analysis (35, 36). Data for each assay are shown in Table V. The experiment was repeated (assay III) with the exceptions that the second dose was repeated after 3 h, the animals were sacrificed 3 h after the last dose, and only the hearts were removed and assayed (35).

RESULTS AND DISCUSSION

From the tyrosine hydroxylase data (Table III), it appears that the active compounds are those that possess a substituent at the 9-position. In the 9-[3-(dimethylamino)propyl] series, the 6-nitro substitution is essential for activity, as IX and XIX were inactive while both XIV and XXIII were active. In the 9-[2-(1-piperidino)ethyl] series, both X (the unsubstituted carbazole) and XVI (the 6-nitro analogue) were active. In the 9-(3-cyanopropyl) series, the initial conclusion reached with the previous analogues held for XI and XVII, but failed with XXI and XXVI due to the extreme insolubility of the latter. In the 9-(3-propionic acid) series, the 6-nitro derivative (XVIII) was inactive, while XII (the unsubstituted analogue) was active. As in the case of the cyanopropyl series, the extreme insolubility of XVIII was a prime factor in the correlation. The hexahydro analogue of X (XXX) was inactive. Inhibition of tyrosine hydroxylase by the tetrahydrocarbazoles was noncompetitive

with tyrosine, as seen in Fig. 1 for X and XIV. Whether this effect is exerted on either tetrahydrofolate or tetrahydropteridine (18) must await further study. All active compounds were assayed for inhibition of dopamine-β-hydroxylase (Table IV). From the data, X was shown to be the most active overall in both systems and was selected for the *in vivo* assay.

In vivo results of X (Table V) are explained on the basis of the assays performed. Assays I and III (35) are paired and show no inhibition. Assay I was repeated due to a high norepinephrine level after α-methyltyrosine treatment. Assay II results indicate significant inhibition; however, the correction for the recovery of norepinephrine from alumina is not included in assay II, while I and III allow for this error[13]. Thus, while X inhibited both tyrosine hydroxylase and dopamine-β-hydroxylase *in vitro*, it was not active *in vivo*. Whether X is metabolized too rapidly and fails to attain the required tissue concentration is not known.

Presented in part at the First Annual Undergraduate Research Seminar, University of West Virginia, 1979.

The authors thank the following: Dr. Andre A. Asselin, Ayerst Pharmaceuticals, Montreal, for helpful discussions on the structural assignments; Drs. Steven L. Platt and Andy Evans, Varian Instrument Division, for the use of their NMR spectrometer; Dr. Nicholas Zenker, University of Maryland, for helpful suggestions on the preparation of tyrosine hydroxylase; Dr. Joseph J. Villafranca, Pennsylvania State University, for sharing his pre-publication manuscript on dopamine-β-hydroxylase; and Dr. Irwin Kopin, NIH, who provided the laboratory space, instruments, animals, and encouragement to complete the final phase of the work.

Direct Preparation of Spherically Agglomerated Salicylic Acid Crystals During Crystallization

Y. KAWASHIMA *[x], M. OKUMURA *, H. TAKENAKA *, and A. KOJIMA[‡]

Received August 17, 1983 from the **Gifu Pharmaceutical University, 5-6-1, Mitahora-higashi, Gifu 502, Japan* and the [‡]*Sanwa Chemical Research Laboratory, 1212, Shimojyo, Kasugai 486, Japan.* Accepted for publication October 11, 1983.

Abstract □ Needle-like salicylic acid crystals were transformed into a spherically shaped dense form during crystallization by the spherical crystallization technique. Agitation of a mixture of ethanol–water–chloroform containing salicylic acid yielded spherically agglomerated salicylic acid crystals. The crystallinity of the agglomerated salicylic acid decreased when the amount of ethanol in the solvent mixture was decreased. The wettability of the agglomerated crystals increased when the amount of ethanol in the solvent mixture was decreased, and this enhanced the dissolution rate of the crystals. The remarkable improvements in the flow and packing of the agglomerated crystals enabled the direct compression of the crystals.

Keyphrases □ Salicylic acid—crystallization of spherically agglomerated crystals □ Crystallization—agglomeration of salicylic acid crystals

A novel agglomeration technique to transform a microcrystalline drug into an agglomerated form during the crystallization process was previously described (1). This technique could enable subsequent processes, such as separation, filtration, drying, etc. to be carried out more efficiently. Furthermore, the resultant agglomerated crystals could be easily

with tyrosine, as seen in Fig. 1 for X and XIV. Whether this effect is exerted on either tetrahydrofolate or tetrahydropteridine (18) must await further study. All active compounds were assayed for inhibition of dopamine-β-hydroxylase (Table IV). From the data, X was shown to be the most active overall in both systems and was selected for the *in vivo* assay.

In vivo results of X (Table V) are explained on the basis of the assays performed. Assays I and III (35) are paired and show no inhibition. Assay I was repeated due to a high norepinephrine level after α-methyltyrosine treatment. Assay II results indicate significant inhibition; however, the correction for the recovery of norepinephrine from alumina is not included in assay II, while I and III allow for this error[13]. Thus, while X inhibited both tyrosine hydroxylase and dopamine-β-hydroxylase *in vitro*, it was not active *in vivo*. Whether X is metabolized too rapidly and fails to attain the required tissue concentration is not known.

Direct Preparation of Spherically Agglomerated Salicylic Acid Crystals During Crystallization

Y. KAWASHIMA *[x], M. OKUMURA *, H. TAKENAKA *, and A. KOJIMA[‡]

Received August 17, 1983 from the **Gifu Pharmaceutical University, 5-6-1, Mitahora-higashi, Gifu 502, Japan* and the [‡]*Sanwa Chemical Research Laboratory, 1212, Shimojyo, Kasugai 486, Japan.* Accepted for publication October 11, 1983.

Abstract □ Needle-like salicylic acid crystals were transformed into a spherically shaped dense form during crystallization by the spherical crystallization technique. Agitation of a mixture of ethanol–water–chloroform containing salicylic acid yielded spherically agglomerated salicylic acid crystals. The crystallinity of the agglomerated salicylic acid decreased when the amount of ethanol in the solvent mixture was decreased. The wettability of the agglomerated crystals increased when the amount of ethanol in the solvent mixture was decreased, and this enhanced the dissolution rate of the crystals. The remarkable improvements in the flow and packing of the agglomerated crystals enabled the direct compression of the crystals.

Keyphrases □ Salicylic acid—crystallization of spherically agglomerated crystals □ Crystallization—agglomeration of salicylic acid crystals

A novel agglomeration technique to transform a microcrystalline drug into an agglomerated form during the crystallization process was previously described (1). This technique could enable subsequent processes, such as separation, filtration, drying, etc. to be carried out more efficiently. Furthermore, the resultant agglomerated crystals could be easily

0022-3549/84/1100-1535$01.00/0

© 1984, American Pharmaceutical Association

compounded with other pharmaceutical powders due to their spherical form. We refer to this technique as "spherical crystallization."

Spherically agglomerated crystals of aminophylline were prepared directly by agitating a mixture of chloroform, ethanol, and water which contained ethylenediamine and theophylline (2). It was found that sodium theophylline monohydrate crystals, produced by salting out, were simultaneously agglomerated into spherical shapes in a mixture of an ethylenediamine solution of theophylline, an aqueous solution of sodium chloride, ethanol, and chloroform (3).

In the present study, the needle-like salicylic acid crystals simultaneously formed and agglomerated into a spherical shape in a mixture of water, ethanol, and chloroform. The aim of the study was to elucidate the effects of the composition of crystallization solvent on the physicochemical properties of the resultant agglomerated crystals, *e.g.*, crystalline form, crystallinity, wettability, dissolution rate, and micromeritic properties. The agglomeration behavior of the crystals was also investigated by measuring the sedimentation volume of the resultant crystals in liquid.

EXPERIMENTAL SECTION

Spherical Crystallization Process—*Method 1*—Salicylic acid[1,2] (0.5 g) was dissolved in ethanol (1–5 mL) in a test tube thermally controlled at 60°C. After cooling the ethanol solution to room temperature, 10 mL of water was added to the solution to yield the needle-like salicylic acid crystals. The mixture was allowed to stand for 1 h, then chloroform (0.3–0.5 mL) was added and the mixture was shaken horizontally at 200–400 cpm, using a shaker[2], for 10 min. The mixture was transferred to a measuring cylinder (25 mL) to measure the equilibrium sedimentation volume of the agglomerated crystals. The agglomerated crystals were separated and dried.

Method 2—Fifty milliliters of the ethanol solution (containing 12.5 g of salicylic acid maintained at 40°C) was poured into a mixture of chloroform (9 mL) and water (250 mL). The system was thermally controlled at 5°C and was agitated at 600 rpm by a turbine agitator with 6 blades for 1 h. The resultant crystals were separated and dried and their micromeritic properties were measured.

Measurement of Physicochemical Properties—The crystalline form of the agglomerated salicylic acid was determined using an X-ray diffractometer[3] with 0.15418 nm radiation. The relative diffraction intensity of salicylic acid (2θ = 17.1°) to that of sodium chloride (2θ = 31.6°), used as an internal standard, was taken as a measure of the crystallinity of salicylic acid. Sodium chloride particles fractionated into 150–200 mesh were incorporated into the diffraction samples with an agate mortar and pestle. The coefficient of variation of the relative intensities of diffraction peaks, due to the preferred orientation of particles in a powder, was 0.24. Wettability of the agglomerated crystals for water was determined by the contact angle of water to the agglomerated crystals and measured by the method of Lerk *et al.* (4). The agglomerated crystals weighing 2 g were compressed into a tablet (19.9 mm diameter, 5.3–5.8 mm thickness) at 50–60 kg/cm^2. The pressure was applied for 10–15 min to obtain an acceptable tablet without disintegration during the measurement. A large drop of saturated solution of salicylic acid was placed on the tablet surface, and the height of the drop was measured by a cathetometer. The contant angle (θ) was determined by using the following equations:

$$\theta > 90° \qquad \cos\theta = -1 + \sqrt{\frac{2}{3(1-\epsilon)}\left(\frac{2}{Bh^2} - 1\right)} \qquad \text{(Eq. 1)}$$

$$\theta > 90° \qquad \cos\theta = 1 - \sqrt{\frac{Bh^2}{3(1-\epsilon)(1 - Bh^2/2)}} \qquad \text{(Eq. 2)}$$

$$B = \frac{\rho g}{2\gamma} \qquad \text{(Eq. 3)}$$

where h is the height of the drop, ϵ is the porosity of the tablet, and ρ and γ are the density and the surface tension of the liquid drop. The porosity of the tablet was determined by measuring the apparent density of the tablet and the true density of the agglomerated crystals using a helium-air comparison pycnometer[4]. The surface tension of the salicylic acid saturated solution was measured by a surface tensiometer[5]. The dissolution test of the agglomerated crystals was carried out by the rotating basket method specified in USP at 100 rpm and 37°C (5). One hundred milligrams of the agglomerated crystals were dissolved in deaerated distilled water. Two-milliliter aliquots were withdrawn at appropriate intervals and an equal volume of water was replaced to the vessel. Salicylic acid was assayed spectrophotometrically[6] at 530 nm after adding 1% ferric nitrate to the aliquot.

Measurement of Micromeritic Properties of the Agglomerated Crystals—As a measure of the flow of the crystals, the angle of repose of the agglomerated crystals was measured by pouring powder on a plate (10 cm diameter)[7]. The packing ability of the agglomerated crystals was investigated by tapping them into a 50-mL measuring cylinder using a tapping machine[7]. The ability of the crystals to be formed into tablets was tested by using a single punch machine[8]. The average weight and dimension of the tablets were: 0.382 g, 10.05 mm diameter, and 4.14 mm thickness, respectively. The hardness was measured by a moving plate hardness tester[9].

Table I—Solubility and Degree of Supersaturation

	Ethanol Fraction in the Solvent, %	Conc., μg/mL	Degree of Supersaturation
With Agglomeration	8.8	2.39	19.02
	16.0	3.16	13.19
	22.4	4.65	8.27
	28.0	9.05	3.95
	32.7	16.39	2.03
Without Agglomeration	8.8	2.22	20.48
	16.0	2.82	14.78
	22.4	4.00	9.62
	28.0	6.87	5.20
	32.7	14.28	2.33

RESULTS AND DISCUSSION

Agglomeration Behavior of Salicylic Acid Crystals in Liquid—The recovery of the crystals agglomerated by spherical crystallization (method 1) sharply decreased with >25–30% ethanol in the solvent mixture (Fig. 1). With 33% ethanol in the solvent mixture, 28% of the loading was recovered as agglomerated crystals. Without agglomeration, when no chloroform was added to

the system, the recovery of the crystals was 63%. This finding indicated that the solubility of salicyclic acid in the solvent for spherical crystallization, *i.e.*, ethanol–water–chloroform, was higher than in the ethanol–water mixture without agglomeration, as suggested in Table I.

The sedimentation volume of the agglomerated crystals prepared by spherical crystallization (method 1) was measured to investigate the effect of the composition of the solvent mixture on the agglomeration behavior. Bulk density of the agglomerated crystals, defined as the weight of the crystals recovered divided by the equilibrium sedimentation volume, was plotted against the ethanol fraction of the solvent. The bulk density decreased linearly when the amount of ethanol in the solvent mixture was increased (see Fig. 1). The size of the particles composing the agglomerated crystals decreased with a decrease in the amount of ethanol in the solvent mixture as shown in Fig. 2. Elworthy and Worthington (6) reported that finer sulfadiazine crystals were produced in more highly supersaturated solvents. The degree of supersaturation (Sd) was defined by:

$$Sd = \frac{Co}{Ce} \qquad \text{(Eq. 4)}$$

where Co and Ce are the initial loading and the remaining drug concentrations after crystallization in the solvent, respectively.

As shown in Table I, decreasing the amount of ethanol increased the degree of supersaturation, resulting in fine crystals. The larger agglomerated crystals were loosely compacted and elongated as shown in Fig. 2, resulting in a higher sedimentation volume, *i.e.*, a lower bulk density. The strength of the agglomerated crystals prepared in a solvent mixture with 28.0% ethanol was not enough to hold an agglomerated form after drying. In this study, the solvent mixture with small amount of ethanol afforded the dense, spherically agglomerated crystals.

Physicochemical Properties of the Resultant Crystals—The X-ray diffraction patterns of the agglomerated crystals are shown in Fig. 3; all the patterns coincided with that of the original salicylic acid, and no change in the crystalline form of the basic crystals was found, even after agglomeration. The diffraction intensity varied with the amount of ethanol in the solvent mixture, and may be dependent on the basic crystal size. Increasing the amount of ethanol in the solvent mixture caused the diffraction peaks to increase. The relative diffraction intensities of salicylic acid (17.1°) to that of sodium chloride (31.6°) are shown in Fig. 4 as a function of the amount of ethanol in the solvent mixture. The relative diffraction intensities were assumed as the crystallinity of the elementary crystals composing the agglomerate. As expected, the crystallinity increased when the amount of ethanol in the solvent mixture was increased. The crystallinity of the agglomerated crystals were influenced more strongly by the amount of ethanol in the solvent mixture than the crystals that were not agglomerated. Recrystallization of salicylic acid from chloroform occluded in the agglomerated crystals during drying may have increased the crystallinity of the dried agglomerated crystals, when compared with those that were not agglomerated.

Wettability of the agglomerated crystals by water was investigated by measuring the contact angle of water to the compressed crystals. It was expected that the contact angle would vary with the amount of ethanol in the solvent mixture, since the crystallinity and the elementary crystal size of the agglomerated crystals varied with the amount of ethanol. Gulinkina *et al.* (7) found that a dye crystal with a low crystallinity was more wettable than a dye crystal with a high crystallinity. The contact angles of the agglomerated crystals produced in the solvent with >25% ethanol were higher than those of the crystals that were not agglomerated, as shown in Fig. 5, due to their higher crystallinities. When the amount of ethanol was <25%, the contact angles of the agglomerated crystals became smaller than those of the primary crystals that were not agglomerated. This may be due to the fact that the basic crystal size of the agglomerated material produced in the solvent mixture with small amounts of ethanol was larger than that of the crystals that were not agglomerated.

The differences in the wettability of the crystals suggested that the dissolution behavior of the crystals might vary. The time required for 50% of solute dissolution of the agglomerated crystals prepared from the solvent with 22.4% ethanol (T_{50} = 7 min) was significantly shorter than the others (T_{50} = 20–22 min) at the 1% level, since the crystals were easily wetted, as shown in Fig. 5. Furthermore, their specific surface areas were fairly large, compared with

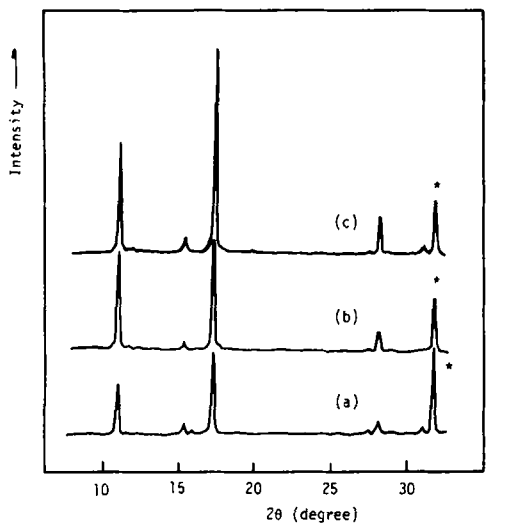

Figure 3—*X-ray powder diffraction patterns of agglomerated salicylic acid crystals. The ethanol fractions for (a), (b), and (c) are 8.8, 22.4, and 28.0%, respectively; (*) denotes the diffraction peak of sodium chloride.*

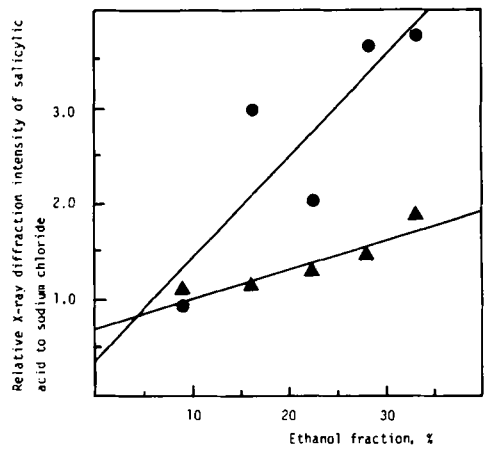

Figure 4—*Effect of ethanol fraction in the solvent on the crystallinity of salicylic acid. Key: (●) agglomerated crystals and (▲) primary crystals.*

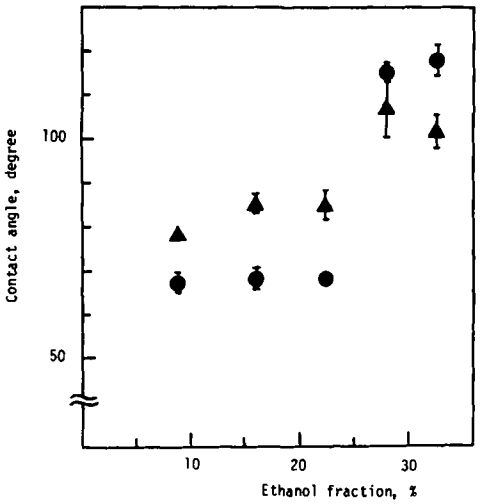

Figure 5—*Contact angles of agglomerated and primary crystals as a function of the ethanol fraction in the solvent. Key: (●) agglomerated crystals and (▲) primary crystals.*

those of the agglomerated crystals prepared with 8.8% ethanol, as suggested in Fig. 2. Although the agglomerated crystals prepared with 28.0% ethanol had large specific surface areas, their poor wettability resulted in a slower dissolution rate (Fig. 6). The dissolution rate of the spherically agglomerated crystals in Fig. 2d did not decrease as much as predicted from their low specific surface areas because of their improved wettability (Fig. 5).

Micromeritic Properties of Agglomerated Salicylic Acid Crystals Prepared by method 2—The agglomerated crystals prepared by method 2 were more compact and more spherical than those prepared by method 1, as shown in Fig. 2. The average diameter of the agglomerated crystals was 930 μm, with a size range from 460 to 1210 μm. The micromeritic properties of the agglomerated crystals were significantly improved compared with those of the crystals that were not agglomerated. The angle of repose of the agglomerated crystal was 36°, while that of the crystals that were not agglomerated was 51°. The packing ability was investigated by tapping the crystals in a measuring cylinder. The data were analyzed by Kawakita and Lüdde (8) and Kuno (9) equations, represented by Eqs. 5 and 6, respectively:

$$\frac{n}{c} = \frac{1}{ab} + \frac{n}{a}$$

$$a = \frac{V_0 - V_\infty}{V_0}, \quad c = \frac{V_0 - V_n}{V_0} \qquad \text{(Eq. 5)}$$

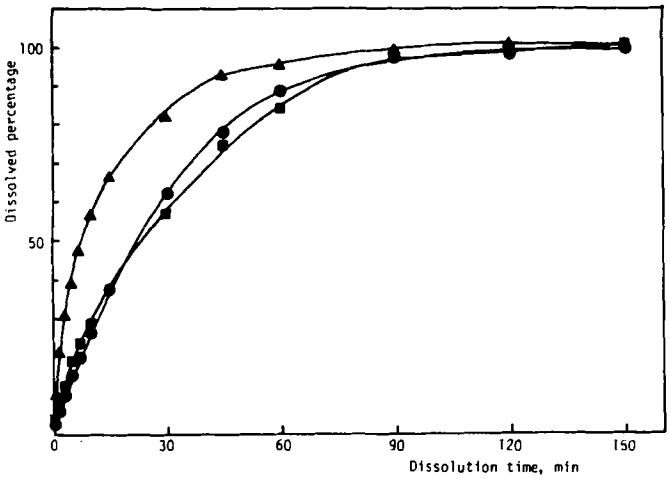

Figure 6—*Dissolution patterns of agglomerated crystals. Key: ethanol fractions of (●) 8.8, (▲) 22.4, and (■) 28.0%.*

Table II—Micromeritic Properties of Primary Crystals and Agglomerates

Micromeritic Properties	Agglomerates	Primary Crystals
Angle of repose	36°	51°
a^a	0.0955	0.3397
b^a	0.0466	0.0295
k^b	0.0049	0.0092
Closest packing density	0.488 g/cm³	0.160 g/cm³
Tablet	Compressible[c]	Not Compressible

[a] Parameter in Eq. 5. [b] Parameter in Eq. 6. [c] Tablet properties: diameter, 10.05 mm; thickness, 4.14 mm; average weight, 0.382 g; weight variation, 2.56% (the maximum percentage difference from the mean weight).

where a and b are the constants, n is the tap number, and V_0, V_n, and V_∞ are the powder bed volumes at initial, nth tapped, and equilibrium state, respectively.

$$\rho_f - \rho_n = (\rho_f - \rho_0) \exp(-kn) \qquad \text{(Eq. 6)}$$

where ρ_f, ρ_n, and ρ_0 are the apparent densities at equilibrium, nth tapped, and initial state, respectively, and k is the constant. All the data satisfied the relationships represented by Eqs. 5 and 6. The packing ability was assessed by comparing the constants a, b, and k in Eqs. 5 and 6, respectively, as shown in Table II. The constant a represents the proportion of consolidation at the closest packing attained. The reciprocals of b and k represent the packing velocity. The constant a for the agglomerated crystals was smaller than that for the crystals that were not agglomerated. This indicated that the agglomerated crystals were easily packed, even without tapping. The larger b value for the agglomerated crystals proved that the packing velocity of the agglomerated crystals by tapping was slower than that of the crystals that were not agglomerated. The smaller k in Eq. 6 for the agglomerated crystals coincided with the above finding. The slow packing velocity corresponded with the proportion of the consolidation of powder bed per tap, which was low. The closest packing density of the agglomerated crystals was larger than that of the crystals that were not agglomerated. Due to the improved flow properties and packing ability of the agglomerated crystals, they were directly compressible; whereas, the crystals that were not agglomerated were not compressible due to their poor flow properties.

Effect of Aging on Hydrocortisone–Polyethylene Glycol 4000 and Hydrocortisone–Polyvinylpyrrolidone Dispersions

B. R. HAJRATWALA *x **and D. S. S. HO** ‡§

Received April 19, 1982, from the *Pharmaceutics Division, Wayne State University, Detroit, MI 48202 and the ‡Pharmaceutics Department, University of Otago, Dunedin, New Zealand. Accepted for publication October 14, 1983. §Present address: 121 Jalan Kuala Kangsar, Ipoh, Malaysia.

Abstract □ Dispersions containing 40% hydrocortisone were prepared by the solvent method in polyethylene glycol 4000. Dispersions in polyvinylpyrrolidone were prepared by slow evaporation of solvent (type A) and by fast evaporation of solvent (type B). These dispersions were stored at 25°C for 30 d. Plots of time required for 50% ($t_{50\%}$) and 70% ($t_{70\%}$) of the hydrocortisone dispersion to dissolve (beaker method) *versus* time were obtained. Hydrocortisone–polyethylene glycol showed no apparent significant change in either dissolution rate, X-ray spectra, or scanning electron micrographs. Type A dispersions showed an increase in dissolution rate up to 8 d. Type B dispersions showed an initial decrease followed by an increase in dissolution rate. The initial decrease in dissolution rate of type B dispersions is due to hydrocortisone crystallizing out of the polyvinylpyrrolidone matrix. The increased dissolution for both types of polyvinylpyrrolidone dispersions was not expected and is explained by an increased proportion of the high-energy amorphous component, based on X-ray spectra. Other possibilities such as the presence of polymorphic forms of hydrocortisone and/or reduction in particle aggregation could not be discounted.

Keyphrases □ Hydrocortisone– dispersions with polyethylene glycol 4000 and polyvinylpyrrolidone, effect of aging □ Aging–effect on dispersions, hydrocortisone–polyethylene glycol 4000, hydrocortisone–polyvinylpyrrolidone.

Incorporation of water-soluble carriers with poorly soluble drugs, to increase the dissolution rate of the latter, has been widely studied and extensively reviewed (1, 2). Polyethylene glycol (3–5) and polyvinylpyrrolidone (6–8) have been popular choices as inert carriers for dispersions prepared by solvent or coprecipitation methods.

The effect of aging on solid dispersion systems has not been reported extensively. Aspirin was reported to undergo faster degradation in solid dispersions (9), whereas dissolution profiles for dicumarol–polyethylene glycol tablets did not change appreciably after 1 year of storage (3). Changes in dissolution profiles of other solid dispersions have not been reported. The corticosteroids continue to be of interest due to their poor water solubility and unpredictable dissolution rates (4–7, 10, 11). The present investigation reports the dissolution characteristics of hydrocortisone–polyvinylpyrrolidone dispersions stored at 25°C for 30 d.

EXPERIMENTAL SECTION

Materials—Micronized hydrocortisone[1], polyethylene glycol 4000[2], and polyvinylpyrrolidone[3] (average mol. wt. 30,000–40,000) were used. All other reagents and solvents were of analytical grade.

Sample Preparation and Storage—The solid dispersions of hydrocortisone in polyethylene glycol were prepared by the solvent method (1, 4). Hydrocortisone and varying quantities of carrier were accurately weighed and dissolved in 20 mL of 96% ethanol. The solvent was evaporated under a stream of nitrogen. The resultant solid dispersions were then dried under reduced pressure at 37°C over silica gel for 1 d. The hardened mass was powered and 85/235-mesh (sieve size) particles were used.

The solid dispersions of hydrocortisone–polyvinylpyrrolidone were prepared using the same technique. During an earlier investigation (6) it was found that the rate of evaporation of the solvent had an effect on dispersions. Dispersions were prepared by slow evaporation (type A) and by rapid evaporation (type B) of solvent. All samples were prepared in duplicate and stored in amber bottles in a desiccator over silica gel at 25°C.

Dissolution Studies—Approximately 50 mg of the solid dispersion was introduced directly on the surface of 500 mL of distilled water in a 1-L beaker at 25 ± 0.1°C and stirred at 100 rpm. The dissolution was followed by withdrawing 4-mL samples with a glass syringe fitted with a filter[4] (0.45 μm) to exclude particles. Hydrocortisone was assayed spectrophotometrically at 247.5 nm. Corrections were made for any absorption due to the carrier. The slope of the Beer's law plot was 0.0454 mg^{-1} (SEM = 0.0316, r = 0.9997).

The $t_{50\%}$ and $t_{70\%}$ values were obtained from plots of percent hydrocortisone dissolved *versus* time. All plots were obtained in duplicate. The results were analyzed for significance using the SPSS program for a one-way ANOVA with interval testing and a two-tailed t test.

X-ray Diffraction Studies—Dispersions were spread on glass slides as a thin layer with a small amount of petroleum jelly. CuK radiation was used. Diffraction patterns[5] were obtained by scanning at 1°/min in terms of the 2θ angle.

Thin-Layer Chromatography Studies—Silica gel-coated plates[6] were spotted with solutions containing 10 mg of dispersions in 5 mL of 95% ethanol. The plates were chromatographed using a two-dimensional method. The solvent system used was acetone–benzene (50:50, v/v) followed by dichloroethane–methanol–water (92:8:0.5, v/v/v). The plates were developed with tetrazolium blue (0.05%) and sodium hydroxide (8%) in methanol.

Scanning Electron Microscope Studies—Scanning electron micrographs were obtained from powdered dispersions mounted on stumps with double-sided cellophane tape and coated with gold.

RESULTS AND DISCUSSION

All dispersions contained 40% hydrocortisone; this selection was based on the results of an earlier study (6). At 40% concentration, hydrocortisone–polyvinylpyrrolidone dispersions showed the following changes in dissolution rate. Plots of time required for 50% and 70% of the hydrocortisone in the dispersion to dissolve *versus* percent hydrocortisone yielded zero slopes for dispersions with <40% hydrocortisone and positive slopes for dispersions with >40% hydrocortisone; dispersions with >40% hydrocortisone also exhibited an increased crystalline structure as evidenced by X-ray diffraction spectra (6). A limited study of the effect of aging on 40% hydrocortisone dispersions was therefore undertaken.

Effects of Storage for 30 d on Hydrocortisone–Polyethylene Glycol 4000 Dispersions—The dispersions were white. Thin-layer chromatography detected no decomposition during this study.

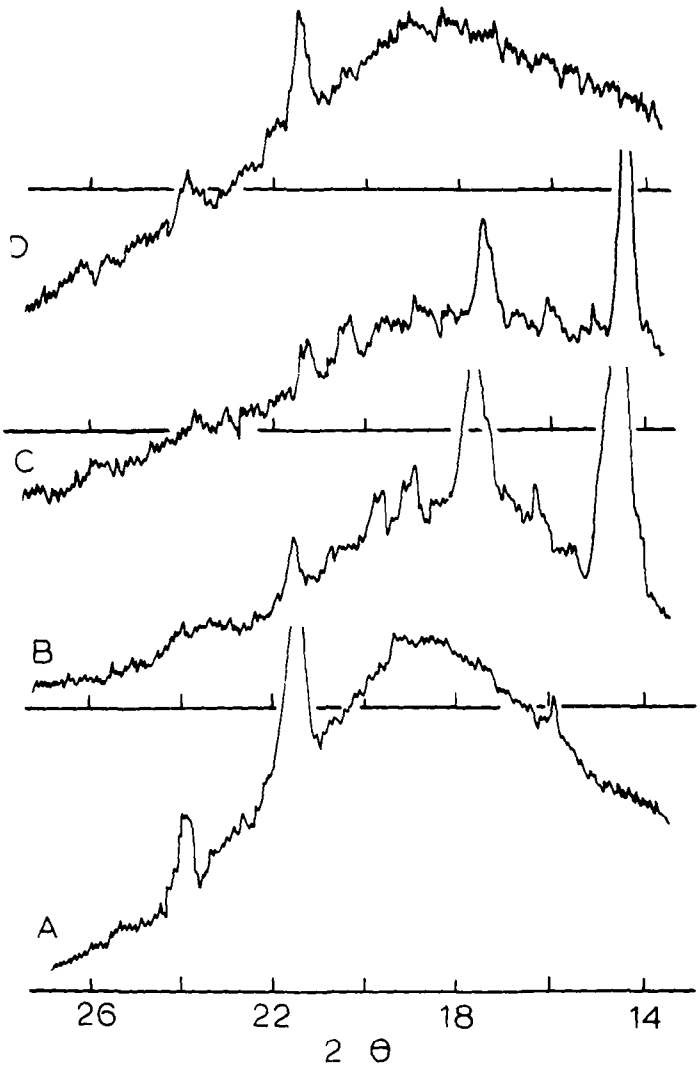

Figure 2—*X-ray diffraction spectra of polyvinylpyrrolidone (A), hydrocortisone (B), hydrocortisone-polyvinylpyrrolidone (type A) dispersion on day 2 (C), and hydrocortisone-polyvinylpyrrolidone (type B) dispersion on day 3 (D).*

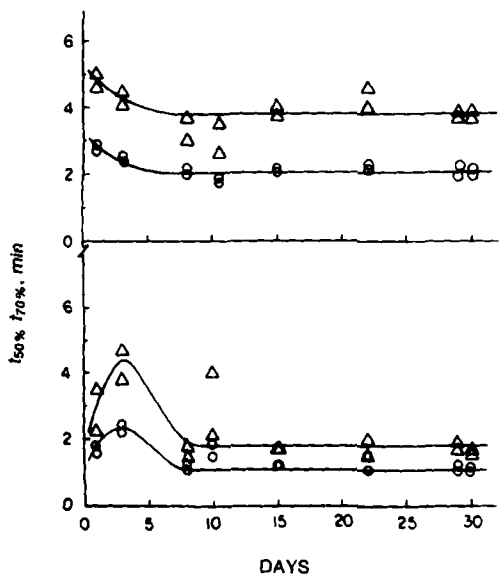

Figure 3—*Plot of* $t_{70\%}$ (△) *and* $t_{50\%}$ (○) *for hydrocortisone-polyvinylpyrrolidone dispersions* versus *time. Dispersions were prepared by the solvent method using a slow rate (upper curve, type A) and a fast rate (lower curve, type B) of evaporation.*

Figure 1 shows a plot of $t_{50\%}$ and $t_{70\%}$ (time required, respectively, for 50% and 70% of the hydrocortisone in the dispersion to dissolve) *versus* time. A one-way ANOVA with interval testing yielded a significant difference between $t_{50\%}$ and $t_{70\%}$ ($p = 0.07$); the two-tailed t test yielded $p < 0.001$. There does not appear to be any change in the dissolution of hydrocortisone over the 30-d storage period. These results are consistent with an earlier study of other polyethylene glycol dispersions (3).

X-ray diffraction spectra showed slight variations in peak heights at different days. These spectra also showed a slight increase in the scattering hump of the dispersions; however, no apparent trend was discernible over the period of this study. Thus, minor changes in X-ray diffraction spectra are not considered significant with respect to the observed dissolution rates. The scanning electron micrographs also did not show any apparent change in these dispersions.

X-ray Diffraction of Polyvinylpyrrolidone and Hydrocortisone—Polyvinylpyrrolidone, a high-molecular-weight polymer, is known to exist in a glass state and to have a relatively high glass-transition temperature of 175°C (12). Physically this polymer is a yellowish, transparent, brittle, glass solid, but the X-ray diffraction pattern (Fig. 2) shows that it is not completely amorphous. Weak diffraction peaks show a degree of order; the ordered portion seems small and the major portion of the solid seems amorphous. This is evident by the presence of the large diffused scattering hump in the spectrum. The diffuse reflection at 18°(2θ) corresponds to a spacing of approximately 0.5 nm, possibly the distance between the polymer chains.

Hydrocortisone is a crystalline compound. A small scattering hump (Fig. 2) is also evident in the diffraction patterns of hydrocortisone and may indicate the presence of a small amount of amorphous hydrocortisone. Such scattering may be caused by the small size of the hydrocortisone crystals.

Effects of Storage for 30 d on Hydrocortisone-Polyvinylpyrrolidone Dispersions—Figure 3 shows plots of $t_{50\%}$ and $t_{70\%}$ *versus* time for type A and B dispersions. For type A dispersions results of a one-way ANOVA with interval testing yielded $p = 0.01$; the two-tailed t test yielded $p < 0.001$. For type B dispersions the first four values in a one-way ANOVA with interval testing resulted in $p = 0.08$; two-tailed t test yielded $p = 0.002$. The last four values in a one-way ANOVA with interval testing resulted in $p = 0.02$; the two-tailed t test yielded $p < 0.001$. For the type A dispersions, $t_{50\%}$ and $t_{70\%}$ initially declined over 10 d and then became constant, indicating an increased dissolution rate in the first 10 d. The type B dispersions show ~50% decrease in dissolution rate in the first 3 d and then a steady increase until about day 10 before leveling off. No attempt was made to develop any mathematical relationship between variables.

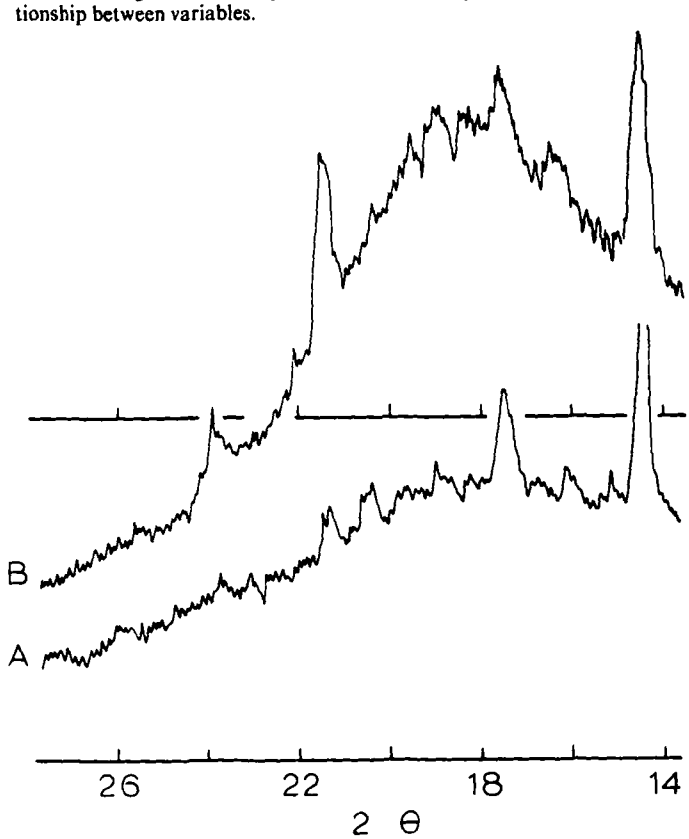

Figure 4—*X-ray diffraction spectra of hydrocortisone-polyvinylpyrrolidone type A dispersions stored at 25°C. Key: (A) after 1 d; (B) after 30 d.*

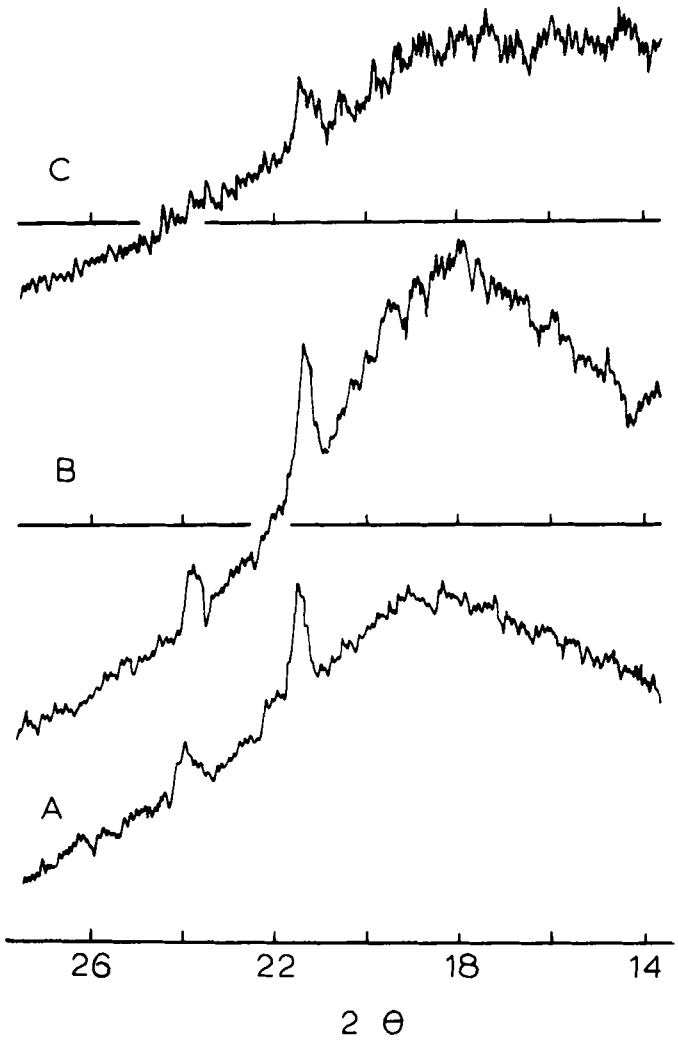

Figure 5—*X-ray diffraction spectra of hydrocortisone-polyvinylpyrrolidone type B dispersions stored at 25°C. Key: (A) after 2 d; (B) after 14 d; (C) after 30 d.*

Figure 2 shows X-ray diffraction spectra for hydrocortisone-polyvinylpyrrolidone dispersions. The X-ray diffraction pattern for type A shows the crystalline structure of hydrocortisone. Type B dispersions show an absence of crystalline structure. Type A dispersions would be expected to show decreased dissolution rates compared with type B. This was observed (Fig. 3) and is consistent with an earlier interpretation (4, 6). However, it is interesting to note that the degree of crystallinity and the resultant modification in dissolution are dependent on the rate of evaporation of solvent during the preparation of these dispersions.

These dispersions are considered to be glassy suspensions of hydrocortisone in polyvinylpyrrolidone. Since such systems are in a metastable state, they may undergo aging transformations yielding stable forms. The rate of the transformations vary with materials and storage conditions. Iopanoic acid and chloramphenicol palmitate were reported to crystallize from a polyvinylpyrrolidone glass solution (1). The initial decrease in the dissolution for type B dispersions (Fig. 3) could be readily explained in terms of hydrocortisone crystallizing out of the polyvinylpyrrolidone matrix.

The increased dissolution rate after an early decrease for type B dispersions and the increased dissolution rate for type A dispersions were unexpected. Figures 4 and 5 show changes in X-ray diffraction spectra for type A and type B dispersions, respectively. Both types of dispersions show increased scattering humps in X-ray diffraction spectra, indicating an increased proportion of an amorphous component. The amorphous forms are high-energy forms and generally possess higher solubility, explaining the increased dissolution. Other possibilities such as the presence of polymorphic form of hydrocortisone in polyvinylpyrrolidone matrix, reduction of particle aggregation, *etc.*, should not be discounted.

Liquid Chromatographic Determination and Plasma Concentration Profile of Optical Isomers of Ibuprofen in Humans

EDMUND J. D. LEE *§x, KENNETH M. WILLIAMS *, GARRY G. GRAHAM ‡, RICHARD O. DAY *, and G. DAVID CHAMPION *

Received August 17, 1983, from the *Department of Clinical Pharmacology, St. Vincent's Hospital, Darlinghurst, 2010, Australia and ‡Department of Pharmacology and Physiology, University of New South Wales, Kensington, 2033, Australia. Accepted for publication December 12, 1983.
§Present address: Department of Pharmacology, National University of Singapore, Kent Ridge, Singapore 0511.

Abstract □ A sensitive and specific high-performance liquid chromatographic assay for the optical isomers of ibuprofen in plasma is reported. The isomers were converted to their diastereoisomeric *S*(+)-2-octyl esters and were resolved with two silica columns in series and a mobile phase containing 0.05% isopropyl alcohol in heptane. The lower limit of sensitivity was 0.5 μg/mL. The plasma concentrations of the optical isomers in a normal volunteer following administration of racemic, *S*(+)-, and *R*(−)-ibuprofen are reported. Following administration of *R*(−)-ibuprofen, there was stereoselective inversion of *R*(−)- to *S*(+)-ibuprofen.

Keyphrases □ Optical isomers—liquid chromatography, plasma concentration profiles, ibuprofen, humans □ Ibuprofen—liquid chromatography, plasma concentration profile, optical isomers, humans

The chromatographic resolution of optical isomers is difficult because they have the same physicochemical properties. Methods available for resolution include the use of an optically active stationary phase (1), an optically active mobile phase (2), or, more conventionally, conversion of the optical isomers to diastereoisomers by reaction with an optically active reagent. Separation of isomers of arylpropionic acid derivatives usually can be achieved by the formation of the diastereoisomeric amides with optically active reagents like *R*(+)-α-phenylethylamine (3), *S*(−)-α-methylbenzylamine (4, 5), (*R*)-4-(dimethylamino)-α-methyl-1-naphthalenemethyl-amine (6), and L-leucine (7). Johnson *et al.* (8) have reported a liquid chromatographic assay for the isomers of naproxen based on the formation of diastereoisomeric *S*(+)-2-octyl esters. In this paper is reported the successful modification of the latter method for the quantification of ibuprofen optical isomers in plasma.

Ibuprofen (I) is a nonsteroidal anti-inflammatory agent exhibiting optical isomerism because of a chiral carbon atom on the propionic acid side chain. It is administered clinically as the racemate. In early *in vitro* studies, it has been demonstrated that the *S*(+)-isomer (III) was responsible for the anti-inflammatory activity. However, the *R*(−)-isomer (II) was as active as III *in vivo* (9) because there was stereoselective inversion of II to III *in vivo* (10–13).

There have been few studies in which the pharmacokinetics of II and III in humans have been described because of the difficulty in resolving II and III. Although the inversion of II to III has been inferred from the examination of the urinary metabolites of II and III in humans (10, 11, 13), no data have been presented detailing the time course of the plasma concentrations of each isomer following the administration of II and III. A sensitive and specific high-performance liquid chromatographic (HPLC) assay is described for the determination of II and III in plasma. It was used to follow the concentrations of II and III after oral administration of I (800 mg), II (400 mg), and III (400 mg) and to document the inversion of II to III in humans.

EXPERIMENTAL SECTION

Apparatus—An HPLC pump[1] was attached to an autosampler[2] and a variable-wavelength UV detector[3] set at 220 nm. Two 5-μm silica columns[4] (25 × 0.46 cm) were used in series. The detector signal was recorded and reported as peak areas on a plotter recorder[5]. The whole operation was coordinated by means of a system controller[6].

Reagents—*n*-Hexane and *n*-heptane were HPLC grade[7]; isopropyl alcohol was analytical grade[7]; *S*(+)-2-octanol (>99% pure) was obtained commercially[8]. Hydrogen chloride was bubbled through the octanol. Dichloromethane[7] and methanol[7] were dried over sodium and anhydrous sodium sulfate, respectively.

Standard Solutions—Stock solutions of I[9] were prepared by using dilute sodium hydroxide (solution A, 50 μg/mL; solution B, 500 μg/mL). A stock solution of the internal standard, 4-*n*-pentylphenylacetic acid (IV)[9], was prepared (80 μg/mL). Plasma standard curves for each isomer were constructed (at each run) over the concentration ranges of 0.5–5 and 5–60 μg/mL. In each case, the peak area ratios of each isomer to internal standard were plotted against the concentration of the isomers.

Sample Preparation—Venous blood (10 mL) was collected *via* an indwelling catheter in heparinized tubes[10]. Duplicate plasma samples (1 mL) were then transferred to screw-capped glass tubes (12 mL). Internal standard (100 μL) was added, and the mixture was acidified with 3 M hydrochloric acid (200 μL). Isopropyl alcohol (0.1% v/v) in hexane (10 mL) was added, and the tube was capped and shaken for 5 min. The organic phase was then transferred to a glass tube (20 mL). The extraction was repeated, and the second volume of the organic phase was added to the first volume before being blown to dryness under air at 40°C. The walls of the tube were washed with chloroform (2 mL) which was then transferred to a reaction vial (2 mL). Acidified *S*(+)-2-octanol (25 μL) was added, and the vial was capped and incubated for 1 h at 150°C. On cooling, 0.1% isopropyl alcohol in hexane (2 mL) and saturated sodium bicarbonate (150 μL) were added. The vials were recapped and the mixture vortexed for 30 s and then centrifuged for 5 min. The organic phase was transferred to conical tubes and the solvent evaporated under a stream of air at 40°C. The residue was then reconstituted in mobile phase (100 μL) and transferred to 200-μL sampling vials. An aliquot (4–40 μL) was then injected *via* the autosampler.

To obtain standard curves, either solution A (20–200 μL) or B (20–240 μL) was transferred into screw-capped glass tubes (12 mL). The volume was made up to 1 mL by the addition of blank plasma, and the resultant mixture was treated in a manner similar to that for the unknown samples.

Chromatography—Chromatography was performed at ambient temperature, and resolution of the octyl esters of II, III, and IV was achieved by using two 5-μm silica columns connected in series. The mobile phase was 0.05% v/v isopropyl alcohol in heptane and was pumped at a flow rate of 1 mL/min for 30 min followed by a 20-min washout period at 2 mL/min. The pressure at 1 mL/min was ~800 psi.

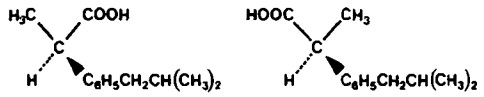
After every 12 injections there was a 30-min washout period at 2 mL/min. At regular intervals (about 150 injections), the columns were generated by pumping 20 column volumes of dry dichloromethane, 20 column volumes of dry methanol, and then another 20 column volumes of dry dichloromethane through the columns. The columns were reequilibrated with at least 50 column volumes of 0.05% isopropyl alcohol in heptane before use. No attempt was made to dry the isopropyl alcohol–heptane mixture.

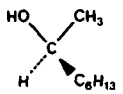
The individual peaks were identified by HPLC of the octyl esters of pure II, III, and IV. The eluting fractions representing the octyl esters of II and III were subjected to GC–MS.[11]

To exclude possible interference by other nonsteroidal anti-inflammatory agents, standard solutions of aspirin, carprofen, diflunisal, flurbiprofen, indomethacin, naproxen, and salicylic acid were esterified and chromatographed as described above for I.

Volunteer Study—A normal subject was given I (800 mg)[9], II (400 mg)[9], and III (400 mg)[9] orally on three separate occasions, 1 week apart. Compounds I, II, and III were administered orally in solution. These test solutions were prepared by first dissolving appropriate amounts of pure I, II, or III in dilute sodium hydroxide (0.1 M, 10–20 mL). The volume was then made up to 250 mL with distilled water. Prior to each study, the subject fasted overnight and until 4 h after administration of the drug. Frequent blood samples were collected up to 14 h after administration of the dose.



R(–) IBUPROFEN (II) S(+) IBUPROFEN (III)



S(+)-2-OCTANOL

RESULTS AND DISCUSSION

Chromatography—The *S*(+)-2-octyl esters of II and III can be separated chromatographically with retention times of ~20 and ~21 min, respectively (Fig. 1). The retention time for the ester of IV was ~26 min. Presence of other anti-inflammatory agents like aspirin, carprofen, diflunisal, flurbiprofen, indomethacin, naproxen, and salicylic acid did not interfere with the assay.

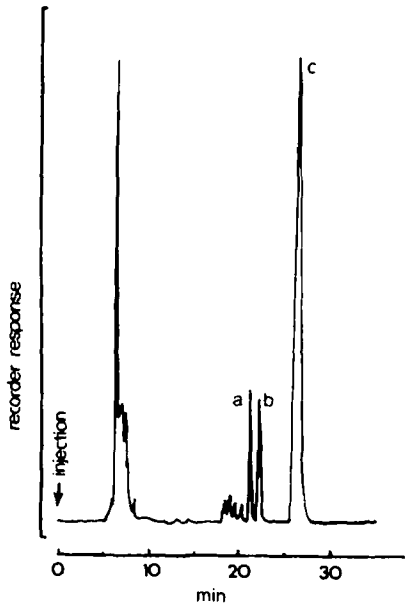


Figure 1—*Typical chromatogram of the S(+)-2-octyl esters of II (0.5 μg/mL of plasma) (a), III (0.5 μg/mL of plasma) (b), and IV (c).*

[11] Model 3200; Finnigan CI-GCMS.

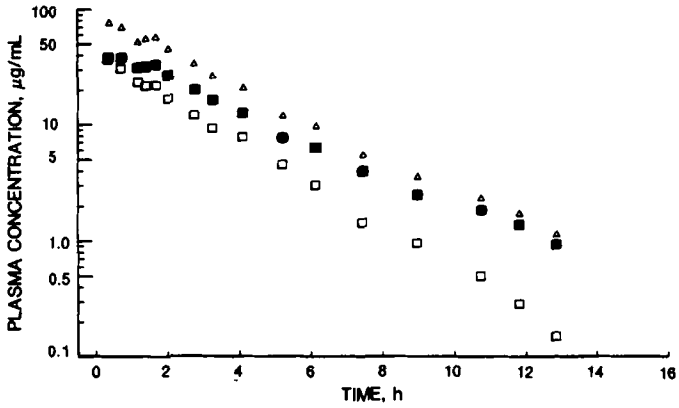

Figure 2—*Plasma levels of I (△), II (□), and III (■) following oral administration of I (800 mg).*

When a sample of II which showed one peak on HPLC was esterified and chromatographed, some III was detected. The amount of III thus detected was small and represented only ~2% of the total amount of II. A similar amount of II was found to be present when a sample of III which showed one peak on HPLC was esterified and chromatographed. These results can be attributed to impurity of the sample, impurity of the octanol, or the possibility of a fractional amount of racemization occurring during sample preparation.

Chromatographic conditions were selected to maintain the retention times described above at which resolution and peak shapes were optimal.

The methane chemical ionization mass spectrum for the esters of II and III were similar and gave the following mass ions: $(M - H)^+$ m/z 317 (28%); $(M - CH_3)^+$ m/z 303 (10%); $(M - C_6H_{11})$ m/z 235 (16%); $(M - C_8H_{15})^+$ m/z (207 (100%); $(M - C_8H_{17}O)$ m/z 189 (8%); $(M - C_8H_{17}OCO)$ m/z 161 (50%).

During development of the assay, four to five peaks, possibly due to contaminants extracted from plasma, were found to elute just prior to that of the octyl ester of II. Significant interference from these peaks occurred at low concentrations of II (<0.5 μg/mL). However, interference could be minimized by maintaining the retention time of II beyond 20 min.

Sample Preparation—Various extraction methods were assessed. In general, more polar solvents extracted greater amounts of plasma contaminants. Extraction with *n*-hexane was found to produce the least interference by contaminants with reasonable recovery of II and III. By using 0.1% isopropyl alcohol in hexane, recovery of II and III was found to be ~64 and 84% after single and double extractions, respectively. Recovering of IV was 74% after two extractions. (Recovery was defined by the ratio of peak areas obtained after treatment of spiked plasma extracts to that obtained after direct esterification of equivalent amounts of II, III, or IV.) Esterification of II and III was complete after 0.5 h at 150°C.

Assay Reproducibility and Sensitivity—It was necessary to construct a standard curve for each of the plasma concentration ranges, 0–10 and 10–60 μg/mL. Typical intercepts and slopes were, respectively, 0.2 and 9.26 for the former and −0.66 and 8.76 for the latter standard curves. The within-run coefficient of variation (*CV*) at plasma concentrations of 2.5 and 50 μg of the octyl ester of II/mL were 4.0 and 5.0%, respectively (n = 5). The corre-

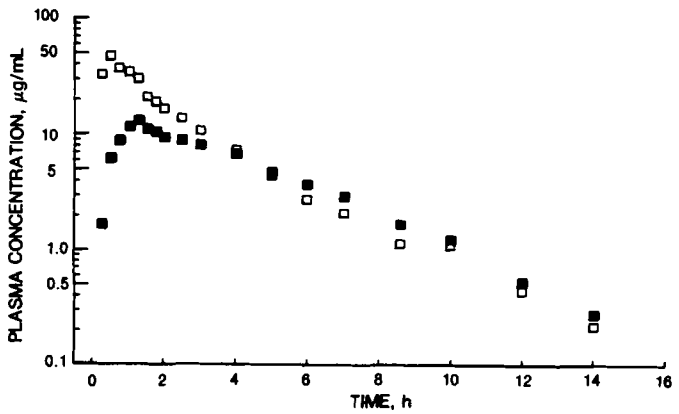

Figure 3—*Plasma levels of II (□) and III (■) following oral administration of II (400 mg).*

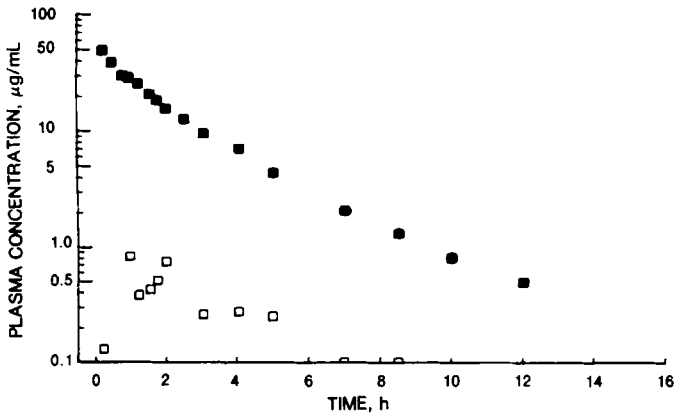

Figure 4—*Plasma levels of II (□) and III (■) following oral administration of III (400 mg).*

sponding *CV* values for the octyl ester of IV were 3.4 and 5.1%. Concentrations of II and III down to 0.5 μg/mL could be measured confidently. Values below this were rejected because of significant interference from the contaminating peaks mentioned above.

Volunteer Study—The applicability of the assay was demonstrated by a preliminary study of the plasma concentration profile of II and III in a normal subject. Absorption after administration of I, II, or III was rapid. Peak levels were attained within 0.5 h (Figs. 2–4). In most of the profiles, a definite biphasic decline could be discerned. Following administration of I, III was apparently eliminated more slowly than II (Fig. 2). This was presumably due to the contribution of the inversion of II to III. Following administration of II, plasma concentrations of III gradually increased and peaked at 1.3 h (Fig. 3). The concentration of III then declined more slowly than that of II. The concentration of III equaled that of II at ~4–5 h and subsequently remained higher than that of II. The peak concentration of III achieved after administrations of II was ~28% of that attained by II.

Only a small amount of II was detected after administration of III (Fig. 4). The low plasma concentrations of II that were observed may be attributed to incomplete optical purity of the *S*(+)-2-octanol and also possibly to some racemization of III during derivatization. However, as the rate of increase of II was slower than that observed for III, it is likely that some inversion of III to II occurs *in vivo*, although this is clearly insignificant compared with the inversion of II to III observed in these studies.

Ibuprofen is cleared almost entirely by metabolism (13). Disposition of the isomers is complicated by the stereoselective inversion of II to III. This metabolic pathway may be common to all the arylpropionic acids, although this area has received little attention (6, 7, 14). The inversion apparently proceeds *via* stereoselective formation of the coenzyme A (CoA) ester of the *R*(−)-arylpropionic acid, with subsequent racemization and release of the *R*(−)- and *S*(+)-enantiomers (15). This mechanism suggests that the "racemase" may be methylmalonyl CoA epimerase. Furthermore, as CoA esters of ibuprofen, fenoprofen, and ketoprofen have been shown to be incorporated into "hybrid triglycerides" (16), we are currently investigating our hypothesis that arylpropionic acids may be stereoselectively sequestered into adipose tissue.

Direct evidence of the stereoselective inversion of II has not been previously demonstrated in humans, and inference of its existence has so far been based on the predominance of dextrorotatory metabolites in urine (10, 11, 13).

This HPLC assay was found to be reproducible and convenient for routine use and has been used to demonstrate unequivocally the *in vivo* inversion of II to III in humans. The method suffers from the drawback of having a long assay time. However, this disadvantage can be overcome by automation of sampling and peak integration. The method was also found to be suitable for analysis of urine and synovial fluid samples and was utilized in formal pharmacokinetic studies. The details of these studies and of the stereospecific uptake of *R*(−)-ibuprofen into adipose tissue will be the subject of later reports.

Mechanism for the High Bias in the USP Colorimetric Assay for Diazotizable Substances in Hydrochlorothiazide

DAVID H. SIEH ˣ and SOLOMON PERLMAN

Received February 14, 1983, from *The Squibb Institute for Medical Research, E. R. Squibb & Sons, Inc., New Brunswick, NJ 08903.* Accepted for publication October 6, 1983.

Abstract □ The USP XX colorimetric assay for the determination of diazotizable substances in hydrochlorothiazide was studied. Colorimetric assay results of hydrochlorothiazide bulk powder and captopril-hydrochlorothiazide combination tablets were found to have a high bias when compared with HPLC. A kinetic study of the diazotization step in the colorimetric assay and extrapolation of the free amine content, *i.e.*, 4-amino-6-chloro-1,3-benzenedisulfonamide, to time zero provided results which correlated favorably with those obtained by HPLC. The high bias of the colorimetric assay was shown to result from the formation of 4-nitroso derivative of hydrochlorothiazide, which is formed by acid hydrolysis during the diazotization step. Bendroflumethiazide and flumethiazide also showed increasing free amine content when the time of diazotization was increased.

Keyphrases □ Hydrochlorothiazide—bias of USP XX colorimetric assay for diazotizable substances, free amine content □ Colorimetry—high bias in USP XX assay for diazotizable substances, free amine, hydrochlorothiazide

One of the standard compendial assays performed on benzothiadiazines is the colorimetric test for diazotizable substances (free amine). Here, free amine is a general term used to designate any primary aromatic amine present in the material undergoing testing. In this report, free amine specifically refers to the primary aromatic amide decomposition product of hydrochlorothiazide, *i.e.*, 4-amino-6-chloro-1,3-benzenedisulfonamide. In the compendial assays, any free amine is diazotized with nitrous acid, and the resulting diazonium ion reacts with a color reagent such as disodium 4,5-dihydroxynaphthalene-2,7-disulfonate (disodium chromotropate) or *N*-(1-naphthyl)ethylenediamine dihydrochloride (Bratton-Marshall reaction). There is little precedent in the literature regarding problems with this colorimetric assay. In 1970, Turner and co-workers (1) reported difficulty in reproducing the procedure reported in the British Pharmacopoeia (2) for the determination of free amine in bendroflumethazide. They suggested lengthening the time of diazotization to 5 min rather than the recommended 1 min. This modification was incorporated into the procedures of the British and U.S. Pharmacopeias. Currently, the British Pharmacopoeia suggests use of a TLC assay (3), but the U.S. Pharmacopeia suggests the continued use of the colorimetric assay.

HPLC methods have been developed for the determination of free amine in hydrochlorothiazide bulk powder and captopril-hydrochlorothiazide combination tablets (4) and in nadolol-bendroflumethiazide combination tablet formulations (5). The active ingredients have also been assayed by HPLC methods. When compared with HPLC, the colorimetric assay gave results which consistently showed a high bias. Consequently, a kinetic study of the diazotization and extrapolation to time zero is reported, along with a discussion of the source of the anomoly produced in the diazotization step. A mechanism for the production of this artifactual value is also given.

EXPERIMENTAL SECTION

Materials—Hydrochlorothiazide[1] bulk powder and captopril-hydrochlorothiazide combination tablets[2] were used as received. 4-Amino-6-chloro-1,3-benzenedisulfonamide[3] and ACS reagent-grade disodium 4,5-dihydroxynaphthalene-2,7-disulfonate[4], phosphoric acid[4], hydrochloric acid[4], sodium nitrite[4], and ammonium sulfamate[4] were obtained commercially and used without further purification. The *N*-nitroso derivative of hydrochlorothiazide was prepared by the method of Gold and Mirvish (6), mp 155–156°C (dec.) [lit. (6) mp 155–156°C (dec.)].

High-Performance Liquid Chromatography—A prepacked, reverse-phase, medium-polarity column[5] (250 × 4.6 mm i.d.) containing 5-μm particles was used. The mobile phase was double-distilled water–methanol–phosphoric acid (80:20:0.05) at a flow rate of 2.0 mL/min, with detection at 210 nm. Details of the conditions used have been described previously (5).

Kinetic Studies—The USP procedure (7) for the determination of diazotizable substances in hydrochlorothiazide was followed. In a typical study, four weighings of hydrochlorothiazide powder (100 mg each), each with its own blank and standard, were carried through the procedure up to the addition of the sodium nitrite and hydrochloric acid (diazotization). The diazotization was then allowed to proceed for 5, 10, 15, and 30 min, respectively, at ambient temperature. Then, each solution was carried through to the end of the USP procedure.

The kinetic study was repeated exactly as described above with the 4-nitroso derivative of hydrochlorothiazide instead of hydrochlorothiazide. A third experiment was carried out by omitting the addition of sodium nitrite in the diazotization step while carrying the 4-nitroso derivative of hydrochlorothiazide through the procedure.

An extraction procedure[6] was used to prepare the captopril–hydrochlorothiazide combination tablets for free amine analysis. An acidified aqueous tablet extract was washed with chloroform to remove the interfering captopril, and the resulting aqueous phase was carried through the kinetic study as described above.

RESULTS AND DISCUSSION

The free amine content of hydrochlorothiazide bulk powder was determined by the procedure described in USP XX (6). The current USP procedure calls for a 5-min diazotization. A kinetic study of the diazotization step yielded increasing free amine content with increasing reaction time (Fig. 1). Extrapolation of the free amine content to time zero, *i.e.*, *y*-intercept, with linear regression analysis gave results of 0.0004% (r^2 = 0.977) and 0.06% (r^2 = 0.994) for two batches of hydrochlorothiazide. In Table I the data used to calculate these results are shown. Linear regression analysis also gave slopes of 0.0191 ± 0.0021 (11.0%) and 0.0174 ± 0.0019 (10.9%), respectively, for the two batches of hydrochlorothiazide.

In Fig. 1, a similar phenomenon which occurred when captopril-hydrochlorothiazide tablets were assayed for free amine content by the USP procedure is also shown. Once again, a kinetic study of the diazotization step yielded increasing free amine content with increasing reaction time. Extrapolation of the free amine content to zero time, *i.e.*, *y*-intercept with linear regression analysis, gave a result of 0.11% (r^2 = 0.999) for captopril-hydrochlorothiazide tablets which contained 15 mg of hydrochlorothiazide per tablet and 0.13% (r^2 = 0.999) for tablets which contained 25 mg of hydrochlorothiazide per tablet. In Table I, the data used to calculate these results are

	10	0.21	10	0.23
	15	0.24	15	0.30
	30	0.59	30	0.59

[a] The tablets contained 15 mg of hydrochlorothiazide. [b] The tablets contained 25 mg of hydrochlorothiazide.

shown. Linear regression analysis also gave slopes of 0.0143 ± 0.0015 (10.5%) and 0.0123 ± 0.0013 (10.6%), respectively, for the combination tablets.

The *RSD* of the slopes was calculated to be 19.5%. This value is surprisingly high in light of the fact that each individual set of data points provided excellent correlation coefficients. One possible factor is that the temperature of the reaction was not strictly controlled, *i.e.*, it was performed at room temperature. An increase in room temperature would be paralleled by an increase in the slope of the line, and a decrease in room temperature would be paralleled by a decrease in the slope of the line.

The extrapolated values are compared with the values obtained from the HPLC assay (Table II). In Table II are also included the values determined by the USP procedure, which has a 5-min diazotization. A high bias exists in the USP method. Since the HPLC assay has a limit of detection of 0.1% and the results of the kinetic study are close to that limit, it is difficult to make a quantitative comparison. Qualitatively, the HPLC assay and the kinetic assay gave results that were substantially lower than those of the USP procedure.

It is tempting to attribute the increase in free amine content to the acid-catalyzed hydrolysis of hydrochlorothiazide. This, however, is not the case. When hydrochlorothiazide was allowed to stand in dilute hydrochloric acid (1:10), no increase in free amine content was observed even after 1 h. The kinetics and rate of decomposition of hydrochlorothiazide in acidic media have been studied by other investigators. For example, Yamana *et al.* (8) have published a report covering the pH-rate profile of hydrochlorothiazide. Mollica *et al.* (9) have published an extensive report on the hydrolysis of benzothiadiazines. They reported the rate constant for hydrolysis of hydrochlorothiazide at pH 1.47 and 45°C to be 1.46×10^{-3} h^{-1}. By using the Arrhenius relationship, the rate constant at 25°C should be $\sim 1.5 \times 10^{-4}$ h^{-1}. This translates into a half-life of 4620 h. Thus, under the acid treatment employed in the colorimetric procedure, a negligible amount of hydrochlorothiazide is hydrolyzed to free amine.

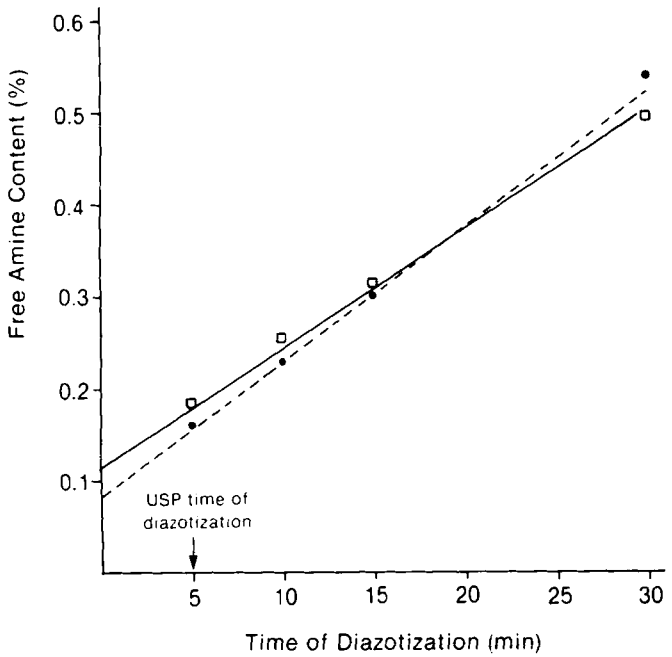

Figure 1—*Free amine content of hydrochlorothiazide bulk powder* (●) *and captopril-hydrochlorothiazide combination tablets* (□) *as a function of time of diazotization.*

Table II—Comparison of HPLC and Kinetic Assays for the Determination of Free Amine Content in Hydrochlorothiazide Bulk Powder and Captopril-Hydrochlorothiazide Combination Tablets

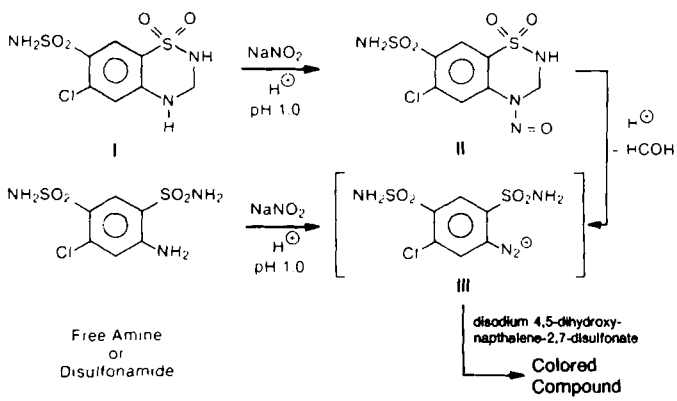
Formulation	Free Amine Content, % HPLC	Colorimetry USP	Colorimetry Kinetic
Captopril-hydrochlorothiazide Combination tablets	≤0.1[a]	0.17[a]	0.11[a]
	≤0.1[b]	0.23[b]	0.13[b]
Hydrochlorothiazide bulk powder	≤0.1[c]	0.11[c]	0.0004[c]
	≤0.1[d]	0.13[d]	0.06[d]

[a] The tablets contained 15 mg of hydrochlorothiazide. [b] Tablets contained 25 mg of hydrochlorothiazide. [c] Lot NX008. [d] NX018.

One of the standard syntheses of *N*-nitrosamines is nitrous acid addition to a secondary amine in which the nitrous acid is generated *in situ* by the addition of sodium nitrite to an aqueous acidic solution of the amine. Depending on the secondary amine, this nitrosation can be very slow (*e.g.*, dimethylamine) or quite rapid (*e.g.*, *N*-methylaniline) (10). In fact, for secondary aromatic amines, the reaction mixture is usually cooled to 0°C to allow nitrosation to take place at a reasonable rate. Since hydrochlorothiazide is a secondary aromatic amine, it would not be surprising that some nitrosamine would be generated in the diazotization reaction. This was found to be the case.

The nitrosation kinetics of hydrochlorothiazide have been reported by Gold and Mirvish (6). They have reported that the reaction was second order and possessed a rate constant of 0.76 M^{-1} s^{-1}. Hydrochlorothiazide was dissolved in 25% aqueous acetic acid, the pH was adjusted to 1.0 with 70% perchloric acid mixed with an aqueous sodium nitrite solution, and the kinetics were followed by measuring the disappearance of the UV maximum and appearance of the λ_{max} of the nitrosamine at 392 nm. The conditions used by Gold and Mirvish are nearly identical to those present in the diazotization reaction in the procedure described in USP XX, *i.e.*, pH 1.0 at 25°C in aqueous media. We can approximate the amount of hydrochlorothiazide nitrosated under these conditions by using the second-order rate equation: $(1/a - x) - (1/a) = kt$, where a is the initial concentration of hydrochlorothiazide (~0.003 M), x is the concentration of the nitrosamine at time t, and k is 0.76 M^{-1} s^{-1}. For example, in 5 and 30 min, 41 and 81% of the hydrochlorothiazide, respectively, was nitrosated.

In Scheme I is depicted the reactions of both hydrochlorothiazide and any



Scheme I

Table III—Acid-Catalyzed Decomposition of the 4-Nitroso Derivative of Hydrochlorothiazide

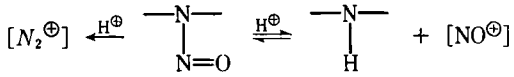
[a] Procedures described in USP XX for diazotizable substances.

free amine present under nitrosation conditions. The addition of the nitroso group in the 4-position (II) greatly increases the acid lability of the compound compared with hydrochlorothiazide (I). Acid-catalyzed hydrolysis of the 4-nitroso derivative of hydrochlorothiazide could lead to the same intermediate diazonium ion that would be produced by the diazotization of any free amine. This diazonium ion is subsequently reacted with disodium 4,5-dihydroxynaphthalene-2,7-disulfonate, and the resulting colored compound is quantitated by reading at 500 nm.

To prove this hypothesis, the 4-nitroso derivative of hydrochlorothiazide was synthesized by previously reported procedures (6), recrystallized, and then assayed for free amine content by the procedure described in USP XX. The free amine content increased with time just as in the determination of free amine in hydrochlorothiazide (Table III). The nitrosamine was also allowed to react in dilute HCl (1:10) for various periods of time, with no sodium nitrite present. Once again, increasing free amine content with increasing time was observed. Obviously, the nitrosamine is undergoing acid-catalyzed decomposition to the diazonium ion (III, Scheme I), which is subsequently reacting with the color reagent in the assay.

The rate of decomposition of the 4-nitroso derivative of hydrochlorothiazide in nitrous acid was found to be about twice that in dilute HCl (Table III.) This might be due to an equilibrium shift. In addition to the decomposition to the diazonium ion, secondary *N*-nitrosamines can undergo denitrosation back to the secondary amine. This denitrosation is an equilibrium process:



In dilute HCl when $NaNO_2$ is present, the concentration of NO^+ present is increased. Thus, the equilibrium is shifted to the left causing the observed increase in the rate of decomposition.

The results of these experiments indicate conclusively that the diazotization step generates an artifactual interference in the colorimetric assay. Although HPLC is an excellent alternative for the determination of the free amine (disulfonamide) content of hydrochlorothiazide bulk powder and captopril–hydrochlorothiazide combination tablets, it has a limit of detection of ~0.1%. To achieve the sensitivity of the procedure described in USP XX, an alternative colorimetric procedure has been developed[7] which will be discussed in a later report.

All other colorimetric USP XX tests for diazotizable substances in benzothiadiazines in which sodium nitrite in acid media is used have been thrown into doubt as a result of these experiments. In fact, bendroflumethiazide and flumethiazide were shown to yield increasing free amine content with increasing time of diazotization. For example, USP free amine assays gave contents of 0.8% for bendroflumethiazide bulk powder, whereas a value of 0.2% was obtained by HPLC (4).

Numerous *N*-nitrosamines are known carcinogens and mutagens. However, the 4-nitroso derivative of hydrochlorothiazide has been found to be neither carcinogenic nor mutagenic[8] and does not pose any danger in handling. Since the other 4-nitrosobenzothiadiazines have not been tested for carcinogenicity and mutagenicity, care should be exercised when performing the assay for diazotizable substances. In the new colorimetric procedure[7], no *N*-nitrosamines are formed.

α-Phenyl-β-(3,4-dimethoxy)phenethylamines: Novel Inhibitors of Choline Acetyltransferase from *Torpedo* Electric Organ

RAGAB M. SHAFIK *x, RAAFAT SOLIMAN *, SOAD A. EL-HAWASH *, MAHMOUD MORSHEDY ‡, and NABIL A. MANSOUR ‡

Received April 12, 1983, from the **Department of Pharmaceutical Chemistry, Faculty of Pharmacy* and the ‡ *Department of Pesticide Chemistry, Faculty of Agriculture, University of Alexandria, Alexandria, Egypt.* Accepted for publication September 7, 1983.

Abstract □ Some derivatives of α-phenyl-β-(3,4-dimethoxy)phenethylamine that might bear a certain conformational resemblance to choline were prepared. The *in vitro* inhibition of choline acetyltransferase from *Torpedo* electric organ was investigated. These compounds gave variable degrees of inhibition; the most potent inhibitor was, *N,N,N*-trimethyl-α-phenyl-β-(3,4-dimethoxy)phenethylammonium iodide, with an I_{50} of 1.3×10^{-5} M. The inhibition of choline acetyltransferase from *Spodoptera littoralis* larval brains was also determined for comparative study. The aforementioned compound has an I_{50} of 9×10^{-6} M on choline acetyltransferase from this source.

Keyphrases □ α - Phenyl -β- (3,4 - dimethoxy)phenethylamines—synthesis, inhibition of choline acetyltransferase □ Choline acetyltransferase—inhibition, α-phenyl-β-(3,4-dimethoxy)phenethylamines

The phenethylamine (I) skeleton is an integral moiety for many naturally occuring compounds which possess remarkable biological properties, *e.g.*, morphine (1), ephedrine (2), epinephrine (3), norepinephrine (3), and papaverine (4, 5). The structural feature of choline base (II), the β-hydroxy ethylamine derivative, bears some conformational resemblance to I. It has been shown (6) that the most favorable conformation of II, at physiological pH, is the *gauche* disposition (IIa). The latter might be the most suitable conformer for interaction with the choline acetyltransferase (E.C. 2.3.1.6) surface prior to acetylation (7, 8). A bioisosteric *gauche* arrangement (Ia) would be assured by introducing a phenyl group in the α-position. This would also increase lipophilicity. Therefore, we prepared some derivatives (III) of α-phenyl-β-(3,4-dimethoxy)phenethylamine and evaluated them as inhibitors of choline acetyltransferase.

III

Choline acetyltransferase catalyzes the synthesis of acetylcholine, and both O'Brien (9) and Yu and Booth (10) recognized the potential of this enzyme as a target for new drugs and insecticides. For biochemical studies, choline acetyltransferase from *Torpedo* electric organ was used, and the results were compared with those recorded for choline acetyltransferase from *Spodoptera littoralis* larval brains.

Few potent inhibitors of choline acetyltransferase are known, and those that have been tested have not proved useful as insecticides (10). Other reports dealing with mammalian inhibitors of this enzyme have been published, *e.g.*, 5-hydroxy-1,4-naphthalenedione and 4-(1-naphthylvinyl)pyridine (11), halogenoacetylcholines (12), and (2-benzoylethyl)trimethylammonium chloride (13, 14). Most of these compounds are either esters or aromatic ketones which are relatively unstable (12, 14). On the other hand the compounds described here are neither esters nor ketones. Some clear differences existed between the choline acetyltransferases of mites, houseflies, and rats toward their substrate specificity (9). It was also reported that quite marked variation in sensitivity between insect and mouse choline acetyltransferases were displayed when both enzymes were tested against known inhibitors, such as the styrylpyridines (10).

The synthetic approach followed is outlined in Scheme I. 3,4-Dimethoxy-α-nitrostilbene (VI) was prepared using a modification of the method described by Owari (15). α-Phenyl-β-(3,4-dimethoxy)phenethylamine (III) was obtained by reduction of VI with lithium aluminum hydride in ether. The *N*-formyl derivative (VIIa) was obtained from III using the method of Sam *et al.* (16). Treatment of III with ethyl chloroformate in the presence of pyridine afforded the *N*-ethoxycarbonyl derivative (VIIb). The *N*-methyl derivative (VIII) was prepared either from VIIa or VIIb by reduction with lithium aluminum hydride in tetrahydrofuran or ether, respectively. The *N,N*-dimethyl derivative (IX) was obtained by applying an analogous procedure reported by Shafik *et al.* (5) for the preparation of similar compounds. The quaternarization of IX to give the trimethylammonium derivative (X) was carried out by using an excess of methyl iodide in ether.

EXPERIMENTAL SECTION[1]

3,4-Dimethoxy-α-nitrostilbene (VI)—To a solution of 16.6 g (0.1 mol) of veratraldehyde (IV) in 15 mL of methanol was added 13.7 g (0.1 mol) of phenylnitromethane (17) (V) and 0.5 mL of *n*-butylamine. The mixture was kept at room temperature for 72 h, and then the product was removed by filtration, dried, and recrystallized from ethanol to give 10.0 g (35% yield) of yellow needles, mp 105–107°C [lit (18) mp 109°C]; IR ν_{max}: 1365 and 1595 cm^{-1} (C—NO_2).

[1] Melting points were taken in open glass capillaries and are uncorrected. The IR spectra were scanned on a Beckman IR-4210 spectrophotometer with KBr pellets. The ^{1}H-NMR spectra were determined, for solutions in Me_2SO-d_6, on a Varian EM-390 NMR spectrometer, and are reported in δ values (ppm) relative to an internal standard of tetramethylsilane. Analyses were performed by members of the Microanalytical Unit, Faculty of Science, University of Cairo, Egypt.

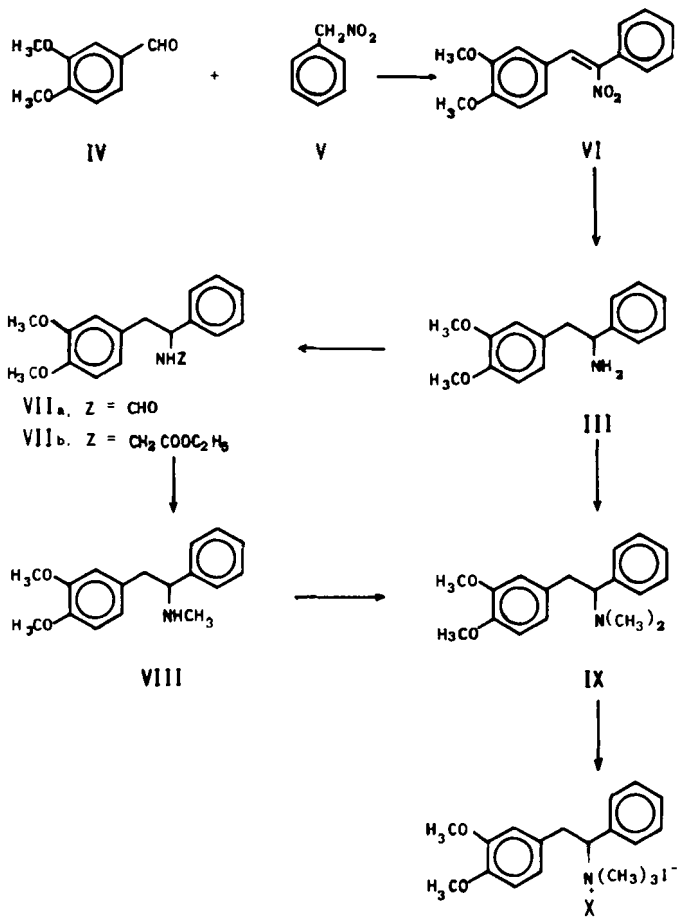

SCHEME I

α-Phenyl-β-(3,4-dimethoxy)phenethylamine (III)—To a stirred mixture of 1.9 g (0.05 mol) of lithium aluminum hydride and 300 mL of ether was added 2.8 g (0.01 mol) of VI. The mixture was refluxed for 72 h, and then chilled. The excess lithium aluminum hydride was destroyed with crushed ice and 20% aqueous NaOH, respectively. The product was isolated by ether extraction and was purified in the usual manner (5) by alternative pH adjustments to give 1.9 g (67% yield) of III as pale-yellow needles, mp 65°C [lit (15) mp 66–67°C]. The hydrochloride salt was obtained by passing dry hydrogen chloride into the ethereal solution of III to give white needles, which were recrystallized from methanol–ether to give 1.9 g (67% yield) of white crystals, mp 176–177°C [lit (19) mp 176–177°C]; IR ν_{max}: 2650 cm^{-1} (NH_3^+); ^{1}H-NMR (Me_2SO-d_6): δ 3.45 (s, 6), 3.55 (d, 2, J = 6 Hz), 4.4 (m, 1), 6.65 (m, 3, ArH), and 7.35 ppm (m, 5, ArH).

N-Formyl-α-phenyl-β-(3,4-dimethoxy)phenethylamine (VIIa)—A solution of 2.6 g (0.01 mol) of III in a mixture of 15 mL of 98% formic acid and 18 mL of acetic anhydride was refluxed for 5 h and then diluted with 100 mL of water. The mixture was extracted with ether and washed with 10% NaOH, then 10% HCl, and water. The ethereal extract was dried (Na_2SO_4), and the solvent was removed under reduced pressure. The oily residue that solidified on standing was recrystallized from benzene–petroleum ether (bp 40–60°C) to give 1.2 g (43% yield) of white crystals, mp 120–121°C; IR ν_{max}: 3400 (NH), 1650, 1550, and 1250 cm^{-1} (amide bands).

Anal.—Calc. for $C_{17}H_{19}NO_3$: C, 71.6; H, 6.6; N, 4.9. Found: C, 71.5; H, 6.2; N, 5.3.

N-Ethoxycarbonyl-α-phenyl-β-(3,4-dimethoxy)phenethylamine (VIIb)—A solution of 2.7 g (0.025 mol) of ethyl chloroformate in 10 mL of benzene was added, dropwise, to a cold, stirred solution of 6.2 g (0.024 mol) of III in 30 mL of pyridine. The mixture was stirred for an additional 3 h and then was refluxed for 4 h. The mixture was poured onto 25 mL of 10% HCl and extracted with benzene. The organic phase was washed with 2 M NaOH and water, and dried (Na_2SO_4). The solvent was removed under reduced pressure to give an oily residue that solidified on standing at room temperature. Recrystallization from benzene–petroleum ether (bp 40–60°C) gave 1.6 g (47% yield) of pale-yellow crystals of VIIb, mp 107°C; IR ν_{max}: 3450 (NH), 1670, 1550, and 1265 cm^{-1} (amide bands).

Anal.—Calc. for $C_{19}H_{23}NO_4$: C, 69.3; H, 7.0; N, 4.3. Found: C, 69.1; H, 7.4; N, 4.3.

N-Methyl-α-phenyl-β-(3,4-dimethoxy)phenethylamine Hydrochloride (VIII)—*Method A*—To a stirred mixture of 1.9 g (0.05 mol) of lithium aluminum hydride and 200 mL of tetrahydrofuran was added 2.8 g (0.01 mol) of VIIa. The mixture was heated at reflux for 16 h, and the solvent was removed under reduced pressure. The residue was chilled to give (as in the preparation of III) the hydrochloride salt, 1.7 g (62% yield) as white crystals, mp 164–165°C.

Anal.—Calc. for $C_{17}H_{22}ClNO_2$: C, 66.3; H, 7.2; Cl, 11.5; N, 4.6. Found: C, 66.5; H, 7.2; Cl, 11.4; N, 4.2.

Method B—To a stirred mixture of 1.9 g (0.05 mol) of lithium aluminum hydride and 300 mL of ether was added 3.3 g (0.01 mol) of VIIb. The mixture was heated at reflux for 14 h. The hydrochloride salt was recrystallized from methanol–ether to give 2.4 g (72% yield) as white crystals, mp 164–165°C. Admixture of the products obtained by both methods (A and B) showed no melting point depression.

N,N-Dimethyl-α-phenyl-β-(3,4-dimethoxy)phenethylamine Hydrochloride (IX)—A mixture of 0.01 mol of the hydrochloride salt of III or VIII, 2.3 g (0.05 mol) of formic acid (98%), and 0.66 g (0.022 mol) of 38% formaldehyde was refluxed for 12 h. The mixture was transferred to an evaporating dish and heated on a water bath until most of the unreacted formic acid and formaldehyde were removed. The syrupy residue was treated with 0.6 mL of formic acid (98%) and 0.2 mL of 38% formaldehyde and allowed to evaporate on the water bath until dryness. The last traces of water were removed by azeotropic distillation with absolute ethanol and benzene. The residual hydrochloride salt was recrystallized from methanol–ether to give 2.0 g (78% yield) as white crystals, mp 218–220°C; IR ν_{max}: 2600 cm^{-1} (NH^+); ^{1}H-NMR (Me_2SO-d_6): δ 2.90 (s, 6), 3.30 (s, 6), 3.80 (d, 2, J = 5 Hz), 4.80 (m, 1), 6.90 (d, 3, J = 9 Hz, ArH), 7.60 ppm (m, 5, ArH).

Anal.—Calc. for $C_{18}H_{24}ClNO_2$: C, 67.2; H, 7.5; Cl, 11.0; N, 4.4. Found: C, 67.4; H, 7.1; Cl, 10.6; N, 4.0.

N,N,N-Trimethyl-α-phenyl-β-(3,4-dimethoxy)phenethylammonium Iodide (X)—To a solution of 2.9 g (0.01 mol) of IX in 100 mL of ether was added 1.7 g (0.012 mol) of methyl iodide. The mixture was allowed to stand at room temperature for 24 h. The crystalline material was removed by filtration and recrystallized from methanol–ether to give 1.8 g (63% yield) of yellow crystals, mp 228–230°C; ^{1}H-NMR (Me_2SO-d_6): δ 3.40 (s, 9), 3.75 (s, 6), 4.50 (m, 2), 6.90 (s, 1), 7.50 (m, 3, ArH), and 7.80 ppm (m, 5, ArH).

Anal.—Calc. for $C_{19}H_{26}INO_2$: C, 53.43; H, 6.1; N, 3.3. Found: C, 53.7; H, 5.9; N, 3.6.

Biochemical Assays—Membranes were prepared from the electric organ of *Torpedo ocellata* (collected near Alexandria, Egypt, and stored frozen at −90°C for up to 6 months) by homogenization (50%, w/v) in ice-cold 10 mM EDTA–20 mM Na_2HPO_4 buffer (pH 7.4). An emulsifier[2] (0.2%, v/v) was added to the homogenate, and the suspension was shaken lightly by hand for few seconds, filtered through cheesecloth, and centrifuged at 100,000×g for 30 min. The supernatant was used as the enzyme source. Head capsules of fourth instar *Spodoptera littoralis* larvae were homogenized in the aforementioned buffer (1 mL/10 head capsules) using a similar procedure. Protein was assayed by the method of Lowry *et al.* (20).

The radiochemical method was used for the determination of choline acetyltransferase activity (21). The incubation mixture contained 0.2 mM [1-^{14}C]acetyl CoA[3] (50 mCi/mmol), 300 mM NaCl, 50 mM Na_2HPO_4 buffer (pH 7.4), 8 mM choline bromide, 20 mM EDTA, and 0.1 mM physostigmine. The labeled acetyl CoA was diluted with the unlabeled compound[4]. In the inhibition studies of choline acetyltransferase activity, the enzyme preparation was incubated with 10 μL of the inhibitor solution for different intervals.

RESULTS AND DISCUSSION

The radioactivity assay was used to find the acetyl CoA concentration in the incubation medium and different protein concentrations for optimal *Torpedo* electric organ choline acetyltransferase activity. A range of 0.1–0.2 mM acetyl CoA was necessary to give near-optimal activities. Such high acetyl CoA concentrations gave linear activity curves over a greater range, maintaining linearity up to 120 μg of enzyme in the incubation mixture. Under these conditions the enzyme-specific activities of six different preparations were 14.60 ± 0.16 (mean ± SD) and 6.64 ± 0.12 λ_{max} 412·mg^{-1} of protein·h^{-1} for *Torpedo* electric organ and *Spodoptera* larval brain preparations, respectively. The differences in membrane binding might be due to differences among the surface charges of choline acetyltransferase from the two species.

As can be seen from the structures of I and II, the quaternary ammonium derivative (X) was the most potent inhibitor in a micromolar range for choline

Table I—*In Vitro* Inhibition of Choline Acetyltransferase Activity from Two Sources by α-Phenyl-β-(3,4-dimethoxy)phenethylamine Derivatives

Compound[a]	Inhibition Constants			
	Torpedo		*Spodoptera*	
	I_{50}, M	K_i, μM	I_{50}, M	K_i, μM
III	7.0×10^{-5}	60	2.7×10^{-5}	40
VIII	5.8×10^{-5}	45	2.5×10^{-5}	32
IX	4.0×10^{-5}	35	1.8×10^{-5}	25
X	1.3×10^{-5}	10	9.0×10^{-6}	6

[a] The I_{50} values were compared with those determined for diisopropylfluorophosphonate ($I_{50} = 5 \times 10^{-4}$ M from both sources). Lit. (10) data reported for diisopropylfluorophosphonate using choline acetyltransferase (house fly or mouse): $I_{50} = 1 \times 10^{-4}$ M.

acetyltransferase from both sources. From the I_{50} and K_i values obtained, the *Spodoptera* larval enzymes were shown to be more sensitive toward the synthesized compounds (III and VIII–X) than the *Torpedo* electric organ enzymes. However, the best *in vitro* choline acetyltransferase inhibitor was the charged compound (X), whereas the uncharged compounds (III, VIII, and IX) were relatively poor inhibitors (Table I).

Several choline analogues ($SCNCH_2CH_2\overset{+}{N}R^1R^2R^3X^-$) were previously tested (22) on rats as possible *in vivo* choline acetyltransferase inhibitors; the data revealed poor correlation between the K_i value and the insecticidal activity of such compounds when tested against several insect species. The most likely explanation was that since the molecule is charged, it would not readily penetrate the nerve cord and reach the cells in which the enzyme is located. The present work was thus directed toward *in vitro* inhibition studies using some uncharged phenethylamines (III, VIII, and IX) to avoid the problems of compound penetration to the target. The quaternary analogue (X) was also investigated.

Excitatory Amino Acid Receptor Interactions of a Novel α-Phosphinic Acid Analogue of α-Methylaspartic Acid

L. A. CATES *x, V-S. LI *, Z-S. HU *, J. LEHMANN ‡, J. T. COYLE ‡, and J. W. FERKANY ‡

Received October 14, 1983, from the **Department of Medicinal Chemistry, College of Pharmacy, University of Houston, Houston, TX 77004* and the ‡*Departments of Neuroscience, Pharmacology, and Psychiatry, Division of Child Psychiatry, Johns-Hopkins University, School of Medicine, Baltimore, MD 21205.* Accepted for publication November 30, 1983.

Abstract □ An α-phosphino analogue of α-methylaspartate has been synthesized. The compound may not interact with excitatory amino acid receptors directly, as assessed by direct *in vitro* radioreceptor binding methods; however, it possesses weak anticonvulsant activity and exhibits an excitant action *in vitro* that is apparently not mediated by a *N*-methyl-D-aspartate receptor.

Keyphrases □ Excitatory amino acid receptors—*N*-methyl-D-aspartate, glutamate, kainate □ Anticonvulsants—*in vitro*, rats, excitatory amino acids □ Phosphinic acids—excitatory amino acid receptors, anticonvulsant activity

Phosphorus analogues of amino acids have been investigated previously; however, most studies have involved phosphonic acid derivatives such as aminomethanephosphonic acid (I). Only in recent years have aminophosphinic acids with unsubstituted amino groups been prepared. The first, glycine analogue II, was synthesized in 1964 by a procedure which provides only limited types of products (1).

Phosphinic acids possess a hydrogen atom in lieu of one of the two hydroxyl groups found in phosphonic acids and, therefore, are monobasic with less bulk on the phosphorus atom. Phosphinic acids are the closest phosphorus analogues of carboxylic acids and this similarity has led to a limited number of investigations of aminophosphinic acids for biological activity. In 1961, Linfield *et al.* prepared phosphinic acids bearing substituted α-anilino and phenyl groups (III) by the addition of hypophosphorus acid to the appropriate

Table I—*In Vitro* Inhibition of Choline Acetyltransferase Activity from Two Sources by α-Phenyl-β-(3,4-dimethoxy)phenethylamine Derivatives

Compound[a]	Inhibition Constants			
	Torpedo		*Spodoptera*	
	I_{50}, M	K_i, μM	I_{50}, M	K_i, μM
III	7.0×10^{-5}	60	2.7×10^{-5}	40
VIII	5.8×10^{-5}	45	2.5×10^{-5}	32
IX	4.0×10^{-5}	35	1.8×10^{-5}	25
X	1.3×10^{-5}	10	9.0×10^{-6}	6

[a] The I_{50} values were compared with those determined for diisopropylfluorophosphonate ($I_{50} = 5 \times 10^{-4}$ M from both sources). Lit. (10) data reported for diisopropylfluorophosphonate using choline acetyltransferase (house fly or mouse): $I_{50} = 1 \times 10^{-4}$ M.

acetyltransferase from both sources. From the I_{50} and K_i values obtained, the *Spodoptera* larval enzymes were shown to be more sensitive toward the synthesized compounds (III and VIII–X) than the *Torpedo* electric organ enzymes. However, the best *in vitro* choline acetyltransferase inhibitor was the charged compound (X), whereas the uncharged compounds (III, VIII, and IX) were relatively poor inhibitors (Table I).

Several choline analogues ($SCNCH_2CH_2\overset{+}{N}R^1R^2R^3X^-$) were previously tested (22) on rats as possible *in vivo* choline acetyltransferase inhibitors; the data revealed poor correlation between the K_i value and the insecticidal activity of such compounds when tested against several insect species. The most likely explanation was that since the molecule is charged, it would not readily penetrate the nerve cord and reach the cells in which the enzyme is located. The present work was thus directed toward *in vitro* inhibition studies using some uncharged phenethylamines (III, VIII, and IX) to avoid the problems of compound penetration to the target. The quaternary analogue (X) was also investigated.

Schiff bases and reported antibacterial properties associated with some of these derivatives (2). Except for II, the only unsubstituted α-aminophosphinic acids reported are those by Khomutov and Osipova (3) and Bayliss *et al.* (4), which were synthesized by the addition of hypophosphorus acid to oximes and diphenylmethylimines, respectively. The amino acid analogues resulting from the latter process were investigated for antibacterial properties with alanine (IV), valine (V), and methionine (VI) derivatives displaying significant activity. In addition, the effect of V was reversed by valine, an indication that a false substrate mechanism was operative.

In this paper we describe the synthesis (*Scheme I*) and biological testing of DL-α-amino-α-methyl-β-carboxyethanephosphinic acid (IX) and two of its precursors (VII and VIII). Compound IX represents the bioisosteric replacement of one carboxyl group of α-methylaspartic acid with a P(O)H(OH) moiety. α-Methylaspartic acid has been investigated for its ability to reduce aspartic acid utilization (5) and for its effect in many enzyme systems such as inhibition of tyrosine aminotransferase (6) and asparaginase (7). Moreover, IX is related to the antagonists of amino acid receptors including 2-amino-4-phosphonobutyric acid and 2-amino-7-phosphonoheptanoic acid.

Table I—Effect of VII, VIII, and IX on the Specific Binding of Tritiated Kainic Acid, L-Glutamate, and 2-Amino-7-phosphonoheptanoic Acid to Rat Brain Membranes *In Vitro*[a]

Compound	Specifically Bound Ligand, % Displacement: Tritiated L-Glutamate	Tritiated Kainic Acid	Tritiated 2-Amino-7-phosphoheptanoic Acid
	Tris-Citrate		
VII	14	8	0
VIII	0	7	0
IX	0	11	28
	Tris-HCl		
VII	6	—	—
VIII	8	—	—
IX	8	—	—

[a] Compounds (10^{-4} M) were incubated in the presence of the indicated ligand as described. Reference IC_{50} values for L-glutamate, kainic acid, and 2-amino-7-phosphonoheptanoic acid are 1 μM, 5 nM, and 5 μM, respectively.

Three different types of excitatory amino acid receptors have been proposed to exist (8): (a) "glutamate receptors," which may be preferentially activated by L-glutamic acid or quisqualate, and blocked by glutamate diethyl ester or 2-amino-4-phosphonobutyric acid; (b) "kainate receptors," preferentially activated by kainate and closely related structures, for which there are no known receptor antagonists; (c) "*N*-methyl-D-aspartate receptors," preferentially activated by *N*-methyl-D-aspartate and ibotenic acid, and antagonized by 2-amino-5-phosphonopentanoate and 2-amino-7-phosphonoheptanoate. Excitatory amino acids may be the most common neurotransmitters in the brain. Antagonists of excitatory amino acid receptors are sought for application in controlling seizures and suppressing certain neurodegenerative disorders.

RESULTS AND DISCUSSION

Compounds VII–IX were tested for direct interactions with excitatory amino acid receptors in available *in vitro* excitatory amino acid receptor binding assays (9–11). As shown in Table I, none of the compounds possessed inhibitory activity, with the exception of the marginal effects of IX, at the site labeled by tritiated 2-amino-7-phosphonoheptanoic acid.

The major role of inactivation of synaptically released excitatory amino acid neurotransmitters is high-affinity, sodium-dependent reuptake (5). Compound IX inhibited such uptake by slightly more than 50% at a concentration of 5×10^{-4} M (Table II), which is at least 100-fold less potent than L-glutamate or D- or L-aspartate in this respect (12). Thus, IX is a weak inhibitor of high-affinity excitatory amino acid uptake in the rat brain. These data may suggest that IX itself is transported into synaptosomes by the excitatory amino acid carrier, albeit with low affinity. Compounds VII and VIII demonstrated no interaction with the carrier.

In the [^{3}H]acetylcholine release system, which reflects the neuronal excitation induced by excitatory amino acids acting at *N*-methyl-D-aspartate receptors (13), IX caused an increase in spontaneous [^{3}H]acetylcholine release and tended to enhance *N*-methyl-DL-aspartate-evoked [^{3}H]acetylcholine release (Table III). Compound VIII caused an increase in spontaneous [^{3}H]acetylcholine release (Table III).

Compounds VII–IX were tested *in vivo* for ability to protect against electroshock and subcutaneously administered pentylenetetrazol[1]-induced (scMet) seizures. Compounds VII and IX afforded protection against scMet of 25 and 50%, respectively, at doses of 600 mg/kg. No acute disruption of neurological function was detected in the rotorod test for VII–IX at doses of ≥600 mg/kg.

Of these results, the most striking is the coincidence of the activity of IX in enhancing spontaneous [^{3}H]acetylcholine release and as an anticonvulsant. Because the response to *N*-methyl-D-L-aspartate was not decreased during exposure to IX, it is unlikely that IX interacts directly with *N*-methyl-D-aspartate receptors. Since IX is only weakly active in inhibiting the specific

[1] Metrazol.

Table II—Effect of VII, VIII, and IX on the Uptake of L-[^{3}H]Glutamate, D-[^{3}H]Aspartate, and L-[^{3}H]Aspartate into Synaptosomes Prepared from Rat Corpus Striatum or Cerebellum [a]

Compound	Specific Uptake, % Inhibition		
	L-[^{3}H]Glutamate	D-[^{3}H]Aspartate	L-[^{3}H]Aspartate
	Corpus Striatum		
VII	0	0	0
VIII	0	7	0
IX	53	56	56
	Cerebellum		
VII	2	0	0
VIII	4	0	5
IX	59	57	59

[a] Synaptosomes were incubated in the presence of various ligands with or without the compounds (at a concentration of 5×10^{-4} M). Reference IC_{50} values for L-glutamate, D-aspartate, and L-aspartate are 1–5 μM (12).

Table III—[^{3}H]Acetylcholine Release Studies [a]

		[^{3}H]Acetylcholine Release, % of Control	
		Spontaneous	Evoked [b]
Control	9	100 ± 3.8	100 ± 9.8
VII, 0.3 mM	4	103 ± 5.0	70 ± 6.1
VII, 0.3 mM	4	116 ± 3.8 [d]	108 ± 4.9
IX, 0.3 mM	3	113 ± 1.3 [c]	87 ± 2.4
IX, 1.0 mM	3	166 ± 5.0 [c]	129 ± 39.3

[a] Test substances were added on interval six. Stimulation, a 2-min application of 50 μM *N*-methyl-D-aspartate, was applied at intervals three and nine. The effect of test substances on the parameters S_{pII}/S_{pI} and $S_{II} - S_{pII}/S_I - S_{pI}$ is expressed as percent of control (13). [b] *N*-Methyl-DL-aspartate-evoked release. [c] $p < 0.05$, Mann–Whitney two-tailed U test.

binding of the *N*-methyl-D-aspartate receptor antagonist tritiated 2-amino-7-phosphonoheptanoic acid, interaction of IX with *N*-methyl-D-aspartate receptors is unlikely to be the mechanism of action of this compound. Further biological investigations are required to determine the mechanism of action by which IX exerts its effects in these various biological systems.

DL-α-Benzhydrylamino-α-methyl-β-carbethoxyethanephosphinic Acid (VII)—This compound was prepared using a modification of previously reported procedures (2, 4). A mixture of 23.65 g (0.129 mol) of 1,1-diphenylmethylamine (14) and 16.78 g (0.129 mol) of ethyl acetoacetate in 80 mL of benzene was refluxed for 2 h and then distilled with azeotropic removal of water using a Dean–Stark trap. To the cooled residue was slowly added 8.96 g (0.129 mol) of 95% hypophosphorous acid, which was obtained by evaporation of a commercial 50% aqueous solution at 30–40°C (2 mm) and the mixture was heated at reflux for 2 h. The resultant solid was removed by filtration, washed with benzene, and dried in a vacuum oven at 50°C to yield 16.2 g (35%) of the product as white granules, mp (ethanol) 172–173°C; IR (KBr): 2600 (P—OH), 2350 (P—H), 1740 (C=O), 1600 (C=C), and 1200 (P=O) cm^{-1}; ^{1}H-NMR (D_2O–NaOD): δ 1.08 (d, 3, J = 16 Hz, CH_3), 1.19 (CH_2O), 5.52 (s, 1, CH), 7.23–7.59 (m, 10, ArH), and 3.52 and 9.94 ppm (1:1 d, 1, J = 510 Hz, P—H).

Anal.—Calc. for $C_{19}H_{24}NO_4P$: C, 63.12; H, 6.69; N, 3.87. Found: C, 63.24; H, 6.72; N, 3.84.

DL-α-Benzhydrylamino-α-methyl-β-carboxyethanephosphinic Acid (VIII)—Ten grams of VII in 150 mL of 0.5 M NaOH was heated at 90°C for 4 h. The resultant solution was cooled and treated with concentrated HCl (pH 1). The precipitate thus formed was removed by filtration, washed with water until free of NaCl, and dried in a vacuum oven at 55°C to give 8.4 g (91% yield) of the product as a white powder, mp 190–191°C; IR (KBr): 2500–2700 (P—OH, C—OH), 2300 (P—H), 1700 (C=O), 1600 (C=C), and 1190 (P=O) cm^{-1}; ^{1}H-NMR (D_2O–NaOD): 1.14 (d, 3, J = 14 Hz, CH_3), 2.46 (d, 2, J = 10 Hz, CH_2), 5.56 (s, 1, CH), 7.25–7.63 (m, 10, ArH), and 3.59 and 10.01 ppm (1:1 d, 1, J = 510 Hz, P—H).

Anal.—Calc. for $C_{17}H_{20}NO_4P$: C, 61.26; H, 6.05; N, 4.20. Found: C, 61.17; H, 6.09; N, 4.20.

DL-α-Amino-α-methyl-β-carboxyethanephosphinic Acid (IX)—Using a modification of the method of Dingwall *et al.* (15), 2.6 g of VIII in 40 mL of 48% HBr was heated at 75°C for 4 h. The benzhydryl bromide was extracted with benzene, and the aqueous layer was treated with propylene oxide at pH 3–4. The resulting solution was concentrated under reduced pressure and the resulting solid was removed by filtration, washed with ethanol and ether, and dried in a vacuum oven at 55°C to yield 0.5 g (38%) of IX, mp 214–215°C; IR (KBr): 3240 (NH_3^+), 2700–2500 (P—OH, C—OH), 2380 (P—H), and 1685 (C=O) cm^{-1}; ^{1}H-NMR (D_2O): δ 1.47 (d, 3, J = 14 Hz, CH_3), 2.88, 2.76 (dd, 2, J = 9 Hz, CH_2), and 3.53 and 10.32 ppm (1:1 d, 1, J = 540 Hz, P—H).

Anal.—Calc for $C_4H_{10}NO_4P$: C, 28.93; H, 6.07; N, 8.43. Found: C, 28.85, H, 6.03, N, 8.34.

Biological Testing—*Animals*—For *in vitro* neurochemical studies, adult, male, albino rats[3] weighing 150–200 g were employed. *In vivo* testing for anticonvulsant activity and neurological toxicity of compounds was performed using mice[4].

Anticonvulsant Activity and Neurological Toxicity—Anticonvulsant activity of the compounds was evaluated against both maximal electroshock (MES) and pentylenetetrazol-induced seizures (scMet) by contractors of the Antiepileptic Drug Development Program administered by the National Institute for Neurological and Communicative Disorders and Stroke, Bethesda, Md, according to previously described procedures (16).

Neurochemical Assays—*Excitatory Amino Acid Uptake*—Crude synaptosomal fractions of rat cerebellum or corpus striatum were prepared as previously described (17) and resuspended in 0.32 M sucrose. Two hundred-microliter aliquots (100 μg of protein) of the suspension were added to borosilicate tubes containing 800 μL of Krebs HEPES buffer (pH 7.4) and 0.5 μM of D-[^{3}H]aspartate, L-[^{3}H]aspartate, or L-[^{3}H]glutamate with or without the test substance. Following a 3 min incubation at 30°C, the reaction was terminated by rapid filtration over glass fiber filters[5] maintained under reduced pressure. The filters were washed with 1 × 5 mL of ice-cold buffer, dried, and the radioactivity was determined by liquid scintillation counting. Parallel incubations were performed at 2°C to determine nonspecific uptake.

Receptor Binding Assays—Specific binding of excitatory amino acid analogues to brain membranes was performed, with minor modifications, according to previously published procedures. Briefly, brain membranes were prepared according to the method of Enna and Snyder (18) and stored frozen at −80°C until use. For assay, the membranes were thawed and washed four times by centrifugation, and the final pellet was resuspended in sufficient buffer to yield a protein concentration of 0.15–0.2 mg/mL. Specific binding of [^{3}H]kainic acid (2 nM) was assayed according to the procedure of London and Coyle (9). Specific binding of tritiated 2-amino-7-phosphonoheptanoic acid (50 nM) was assayed as described by Ferkany and Coyle (10). Specific binding of L-[^{3}H]glutamate (100 nM) was assayed by the method of Slevin *et al.* (11), with the exception that the assay was conducted in both Tris-citrate and Tris-HCl buffers (pH 7.1, 37°C, 0.05 M). In all instances, nonspecific binding was defined as that obtained by incubating the membranes in the presence of the indicated ligand and 10^{-3} M L-glutamate. The assays were terminated by centrifugation, and the pellets were rinsed rapidly and superficially with ice-cold buffer and solubilized[6]. Radioactivity was determined by liquid scintillation counting.

[^{3}H]Acetylcholine Release Evoked by *N*-Methyl-D-aspartate Receptor Stimulation—The release of [^{3}H]acetylcholine from the corpus striatum of the brain, evolved by exposure to excitatory amino acid receptor agonists, was measured as previously described (13). Striatal slices were exposed by [^{3}H]choline, which is selectively accumulated by cholinergic interneurons and synthesized into [^{3}H]acetylcholine. The slices were placed in chambers and superfused with Krebs medium, the superfused phase was collected, and the radioactivity released from the tissue into the superfused phase was measured by liquid scintillation counting. Exposure to agonists of *N*-methyl-D-aspartate receptors caused an increase in release while addition of magnesium or *N*-methyl-D-aspartate receptor antagonists, such as 2-amino-5-phosphonopentanoic acid or 2-amino-7-phosphonoheptanoic acid, inhibited release caused by agonists. Agonists or antagonists of other excitatory amino acid receptors (*e.g.*, quisqualate or kainate) have little or no effect in general (13).

The action of test substances in this paradigm were assessed by determining if (*a*) they evoked [^{3}H]acetylcholine release by themselves or (*b*) they inhibited the release of [^{3}H]acetylcholine evoked by *N*-methyl-DL-aspartate (50 μM).

Quantitation of Acetaminophen, Chlorpheniramine Maleate, Dextromethorphan Hydrobromide, and Phenylpropanolamine Hydrochloride in Combination Using High-Performance Liquid Chromatography

V. DAS GUPTA *x and ARUN R. HEBLE ‡

Received July 5, 1983, from the **Department of Pharmaceutics, University of Houston, Houston, TX 77030* and ‡*Ohm Laboratories, New Brunswick, NJ 08902.* Accepted for publication November 22, 1983.

Abstract □ A high-performance liquid chromatographic (HPLC) method has been developed for the quantitation of acetaminophen, chlorpheniramine maleate, dextromethorphan hydrobromide, and phenylpropanolamine hydrochloride in combination in pharmaceutical dosage forms using a single column and three different mobile phases. The method developed is sensitive for the content uniformity test for tablets. No preliminary extraction procedure is required for liquid preparation and a very simple extraction procedure is required for tablets. The method is accurate and precise with *RSD* (based on five injections) of 1.2, 2.4, 1.9, and 1.6% for acetaminophen, chlorpheniramine, dextromethorphan, and phenylpropanolamine, respectively.

Keyphrases □ Acetaminophen—HPLC, content uniformity □ Chlorpheniramine maleate—HPLC, content uniformity □ Dextromethorphan hydrobromide—HPLC, content uniformity □ Phenylpropanolamine hydrochloride—HPLC, content uniformity

One popular commercial product[1] contains an analgesic (acetaminophen), an antihistamine (chlorpheniramine maleate), an antitussive (dextromethorphan hydrobromide), and a decongestant (phenylpropanolamine hydrochloride). The product is extensively used for the relief of symptoms of coughs and colds. The dosage forms also contain excipients, some of which may interfere with the analysis of the active ingredients. The problem of analysis is further complicated by the presence of 325 mg of acetaminophen *versus* only 1 mg of chlorpheniramine maleate per tablet (or per 15 mL of the liquid). The quantities of dextromethorphan hydrobromide and phenylpropanolamine hydrochloride present are 10 and 12.5 mg per tablet (or 15 mL of the liquid), respectively. Acetaminophen has high absorbance in the useful UV range, but that of phenylpropanolamine hydrochloride is very poor. For example, at 256 nm (the wavelength of maximum absorption of phenylpropanolamine hydrochloride) a 1350-μg/mL aqueous solution of phenylpropanolamine hydrochloride has an absorption similar to a 20-μg/mL solution of acetaminophen. No single method is available to determine the active ingredients quantitatively in this combination.

High-performance liquid chromatographic (HPLC) methods for the quantitation of acetaminophen (1–4), chlorpheniramine maleate (5, 6), dextromethorphan hydrobromide (3, 7, 8), and phenylpropanolamine hydrochloride (6, 9–11) have been reported. None of the reported methods is applicable when ingredients are present in this combination.

This paper reports the quantitation of acetaminophen (I), chlorpheniramine maleate (II), dextromethorphan hydrobromide (III), and phenylpropanolamine hydrochloride (IV) in combination, using HPLC. The method requires three different mobile phases for complete analysis.

EXPERIMENTAL SECTION

Materials—All chemicals and reagents were USP, NF, or ACS quality and used without further purification. The sodium salt of 1-heptanesulfonic acid[2] was used as received.

A liquid chromatograph[3] attached to a multiple-wavelength detector[4] and a recorder[5] was used. The column[6] (30 cm × 4 mm i.d.) was purchased and

Table I—Chromatographic Conditions

Compound	Mobile Phase	Flow Rate, mL/min	Sensitivity	Wavelength, nm
Acetaminophen	1	1.5	0.04	256 (Fig. 1)
Phenylpropanolamine	2	2.5	0.02	256 (Fig. 1)
Chlorpheniramine and dextromethorphan	3	2.0	0.02	262 (Fig. 2)
Dextromethorphan[a]	4	2.0	0.02	279 (Fig. 3)
Chlorpheniramine and dextromethorphan[a]	4	2.3	0.02	262 (Fig. 4)

[a] It was necessary to develop another mobile phase due to interference from the excipients in liquid dosage form.

used as received. The four different mobile phases used were an aqueous buffer (pH ~ 7) containing 0.02 M ammonium acetate and 15% v/v of methanol (mobile phase 1); an aqueous buffer containing 0.02 M KH_2PO_4 with pH adjusted[7] to ~2.6 with an 85% aqueous solution of phosphoric acid (0.4 mL/L) (mobile phase 2); an aqueous buffer (pH ~ 3.3) containing 0.005 M sodium 1-heptanesulfonate, 1% v/v of glacial acetic acid, and 48% v/v of methanol (mobile phase 3); and an aqueous buffer (pH ~ 4.1) containing 1% v/v of ammonium formate buffer (3) and 40% v/v of methanol (mobile phase 4). The temperature was ambient and the chromatograph chart speed was 30.5 cm/h. Other chromatographic conditions are listed in Table I.

Preparation of Stock and Standard Solutions—The stock solution of acetaminophen (1.0 mg/mL) was prepared by dissolving 100 mg of acetaminophen in methanol to make 100 mL of the solution. A stock solution of chlorpheniramine maleate was prepared by dissolving 50 mg in water to make 100 mL. The standard solutions were prepared as follows: for acetaminophen, 2 mL of the stock solution was diluted to 100 mL with water; for phenylpropanolamine hydrochloride, 50 mg of the powder was dissolved in water to make 100 mL; for dextromethorphan hydrobromide, 40 mg of the powder was dissolved in water to make 200 mL; for a mixture of chlorpheniramine maleate and dextromethorphan hydrobromide, dextromethorphan hydrobromide powder (40 mg) was mixed with 8.0 mL of the stock solution of chlorpheniramine maleate and brought to 100 mL with water. Other solutions of different concentrations were prepared as needed.

Sample Preparation—*Commercial Liquid*—For the acetaminophen assay, a 2.3-mL quantity of the commercial liquid was diluted to 50 mL with water. A 2-mL quantity of this solution was mixed with 2 mL of methanol and diluted to 100 mL with water. For all others, 15 mL of the liquid was diluted to 25 mL with water. If dextromethorphan hydrobromide was to be assayed at 279 nm (Table I), then 7.5 mL of the liquid was diluted to 25 mL with water.

Tablets—Ten tablets were accurately weighed and ground to a fine powder. For the acetaminophen assay, enough powder to represent 50 mg of acetaminophen was mixed with ~40 mL of methanol. The mixture was stirred for 2–3 min, brought to volume (50 mL) with methanol, and filtered. The first 10 mL of the filtrate was rejected, and then a portion was collected and diluted (2 mL to 100 mL) with water. For all others, enough powder to represent two tablets was mixed with ~45 mL of water and stirred for 4–5 min. The mixture was brought to volume (50 mL) with water and filtered. The first 10 mL of the filtrate was rejected, and then a portion of the clear filtrate was collected for assay. If dextromethorphan was to be assayed at 279 nm, then powder representing one tablet was used. The rest of the procedure was as described.

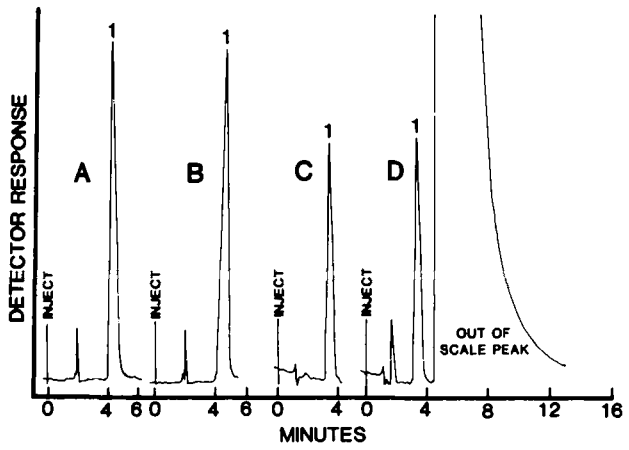

Figure 1—*Sample chromatograms. Key: (A) standard solution of acetaminophen (I); (B) tablet of I; (C) standard solution of phenylpropanolamine hydrochloride (IV); (D) tablet of IV. Peak 1 is the respective drug peak; the out of scale peak in chromatogram D is from acetaminophen.*

[7] Beckman Zeromatic SS-3 pH meter; Beckman Instruments, Fullerton, Calif.

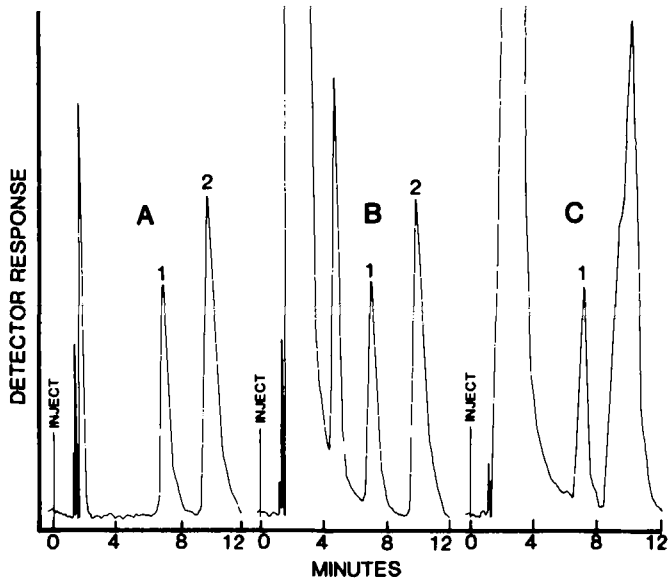

Figure 2—*Sample chromatograms from a standard solution (A), a tablet (B), and a liquid preparation (C) using mobile phase 3 at 262 nm. Key: (1) chlorpheniramine; (2) dextromethorphan. The out of scale peaks in chromatograms B and C are from acetaminophen. The other peak in chromatogram C is from the excipient and dextromethorphan (upper part).*

Content Uniformity of the Tablets (Except Acetaminophen)—A single tablet was ground to a fine powder, mixed with ~23 mL of water, and stirred for 4–5 min. The mixture was brought to volume (25.0 mL) with water and filtered. The first 7 mL of the filtrate was rejected, and then a portion of the clear filtrate was collected for assay. If dextromethorphan hydrobromide was to be assayed at 279 nm, the filtrate was diluted (1:1) with water. It was not considered necessary to determine the content uniformity of acetaminophen (325 mg/tablet) since it represented the bulk of the tablet.

Chromatographic Procedure—The assay sample (20.0 μL) was injected into the chromatograph under the described conditions. For comparison, an identical volume of the standard solution was injected after the assay sample eluted.

Since preliminary investigations indicated that peak heights were directly related to the concentrations (range tested ±50% of the standard solutions), the results were calculated by:

$$\frac{Ph_a}{Ph_s} \times 100 = \text{Percent of the label claim}$$

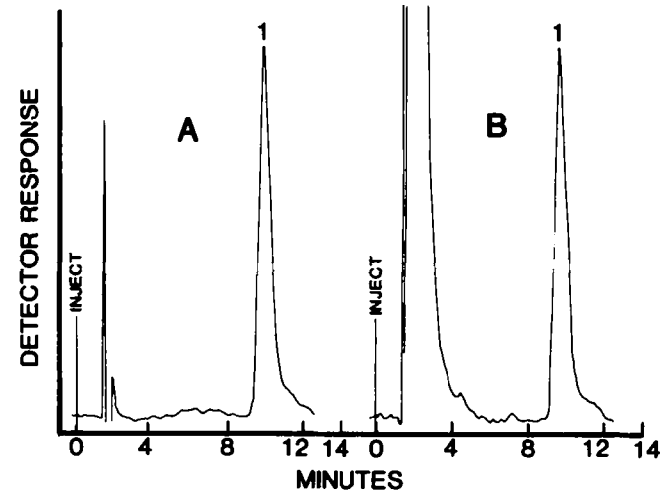

Figure 3—*Sample chromatograms from a standard solution and a liquid dosage form using mobile phase 4 at 279 nm. Key: (1) dextromethorphan. At this wavelength, the peak from chlorpheniramine was very small (peak before peak 1).*

[a] The label claim per tablet or per 15 mL of the liquid was: acetaminophen, 325 mg; chlorpheniramine maleate, 1 mg; dextromethorphan hydrobromide, 10 mg; phenylpropanolamine hydrochloride, 12.5 mg. [b] Ohm Laboratories; N. Brunswick, N.J. [c] Using mobile phase 3. In tablets of one manufacturer, the excipients interfered with dextromethorphan assay when mobile phase 4 was used. [d] Bristol-Myers; New York, N.Y. [e] Using mobile phase 4 at 262 nm. There was interference with dextromethorphan assay from the excipients when mobile phase 3 was used. [f] Using mobile phase 4 at 279 nm. [g] Contained the same active ingredients as stated under footnote *a* per 500 mg of powder plus 31.5 mg of corn starch and 120 mg of lactose. [h] Not determined.

where Ph_a is the peak height of the assay sample and Ph_s is that of the standard solution, which contained identical concentrations of drugs based on the label claim.

RESULTS AND DISCUSSION

Acetaminophen Assay—The results (Table II) indicate that the developed method can be adopted for the quantitation of acetaminophen in tablets and liquids without any interference from other active ingredients and excipients (Fig. 1A and B). This was expected since the bulk of the tablet was acetaminophen and the liquid contained 325 mg/15 mL. The peak heights were related to the concentrations (range tested, 0.2–0.6 μg) with an *RSD* of 1.2% based on five injections.

Phenylpropanolamine Hydrochloride (IV)—The results (Table II) indicate that the developed method can be used to quantify IV in tablets and liquids. It was tedious to separate phenylpropanolamine from other ingredients, especially from the out of scale peak (Fig. 1D) of acetaminophen. Many different mobile phases were tried, including an aqueous solution buffered with either 0.02 M ammonium acetate or 0.02 M KH_2PO_4, with the pH adjusted to ≥3.2 with acetic acid. In each case, I did not separate from IV, *i.e.*, acetaminophen started eluting before all of the phenylpropanolamine had eluted. It was necessary to decrease the retention time of IV and increase that of I. Initially, the mobile phases had methanol (≤15%) and the pH was >3. Subsequently, only water was used in the mobile phase (to increase the retention time of I), and the pH was adjusted to 2.6 (to decrease the retention time of IV) with phosphoric acid. This mobile phase (Table I), which gave excellent separation (Fig. 1C and D), could be used to analyze IV in tablets and liquids (Table II) and for content uniformity tests. The peak heights were related to the concentrations (range tested, 5–15 μg) with an *RSD* of 1.6% based on five injections.

Chlorpheniramine Maleate (II) and Dextromethorphen Hydrobromide (III)—The assay method can be adapted for the quantitation of chlorpheniramine and dextromethorphan (Table II) in tablets and liquids using mobile phase 3 or 4. Initially, mobile phase 3, similar to one reported in the literature (6), was developed. This mobile phase separated both chlorpheniramine (II) and dextromethorphan (III) from the other tablet ingredients (Fig. 2A and B). In the liquid dosage form, the excipients (probably a preservative not disclosed on the label) interfered (Fig. 2C) with the dextromethorphan assay peak. Therefore, it was necessary to develop another mobile phase for dextromethorphan in the liquid dosage form. Mobile phase 4, similar to that reported previously (3), was used (Fig. 3) to successfully quantify dextromethorphan in the liquid dosage form at 279 nm (wavelength of maximum absorption). By selecting this wavelength, it was possible to increase the sensitivity of the method twofold for the analysis of dextromethorphan. However, mobile phase 4 at 262 nm could also be used to analyze both chlorpheniramine and dextromethorphan (Fig. 4) in the liquid dosage and tablet forms from one manufacturer. In tablets from a different manufacturer, there was interference with the dextromethorphan peak from the excipients (probably the yellow color) not disclosed on the label (Fig. 4C) when mobile phase 4 was used. Although either mobile phase 3 or 4 could be used to analyze II and III for one manufacturer's tablets, only mobile phase 3 could be used to assay the same ingredients in the second manufacturer's tablets. In the liquid dosage form from the second manufacturer, only mobile phase 4 could be used to analyze II and III.

The peak heights were related to concentrations (range tested, 0.4–1.2 μg for II and 4–12 μg for III at 262 nm or 2–6 μg at 279 nm) and the *RSD* values, based on five injections, were 2.4 and 1.9% for II and III, respectively.

The developed method can be adapted for the quantitation of I–IV in pharmaceutical dosage forms using a single column and three different mobile phases. The method can also be used for the determination of the content uniformity of the tablets (Table II). This is important since the quantity of chlorpheniramine maleate was only 1 mg in a >500-mg tablet.

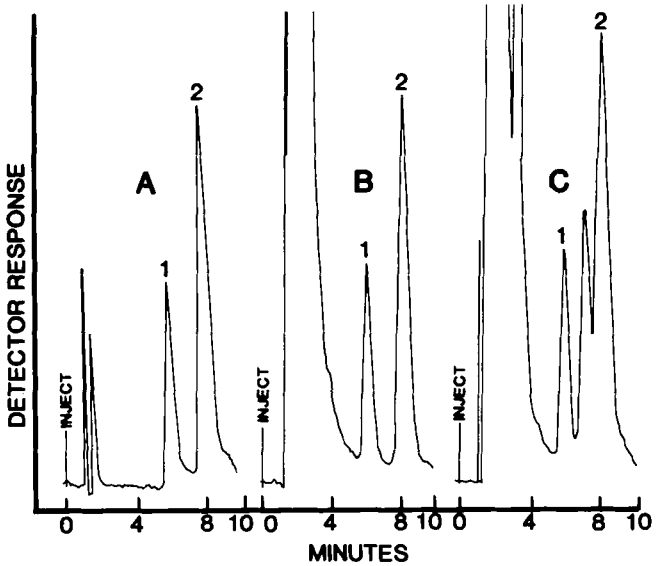

Figure 4—*Sample chromatograms from a standard solution, a liquid dosage form, and a tablet using mobile phase 4 at 262 nm. Key: (1) chlorpheniramine; (2) dextromethorphan. At this wavelength, chlorpheniramine could also be assayed. In chromatogram C, the excipients from the tablet interfered with the peak of dextromethorphan.*

Determination of Codeine in Human Plasma by Reverse-Phase High-Performance Liquid Chromatography

V. NITSCHE *x and H. MASCHER

Received January 1, 1983, from the *Pharmakologische Untersuchungsgesellschaft m.b.H., A-1171 Vienna, Austria.* Accepted for publication November 16, 1983. * Present address: Biokinet, A-1080 Vienna, Austria.

Abstract □ A high-performance liquid chromatographic (HPLC) method for the determination of codeine in human plasma is described. The specific, precise, and sensitive method can be used to determine plasma codeine levels after administration of therapeutic doses of codeine. After purification on a C_{18} extraction column, codeine in the form of hydrochloride is eluted. After addition of the internal standard, the codeine is separated on a reverse-phase C_{18} column using a slightly alkaline mobile phase and is then determined by UV detection. The analysis takes 3.5 min per run; the limit of detection is ~3 μg/L for a 50-μL loop and 800 μL of plasma. The absolute recovery is 98.4 ± 6.7% (n = 14) in the 10-300-μg/L range. Within the range, the calibration curve is linear.

Keyphrases □ Bioavailability—codeine, human plasma, HPLC □ Codeine—bioavailability, HPLC □ HPLC—bioavailability of codeine

Numerous methods for the detection of codeine are reported in the literature, including GC (1-5), GC-MS (6-9), TLC (10-12), RIA (3, 13-15), radioactive labeling (16, 17), and several high-performance liquid chromatographic (HPLC) methods. However, with one exception (18), these have not been used to detect codeine in plasma (19-21).

Some of the detection methods are not sufficiently sensitive or selective and others require sophisticated equipment (GC-MS) or specialized techniques (RIA). Our objective was to develop an HPLC method which is well suited for routine determination of codeine in plasma.

EXPERIMENTAL SECTION

Material and Methods—A liquid chromatograph[1] equipped with a UV detector[2] was used. The loop volume was 50 μL, but could be increased to 150 μL without affecting separation performance. Membrane filters[3] (pore size, 0.45 μm) and a 10-μL syringe[4] were also used.

Codeine hydrochloride[5] and diazepam[5] (internal standard) were used as supplied. Methanol[6] and ammonium carbonate[7] were AR grade. The C_{18} extraction columns[6] had a volume of 1 mL. Solutions of 0.1 M HCl, 1 M ammonium hydroxide, methanol-0.1 M ammonium hydroxide (20:80; mixture A), and methanol-0.1 M HCl (50:50; mixture B) were prepared. The internal standard solution was ~200 μg of diazepam/20 mL of methanol.

The buffer (pH 8.9) was made with 80.5 mL of 0.1 M borate solution (1.237 g of boric acid in 10 mL of 0.1 M NaOH) and 19.5 mL of 0.1 M HCl. Distilled water was used throughout.

The mobile phase was methanol-0.1 M ammonium carbonate (70:30). The mixture was used within 2-3 d, because tailing at the codeine peak was sometimes observed with older mixtures.

The chromatographic conditions included a 250 × 4-mm column[8], filled in-house[9] with Polygosil C 18, 7.5 μm; the flow rate was 2.0 mL/min; the column oven temperature was 45°C; the detector wavelength was 220 nm, 0.01 AUFS, time constant 1 min; the injection volume was 50-150 μL by loop; and the recorder advance was 10 mm/min.

Sample Preparation—Plasma (citrate anticoagulant) was filtered through a 0.45-μm membrane filter and 0.8 mL was mixed with 0.3 mL of buffer (pH 8.9). The mixture was quantitatively transferred into a C_{18} extraction column[6] and centrifuged at 500×g for 1-2 min; the plasma passed completely through the tube. To eliminate interfering substances, the extraction column was washed with 1 mL of 0.1 M HCl, 1 mL of mixture A, and 0.3 mL of 0.1 M HCl (each wash was followed by a 1-min centrifugation at 500×g). The eluates were discarded. Codeine was then eluted with 300 μL of mixture B. With commonly used centrifuges, 10-40 extraction columns can be eluted at the same time, which shortens the analysis time. The ammonium hydroxide solution (~30 μL, pH >8) and 5 μL of the internal standard solution were added to the eluate. After thorough mixing, the loop was rinsed and filled with ~100 μL (~180 μL if a 150-μL loop was used) of this solution.

Standard Preparation—Samples (2, 8, 20 and 40 μL) of a solution containing 4 ng of codeine base/μL (weighed as codeine hydrochloride, dissolved in water and diluted accordingly) were added to 0.8-mL plasma blanks. The remainder of the procedure is as described in *Sample Preparation*.

The quotients of the peak areas (codeine-internal standard) of the samples were compared with a calibration curve.

Bioavailability Study—In a randomized crossover study, bioavailability was determined with six healthy male volunteers (mean age, 46.8 ± 15.2; mean weight, 74.1 ± 9.7 kg; and mean height 178.3 ± 6.25 cm). The subjects underwent medical examinations and laboratory tests which showed them to be in good health. All subjects had been informed of the investigation procedures and had expressed their agreement in writing.

The subjects received two different oral codeine-doxycycline preparations on different days. The test preparations were 100 mg of doxycycline with 30 mg of codeine base as the phosphate in diffusion pellets (preparation 1)[10] and 100 mg of doxycycline with 30 mg of codeine base as resinate (preparation 2)[11]; both were sustained-release preparations. The dose was two capsules per

Determination of Codeine in Human Plasma by Reverse-Phase High-Performance Liquid Chromatography

V. NITSCHE *x and H. MASCHER

Received January 1, 1983, from the *Pharmakologische Untersuchungsgesellschaft m.b.H., A-1171 Vienna, Austria.* Accepted for publication November 16, 1983. * Present address: Biokinet, A-1080 Vienna, Austria.

Abstract □ A high-performance liquid chromatographic (HPLC) method for the determination of codeine in human plasma is described. The specific, precise, and sensitive method can be used to determine plasma codeine levels after administration of therapeutic doses of codeine. After purification on a C_{18} extraction column, codeine in the form of hydrochloride is eluted. After addition of the internal standard, the codeine is separated on a reverse-phase C_{18} column using a slightly alkaline mobile phase and is then determined by UV detection. The analysis takes 3.5 min per run; the limit of detection is ~3 μg/L for a 50-μL loop and 800 μL of plasma. The absolute recovery is 98.4 ± 6.7% (n = 14) in the 10-300-μg/L range. Within the range, the calibration curve is linear.

Keyphrases □ Bioavailability—codeine, human plasma, HPLC □ Codeine—bioavailability, HPLC □ HPLC—bioavailability of codeine

Numerous methods for the detection of codeine are reported in the literature, including GC (1-5), GC-MS (6-9), TLC (10-12), RIA (3, 13-15), radioactive labeling (16, 17), and several high-performance liquid chromatographic (HPLC) methods. However, with one exception (18), these have not been used to detect codeine in plasma (19-21).

Some of the detection methods are not sufficiently sensitive or selective and others require sophisticated equipment (GC-MS) or specialized techniques (RIA). Our objective was to develop an HPLC method which is well suited for routine determination of codeine in plasma.

EXPERIMENTAL SECTION

Material and Methods—A liquid chromatograph[1] equipped with a UV detector[2] was used. The loop volume was 50 μL, but could be increased to 150 μL without affecting separation performance. Membrane filters[3] (pore size, 0.45 μm) and a 10-μL syringe[4] were also used.

Codeine hydrochloride[5] and diazepam[5] (internal standard) were used as supplied. Methanol[6] and ammonium carbonate[7] were AR grade. The C_{18} extraction columns[6] had a volume of 1 mL. Solutions of 0.1 M HCl, 1 M ammonium hydroxide, methanol-0.1 M ammonium hydroxide (20:80; mixture A), and methanol-0.1 M HCl (50:50; mixture B) were prepared. The internal standard solution was ~200 μg of diazepam/20 mL of methanol.

The buffer (pH 8.9) was made with 80.5 mL of 0.1 M borate solution (1.237 g of boric acid in 10 mL of 0.1 M NaOH) and 19.5 mL of 0.1 M HCl. Distilled water was used throughout.

The mobile phase was methanol-0.1 M ammonium carbonate (70:30). The mixture was used within 2-3 d, because tailing at the codeine peak was sometimes observed with older mixtures.

The chromatographic conditions included a 250 × 4-mm column[8], filled in-house[9] with Polygosil C 18, 7.5 μm; the flow rate was 2.0 mL/min; the column oven temperature was 45°C; the detector wavelength was 220 nm, 0.01 AUFS, time constant 1 min; the injection volume was 50-150 μL by loop; and the recorder advance was 10 mm/min.

Sample Preparation—Plasma (citrate anticoagulant) was filtered through a 0.45-μm membrane filter and 0.8 mL was mixed with 0.3 mL of buffer (pH 8.9). The mixture was quantitatively transferred into a C_{18} extraction column[6] and centrifuged at 500×g for 1-2 min; the plasma passed completely through the tube. To eliminate interfering substances, the extraction column was washed with 1 mL of 0.1 M HCl, 1 mL of mixture A, and 0.3 mL of 0.1 M HCl (each wash was followed by a 1-min centrifugation at 500×g). The eluates were discarded. Codeine was then eluted with 300 μL of mixture B. With commonly used centrifuges, 10-40 extraction columns can be eluted at the same time, which shortens the analysis time. The ammonium hydroxide solution (~30 μL, pH >8) and 5 μL of the internal standard solution were added to the eluate. After thorough mixing, the loop was rinsed and filled with ~100 μL (~180 μL if a 150-μL loop was used) of this solution.

Standard Preparation—Samples (2, 8, 20 and 40 μL) of a solution containing 4 ng of codeine base/μL (weighed as codeine hydrochloride, dissolved in water and diluted accordingly) were added to 0.8-mL plasma blanks. The remainder of the procedure is as described in *Sample Preparation*.

The quotients of the peak areas (codeine-internal standard) of the samples were compared with a calibration curve.

Bioavailability Study—In a randomized crossover study, bioavailability was determined with six healthy male volunteers (mean age, 46.8 ± 15.2; mean weight, 74.1 ± 9.7 kg; and mean height 178.3 ± 6.25 cm). The subjects underwent medical examinations and laboratory tests which showed them to be in good health. Table I—Reproducibility of Codeine Determination in Blank Plasma Spiked with Codeine

Codeine Added, μg/L	Codeine Found, μg/L (mean ± *SD*)
303	304.8 ± 3.70[a]
152	147.3 ± 6.24[b]
19	16.9 ± 1.94[c]

[a] $n = 4$. [b] $n = 5$. [c] $n = 3$.

person (60 mg of codeine). A 1-week wash-out phase passed between the examination days. The subjects ingested the preparations with liquid in the morning after fasting overnight. Two hours after administration they had a light breakfast.

Blood samples were taken at 0, 1, 2, 3, 4, 5, 7, and 24 h after administration. The plasma obtained from the blood samples was frozen until assayed. The samples were analyzed by the method described above. A Student's *t* test for dependent samples was used to statistically compare the areas under the curves (AUC). Concentrations in the plasma after 24 h were usually at the limit of detection and could not be accurately determined; therefore, the values have not been included.

RESULTS

Recovery and Reproducibility—Codeine was added to the plasma and assayed according to specifications. The results were compared with those of codeine added to 300 μL of distilled water (plus internal standard and ammonium hydroxide) directly injected into the chromatograph. The recovery was 98.4 ± 6.6% (mean value ± *SD*; $n = 16$) (Table I).

Extracts of samples from the bioavailability study were injected twice within 15 h. The *SD* was 0.3–5.9 with a *CV* of 0.6–10%. Repeated extraction and injection of several samples (20–155 μg/L of plasma) gave an *SD* of 0.14–11 with a *CV* of 0.8–12.9%.

We found a linear regression ($r = 0.9989$; $n = 14$; $k = 0.0038596$; $d = 0.01646$) of the calibration curve in the 10–300-μg/L range by adding codeine to blank plasma (Table I). The limit of detection with 0.8 mL of plasma and a 50-μL loop is 3 μg/L of plasma. If a 150-μL loop and greater volume of plasma are used, the limit of detection can be reduced to <1 μg/L of plasma. There are no interfering substances present in the chromatogram; the limit is due to UV absorption constraints.

Bioavailability Study—Representative chromatograms of plasma samples are shown in Fig. 1. The individual and mean (±*SD*) values obtained in the bioavailability study are given in Tables II and III and are graphically represented in Fig. 2. The AUC value, a measure of relative bioavailability, and the half-life calculated from each plasma level curve are shown in Table III.

DISCUSSION

The method outlined above offers advantages over GC, GC–MS, and TLC with regard to handling and analysis duration. Moreover, the rate of recovery is extremely high.

The only substantial obstacle encountered in the development of this assay

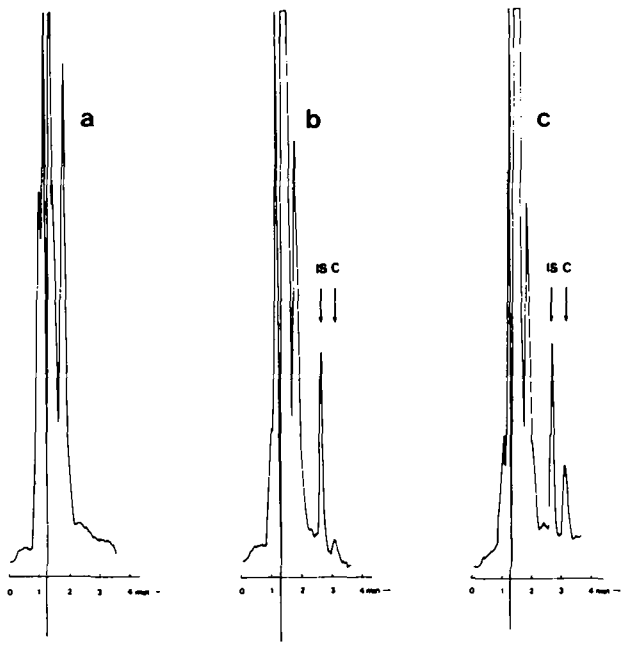

Figure 1—*Chromatograms of blank plasma (a), plasma with 13 μg/L of codeine (b), and plasma with 59 μg/L of codeine (c). Key: (IS) internal standard; (C) codeine.*

method was the multitude of endogenous substances detected in the codeine range at a wavelength of 220 nm. The problem was solved by selective prepurification of the plasma on a C_{18} extraction column[6]. Any neutral substances and acids that could interfere with the determination of codeine in the chromatogram with an alkaline mobile phase were retained by the extraction column or eluted during the washing; codeine was eluted quantitatively in the form of its salt. No interference was found with frequently coadministered drugs, such as benzodiazepines (*e.g.*, oxazepam, diazepam, flurazepam, and nitrazepam), doxycycline, bromhexine, amoxicillin, and ethambutol, using this procedure. The metabolites of codeine, its glucuronide, and some other narcotics do not interfere with codeine (retention times: codeine, 3.1 min; codeine glucuronide, 1.4 min; norcodeine, <1.6 min; morphine, 1.7 min; nalorphin, 1.3 min).

The results of bioavailability studies using this HPLC method agree with results obtained by other methods with similar dosages. After administration of 60 mg of codeine sulfate, a maximum level of 100–120 μg/L and an elimination half-life of 3.0–4.2 h (4) were obtained by GC. After administration of 65 mg of codeine phosphate, a maximum of 117 μg/L and an elimination half-life of 3.60 ± 0.15 ($n = 6$) were found by RIA (12). With a 25-mg dose of labeled codeine phosphate, a maximum level of ~40 μg/L and elimination half-lives of 2.2 h (1.8–2.8; $n = 4$) for tablets and 4.2 h (3.2–5.2; $n = 4$) for slow-release capsules were obtained (14). TLC indicates a maximum level of 90 μg/L after administration of 70 mg of codeine phosphate in the form

of a slow-release preparation, with a maximum level of ~95 μg/L and an elimination half-life of 2.2–3.9 h after administration of 35 mg of codeine phosphate in tablet form (9). This rapid HPLC method is, therefore, well suited for pharmacokinetic and clinical detection of codeine in plasma.

Influence of Lipid Composition and Ionic Strength on the Physical Stability of Liposomes

DAAN J. A. CROMMELIN

Received February 3, 1983, from the *Department of Pharmaceutics, Pharmaceutical Laboratory, University of Utrecht, 3511 GH Utrecht, The Netherlands.* Accepted for publication November 22, 1983.

Abstract □ The effect of including charge-inducing agents (stearylamine or phosphatidylserine) on the zeta potential of phosphatidylcholine-cholesterol-containing liposomes in aqueous media with varying ionic strength (sodium chloride) was investigated. In 150 mM ionic strength solutions, the experimentally obtained zeta potentials were in good agreement with predictions made with the Gouy-Chapman equation, after proper correction for bulk ionic interaction. However, at low ionic strength, substantial deviations occurred which were ascribed to incomplete dissociation of the phosphatidylserine molecules or protonation of the stearylamine molecules due to the large diffuse double layer (Debye length). Predictions were made on the physical stability of the liposomes based on the Derjaguin-Landau-Verwey-Overbeek (DLVO) theory and current knowledge of hydration effects on interparticle interaction. For negatively charged liposomes, both at low and high ionic strength, no increase in particle size was found after storage. For low ionic strength solutions, this agreed with the calculations; for the high ionic strength solutions, aggregate formation in a secondary minimum was expected. For positively charged liposomes, the physical stability predicted from theoretical considerations did not correlate with the experimentally observed stability.

Keyphrases □ Liposomes—phosphatidylcholine-cholesterol, ionic strength, lipid composition physical stability □ Stearylamine—liposomes with phosphatidylcholine and cholesterol, physical stability □ Phosphatidylserine—liposomes with phosphatidylcholine and cholesterol, physical stability

The surface potential is an important parameter influencing liposomal behavior. *In vivo*, the surface charge density has been found to influence the distribution of liposomes (1, 2) and *in vitro*, a high potential might contribute to their physical stability by reducing the rate of aggregation and fusion. Frøkjaer *et al.* (3) reported an increase in physical stability of liposomes (against aggregation or fusion) by decreasing the ionic strength and increasing the surface charge density of liposomes consisting of phosphatidylcholine (I) and phosphatidylserine (II). However, if there is no electrostatic repulsion between two liposomes this will not necessarily result in aggregate formation or fusion of the colliding particles, as many uncharged liposomes are fully stabilized by hydration energies (4, 5).

The influence of the surface charge density and ionic strength on the zeta potential of I and cholesterol-containing liposomes with stearylamine (III) or II was investigated by microelectrophoresis. The zeta potentials obtained experimentally were compared with surface potentials (Ψ_0) predicted by the Gouy-Chapman equation.

Using the Derjaguin-Landau-Verwey-Overbeek (DLVO) theory (6) and information on hydration energies between phospholipid vesicles (4, 5), calculations were made on the physical stability of the liposomes against aggregation or fusion. These predictions were verified by determining the actual size by dynamic light scattering. Because the surface potential cannot be measured by electrophoresis, the zeta potential, instead of Ψ_0, was used for the evaluation of the experimental results.

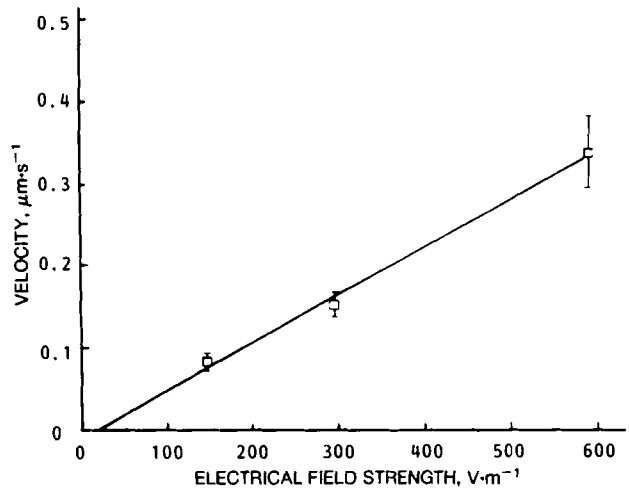

Figure 1—*Dependence of velocity on electrical field strength for liposomes composed of phosphatidylcholine-cholesterol-stearylamine (10:4:2); ionic strength, 2.3 mM. The line represents least-squares fit and the vertical bars are* SD.

EXPERIMENTAL SECTION

Positively and negatively charged multilamellar liposomes were prepared by the "film" method (7). Positive liposomes consisted of phosphatidylcholine (I)[1], cholesterol[2], and stearylamine (III)[3] in the molar ratio 10:4:1, 2, or 3, corresponding to maximum (positive) surface charge densities of 0.019, 0.037, or 0.054 C·m^{-2}, respectively. For negative liposomes, phosphatidylserine (II)[4] was used instead of III. With II, maximum (negative) charge densities of ~0.018, 0.034, or 0.047 C·m^{-2}, respectively, can be reached.

After film formation in pear-shaped flasks in a rotary evaporator at 40–45°C, the film was left under reduced pressure for ≥2 h in a desiccator. It was hydrated with NaCl solution (ionic strength, 2–150 mM). The water was

freshly distilled in glass, and nitrogen was passed through the solution for 10 min. The final phospholipid concentration was ~7.5 μmol/mL. Negative liposome dispersions contained 1 mM EDTA. The pH was adjusted to 5.9 ± 0.1 with dilute HCl or NaOH. After pH adjustment, the concentration of NaCl in the dispersion was determined conductometrically[5]. If necessary, corrections for EDTA were applied. After complete dispersion of the film by shaking and vortexing at 40-45°C, the liposomes were stored overnight at 4-6°C and extruded the next day through membrane filters[6] with 400-nm pores (8).

Mobilities of the liposomes were measured in a cylindrical-cell microelectrophoresis apparatus[7] at 25°C. Heat effects were minimized by using currents of <2 mA and short current passage times. The liposome dispersions were diluted with the hydration medium to avoid an overcrowded field of view. To minimize electrode polarization, successive measurements were made in both current directions. At least 20 particles were measured in each direction at the lower and upper stationary levels. Data obtained for both directions of liposome movement did not differ significantly (Student's t test; $p = 0.95$) and were averaged.

Mean diameters of the liposomes were measured with a dynamic light-scattering technique[8] 1 d after extrusion and after 7 and 14 d. A polydispersity index was also obtained[8]. This index ranges from 0 to 9; 0 refers to a monodispersed system, 9 to an extremely polydispersed system. A gold suspension approaching a normal size distribution with a mean diameter of ~50 nm and a CV of 15% has a polydispersity index of 3[9]. The dispersions were stored at

4-6°C, protected from light. Before measuring the mean diameter, the dispersions were equilibrated for at least 3 h at room temperature (20-25°C). Appropriate corrections were made for temperature-dependent parameters (*e.g.*, medium viscosity). Before taking the readings, the dispersions were diluted 10-100 times with solutions of the same ionic strength. For these dilute dispersions, the influence of the ionic strength on the particle size measurement is negligible (9).

The influence of dilution on the calculated diameters and polydispersity indices was investigated. In the concentration range covered by the dynamic light-scattering technique, the average size of primary or fused vesicles and the aggregate dimensions did not depend on the phospholipid concentration. The absorption (at 700 nm) per μmol/mL of phospholipid per cm path length was constant after dilution. These findings justify the conversion of the data obtained with the dilute dispersions to the original dispersions.

The purity of I and II was assessed as described by Frøkjaer *et al.* (3). Lysophosphatidylcholine and lysophosphatidylserine were separated from intact phospholipids by TLC [silica gel[10], chloroform-methanol-water (65:35:5)] visualized with iodine vapor. The spots were scraped off, and the compounds were extracted with methanol. The lysophosphatidylcholine and lysophosphatidylserine content was determined by phosphate analysis (10). Before the liposome preparation, <2 and 5% of these compounds were detectable in I- and II-containing vials, respectively. In a comparable system, Kitagawa *et al.* (11) found that the presence of these compounds in these concentrations had a negligible effect on particle size. One week after liposome preparation, no detectable lysophosphatidylcholine and lysophosphatidylserine increase was observed.

RESULTS AND DISCUSSION

A linear relationship between the velocity of liposomes and the electrical field strength is predicted by theory. In our experiment, results agreed with theory (Fig. 1). There was no difference between mobilities at the lower and the upper stationary levels for the same dispersion. All calculated zeta potentials were taken from upper stationary level data. The Helmholtz-Smoluchowski equation was used to calculate the zeta potential from mobility data. In cases of low ionic strength, particles with an estimated diameter >1 μm were selected for mobility measurements to avoid corrections for relaxation (12, 13).

Figure 2 is a plot of the zeta potential *versus* the surface charge density (σ). This parameter was calculated assuming a surface area of 0.70 nm^2 per I or II molecule. Values from 0.67 nm^2 (14) to 0.72 nm^2 (15, 16) were reported for I and 0.70 nm^2 for II (17, 18). The value used for the area covered by one cholesterol molecule was 0.28 nm^2 (7), and for one molecule of III the value used was 0.25 nm^2. For 1:1 bilayer combinations consisting of I and cholesterol, an area of 0.96 nm^2 was found for a unit consisting of one molecule of I and one molecule of cholesterol (5). This indicated that interactions between the different molecular species in the bilayer do not substantially influence the area covered by the individual molecules. The surface charge density could be calculated (19) from these data. It was assumed that the phospholipids and additives spread evenly and laterally over the bilayers (20). For I- and II-containing vesicles with relatively large radii of curvature (like those used in this study), the distribution over the two halves of the bilayer is expected to be fairly symmetrical (20, 21). At the experimental pH, both the deprotonation of II and the protonation of III were almost complete (22, 23). For negative liposomes, zeta potentials were obtained at two ionic strength levels as a function of II content. For an ionic strength of 152 mM, a nearly linear increase of the zeta potential with surface charge density was observed. For low ionic strength data (6.6 mM), this increase was less pronounced.

A comparison was made between the experimentally obtained zeta potentials and surface potentials calculated from the surface charge density. The effect of ionic strength on the zeta potential for the negative liposomes with an intermediate II content (charge density 0.034 $C \cdot m^{-2}$) is shown in Fig. 3. Line a represents the effect on the surface potential as predicted by the Gouy-Chapman equation for a single symmetrical electrolyte (Eq. 1):

$$\sigma = (8 \cdot N \cdot \epsilon_r \cdot \epsilon_0 \cdot kT)^{1/2} \cdot C^{1/2} \cdot \sinh (0.5 \cdot e \cdot \Psi_0/kT) \quad \text{(Eq. 1)}$$

Line b gives the surface potential calculated (with Eq. 1) after correction of the surface-charge density for the sodium ion interaction with II (Eq. 2). This interaction reduces the effective surface charge density (24):

$$\sigma_{corr} = \frac{\sigma}{1 + K \cdot C \cdot \exp\left(\frac{-e \cdot \Psi_0}{kT}\right)} \quad \text{(Eq. 2)}$$

where σ_{corr} and σ are the corrected and uncorrected surface charge density ($C \cdot m^{-2}$), respectively; e is the charge of a proton (C); k is the Boltzmann constant ($J \cdot K^{-1}$); T is absolute temperature (K); K is the intrinsic binding constant (m^3/mol); C is the concentration (mol/m^3); N is Avogadro constant (mol^{-1}); ϵ_0 is the permittivity ($C \cdot V^{-1} \cdot m^{-1}$); and ϵ_r is the relative permittivity (no units).

A value of 0.8×10^{-3} $m^3 \cdot mol^{-1}$ was used (25) for the instrinsic binding constant of the sodium ion to II, and the value for the relative permittivity of water was 78.3 (26). The zeta potential data comply reasonably well with the corrected surface potentials for the dispersions in 61 and 152 mM NaCl. In principle, the surface potential always has to exceed the zeta potential as the hydrodynamic plane of shear does not coincide with the surface, but is positioned at a finite distance from it (27). For the lower NaCl concentrations, the deviation between experimental and theoretical data increased. The influence of the divalence of the $EDTA^{2-}$ ion was neglected in the calculations, as the inclusion of a divalent ion complicated them considerably. This approach was justified because it was found experimentally that for the negative liposomes, under conditions where the influence of the $EDTA^{2-}$ ion is expected to be most pronounced (low II content, low ionic strength), the presence of $EDTA^{2-}$ ion in the aqueous medium did not change the zeta potential significantly [Student's t test, $p = 0.95$]: with EDTA, 58 mV (SD 8 mV, $n = 42$), without EDTA, 55 mV (SD 7.5 mV, $n = 35$).

The correction proposed by Nir and Bentz (24) takes into account interactions of the bilayer II molecules with cations from the bulk. The large deviation from the theoretical predictions at low ionic strength might be caused by a limitation in the ionization of II. In a solution of NaCl with an ionic strength of 5 mM, the Debye length ($1/\kappa$) is 4.4 nm and exceeds the distance between the molecules (2-3 nm, assuming the II molecules to be spread evenly over the bilayer). Therefore, mutual interference cannot be excluded. For a solution of 150 mM ionic strength, the Debye length is only 0.8 nm and no interaction is expected. Hauser *et al.* (20) suggested an analogous mechanism for the incomplete ionization of fatty acids clustering in bilayers.

[h] Polydispersity index 2-3 for all negative liposomes.

The results obtained with positive liposomes at two ionic strength levels are plotted in Fig. 4. For the 150 mM ionic strength series, the zeta potential increase leveled off at charge densities >0.037 $C \cdot m^{-2}$. Little increase of the potential with the surface charge density was found for solutions of 2.3 mM ionic strength.

Table I gives the zeta potentials of the positive liposomes with an intermediate III content over an ionic strength range from 2.3 to 150 mM. The experimental results were compared with the calculated surface potentials (Gouy-Chapman equation) listed in the last column. Here, as with the negative liposomes, for the high ionic strength dispersions a good agreement with theory was found; for low ionic strength, the experimental values for the zeta potentials were too low.

The proposed explanation for the deviation of the experimental zeta potentials from theory implies that changing the outer aqueous medium of the liposome dispersions from low to high ionic strength and *vice versa*, has in principle a reversible impact on the zeta potential. The effect of changes in the ionic strength in the aqueous phase outside the bilayer on the zeta potential was investigated. The positive and negative liposomes with intermediate III and II content, respectively, prepared under low ionic strength conditions, were mixed with at least 100-fold excess of an NaCl solution of high ionic strength (150 mM). After 2 h of equilibration, the mobilities were determined. For the positive liposomes, the reverse was done: dispersions in the high ionic strength medium were diluted with the low ionic strength solution. The results are listed in Table II. Changing the medium resulted in zeta potentials comparable with those existing after preparation of the liposomes at that particular ionic strength. This is an indication that preparing these types of liposomes at low or high ionic strength does not result in structures that differ irreversibly from each other.

The physical stability, on storage at 4°C, was investigated for various types of positively and negatively charged liposomes. Results of particle size measurements 1 d and 7 d after extrusion through 400-nm membrane filters are shown in Table III. Deviations of the reported particle diameter from the pore diameter (400 nm) were ascribed to differences in filtered liposome dispersion volumes. The initial filtrate generally contained smaller-sized liposomes. There was a distinct difference between the behavior of stable and unstable dispersions. For unstable dispersions, the mean particle diameter was at least double the diameter of the membrane pore with a polydispersity index >7 after 1

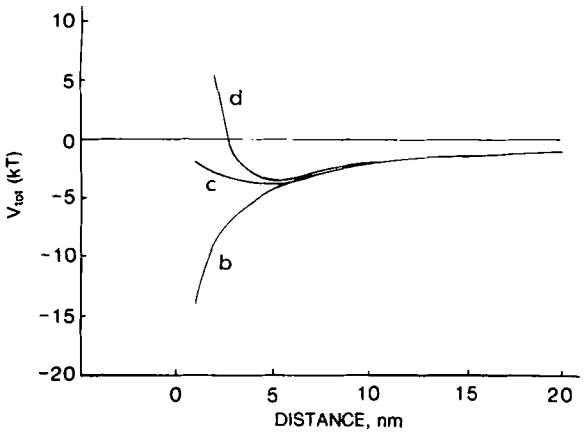

Figure 6—*Magnification of part of Fig. 5 to show occurrence of secondary minima.*

week. Stable dispersions had diameters <400 nm and polydispersity indices of 2–3 both at the day of extrusion and after 1 week. In all cases, changes in particle size occurred independently of phospholipid concentration within the first week of storage. No difference was found in particle diameters of the negative liposomes measured after 7 or 14 d of storage. This was also true for the two stable positive liposome dispersions.

Frøkjaer *et al.* (3) found, for I- and II-containing liposomes, an enhanced stability with decreasing ionic strength and increasing II content. Under the experimental conditions in this study, negative liposomes were stable independent of ionic strength and surface charge density. Positive liposomes had no correlation between the zeta potential and particle size stability; those with low surface charge density were stable at an ionic strength of 2.3 mM. Liposomes with high surface charge density, on the other hand, were stable at an ionic strength of 150 mM. A high positive zeta potential (61 or 57 mV), as was observed with the low ionic strength medium, did not therefore, guarantee a stable dispersion. Whether particle size growth was caused by aggregation or fusion of the particles was not studied.

We investigated whether the experimental results could be predicted by the existing theories on the physical stability of liposome dispersions. The interaction energy between two approaching liposomes was calculated according to the DLVO theory (6) using $V_{tot} = V_{att} + V^{el}_{rep}$, or:

$$V_{tot} = -\frac{aA}{12H} + 2\epsilon_r\epsilon_0\Psi_0^2 a \cdot \ln(1 + e^{-\kappa H}) \qquad \text{(Eq. 3)}$$

where V_{tot}, V^{el}_{rep}, and V_{att} are the total, electrostatic repulsive, and attractive energies, respectively; a is the radius of the liposome; H is the distance between the bilayer surfaces; and A is the effective Hamaker constant. In Eq. 3, V_{att} is calculated with a simplified equation for solid spheres and $H \ll a$. Results obtained with the complete equation for spherical shells, as given by Nir and Bentz (24), differed <5% for $H \leq 20$ nm.

The results suggest that, for low ionic strength (3 mM) dispersions with a zeta potential of >30 mV, a V_{tot} of at least 100 kT can be reached (Fig. 5). This implies that the rate of aggregation of these charged primary particles (compared with uncharged particles) is reduced by at least a factor of 10^9, and that dimer formation is limited to <10% of the primary particles over 2 weeks (6). Therefore, at low ionic strength the dispersions used should be stable (Figs. 2 and 4). Aggregation in the primary or secondary minimum was unlikely as the electrostatic repulsion exceeded the van der Waals attraction. These calculations are estimates because the effective Hamaker constants for the I, cholesterol, and II or III systems are not known precisely. Rand (5) reported a value of 9×10^{-21} J for pure I and 1.2×10^{-21} J for I-cholesterol (1:1) bilayers. We chose 5×10^{-21} J for our calculations. For low ionic strengths, all dispersions were predicted to be stable. However, for the positive liposomes, aggregation or fusion occurred with two of three dispersions.

For the 150 mM ionic strength dispersions, V^{el}_{rep} was not dominant. Secondary minima could be observed by using realistic Ψ_0 values (Fig. 6). The secondary minima are not affected by repulsive hydration energy, as the influence of this energy decreases steeply with increasing interparticle distance and can virtually be neglected for interparticle distances >2.5 nm (5). As far as electrical repulsion is concerned, the dispersions with low III and intermediate II content should behave similarly under 150 mM ionic strength conditions as they have similar zeta potentials (−17 and −20 mV, respectively). Experimentally, the negative liposomes were stable, and the positive liposomes were unstable. Apparently factors other than the electrical repulsion (*e.g.*, V_{att}) control stability. As stated above, the secondary minima shown in Fig. 6 are not affected by the hydration forces. In the case of negatively charged liposomes containing 100% II, aggregation in the secondary minimum is assumed to be a reversible process in the presence of sodium ions (28). In these dispersions, both aggregate formation and dissociation occur. In the dispersions under investigation, an analogous situation is likely. The mass average aggregate size at equilibrium was calculated for a −4-kT secondary minimum for negative liposomes of the compositions used in this study. Diameters of 200 and 400 nm were taken with phospholipid concentrations between 7.5×10^{-3} M (the concentration of the dispersions on storage) and 7.5×10^{-5} M (the minimum concentration used in dynamic light-scattering studies). The equations and boundary conditions for these calculations have been described by Bentz and Nir (28). Under the chosen conditions substantial aggregate formation was predicted, depending on the phospholipid concentration. This could not be confirmed experimentally, as no concentration-dependent mean diameter or polydispersity was observed in this study.

The negatively charged liposome dispersion (predicted to aggregate in the secondary minimum) was stable. If the physical model that was used to predict the stability is correct, the experimental results indicate that V_{att} is overrated for the negatively charged liposomes. This might be ascribed to an overestimation of the value for the Hamaker constant.

It is remarkable that two positively charged liposome dispersions (zeta potentials of 34 and 39 mV) that are both predicted to form aggregates in the secondary minimum (Table III) behave differently. The first one forms aggregates; the second is stable for at least 2 weeks.

CONCLUSIONS

Increasing the charge density from ~0.018 to 0.050 C·m^{-2} resulted in considerably larger zeta potentials for the dispersions with an ionic strength of 150 mM. Almost no increase was found at an ionic strength of ~5 mM. The zeta potentials were larger at low ionic strength, but not as large as predicted by the (corrected) Gouy-Chapman equation. Based on these data for low ionic strength, high electrostatic repulsive energies, and thus stable dispersions, were expected. However, two of the positive liposome dispersions were not stable. Apparently, in these systems particles can form aggregates because of a mechanism interfering with the "classical" DLVO theory (with consideration given to repulsive hydration forces).

On the other hand, for high ionic strength dispersions, DLVO calculations predicted an irreversible aggregation in a primary minimum or a reversible aggregation in the secondary minimum. However, no aggregation at all (negative liposomes and one positive liposome dispersion) or irreversible aggregation was found. This unexpected stability against aggregation in the primary minimum can be ascribed to the hydration forces. However, hydration forces do not extend far enough from the surface of the bilayer to affect the reversible aggregation in the secondary minimum.

Hydrolysis of Some Poly(*ortho*-ester)s in Homogeneous Solutions

TUE HUU NGUYEN *, CHUNG SHIH[§], KENNETH J. HIMMELSTEIN *[§‡x], and TAKERU HIGUCHI *[§]

Received November 14, 1983, from the **Departments of Pharmaceutical Chemistry and* [‡]*Chemical and Petroleum Engineering, The University of Kansas, Lawrence, KS 66045* and [§]*INTER$_x$ Research Corp., Merck Sharp & Dohme Research Laboratories, Lawrence, KS 66044.* Accepted for publication January 13, 1984.

Abstract □ The hydrolysis of poly(*ortho*-ester)s and a monomeric model compound, 3,9-dibenzyloxy-3,9-diethyl-2,4,8,10-tetraoxaspiro[5,5]undecane, was carried out in dioxane-d_8–dioxane and followed by ^{1}H-NMR and HPLC, respectively. Experimental results suggested that the polymer degradation proceeds to a large extent *via* random scission. The hydrolysis was catalyzed by the acid; the catalytic rate constant increased predictably with decreasing aqueous pK_a of the acid. The reaction is first order with respect to the catalyst concentration and the number of *ortho*-ester linkages present, and it is independent of water in the concentration range studied. Strain at the *ortho*-ester bond may be a factor influencing the hydrolysis rate.

Keyphrases □ Hydrolysis—poly(*ortho*-ester)s, homogeneous solutions □ Polymers—hydrolysis of poly(*ortho*-ester)s, homogeneous solutions □ Degradation—polymers, hydrolysis of poly(*ortho*-ester)s, homogeneous solutions □ Poly(*ortho*-ester)s—hydrolysis, homogeneous solutions

Poly(*ortho*-ester)s are a novel class of polymers with potential utility in drug delivery systems. Their use as an erodible matrix for the delivery of a steroid has been demonstrated by Heller *et al.* (1). In these systems, water-soluble salts were incorporated into the polymer, and the release mechanism appeared to be similar in part to that described by Fedors (2). Osmotic imbibition of water induced the swelling of the matrix, which subsequently burst and released the drug.

Poly(*ortho*-ester)s, as with most *ortho*-esters, undergo acid-catalyzed hydrolysis quite readily and are relatively unreactive in neutral or basic media (3, 4). Thus, when exposed to an aqueous environment, the erosion of the polymeric matrix may be induced by the presence of an acidic catalyst. The acid may be external or may be generated *in situ* by an acid-producing agent such as acid anhydride incorporated in the device. Since acid anhydrides are neutral, and therefore noncatalytic, they add to the stability of the device during storage.

Following this rationale Shih *et al.* (5) have demonstrated the use of poly(*ortho*-ester)s delivery systems, achieving zero-order release of timolol maleate. The release rate was effectively controlled by the amount of acid anhydride incorporated into the device and the aqueous pK_a of the corresponding acid. It was proposed that the mechanism of drug release from such a system results from the contribution of several processes, namely, the permeation of water into the polymer matrix, the hydrolysis of the acid anhydride to the corresponding acid, the hydrolysis of the *ortho*-ester linkages, and the dissolution of the drug species into the medium (5).

The present studies were undertaken as part of an effort to understand the various physicochemical processes which govern the release of drugs from poly(*ortho*-ester)s delivery systems. In an attempt to separate the various contributing factors, we report the kinetics of the hydrolysis of poly(*ortho*-ester)s [poly(3,9-dialkyloxy-3,9-diethyl-2,4,8,10-

Abstract □ The hydrolysis of poly(*ortho*-ester)s and a monomeric model compound, 3,9-dibenzyloxy-3,9-diethyl-2,4,8,10-tetraoxaspiro[5,5]undecane, was carried out in dioxane-d_8–dioxane and followed by ^{1}H-NMR and HPLC, respectively. Experimental results suggested that the polymer degradation proceeds to a large extent *via* random scission. The hydrolysis was catalyzed by the acid; the catalytic rate constant increased predictably with decreasing aqueous pK_a of the acid. The reaction is first order with respect to the catalyst concentration and the number of *ortho*-ester linkages present, and it is independent of water in the concentration range studied. Strain at the *ortho*-ester bond may be a factor influencing the hydrolysis rate.

Keyphrases □ Hydrolysis—poly(*ortho*-ester)s, homogeneous solutions □ Polymers—hydrolysis of poly(*ortho*-ester)s, homogeneous solutions □ Degradation—polymers, hydrolysis of poly(*ortho*-ester)s, homogeneous solutions □ Poly(*ortho*-ester)s—hydrolysis, homogeneous solutions

Poly(*ortho*-ester)s are a novel class of polymers with potential utility in drug delivery systems. Their use as an erodible matrix for the delivery of a steroid has been demonstrated by Heller *et al.* (1). In these systems, water-soluble salts were incorporated into the polymer, and the release mechanism appeared to be similar in part to that described by Fedors (2). Osmotic imbibition of water induced the swelling of the matrix, which subsequently burst and released the drug.

Poly(*ortho*-ester)s, as with most *ortho*-esters, undergo acid-catalyzed hydrolysis quite readily and are relatively unreactive in neutral or basic media (3, 4). Thus, when exposed to an aqueous environment, the erosion of the polymeric matrix may be induced by the presence of an acidic catalyst. The acid may be external or may be generated *in situ* by an acid-producing agent such as acid anhydride incorporated in the device. Since acid anhydrides are neutral, and therefore noncatalytic, they add to the stability of the device during storage.

Following this rationale Shih *et al.* (5) have demonstrated the use of poly(*ortho*-ester)s delivery systems, achieving zero-order release of timolol maleate. The release rate was effectively controlled by the amount of acid anhydride incorporated into the device and the aqueous pK_a of the corresponding acid. It was proposed that the mechanism of drug release from such a system results from the contribution of several processes, namely, the permeation of water into the polymer matrix, the hydrolysis of the acid anhydride to the corresponding acid, the hydrolysis of the *ortho*-ester linkages, and the dissolution of the drug species into the medium (5).

The present studies were undertaken as part of an effort to understand the various physicochemical processes which govern the release of drugs from poly(*ortho*-ester)s delivery systems. In an attempt to separate the various contributing factors, we report the kinetics of the hydrolysis of poly(*ortho*-ester)s [poly(3,9-dialkyloxy-3,9-diethyl-2,4,8,10-

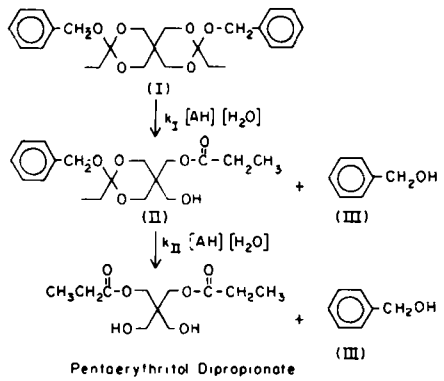

Scheme II—Acid-catalyzed hydrolysis of 3,9-dibenzyloxy-3,9-diethyl-2,4,8,10-tetraoxaspiro[5,5]undecane.

tetraoxaspiro[5,5]undecane)] and a monomeric model compound, 3,9-dibenzyloxy-3,9-diethyl-2,4,8,10-tetraoxaspiro[5,5]undecane (I) in homogeneous solutions. From this experiment, the intrinsic reactivity of the polymers may be independently obtained. The mode of depolymerization, the reaction rate constants, and the sensitivity of the reaction to the nature of the catalysts and to the concentration of water and acid were determined.

Several papers and reviews on *ortho*-ester chemistry have been published (3, 4, 6–11). The acid-catalyzed hydrolyses of *ortho*-esters is now thought to proceed *via* three steps. The first, and generally the rate-determining, step is the generation of a dialkoxycarbonium ion and an alcohol. The carbonium ion hydrates readily in the second step to form an unstable intermediate, the hydrogen *ortho*-ester, which breaks down to give an ester and an alcohol. For cyclic *ortho*-esters, the exocyclic alkoxy group is normally expelled in the first stage (11). Accordingly, the acid-catalyzed hydrolysis of I and poly(*ortho*-ester)s may be described as shown in Schemes I and II. The final products, alcohol and pentaerythritol dipropionate, were isolated and identified by HPLC comparison with authentic samples.

EXPERIMENTAL SECTION

Materials—Compound I and all polymers were used as provided[1]. Compound I was further purified by preparative TLC with precoated silica-gel glass plate[2]. The solvent system was 5% v/v ethyl acetate[3] in hexane[3]. The band at R_f 0.89 was located under short-wavelength UV light, removed from the plate, and extracted with methylene chloride[3]. The solvent was evaporated with a commercial evaporator[4], and the residual solvent was removed under reduced pressure at room temperature for 12 h. Water was distilled in an all-glass apparatus. Dioxane[3] was dried with lithium aluminum hydride[5] and distilled. Acetonitrile[3], HPLC grade, dioxane-d_8[6], trichloroacetic acid[6], dichloroacetic acid[6], monochloroacetic acid[6], formic acid[6], phthalic acid[6], and maleic acid[6] were used as received.

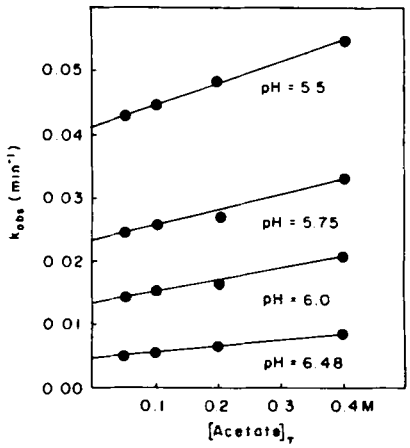

Figure 1—*Buffer-catalyzed hydrolysis of I in dioxane–water (50:50, v/v) at 25°C; μ = 0.5 M with KCl. Plot of the observed rate constant* versus *total buffer concentration.*

Methods—The hydrolysis of I was conducted both in 50% v/v buffered dioxane–water solutions and in pure dioxane. Samples of I were accurately weighed into 5-mL volumetric flasks and dissolved in 4 mL of dioxane. To start the experiment, measured amounts of water and acid stock solution in dioxane were transferred to the flask, and the volumes were brought to 5 mL with dioxane. The initial concentration of I was 0.01 M. In experiments in buffered solutions, 100 μL of a stock solution of I in dioxane was injected directly into 4 mL of buffered solution; the volume was then made up to 5 mL with the same solution resulting in an initial 0.02 M concentration of I. The flasks were stoppered and sealed[7] and then placed in a water bath. The reaction was monitored by following the disappearance of I and the appearance of benzyl alcohol (III) by HPLC. The mobile phase consisted of 20% v/v acetonitrile–water for III and 80% v/v acetonitrile–water for I. The flow rate was 2 mL/min, and the detector was set at 254 nm. The column employed was an ultrasphere-octadecysilane[8].

A series of four poly(*ortho*-ester)s, the structures of which are shown, was chosen for the study. Accurately weighed amounts of polymer were dissolved in dioxane-d_9. A total of 400 μL of the solution was transferred into ^{1}H-NMR sample tubes[9]. Immediately before the experiment, measured quantities of water and stock solution of acid in dioxane-d_8 were injected into the tube. The total volume was brought to 500 μL with dioxane-d_8 and mixed. The resulting concentration of polymer was 8% w/v. The sample tubes were then sealed and placed in a water bath at 37°C. Readings were performed periodically on a ^{1}H-NMR spectrometer[10].

For the condensation copolymer of 3,9-bis(ethylidene)-2,4,8,10-tetraoxaspiro[5,5]undecane (IV) and 1,4-benzenedimethanol (V), monitoring of the disappearance of the peaks at δ = 1.8 ppm corresponding to the α methylene group or the appearance of the methylene group α to the carbonyl carbon of the degraded product at δ = 2.3 ppm gives a direct account of the rate of bond

cleavage. Only the appearance of the quartet at δ = 2.3 ppm can be used in the cases of the condensation copolymers of IV and diols such as 1,4-*trans*-cyclohexanedimethanol (VI) and 1,6-hexanediol (VII) due to interference of other protons in the system.

RESULTS AND DISCUSSION

pH-Rate Profile—The hydrolysis of I was carried out in 50% v/v buffered dioxane-water solutions at 25°C. The use of mixed solvent rendered the interpretation of the pH determination[11] somewhat difficult. However, when the apparent pH in the 50% v/v dioxane-water solvent system was plotted against the pH of the aqueous buffered solutions, prepared similarly but without dioxane, a straight line was obtained with a zero-intercept and a slope of 1.05. This seems to suggest that the changes in the pH-meter readings were proportional to the changes in the hydronium ion activity in this system. The pH range studied was from 4 to 8. The buffer concentration was varied from 0.4 to 0.005 M, whereas the ionic strength was kept at 0.1 or 0.5 M with KCl. It was assumed that the salts employed were fully ionized. The loss of I was followed by HPLC and found to follow pseudo-first-order kinetics. The effect of acetate buffer concentration on the reaction rate is illustrated in Fig. 1. The observed rate constant seems to increase linearly with buffer concentration. The slope of the lines increases with decreasing pH, suggesting that the free acid is the catalytic species. However, a plot of the rate constants of the general acid-catalyzed reaction against the fraction of free acid (Fig. 2) did not yield a straight line as expected. A change in the activity coefficient of the free acid and the anion at high buffer concentrations may be a possible explanation. The pK_a of acetic acid under the reaction conditions was determined to be 6.22 by pH titration.

The rate constants extrapolated to zero buffer concentration were employed to construct the pH-rate profile. As evident from the linearity of the plot of

the logarithm of the pseudo-first-order rate constant extrapolated to zero buffer concentration *versus* pH with a slope of −1 (Fig. 3), hydronium ions appear to be the catalyst in this pH range. The reaction was also studied at pH 13. No noticeable degradation could be detected. The value for the specific acid-catalyzed reaction (k_{H^+}) was obtained from the intercept of the line with the ordinate. A k_{H^+} value of 1.03×10^4 min^{-1} M^{-1} at μ = 0.1 M was only slightly smaller than the k_{H^+} of 1.09×10^4 min^{-1} M^{-1} at μ = 0.5 M, suggesting that the effect of the salt was not significant.

Mode of Depolymerization—There are two types of linkages involved, the internal linkages and those at the end of the polymer chain. Differentiation of their reactivity directly from the polymer molecules is difficult. However, I has two *ortho*-ester linkages. When they are intact, the bonds are similar to the internal bonds. When one bond is broken, the remaining one resembles the one at the end of the chain. Thus, according to Scheme II, it is possible to determine the relative reactivity of those two types of bonds by comparing the rate of disappearance of I and the monoester (II), its partially degraded product.

The reaction was carried out in dioxane at 37°C. The concentrations of I and water were 0.01 and 2 M, respectively. The maleic acid concentration was varied from 2.5×10^{-4} to 5×10^{-3} M. The loss of I and the formation of III were followed by HPLC.

The differential equations defining the kinetic system are:

$$\frac{-d[I]}{dt} = k_I [I] \qquad \text{(Eq. 1)}$$

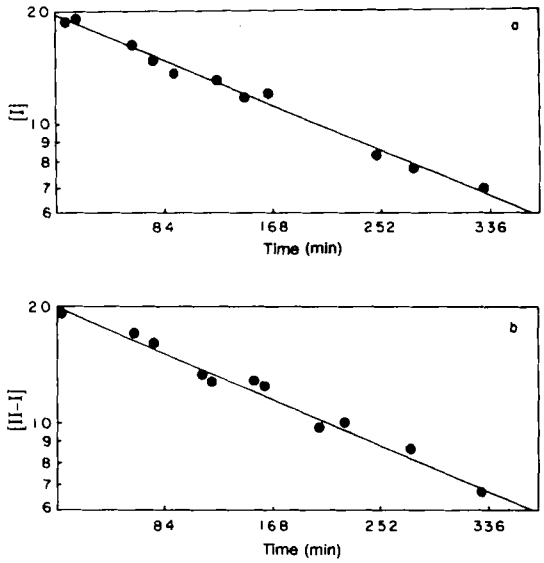

Figure 6—*Hydrolysis of the IV-V copolymer in dioxane-d_8 at 37°C; water, 2 M; trichloroacetic acid, 1.25 × 10⁻³ M. Plot of logarithm of peak integration* versus *time. [I], integration of NMR peaks during the reaction; [II], integration of peaks when the reaction is completed. Key: (a) disappearance of the α-methylene protons in the polymer; (b) appearance of methylene protons α to the carbonyl carbon in the degradation product.*

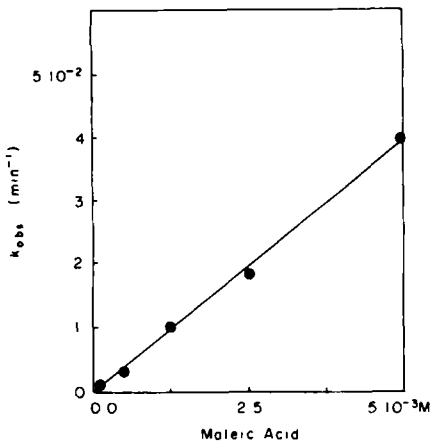

Figure 7—*Hydrolysis of I in dioxane at 37°C; water, 2 M. Plot of the observed rate constant* versus *maleic acid concentration.*

$$\frac{d[II]}{dt} = k_I [I] - k_{II} [II] \quad \text{(Eq. 2)}$$

$$\frac{d[III]}{dt} = k_I [I] + k_{II} [II] \quad \text{(Eq. 3)}$$

At $t = 0$, $[I] = [I]_0$, which is the initial concentration of I, and $[II] = [III] = 0$.

The estimation of k_I and k_{II}, the apparent pseudo-first-order rate constants for the two consecutive steps, respectively, was performed on a computer[12] by a nonlinear regression program based on a pattern-search algorithm. Typical experimental data and the fitted curves generated for the reaction from the kinetic model above are shown in Fig. 4.

The constants k_I and k_{II} obtained for various maleic acid concentrations are plotted in Fig. 5. The slope of the lines was taken to be the second-order rate constant for the reaction. The ratio k_{II}/k_I was ~1.55, suggesting that the bonds at the end of the chain are only slightly more reactive than the internal linkages.

In fig. 6, a semilogarithmic plot of the ^{1}H-NMR peak integration of the IV-V copolymer, as a function of time resulting from the hydrolysis in dioxane-d_8 at 37°C catalyzed by 2.55×10^{-3} M dichloroacetic acid, is shown. The water concentration was 2 M. The concentration of the IV-V copolymer was 8% w/v or ~0.23 M of the monomeric unit. Since each monomer has two *ortho*-ester linkages, the amount of water present was about five times that required for complete hydrolysis of the sample.

The pseudo-first-order rate constants for the disappearance of the methylene group and for the appearance of the methylene group α to the carbonyl carbon are 3.69×10^{-3} min^{-1} and 3.81×10^{-3} min^{-1}, respectively. This seems to validate the analytical procedure. The linear relationship suggests a random scission process in which the majority of the bonds are of equal accessibility

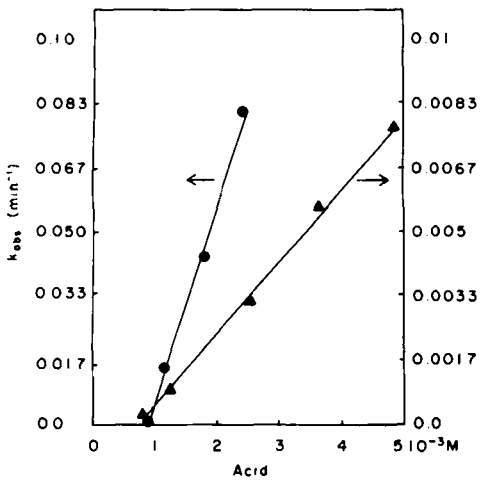

Figure 8—*Hydrolysis of the IV-V copolymer in dioxane-*d_8 *at 37°C; water, 2 M. Plot of the observed rate constant* versus *acid concentration. Key: (●) catalyzed by trichloroacetic acid; (▲) catalyzed by dichloroacetic acid.*

Maleic acid	1.83, 6.07	7.26	3.73
Phthalic acid	2.89, 5.51	0.47	

[a] The concentration of water was 2 M.

and the rate of scission is first order with respect to the number of *ortho*-ester linkages.

Effect of Acid Concentration and pK_a on the Hydrolysis of Poly(*ortho*-ester)s—The observed rate constant of the hydrolysis of I in dioxane at 37°C was plotted against the maleic acid concentration (Fig. 7). The reaction velocity of the IV-V copolymer in dioxane-d_8 at 37°C in the presence of different amounts of trichloroacetic acid and dichloroacetic acid is shown in Fig. 8. A linear relationship was apparent in all cases in the concentration range studied. The slope of the lines was taken as the second-order rate constant (k_2) of the reaction. The nonzero-intercept seen with the IV-V copolymer can be attributed to the presence of a small amount of alkaline impurities in the polymer.

The second-order rate constants for the hydrolytic reaction catalyzed by different acids are listed in Table I. A straight line can be drawn through the plot (Fig. 9) of log k_2 *versus* acid aqueous pK_a. A positive deviation was observed for the points corresponding to phthalic acid and maleic acid.

The unusually high acidity of the first dissociable proton of maleic acid (pK_{a_1}, 1.83), a diacid with its carboxylic groups in a *cis* position to each other, as compared with that of its *trans*-isomer, fumaric acid (pK_{a_1}, 3.03), was attributed to intramolecular hydrogen bonding which stabilizes the carboxylate monoanion. This interaction is further enhanced in an aprotic environment (12). Thus, it was not unexpected to see the deviation from a linear relationship found with the monoacid. A similar explanation should also hold true for phthalic acid, in which the second carboxyl group is in the *ortho*-position. The k_2 values for the hydrolysis of I are approximately twice that of the IV-V copolymer. The difference is probably due to the analytical methods employed. The degradation of I was monitored by following its disappearance by HPLC. Thus, the scission of one *ortho*-ester linkage results in the loss of one molecule of I. The NMR technique gives a true account of the rate of cleavage of the linkages. Statistically, it is expected that the rate constant of the disappearance of I should be approximately twice as fast as the rate of bond cleavage if the reactivity of the *ortho*-ester bond on the monomer and on the polymers is similar. This was further confirmed when

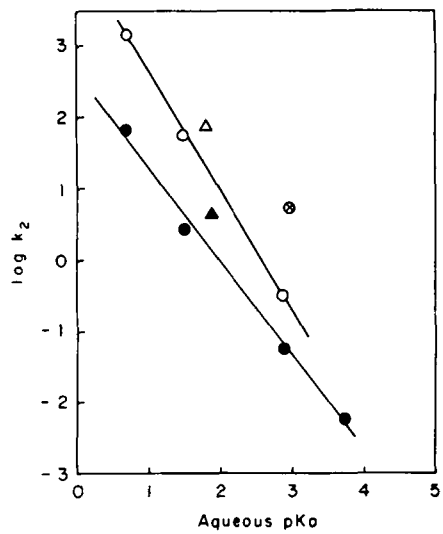

Figure 9—*Plot of the logarithm of the second-order rate constant* versus *aqueous* pK_a; *water, 2 M. Table III—Hydrolysis of Poly(*ortho*-ester)s in Dioxane-d_8 at 37°C Catalyzed by Dichloroacetic Acid

Polymer	k_2, $M^{-1} \cdot min^{-1}$
IV-VI copolymer	0.87
IV-VII copolymer	1.80
IV-V copolymer	1.96
IV-VIII copolymer	2.81

k_2 values for the hydrolysis of I in dioxane at 37°C in the presence of maleic acid and 2 M water obtained by ^{1}H-NMR were compared with those obtained under the same conditions by HPLC. The ratio of k_2 HPLC-k_2 ^{1}H-NMR was 2.15.

Effect of Water Concentration on the Hydrolysis of Poly(*ortho*-ester)s—A semilogarithmic plot of the degradation of the 8% w/v IV-V copolymer in dioxane-d_8 at 37°C catalyzed by 3.5×10^{-3} M dichloroacetic acid in the presence of 0.1 M water is presented in Fig. 10. As expected, the reaction proceeded until ~25% of the *ortho*-ester linkages were cleaved. The initial slope was employed a the pseudo-first-order rate constant for the reaction. The observed rate constants for the reaction at different water concentrations are listed in Table II, along with the estimated dielectric constant of the dioxane-water system. These are computed from the dielectric constant of water of 78.54 (13) and from the dielectric constant for dioxane of 2.209 (13), assuming that the contribution of each component to the dielectric constant of the system is proportional to its mole fraction. The observed rate constant increases only 1.5-fold for a 30-fold increase in water concentration. A similar observation can be made for the hydrolysis of I in dioxane at 37°C catalyzed by 2.5×10^{-3} M maleic acid. When the rate constants were plotted (Fig. 11) against the solvent dielectric constant, an apparent linear relationship with a nonzero-intercept was observed. Thus, the experimental results suggest that, over the range studied, the reaction proceeds independently of the amount of water present, and the increase in reaction velocity is due to the change in polarity of the reaction medium. This is reasonable since the rate-determining step of the reaction is the formation of the dialkoxy carbonium ion which is independent of the water concentration.

Effect of Polymer Structure on the Hydrolysis Rate—The second-order rate constants for the hydrolysis of four polymers in dioxane-d_8 at 37°C catalyzed by dichloroacetic acid are shown in Table III. The polymers and water concentrations were held constant at 8% w/v and 2 M, respectively. Bunton and DeWolfe (7) have shown that an increase in the basicity of the oxygen atom on the leaving alkoxy group or a stabilization of the forming carbonium ion will result in a more reactive *ortho*-ester. For the polymers under consideration, once the alkoxy groups are cleaved, the resulting carbonium ions are identical; thus, if the observations of Bunton and DeWolfe are applicable, the difference in their reactivity should originate from the difference in the basicity

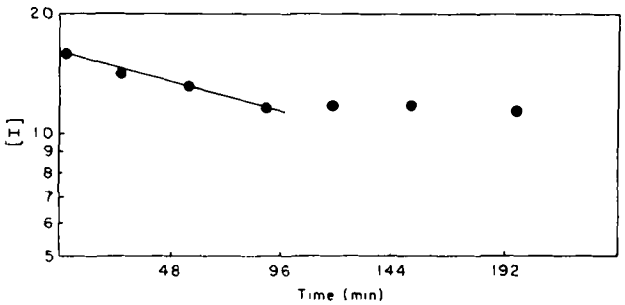

Figure 10—*Hydrolysis of the IV-V copolymer in dioxane-*d_8 *at 37°C; water, 0.1 M; polymer, 8.17% w/v; dichloroacetic acid, 3.5×10^{-3} M. [I], integration of NMR peaks during the reaction.*

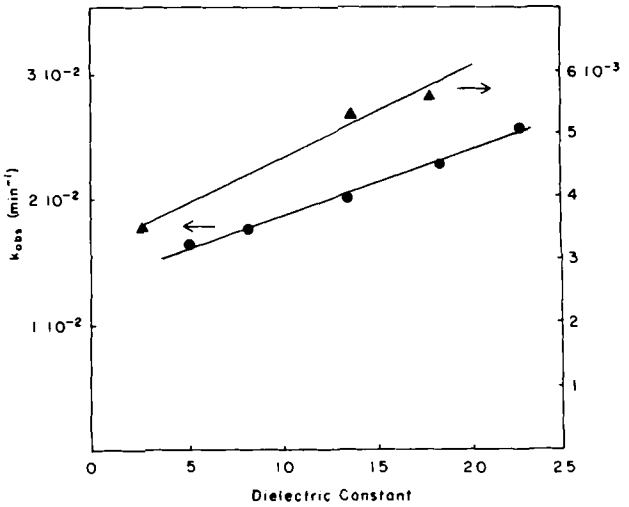

Figure 11—*Plot of the observed rate constant* versus *dielectric constant. Key (▲) hydrolysis of the IV-V copolymer in dioxane-*d_8 *catalyzed by 3.5×10^{-3} M dichloroacetic acid; (●) hydrolysis of I in dioxane at 37°C catalyzed by 2.5×10^{-3} M maleic acid.*

of the diol oxygen atoms. This would predict that IV-V and IV-ethylene glycol (VIII) copolymers are the most stable. The fact that the rank order of the second-order rate constant for the polymers studied cannot be rationalized in terms of the inductive effect of the diol alkyl chain on the basicity of the oxygen atoms at the reaction site implies that another driving force may be more influential. When the rate constants are compared with the molecular size of the diols, an apparent correlation is found. The smaller the diol molecule, the more reactive the polymer, suggesting that strain at the *ortho*-ester bond may be a factor determining the hydrolysis rate.

CONCLUSIONS

The hydrolysis of four poly(*ortho*-ester)s and a monomeric model compound in homogeneous solution was investigated. It appears that the reactivity of the *ortho*-ester linkage in the polymer chain is comparable to that of the linkage in the monomeric model compound. In 50% dioxane-water, the reaction is subject to both specific and general acid catalysis. In dioxane, the hydrolysis reaction is acid catalyzed and independent of the water concentration in the range studied. The rate equation for the hydrolysis of poly(*ortho*-ester)s in dioxane may be written as:

$$\frac{-d[n]}{dt} = k_2 [n] [AH] \qquad \text{(Eq. 4)}$$

where n is the concentration of *ortho*-ester linkage, AH is the concentration of the acid, and k_2 is the second-order rate constant of the reaction. The logarithm of the second-order rate constant is linearly related to the aqueous pK_a of the catalyst. The experimental results suggest that the bonds at the end of the polymer chain may be slightly more reactive than the internal linkages, but overall, the reaction proceeds to a large extent *via* random scission. Strain at the *ortho*-ester linkages may play a role in the determination of its reactivity.

Synthesis and *In Vitro* Antiviral Activity of 3′-*O*-Acyl Derivatives of 5′-Amino-5′-deoxythymidine: Potential Prodrugs for Topical Application

TAI-SHUN LIN

Received April 20, 1983, from the *Department of Pharmacology and Comprehensive Cancer Center, Yale University School of Medicine, New Haven, CT 06510.* Accepted for publication September 19, 1983.

Abstract □ A series of 3′-*O*-acyl derivatives of 5′-amino-5′-deoxythymidine (5′-NH_2-TdR) (IIIa–j) was synthesized by acylation of 5′-azido-5′-deoxythymidine (I). The resulting acetoxy azides were reduced by catalytic hydrogenation to give the corresponding amines. The antiviral activity against herpes simplex virus type 1 (HSV-1) *in vitro*, the aqueous solubilities, and the octanol–water partition coefficients of these compounds were determined. All these derivatives have shown potency against HSV-1 virus similar to the parent compound, except the aromatic and highly branched aliphatic esters, IIIi and IIIj, which are less active. Because of their markedly improved lipophilicity, these compounds are believed to penetrate the biological membranes more easily, and thus, would be more effective for the topical treatment of cutaneous herpes virus infections.

Keyphrases □ 3′-*O*-Acyl derivatives of 5′-amino-5′-deoxythymidine—synthesis, antiviral activity □ Prodrugs—potential, topical application. 3′-*O*-acyl derivatives of 5′-amino-5′-deoxythymidine

The 5′-amino analogue of thymidine (5′-NH_2-TdR) has demonstrated potent antiviral activity against herpes simplex virus type 1 (HSV-1) in the complete absence of toxicity to the uninfected host Vero cells in culture (1, 2). This compound was therapeutically effective in the topical therapy of herpetic keratouveitis in rabbits, and systemic administration into the neonatal mouse revealed no adverse effect *in vivo* or by the histopathological examination (3). Chen *et al.* (4) have recently found that 5-NH_2-TdR was a substrate for the HSV-1-encoded thymidine kinase but was not a substrate for the cellular thymidine kinase. The complete lack of toxicity of 5′-NH_2-TdR to the uninfected Vero cells is probably due to the lack of the herpes simplex virus-induced thymidine kinase which is required for activation (4, 5).

Recently, Baker *et al.* (6) have reported the synthesis of a series of 5′-*O*-acyl derivatives of 9-β-D-arabinofuranosyladenine (vidarabine, ara-A). These compounds were designed as prodrugs for vidarabine and have demonstrated better lipophilicity, and thus, the potential for improved membrane transport over vidarabine. Among these compounds, the 5′-*O*-valeryl derivative has shown a marked increase in both lipophilicity and antiviral activity compared with that of vidarabine.

Recently, Hettinger *et al.* (7) have reported that both 5-iodo-2′-deoxyuridine (idoxuridine, IUdR) and 5-iodo-3′,5′-di-*O*-acetyl-2′-deoxyuridine (Ac_2IDU), an *O*-acetyl derivative of IUdR, were effective against keratitis. However, Ac_2IDU was significantly more effective than the placebo 1 d sooner than was idoxuridine. The greater lipid solubility of the Ac_2IDU that resulted in greater epithelial penetration could account for this difference. Based on these findings, a series of 3′-*O*-acyl derivatives of 5′-NH_2-TdR has been synthesized. Preliminary studies indicated that all these compounds retain the same degree of antiviral activity in comparison with the parent compound, except the 3′-*O*-*tert*-butylacetyl and 3′-*O*-benzoyl esters, IIIi and IIIj, which were found to be less active. The lipophilicities of these derivatives increased

[a] Determined in 0.1 M phosphate buffer (pH 7.0). [b] At λ_{max} 265 in 0.1 M phosphate buffer (pH 7.0). [c] At λ_{max} 265 in 1-octanol. [d] P = $[solute]_{1\text{-octanol}}/[solute]_{phosphate\ buffer}$.

markedly with the increase of the carbon-chain length, the 3′-*O*-octanoyl ester IIIg showing the highest lipophilicity. Because of their increased lipophilicity, these prodrugs might penetrate the biological membranes and the lipoidal stratum corneum more readily (8), and therefore, would be more suitable and effective for topical application for treatment of cutaneous virus infections.

RESULTS AND DISCUSSION

Chemistry—A series of 3′-*O*-acyl derivatives of 5′-amino-5′-deoxythymidine (5′-NH_2-TdR) with various chain lengths (IIIa-i) and aromatic substituents (IIIj) were synthesized as outlined in Scheme I. Treatment of 5′-azido-5′-deoxythymidine (I) (2) with the corresponding acyl chloride in pyridine at 4°C for 24 h gave the 5′-azido-3′-*O*-acyl compounds IIa-j. Catalytic (10% palladium on charcoal) hydrogenation of IIa-j in EtOH afforded the desired 5′-amino-3′-*O*-acyl derivatives IIIa-j. These compounds were characterized by ^{1}H-NMR spectroscopy and elemental analysis. The ^{1}H-NMR spectra (Me_2SO-d_6) showed a downfield shift for the 3′-methinyl protons in all of these compounds in comparison with 5′-amino-5′-deoxythymidine, except the highly branched 3′-*O*-*tert*-butylacetyl ester IIIi. The downfield shift probably is caused by the deshielding effect of the 3′-*O*-acyl function. The C-1′, C-2′, C-4′, and C-5′ protons in the sugar moiety, and the C-6 proton in the pyrimidine base ring in IIIi, shifted upfield relative to that of the parent compound. This upfield shift appears to be the result of the shielding effect exerted by the highly branched *tert*-butylacetyl substituent in the 3′-*O*-acyl group.

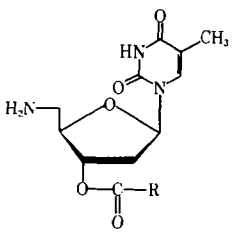
The water solubility and partition coefficient (P) of IIIa-j were determined by UV spectroscopy (6, 9, 10), and the data are summarized in Table I. The aqueous solubilities of the short-chain (R = 1-3 carbons) esters, IIIa-c, increase 6-, 1.5-, and 7.5-fold, respectively, over that of the parent compound, 5′-amino-5′-deoxythymidine (5′-NH_2-TdR). As the carbon-chain length increases to five-seven carbon atoms (IIId-f), the aqueous solubilities decrease. In this series, the 3′-*O*-hexanoyl derivative IIIe is the least soluble in water, with a solubility of 6.9 mg/mL. Unexpectedly, the water solubility of the eight-carbon chain ester, IIIg, increased to 131.1 mg/mL, which is ~2 times greater than that of the parent compound (57.5 mg/mL). Among these 3′-*O*-acyl derivatives, the 3′-*O*-butyryl ester IIIc and the 3′-*O*-benzoyl ester IIIj possess the highest and the lowest water solubilities, with values of 433.7 mg/mL and 3.0 mg/mL, respectively. The highly branched 3′-*O*-*tert*-butylacetyl ester IIIi, has the second highest water solubility (407.8 mg/mL).

The lipophilicities of these 3′-*O*-acyl derivatives (IIIa-j) were determined *via* a 1-octanol–water (0.1 M phosphate buffer) distribution measured in terms of partition coefficient (P). As expected, the lipophilicities of these compounds increase commensurately with the increase of the carbon-chain length. The 3′-*O*-octanoyl ester IIIg has the greatest lipophilicity, as reflected by the P value which approaches 2.21. Compound IIIg was found to be ~250 times more lipid soluble than the parent compound (5′-NH_2-TdR, P = 0.00886). The highly branched 3′-*O*-*tert*-butylacetyl and the aromatic substituted 3′-*O*-benzoyl derivatives, IIIi and IIIj, are also quite lipid soluble, with P values of 0.333 and 0.357, respectively.

Biological Activity—The antiviral activity of these compounds against herpes simplex virus type 1 (HSV-1) was determined. The effect of these compounds on the replication of the uninfected host Vero cells was also investigated. The results are listed in Table II. At 400 μM, IIIa-h show significant antiviral activity by inhibition of the formation of infectious HSV-1 virions, the inhibition ranging from 95% for IIIa to 99% for IIIe. The aromatic substituted 3′-*O*-benzoyl derivative IIIj is less active than the aliphatic straight-chain esters, and the highly branched *tert*-butylacetyl ester IIIi demonstrates little antiviral activity.

All compounds, except the long-chain esters IIIf and IIIg, show little or no cytotoxicity to the host Vero cells at the test concentrations. However, IIIf and IIIg were found to be somewhat cytotoxic against the Vero cells at 400 and 200 μM, respectively. It is worthwhile to acknowledge that among these compounds the valeryl ester IIId and the hexanoyl ester IIIc have shown significant antiviral activity and favorable lipophilicity with no apparent cytotoxicity to the host.

Table II—Effect of Various 5′-Amino-3′-*O*-acyl-thymidine Derivatives on the Replication of Herpes Simplex Virus Type 1 and Vero Cells *In Vitro*[a]



Compound	R	Conc., μM	Percent Inhibition

[a] Assays were carried out in triplicate with appropriate controls. Virus titer in absence of compound was 2.1×10^7 pfu.

EXPERIMENTAL SECTION[1]

General Procedure for the Synthesis of IIIa–j—Compound I (10.0 g, 0.037 mol) was dissolved in 100 mL of pyridine at room temperature. The solution was cooled in an ice-bath, and, with stirring, 0.045 mol of the appropriate acyl chloride was added dropwise *via* an addition funnel. The mixture was stirred at 4°C for 24 h, and then 8 mL of water was added. The solvent was evaporated under reduced pressure below 30°C. The glassy residue was dissolved

[1] Melting points were taken on a Thomas-Hoover Unimelt apparatus and are not corrected. The thin-layer chromatography was performed on EM Silica gel 60 F_{254} sheets (0.2 mm). The UV spectra were recorded on a Beckman-25 spectrophotometer, and the NMR spectra were taken on a Varian T-60 spectrometer at 60 MHz, using Me_4Si as internal reference. The elemental analyses were carried out by Baron Consulting Co., Analytical Services, Orange, Conn. Where analyses are indicated only by symbols of the elements, the analytical results obtained for those elements were within ±0.4% of the theoretical values.

Table III—Characteristics of 5′-*O*-Acyl Derivatives of 5′-Amino-5′-deoxythymidine

Compound	Formula[a]	Description	Yield, %[b]	Melting Point, °C
IIIa	$C_{12}H_{17}N_3O_5$	white powder	62	137–138

[a] All compounds were analyzed for C, H, and N; all values were within ±0.4% of the theoretical value. [b] Yield calculations are based on 5′-azido-5′-deoxythymidine (I).

in 200 mL of $CHCl_3$ and the organic phase was washed with H_2O, saturated $NaHCO_3$ solution, and H_2O. The solution was then clarified with amorphous carbon[2], filtered, and dried over anhydrous $MgSO_4$. The solvent was removed under reduced pressure to give the corresponding 5′-azido-3′-*O*-acyl derivatives IIa–j.

Solutions of IIa–j in 100 mL of EtOH were hydrogenated at 50 psi at room temperature in the presence of 10% palladium on charcoal (0.5 g) for 2 h. After filtration, the filtrates were concentrated to afford glassy residues which were crystallized from EtOH–Et_2O to give the 5′-amino-3′-*O*-acyl derivatives IIIa–j. The physical data of these compounds are listed in Tables I and III.

Determination of Solubility for IIIa–j—Each compound (10 mg) was stirred overnight at room temperature (21°C) in 10 mL of 0.1 M phosphate buffer. Excess compound was removed by filtration through a sintered glass funnel, and the concentration of the solute was determined by UV spectroscopy using the epsilon (ϵ) value, which was previously determined in the phosphate buffer.

Determination of Partition Coefficients for IIIa–j—Solutions (10 mL) of each compound in 0.1 M phosphate buffer having a UV absorbance of 1.0–1.7 of the λ_{max} were vigorously stirred at room temperature (21°C) for 2 h with 10 mL of 1-octanol. The solutions were then transferred to a 60-mL separatory funnel, and the layers were separated. The concentration of the solutes in aqueous phosphate buffer and in 1-octanol at equilibrium were determined by the UV spectroscopic technique, and the partition coefficient of each compound was calculated as $P = [\text{solute}]_{\text{1-octanol}}/[\text{solute}]_{\text{water}}$.

^{1}H-NMR Data (Me_2SO-d_6)—*5′-Amino-5′-deoxythymidine*—δ 1.80 (s, 3, 5-CH_3), 2.15 (t, 2, 2′-H), 2.77 (br d, 2, 5′-H), 3.70 (m, 1, 4′-H), 4.25 (m, 1, 3′-H), 4.78 (br s, 2, 5′-NH_2, D_2O exchangeable), 6.17 (t, 1, $J_{1',2'}$ = 7 Hz, 1′-H), and 7.62 ppm (s, 1, 6-H).

Compound IIIa—δ 1.80 (s, 3, 5-CH_3), 2.11 (s, 3, $COCH_3$), 2.21–2.53 (m, 2, 2′-H), 2.83 (br d, 2, 5′-H), 3.88 (m, 1, 4′-H), 4.63 (br s, 2, 5′-NH_2, D_2O exchangeable), 5.26 (m, 1, 3′-H), 6.18 (t, 1, $J_{1',2'}$ = 7 Hz, 1′-H), and 7.78 ppm (s, 1, 6-H).

Compound IIIb—δ 1.02 (t, 3, C—CH_3), 1.79 (s, 3, 5-CH_3), 2.02–2.62 (m, 4, 2′-H and -$COCH_2$-C), 2.77 (br d, 2, 5′-H), 3.82 (m, 1, 4′-H), 4.59 (br s, 2, 5′-NH_2, D_2O exchangeable), 5.22 (m, 1, 3′-H), 6.12 (t, 1, $J_{1',2'}$ = 7 Hz, 1′-H), and 7.72 ppm (s, 1, 6-H).

Compound IIIc—δ 0.92 (t, 3, C—CH_3), 1.62 (m, 2, C-CH_2-C), 1.82 (s, 3, 5-CH_3), 2.11–2.61 (m, 4, 2′-H and -$COCH_2$-C), 3.12 (br d, 2, 5′-H), 4.16 (m, 1, 4′-H), 5.21 (m, 1, 3′-H), 6.16 (t, 1, $J_{1',2'}$ = 7 Hz, 1′-H), 7.68 (s, 1, 6-H), and 8.48 ppm (br s, 2, 5′-NH_2, D_2O exchangeable).

Compound IIId—δ 0.95 (m, 3, C-CH_3), 1.10–1.70 [m, 4, C-$(CH_2)_2$-C], 1.80 (s, 3, 5-CH_3), 2.38 (t, 4, 2′-H and -$COCH_2$-C), 3.14 (br d, 2, 5′-H), 4.12 (m, 1, 4′-H), 5.19 (m, 1, 3′-H), 6.11 (t, 1, $J_{1',2'}$ = 7 Hz, 1′-H), 7.68 (s, 1, 6-H), and 7.90 ppm (br s, 2, 5′-NH_2, D_2O exchangeable).

Compound IIIe—δ 0.90 (m, 3, C-CH_3), 1.04–1.59 [m, 6, C-$(CH_2)_3$-C], 1.74 (s, 3, 5-CH_3), 2.32 (m, 4, 2′-H and -$COCH_2$-C), 2.80 (br d, 2, 5′-H), 3.84 (m, 1, 4′-H), 4.61 (br s, 2, 5′-NH_2, D_2O exchangeable), 5.20 (m, 1, 3′-H), 6.10 (t, 1, $J_{1',2'}$ = 7 Hz, 1′-H), and 7.70 ppm (s, 1, 6-H).

Compound IIIf—δ 0.90 (m, 3, C-CH_3), 1.10–1.68 [m, 8, C-$(CH_2)_4$-C], 1.80 (s, 3, 5-CH_3), 2.39 (br t, 4, 2′-H and -$COCH_2$-C), 3.20 (br d, 2, 5′-H), 4.20 (m, 1, 4′-H), 5.26 (m, 1, 3′-H), 6.09 (t, 1, $J_{1',2'}$ = 6.5 Hz, 1′-H), 7.79 (s, 1, 6-H), and 8.59 ppm (br s, 2, 5′-NH_2, D_2O exchangeable).

Compound IIIg—δ 0.88 (m, 3, C-CH_3), 1.02–1.68 [m, 10, C-$(CH_2)_5$-C], 1.80 (s, 3, 5-CH_3), 2.34 (br t, 4, 2′-H and -$COCH_2$-C), 3.18 (br d, 2, 5′-H), 4.16 (m, 1, 4′-H), 5.22 (m, 1, 3′-H), 6.13 (t, 1, $J_{1',2'}$ = 7.5 Hz, 1′-H), 7.72 (s, 1, 6-H), and 8.52 ppm (br s, 2, 5′-NH_2, D_2O exchangeable).

Compound IIIh—δ 1.05 (s, 3, C-CH_3), 1.17 (s, 3, C-CH_3), 1.83 (s, 3, 5-CH_3), 2.25–3.85 (m, 3, 2′-H and -$COCH<$), 3.17 (br d, 2, 5′-H), 4.18 (m, 1, 4′-H), 5.20 (m, 1, 3′-H), 6.12 (t, 1, $J_{1',2'}$ = 6.5 Hz, 1′-H), 7.70 (s, 1, 6-H), and 8.55 ppm (br s, 2, 5′-NH_2, D_2O exchangeable).

Compound IIIi—δ 0.82 [s, 9, C-$(CH_3)_3$], 1.26 (s, 3, 5-CH_3), 1.02–1.70 (m, 4, 2′-H and -$COCH_2$-C, overlapping with 5-CH_3), 2.20 (br d, 2, 5′-H), 3.20 (m, 1, 4′-H), 4.22 (m, 1, 3′-H), 5.18 (t, 1, $J_{1',2'}$ = 7 Hz, 1′-H), 6.72 (s, 1, 6-H), and 7.48 ppm (br s, 2, 5′-NH_2, D_2O exchangeable).

Compound IIIj—δ 1.84 (s, 3, 5-CH_3), 2.55 (m, 2, 2′-H), 3.32 (m, 2, 5′-H), 4.40 (m, 1, 4′-H), 5.52 (m, 1, 3′-H), 6.30 (t, 1, $J_{1',2'}$ = 7 Hz, 1′-H), 7.32–8.20 (m, 6, 6-H and -C_6H_5), and 8.42 ppm (br s, 2, 5′-NH_2, D_2O exchangeable).

Biological Test Procedures—The antiviral activities of various compounds listed in Table I were determined. Vero cells were grown to confluency in 25-cm^2 flasks using Dulbecco's medium supplemented with 10% fetal calf serum. The cells were then infected with Herpes simplex virus type 1 (CL-101)[3] at a multiplicity of infection (MOI) of 20. After a 1-h absorption period at 37°C, the viral inoculum was removed, and the flask was washed once with phosphate-buffered saline. The test compounds indicated in Table I were dissolved in Dulbecco's medium supplemented with serum and then added to the flask. The infected cultures were incubated at 37°C for 40 h and then frozen until virus titrations were performed. Virus was released by freezing and thawing the media–cell suspension one time. The cell lysates were diluted directly, and the virus yield was assayed by plaque formation on Vero cells. The number of plaque-forming units (pfu) of virus in the drug-treated cultures relative to that found in the drug-free condition was determined and expressed as percent inhibition in Table III.

The cytotoxicity of the various test compounds on the uninfected host Vero cells was determined (Table III). Vero cells in Dulbecco's medium (2.5 mL) supplemented with 10% fetal calf serum were added to eight 25-cm^2 flasks at a concentration equivalent to 0.1 confluency for each compound under assay. After incubation at 37°C in 5% CO_2–95% air for 1 d, the test compound, dissolved in 2.5 mL of the above growth medium, was added and two flasks were harvested immediately by decanting the medium, washing once with 5 mL of buffered saline, and then incubating at 37°C for 15 min with a 5-mL solution of trypsin (0.125%) and EDTA (0.02%). The cells dislodged from the flask by this latter procedure were generally in clumps and were dispersed by repeated forceful pipetting of the suspension against the surface of the flask. To 1 mL of the well-dispersed cell suspension, 0.2 mL of trypan blue solution was added, and the number of cells was counted using a hemocytometer. Each day for the next 3 d, two of the remaining flasks were harvested in the aforementioned manner for determination of cell number.

Determination of Orally Coadministered Nadolol and Its Deuterated Analogue in Human Serum and Urine by Gas Chromatography with Selected-Ion Monitoring Mass Spectrometry

ALLEN I. COHEN [§x], RICHARD G. DEVLIN [‡¶], EUGENE IVASHKIV [*§], PHILLIP T. FUNKE [*¶], and TERRENCE McCORMICK [*¶]

Received April 4, 1983, from the *Departments of *Analytical Research and [‡]Clinical Pharmacology, The Squibb Institute for Medical Research, [§]New Brunswick, NJ 08903* and [¶]*Princeton, NJ 08540.* Accepted for publication September 23, 1983.

Abstract □ A cartridge serum and urine extraction procedure of the β-adrenergic antagonist, nadolol, employing a cross-linked styrene-divinyl benzene macroreticular resin is described. Samples were analyzed as the silylated derivative by gas chromatography–mass spectrometry (GC–MS) using selected-ion monitoring. When nadolol was orally coadministered with its deuterated analogue, relative bioavailability could be demonstrated with six or fewer subjects. Employing a base-deactivated GC phase, the limit of detection is 1 ng and 0.5 ng/mL of serum for nadolol and the deuterated analogue, respectively. For levels of <10 ng/mL, the respective coefficients of variation are 4 and 2%. For concentrations of >10 ng/mL, the *CV* is 1% for nadolol and nadolol-d_9.

Keyphrases □ Nadolol—human serum and urine, GC–MS, selected-ion monitoring, nadolol-d_9 □ GC–MS—selected-ion monitoring, nadolol, human serum and urine, nadolol-d_9

Nadolol (I) is a nonselective β-adrenergic antagonist recommended for the treatment of hypertension and angina pectoris (1, 2). Dreyfuss *et al.* have determined bioavailability parameters of orally and intravenously administered [^{14}C]-nadolol (3, 4) in mildly hypertensive humans. Nadolol is partially and variably absorbed (1), like other β blockers, but it is eliminated without metabolism. With oral administration, the pharmacokinetic profile of nadolol is described by an open two-compartment model with respective absorption, distribution, and elimination half-lives of ~1, 1.5, and 17 h (3, 4).

A gas chromatography–selected-ion monitoring mass spectrometry (GC–SIM MS) determination of nadolol serum levels was previously reported (5). Carlin *et al.* (6) have recently presented an elegant application of GC–SIM MS to the measurement of low levels of the β-blocker timolol and its deuterated analogue in a coadministration bioavailability evaluation. Coadministration bioavailability studies for other drug types have been reported by Strong *et al.* (7), Wolen *et al.* (8), d'A. Heck *et al.* (9), Walle and Walle (10), Alkalay *et al.* (11), Murphy and Sullivan (12), and most recently by Cohen *et al.* (13). The extraction and isolation procedure (5) has been simplified for more effective sample processing by GC–SIM MS (13). The bioavailability of two 80-mg formulations of nadolol (I) given to six subjects, administered either as a tablet or solution along with a concomitant 80-mg solution of nonadeuterated nadolol (II) is presented.

epoxyketal intermediate (VII) (14) by the reaction with 98 atom-% deuterium-labeled *tert*-butylamine (VIII)[1].

Synthesis of II—A solution of 17 mL of methanol containing 4.9 g (17.7 mmol) of VII and 4.3 g (52.4 mmol) of V was refluxed for 2.5 h using a dry-ice condenser. The volatiles were then distilled into a dry-ice trap at 60–70°C at 20 torr and used again until the remaining VIII was <10% of the original amount. The combined residues were purified by extraction with 100 and 50 mL of 6% w/v aqueous citric acid from 100 mL of ether. The aqueous layer was adjusted to pH 10.8 with 5 M NaOH and then was extracted with 200 mL of ether (4×). The dried residue was dissolved in 60 mL of warm water containing 8 mL concentrated hydrochloric acid, and was allowed to stand for 3 h. The pH of the cooled aqueous solution was adjusted to pH 7.8 with 5 M NaOH, washed with 100 mL of dichloromethane, then made to pH 10.2 with 10 M NaOH, saturated with sodium chloride, and exhaustively extracted with dichloromethane. The pooled extract was then treated with activated charcoal and concentrated under reduced pressure. The crude product was crystallized from 350 mL of warm acetone and then cooled to room temperature. The slurry was cooled in an ice bath, and 350 mL of hexane was gradually added. The crystalline material was collected by filtration, and then the material was washed with 100 mL of cold acetone–hexane (1:1) and dried, to give (70% yield) a crystalline powder, mp 128–130°C; IR (KBr): 2208 cm^{-1} (C—D stretch); 100-MHz ^{1}H-NMR (methanol-d_4): δ 2.5–3 (m, 6, CH_2N, 2 CH_2Ar), 6.5–7.1 (m, 3, ArH), and 3.8–4.1 ppm (m, 5, CH—O) [identical patterns as I except δ 1.12 ppm (s, 9, CH_3) is replaced with a broad weak peak (CD_2H—)]; EI-MS M^+: *m/z* 318, 300 ($M^+ - CD_3$), 274 (rearrangement, $M^+ - C_2H_4O$), and 95 [$CH_2NHC(CD_3)_3$ base ion] (estimated octadeutero analogue 10–15%). EI GC-MS of V M^+: *m/z* 534 (absent), 519 ($M^+ - CH_3$), 516 ($M^+ - CD_3$), 95 (base ion) (*c.f.*, Fig. 1); PCI GC-MS of V MH^+: *m/z* 535 (*c.f.*, Fig. 2) (estimated octadeutero analogue 10–15%).

Anal.—Calc. for $C_{17}H_{18}D_9NO_4$: C, 64.12; D and H, 11.39 (8.55 as H); N, 4.40. Calc. for $C_{17}H_{27}NO_4$: C, 65.99; H, 8.80; N, 4.53. Found: C, 64.10; H, 8.69 (H equivalent to 27 atoms/mol), N, 4.38.

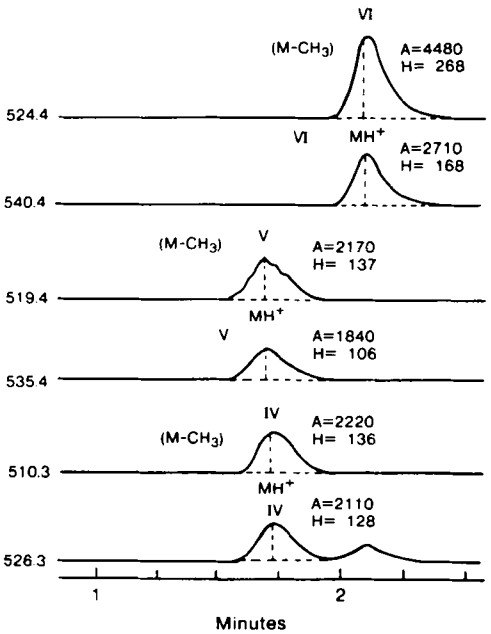

Figure 2—*PCI-SIM of a typical processed serum extract containing 122, 127, and 250 ng/mL of I, II, and III, respectively, measured as their trimethylsilylated derivatives, IV, V, and VI.*

The extraction cartridges[2] were used as received. *N*-(Trimethylsilyl)imidazole in pyridine[3] (1.5 mEq/mL) was obtained in 1-mL sealed ampules.

Standard Solutions—Stock solutions of I, II, and III prepared in 0.1 M HCl were refrigerated and used for at least 6 months. Diluted working solutions were prepared daily in 0.1 M HCl.

Equipment—Various equipment used in the sample preparation include: evaporators[4,5], vortex mixer[6], reaction vials[7], vial seals[8], crimper[9], centrifuge[10], screw-cap culture tubes[11], disposable Pasteur pipets[12], syringes[13], repipet dispenser[14], and dessicators.

Extraction Procedure—*Serum*—Thawed and centrifuged 1-mL serum samples, processed in groups of 35, were transferred to the extraction cartridges[2], placed on 150 mL screw-top culture tubes, and 250 ng of internal reference solution III and 1 mL of distilled water were added to each cartridge. A 1.0-mL blank serum sample containing 500 ng of I, 500 ng of II, and 250 ng of III was processed with each set of samples. A calibration sample curve was prepared using blank serum to which 0–500 ng each of I and II and 250 ng of III were added.

The cartridges were centrifuged at 800 rpm for 30 s. The cartridge caps were removed, and the cartridges were then centrifuged for 5 min at 1000 rpm, and, if required at 1500 rpm until centrifugation was complete. After the addition of 4 mL of water, the cartridge was centrifuged at 1000 rpm for 4 min, followed by 1500 rpm for 1 min. To each cartridge, placed on a scintillation vial, 2 mL of methanol was added, and the cartridges were centrifuged at 1000 rpm for 5 min. The contents of the cartridge was evaporated in a sample concentrator at 65°C, reconstituted in 0.5 mL of methanol, and transferred to a 1-mL reaction vial. A solution of I, II, and III, which constitutes the unextracted control, was evaporated[4]. Each solution was evaporated[5] to dryness under nitrogen at 60°C. After drying under reduced pressure in a desiccator for 30 min, the samples were capped.

Urine—To each cartridge 0.5 or 0.1 mL of thawed urine was added, followed by 0.5 μg of III internal reference solution and 3 mL of H_2O. These samples were then processed in the same manner as serum samples.

Calibration and Preparation of Control Blood and Urine Samples—Varying amounts of I (and an equal amount of II for simultaneous measurements) were added to cartridges containing 1 mL of serum to yield concentrations from 0 to 500 ng/mL. To each cartridge, 250 ng of internal reference III was added. The control sample represents the calibration point equal to 500 ng of I and II and 250 ng of III.

The urine standard curve was prepared from urine samples containing from 0 to 1 μg of I and II and 0.5 μg of III. Only 0.1 mL of urine was needed from samples collected within the first 4 h, and 0.5 mL was required after 4 h. Like the serum control, the control urine represents the 2:1 calibration point. The ratio of the maximum peak heights *versus* the respective nanogram (or microgram) ratio was fitted by linear regression[15] (13). For serum:

$$R_1 = 0.01916 + 1.0654R'_1 \text{ (nadolol)} \qquad \text{(Eq. 1)}$$

$$R_2 = 0.00467 + 0.7969R'_2 \text{ (deuterated nadolol)} \qquad \text{(Eq. 2)}$$

For urine:

$$R_1 = 0.05734 + 0.9781R'_1 \text{ (nadolol)} \quad \text{(Eq. 3)}$$

$$R_2 = 0.04410 + 0.8248R'_2 \text{ (deuterated nadolol)} \quad \text{(Eq. 4)}$$

where R'_1 and R'_2 are concentration ratios and R_1 and R_2 are the measured ratios (13).

Selected-Ion Monitoring—The extracted samples were reconstituted in 40 μL of *N*-(trimethylsilyl)imidazole in pyridine[3] at least 1 h prior to analysis. *N*-(Trimethylsilyl)imidazole (0.25 μL in pyridine) was drawn into a 10-μL syringe, followed by 1 μL of solution. The appropriate ion profiles (*m/z* 86.1, *m/z* 95.2, and *m/z* 100.2) were obtained by selected-ion monitoring (SIM). The maximum peak heights were measured using a program written especially for the batch processing of data (13).

Instrumental Procedure—The combined GC–MS, with the data system[16], was tuned[17] for electron-impact (EI) MS from 69 to 502 D using perfluorobutylamine at an ionization voltage of 70 eV and at an emission of 300 μA. The ion source was controlled at a constant temperature of 200°C. For positive chemical ionization (PCI) MS the source parameters were optimized at an ionization voltage of 300 eV.

A septum guide[18] was attached to the GC injector. The analysis was carried out on an 80-cm × 2-mm i.d. silanized glass column packed with 3% SP-2100DB[19], which was connected through a single-stage jet separator. The transfer line and separator were maintained at 275°C, while the column was kept at an isothermal temperature of 230°C and the injector was heated to 265°C. Typical retention times of 1.9 min for the silylated compounds (IV and V) and 2.5 min for the silylated internal reference (VI) were obtained at a helium flow rate of 30 mL/min (Fig. 1). Helium, otherwise diverted, was allowed to flow into the ion source at 1.3 min after sample injection until the end of the measurement. The multiplier and electron voltages were only applied during the data collection period, from 1.5 min after injection until the termination of the run.

Positive CI GC–MS was obtained with methane as the GC carrier gas, at a flow rate of 20 mL/min, flowing directly into the source to create a 1-torr source pressure (Fig. 2). Otherwise, the chromatographic conditions were identical to that of the EI GC–SIM MS.

Drug Administration—All subjects fasted for 8 h prior to and for 4 h after dosing. Twenty-milliliter blood samples were drawn[20] from an antecubital vein, under sterile conditions. The whole blood was allowed to clot and was then centrifuged. Urine was collected for 0–4, 4–8, 8–12, 12–24, and 24–48 h after dosing. After measurement of the total volume for each collection, a 15-mL aliquot was transferred to a small, labeled plastic container and frozen.

RESULTS AND DISCUSSION

The cartridge extraction procedure (16) is based on a column packed with cross-linked styrene–divinyl benzene macroreticular resin, processed manually with a conventional laboratory centrifuge. Timolol samples were separated on a reverse-phase C_{18} cartridge, supplemented with acid–base extractions (6). Using [^{14}C]nadolol as a tracer, nadolol is quantitatively absorbed on the column from pH 2–13.5 solutions. Washing with distilled water removed potentially interfering serum components without disturbing the absorbed I. Nadolol is quantitatively displaced with methanol, but <80% is displaced by equal amounts of acetone. Lower polarity solvents such as dichloromethane did not displace I at all. On the other hand, solvent mixtures containing ≥25% methanol also produced quantitative elution. The radioactivity was quantitatively recovered with 0.5–2 mL of methanol. The dried eluate was sufficiently pure to be directly silylated for GC–MS analysis. Similarly, processed urine samples yielded excellent recoveries for microgram quantities of I. This isolation procedure directly replaces the fluorometric (17) and MS (5) extraction procedures. It is also likely that other β-adrenergic agents would behave similarly in this extraction system.

The GC–MS SIM processing efficiency was improved by reducing "ghosting" and tailing of the underivatized secondary amine. A glass column containing a specially base-deactivated methyl silicone polymer packed phase[19] was operated isothermally. Background components with interfering ions were minor, although the background at *m/z* 95 was somewhat greater than at the even-mass *m/z* 86 and 100 ions (Fig. 1). Confirmation of the structures of the silylated derivatives was made by PCI GC–MS SIM (Fig. 2). For I the limit of detection is at least 1 ng/mL, and for the deuterated analogue (II) it is ~50% of that value. Nine of twelve time-zero samples were found to have no detectable I, while two contained 0.1 ng and another 0.3 ng per milliliter. All 12 deuterated analogue (II) values were measured as zero. All 48-h serum samples had nonzero values (Tables I–III). The estimated *CV* for measurements at 10 ng/mL are 4% for I and 2% for II, which decreases to 1% for both I and II at greater concentrations.

Urine contained from 0.2 to 24 μg/mL of I and II. As a percentage of the dose, the amounts excreted with time were not necessarily influenced by urine

volume (Tables IV and V). The amount of drug excreted is directly related to the circulating serum levels just prior to or during the collection period.

Since the deuterated analogue (II) was administered to all subjects, an evaluation of the variation bioavailability can be readily assessed. As a rule, no subject exhibited identical bioavailability for II with respect to maximum concentration levels, time to maximum, and area under the curve. Consequently comparison of intrasubject data is unreliable, which then requires treating the composite data (Table III). With this limited data set of six subjects, sufficient smoothing has occurred to begin to show equivalence between the legs of the administration of the deuterated analogue (Table III).

[a] No statistically significant differences were observed between tablet and solution or between deuterated solutions.

The urinary excretion patterns of nadolol (I) and nadolol-d_9 (II) are summarized in Tables IV and V. Depending on the drug form, subject, and leg, 8–20% (mean 12%) and 7–17% (mean 10%) of the respective doses of I and II are excreted in 48 h. Although not entirely unexpected, the deuterated solution formulation (II) has lower bioavailability than either the solution or tablet formulations of I. From the statistical criteria applied to absolute bioavailability data, the deuterated solution formulation is marginally bioequivalent, differing by <20% from the nondeuterated tablet and solution formulations. The tablet and solution formulations of I are bioequivalent, on the other hand, and the urinary excretion values also parallel these observations.

The use of the nonadeuterated analogue was based on the availability of intermediates. Apparently extensive deuterium labeling in the side chain resulted in reduced absorption and lower bioavailability. While it might have been more appropriate to have used ^{13}C- and ^{15}N-labeled nadolol to reduce the isotope effects, the deuterated form yielded reliable results which paralleled those of the nonlabeled forms of I.

The mean serum values of the area under the bioavailability curve can be calculated from the absolute areas in the conventional way (18)[21] or from the relative area, defined as absolute area the formulation of I divided by the value for the coadministered II (Table VI). From the absolute area, seven to eight subjects would be required as the minimum number to demonstrate bioequivalence, while only four to five subjects would be required to show the bioequivalence using coadministration[21]. Increasing this number to six ensures staying within the confidence of establishing bioequivalence. The use of the relative parameter is even more striking in the evaluation of the urinary excretion data, which required a minimum of 10 subjects in the normal approach and either 2 or 4 subjects using relative bioavailability (Table VII).

For studies employing analytical methods with reasonable precision, the limitation in bioavailability studies continues to be in the variability of the disposition by the subjects. In these instances, the use of coadministration represents the optimum method of generating a reliable data set with a minimum of subjects. Rapidly processed, an early evaluation of the bioavailability of a new dosage form can be made. It also takes the greatest advantage of the MS selective capability. Finally, the introduction of new low-priced high-performance EI mass selective detectors should result in a wider acceptance of coadministration relative bioavailability and absolute bioavailability MS evaluations.

A New Series of Reductive Amination Derivatives of Daunorubicin: Syntheses, Partition Coefficients, and DNA Binding

SHAU-FONG YEN *, W. DAVID WILSON *x, STEVENS W. PEARCE §, and EDMOND J. GABBAY §†

Received April 19, 1983, from the **Department of Chemistry, Georgia State University, Atlanta, GA 30303* and the §*Department of Chemistry, University of Florida, Gainesville, FL, 32611.* Accepted for publication December 6, 1983. †Deceased.

Abstract □ A series of daunorubicin derivatives were prepared by sodium cyanoborohydride reductive amination of daunorubicin with appropriate amines. All derivatives were found to bind quite strongly to DNA and viscosity increases with linear DNA indicated that each formed an intercalation complex. A range of octanol-aqueous buffer partition coefficients was obtained, around the values of daunorubicin and dauxorubicin hydrochloride, by varying the character of the starting amine. All monoamine derivatives had activity against P388 leukemia in mice which was similar to that of daunorubicin. A diamine derivative had reduced activity against P388. Several anthracyclines administered as DNA complexes had similar activity against P388 but significantly reduced toxicity compared to the uncomplexed compounds. For anthracyclines which bind strongly to DNA, optimum activity against P388 leukemia in mice seems to be centered on compounds with octanol-buffer partition coefficients in the range of 0.5–0.8.

Keyphrases □ Anthracyclines—new derivatives, antineoplastic agents □ Toxicity—reduced cardiotoxicity, anthracyclines

The glycosidic anthracycline antibiotics daunorubicin (I) and dauxorubicin hydrochloride (II), are being clinically used as antineoplastic agents (1–8). Unfortunately, these drugs are severely limited by their dose related cardiotoxicity (1–5). Although the molecular basis of the cardiotoxicity is not clear, two proposed mechanisms are widely accepted. First, the anthracyclines are reduced to semiquinone free radicals and, subsequently, generate oxygen radicals which cause membrane lipid peroxidation and DNA strand scission (9–11). Second, the chemically labile glycosidic bonds of I and II are cleaved by glycosidases to form the respective aglycons during *in vivo* metabolism (1–4, 9, 12). The water insoluble aglycons accu-

The urinary excretion patterns of nadolol (I) and nadolol-d_9 (II) are summarized in Tables IV and V. Depending on the drug form, subject, and leg, 8–20% (mean 12%) and 7–17% (mean 10%) of the respective doses of I and II are excreted in 48 h. Although not entirely unexpected, the deuterated solution formulation (II) has lower bioavailability than either the solution or tablet formulations of I. From the statistical criteria applied to absolute bioavailability data, the deuterated solution formulation is marginally bioequivalent, differing by <20% from the nondeuterated tablet and solution formulations. The tablet and solution formulations of I are bioequivalent, on the other hand, and the urinary excretion values also parallel these observations.

The use of the nonadeuterated analogue was based on the availability of intermediates. Apparently extensive deuterium labeling in the side chain resulted in reduced absorption and lower bioavailability. While it might have been more appropriate to have used ^{13}C- and ^{15}N-labeled nadolol to reduce the isotope effects, the deuterated form yielded reliable results which paralleled those of the nonlabeled forms of I.

The mean serum values of the area under the bioavailability curve can be calculated from the absolute areas in the conventional way (18)[21] or from the relative area, defined as absolute area the formulation of I divided by the value for the coadministered II (Table VI). From the absolute area, seven to eight subjects would be required as the minimum number to demonstrate bioequivalence, while only four to five subjects would be required to show the bioequivalence using coadministration[21]. Increasing this number to six ensures staying within the confidence of establishing bioequivalence. The use of the relative parameter is even more striking in the evaluation of the urinary excretion data, which required a minimum of 10 subjects in the normal approach and either 2 or 4 subjects using relative bioavailability (Table VII).

For studies employing analytical methods with reasonable precision, the limitation in bioavailability studies continues to be in the variability of the disposition by the subjects. In these instances, the use of coadministration represents the optimum method of generating a reliable data set with a minimum of subjects. Rapidly processed, an early evaluation of the bioavailability of a new dosage form can be made. It also takes the greatest advantage of the MS selective capability. Finally, the introduction of new low-priced high-performance EI mass selective detectors should result in a wider acceptance of coadministration relative bioavailability and absolute bioavailability MS evaluations.

A New Series of Reductive Amination Derivatives of Daunorubicin: Syntheses, Partition Coefficients, and DNA Binding

SHAU-FONG YEN *, W. DAVID WILSON *x, STEVENS W. PEARCE §, and EDMOND J. GABBAY §†

Received April 19, 1983, from the **Department of Chemistry, Georgia State University, Atlanta, GA 30303* and the §*Department of Chemistry, University of Florida, Gainesville, FL, 32611.* Accepted for publication December 6, 1983. †Deceased.

Abstract □ A series of daunorubicin derivatives were prepared by sodium cyanoborohydride reductive amination of daunorubicin with appropriate amines. All derivatives were found to bind quite strongly to DNA and viscosity increases with linear DNA indicated that each formed an intercalation complex. A range of octanol-aqueous buffer partition coefficients was obtained, around the values of daunorubicin and dauxorubicin hydrochloride, by varying the character of the starting amine. All monoamine derivatives had activity against P388 leukemia in mice which was similar to that of daunorubicin. A diamine derivative had reduced activity against P388. Several anthracyclines administered as DNA complexes had similar activity against P388 but significantly reduced toxicity compared to the uncomplexed compounds. For anthracyclines which bind strongly to DNA, optimum activity against P388 leukemia in mice seems to be centered on compounds with octanol-buffer partition coefficients in the range of 0.5–0.8.

Keyphrases □ Anthracyclines—new derivatives, antineoplastic agents □ Toxicity—reduced cardiotoxicity, anthracyclines

The glycosidic anthracycline antibiotics daunorubicin (I) and dauxorubicin hydrochloride (II), are being clinically used as antineoplastic agents (1–8). Unfortunately, these drugs are severely limited by their dose related cardiotoxicity (1–5). Although the molecular basis of the cardiotoxicity is not clear, two proposed mechanisms are widely accepted. First, the anthracyclines are reduced to semiquinone free radicals and, subsequently, generate oxygen radicals which cause membrane lipid peroxidation and DNA strand scission (9–11). Second, the chemically labile glycosidic bonds of I and II are cleaved by glycosidases to form the respective aglycons during *in vivo* metabolism (1–4, 9, 12). The water insoluble aglycons accu-

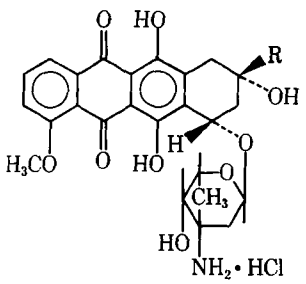
mulate in heart tissue. The anthracyclines are no doubt capable of multiple mechanisms of action at several biological sites. Their antitumor activity is believed to be at least partially due to their ability to bind *in vivo* to DNA of nuclear deoxyribonucleoprotein (1-8). The results of X-ray diffraction and model building studies have shown that there is a specific complex formed between the anthracyclines and DNA (7, 8). As part of a continuing effort (13, 14) to prepare derivatives of I and II with higher specificity, reduced toxicity, and also to develop *in vitro* methods for biological activity evaluation, we report the synthesis and biological effects of a new series of anthracycline amine derivatives IV–VII. The results of *in vivo* testing for the DNA complexes with some of the new analogues are also presented.

Since bulky substituents at C-13, such as rubidazone, III, maintain high antineoplastic activity (1), it is reasonable to expect that anthracycline analogues at this position would be active. In an attempt to reduce the accumulation of the aglycons in heart tissue, their water solubility was increased by introducing charged amino derivatives at C-13. It should be noted that these cationic groups could also potentially enhance binding affinity to DNA. In addition, varying the hydrophobic character of the substituents on C-13 was used to vary the partition coefficient of these C-13 derivatives.



I, R = $COCH_3$ (Daunorubicin)
II, R = $COCH_2OH$ (Dauxorubicin)
III, R = $C(NNHCOC_6H_5)CH_3$ (Rubidazone)
IV, R = $CH(NHCH_3{\cdot}HCl)CH_3$
V, R = $CH(NH(CH_2)_3CH_3{\cdot}HCl)CH_3$
VI, R = $CH(NH(CH_2)_3OH{\cdot}HCl)CH_3$
VII, R = $CH(NH(CH_2)_3NH_2(CH_3)_2{\cdot}2HCl)CH_3$
VIII, R = $CH(OH)CH_3$ (Daunorubicinol)

EXPERIMENTAL SECTION[1]

(7*S*,9*S*)-7-[(3-Amino-2,3,6-trideoxy-α-L-lyxo-hexopyranosyl)oxy]-9-(1-methylaminoethyl)-7,8,9,10-tetrahydro-6,9,11-trihydroxy-4-methoxy-5,12-naphthacenedione Dihydrochloride (C-13-Methylaminohydrodaunorubicin; IV)—Methylamine hydrochloride (2.0 g, 30 mmol) and I (175 mg, 0.3 mmol) were dissolved in 20 mL of methanol. To this was added 0.3 mL of a 1.0 M methanolic solution of NaOH and, after 15 min equilibration, 1.0 mL of a freshly prepared methanolic solution of $NaCNBH_3$ (0.3 mmol/mL). The reaction was carried out at room temperature in a sealed tube for 12 h, at which time TLC of the reaction mixture on silica-gel plates (20% methanol–chloroform) indicated only the presence of IV and a trace amount of VIII. The amount of NaOH added only partially neutralizes the added amine hydrochloride. It was found experimentally that addition of larger amounts of NaOH caused the appearance of numerous unidentified side products (TLC analysis) which were difficult to remove. Addition of less NaOH caused the reaction to proceed quite slowly and allowed the formation of larger amounts of daunorubicinol, VIII. The amount of NaOH added was, thus, chosen to optimize the yield of the desired product. The methanol was evaporated under reduced pressure and then the residue was dissolved in 10 mL of pH 10.4 aqueous borate buffer (0.01 M) and extracted three times with a total of 30 mL of $CHCl_3$. The combined chloroform extracts were washed three times with distilled water, dried over Na_2SO_4, and evaporated under reduced pressure. The solid was dissolved in methanol and acidified with slightly more than two equivalents of aqueous 12 M HCl. The solvent was evaporated under reduced pressure and the residue triturated three times with 1% methanol in chloroform. At this time only IV could be detected by TLC. The dark red solid was recrystallized from ethanol–ethylacetate to give 80 mg (45%) of IV (mp, slowly dec. >179°C); TLC (silica gel, 30% CH_3OH in CH_2Cl_2): R_f 0.19; IR (KBr): 3452 (N—H), 1622, and 1589 cm^{-1} (C=O of C ring); ^{1}H-NMR (free base in $CDCl_3$): δ 8.07 (d, J = 8.0 Hz, H-1), 7.78 (t, J = 1.5 Hz, H-2), 7.37 (d, J = 8.2 Hz, H-3), 5.52 (m, H-1′), 5.28 (m, H-7), 4.06 (s, OCH_3), 4.2–3.8 (br m, OH-9, H-5′, and H-3′), 3.6–2.4 (br m, H-4′, H-10, and H-13), 2.57 (d, J = 2.8 Hz, NCH_3), 2.0–1.3 (br m, H-8 and CH_2-2′), 1.26 (d, J = 7.3 Hz, CH_3-5′), and 1.18 ppm (d, J = 6.5 Hz, CH_3-14).

(7*S*,9*S*)-7-[(3-Amino-2,3,6-trideoxy-α-L-lyxo-hexopyranosyl)oxy]-9-[1-(3-hydroxypranyl)aminoethyl]-7,8,9,10-tetrahydro-6,9,11-trihydroxy-4-methoxy-5,12-naphthacenedione Dihydrochloride (C-13-1-Propanolaminohydrodaunorubicin; VI)—The reaction of 3-amino-1 propanol hydrochloride with daunorubicin was conducted as for IV and the product was purified to give dark red solid VI in 38% yield (mp slowly dec. >174°C); TLC (silica gel, 20% CH_3OH in CH_2Cl_2): R_f 0.58; IR (KBr): 3443 (N—H), 1622, and 1581 cm^{-1} (C=O of C ring); ^{1}H-NMR (free base in $CDCl_3$): δ 8.05 (d, J = 7.3 Hz, H-1), 7.76 (t, J = 1.0 Hz, H-2), 7.37 (d, J = 8.2 Hz, H-3), 5.52 (m, H-1′), 5.28 (m, H-7), 4.10 (s, OCH_3), 4.5–3.6 (br m, OH-9, H-5′, H-3′), 3.5–2.2 (two m, CH_2—γ-propanol, CH_2—α-propanol, H-4′, H-10, and H-13), 1.9–1.5 (br m, H-8, CH_2-2′ and CH_2—β-propanol), 1.36 (d, J = 6.4 Hz, CH_3-5′), and 1.29 ppm (m, J = 5.5 Hz, CH_3-14).

Anal.—Calc. for $C_{30}H_{40}Cl_2N_2O_{10}$: C, 54.61; H, 5.96. Found: C, 54.71; H, 5.97.

(7*S*,9*S*)-7-[(13-Amino-2,3,6-trideoxy-α-L-lyxo-hexopyranosyl)oxy]-9-[1-(3,3-dimethyl-1,3-diaminoethyl)]-7,8,9,10-tetrahydro-6,9,11-trihydroxy-4-methoxy-5,12-naphthacenedione Trihydrochloride (C-13-*N*,*N*-Dimethyl-1,3-propanediaminohydrodaunorubicin; VII)—The reaction of N,N-dimethyl-1,3-diaminopropane dihydrochloride with I was conducted as for IV and the product was purified to give dark red solid VII in 70% yield (slowly dec. >180°C); TLC (silica gel, 30% CH_3OH in CH_2Cl_2): R_f 0.08; IR (KBr): 3451 (N—H), 1622, and 1589 cm^{-1} (C=O of C ring); ^{1}H-NMR (free base in $CDCl_3$): δ 7.94 (d, J = 7.8 Hz, H-1), 7.72 (t, J = 1.5 Hz, H-2), 7.34 (d, J = 8.0 Hz, H-3), 5.45 (m, H-1′), 5.17 (m, H-7), 4.05 (s, OCH_3), 4.5–3.9 (br m, OH-9, H-5′, and H-3′), 3.5–2.0 (br m, H-4′, H-10, H-13, CH_2—α-N-ethylene, and CH_2—β-N-ethylene), 2.23 (s, NCH_3), 1.8–1.1 (br m, H-8, CH_2-2′), 1.29 (d, J = 7.3 Hz, CH_3-5′) and 1.09 ppm (d, J = 6.5 Hz, CH_3-14).

Anal.—Calc. for $C_{32}H_{46}Cl_3N_3O_9{\cdot}H_2O$: C, 51.86; H, 6.53. Found: C, 51.77; H, 6.53.

Octanol–buffer partition coefficients were determined by standard equilibration methods (15). Extinction coefficients at 480 nm, determined for the two different phases, were used for concentration determinations. Binding constants of the derivatives were determined as previously described (16) using spectrophotometric changes at 480 nm. The results were analyzed using standard methods (16–18). Viscosity measurements were made using a viscometer[2] with electronic timing as previously described (13, 14). The system for determining inhibition of *E. coli* RNA polymerase is the same as previously described for anthracycline derivatives (13). Salmon sperm DNA was used as obtained[3]. Stock solutions of DNA were made in 2 mM [1,4-piperazinebis(ethanesulfonic acid)] buffer (PIPES), pH 7.8, with NaCl added to adjust ionic strength. Anthracycline stock solutions (10 mM) were made in distilled

[1] NMR spectra were recorded from 0–10 ppm on either a JEOL GX270 or on a Varian XL-100 spectrometer. Elemental analyses were performed at Atlantic Microlab, Inc., Atlanta, Georgia. Compounds I–III were obtained from the Drug Development Branch of NCI.

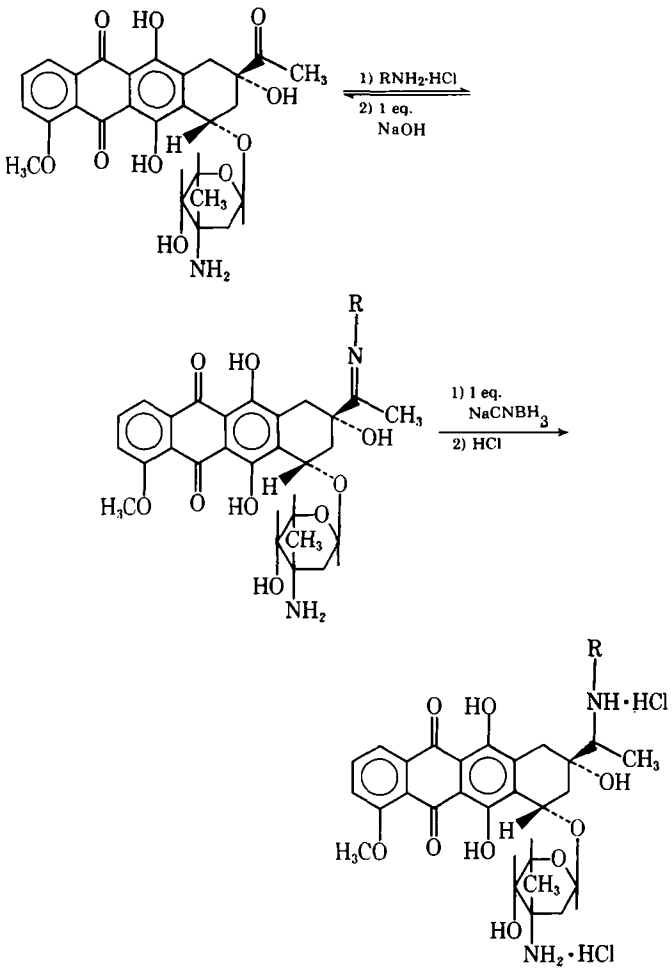

Scheme I—Synthesis of reductive derivatives of daunorubicin, IV-VII.

water and diluted with appropriate buffer as needed.

Anthracycline-DNA complexes for biological testing were prepared by dissolving DNA (5 mM) in 0.1 mM phosphate buffer at pH 7. Anthracyclines were dissolved (0.01 M) in water and added very slowly with vigorous stirring to the DNA solution until a ratio of 1:5 of drug to DNA was obtained. The solution was warmed to 40°C with stirring until all solids had dissolved and then was lyophilized. Volumes were varied depending on the amount of drug desired.

RESULTS

Chemistry—The syntheses of IV-VII were carried out in good yield by treating daunorubicin with appropriate amines and $NaCNBH_3$ (19) as shown in Scheme I. The reactions were monitored by TLC. Typically, four spots of a reaction mixture were observed: (*a*) starting material, I; (*b*) daunorubicinol, VIII, which results from the reduction of I by $NaCNBH_3$; (*c*) a component with high mobility which is presumably the aglycon of I; (*d*) the component which after purification was identified as the desired product and which always had the smallest R_f value. Daunorubicinol, VIII, was identified by treating I with $NaCNBH_3$ directly under mild conditions. Typically, at the end of a reaction, the first three components were present in trace amount and frequently no starting material was detected.

All reactions were performed on a relatively small scale due to the expense of I. In addition to elemental analysis, the authenticity and purity of IV-VII were confirmed as follows: (*a*) NMR of aromatic, sugar, and methoxy peaks of the neutral species in $CDCl_3$ showed no significant change from I; (*b*) the C=O IR stretching vibrations of C-13 at 1712 cm^{-1} disappear after reaction; (*c*) the bands at 1622 and 1581 cm^{-1} of the two carbonyl groups of the C ring remain unchanged, indicating that the quinone is not reduced by $NaCNBH_3$; (*d*) the UV-visible spectra of the derivatives are similar to the parent compound I, indicating that the chromophore is not modified; (*e*) TLC of the purified compounds on silica gel gives only a single spot.

Biological Testing—Compounds IV-VII, along with I and II, were submitted to the National Cancer Institute for antitumor activity testing against lymphocytic leukemia P388 in mice. As shown in Table I, all derivatives are

Table I—Biological Testing Results Against Mouse Lymphocytic Leukemia [a]

Compound	NSC Number	Optimal Dose, mg/kg	Toxic Dose, mg/kg[b]	T/C[c]

VI	266537	16.0	32.0	188
VII	256466	6.25	20.0	131

[a] All tests were arranged through the Drug Research and Development Program, Division of Cancer Treatment, National Cancer Institute. CDF mice bearing intraperitoneally implanted P388 lymphocytic leukemia (10^6 cells) on day 0 were treated on days 1-9 with the specified intraperitoneal dose of aqueous drug solutions. Detailed protocols are described in Ref. 22. The toxic dose is defined as the dose at which T/C has dropped from its maximum value to 100. [c] T/C is the mean survival time of treated/control animals, in percent, and must be ≥125 for an active result.

Table II—Binding of the Anthracycline Drugs to DNA [a]

Compound	K_0[b] × 10^{-5} (PIPES/51 mM Na^+) [c]	K_0[b] × 10^{-5} (PIPES/201 mM Na^+) [c]
I	9.3	5.8

V	10.5	2.6
VI	5.8	1.6
VII	28.0	10.9

[a] Binding measurements were conducted using spectrophotometric changes at 480 nm as previously described (10, 11, 18). [b] K_0 represents the equilibrium constant for binding of a drug molecule to an isolated site on the DNA double helix. It is determined from the intercept on the vertical axis of a Scatchard plot of binding data. [c] 2 mM PIPES buffer, pH 7.8, with 40 mM NaCl added. [d] 2 mM PIPES buffer, pH 7.8, with 200 mM NaCl added.

active with V and VI showing greater activity than the parent compound I. Relative to I and II, all derivatives require larger amounts of compound (mg/kg) to reach both the optimum and toxic doses (Table I). The ratio of toxic to the optimal dose is approximately two for I and is not significantly increased for any of the derivatives. The activity of V and VI is quite encouraging and we have, therefore, analyzed the interaction of all of these compounds with DNA and have measured their octanol-water partition coefficients to determine how the biological testing results correlate with the binding and the partitioning properties.

Mode of Binding—Since I and II are known to bind to DNA by intercalation, IV through VII might also be expected to intercalate. A consistent indicator of intercalation is the ability of a drug to increase the length of linear DNA (20). All of the derivatives gave large increases in viscosity, as expected for intercalators in the presence of linear DNA[4] (16). The increases, at similar amounts of bound drug, were only ~80% of that obtained with I and II, indicating that replacing the keto function by the amino substituents perturbs the interaction of the anthracycline ring system with the double helix. It seems conclusive that all of the derivatives bind to DNA by intercalation, but the structure of the complex formed could be somewhat different from that for I and II with DNA.

DNA-Induced Absorption Spectral Changes and DNA Binding Studies—The anthracycline chromophore has an intense visible absorption band near 480 nm which exhibits shifts to longer wavelengths and hypochromism on intercalation with DNA. Similar effects are seen for the derivatives IV-VII as for I and II. These spectral changes can be used to calculate equilibrium constants for the interaction of the anthracyclines with DNA (14, 16). Because the binding of these compounds to DNA is complex (17), their interactions with DNA have been compared by determining the intercept on the vertical axis from Scatchard plots of spectrophotometric binding data. This limit should be the apparent equilibrium constant, K_0, for binding of a drug molecule to an isolated binding site in DNA (16). This method has the advantage of giving accurate relative binding strengths for a series of derivatives while not requiring any specific assumption about binding models for the DNA-drug interaction. A similar treatment has been used to compare the binding of antitumor platinum drugs with DNA (18). The results for derivatives IV-VII compared to I are shown in Table II at two different ionic strengths.

Inhibition of *Escherichia coli* RNA Polymerase—If the anthracyclines function in part by binding to DNA, they should exert dramatic effects on the biological as well as the physical properties of DNA. The potential biological inhibition in a standard *E. coli* RNA polymerase assay system (9) was mon-

[a] Testing results and column headings are as in Table I. [b] All compounds were prepared at a 1:5 ratio of drug to DNA as described in the *Experimental Section*: nDNA is native salmon sperm DNA; sDNA is sonicated; dDNA is denatured. [c] Doses are calculated based on the amount of drug in the DNA–drug complex. The actual dose of the complex was six times greater than that indicated. [d] This indicates the maximum dose administered in the test. The optimum or toxic doses may be greater than this value.

itored and the results are shown in Table III. As with other anthracycline derivatives, the polymerase inhibition results parallel binding interactions (13, 14) and strong inhibition of the polymerase is obtained for IV–VII.

Partition Coefficients—The charged amine function on an already slightly polar parent molecule obviously has the potential for reducing membrane permeability. Octanol–buffer partition coefficients (15) were determined to assess the relative ability of the derivatives to pass through membranes as compared to I and II. The partition coefficients are listed in Table IV and, as expected, show decreases for IV, VI, and a large decrease for VII. The butyl derivative actually partitions better into the organic phase than I.

DNA–Anthracycline Complexes: Biological Testing—It has been proposed that complexes of drugs such as the anthracyclines with suitable biopolymers should be absorbed faster into tumor cells than into normal cells due to the higher potential endocytic activity of tumor cells (21). Since the absorption of drugs through their macromolecular complexes should depend much less on their partition coefficients than absorption of free drugs, complexes of I, II, V, VI, and VII with DNA were prepared. The testing results for these complexes are shown in Table V. As can be seen from the results with I, the physical state of the DNA has some effect on activity, with the native high molecular weight DNA complex giving higher activity than the sonicated or denatured samples. The complex of I with native DNA has higher activity than I alone, has a similar optimum dose (based on the amount of drug in the dose), and has a significantly improved chemotherapeutic index as compared with uncomplexed I. The results with the derivatives indicate similar behavior. The complex with VI could not be thoroughly investigated due to limitations in the amount of material available. The complex with VII was better than the free drug but not as significantly improved as one might expect based on its DNA binding properties. The complex with V shows marked improvement and has the highest activity in this series.

DISCUSSION

All of the derivatives of this study have been shown to bind strongly to DNA through an intercalation complex. The enhanced binding of IV and V relative to I is due to increased sodium ion release by these compounds on complexation with DNA (16). This might also partially account for the greater binding of VII, but the large enhancement for this compound, even at higher ionic strength, indicates some additional favorable interactions with DNA. At the higher ionic strength, which is closer to physiological conditions, only VII binds to DNA better than I. The slightly reduced binding of VI could be due to problems of hydration of the alcohol in the complex *versus* the free solution state.

Compounds IV and V bind quite similarly to DNA (Table II) whereas VII binds much more strongly to DNA than IV or V but partitions poorly (Table IV) and has the lowest activity of all of the compounds of this series. The propanolamine derivative VI has a lower binding constant than the other analogues (although it still binds strongly to DNA), and it has an intermediate partition coefficient. This compound has the highest *in vivo* activity of any of the derivatives and is more active than the parent compound I. Although there are too few compounds here to construct a structure–activity plot, it is interesting to note that dauxorubicin hydrochloride also has high activity coupled with a high DNA binding constant and an intermediate partition coefficient. This suggests that activity for those anthracycline derivatives which bind strongly to DNA and do not have other complicating factors might be found to peak at a partition coefficient of ~0.7. The low dose of II required relative to VI could be due, in part, to the larger DNA binding constant of II (Table II). Further investigation with a series of anthracyclines with partition coefficients of ~0.7 and high DNA binding constants would be of interest.

Because of the high DNA binding constant and low partition coefficient for VII it was expected that a dramatic enhancement in activity against P388 might be obtained for this compound through preparation and administration of a DNA complex. This idea is based on the so called "lysosomotropic" principle, which predicts selective uptake by antineoplastic cells of high molecular weight macromolecule–drug complexes. This delivery system could potentially increase the efficacy of the complexed drug relative to the free species, especially for derivatives such as VII which have low partition coefficients but bind strongly to DNA. As can be seen by comparison of biological testing results on VII in Tables I and V, although activity was increased, the results were not remarkable. All of the compounds analyzed as DNA complexes had similar optimal doses both complexed and uncomplexed. The toxic doses were generally significantly increased in the complexes relative to the uncomplexed derivatives. This suggests that the DNA is acting more to prevent toxicity than enhance activity. Obviously, if toxicity is lowered, the mean survival time for treated/control animals (T/C) at the maximum could rise slightly as the probability of a toxic reaction is shifted to higher dose levels relative to the optimum dose. Metabolic reactions, such as aglycon formation, would also be expected to be slower when an anthracycline is bound to DNA; this may be one of the major advantages of administering these compounds as DNA complexes. The activity of the V–DNA complex is encouraging and this compound and its DNA complex are being further investigated in *in vivo* systems.

Liquid Membrane Phenomenon in Diuretics

S. B. BHISE, D. BHATTACHARJEE, and R. C. SRIVASTAVA ˣ

Received March 17, 1983, from the *Birla Institute of Technology and Science, Pilani-333031, India.* Accepted for publication February 24, 1984.

Abstract □ Surface activity and critical micelle concentrations are reported for two diuretic drugs, furosemide and triamterene. The drugs generate a liquid membrane on a supporting membrane. Transport of chloride, sodium, and potassium ions through the liquid membranes generated by the drugs was studied. The data suggest that the phenomenon of liquid membrane formation may contribute to the diuretic action.

Keyphrases □ Diuretics—liquid membrane phenomenon, critical micelle concentrations, chloride, sodium, potassium ion transport, furosemide, triamterene □ Furosemide—liquid membrane phenomenon, anion/cation transport □ Triamterene—liquid membrane phenomenon, anion/cation transport

Drugs known to act by altering the permeability of cell membranes are mostly surface active. Surface-active agents added to an aqueous phase are known to generate a surfactant-layer liquid membrane at the interface which modifies material transport across it (1). It is therefore likely that the liquid membranes generated by surface-active drugs play a role in the mechanism of drug action. A wide category of surface-active drugs have been investigated in this laboratory (2-7), and results indicated that the liquid membranes contribute to the mechanism of drug action.

Most of the high-ceiling diuretics (8) are known to act by altering the reabsorption of cations (*e.g.*, Na^+) and anions (*e.g.*, Cl^-) in the ascending limb of the loop of Henle (8). Although diuretics act by modifying the membrane permeability, their surface activity is not documented in the literature. In the present study, surface activity of these drugs is demonstrated—critical micelle concentrations (CMC) have been determined—and the existence of liquid membranes generated by them at the interface is confirmed. Transport of relevant cations and anions in the presence of the liquid membranes generated by the drugs has been studied. The data indicate that the liquid membranes generated by the diuretic drugs contribute to the mechanism of their action. A cellulose nitrate microfiltration membrane/aqueous interface was chosen as a site for the formation of the liquid membranes to eliminate the possibility of active and specific interaction of the drugs with the constituents of the biological membranes and to highlight the role of passive transport through the liquid membranes. Two structurally dissimilar diuretic drugs (furosemide and triamterene) were chosen for the present study.

EXPERIMENTAL SECTION

Material—Furosemide[1], triamterene[2], sodium chloride[3], potassium chloride[3], and water (glass distilled over potassium permanganate) were used.

Methods—The critical micelle concentration (CMC) of aqueous furosemide and triamterene solutions were determined from the variation in surface tension with concentration at 37 ± 0.1°C. The surface tensions were measured using a tensiometer[4]. To prepare an aqueous solution of furosemide, the drug

was dissolved in acetone and added (stirred constantly) to the aqueous phase. The concentration of acetone in all the furosemide solutions was ≤0.4% (v/v). A corresponding control solution with 0.4% (v/v) acetone was used as a blank. For preparing aqueous solutions of triamterene, a 0.12% (v/v) aqueous solution of dioxane was used as a solvent. A corresponding blank solution, without triamterene, was used for comparison of surface tension values. The CMC values for furosemide and triamterene were 8.3×10^{-5} and 1×10^{-5} M, respectively.

The all-glass transport cell previously desribed (2) was used for the transport studies. A cellulose nitrate microfiltration membrane[5], which acted as support for the liquid membrane, separated the cell into two compartments, C and D. The hydraulic permeability data were obtained at concentrations below and above the CMC values of the drugs, using the method previously described (2).

The solute permeability (ω) of chloride ions was measured in the presence of furosemide; that of sodium and potassium ions was measured in the presence of triamterene using (9, 10):

$$\left(\frac{J_s}{\Delta\pi}\right)_{J_V=0} = \omega \qquad \text{(Eq. 1)}$$

where J_s and J_V are, respectively, the solute flux and the volume flux per unit area of the membrane; $\Delta\pi$ is the osmotic pressure difference across the membrane. The method of measurement has been described (2).

Two sets of experiments were performed for solute permeability measurements. In the first set, aqueous solutions of the drugs and the permeating species were kept in one compartment (compartment C of the transport cell, Fig. 1. of Ref. 2) and the other compartment (D) was filled with distilled water. In the second set of experiments, aqueous solutions of the drugs were taken in compartment D while compartment C contained aqueous solutions of the permeating species. No drug was used in the control experiments. Since hydrophobic ends of the surface-active drugs would be preferentially oriented towards the hydrophobic supporting membrane (the cellulose nitrate microfiltration membrane) in the first set of experiments, the permeating species would face the hydrophilic surface of the drug liquid membrane. In the second set of experiments, however, the permeating species would face the hydrophobic surface of the drug liquid membranes.

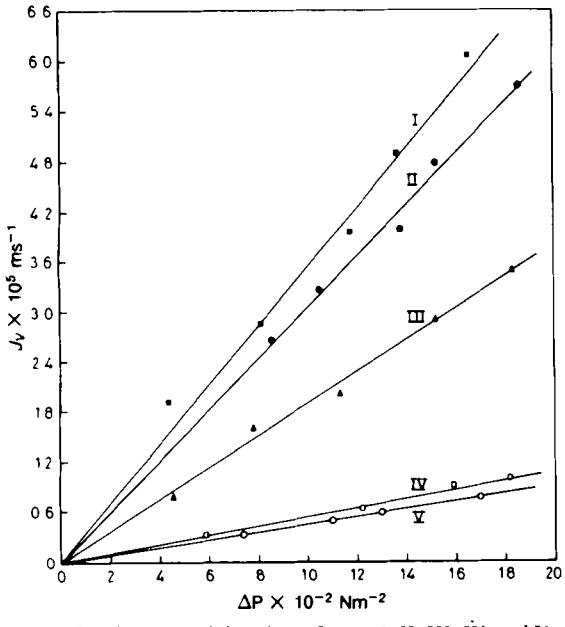

Figure 2—*Hydraulic permeability data. Curves I, II, III, IV, and V are for 0, 2.0×10^{-6}, 5.0×10^{-6}, 1.0×10^{-5}, and 3.0×10^{-5} M triamterene concentrations, respectively.*

[5] Cat. No. 11307; Sartorius (thickness, 1×10^{-4} M; area, 1.794×10^{-5} m^2).

The concentrations of the diuretic drugs used in the solute permeability experiments were always higher than their CMC values to ensure that the supporting membrane was completely covered by the liquid membranes generated by them. The concentration of furosemide was 2.5×10^{-4} M and that of triamterene was 3.0×10^{-5} M. Fifteen replicates were taken for each value of ω. All measurements were made at a constant temperature using a thermostat set at 37 ± 0.1°C.

Assays—The amount of chloride ions transported to the other compartment was measured by the spectrophotometric[6] determination at 540 nm of its product with brucine[3] and potassium persulfate[3] (11). The amounts of sodium and potassium ions transported to the other compartment were measured using a flame photometer[7].

RESULTS AND DISCUSSION

Hydraulic Permeability Data—The hydraulic permeability data at various concentrations of the diuretic drugs, in the case of both furosemide and triamterene, were found to obey the linear relationship (9);

$$J_V = L\Delta P \qquad \text{(Eq. 2)}$$

where J_V represents the volume flux per unit area of the membrane, ΔP is the applied pressure difference, and L is the hydraulic conductivity coefficient. The data for furosemide and triamterene are shown in Figs. 1 and 2, respectively. The values of L, calculated from the slopes of the straight lines in Figs. 1 and 2, show a progressive decrease (Table I) with increase in drug concentration up to the CMC, after which they become more or less constant. This gradation (Table I) is in keeping with the liquid membrane hypothesis (1) and indicates the progressive coverage of the supporting membrane with the liquid membrane with an increase in the concentration of the drug up to its CMC; at this concentration it is completely covered. Analysis of the flow data (Figs. 1 and 2, Table I) in the light of the mosaic membrane model (12–14) furnishes additional support for liquid membrane formation in series with the supporting membrane. The values of L (for both furosemide and triamterene), calculated using the mosaic membrane model at concentrations below the CMC values of the drugs, match the experimentally determined values (Table I) lending support to liquid membrane formation. The method of calculation is described in earlier publications (2–7).

Role of Liquid Membrane Formation in Diuretic Action—The primary action of furosemide is to reduce active absorption of chloride ions (8). The results indicate that the liquid membrane formed by furosemide, even on an inert support, impedes the transport of chloride ions (Table II). Similarly, the liquid membrane generated by triamterene offers resistance to the transport of Na^+ and K^+ ions (Table II). The significance of these observations is enhanced because the concentrations at which the complete liquid membranes are generated in series with the supporting membrane are low (on the order of μM) and compares favorably with the concentrations of these drugs in renal tubules (15, 16).

In the case of triamterene, the data indicate (Table II) that the transport of potassium ions is impeded more than the transport of sodium ions. This agrees with the reported observations on biological cells that triamterene is a potassium-sparing diuretic (17). In spite of the fact that in the present study an inert membrane like cellulose nitrate microfiltration membrane was used as support for the liquid membranes, the trend observed in the permeability of the cations is similar to that expected in biological cells. This strongly indicates that the liquid membranes generated by diuretic drugs, like triamterene, play a significant role in the mechanism of its action.

An examination of Table II reveals that the resistance offered to the transport of chloride ions (in the case of furosemide) and that of potassium ions (in the case of triamterene) is maximal when the liquid membranes generated by these drugs presented a hydrophilic surface to the approaching

permeating species (the first set of experiments). In the light of these observations, it appears likely that the action sites of diuretic drugs like furosemide and triamterene themselves may be hydrophobic so that the hydrophobic ends of these drugs get attached to them leaving the hydrophilic parts to face the permeating species. If the action sites are hydrophobic they should be located within the hydrophobic core of the lipid bilayer of the membranes. To substantiate these conjectures, which appear logical in the light of the trends observed in the present experiments, further investigations are needed.

The permeability of sodium ions is impeded most when the triamterene liquid membrane presents its hydrophobic surface to the cation (Table II). The observation, however, is of limited biological significance because triamterene is known to be a potassium-sparing diuretic (17).

Diuretic drugs are also known to cause reduction in bile flow (18) and to alter ionic fluxes across isolated erythrocytes (19). The phenomenon of liquid membrane formation may be a plausible explanation for these effects. The decrease in reabsorption of water which results in diuresis is considered mainly a consequence of modification in the permeability of ions (8). The present study, however, indicates that the liquid membrane generated by the diuretic drug itself offers resistance to volume flux of water.

Though the observed reduction in permeability of the ions (Table II), due to the liquid membrane generated by the drugs, is passive in nature, it is likely to be accompanied by a consequent decrease in active transport. This would occur because access of the permeating species to the active sites on the biological membrane would be reduced due to the formation of the liquid membranes in series with the biological membrane. Thus, the liquid membranes generated by diuretic drugs may contribute significantly to the mechanism of drug action by impeding transport of ions as well as water.

Difference Spectrophotometric Assay of 1,2-Diphenolic Drugs in Pharmaceutical Formulations II: Germanium Dioxide Reagent

ALEXANDER G. DAVIDSON

Received August 8, 1983, from the *Department of Pharmacy, University of Strathclyde, Glasgow G1 1XW, United Kingdom.* Accepted for publication November 28, 1983.

Abstract □ A rapid, difference UV spectrophotometric assay of formulated drugs containing a 1,2-diphenolic group is described. In this assay are utilized the bathochromic shift of the absorption band of 1,2-diphenolic substances from ~280 to ~287 nm and the concomitant hyperchromic effect induced by the addition of germanium dioxide to an aqueous solution of the drug buffered at pH 6. The absorbance of the solution of the complexed drug relative to that of an equimolar solution of the free drug, which is maximum at ~292 nm, is proportional to the concentration of the drug and is unaffected by the presence of other UV-absorbing substances in the formulations that lack the 1,2-diphenolic moiety. Applications of the assay are described for formulations containing epinephrine, isoetharine, isoproterenol, levodopa, and methyldopa.

Keyphrases □ 1,2-Diphenolic drugs—difference UV assay in formulations □ Difference absorption spectrophotometry—assay of 1,2-diphenolic substances

To avoid the interference that may occur in conventional UV-spectrophotometric procedures for the determination of 1,2-diphenolic drugs [*e.g.*, epinephrine (adrenaline), levodopa, and methyldopa] in formulations due to the presence of coformulated drugs, oxidation products, and formulation excipients, many of the absorption spectrophotometric methods currently employed involve the conversion of the drugs to colored derivatives and the measurement of absorbance in the visible region (1–5). In a previous report (6), a new difference UV-spectrophotometric procedure for drugs containing a 1,2-diphenolic moiety was described, based on the measurement of the difference absorbance (ΔA) at ~292 nm between two equimolar solutions of the drug in pH 7 phosphate buffer, one of which also contains 0.1 M boric acid. The boric acid esters of the drugs form very rapidly and have a longer wavelength of maximum absorption (λ_{max}) and a greater absorptivity than the nonesterified drug. The absorbance of the solution containing boric acid relative to that of the nonesterified drug is proportional to the concentration of the drug and is unaffected by the presence of other UV-absorbing substances in the sample, including monophenols, provided that the absorbance of these substances at the wavelength of measurement is unchanged by the boric acid.

Dihydroxylic and polyhydroxylic substances are known to react with other inorganic acids in addition to boric acid, *e.g.*, arsenious acid (7), orthotelluric acid (8), and germanium dioxide[1] (9, 10). The reaction of germanium dioxide with certain dihydroxylic and polyhydroxylic reagents has been used in both the identification (11) and quantitative determination (12) of trace levels of germanium. In this report, the reagent germanium dioxide is examined for application in the difference spectrophotometric assay of 1,2-diphenolic drugs.

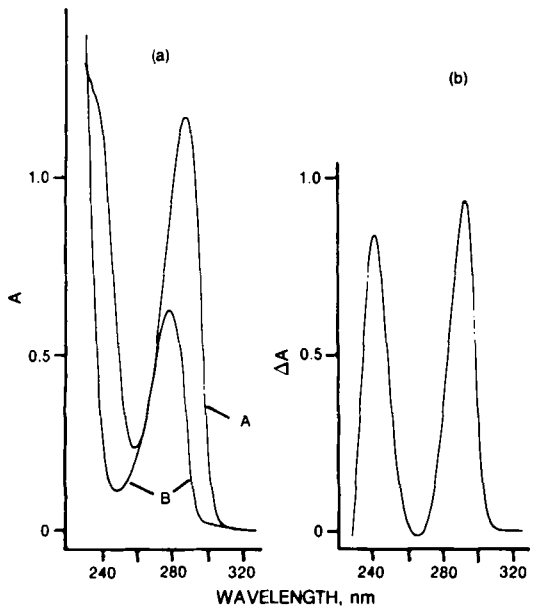

Figure 1—*(a) UV absorption spectra of aqueous solutions of epinephrine bitartrate (2×10^{-4} M) at pH 6 in the presence (A) and absence (B) of germanium dioxide (0.4 mg·mL^{-1}). (b) Difference UV absorption spectrum of epinephrine bitartrate (2×10^{-4} M) (solution A relative to solution B).*

EXPERIMENTAL SECTION

Apparatus—Absorption and difference absorption spectra of solutions in 1-cm silica quartz cells were recorded from 330 to 220 nm with a recording double-beam UV-visible spectrophotometer[2]. The spectral slit width was 1 nm, the scan speed was 1 nm s^{-1}, and the response (time constant) was 0.5 s.

Reagents—Epinephrine bitartrate[3], isoproterenol sulfate[4], isoetharine hydrochloride[5], levodopa[6], and methyldopa[6] were obtained commercially. Stock buffer (pH 6) was prepared by dissolving 9.67 g of citric acid and 22.40 g of anhydrous sodium monohydrogen phosphate in water and diluting to 500.0 mL. The working buffer (pH 6) was prepared by diluting 100.0 mL of stock buffer to 500.0 mL with water. The germanium dioxide reagent was prepared by dissolving, with heat, 500 mg of germanium dioxide[3] in 100.0 mL of stock buffer (pH 6); the solution was allowed to cool and diluted to 500.0 mL with water.

Standard Solutions—Approximately 50 mg of the reference substance was accurately weighed into a 250.0-mL calibrated flask, dissolved in 50 mL of water and 2.5 mL of 0.1 M HCl[7], and diluted to volume with water. A 5.0-mL aliquot was transferred to each of two 25.0-mL calibrated flasks containing 10 mL of pH 6 buffer and 10 mL of germanium dioxide reagent, respectively, and diluted to volume with water. Five minutes later, the absorbance (at the wavelength of maximum difference absorbance, ~292 nm) of the solution containing germanium dioxide in the sample cell was measured relative to that of the free drug in the reference cell. The measured difference in absorbance was corrected only for the blank buffer solutions, which were prepared by diluting the pH 6 buffer and the germanium dioxide reagent (2:3) with water, as described above for the standard solutions.

Sample Solutions—*Aqueous Formulations*—The samples were diluted with water to give a 0.2-mg·mL^{-1} drug concentration based on the declared

concentration of the drug in the formulation, and the assay was continued as described above.

Tablets—Twenty tablets were weighed and powdered. Powder containing ~20 mg of drug was shaken mechanically with 80 mL of water and 1 mL of 0.1 M HCl[7] for 30 min and then diluted with water to 100.0 mL in a calibrated flask. The extract was clarified through filter paper[8]. The first 10 mL was discarded, and the assay was continued as described above.

Treatment of the Results—The concentration of drug in the sample solutions, and hence in the sample, was calculated from the proportional relationship that exists between the measured difference absorbance and the concentration of the drug.

RESULTS AND DISCUSSION

Potentiometric investigations have shown that strong chelates are formed between germanium and dihydroxylic and polyhydroxylic compounds with at least two hydroxyl groups in the vicinal position. Germanium-ligand chelates, 1:1 or 1:2, are formed with glycols and polyhydroxylic sugars (13), whereas 1,2-diphenols form chelates with 1:3 ratios (14).

Complexation of 1,2-diphenols with germanium dioxide, like that with boric acid (6), induces a bathochromic shift of their UV-absorption bands (15). The effect is illustrated in Fig. 1a for aqueous solutions of epinephrine at pH 6, where a shift in the λ_{max} from 279 nm to 287 nm and a large increase in absorbance in the presence of germanium dioxide is shown. The maximum ΔA of the solution of epinephrine in the presence of germanium dioxide relative to an equimolar solution of free drug occurs at 291.5 nm, which is almost identical to that of the epinephrine–boric acid product (6). The magnitude of the $\Delta A_{291.5}$ generated by the germanium dioxide reagent was, however, ~75% greater than that given by boric acid (Table I). Other 1,2-diphenolic substances give similar values for the wavelength of maximum ΔA (292 ± 0.5 nm) [except for 1,2-benzenediol (287 nm) and 3-methyl-1,2-benzediol (285 nm)] with a corresponding increase in ΔA values compared with those given by boric acid (Table I).

The pH and the concentration of germanium dioxide were chosen to provide conditions of high sensitivity, reproducible ΔA, and a proportional relationship between the measured ΔA and concentration of drug. The effects of variation of pH and concentration of germanium dioxide on the absorbance at 291.5 nm of equimolar solutions of epinephrine (1.4×10^{-4} M) are shown in Fig. 2. The highest $A_{291.5}$ was obtained with the higher pH values and concentrations of germanium dioxide. Parallel investigations of the assay conditions, however, showed that, although there was a linear relationship significant at the 99% confidence level between the measured $\Delta A_{291.5}$ and the concentration of epinephrine, a small but not insignificant negative intercept was consistently obtained when the solutions were buffered at pH 7. This was not observed with solutions at pH 6. Therefore, pH 6 and a final germanium dioxide concentration of 0.4 mg·mL^{-1} (3.8×10^{-3} M) were chosen for the assay as a compromise which satisfied the requirements of high sensitivity and the proportionality of the measured value with concentration of analyte. The smaller concentration of germanium dioxide necessary for maximum complex formation compared with that of boric acid (0.1 M) is consistent with the observation that the stability constants of 1,2-diphenol–germanium complexes are considerably higher than those of the boric acid esters (15).

Although the 1,2-diphenol–germanium complexes appear to form rapidly, as observed by an almost instantaneous increase in the ΔA_{292} on mixing of the reagents, there is a gradual decrease of ~2% in the A_{292} of the complex during the first 5 min, after which the A_{292} and ΔA_{292} are stable for at least an additional 30 min. Measurement of the ΔA was, therefore, carried out 5 min after the preparation of the solutions.

Validation—All five drugs for which assays of formulations have been developed (Table II) were found to show a proportional relationship between the ΔA at its λ_{max} at ~292 nm and the concentration of the drug in the range of 0–60 μg·mL^{-1} when the solutions were buffered at pH 6. For example, the linear regression equation for epinephrine bitartrate was $y = 0.01307x - 0.0011$, where y is $\Delta A_{291.5}$ and x is the concentration of the drug in micrograms per milliliter ($n = 6$; correlation coefficient = 0.99998). The other four drugs also gave satisfactory linear graphs with intercepts which, being <0.5% of the measured ΔA at the analytical concentration of 40 μg·mL^{-1}, were negligible. For comparison, the linear regression equation for a similar series of solutions of epinephrine bitartrate buffered at pH 7 was $y = 0.01388x - 0.0224$, confirming the slightly greater sensitivity and unsatisfactory proportionality of the measured value and concentration at this pH.

In precision studies in which a sample of adrenaline injection BP was assayed 10 times by the described procedure, the mean concentration was found to be 100.7% of the declared amount, and the *RSD* of $\Delta A_{291.5}$ of the sample solutions was 0.27%, indicating that the reproducibility of the measured value was excellent.

To investigate the specificity of the procedure for 1,2-diphenolic substances, a number of monophenols, diphenols, and triphenols were examined for difference absorbance at 292 nm under the conditions of the assay. The results in Table I indicate the $\Delta\epsilon_{292}$ for those substances that contain a 1,2-diphenolic group. Also shown are the ratios of difference absorptivity at 292 nm, using germanium dioxide and boric acid reagents, to the absorptivity of the free drug at its λ_{max} (~280 nm). The results demonstrate that the ΔA generated by germanium dioxide is 40–64% greater than the absorbance of the free drug and that the ΔA procedure using germanium dioxide is more sensitive than both a conventional UV-spectrophotometric assay and the ΔA procedure using boric acid.

Substances containing a 1,2,3-triphenolic group show difference absorbance, also observed for the boric acid reagent (6), although the λ_{max} of the complexes and their $\Delta\epsilon_{292}$ are much less consistent than those given by the 1,2-diphenols.

Monophenols (*o*-, *m*-, and *p*-cresols; *o*-, *m*-, and *p*-aminophenols; 4-methyl-2-nitrophenol; 2-methoxyphenol; 4-chloro-*m*-cresol; *p*-hydroxybenzoic acid; orciprenaline; acetaminophen; 2,7-dihydroxynaphthalene; salicylaldehyde), diphenols (resorcinol and hydroquinone), and a triphenol (phloroglucinol) lacking the 1,2-diphenolic group do not display difference absorbance and do not interfere in the ΔA procedure for 1,2-diphenolic substances. Salicylic acid and salicylamide, which were found to give weak ΔA_{292} values with boric acid (6), gave zero ΔA_{292} values with the germanium dioxide reagent. Papaverine, hydrochlorothiazide, and atropine, which are coformulated drugs in certain formulations of 1,2-diphenolic drugs (Table II), also give zero ΔA_{292} values and do not interfere in the assay. The coincidence of the isosbestic points at ~270 and 263 nm in the difference spectra of the sample solutions and appropriate reference solutions (*i.e.*, wavelengths of zero difference absorbance due to the equal absorptivity of the complexed and free forms of the drug) provide additional evidence of the selectivity of the procedure (6).

Assay Results—The accuracy of the ΔA procedures for formulations was investigated by comparing the results obtained in this study with those given by the official procedures of the British Pharmacopoeia (16, 17) and British Pharmaceutical Codex (18, 19) for preparations containing a 1,2-diphenolic drug, that were either commercial samples purchased locally or samples prepared in the laboratory by compendial formulations.

The results in Table II indicate that good agreement was achieved between the assay values of the ΔA procedure and the official procedures for both the prepared samples and the commercial samples, including those containing UV-absorbing substances that interfere in a conventional UV assay. The excellent recoveries of added drugs in the prepared samples confirm the accuracy of the ΔA method and indicate its application as a rapid and selective procedure for the assay of 1,2-diphenolic drugs in formulations.

Synthesis and Dopaminergic Activity of 3-(3,4-Dihydroxyphenyl)-1-*n*-propylpyrrolidine Hydrobromide

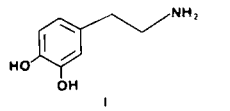
A. MICHAEL CRIDER *§ˣ, TALAL F. HEMDI *, MOHAMED N. HASSAN ‡, and STANLEY FAHN ‡

Received June 20, 1983, from the *College of Pharmacy, University of Toledo, Toledo, OH 43606 and the ‡Department of Neurology, Columbia University College of Physicians and Surgeons, New York, NY 10032. Accepted for publication December 12, 1983. Present address: §School of Pharmacy, Northeast Louisiana University, Monroe, LA 71209

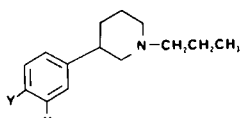
Abstract □ 3-(3,4-Dihydroxyphenyl)-1-*n*-propylpyrrolidine hydrobromide was synthesized by a six-step reaction sequence and was evaluated, and compared with apomorphine, for central dopaminergic agonist activity. The compound produced behavioral and biochemical changes characteristic of central dopaminergic stimulation. Administration of 3-(3,4-dihydroxyphenyl)-1-*n*-propylpyrrolidine hydrobromide to rats resulted in the reversal of the reserpine syndrome, stereotypic behavior, contralateral turning following 6-hydroxydopamine lesion of the substantia nigra, a decrease in dopamine turnover, and inhibition of prolactin release. These results indicate that 3-(3,4-dihydroxyphenyl)-1-*n*-propylpyrrolidine hydrobromide is a dopaminergic agonist. However, the compound exhibited a lower potency but a slightly longer duration of action than apomorphine.

Keyphrases □ 3-(3,4-Dihydroxyphenyl)-1-*n*-propylpyrrolidine hydrobromide—synthesis, central dopaminergic activity, compared with apomorphine □ Dopaminergic activity—central, apomorphine, 3-(3,4-dihydroxyphenyl)-1-*n*-propylpyrrolidine hydrobromide

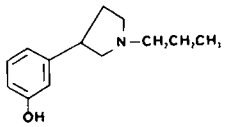
In an attempt (1) to prepare compounds with dopaminergic activity, our efforts were directed toward the synthesis of a compound in which the ethylamine chain of dopamine (I) is embodied in a pyrrolidine ring. Specifically, the purpose of this investigation was to synthesize and evaluate the dopaminergic activity of 3-(3,4-dihydroxyphenyl)-1-*n*-propylpyrrolidine (XI). The substitution of an *n*-propyl group on nitrogen has been shown to optimize activity in a variety of dopamine agonists (2, 3). Thus, the *n*-propyl substitution on the pyrrolidine ring nitrogen should maximize dopaminergic activity.



I

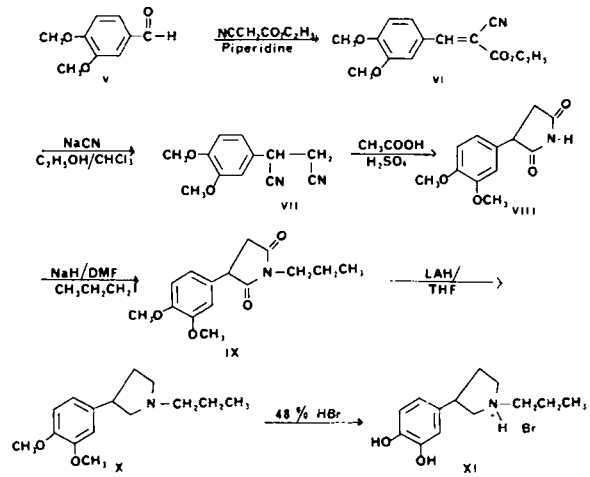


II : X = OH, Y = H
III : X = OH, Y = OH



IV

During the course of this investigation, a preliminary report indicated that II was a selectively acting dopamine autoreceptor agonist (4). Further testing of II has shown that this compound is a centrally acting dopamine autoreceptor agonist (5, 6). Structure-activity studies revealed that the pyrrolidine analogue IV of 3-(3-hydroxyphenyl)-1-*n*-propylpiperidine (II) was very weak as a dopamine autoreceptor agonist (7). These workers did not report the synthesis and biological activity of the target compound of their investigation. However, the (3,4-dihydroxyphenyl)piperidine III was prepared and pharmacologically evaluated. Compound III, unlike II, exhibited potent postsynaptic dopaminergic agonism.



Scheme I

EXPERIMENTAL SECTION[1]

Ethyl α-Cyano-β-(3,4-dimethoxyphenyl)acrylate (VI)—A mixture of 3,4-dimethoxybenzaldehyde (V) (20.0 g, 0.120 mol), ethyl cyanoacetate (12.8 g, 0.120 mol), and piperidine (1.5 mL) in toluene (200 mL) was heated to 110 °C. Water was removed during heating *via* a Dean-Stark trap. The mixture was cooled, and the solvent was removed under reduced pressure to yield 28.4 g (90%) of a light-yellow solid. An analytical sample was prepared by recrystallization from ethanol-chloroform to give VI, mp 156–158 °C [lit. (8) mp 155 °C]; IR (KBr): 2275 (C≡N), 1740 (C=O, ester), and 1610 cm^{-1} (C=C); ^{1}H-NMR ($CDCl_3$): δ 1.40 (t, 3, J = 8 Hz, CH_3), 3.97 (s, 6, OCH_3), 4.33 (q, 2, J = 8 Hz, CH_2), 6.83–7.80 (m, 3, ArH), and 8.17 ppm (s, 1, CH=C).

Anal.—Calc. for $C_{14}H_{15}NO_4$: C, 64.35; H, 5.80; N, 5.36. Found: C, 64.16; H, 5.95; N, 5.24.

(3,4-Dimethoxyphenyl)succinonitrile (VII)—Ethyl α-cyano-β-(3,4-dimethoxyphenyl)acrylate (35.0 g, 0.134 mol) was dissolved in a mixture of chloroform (400 mL) and ethanol (300 mL) and treated dropwise with a solution of sodium cyanide (6.90 g, 0.141 mol) in water (100 mL). The mixture was refluxed for 15 h, cooled, and acidified with concentrated hydrochloric acid. Evaporation of the solvents under reduced pressure gave a light-pink solid that was partitioned between water (300 mL) and chloroform (200 mL). The aqueous phase was extracted with chloroform (2 × 200 mL), and the combined chloroform extracts were dried (sodium sulfate), filtered, and evaporated to afford a light-pink solid. Recrystallization from ethanol afforded 24.4 g (84%) of VII, mp 108–110°C; IR (KBr): 2300 (C≡N), 1620 (ArH), and 1280 cm^{-1} (C—O, ether); ^{1}H-NMR (Me_2SO-d_6): δ 3.33 (d, 2, J = 7 Hz, CH_2CN), 3.80 (s, 6, OCH_3), 4.67 (t, 1, J = 6 Hz, CHCN), and 7.03 ppm (m, 3, ArH).

Anal.—Calc. for $C_{12}H_{12}N_2O_2$: C, 66.64; H, 5.60; N, 12.96. Found: C, 66.24; H, 5.67; N, 12.78.

2-(3,4-Dimethoxyphenyl)succinimide (VIII)—Compound VIII was prepared according to the procedure of Crooks (9) for the preparation of spirosuccini-

[1] Melting points were determined on a Fisher-Johns melting point apparatus and are uncorrected. IR spectra were recorded as potassium bromide pellets with a Perkin-Elmer 137 Spectrophotometer. NMR spectra were recorded on a Varian EM360A spectrometer. Chemical shifts are reported in parts per million (δ) relative to tetramethylsilane (1%) or, in the case of D_2O (1%), sodium 2,2-dimethyl-2-silapentane-5-sulfonate. Analytical data were obtained from Micro-Analysis Inc., Wilmington, DE. Male Sprague-Dawley rats weighing 175–225 g were given free access to food and water and exposed to a 14:10 h light-dark cycle. Drugs were administered by intraperitoneal injections. Drugs and analytical-grade chemicals were purchased from commercial sources. Spiperone was a gift from Janssen Pharmaceutical Company, Inc. (New Brunswick, NJ). The vehicle for XI and apomorphine was 0.01 M sodium bisulfite solution.

Table I—Behavioral Changes Effected by Apomorphine and XI [a,b]

Treatment	Catalepsy	Stereotypy	Locomotor Activity	Number of Rotations
Control	3	0	250 ± 35	0
Apomorphine	0	3	1825 ± 225	650 ± 125
XI	0	3	1798 ± 206	635 ± 140

[a] Catalepsy, stereotypy, and locomotor activity were assessed in rats ($n = 6$) pretreated with reserpine (5 mg/kg). Catalepsy and stereotypy were scored (see text) before the administration, and at the time of peak effect, of the dopamine agonists. Rotating rats ($n = 9$) were treated with dopamine agonists or vehicle. Results are expressed as mean ± *SEM*. All changes were statistically significant ($p < 0.05$). [b] Apomorphine and compound XI were administered at dosages of 2 and 100 mg/kg ip, respectively.

Table II—Biochemical Effects of Apomorphine and XI [a,b]

Treatment	Dopamine	Dihydroxyphenylacetic Acid	Homovanillic Acid	Prolactin
Control	7.2 ± 0.4	0.75 ± 0.3	0.44 ± 0.4	20.0 ± 4.0
Apomorphine	9.0 ± 0.5	0.50 ± 0.3	0.28 ± 0.4	2.0 ± 1.0
XI	10.1 ± 0.4	0.46 ± 0.5	0.24 ± 0.3	4.5 ± 2.5

[a] Dopamine, dihydroxyphenylacetic acid, and homovanillic acid are expressed as nanogram per milligram of striatal tissue, and prolactin as nanogram per milliliter of serum. The results represent the mean ± *SEM* of $n = 5$. All changes were statistically significant ($p < 0.05$). [b] Apomorphine and XI were administered at doses of 2 and 100 mg/kg ip, respectively.

mides. A mixture of (3,4-dimethoxyphenyl)succinonitrile (25.6 g, 0.118 mol), glacial acetic acid (150 mL), and 78% sulfuric acid (25 mL) was refluxed for 1 h, cooled, and evaporated under reduced pressure. The resulting mass was triturated with water (300 mL), and the solid material was removed by filtration. Recrystallization from ethanol gave 12.9 g (46%) of white crystals, mp 181–183°C; IR (KBr): 1785 (C=O, imide), 1725 (C=O, imide), and 1280 cm^{-1} (C—O, ether); ^{1}H-NMR (Me_2SO-d_6): δ 2.90 (m, 2, ring CH_2), 3.70 (s, 6, OCH_3), 4.03 (m, 1, ring CH), and 6.87 ppm (m, 3, ArH).

Anal.—Calc. for $C_{12}H_{13}NO_4$: C, 61.26; H, 5.58; N, 5.96. Found: C, 61.15; H, 5.60; N, 5.97.

2-(3,4-Dimethoxyphenyl)-*N*-(*n*-propyl)succinimide (IX)—A 50% mineral oil dispersion of sodium hydride (5.28 g, 0.11 mol) was washed with hexane (3 × 30 mL) and suspended in dimethylformamide (100 mL). A solution of 2-(3,4-dimethoxyphenyl)succinimide (25.8 g, 0.11 mol) in dimethylformamide (100 mL) was added to the sodium hydride suspension in a dropwise manner while maintaining a nitrogen atmosphere. After the addition had been completed, the mixture was heated at 80°C for 2 h and cooled to room temperature. A solution of *n*-propyl iodide (18.7 g, 0.11 mol) in dimethylformamide (30 mL) was added dropwise and the mixture was heated at 80°C for 15 h. The mixture was cooled, treated with a few drops of absolute ethanol, filtered, and the solvent was evaporated to give a light-tan solid. Recrystallization from isopropyl alcohol yielded 18.7 g (61%) of a white solid, mp 76–77°C; IR (KBr): 1785 (C=O, imide) and 1725 cm^{-1} (C=O, imide); ^{1}H-NMR ($CDCl_3$): δ 0.90 (t, 3, $J = 6$ Hz, CH_3), 1.33–4.07 (m, 13, including singlet 3.90, OCH_3), and 6.80 ppm (m, 3, ArH).

Anal.—Calc. for $C_{15}H_{19}NO_4$: C, 64.95; H, 6.92; N, 5.05. Found: C, 64.79; H, 7.01; N, 4.93.

3-(3,4-Dimethoxyphenyl)-1-*n*-propylpyrrolidine (X)—A solution of IX (18.0 g, 0.065 mol) in anhydrous tetrahydrofuran (100 mL) was added to a suspension of lithium aluminum hydride (14.8 g, 0.389 mol) in tetrahydrofuran (100 mL). The mixture was refluxed for 19 h, cooled, and the excess lithium aluminum hydride was decomposed by the dropwise addition of water. The resulting sludge was filtered and the inorganic residue was washed with tetrahydrofuran (2 × 50 mL). The combined solvents were evaporated, and the residue was partitioned between chloroform (300 mL) and water (100 mL). The chloroform phase was dried (sodium sulfate), filtered, and the solvent was evaporated to afford a dark-brown oil. Vacuum distillation gave 12.0 g (74%) of a colorless oil, bp 136–138°C (0.7 mm). The hydrochloride of X was prepared and recrystallized from ethanol–ether to yield a white solid, mp 131–133°C; ^{1}H-NMR (D_2O): δ 1.13 (t, 3, $J = 6$ Hz, CH_3), 1.57–3.97 (m, 17, including singlets at 3.93 and 3.97, OCH_3), and 7.03 ppm (m, 3, ArH).

Anal.—Calc. for $C_{15}H_{24}ClNO_2$: C, 63.02; H, 8.48; N, 4.90. Found: C, 63.34; H, 8.35; N, 4.82.

3-(3,4-Dihydroxyphenyl)-1-*n*-propylpyrrolidine Hydrobromide (XI)—A solution of X (3.0 g, 0.012 mol) in 48% aqueous hydrobromic acid (30 mL) was refluxed for 3 h under a nitrogen atmosphere. The solvent was evaporated under reduced pressure, and water was removed from the resulting oil by azeotropic distillation with absolute ethanol several times. Trituration of the oil with ether gave a light-yellow solid. Recrystallization from absolute ethanol ether afforded 2.2 g (60%) of a tan solid, mp 152–154°C; IR (KBr): 3450 cm^{-1} (OH, phenol); ^{1}H-NMR (D_2O): δ 1.03 (t, 3, $J = 6$ Hz, CH_3), 1.30–4.47 (m, 11, aliphatic CH_2, ring CH_2, and ring CH), and 6.90 ppm (m, 3, ArH).

Anal.—Calc. for $C_{13}H_{20}BrNO_2$: C, 51.66; H, 6.68; Br, 26.44; N, 4.46. Found: C, 51.53; H, 6.55; Br, 26.34; N, 4.60.

Locomotor Activity—Rats treated 12–18 h previously with reserpine (5 mg/kg) were given vehicle, apomorphine (0.12–2.0 mg/kg), or XI (10–100 mg/kg) and tested for increases in locomotor activity. Locomotor activity[2] was monitored by the minute in single rats by electronic activity meters[3] with an input to a multichannel recorder. Testing was done every 5–7 d to allow recovery from the drugs.

Catalepsy—This was assessed, using the method of Kolbe *et al.* (10), by the length of time a reserpinized rat maintained an abnormal posture with its front paws over a bar (2 cm diameter) 7 cm from bench level. Catalepsy was scored in control reserpinized rats, and in experimental animals, just prior to drug administration and at the peak of effect of apomorphine or XI as follows: 0–9 s = 0; 10 s–2.5 min = 1; 2.6–5.0 min = 2; 5.1–10 min = 3; 10.1–20 min = 4; >20 min = 5.

Stereotypy—This was scored by the method of Kolbe *et al.* (10) at the peak effect of apomorphine or XI as follows: animals indistinguishable from vehicle-treated controls = 0; discontinuous sniffing and continuous locomotor activity = 1; continuous sniffing and discontinuous locomotor activity = 2; continuous sniffing and discontinuous biting, licking, or gnawing = 3; continuous compulsive biting, licking, or gnawing with no locomotor activity = 4.

Rotational Behavior—The left substantia nigra was lesioned according to the method of Reches *et al.* (11). Coordinates were AP −3.7 mm, L +1.9 mm, and DV −7.3 mm. Two weeks after lesioning, apomorphine (0.12–2.0 mg/kg) or XI (10–100 mg/kg) was administered and the resulting total number of rotations recorded. Rats were allowed 4–5 d between test doses. There was no rotation either spontaneously or in response to vehicle administration.

Effects of Apomorphine and XI on Dopamine Turnover—Rats were treated with vehicle, a single maximal dose of apomorphine (2 mg/kg), or XI (100 mg/kg), and the time courses of changes in striatal dopamine were determined. Dose-dependent changes in striatal dopamine were also obtained with apomorphine (0.12–2.0 mg/kg) and XI (10–100 mg/kg). In this study, rats were sacrificed at the times of peak effect of the dopamine agonists as determined from the time-response studies.

In the above studies, the animals were sacrificed by decapitation and the brains rapidly removed. The corpora striata were dissected on an ice-cold glass plate and immediately frozen on dry ice. Dopamine, dihydroxyphenylacetic acid, and homovanillic acid were measured by HPLC with electrochemical detection as previously described (12).

Effects of Apomorphine and XI on Serum Prolactin—Time and dose-dependent changes in serum prolactin induced by the dopamine agonists were investigated simultaneously with dopamine turnover. Following decapitation, trunk blood was collected and allowed to clot, samples were centrifuged at 5000×*g* for 5 min, and serum was stored at −70°C until assayed. Serum prolactin levels were determined by the double-antibody radioimmunoassay method using the reagents supplied by the NIAMDD rat pituitary hormones program. Results are expressed as nanograms per milliliter.

[^{3}H]Spiperone Binding—Competitive inhibition of [^{3}H]spiperone binding by the dopamine agonists was performed by the method of Seeman *et al.* (13) using fresh striatal membrane preparations. Protein concentrations, as measured by Lowry assay (14), were 250–400 ng/mL. Binding assays were performed in triplicate twice.

RESULTS AND DISCUSSION

Neuroleptic-induced hypomotility and catalepsy in rodents are dependent on the inhibition of dopaminergic function (15). The neuroleptic-induced state is antagonized by levodopa (16), apomorphine, or bromocriptine (17). Reserpine induces experimental parkinsonism because it depletes presynaptic dopamine by inhibiting the ATP-Mg^{2+} facilitated transport mechanism at the membrane of the intracellular storage granules (18). Apomorphine or XI reverses the reserpine syndrome and produces stereotypic behavior in a manner similar to other known dopamine agonists. The behavioral effects of XI and apomorphine in rats are summarized in Table I.

Reserpine-induced catalepsy (mean score = 3) was antagonized by both apomorphine and XI in a dose-related manner. The minimum doses of apomorphine and XI which produced a score of zero were 1.0 and 25 mg/kg, re-

[2] All behavioral observations were made between 08:00 and 14:00 hr.
[3] Columbus Instruments, Columbus, Ohio.

spectively. Apomorphine and XI also produced complete clearing of the reserpine-induced ptosis and hunched posture.

Both apomorphine and XI induced dose-dependent stereotyped behavior. A peak score of three (continuous sniffing with discontinuous licking or gnawing) was seen with apomorphine and XI at doses of 2.0 and 100 mg/kg, respectively. Maximal stereotypy was seen at 15 min following the administration of apomorphine and at 30 min after XI had been administered.

6-Hydroxydopamine destroys the presynaptic nerve terminals of the nigro-striatal pathway, causing postsynaptic denervation supersensitivity on the side of the lesion. Contralateral rotation in this model is indicative of direct stimulation of dopaminergic receptors in the denervated caudate nucleus (19). Apomorphine and XI (Table I) were both effective in producing this type of turning behavior. The minimal effective dose with XI was 10 mg/kg while a dose of 40–50 mg/kg produced 50% of maximal rotation. The time of peak effect was 20 min with a duration of 75–90 min. With apomorphine, the minimal effective dose was 0.25 mg/kg and the dose that produced 50% of maximal rotation was 1.0 mg/kg. Apomorphine exhibited its peak effect at 20 min and caused rotation for a period of 50–60 min. Rotation was apparent by 2–3 min for both XI and apomorphine.

The results of the biochemical studies on 3-(3,4-dihydroxyphenyl)-1-*n*-propylpyrrolidine hydrobromide (XI) and apomorphine are summarized in Table II. Apomorphine (2.0 mg/kg) and XI (100 mg/kg) induced rapid increases in dopamine accumulation. Maximal effect of ~30–35% increases was obtained with both compounds at 15–20 min with a return to the control value at ~90 min. Both apomorphine and XI produced striatal dopamine accumulation in a dose-dependent manner with EC_{50} values of ~0.75 and 40 mg/kg, respectively. Apomorphine and XI also induced dose-related decreases in dihydroxyphenylacetic acid and homovanillic acid.

The administration of XI (100 mg/kg) or apomorphine (2 mg/kg) resulted in rapid decreases in serum prolactin levels. Maximal decreases were obtained 20–45 min after administration of the test compound. In the dose-response study, apomorphine and XI produced dose-dependent decreases in serum prolactin levels with IC_{50} values of 0.5 and 15 mg/kg, respectively.

Compound XI inhibited [^{3}H]spiperone binding to striatal membrane preparations with an IC_{50} of ~10 μM. The IC_{50} value for apomorphine was 200 nM. The time courses of the behavioral and biochemical effects of both apomorphine and XI are generally in close agreement. Compound XI exhibited a much lower affinity for the butyrophenone binding site in the competition binding studies with [^{3}H]spiperone than apomorphine or other known dopamine agonists. However, this low affinity correlates with the potency observed in behavioral and biochemical studies, as apomorphine and XI have similar molecular weights.

3-Phenylpiperidines may exist in a stable conformation in which the β-phenethylamine system assumes a *trans* (antiperiplanar) conformation (20). This conformation is preferred by most dopamine agonists (7). The lack of dopamine autoreceptor activity by the pyrrolidine analogue IV has been attributed to an inability to attain this conformation (7, 20). Thus, XI may not be optimally binding at its receptor sites.

In vivo, apomorphine or bromocriptine produce behavioral and biochemical changes characteristic of central dopaminergic stimulation; these include reversal of the reserpine syndrome, stereotypic behavior, contralateral rotation following unilateral 6-hydroxydopamine lesion of the substantia nigra, reduction in the rate of dopamine turnover, and inhibition of prolactin release. We have compared 3-(3,4-dihydroxyphenyl)-1-*n*-propylpyrrolidine hydrobromide (XI) with apomorphine for these behavioral and biochemical actions. The results reported here show that XI induced typical changes, and it may, therefore, be tentatively concluded that it acts as an effective dopaminergic agonist, with a much lower potency but a slightly longer duration of action, than apomorphine.

Further work is in progress to compare the dopaminergic activity of XI with other known dopamine agonists. Additionally, structure-activity studies are currently being performed with the 3-phenylpyrrolidine series.

Physical Model Approach to Gastrointestinal Absorption of Prostaglandins II: *In Situ* Rat Intestinal Absorption of Dinoprost

J. Y. PARK *[¶], N. F. H. HO *[§x], and W. MOROZOWICH [‡]

Received March 29, 1976, from the *College of Pharmacy, University of Michigan, Ann Arbor, MI 48109 and the [‡]Upjohn Co., Kalamazoo, MI 49001. Accepted for publication November 11, 1976. Present addresses: [§]Upjohn Co., Kalamazoo, MI 49001 and [¶]Boehringer Ingelheim, Ridgefield, CT 06877.

Abstract □ *In situ* absorption studies with dinoprost in the rat jejunum were carried out using a modified Doluisio technique. The absorption rate was first order. There was a sigmoidal decrease in the rate with increasing buffer pH (from 3.5 to 9.5), which strongly indicated the partitioning of weak acid species into the lipoidal membrane. An asymptotic minimum rate was attained from buffer pH 7.5 to 9.5, operationally indicative of transport of anions across aqueous pores. The importance of the aqueous diffusion layer on the mucosal side of the membrane was evident; rates at pH 3.5 and 4.5 were faster at high agitation hydrodynamics in the lumen solution. Preliminary studies showed that there was no metabolism in the lumenal solution and that metabolism occurred within the membrane. The transport mechanism involved simultaneous passive diffusion and bioconversion in the membrane because (*a*) a 1.5 × 10^4-fold range in dinoprost concentration (0.014–210 μM) showed no saturable carrier-mediated tendency on the rate, (*b*) iodoacetic acid and indomethacin did not inhibit the absorption rate, and (*c*) the shape of the absorption-pH profiles was suggestive of passive diffusion. The prostaglandin did not have apparent adverse membrane and vascular effects under the conditions employed. The quantification and factorization of the physically meaningful transport parameters were accomplished using the physical model previously described. The permeability coefficients of the aqueous diffusion layer for the oscillation and static hydrodynamic situations were 0.8 × 10^{-4} and 1.7 × 10^{-4} cm/s, respectively. The effective transport-bioconversion permeability coefficients of the membrane were 2.57 × 10^{-4} cm/s at buffer pH 3.5 and 1.46 × 10^{-4} cm/s at pH 4.5; the effective permeability coefficient of the aqueous pores was 1.5 × 10^{-5} cm/s. Depending upon the buffer pH, 3.5 or 4.5, and the two hydrodynamic situations, the total transport rate was 45–76% aqueous diffusion controlled.

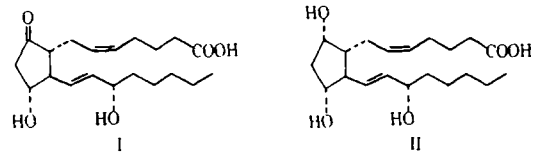
Keyphrases □ Dinoprost—GI absorption, effect of concentration, pH, buffer capacity, and hydrodynamics, rats □ Absorption, GI—dinoprost, effect on concentration, pH, buffer capacity, and hydrodynamics, rats □ Prostaglandins—dinoprost, GI absorption, effect of concentration, pH, buffer capacity, and hydrodynamics, rats

The purpose of this paper is to provide a quantitative insight into some aspects of the absorption process of dinoprost[1] in rat intestines and to identify and assess potential physiological reactions of the membrane and mesenteric circulatory system that may compromise the attainment of an unambiguous physicochemical interpretation of the absorption mechanism. This goal is only part of the larger objectives of a rational biopharmaceutical development of oral delivery systems of the prostaglandins and the molecular design of prostaglandin derivatives and analogues.

To provide the conceptual basis for the biopharmaceutical design, special emphasis is placed on the *in situ* experiments with dinoprost, on the transport processes, and on quantification of the transport and enzymatic kinetic parameters.

Absorption of dinoprost (II), dinoprostone (I), and the methyl ester of the 15-methyl derivative of dinoprost is accompanied by extensive metabolism in the small intestines of the rat (1). Similar results were found in absorption experiments using intact intestinal loops of dogs (2). Using 1-[^{14}C]prostaglandin E_1, Parkinson and Schneider (3) found that only minute amounts of the intact weak acid survived the transport from the mucosal to the serosal fluid of rat jejunum segments *in vitro*. They attributed the loss of the ^{14}C-label to an oxidative process leading to the formation of carbon dioxide. Prostaglandin E_1 is metabolized by homogenates of both rat and dog stomach and jejunum (4). Intestinal absorption of prostaglandin E_1 and dinoprost *via* the lymphatic system appear to be insignificant (2, 5).

The absorption, distribution, excretion, and metabolism of dinoprostone were studied in female rats following oral administration (6). Recently, Bito (7) reviewed the literature and made postulations on the membrane carrier-mediated transport mechanism of the prostaglandins with respect to specific tissues and tissue functionality. Although the transport of dinoprost across the rabbit vagina appears to be a saturable carrier-mediated process, definitive mechanistic studies on intestinal transport in animals are lacking.



The literature on the chemistry, metabolism, and biology of prostaglandins is extensive and was reviewed previously (8). Prostaglandins are substrates to NAD^+-dependent 15-hydroxyprostaglandin dehydrogenase, Δ^{13}-reductase, β-oxidase, and ω-oxidase (9–11). The bioconversion to the 15-oxo and then the 13,14-dihydro-15-oxo forms is sequential. The pK_a of dinoprost is 4.9, and the solubility of the free acid in water is 1.5 mg/mL. The critical micelle concentration (CMC) increases with pH and is ~4 × 10^{-3} M at pH 3 and ~2 × 10^{-2} M at pH 6.0 (12).

Aqueous solutions of a 5-mg/mL dinoprost equivalent as the tromethamine salt are stable for at least 3 months at room temperature and pH 7–9. No decomposition of 15-mg/mL aqueous solutions at about pH 6.7 was found over 7 d and a 4–47°C temperature range (13). Epimerization to the 15-epi derivative of dinoprost occurs at very low pH, but there are no kinetic data. However, studies in the epimerization kinetics of 15(*R*)- and 15(*S*)-15-methyl derivatives of dinoprost methyl ester serve as a useful guideline (14). When each analogue was incubated in an acidic medium, each epimerized at C-15 to give approximately a 1:1 mixture of the 15(*R*)- and 15(*S*)-forms. About 50% epimerized in 1 h at pH 1.36, and 5% epimerized in 3 h at pH 3.12.

EXPERIMENTAL SECTION

Materials and Apparatus—Dinoprost tromethamine and the 15-oxo and 13,14-dihydro-15-oxo derivatives were used without further purification[2]. [9-^{3}H]Dinoprost(prostaglandin $F_{2\alpha}$)(9.2 Ci/mmol) was obtained from two sources[2,3]. Other radiolabeled chemicals[3] included ^{14}C-labeled 1-butanol (10 mCi/mmol), 1-octanol (10 mCi/mmol), and benzoic acid (5 mCi/mmol). Indomethacin and iodoacetic acid also were used. The isotonic buffers are

[1] Dinoprost is prostaglandin $F_{2\alpha}$; dinoprostone is prostaglandin E_1.

Distilled water[c]	*q.s.*	*q.s.*	*q.s.*	*q.s.*	*q.s.*

[a] Reagent-grade chemicals were used without further purification. All solutions were adjusted to 300–310 mOsm/kg with potassium sulfate. For buffer solutions less than the buffer capacities of the standard preparations, the concentrations of buffer reagents were reduced proportionally and adjusted to isoosmotic conditions with potassium sulfate. [b] The pH was adjusted with 1 M NaOH. [c] The final volume was 1 L.

listed in Table I. A commercial scintillation cocktail[3] was used. A liquid scintillation counter[4], research pH meter[4], osmometer[5], two-directional flow pump[6], and a centrifuge[7] were used.

***In Situ* Absorption Procedures**—Male Sprague–Dawley rats, 220–275 g, fasted for 12–16 h, were anesthetized with 20% urethane solution, 1–2 mg/g ip. An appropriate 22-cm section of the jejunum was selected, washed profusely with normal saline, cannulated, connected to two 5.0-mL syringe barrels and the two-directional pump. The last wash consisted of the buffer intended for the ensuing experiment.

Exactly 2 mL of the radiolabeled solute in isotonic buffer was introduced into the lumen of the jejunum. With the aid of the flow pump, 0.5 mL of solution was pushed up the barrel of one syringe at the rate of 0.075 mL/s, up the other syringe, and finally up the first syringe, whereupon a 20-μL sample was withdrawn with an automatic pipet for assay. This first sample was regarded as the time zero sample, which was 30–35 s after the initial introduction of the 2-mL drug solution into the intestinal lumen.

The initial oscillation of the lumenal solution was done to obtain a uniform mixing of the 2-mL drug solution with the residual solution in the gut lumen from the final wash. The apparent surface area to volume ratio was 11.2[8]. All absorption experiments were carried out at 37°C.

In experiments involving static hydrodynamic conditions, the drug remained in the lumen until, at regular 150-s sampling intervals, 0.5 mL of the lumenal solution was pushed up into the barrel of the syringe with the pump at 0.075 mL/s, and a 20-μL sample was withdrawn. Then the solution was pumped back into the lumen and remained there until the next regular sampling interval. This sampling procedure took no more than 10 s, and at least 75% of the solution volume always remained in the lumen. The regularity of the sampling time interval under these "static" experimental conditions was necessary physicochemically to maintain some constancy in the hydrodynamics of the solution in the gut lumen. This constancy is important when the transport rate is influenced significantly by the permeability of the unstirred aqueous layer.

Chromatography—For TLC, precoated silica gel F-250 plates[9] were developed in ethyl acetate–acetic acid–isooctane–water (90:20:50:100, by volume) (15). Dinoprost and its metabolites were readily observed by spraying with 15% ammonium sulfate. Zones of radioactivity were quantified in the scintillation cocktail with 0.5-cm scrapings. With this TLC system, no impurities in the original [^{3}H]dinoprost solutions were detected.

During the *in situ* intestinal absorption studies, samples from the lumenal solution, blood, and small intestine were taken. Lumenal solution or blood, 0.1 mL, was extracted two to three times with 2 mL of ethyl acetate, concentrated by evaporation with a nitrogen stream, and then spotted. A 1-cm intestinal segment, previously washed with normal saline, was excised, homogenized in the cold, extracted three times with 2 mL of ethyl acetate, concentrated with a nitrogen stream, and spotted.

Qualitative and quantitative analyses of samples from the lumenal solution and the blood (after extraction with ethyl acetate) were performed by HPLC[10]

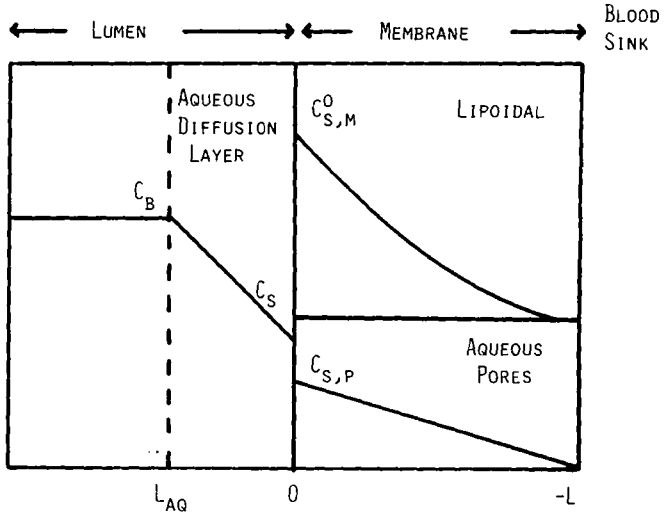

Figure 1—*Physical model for the simultaneous intestinal membrane transport of dinoprost. An aqueous diffusion layer is in series with the membrane consisting of two parallel pathways: the diffusional transport-bioconversion pathway and the aqueous pore pathway. The model depicts the boundary concentrations and distances.*

after conversion of the prostaglandins to the *p*-nitrophenacyl esters as described previously (16).

THEORETICAL SECTION

As will be seen, the following physical model (17) is consistent with the dinoprost absorption in the rat jejunum (Fig. 1). It consists of an aqueous diffusion layer (often referred to as the unstirred aqueous layer) in the lumen in series with the intestinal membrane followed by the blood sink. Operationally, the membrane is comprised of two parallel pathways: the simultaneous diffusional transport-bioconversion pathway in the lipoidal fraction of the membrane and the aqueous pore pathway. It is assumed that the nondissociated and anionic species have equal facility across the aqueous pores. This approach leads to the semilogarithmic expression:

$$\ln C_b = \ln C_b(0) - k_u t \qquad \text{(Eq. 1)}$$

where C_b are the total drug concentration remaining in the lumenal solution at time t, and $C_b(0)$ is the initial concentration. The apparent first-order absorption rate constant, k_u, is given by:

$$k_u = \frac{A}{V} \cdot \frac{1}{\frac{1}{P_{aq}} + \frac{1}{P_{e,m}}} \qquad \text{(Eq. 2)}$$

where A/V is the apparent surface area to solution volume ratio, and P_{aq} and $P_{e,m}$ are the effective permeability coefficients of the aqueous diffusion layer and the membrane, respectively. Furthermore:

$$P_{e,m} = \frac{\alpha K X_s \sqrt{kD}}{\tanh\left(L\sqrt{k/D}\right),} + P_p \qquad \text{(Eq. 3)}$$

where K is the membrane lipoidal biophase–aqueous partition coefficient, X_s is the fraction of nondissociated species at the membrane surface, L is the thickness of the membrane, D is the diffusion coefficient in the membrane, k is the apparent first-order bioconversion rate constant, P_p is the permeability coefficient of the aqueous pores, and α is the volume fraction of the diffusional transport-bioconversion pathway of the lipoidal membrane.

The concentration profile in the diffusional transport-bioconversion pathway is described by:

$$C_m = \frac{C_{m,s} \sinh\left[\sqrt{k/D}(L + x)\right]}{\sinh\left(L\sqrt{k/D}\right)} \qquad (0 \geq x \leq -L) \qquad \text{(Eq. 4)}$$

where $C_{m,s}$ is the concentration of the drug at the surface on the membrane side. Thus, this model assumes that only intracellular metabolism is significant and that cavital and membrane digestion is insignificant (17, 18).

RESULTS AND DISCUSSION

General Absorption Studies—The absorption of [^{3}H]dinoprost at various isotonic buffer values pH and high buffer capacity under the continuous oscillation procedure is shown in Fig. 2. There was a logarithmic change in the concentration remaining in the lumen of the jejunum with time. The slopes decreased with increasing pH. At pH 7.5 and 9.5, the finite rate constants of

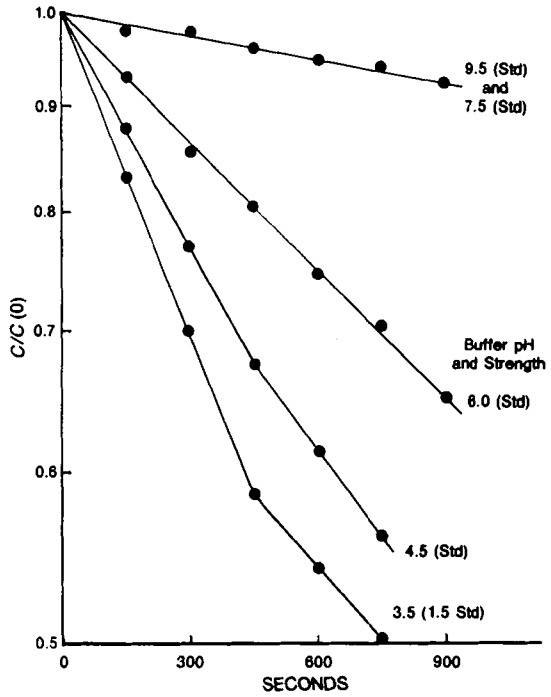

Figure 2—*Semilogarithmic change in the fraction of [^3H]dinoprost remaining in the lumen with time.*

the anionic species were about the same. The absorption at pH 3.5 and 4.5 tended to depart from linearity at later times, most likely due to the flow of intestinal secretions changing the surface and bulk pH with time.

The marked influence of the aqueous diffusion layer on the transport kinetics is observed in the first-order plots in Fig. 3. All other factors being constant, the hydrodynamics produced by the oscillation of the lumenal solution had a larger effect on the slope than the hydrodynamics produced by the static method with 150-s sampling intervals. The higher the degree of agitation, the thinner the aqueous diffusion layer on the mucosal side of the intestinal membrane (19).

Table II is a summary of the absorption experiments at tracer concentrations in the jejunum; the results are also illustrated in Fig. 4. The k_u-pH

profiles were similar to those expected for weak acids such as the 1-alkanoic acids (20). At low pH, the absorption under the higher degree of agitation of the solution was greater and less aqueous diffusion controlled than the absorption under less agitation. The differences in the absorption rate constants between the two hydrodynamic conditions became smaller with increasing pH. This result is attributed to the increasing importance of the membrane as the rate-controlling transport barrier. From about pH 7.5 and higher, the k_u-pH profiles for the two hydrodynamic situations converged to an asymptotic minimum. In an operational way, this result is indicative of the rate-limiting transport of the anions across the aqueous pores of the jejunal membrane.

Physiological Effects of Dinoprost on Membrane System—The objectives of the following studies were to identify and to assess potential physiological membrane reactions to dinoprost that may compromise an unambiguous biophysical interpretation and quantification of the absorption mechanism. These objectives were accomplished by following dinoprost absorption at varying concentrations repeatedly within the same intestinal segment of a rat and also between rats and by absorption experiments with selective permeating species in the absence and presence of dinoprost.

Tables III and IV show the results of successive absorption experiments in the same jejunal segment of a rat with various buffer pH combinations and with prostaglandin concentration combinations (up to 10 μg/mL) at pH 6. Taken together, the results indicated that pH and dinoprost did not have adverse effects on the membrane under the experimental conditions. The within-rat variation was small. A 1.5×10^4-fold increase in the concentration, corresponding to 0.014 and 210 mM, respectvely, did not influence the absorption rate constant.

presence of dinoprost were not statistically different (Table V), providing further support that there were no significant adverse membrane and vascular effects to transport. There was also no effect on the transport of 1-[^{14}C]octanol at pH 4.5 (Fig. 5). The fact that the absorption of [^{14}C]benzoate anions at pH 8.5 was not influenced by the presence of dinoprost indicated that the prostaglandin did not significantly affect the aqueous pore pathway of the jejunal membrane (Table VI). It is concluded that dinoprost does not have apparent adverse membrane and vascular effects under the experimental conditions employed.

Mechanism of Membrane Transport—It was postulated that the transport of dinoprost in the rat occurs by passive transport across the aqueous diffusion layer and then by the simultaneous passive membrane transport and bioconversion mechanism. The k_u-pH plots in Fig. 4, which are of the kind predicted by the pH-partition-aqueous diffusion layer hypothesis for the passive absorption of weak acids, serve as part of the basis for the postulation of the passive mechanism of the total transport process across the jejunal membrane *per se*. Comparison of the absorption-pH profiles of dinoprost and *n*-butyric acid (Fig. 6) illustrates this point.

The following results provide additional evidence that the absorption does not involve a membrane-saturable process. The rate constant of dinoprost at pH 6 and 7.5 was not concentration dependent with concentrations from 1.4 $\times 10^{-2}$ to 200 μM (a 1.5×10^4-fold range) (Table VII and Fig. 7). Furthermore, the absorption was not affected by iodoacetic acid and indomethacin, substances that inhibit the carrier-mediated transport of natural prosta-

3	0	4.80	2	4.73	—	—

[a] Oscillation (0.075 mL/s^{-1}) hydrodynamics were employed. The buffer capacity was 1.5 standard. The [^{3}H]dinoprost concentrations were 5×10^{-3} μg/mL for rats A and B and 0.1 μg/mL for rat C.

glandins (21) (Tables VIII and IX). Indomethacin also is a prostaglandin synthetase inhibitor.

Preliminary Metabolism Studies—These studies were carried out to characterize generally dinoprost metabolism in the first 20 min of *in situ* rat intestinal absorption experiments with pH 6.0 buffer. In the first 5 min, <1.0% of the 15-oxo and 13,14-dihydro-15-oxo forms appeared in the lumenal solution (Fig. 8); in 20 min, ~10% of these major metabolites was present. No metabolism occurred *in vitro* in rat blood and the lumenal secretion solution (Fig. 9). However, dinoprost and its two major metabolites were found in the intestinal segments and the blood in the *in situ* absorption studies. If β-oxidation products were present, they could not be detected by the chromatographic techniques employed.

The results of the preliminary *in vitro* and *in situ* studies together indicate

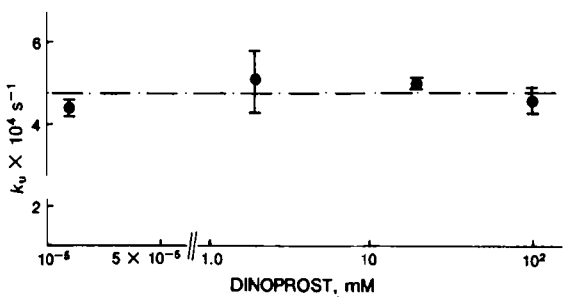

Figure 7—*Effect of dinoprost concentration on the intestinal absorption rate constant at pH 6.0 and oscillation hydrodynamics. The bars represent the standard deviations; the dash line is the mean rate constant for all concentrations, which is equal to 4.8 × 10^{-4} s.*

that there is no dinoprost metabolism in the lumen; metabolism by 15-hydroxyprostaglandin dehydrogenase and Δ^{13}-reductase occurs in the membrane and there is a back-diffusion of metabolites into the lumen. The possibility of membrane contact metabolism seems unlikely, since the enzyme systems usually associated with the membrane surface include the carbohydrases, peptidases, lipases, hydrolases, and isoenzymes of alkaline phosphatase (18). Studies are currently directed toward determining, through the use of inhibitors, whether enzymes relevant to prostaglandin metabolism are present at the membrane surface.

Permeability Coefficients—The theoretical physical model described is operationally consistent with the experimental evidence. Consequently, the permeability coefficients of the aqueous diffusion layer, the diffusional transport-bioconversion, and aqueous pore pathways of the jejunal membrane are readily found.

Between two absorption rate constants obtained at the same buffer pH but under different hydrodynamics in the lumen, the following relationships hold:

$$\frac{1}{P_{aq}} + \frac{1}{P_{e,m}} = \frac{A}{Vk_u} \qquad \text{(Eq. 5)}$$

$$\frac{1}{P_{aq}'} + \frac{1}{P_{e,m}} = \frac{A}{vk_u} \qquad \text{(Eq. 6)}$$

$$r^* = P_{aq}'/P_{aq} \qquad \text{(Eq. 7)}$$

The rate constant, k_u, and the permeability coefficient of the aqueous diffusion layer, P_{aq}, are different from k_u' and P_{aq}' because of the differences in the hydrodynamic conditions. In contrast, the effective permeability coefficient, $P_{e,m}$, is independent of the hydrodynamics. The ratio r^* already was determined for a number of hydrodynamic situations in the rat intestinal tract using the 1-alkanol series (19). Between the continuous oscillation (0.075-mL/s) and the static (150-s) sampling interval cases, r^* is 2.12.

As shown in Table X, the permeability coefficients of P_{aq} for the static and oscillation hydrodynamic situations are 0.8×10^{-4} and 1.7×10^{-4} cm/s,

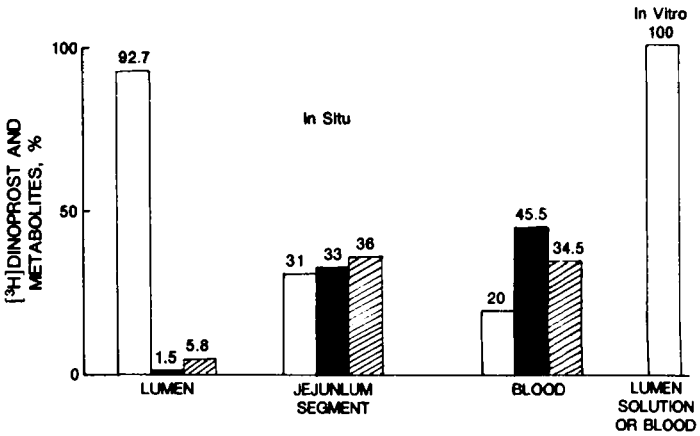

Figure 9—*Percent of radiolabeled dinoprost and metabolites found in the lumenal solution, jejunal gut segment, and blood after 20 min from* in situ *absorption experiments and in the lumenal solution and blood after 20 min exposure from* in vitro *experiments.*

Buffer pH	$k_u \times 10^4$ s^{-1} Static, 150 s	$k_u \times 10^4$ s^{-1} Oscillation, 0.075 mL/s	Permeability Coefficient $\times 10^4$ cm/s $P_{aq(static)}$	Permeability Coefficient $\times 10^4$ cm/s $P_{aq(oscillation)}$
3.5	6.61	11.09	0.8	1.64
4.5	5.66	8.65	0.8	1.64

[a] The P_{aq} for the static and oscillation situations and $P_{c,m}$ were calculated from the experimental rate constants with Eqs. 5 and 6. The r^* is 2.12, and A/V is 11.2.

Table XI—Factorization of the Effective Permeability Coefficients of the Jejunum Membrane at Various Buffer pH Values into the Permeability Coefficients of the Aqueous Pores and Principal Membrane Pathway

Buffer pH	Buffer Capacity	Permeability Coefficient $\times 10^4$ cm/s $P_{c,m}$[a]	P_{pore}	$\frac{KX\sqrt{kD}}{\tanh(L\sqrt{k/D})}$
3.5	1.5 Standard	2.59	0.15	2.44
4.5	Standard	1.44	0.15	1.29
6.0	Standard	0.53	0.15	0.38
7.5	1.5 Standard	0.15	0.15	0
9.5	Standard	0.15	0.15	0

[a] Defined by Eq. 3.

respectively. The $P_{c,m}$ values are 2.57×10^{-4} cm/s at buffer pH 3.5 and 1.46×10^{-4} cm/s at pH 4.5. Since the aqueous diffusion coefficient of dinoprost is equal to 5.1×10^{-6} cm^2/s, the effective diffusion layer thickness is 310 μm for the oscillation hydrodynamics and 662 μm for the static situation.

The permeability coefficient of the aqueous pores, P_p, is determined from the experimental data in the limit of the buffer pH $\gg$ pK_a; thus:

$$k_{u,min} = \frac{A/V}{\frac{1}{P_{aq}} + \frac{1}{P_p}} \qquad \text{(Eq. 8)}$$

Using Tables II and X where the average $k_{u,min}$ is 1.51×10^{-4} s^{-1} and P_{aq} (oscillation) is 1.7×10^{-4} cm/s, one finds that P_p is 1.5×10^{-5} cm/s. In perspective (6), the P_p of the salicylate and *p*-aminobenzoate ions in the jejunum is 2.8×10^{-5} cm/s, and that of taurocholate anions is negligible. It is reasonable to assume that the P_p of the nondissociated dinoprost species is at least equal to, if not slightly larger than, the P_p of the anion. Consequently, the effective permeability coefficient of the principal transport-bioconversion pathway of the membrane, which is pH dependent, can be found to complete the factorization of the effective permeability coefficient of the membrane (Table XI).

The extent to which the transport rate is influenced by the aqueous diffusion layer barrier in front of the mucosal membrane is presented in Table XII. As one would expect, the rate constant was more aqueous diffusion controlled at pH 3.5 than at pH 4.5, and the oscillation situation was less aqueous diffusion controlled as compared with the static situation. Although the degree of agitation of the lumenal solution at pH 3.5 produced by rapidly oscillating the solution was high, the rate was 60% diffusion controlled. At higher pH values, the rate was less aqueous diffusion controlled.

General Observations of Buffer Capacity on Absorption—The first-order absorption-time profiles at pH 3.5 and 4.5 tended to depart from linearity with time (Fig. 2). For cases where different buffer capacities at initial pH 3.5 and 7.5 were used, the rate constants varied with buffer capacity (Table II). Because of these observations and other intestinal absorption studies (22), all absorption studies were carried out at sufficiently high buffer capacities such that the initial rate constants at all buffer pH were independent of buffer strength.

To complete the baseline studies, additional experiments were carried out

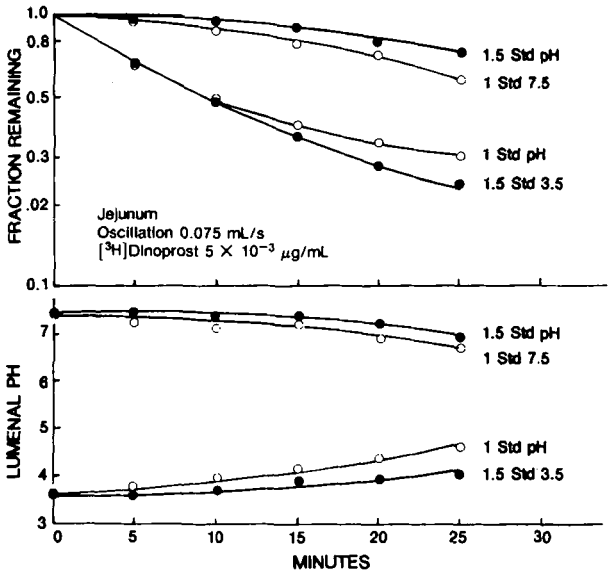

Figure 10—*Semilogarithmic change in the lumenal concentration of dinoprost and bulk pH change with time for pH 3.5 and 7.5 under oscillation hydrodynamics and two buffer strengths.*

wherein both the intestinal absorption and bulk lumenal pH changes with time were simultaneously followed at initial pH 3.5 and 7.5 and two buffer strengths. The first-order absorption curves at pH 3.5 were linear for a short time and then gradually decreased with time, while the bulk lumenal pH increased with time toward pH 6.0 (Fig. 10). These changes occurred more rapidly with the lower of the two buffer strengths. In both cases, the initial slopes in the absorption curves were about the same. In contrast, the increase in the absorption with time at pH 7.5 was accompanied wih a slow decrease in the bulk pH with time. These changes occurred faster at lower buffer capacities.

All of these observations are consistent with the mechanistic studies on the rat intestinal absorption of *n*-butyric acid (19) in which the factors influencing the dynamics of the surface pH, *i.e.*, the pH at the aqueous-membrane interface, were quantitatively assessed. Because the surface pH depends on the net effect of the fluxes of the intestinal buffer secretions and buffer species from the bulk solution, sufficiently high buffer capacity solutions in the lumen must be used to have a baseline control of the surface pH relative to the initial bulk pH.

CONCLUSIONS

The objectives of providing a broad insight into the absorption process and of identifying and assessing potential physiological reactions of the membrane to the prostaglandins that can compromise an unambiguous biophysical interpretation of the absorption mechanism *via* the physical mode approach have been met. *In situ* baseline absorption studies with [^{3}H]dinoprost in the rat jejunum were carried out using a modified Doluisio technique for better control of the hydrodynamics. The experimental variables included a wide range of buffer pH (3.5-9.5), buffer capacity, hydrodynamics, and prostaglandin concentrations. The physical model was applied to the results to obtain quantitative estimates of the permeability coefficients of the aqueous diffusion layer, the aqueous pore pathway, and the effective diffusional transport-bioconversion pathway of the membrane. Studies are in progress to distinguish further the occurrence of metabolism within the membrane from membrane contact metabolism and to obtain the factorization of the apparent *in situ*

Table XII—Influence of the Aqueous Diffusion Layer on the Transport Rate of Dinoprost in the Jejunum

Buffer pH	Hydrodynamic Condition[a]	$k_{u,exp} \times 10^4$ s^{-1}	$k_{u,max} \times 10^4$ s^{-1}	Percent of Rate Constant Aqueous Diffusion Controlled

Present addresses: [¶]Merck, Sharp & Dohme, West Point, PA 19486 and the [§]Upjohn Co., Kalamazoo, MI 49001.

Abstract □ *In situ* absorption studies with dinoprostone in the rat jejunum were carried out to provide a quantitative mechanistic insight of the absorption process. The variables included buffer pH (3.5-9.5), buffer capacity, hydrodynamics in the lumen, and concentration. The disappearance kinetics from the lumen was first order. The rate decreased with increasing pH in a sigmoidal manner and reached a minimum at about pH 9. These results indicate the effects of the partitioning of nondissociated species in the lipoidal membrane and transport across aqueous pores. The rate was higher with the higher degree of agitation of the lumenal solution. Between two hydrodynamic situations, the differences in the rates were large at pH 4.5 where the transport was largely aqueous diffusion controlled and then tended to become smaller with increasing pH where the transport became effectively membrane controlled. The 15-oxo- and 13,14-dihydro-15-oxo metabolites of dinoprostone were found. The physical model was applied to quantify the permeability coefficients of the aqueous diffusion layer and the aqueous pores of the membrane and the effective membrane transport-bioconversion permeability coefficient at various pH values. The overall absorption process of dinoprostone was similar to that of the less lipophilic dinoprost reported earlier and also more rapid. Hence, baseline absorption studies were completed with two major reference prostaglandins from which estimations of intestinal absorption can be made for their analogues and derivatives.

Keyphrases □ Absorption, GI—dinoprostone, rat jejunum, effect of buffer pH, buffer capacity, lumenal hydrodynamics, and concentration □ Dinoprostone—GI absorption, effect of buffer pH, buffer capacity, lumenal hydrodynamics, and concentration □ Prostaglandins—dinoprostone, GI absorption, effect of buffer pH, buffer capacity, lumenal hydrodynamics, and concentration, rat jejunum □ Oxytocic agents—dinoprostone, GI absorption, effect of buffer pH, buffer capacity, lumenal hydrodynamics, and concentration, rat jejunum

In situ absorption studies in the rat jejunum have been carried out to provide a quantitative mechanistic insight into the intestinal absorption of dinoprostone (I)[1]. These studies were intended to serve as baselines for comparisons between dinoprostone and its analogues and derivatives and other natural prostaglandins such as dinoprost (II).

II

Magee *et al.* (1) were the first to study the *in situ* rat intestinal absorption of dinoprostone by the Doluisio *et al.* (2) technique. With the entire small intestines and 0.01 M phosphate buffer (pH 6.4), the disappearance half-life from the intestinal solution was 40 min. The 15-oxo metabolite was found in the lumen. No mechanistic interpretation on the absorption process was made.

Recently, *in situ* absorption studies with dinoprost in the rat jejunum, using a modified Doluisio technique, showed that the absorption rate was first order and was dependent on the pH and hydrodynamics in the intestinal lumen (3). No metabolism involving 15-hydroxyprostaglandin dehydrogenase occurred in the intestinal lumen and at the membrane surface; however, metabolism occurred within the biomembrane. The transport mechanism involved simultaneous passive diffusion and enzymatic bioconversion in the membrane. The quanti-

[1] Dinoprostone is prostaglandin E_2; dinoprost is prostaglandin $F_{2\alpha}$.

[a] Initial concentration of [^{3}H]dinoprostone was 5×10^{-4} mg/mL or 1.7×10^{-6} mg/mL. The k_u is the apparent first-order transport rate constant. Std means standard buffer capacity (see Ref. 3 for buffer formula).

fication and factorization of the permeability coefficients of the aqueous boundary layer in front of the membrane and the passive diffusional-bioconversion and aqueous pore pathways of the membrane were accomplished using the physical model derived previously (4).

EXPERIMENTAL SECTION

In situ absorption studies with dinoprostone in the rat jejunum were carried out by a modified Doluisio technique (4). The experimental variables included a wide range of buffer pH (3.5–9.5), buffer capacity, dinoprostone concentration, and hydrodynamic situations. Dinoprostone[2], [^{3}H]dinoprostone[3], 1-[^{14}C]butanol[3], and *n*-[^{14}C]butyric acid[3] were used without further purification. All buffer and rinsing solutions were isoosmotic.

Male Sprague-Dawley rats, 220–275 g, were used. A 22-cm segment of jejunum was exposed and cannulated. All experiments were conducted at 37°C.

To assess membrane damage, villous immobility, or vasoconstriction caused by concentrations of prostaglandins that might be used in subsequent experiments, the jejunal absorption of 1-[^{14}C]butanol, 1-[^{14}C]octanol, and *p*-[^{14}C]aminobenzoic acid was followed in the presence and absence of experimental concentrations of dinoprostone at constant hydrodynamic conditions. The effect on intestinal secretions was observed by following the absorption of *n*-[^{14}C]butyric acid in the absence and presence of dinoprostone at a constant hydrodynamic condition.

In the *in situ* absorption studies, exactly 2 mL of radiolabeled solute in isotonic buffer was introduced into the lumen of the jejunum by means of the pump. To control the hydrodynamics, the experiments were conducted by the so-called static and oscillation methods. In the oscillation method, the lumenal solution was continuously pumped back and forth at 0.075 mL/s. All sampling points were at 150-s intervals.

At all times, at least 80% of the drug solution remained in the lumenal segment. The initial tracer concentration of [^{3}H]dinoprostone was 0.1 μCi/mL of drug-buffer solution, equivalent to 5×10^{-4} mg/mL. Twenty microliters of lumenal solution was taken at intervals with the aid of an automatic pipet and transferred into 10 mL of a liquid scintillation[4] cocktail[5].

TLC was performed on silica gel plates and developed with the A-IX system (5). Quantitative determinations of radioactivity on the silica gel plates were done from 0.5-cm section scrapings in the scintillation cocktail[5].

THEORETICAL SECTION

Recently, a physical model was derived for the stimultaneous passive transport and bioconversion of dinoprost across the intestinal membrane. It was consistent with the *in situ* absorption studies in the rat jejunum. Because of the similarities of the intestinal absorption of dinoprostone to dinoprost, the identical model is applied here (3, 4).

The disappearance rate in the intestinal lumen follows an apparent first-order transport process:

$$\frac{dC_b}{dt} = -k_u C_b \qquad \text{(Eq. 1)}$$

Table II—Assessment of the Presence of Metabolism and Impurity Compounds on the Determination of the Absorption Rate Constant of Dinoprostone in the Rat Jejunum

Buffer pH	Hydrodynamic Condition	$k_u \times 10^4$ s^{-1} Uncorrected	Corrected
3.5	Static	9.1	8.4
	Oscillation	17.0	16.9
4.5	Static	8.9	8.5
	Oscillation	12.0	11.7
6.0	Static	6.2	5.9
	Oscillation	7.4	7.3

and:

$$k_u = \frac{A/V}{\frac{1}{P_{aq}} + \frac{1}{\frac{KX_s\sqrt{kD}}{\tanh(L\sqrt{k/D})} + P_p}} \quad \text{(Eq. 2)}$$

where C_b is the total dinoprostone concentration in the bulk lumenal solution; t is the time in s; k_u is the apparent first-order absorption rate constant in s^{-1}; P_{aq} is the permeability coefficient of aqueous diffusion layer; P_p is the permeability coefficient of the aqueous pores of the membrane; L is the membrane thickness; k is the apparent first-order enzyme rate constant in s^{-1}; D is the diffusion coefficient of dinoprostone in the membrance (cm^2/s); A is the apparent lumenal surface area; X_s is the fraction of nondissociated dinoprostone species at the membrane surface; K is the lipoidal membrane-aqueous partition coefficient of the nondissociated prostaglandin acid; V is the volume of lumenal solution. The integration of Eq. 1 between the limits of the initial total concentration $C_b(0)$ and $C_b(t)$ leads to the semilogarithmic expression:

$$\ln C_b = \ln C_b(0) - k_u t \quad \text{(Eq. 3)}$$

By using Eq. 2, one can readily determine the apparent absorption rate constants under varying pH and hydrodynamic conditions in the lumen. In turn, the permeability coefficients of the aqueous diffusion layer and the membrane itself can be factored out.

The permeability coefficients of the aqueous diffusion layer are found as follows. Under two hydrodynamic conditions at constant buffer pH, two rates of absorption are expected. Accordingly, this situation is described by the following set of linear algebraic equations:

$$\frac{1}{P_{aq}} + \frac{1}{P_{e,m}} = \frac{A/V}{k_u} \quad \text{(Eq. 4)}$$

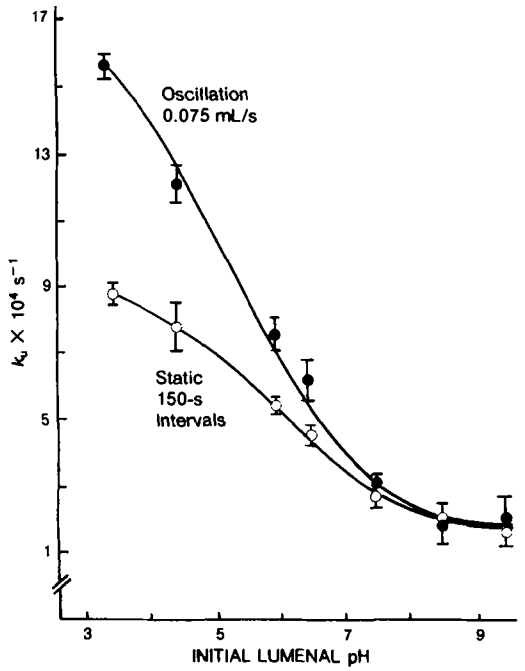

Figure 3—*Apparent absorption rate constants versus high buffer capacity pH under two hydrodynamic conditions for dinoprostone in the rat jejunum.*

Table III—*In Situ* Absorption of 1-[^{14}C]Butanol and 1-[^{14}C]Octanol in the Presence and Absence of Dinoprostone at pH 4.5 and 6.0 under Oscillation (0.075 mL/s) Hydrodynamics; Assessment of Effects on the Aqueous Diffusion Layer, Membrane, and Vascular System

		2	1.76	2.7
	D	1	1.76	3.0
		2	0	2.7

[a] In the same jejunal segment.

$$\frac{1}{P_{aq}'} + \frac{1}{P_{e,m}} = \frac{A/V}{k_u'} \quad \text{(Eq. 5)}$$

where the effective permeability coefficient of the membrane, $P_{e,m}$, is:

$$P_{e,m} = \frac{KX_s\sqrt{kD}}{\tanh(L\sqrt{k/D})} + P_p \quad \text{(Eq. 6)}$$

Here it is noted that the first-order rate constant, k_u, and the permeability coefficient of the aqueous diffusion layer, P_{aq}, are different from k_u' and P_{aq}' due to the difference in hydrodynamic conditions but that the effective permeability coefficient of the membrane is not affected by the hydrodynamics in the lumenal solution. Subsequently, if one knows the value of the ratio between P_{aq} and P_{aq}', *i.e.*:

$$\frac{P_{aq}'}{P_{aq}} = r^* \; (P_{aq}' > P_{aq};\; k_u' > k_u) \quad \text{(Eq. 7)}$$

where $r^* \geq 1.0$, it follows that:

$$\frac{1}{P_{aq}} + \frac{1}{P_{e,m}} = \frac{A/V}{k_u} \quad \text{(Eq. 8)}$$

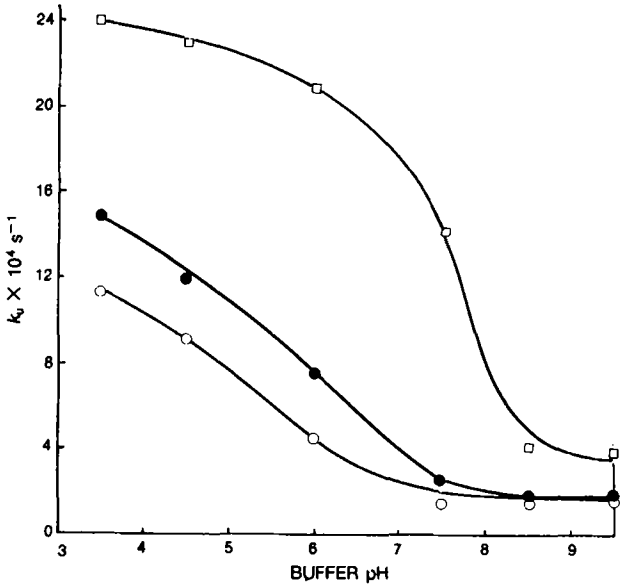

Figure 4—*Comparison of the absorption rate constant-buffer pH profiles of dinoprostone (●), dinoprost (○), and n-butyric acid (□) in the rat jejunum. The pK_a of these acids is 4.9.*

Table IV—*In Situ* Absorption of *n*-[^{14}C]Butyric Acid in the Rat Jejunum in the Presence and Absence of Dinoprostone at Buffer pH 4.5 and 9.5 under Oscillation (0.075 mL/s) Hydrodynamics [a]

4.5	0	3.13
		2.89
	0.5	2.96
		2.63
9.5	0	0.52
		0.52
	0.5	0.5
		0.51

[a] $n = 2$.

$$\frac{1}{r^* P_{aq}} + \frac{1}{P_{e,m}} = \frac{A/V}{k_u'} \qquad \text{(Eq. 9)}$$

Hence, one has a system of two equations in two unknowns, which can be solved in the usual manner. The r^* was determined previously for a number of hydrodynamic situations in the rat intestinal tract using the 1-alkanol series (6).

The permeability coefficient of the aqueous pores of the membrane is determined at buffer pH $\gg$ pK_a. In this situation, X_s approaches zero, causing Eq. 2 to become:

$$k_u = \frac{A}{V} \frac{1}{\frac{1}{P_{aq}} + \frac{1}{P_p}} \qquad \text{(Eq. 10)}$$

RESULTS AND DISCUSSION

General Absorption Experiments—Dinoprostone absorption at various pH values at high buffer capacity and at two hydrodynamic conditions is shown in Figs. 1 and 2. These plots reflect the change in the total radioactivity in the lumenal solution with time. The decrease in rate concomitant with the increase in pH strongly indicates the importance of the partitioning of nondissociated species of dinoprostone (pK_a ~4.9) into the lipoidal diffusion-bioconversion pathway of the membrane as part of the total transport process.

By comparing Figs. 1 and 2, one notices the marked influence of the aqueous diffusion layer on transport kinetics. The hydrodynamics of the oscillation procedure produced a larger effect on the slope than did the hydrodynamics of the static procedure with 150-s sampling intervals; the higher degree of agitation produced a thinner aqueous diffusion layer on the mucosal side of the membrane.

Table I summarizes the absorption experiments using tracer dinoprostone concentrations at various hydrodynamic conditions, buffer pH, and buffer capacities. The buffer capacity effect on the absorption rate constant is evident. For example, at the nominal buffer pH of 4.5, the rate constant was higher at a high buffer capacity than at a lower capacity. This result is attributed to the relative differences in the surface pH and bulk lumenal pH, which depends on the net fluxes of intestinal secretions and bulk buffer species across the aqueous diffusion layer (6). The bulk pH initially at pH 4.5 increased slower with time the higher buffer capacity than with the lower capacity solution. In contrast, in the pH region beyond 6.0–6.5, the bulk pH (*e.g.*, 7.5) tended to decrease slower with time with the high buffer capacity than the lower buffer capacity solution and converged to approximately pH 6.3. These results emphasize the need to have sufficiently high buffer capacity solutions for baseline control of the surface pH relative to the initial bulk pH.

Figure 3 is a plot of k_u *versus* buffer pH at high buffer capacities taken from the results in Table I. The relative differences in the k_u values for the oscillation and static hydrodynamic cases become smaller as the buffer pH increased. At pH 9.5, the rate constants were about the same. These results were expected

B	6.5	Static	4.59	0.83	1.74
		Oscillation	6.22		

[a] Average $P_{aq(static)} = 0.86 \times 10^{-4}$ cm/s. Average $P_{aq(oscillation)} = 1.82 \times 10^{-4}$ cm/s. The P_{aq} value was calculated with the aid of Eqs. 8 and 9 with $A/V = 11.2$ and $r^* = 2.12$.

since the total transport rate is more aqueous diffusion controlled at low pH and more effectively membrane controlled with increasing pH. The shapes of the profiles are similar in character to those reported earlier for dinoprost (4). These prostaglandins are known to undergo metabolism in the jejunal membrane to, at least, the 15-oxo and 13,14-dihydro-15-oxo metabolites.

In following dinoprostone absorption, there was always some concentration of extraneous tritium-labeled compounds in the intestinal lumen as well as in the original stock solution[6] as determined by quantitative TLC. These concentrations were always about 10% of the total activity at all sampling intervals during the absorption experiments. Furthermore, the back-diffusion of the 15-oxo derivative of dinoprostone from the membrane into the lumen was detected with time. *In vitro* studies in rat intestinal secretions at pH 6.0 indicated that no metabolism was occurring. The rate constants taken from first-order absorption–time plots corrected for nondinoprostone substances were no different from constants from uncorrected plots (Table II).

Assessment of Aqueous Diffusion Layer, Membrane, and Vascular Effects of Dinoprostone on Absorption—The absorption of various selected radiolabeled solutes (1-butanol, 1-octanol, *n*-butyric acid, and *p*-aminobenzoic acid) was carried out under various pH conditions in the presence and absence of dinoprostone to evaluate possible effects of the postaglandin on the aqueous diffusion layer, membrane permeability, and vascularity of the intestines affecting the blood sink. 1-Butanol and *n*-butyric acid were chosen because their absorption rates are known to be membrane controlled; the absorption rate of 1-octanol is controlled by diffusion across the aqueous boundary layer (6). Successive experiments were often performed in the same jejunal segment of each rat since within-rat variations are usually smaller than between-rat variations.

When using 1-[^{14}C]butanol to focus principally on the membrane effects and 1-[^{14}C]octanol to focus on the aqueous diffusion layer and vascular effects,

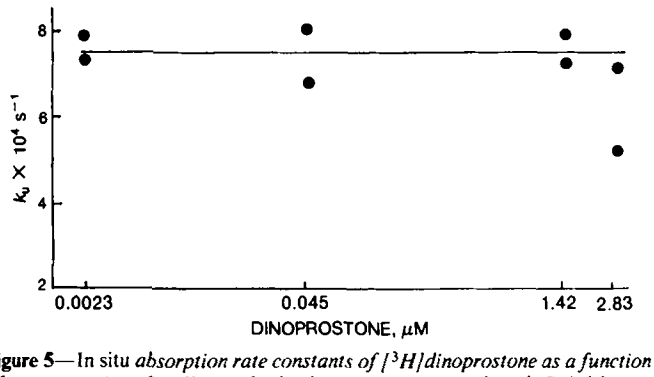

Figure 5—In situ *absorption rate constants of [^{3}H]dinoprostone as a function of concentration. Oscillation hydrodynamics were employed. Solid line is the average rate constant.*

[6] One impurity in the original stock solution had the same R_f as PGA.

[a] $P_{c,m}$ is defined by Eq. 6, and $P_m = \frac{KX_s\sqrt{kD}}{\tanh(L\sqrt{k/D})}$.

the absorption of these solutes was not affected by 1.76 μg/mL of dinoprostone at pH 4.5 and 6.0 (Table III). These pH conditions were chosen since the absorption is pH dependent (Table I) while the alkanol absorption is pH independent. Furthermore, when using *n*-butyric acid at pH 4.5 to assess the lipoidal and aqueous pore pathways of the membrane and *n*-butyric acid and the larger molecular size *p*-aminobenzoic acid at high pH to assess possible changes in the aqueous pores, a 1.76-μg/mL concentration did not have any apparent effect (Tables IV and V). As will be seen later, absorption was not influenced by concentrations up to 1×10^{-3} mg/mL (equivalent to 2.83 μM). From all of these results together, it is concluded that dinoprostone does not have significant adverse effects on the membrane system so that an unambiguous quantification and interpretation of the membrane permeability coefficients can be made.

Mechanism of Dinoprostone Absorption in Intestines—Since dinoprost is transported across the lipoidal membrane by a simultaneous passive diffusion-bioconversion kinetic process (3, 4), this is good reason to expect that dinoprostone follows the identical mechanism. For comparison, the absorption rate constant *versus* buffer pH plots are shown in Fig. 4 for both prostaglandins. Although *n*-butyric is only passively absorbed (6), it is included here to point out the similarities of the general pH-partition phenomena with *n*-butyric acid to the prostaglandins.

As shown in Fig. 4, the absorption rate constants of dinoprost from pH 3.5 to 7.5 were comparatively less than those of the more lipophilic dinoprostone at comparable pH. They tended to converge at about pH 8.5, as might be expected for the transport of the anions across the aqueous pore pathway. In contrast, the absorption-pH profile of *n*-butyric acid was higher than that for the prostaglandins and was also shifted more to the right. The asymptotic minimum absorption rate of *n*-butyric acid across the aqueous pore at pH 8.5 and higher was faster than the prostaglandins by a factor of two. In summary, the comparative profiles of these three weak acids represent the net interplay of the pH and permeabilities of the aqueous diffusion layer barrier in front of the membrane and the membrane itself.

The possibility of a facilitated transport process is virtually eliminated by the absorption data found in Table VI and Fig. 5. Contrary to the theory of the facilitated mechanism, a relatively constant absorption rate at pH 6.0 was found over a 1.25×10^3-fold range of dinoprostone concentrations (from 8×10^{-4} to 1.0 μg/mL).

Permeability Coefficients—The permeability coefficients of the aqueous diffusion layer, estimated from the pH 6.0 and 6.5 absorption data, were 0.86×10^{-4} cm/s for the static hydrodynamics and 1.82×10^{-4} cm/s for the oscillation case (Table VII). The data at pH 3.5 and 4.5 were not employed, since the absorption rates are highly aqueous diffusion controlled where Eqs. 8 and 9 become insensitive. The coefficients compare well with the 0.8×10^{-4} and 1.7×10^{-4} cm/s found in the dinoprost studies (3). Using the P_{aq} values, one gets estimates on how much the total absorption rate is aqueous diffusion controlled or membrane controlled (Table VIII). At low pH, the absorption is governed by diffusion in front of the membrane, while at higher pH it is controlled more by the membrane.

With the average $k_u = 2.0 \times 10^{-4}$ s^{-1} at high pH and Eq. 10, the permeability coefficient of the aqueous pores for the dinoprostone anions is 2.0×10^{-5} cm/s. In perspective, P_p is 1.5×10^{-5} cm/s for dinoprost. Since the permeability coefficients of the aqueous diffusion layer and the aqueous pores of the membrane are known, the factorization of the effective permeability coefficient for the simultaneous membrane transport and bioconversion of dinoprostone, *i.e.*, $KX_s\sqrt{kD}/\tanh(L\sqrt{k/D})$, is readily attained. Table IX summarizes the quantitative estimates of all of the permeability coefficients.

CONCLUSIONS

Baseline intestinal absorption studies of dinoprostone in the rat were established, and the results were mechanistically consistent with dinoprost. These two important prostaglandins provide the reference compounds from which the *in situ* absorption and metabolism in the intestinal membrane of their respective derivatives and analogues can be studied on a predictive level *via* the physical model approach. Such studies are in progress.

Influence of Mode of Intravenous Administration and Blood Sample Collection on Rat Pharmacokinetic Data

FRANCIS L. S. TSE ˣ, TSAILING CHANG, BARBARA FINKELSTEIN, FRANCES BALLARD, and JAMES M. JAFFE

Received June 13, 1983, from the *Drug Metabolism Section, Sandoz, Inc., East Hanover, NJ 07936.* Accepted for publication February 16, 1984.

Abstract □ The influence of the mode of intravenous dosing and blood sample collection on the pharmacokinetics of 4-[(3-methoxyphenyl)-methyl]-2,2,6,6-tetramethyl-1-oxa-4-aza-2,6-disilacyclohexane hydrochloride (I) was studied in the rat. Blood samples obtained from the tail and by exsanguination following injection of the ^{14}C-labeled drug into the caudal vein, the jugular vein, and the heart were analyzed for total radioactivity, and the concentration profiles from the different treatments were compared. Dosing and sampling from the tail vein resulted in significantly different blood levels (and related pharmacokinetic parameters) when compared to other methods, probably attributable to a local depot effect. Intracardiac administration tended to cause higher drug levels in the heart than intravenous doses, although no significant differences were found between the respective blood concentrations. The results showed that caudal vein injection is a simple and adequate method of intravenous administration in rats designated for exsanguinated blood and tissue collection. For serial blood sampling in individual animals, the dose may be given *via* the jugular vein and the blood collected from the cut tail. These methods require little or no surgical preparations and are particularly suitable for prolonged sampling in studies where a relatively large number of animals are involved.

Keyphrases □ Pharmacokinetics—influence of mode of intravenous administration and blood sample collection, rat □ Dosing—pharmacokinetics, mode of intravenous administration, blood sample collection

During the developmental process of a potential therapeutic agent, pharmacokinetic studies are often conducted at the same time as toxicity trials. While the oral route of administration is invariably used in these studies in order to be consistent with the toxicity tests, additional experiments employing intravenous doses are usually performed so that important pharmacokinetic parameters such as the volume of distribution and absolute oral bioavailability or absorption can be determined. In the rat, the caudal vein is often used as the site of injection. In contrast, injection *via* the jugular or femoral vein requires surgical exposure of the vein (1) and can be cumbersome in studies involving a large number of animals. Drugs are also administered by simple cardiac puncture, but the results may not be truly representative of an intravenous dose. Potential complications such as embolization and excessive local drug toxicity are further limitations of the intracardiac route. Intraperitoneal injection, commonly used for the administration of compounds to small animals, is different from intravenous dosing in that drug absorption from the peritoneal cavity is slower (2) and entails passage into the portal circulation, resulting in incomplete systemic bioavailability (3).

In recent years, numerous sensitive analytical methods that require only microsamples of blood have been developed, and pharmacokinetic data from individual rats or similar small animals can be obtained by serial sample collection. Several methods using a chronic indwelling catheter to facilitate repeated blood collection have been described (4–6), but the animal preparation procedures are elaborate and tedious and are incompatible with prolonged sampling periods in studies involving a large number of animals. Other methods of vascular access and their potential complications have been described in a recent review (7). A simple alternative to cannulation is the nonsurgical method of bleeding the rat from the cut end of its tail. However, due to the relatively low regional blood flow (8, 9), which could result in delayed mixing of the administered drug, the validity of tail concentration data remains unclear.

Using a new skeletal muscle relaxant, 4-[(3-methoxyphenyl)-methyl]-2,2,6,6-tetramethyl-1-oxa-4-aza-2,6-disilacyclohexane hydrochloride[1] (I), as a test compound, the present study was undertaken to examine the effect of the mode of intravenous dosing and blood sample collection on pharmacokinetic data in the rat. Blood was obtained from the tail and by exsanguination following injection of the ^{14}C-labeled drug into the caudal vein, the jugular vein, and the heart. Radioactivity concentration in the heart tissue after intracardiac administration was also measured for comparison with existing intravenous data.

Table I—Summary of Treatments

Treatment	Route of Dosing/Sampling	Dose, mg/kg	No. of Rats
1	Caudal Vein/Tail	10	3
2	Caudal Vein/Vena Cava	10	3/time point
3	Jugular Vein/Tail	10	3
4	Jugular Vein/Vena Cava	10	3/time point
5	Intracardiac/Tail	5	3
6	Intracardiac/Vena Cava	5	3/time point

benzyl moiety. The radiochemical purity of the product was established by the inverse isotope dilution method to be >95%, and the specific activity was 3.25 μCi/mg. The dose was prepared as a 10 mg/mL solution in water. For the intravenous doses (10 mg/kg), each rat received 1 mL of the solution/kg body weight. For injection into the caudal vein, the tail was first immersed for 1–2 min in warm water; for jugular vein dosing, the rats were maintained under light ether anesthesia and the vein was exposed by a small skin incision made in the neck to one side of midline. For intracardiac administration, the dose was reduced from 10 to 5 mg/kg due to frequent deaths at the high dose level. Thus, each rat received 1 mL/kg of the solution (5 mg/mL in normal saline) *via* a single cardiac puncture.

Serial blood samples (250 μL) were collected in heparinized micropipettes[2] from three rats in each dose group *via* the cut tail immediately before and at 5, 15, and 30 min and 1, 3, 5, and 8 h postdose. Of the remaining 21 rats three each were sacrificed at 5, 15, and 30 min and 1, 3, 5, and 8 h postdose. Blood (~5 mL) was collected *via* the vena cava. The heart of each sacrificed rat receiving the intracardiac dose was collected (Table I).

Analysis of Radioactivity—Aliquots of dose preparations, blood, and heart tissue homogenates were air dried and combusted in a sample oxidizer[3] using 9 mL of absorption medium[4] and 12 mL of scintillation cocktail[5]. Radioactivity was measured in a liquid scintillation counter[6]. The quench correction and efficiency of the counter were determined from a standard curve constructed using ^{14}C-labeled hexadecane[7] of known specific activity. The limit of sensitivity of the assay was defined as twice the mean background count. Gross sample counts below this level were considered to be not significantly different from zero. Blood and tissue concentrations of radioactivity were calculated as nanogram equivalents of I per milliliter or gram.

Treatment of Data—The dose-normalized blood levels of radioactivity at each sampling time were examined by analysis of variance. Because of the observed differences in data variance between groups, the statistical tests were performed on log-transformed data (10). If differences ($p < 0.05$) due to treatments were observed, results from individual treatments were compared by the Student's t test.

Since, in half of the experiments, blood at each sampling time was collected from different (sacrificed) rats, only mean concentration data were available for pharmacokinetic analysis. For consistency, only mean blood levels from the serially bled animals were used for this purpose. The blood concentration data were fitted to a biexponential function of the form:

$$C = Ae^{-\alpha t} + Be^{-\beta t} \quad (\alpha > \beta) \qquad \text{(Eq. 1)}$$

where C is the blood concentration of radioactivity at time, t, A and B are constants, and α and β are composite first-order rate constants. Attempts to fit the data to a triexponential function resulted in greater errors in parameter values with no increase in coefficients of determination. Initial estimates of pharmacokinetic parameters were obtained by standard graphic methods (11) while improved parameter estimates together with statistical analysis were obtained using the iterative nonlinear regression program NONLIN (12) on a computer[8]. The blood level data were weighted by their reciprocals in the regression analysis.

RESULTS

Mean blood levels of radioactivity, together with statistical analyses, are given in Table II. Results of pharmacokinetic analyses are given in Table III. The goodness of fit of the data to Eq. 1 was demonstrated by correlation coefficients of 0.97–1.00.

Comparison of the blood radioactivity levels showed that dosing and sampling, both from the tail vein (treatment 1), resulted in elevated blood level measurements throughout the 8 h sampling period, although the differences were statistically significant only at 0.083, 0.25, and 8 h. Treatment 1 also had a greater interanimal variability in blood levels, as indicated by the large *RSD* values (coefficients of variation) illustrated in Fig. 1. Comparison of the results from treatments 3 *versus* 4 and treatments 5 *versus* 6 also suggested that blood sampling near the site of drug administration yielded higher initial concentrations than at a more distal sampling site, although the differences were not statistically significant.

From Table III, analysis of blood level data obtained from all six treatments yielded similar distribution half-lives of 15–30 min. The elimination half-lives for treatments 2–5 were ~5 h, identical with those observed in previous experiments in which the drug was administered *via* the tail vein and blood was collected from the vena cava for 24 h (~5 half-lives)[9]. Thus, the 8-h sampling period employed in the present study was sufficient to describe the terminal linear phase. For treatments 1 and 6, the half-lives appeared longer. Because of the higher tail blood concentrations obtained following the caudal vein dose (treatment 1), the area under the curve value was almost 10 times greater than those observed for the other treatments. Accordingly, treatment 1 also resulted in markedly reduced plasma clearance and volumes of distribution.

During the intracardiac dosing experiments, it was necessary to reduce the dose from 10 to 5 mg/kg because of frequent deaths occurring at the high dose level, apparently due to elevated initial drug concentrations in the heart. This was confirmed by comparing the heart radioactivity concentration obtained following the intracardiac injection to existing data[9] measured after dosing *via* the caudal vein (Fig. 2). Despite a twofold difference in dose level, the 10-mg/kg caudal vein dose and the 5-mg/kg intracardiac dose gave similar radioactivity concentration in the heart at all times.

DISCUSSION

Assuming equal metabolic fate for the drug administered *via* the caudal vein, the jugular vein, and the heart, the blood concentration data of total radioactivity alone would generate sufficient information to answer the

questions outlined in the present study. By comparing treatment 1 *versus* 2, treatment 3 *versus* 4, and treatment 5 *versus* 6, the data seem to indicate that blood sampling near the site of drug administration yielded higher initial concentrations than at a more distal sampling site. Nonetheless, tail blood sampling after caudal vein administration (treatment 1) is the only treatment in this study that gave significantly different blood radioactivity levels and related pharmacokinetic parameters. Evidently, dosing *via* the caudal vein results in some residual drug at and/or near the injection site, so that sampling from the same location leads to elevated drug concentrations which are artifacts and which probably do not represent the circulating concentrations in blood. This phenomenon occurred despite the choice of a compound for this study with relatively high aqueous solubility. Furthermore, because it is technically difficult to uniformly dose *via* the tail vein (1), the magnitude of this depot effect can be quite variable, as demonstrated by the large interanimal differences in the blood levels measured for this group (Fig. 1).

However, the artifact which results from high concentrations after caudal vein dosing can be avoided if blood samples are obtained from an appropriate vein such as the vena cava, since the residual drug at the injection site probably represents a minute portion of the dose. Conversely, if the dose is administered *via* a different (*e.g.*, jugular) vein, the tail blood data seem to reflect true kinetics in the rat. These deductions are based on the close similarities in blood levels as well as pharmacokinetic parameters between treatments 2 and 3 and treatment 4. Treatment 4 concerns blood collected from the vena cava following drug administration *via* a major (jugular) vein and, therefore, is believed to provide data which most accurately describe the pharmacokinetics of the drug. From the results of treatments 2 and 4, it can also be deduced that the application of brief ether anesthesia in the jugular vein dosing procedure has no effect on the blood levels and pharmacokinetic parameters of the drug. Previous investigators (13) have reported that ether may interfere with hepatic drug metabolism and should not be used as an anesthetic in kinetic studies of drugs with short elimination half-lives (~15 min), but may be used for drugs with longer half-lives (>1.2 h).

The results of this study also demonstrate the potential differences between intravenous and intracardiac drug administration. After intracardiac dosing, substantial tissue uptake of drug occurred in the heart, resulting in excessive local drug toxicity at the 10-mg/kg dose level. However, the overall amount of drug reaching the systemic circulation appears comparable to that after the intravenous doses, as indicated by the similar blood radioactivity profiles obtained from treatments 2–4, and treatments 5 and 6, after normalizing by the doses.

In summary, dosing and subsequent sampling from the tail vein results in artifactual and variable blood concentration data due probably to a local depot effect. Although intracardiac injection appears to give blood levels similar to those obtained from true intravenous doses, the former tends to cause substantial tissue uptake of drug in the heart and should not be used in tissue distribution studies. For experiments employing a relatively large number of rats designated for exsanguinated blood and tissue collection, caudal vein injection is a convenient and appropriate method of intravenous dosing. On the other hand, if serial blood samples are needed to establish pharmacokinetic profiles in individual animals, they can be obtained simply from the cut tail after administering the dose *via* the jugular vein. Although injection *via* the jugular vein requires surgical preparation of the rat, it appears to be one of the more reliable methods for intravenous drug administration and, unlike most cannulation techiques, imposes no stress which may affect at least some aspects of normal physiology resulting in altered drug kinetics (7, 9, 14, 15).

Although these findings are probably applicable to a variety of drugs, the magnitude of the observed differences could be dependent upon the physicochemical properties of the individual compounds. Thus, further studies using additional compounds with significantly different chemical properties are warranted in order to evaluate the general applicability of these results.

Nonaqueous Cephalosporin Suspension for Parenteral Administration: Cefazolin Sodium

KENNETH S. E. SU ˣ, JOHN F. QUAY, KRISTINA M. CAMPANALE, and JOHN F. STUCKY

Received December 16, 1983, from *Lilly Research Laboratories, Eli Lilly and Company, Indianapolis, IN 46285.* Accepted for publication February 24, 1984.

Abstract □ The flocculation-deflocculation behavior of cefazolin sodium (I) in nonaqueous media and the effect of surfactants as measured by zeta potential, sedimentation, and porosity were studied. A significant difference in zeta potential was observed when the particles were suspended in different nonaqueous media. The addition of surfactant produced a deflocculated state. The surfactant deflocculated the particles by a process of supersaturation and crystallization involving a surfactant-cefazolin complex. The shielding effect of the surfactant on the surface of the particles also apparently affected their electrophoretic properties. Kinetic studies on the stability of the drug as a function of temperature were conducted; it appears that the chemical stability in ethyl oleate at room temperature is adequate for a reasonable shelf life. The efficiency of absorption of the drug from the ethyl oleate suspension was evaluated after intramuscular administration in dogs. The area under the plasma concentration *versus* time curve and urinary recovery indicated that cefazolin was 100% bioavailable from this nonaqueous preparation.

Keyphrases □ Cefazolin sodium—surfactants, stability, bioavailability □ Cephalosporin—nonaqueous suspension, stability, bioavailability

Parenteral pharmaceutical suspensions have been used for a long time (1–4). In general, this dosage form is comprised of a physiologically active agent and a vehicle. The vehicle is typically comprised of a suspending liquid, an emulsifying agent, a surfactant, density- and viscosity-adjusting substances, and preservatives. While water is generally the preferred suspending liquid, some physiologically active agents such as the cephalosporin antibiotics are not chemically stable in water-based parenteral pharmaceutical suspensions. Therefore, to achieve a ready-to-use cephalosporin preparation which can be stored at room temperature, it is desirable to develop a satisfactory suspension utilizing a nonaqueous liquid as the suspending medium. This paper describes the preparation of a unique, simple flocculated ready-to-use cefazolin sodium suspension which is dispersed in a nonaqueous medium. The efficiency of absorption of cefazolin from the nonaqueous system administered intramuscularly in dogs is also reported.

Table I—Flocculation-Deflocculation Behavior of Cefazolin Sodium in Peanut Oil [a]

Conc. of Polysorbate 80, %	Sedimentation Volume, H_u/H_o %[b]	Number of Turns to Redisperse
0	48	268
0.17	87	>3500
0.50	82	∞
3.30	63	∞

[a] In the presence of polysorbate 80. [b] Ultimate settled height (H_u) is based on the sedimentation height on day 33.

EXPERIMENTAL SECTION

The following chemicals were used: sterile micronized cefazolin sodium[1]; polysorbate 80, commercial grade[2]; lecithin[3]; ethyl oleate[4]; peanut oil[5]; cefazolin sodium[6]. For *in vivo* studies, sterile micronized cefazolin sodium and ethyl oleate were prepared under sterile conditions. The sterile cefazolin sodium was aseptically micronized[7] and ethyl oleate was sterilized in a preheated oven at 155°C for 5 h. For *in vitro* studies, the materials were used without further sterilization.

Particle Size Distribution—The determination of particle size distribution was conducted by the sedimentation method using a micromerograph[8]. The mean particle size diameter of the micronized material was 7 μm.

Preparation of Suspensions—For *in vitro* studies, suspensions were prepared using an electric mixer[9] to disperse 12.5 g of micronized cefazolin sodium in 50 mL of peanut oil in the presence of various amounts of polysorbate 80 [*i.e.*, 0, 0.17, 0.50, and 3.3% (w/v), respectively]. Suspensions containing lecithin in ethyl oleate were prepared in the same manner. However, the concentration of lecithin added was 0, 0.2, 0.4, 0.6, 0.8, and 1.0% (w/v). For *in vivo* studies, the suspension was aseptically prepared by dispersing 1 g-equivalent activity of sterile micronized cefazolin sodium in 3.0 mL of sterile ethyl oleate with an electric mixer. The suspension was then passed through a 150-mesh sterile stainless steel screen and mixed until uniform. For *in vivo* control studies, aqueous solutions of cefazolin sodium were prepared for intravenous and intramuscular administration by dissolving the sodium salt[6] in isotonic saline to a final concentration of 100 mg/mL as cefazolin.

Sedimentation Volume—The sedimentation volumes were recorded in terms of the ultimate settled height, H_u, to the original height, H_o, as described in the literature (5, 6):

$$\text{Sedimentation Volume} = H_u/H_o \qquad \text{(Eq. 1)}$$

Redispersibility—The number of revolutions necessary to restore the suspension to homogeneity was recorded by means of a multi-purpose rotator[10] with the modification described by Matthews and Rhodes (7).

Turbidity—The turbidity of the supernatant of the suspensions was measured by an analytical nephelometer[11] after cefazolin sodium suspensions had been kept at 25°C for 1 month. The procedure was carried out as described by the manufacturer (8).

Crystal Growth—Crystal size changes with time were microscopically examined. Cefazolin sodium (I) in the dry state was compared with I in a suspension at initial time, and in a suspension stored for 3 months at 25°C.

Viscosity—The viscosities of ethyl oleate and peanut oil were measured with a viscometer[12].

Porosity—The porosity of a sedimentation bed was determined by the method of Kaneniwa and Takamura (9).

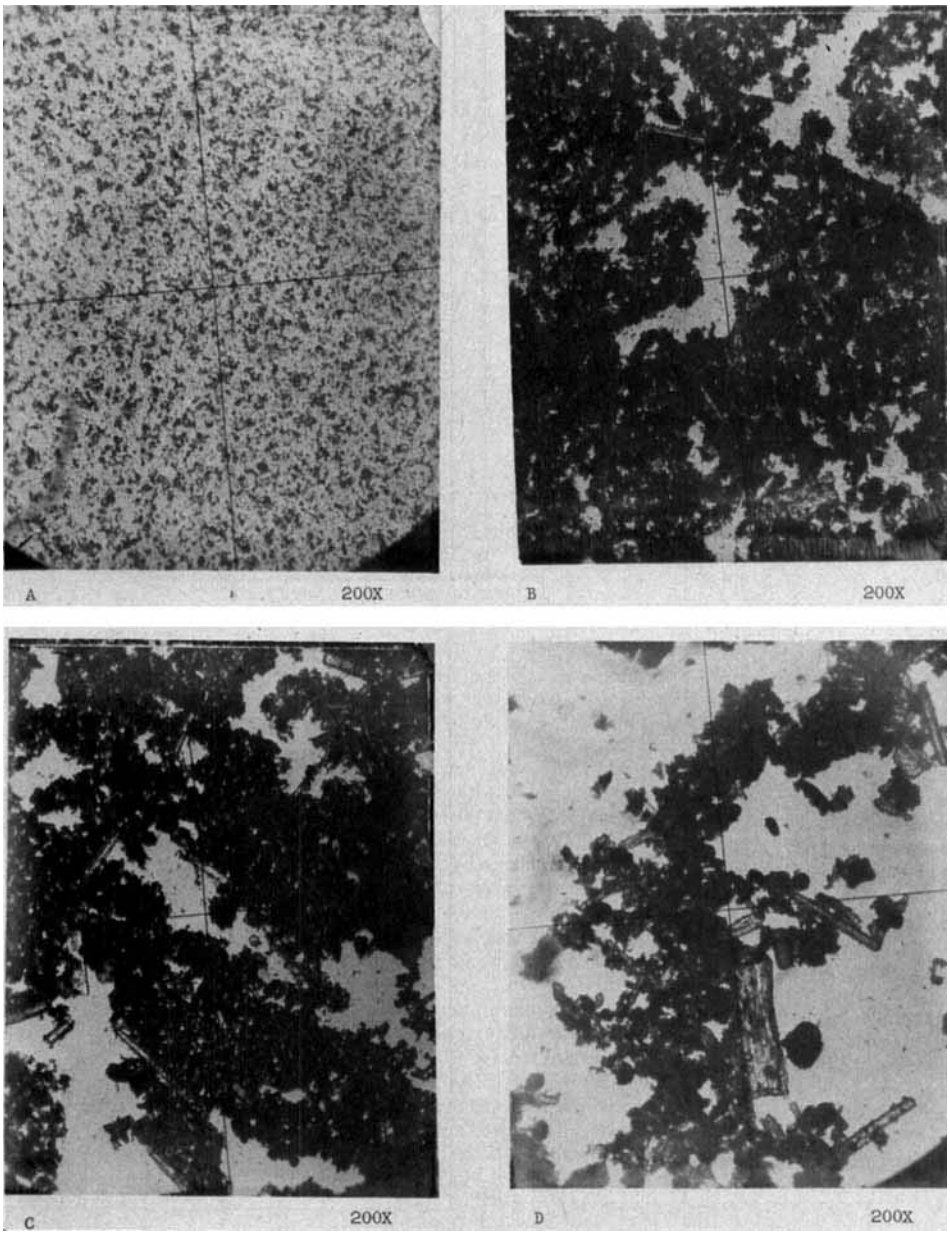

Figure 1—*Microscopic examination of agglomeration and crystal growth of cefazolin sodium suspension in the presence of 0% (A), 0.17% (B), 0.5% (C), and 3.3% (D) polysorbate 80.*

Electrophoretic Mobility—Electrophoretic mobility was measured with a zeta meter[13] equipped with a high voltage power booster[13]. The measurement procedure is described in the literature (10). Zeta potential (ZP) was calculated from the Helmholtz-Smoluchowski equation:

$$ZP = \frac{4\eta}{D} EM \qquad \text{(Eq. 2)}$$

where, at a fixed temperature, η is the viscosity of the suspensing medium in equilibrium, D is the dielectric constant of the suspending medium, EM is the electrophoretic mobility in cm/s per electrostatic volts (esu)/cm, and ZP is the zeta potential of the suspended particle in esu. Since the ZP is always <1 (practical) volt, it is more conveniently expressed in millivolts. Equation 2 then becomes:

$$ZP = 113{,}000 \frac{\eta}{D} EM \qquad \text{(Eq. 3)}$$

where ZP is in the unit of millivolts (mV) and EM is expressed in μm/s per V/cm. The dielectric constants of ethyl oleate and peanut oil have been described (11).

Kinetic Study on Stability of Cefazolin Sodium Suspension—Stability studies were conducted at 57°C, 60°C, 80°C, and 90°C as a function of time. Samples were assayed microbiologically according to CFR§436.105 (*i.e.*, Certified Federation Registration) with *Bacillus subtilis* ATCC 6633 substituted as the assay organism. The kinetic treatment of the data has been previously described (12, 13).

***In Vivo* Bioavailability Evaluation**—Female mongrel dogs (weight 13–20 kg) were fasted overnight with access to water. On the day of the experiment, they were transferred to stocks in which they could stand or sit comfortably for the duration of the test. A retention catheter[14] was inserted into the urinary bladder of each dog for collection of all urine produced during the test period.

Cefazolin sodium (I) was administered as a single 15-mg/kg bolus dose *via* acephalic vein (intravenous) or the biceps femoris muscle (intramuscular). At specified time intervals, samples of urine were collected, chilled in an ice bath, and then frozen until analyzed. At the same time, a blood sample was withdrawn from one cephalic vein into a heparinized evacuated tube[15]. After centrifugation, a plasma sample was removed, chilled, frozen, and analyzed in the following manner. On the day of the assay, the plasma and urine samples were thawed. Urine samples were diluted, as required, in isotonic 0.1 M phosphate buffer (pH 6.0). The antibacterial activity of the diluted samples was assayed in a disk plate agar diffusion test with *B. subtilis* against standard solutions of cefazolin in the same buffer. Plasma samples were diluted with dog serum and assayed in the same way against standard solutions of cefazolin in dog serum.

[a] Mean of three determinations.

RESULTS AND DISCUSSION

During the entire study, cefazolin sodium particles were well suspended in ethyl oleate; a good flocculated system resulted. In contrast, caking was observed in the peanut oil suspensions. A significant difference in zeta potential was observed between cefazolin sodium particles suspended in peanut oil and ethyl oleate (*i.e.*, −2.57 mV ± 0.09 mV *versus* −27.1 mV ± 1.03 mV, respectively). These results are consistent with reported data that the ability to be suspended is correlated with the zeta potential (7, 14).

Effect of a wetting agent on the physical stability of a nonaqueous suspension was evaluated. Surfactants are widely used in pharmaceutical formulations as wetting agents. In the cefazolin sodium suspension in peanut oil, the addition of various amounts of polysorbate 80 produced a deflocculated state. This change was indicated by the difficulty of redispersibility, evidenced by the number of revolutions of the redispersing apparatus required to return the system to a homogenous state (Table I). There was an increase in sedimentation volume by adding 0.17% of polysorbate 80. However, an increase in concentration of polysorbate 80 above this concentration produced a reduction in sedimentation volume. In general, in an aqueous suspension system, a progressive rise in sedimentation volume is accompanied by an increase in the ease of redispersibility (15). In contrast to the conventional aqueous system, no correlation between the redispersibility of the sedimentation bed and the sedimentation volume was found in this nonaqueous system. Considering the interaction of polysorbate 80 with cefazolin sodium, it is possible that cefazolin sodium particles were deflocculated by a process of supersaturating and crystallizing effects produced by the solubilization of the polysorbate 80–cefazolin sodium complex. As shown in Fig. 1, microscopic examination indicated that extensive agglomeration and crystal growth did indeed occur.

An emulsifying agent is commonly included in the formulation of parenteral preparations. Because the agent lowers interfacial tension, the drainage property of a parenteral suspension from the vial can be remarkably improved. In this study, lecithin was chosen as an emulsifying agent and the effect of lecithin on the stability of cefazolin sodium dispersed in ethyl oleate was evaluated. Unlike the peanut oil system, cefazolin sodium in the ethyl oleate suspension in the presence of lecithin produced a deflocculated state accompanied by a decrease in sedimentation volume. The zeta potential of cefazolin sodium decreased with the addition of lecithin and remained essentially constant throughout the concentration range studied (Fig. 2). Furthermore, the effect of increasing lecithin concentration on the zeta potential of cefazolin sodium was paralleled by the effect of lecithin concentration on redispersibility. The data on the porosity of the sedimentation bed correlated well with the data on the sedimentation volume ratio. As shown in Fig. 3, the porosity of the sedimentation bed decreased with the addition of lecithin and the suspension resulted in a deflocculated state which correlates to ability to be suspended.

It is also of interest to compare the appearance of the supernatants of the suspensions relative to their physical stability. As shown in Fig. 4, the turbidity was minimum at 0 and 1.0% of lecithin in the formulation. No correlation was found between the degree of turbidity in the supernatant and the degree of flocculation. These data suggest that the cefazolin sodium particles might be initially well dispersed due to an electrical repulsive force between particles. In the presence of lecithin, however, the contribution of electrical repulsive

Intravenous	1.0	134 ± 15	89.1 ± 2.4	4609 ± 363
Intramuscular	40	32.4 ± 2.4	79.8 ± 2.4	4319 ± 341
Suspension in Ethyl Oleate				
Intramuscular	40	28.1 ± 4.0	94.1 ± 8.0	4512 ± 256

[a] Cumulative (24-h) recovery of antibacterial activity in urine. [b] Area under the plasma concentration *versus* time curve.

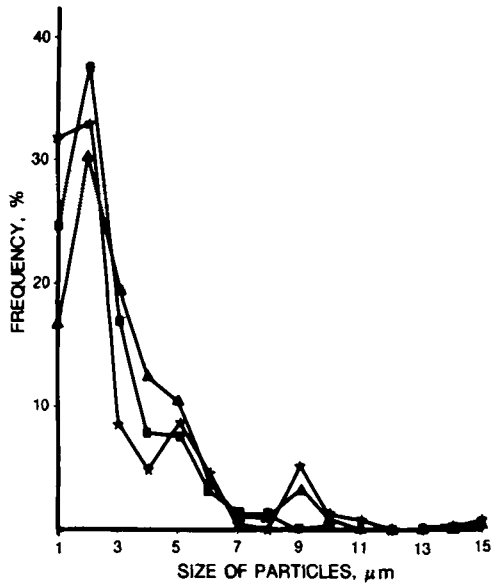

Figure 5—*Particle size frequency distribution curve of cefazolin sodium suspension in ethyl oleate. Key: (■) cefazolin sodium in dry state; (*) cefazolin sodium suspension at initial time; (▲) cefazolin sodium suspension aged 3 months at 25°C.*

force was diminished by a shielding effect on the surface of cefazolin particles as reflected in their electrophoretic properties.

Figure 5 shows the results of the evaluation of crystal growth. Measurement of changing particle size distribution as a function of time under three different storage conditions showed no significant crystal growth.

The potency of cefazolin sodium in ethyl oleate was studied at high temperatures. An Arrhenius plot (with 95% confidence limits) of degradation constants of cefazolin sodium suspension as a function of temperature is shown

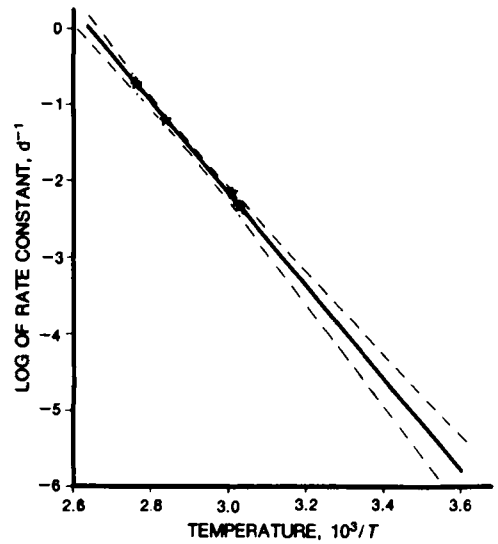

Figure 6—*Arrhenius plot with 95% confidence limits of degradation constants of cefazolin sodium suspension in ethyl oleate:* y = −5.916x + 15.556; r = 0.998.

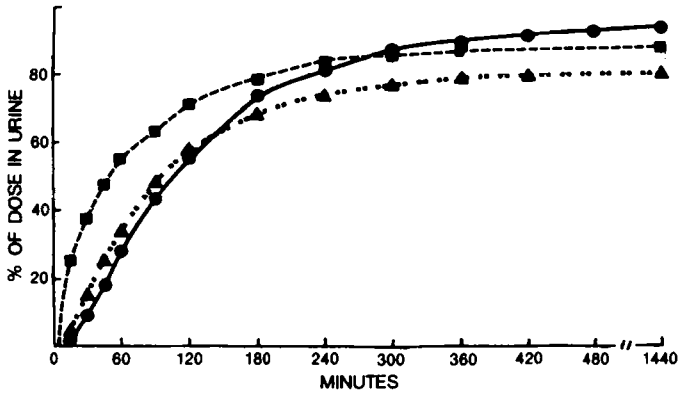

Figure 7—*Mean recovery of antibacterial activity in the urine of female mongrel dogs after administration of 15 mg/kg of cefazolin. Key: (■) aqueous solution administered intravenously; (▲) aqueous solution administered intramuscularly; (●) ethyl oleate suspension administered intramuscularly.*

in Fig. 6 ($y = -5.916x + 15.556$, $r = 0.998$). By extrapolation from the Arrhenius plot, it appears that the chemical stability of cefazolin sodium in ethyl oleate would be adequate for satisfactory shelf life at room temperature. As shown in Table II, the experimental values are well correlated with the predicted values.

In Table III, the performance of one intravenous and two different intramuscular formulations of cefazolin sodium in female mongrel dogs are compared. Based on the results of an analysis of variance, there are no statistically significant differences between the mean values for the area under the plasma concentration *versus* time curves for any of the three treatments ($p > 0.1$). By the same criterion, there are also no differences between the amounts of antibacterial activity recovered in urine by 24 h for the three treatments. The time course of the appearance of antibacterial activity in urine (Fig. 7) suggests that, as expected, cefazolin is more rapidly excreted in the urine following intravenous administration than following intramuscular administration.

The mean peak plasma concentration obtained following intravenous administration of cefazolin was significantly higher than that obtained with the intramuscular preparations, but the mean peak plasma concentrations obtained with the two intramuscular preparations were not different ($p > 0.1$). From these comparisons, it is concluded that in dogs administered 15 mg/kg intramuscularly, the total availability of cefazolin sodium suspended in ethyl oleate is not significantly different from that in aqueous solution. Furthermore, judged by the area under the plasma concentration *versus* time curve and the urinary recovery of antibacterial activity, the bioavailability of cefazolin sodium from this nonaqueous preparation approaches 100%.

In summary, it is known that physical stability is one of the most challenging problems when developing an acceptable suspension. This study demonstrates that by application of fundamental physical parameters, including sedimentation height, sedimentation rate, porosity of sedimentation bed, redispersibility, zeta potential, and turbidity, a good understanding of the physical stability of a nonaqueous cephalosporin suspension can be reached and potential problems relating to physical stability can be identified in the early stages of product development.

Liquid Chromatographic Assay for Diflorasone Diacetate in Cream and Ointment Formulations

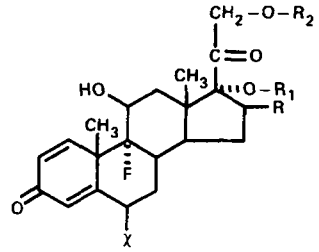
M. C. SHAW and A. J. VANDERWIELEN[x]

Received October 3, 1983, from *Product Control I, The Upjohn Company, Kalamazoo, MI 49001.* Accepted for publication February 29, 1984.

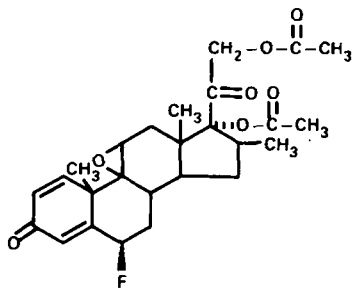
Abstract □ A high-performance liquid chromatographic assay for quantitating diflorasone diacetate (I) in cream and ointment formulations and in bulk form is described. Isoflupredone acetate (II) was used as the internal standard and a 3-μm silica gel column with a mobile phase comprised of water-saturated butyl chloride–water-saturated methylene chloride–tetrahydrofuran–acetic acid (350:125:10:15) led to an efficient separation. The method gave accurate results for four formulations, two creams and two ointments, as well as the bulk drug. The assay has an *RSD* of ~1.8% for the cream formulations, 1.3% for the ointment formulations, and 1.0% for the bulk drug. The method is specific for I and capable of resolving structurally related compounds.

Keyphrases □ Diflorasone diacetate - HPLC, cream, ointment, bulk drug □ HPLC—diflorasone diacetate, cream, ointment, bulk drug

Diflorasone diacetate (I) in topical formulations is indicated for the relief of inflammatory manifestations of acute and chronic corticosteroid-responsive dermatoses (1). It is available as a 0.05% cream- or ointment-based topically applied product[1]. The high-performance liquid chromatographic (HPLC) analysis of similar topical anti-inflammatory steroids has appeared (2). This report describes a new normal-phase HPLC assay that is specific for diflorasone diacetate in two cream and two ointment formulations. The assay is also capable of separating several structurally related compounds: the 9,11-epoxide (III), 6β-fluoro analogue (IV), 6-defluoro analogue (V), the 17-OH,21-OAc analogue (VI), and the 17-OAc,21-OH analogue (VII) of I.



I R=CH_3, R_1=Ac, R_2=Ac, X=α-F
II R=H, R_1=H, R_2=Ac, X=H
IV R=CH_3, R_1=Ac, R_2=Ac, X=β-F
V R=CH_3, R_1=Ac, R_2=Ac, X=H
VI R=CH_3, R_1=H, R_2=Ac, X=α-F
VII R=CH_3, R_1=Ac, R_2=H, X=α-F



III

EXPERIMENTAL SECTION

Materials—Diflorasone diacetate[2] (I), isoflupredone acetate[2] (II), and the related compounds III–VII[2] (3–7) were obtained in pure form and dissolved in water-saturated chloroform for chromatography and spectroscopy. Solvents and reagents were commercial analytical grade. Placebo materials were obtained in-house[2].

Chromatographic Conditions—A modular liquid chromatograph including pump[3], fixed-loop injector[4], fixed-wavelength detector[5] (254 nm), and a minicomputer[6] were used. Commercial 3-μm[7] silica gel columns (10 cm × 4.6 mm i.d.) were used at ambient temperature. The mobile phase, deaerated under vacuum sonication prior to use, consisted of water-saturated butyl

Table I—Response Factors for Related Compounds

Compound	Mean Response Factor[a]
I	1.00
III	1.64
IV	1.04
V	1.23
VI	1.04
VII	0.96

[a] Mean of nine determinations, peak area response. Results calculated as in the *Experimental Section.*

chloride-water-saturated methylene chloride-tetrahydrofuran-acetic acid (350:125:10:15). The flow rate was adjusted to 2.5 mL/min.

Internal Standard—A solution of water-saturated chloroform containing 0.04 mg/mL of isoflupredone acetate (II) was used. About 3 mg of diflorasone diacetate (I) reference standard[2] was weighed accurately and 100.0 mL of internal standard solution was added.

Sample Preparations—*Creams*—Cream containing 1 mg of diflorasone diacetate was accurately weighed into a 35-mL screw-cap disposable vial[8], 30.0 mL of internal standard solution was added, and the solution was shaken for 30 min. The vial was then centrifuged at 2000 rpm for 15 min. The top layer (excipient) was then removed by aspiration leaving a clear lower chloroform layer.

Ointments—Ointment containing 0.5 mg diflorasone diacetate was accurately weighed into a 35-mL screw-cap disposable vial[8], 15.0 mL of internal standard solution was added, and the sample treated as in the cream assay.

Bulk Drug—About 1.5 mg of diflorasone diacetate was dissolved in 50.0 mL of internal standard solution.

Procedure—Aliquots of sample or standard preparation were injected using a 10-μL fixed-loop injector. The resulting chromatograms were recorded and analyzed by computer integration. Two reference standard weighings, weight normalized for response, were run at the beginning and end of the run and at every 6-8 samples. The detector attenuation was set at 0.032 absorbance units.

The diflorasone diacetate (I) content, expressed in milligrams per gram for creams and ointments and in percent for bulk drug, was calculated using the internal standard method and peak area response(8).

Recovery studies were performed by adding 50-150% of the labeled amount of diflorasone diacetate (I) to each of the two types of cream and ointment placebos. The samples were then treated as described under *Sample Preparations.*

The relative response of the structurally related compounds III-VII were determined by comparing the weight-normalized response for accurately prepared water-saturated chloroform solutions of each (~0.05 mg/mL) with a similar preparation of diflorasone diacetate (I). The response factors were calculated using peak area response (Table I).

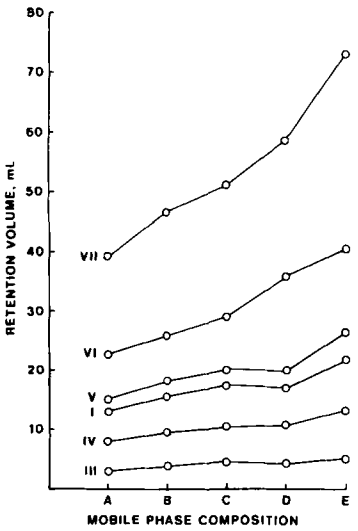

Figure 1—*Plot of retention volume* versus *mobile phase composition of water-saturated butyl chloride-water-saturated methylene chloride-tetrahydrofuran-acetic acid in a ratio of 325:150:10:15 (A), 350:125:10:15 (B), 375:100:10:15 (C), 350:125:5:15 (D), and 350:125:10:5 (E).*

A	99.4	1.5
B	100.1	0.6
Ointment		
C	100.2	0.6
D	100.8	0.9

[a] Six point recovery curve from 50-150% of recommended assay concentration.

RESULTS

Chromatography and Specificity—The selectivity of the chromatographic conditions for I is demonstrated by its ability to resolve compound IV, which differs only in the spatial orientation of the fluorine atom at the 6-position. In addition compound V, which lacks a fluorine atom at the 6-position, is also resolved from I.

The development of chromatographic conditions appropriate for the analysis of I in bulk form and in cream and ointment formulations was based in part on the work of Beyer (9). In addition to the microparticulate column[9] described by Beyer, other 5- and 10-μm silica columns[10] were tried, but with limited success.

Experimentation with mobile phases containing butyl chloride and methylene chloride in addition to polar modifiers (tetrahydrofuran, methanol, acetic acid) revealed that the proportion of methylene chloride was important in column selectivity. Figure 1 depicts the effect on retention volume of selective changes in a mobile phase containing water-saturated methylene chloride. These data were obtained using a small-particle short silica column offering resolution of all peaks of interest, a reasonable analysis time, reproducible chromatography, and lack of placebo interference[7]. The final mobile phase condition chosen (Fig. 1, condition B) was judged to offer the most satisfactory results from the standpoint of resolution and analysis time. The chromatographic separation of compounds I-VII, using condition B, is shown in Fig. 2.

Recovery and Linearity—Recovery of I from either cream- or ointment-spiked placebos was tested by adding 50-150% of the labeled amount of I (0.5 mg of I/g) to each of the cream or ointment placebo formulations. The average recovery of I, calculated using peak area response, for the two cream formulations, "A" and "B," and ointment formulations, "C" and "D," are shown in Table II. A plot of the amount of I added *versus* the amount of I recovered indicated that the slope was within experimental error of the expected slope of I, and the *y*-intercept was 0 for all the formulations tested. The coefficients of correlation, *r*, for the recovery plots were >0.999, indicating that the assay is linear for the cream or ointment formulations tested (50-150% of labeled amount of I, 0.5 mg of I/g).

Table III—Diflorasone Diacetate (I) Assay Results for Cream and Ointment Formulations Using Peak Area Ratio Response

Formulation[a]	I Found, mg/g[b]	Percent of Label, %
Cream		
A	0.494–0.505	98.8–101.0
B	0.483 0.510	96.6–102.0
Ointment		
C	0.488–0.498	97.6–99.6
D	0.451–0.485	90.2–97.0

[a] Product (A and C) and experimental (B and D) formulations. [b] Range of assay results obtained after assaying four lots per formulation.

Quantitation of III–VII was examined to determine if the responses of these structurally related compounds were linear over the 0.1–1.0% (w/w) range. These data were obtained to test the applicability of the method for potential impurities. The individual slopes for the calibration curves using peak area percent for III–VII were all 0.96–1.00 and the y-intercepts were not significantly different from zero. The coefficients of correlation, r, for plots of related compounds added *versus* amount found were all >0.999.

DISCUSSION

Presented in Table III are the range of results obtained using the procedure for cream and ointment product formulations A and C and cream and ointment experimental formulations B and D. The precision of the method was determined by replicate analyses of lots from each formulation. The day-to-day assay precision, expressed as *RSD*, was ~1.8% for cream formulations A and B and ~1.3% for ointment formulations C and D.

In addition to the determination of I in cream and ointment formulations, three lots of bulk drug were assayed for purity on the "as is" basis (Table IV). The *RSD* for the purity determination of I was ~1.0% using peak area ratio response.

The chromatographic method described is an accurate and precise method for the determination of diflorasone diacetate (I) in creams, ointments, and bulk drug. The method was found to be reproducible as well as rugged, making it suitable for use as a routine assay. The ability of the method to separate structurally related compounds makes the method useful for monitoring bulk drug and product stability.

Table IV—Diflorasone Diacetate Assay Results for Bulk Drug Using Peak Area Ratio Response

Lot	Assay[a] %	RSD, %
I1	99.3	1.1
I2	99.2	0.9
I3	99.7	0.7

[a] Calculated on the "as is" basis; the results are averages of six determinations over 2 d.

Effect of Nitroglycerin-Soluble Additives on the Stability of Molded Nitroglycerin Tablets

M. J. PIKAL ˣ, A. L. LUKES, and J. W. CONINE

Received June 22, 1983, from *Eli Lilly and Company, Indianapolis, IN 46285.* Accepted for publication February 1, 1984.

Abstract □ Nitroglycerin vapor pressures at 25°C were determined for additive–nitroglycerin systems over the additive–nitroglycerin weight ratio range of 0.5 to 3.0 for 16 additives exhibiting solubility in nitroglycerin. The effects of the additives on nitroglycerin chemical stability at 25°C and 50°C were also studied. Tablet stability characteristics, *i.e.*, content uniformity, open-dish stability, and chemical decomposition were evaluated for selected tablet formulations. Most additives lowered the vapor pressure of nitroglycerin sufficiently to stabilize content uniformity when used at additive–nitroglycerin weight ratios near 1. Higher additive levels are needed for significant potency stabilization in open-dish stability tests, but these levels normally decrease the chemical stability of nitroglycerin. However, stabilization of content uniformity, a twofold reduction of potency loss in an open-dish stability test, and chemical stability are possible with at least three of the additives studied.

Keyphrases □ Nitroglycerin—vapor pressure in sublingual molded tablets, intertablet migration, effect of additives □ Tablet stability—nitroglycerin sublingual molded tablets, vapor pressure, intertablet migration, effect of additives

A number of workers have emphasized both the physical instability of molded nitroglycerin tablets arising from vaporization, and subsequent migration of nitroglycerin, and the improvement in stability obtained by incorporating a nitroglycerin-soluble additive in the formulation (1–7). The additive lowers the vapor pressure of nitroglycerin which results in: (*a*) a reduction of the evaporation rate of nitroglycerin from tablets exposed to ambient air currents (1); (*b*) a marked decrease in losses due to absorption in packaging material (7); (*c*) stabilized content uniformity, in that most of the intertablet nitroglycerin migration which occurs in conventional (unstabilized) tablets is thermodynamically impossible in a closed system of stabilized tablets (4). A modest vapor pressure reduction is sufficient to stabilize the content uniformity within a sample of tablets (4). However, both evaporation rate and package absorption are least for the formulation of lowest vapor pressure.

Although there have been several reports of chemical instability in nitroglycerin tablets (8, 9), chemical decomposition is normally not a problem in conventional nitroglycerin tablets. However, the agent employed to stabilize content uniformity may have an adverse effect on chemical stability. Several studies (7, 8, 10) suggest that both povidone (7) and polyeth-

[a] At selected R values (R is additive-nitroglycerin weight ratio). [b] Equilibrium solubility is R = 0.9. [c] Equilibrium solubility is R = 0.8. [d] Equilibrium solubility is R = 1.1. [e] Incomplete solubility even at R = 0.5. A small fraction of the sample appears to be essentially insoluble in nitroglycerin.

ylene glycol (8, 10) may accelerate the hydrolysis of nitroglycerin to a point where, at high temperature, decomposition becomes a significant factor in tablet stability. This study was initiated to investigate the effects of selected nitroglycerin-soluble materials on nitroglycerin vapor pressure and on tablet stability as part of an effort to develop tablet formulations which would stabilize content uniformity without adversely affecting chemical stability.

EXPERIMENTAL SECTION

Materials and Assay Procedure—The nitroglycerin and povidone were described previously (4). The other additives were obtained from commercial sources[1] and were used as supplied except for vacuum drying to remove volatiles. Nitroglycerin-additive samples were prepared as previously described (4). Samples denoted "powder" are nitroglycerin-additive-β-lactose systems in powder form containing ~1.5% nitroglycerin.

Nitroglycerin was assayed as described previously (7) while dinitroglycerin and mononitroglycerin were assayed semiquantitatively by TLC (11) and quantitatively by HPLC. The HPLC method[2] employed a partisil ODS column[3] and a 230 nm UV detector[3]. The solvent was 70:30 (v/v) water-acetonitrile at a flow rate of 3 mL/min. Four peaks were observed with partially decomposed nitroglycerin with retention times (1–5 min) in the following order: nitric acid with glycerol, mononitroglycerin (both isomers), dinitroglycerin (both isomers), and nitroglycerin. High levels of povidone yielded a small peak at the dinitroglycerin retention time, making a small povidone correction necessary. This peak appeared to be due to unreacted monomer. Variation in the solvent composition between the sample and the elution medium resulted in small positive or negative peaks at the mononitroglycerin retention time. Probably because of this interference, the mononitroglycerin assay data are much less precise than the corresponding data for the di- and tri-esters.

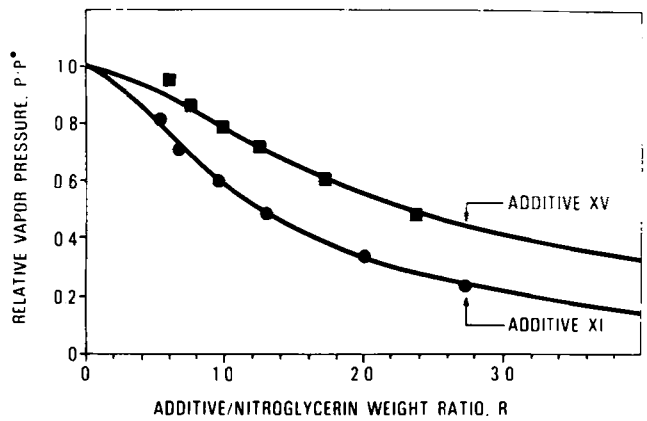

Figure 1—*Vapor pressure of nitroglycerin at 25°C in solutions of nitroglycerin and additive XV (■) and additive XI (●). The lines represent* P/P_0 *calculated from Eq. 1.*

Vapor-Pressure Measurements—Vapor pressures were measured by the modified Knudsen effusion method (4, 12). Powder systems of nominal additive-nitroglycerin weight ratios of 0.5, 1.0, and 2.0 were studied. Differential measurements (4, 12) were made on each sample. Continuous measurements of vapor pressure were made (4) on samples of additive-nitroglycerin weight ratios of 0.5. Replicate measurements were carried out (4).

RESULTS

Vapor-Pressure Reduction—Vapor-pressure results are summarized in Table I. Density data are either measured in this laboratory or were given by the supplier of the additive. The additive molecular weight was calculated from the average chemical formula or was taken directly from information provided by the supplier.

Vapor pressure raw data were found to be well represented by the equation (13):

$$\ln P/P_0 = \ln(1-\phi_2) + \left(1 - \frac{V_1}{V_2}\right)\phi_2 + \chi\phi_2 \qquad \text{(Eq. 1)}$$

where P is the vapor pressure of the additive-nitroglycerin solution, P_0 is the vapor pressure of pure nitroglycerin, ϕ_2 is volume fraction of additive in the

[a] The water contents of the dried powders were all in the range 0.45–0.58% (w/w). [b] Storage in closed glass bottles. Dinitroglycerin content determined by TLC; N = none detected; T = trace observed (~2–5%); M = moderate level observed.

nitroglycerin phase, V_1 and V_2 are the molar volumes of nitroglycerin and additive, respectively, and χ is the interaction parameter which was arbitrarily assumed to have the form:

$$\chi = \chi_0 + b\phi_2^n \qquad \text{(Eq. 2)}$$

where χ_0, b, and n are constants evaluated from the data. An integer value of n was chosen to give the best linear least-squares fit of χ as a function of ϕ_2^n. Additivity of volume was assumed so ϕ_2 may be calculated from the additive-to-nitroglycerin weight ratio, R, according to:

$$\phi_2 = \frac{R}{R + \rho_2/\rho_1} \qquad \text{(Eq. 3)}$$

where ρ_2 and ρ_1 are the densities of additive (Table I) and nitroglycerin (14), respectively.

Data representative of systems exhibiting complete miscibility of nitroglycerin and additive over the composition range studied are shown in Fig. 1. The solid line represents P/P_0 calculated from Eq. 1 while the squares and circles are experimental points obtained by averaging at least four independent measurements. With some additives (III, IV, XII, XIII), miscibility is observed only at lower R values. Consequently, the vapor pressure of these systems at equilibrium is independent of composition at R values larger than the solubility limit (Fig. 2, square symbols). However, during the vapor pressure measurement, R increases as effusion proceeds and normally a supersaturated solution of additive in nitroglycerin is formed. The data represented by circles (Fig. 2) were obtained from supersaturated solutions formed during the effusion measurement.

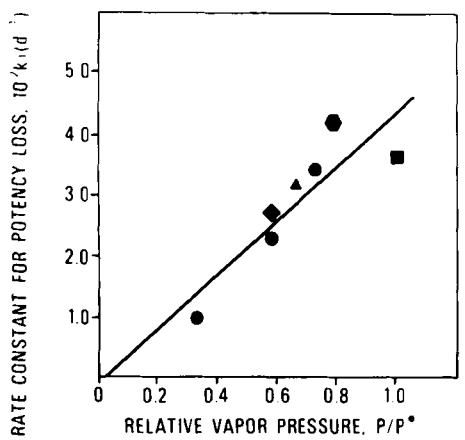

Figure 3—*Correlation between potency losses in open-dish stability tests and nitroglycerin vapor pressures. Key: (■) no additive; (●) additive V; (▲) additive VII; (◆) additive VIII; (●) additive XV.*

Smoothed values of relative vapor pressures, P/P_0, and values of the partial derivative $(\partial \ln P/\partial \ln N)_A$, were calculated from Eq. 1 (Table I). Here, A and N are the masses of additive and nitroglycerin, respectively. A large value of this derivative indicates that evaporation of a small amount of nitroglycerin from the sample produces a large reduction in vapor pressure.

Stability—*Chemical Stability of Powders*—The chemical stability of nitroglycerin in additive–nitroglycerin phases was studied for both dried powders[4] and for powders equilibrated with 87% relative humidity prior to storage (Table II). The systems studied were ~98% lactose powder with the additive–nitroglycerin phase coated on the lactose crystals.

Tablet Stability in Closed Bottles—The effects of selected additives on chemical stability and content uniformity stability were investigated for tablet samples sealed in glass bottles (Table III). As an index of chemical stability at ambient temperature, dinitroglycerin content (HPLC assay) after 2 years storage at 25°C are listed.

Potency losses after 2 years at 25°C averaged 12% for the tablets containing povidone (with no apparent correlation with level of povidone), ~9% for tablet Lot N, an average of 6% for the tablets without an additive, and 2–5% for other tablets. As a measure of chemical stability at high temperature, potency losses after 6 months at 50°C were determined for selected tablet lots (Table III). Potency loss data are uncertain within ~±3%, so except for the greater potency losses shown by lot K, lot N, and the povidone containing lots, all lots are essentially equivalent. Content uniformity (Table III) is expressed as the relative standard deviation for single tablet nitroglycerin assay (weight nitroglycerin per unit tablet weight) of thirty tablets.

Tablet Stability in an Open-Dish Test—Tablets were stored at 25°C in open petri dishes exposed to ambient air currents. Thirty tablet samples were taken for single tablet assay at day six and day twelve. The observed changes in potency and content uniformity are tabulated (Table IV).

DISCUSSION

Vapor Pressure and Open-Dish Stability—The loss in tablet potency during open-dish storage is undoubtedly due to evaporation of nitroglycerin, and therefore the rate of loss should correlate with the nitroglycerin vapor pressure. To provide rate data suitable for correlation with the tablet vapor pressure, effective first-order rate constants for potency loss were determined from the data in Table IV[5]. The resulting rate constants are plotted as a function of relative vapor pressure of nitroglycerin (from Table I) in Fig. 3. The line is the linear regression line ($r = 0.88$). Considering the difficulty in obtaining

[4] The dried samples were air dried in a forced-air oven at 43°C. Relative humidity decreases in ambient air (25°C; relative humidity, ~55%) ~three-fold when heated to 43°C by the drying oven. Thus, the dried samples were equilibrated with ~18% relative humidity at 43°C.

[5] The data were consistent with first-order loss of nitroglycerin, *i.e.*, linear semilogarithmic plots of potency *versus* time. However, insufficient data were available to reveal subtle variations from first-order behavior.

reproducible potency loss data on samples stored in an open dish[6], the correlation is very good. The rate of potency loss is essentially proportional to the initial vapor pressure of nitroglycerin in the tablet formulation.

Content Uniformity of Tablets—Poor content uniformity at the time of manufacture may arise from causes unrelated to the volatility of nitroglycerin, *i.e.*, poor mixing, solution migration during drying and subsequent tablet surface erosion, *etc.* However, a decrease in content uniformity on aging in closed bottles is due to migration of nitroglycerin, largely intertablet migration (2-4).

An additive will be effective in preventing intertablet nitroglycerin migration if two criteria are met (4): (*a*) the additive lowers the vapor pressure of nitroglycerin by more than ~15%; (*b*) Evaporation of nitroglycerin from the additive-nitroglycerin phase results in significant further reduction of vapor pressure [*i.e.*, the quantity $(\partial \ln P/\partial \ln N)_A$ (Table I) should be large[7]].

If criterion *a* is met, condensation of nitroglycerin in empty tablet pores is prevented, while meeting criterion *b* minimizes condensation in tablet pores that are partially filled with nitroglycerin-additive phase (4). Thus, the relative importance of criteria *a* and *b* depends on whether the small pores (condensation sites) in fresh tablets are empty or are partially filled with nitroglycerin-additive phase. This detailed information is not available. However, if both criteria are met, the additive should be effective in preventing significant intertablet transfer of nitroglycerin.

On this basis, all additives studied, with the exception of additive XIV, should stabilize content uniformity if used at the proper level. Additives III, IV, XII, and XIII are soluble in nitroglycerin only at lower R values, and therefore to meet criterion *b*, these additives must be used at levels below the solubility limit. However, in each of these cases, a value of R may be chosen to give both large $(\partial \ln P/\partial \ln N)_A$ and $P/P_0 < 0.85$.

The lower effective limit for $(\partial \ln P/\partial \ln N)_A$ in a formulation is not known. However, content uniformity data (Tables III and IV) suggest that $(\partial \ln P/\partial \ln N)_A > 0.3$ is sufficient. The formulation for tablet lot O (additive XV at R = 1) yields a stabilized tablet with respect to content uniformity with $P/P_0 = 0.79$ and $(\partial \ln P/\partial \ln N)_A = 0.34$. All other tablet formulations with additives produced greater reductions of vapor pressure and larger values $(\partial \ln P/\partial \ln N)_A$ without any obvious improvement in content uniformity stability.

Chemical Decomposition—Except for XV and VII, the additives accelerate the decomposition of nitroglycerin. In general, the effect of the additive on stability is minimal at R = 1 but becomes significant at R = 2. A particularly good example of this behavior is shown by tablets (Table III) and dried powders (Table II) containing additive V. Samples at R = 0.66 and R = 1.0 are essentially stable, while samples at R = 2 are unstable.

Samples containing I, II and X (Tables II and III) appear to be unstable at 50°C, even at R = 1, but at least for I and II, the high temperature stability is not particularly sensitive to additive levels above R = 1. Potency loss data (*Results* section) suggest the same conclusion at 25°C for I, although the dinitroglycerin content decreases as R increases (Table III). However, at 25°C the stability of nitroglycerin is sensitive to the level of soluble polyethylene glycol[8]. Samples with R = 1 apparently are stable, but the 25°C-stability of nitroglycerin in a phase containing a high level of polyethylene glycol (R = 2) is poor[8].

Since hydrolysis is a major reaction pathway for decomposition of nitroglycerin in tablets, water content and alkalinity of the nitroglycerin phase should be important variables. Although the water content of the nitroglycerin phase could not be measured (15), the water content of the powder system as a whole was determined (Table II). The water content of all dried samples was 0.45-0.58% (w/w). As expected, the data generally show greater decomposition for the sample equilibrated at high humidity (I and X are exceptions) than for the corresponding dried sample.

The alkalinity was characterized by measuring the pH of a 10% aqueous solution (or dispersion) of the additive in water[9]. The hydrolysis rate would be expected to be at a minimum in a weak acid (16, 17). The exact relationship between pH of a 10% aqueous solution of additive and acid- or base-catalysis in a nitroglycerin-additive phase is not clear. However, if acidic or basic impurities in the additives used were the dominant factor in stability, one would expect a good correlation (nonlinear) between pH and stability; good correlation was not observed[9].

Disintegration Time—While a detailed discussion of disintegration time is beyond the scope of this study, the effect of the additive on disintegration time merits comment. An additive may function as an additional binder re-

[6] Variations in air currents with storage location and presence of materials which may absorb nitroglycerin near the storage location limit reproducibility of open-dish stability data.

[7] Lilly 0.6-mg tablets are stabilized with Povidone at R = 0.6 which results in $(\partial \ln P/\partial \ln N)_A = 0.59$. Other established stabilized formulations (Lilly 0.3- and 0.4-mg tablets and Parke Davis Nitrostat) yield larger values of this derivative.

[8] Dried powders (lactose-nitroglycerin-additive) were aged 2 years at 25°C. Polyethylene glycol 400 and polyethylene glycol 1000 systems at R = 0.62 showed only trace levels of dinitroglycerin, but at R = 2.2, the ratio of dinitroglycerin species to trinitroglycerin was ~0.6. Potency loss for the polyethylene glycol 400 sample was 52%. Polyethylene glycol 4000 at R = 2.2, which is soluble only to R = 0.9, showed only trace levels of dinitroglycerin. Even at R = 2, potency losses and dinitroglycerin contents (as percentage of total nitroglycerin compounds) were only several percent for additives V, VII, and XV and were <15% for other additives studied (VI, VIII, IX, X, and XI).

[9] The measured pH values for the indicated additives were: I (3.5), II (6.0), V (4.6), VI (2.4), VII (3.5), VIII (3.9), IX (3.9), X (3.8), XI (7.8), and XV (5.8). These additives were all vacuum dried before use.

sulting in an increase in disintegration time, the effect increasing as the additive content of the tablet increases. For example, conventional tablets (Table III) typically disintegrate within ~10 s, but tablets with additives present at 1% of the tablet weight require 20–30 s for all additives except povidone. Tablets formulated with 2% of either additive V or additive VIII require ~100 s for disintegration. These times refer to tablets aged 2 years at 25°C. While 100 s is near the UPS limit for 2 min, a reduction in tablet density will significantly reduce the disintegration time. The data quoted above refer to a fixed tablet density (1.16 g/mL). Thus, it may be possible to reduce the tablet density by using less lactose, thereby reducing the disintegration time to a more acceptable level.

With the exception of tablets containing additive I (povidone), the disintegration times for fresh tablets are essentially the same as for aged tablets. Fresh tablets containing 1% povidone typically disintegrate within 20 s, but after prolonged aging (more than 2 years at 25°C) they may require 1–2 min for disintegration. Evidently the povidone cross-links to some extent which retards disintegration. When these tablets are left undisturbed in water for some time, a "ghost" of insoluble material in the shape of the tablet remains. Thus, with the exception of severely aged povidone-containing tablets, excessive disintegration time is not a problem for the tablet systems studied (Table III), at least for ≤1% additive.

CONCLUSIONS

A number of nitroglycerin-soluble additives sufficiently lower the vapor pressure of nitroglycerin to stabilize the content uniformity of molded nitroglycerin tablets. In general, an additive–nitroglycerin weight ratio, R, of 1 is adequate for this purpose. Tablet potency losses in open-dish evaporation tests are roughly proportional to the vapor pressure of nitroglycerin in the tablet, and higher levels of additive (R = 2) are normally needed to achieve a significant improvement in open-dish stability. However, with few exceptions (VII and XV) high additive levels lead to reduced chemical stability, particularly at high temperature, and a compromise must be made between chemical stability and open-dish stability. For packaging in sealed glass bottles, open-dish potency loss is of little importance, and a compromise of chemical stability is not necessary. For example, additives VII and XV stabilize content uniformity with no measurable loss of chemical stability and several other additives (V in particular) do not seriously affect chemical stability when used at R = 1[10].

γ-Aminobutyric Acid Uptake Inhibition and Anticonvulsant Activity of Nipecotic Acid Esters

A. MICHAEL CRIDER *§x, J. D. WOOD ‡, KATHRYN D. TSCHAPPAT *, CHRISTINE N. HINKO *, and KAREN SEIBERT *

Received May 16, 1983, from the **College of Pharmacy, The University of Toledo, Toledo, OH 43606* and the ‡*Department of Biochemistry, University of Saskatchewan, Saskatoon, Saskatchewan, Canada.* Accepted for publication October 5, 1983. Present address: § School of Pharmacy, Northeast Louisiana University, Monroe, LA 71209.

Abstract □ *n*-Alkyl esters of nipecotic acid were prepared by Fischer esterification, and the esters were evaluated against bicuculline-induced seizures in mice. Evaluation of the alkyl esters for inhibition of γ-aminobutyric acid uptake into mouse whole brain mini-slices revealed that the order of potency was proportional to chain length. The octyl ester inhibited γ-aminobutyric acid and β-alanine uptakes by apparently nonspecific mechanisms. A variety of phenyl esters of nipecotic acid were also synthesized utilizing either dicyclohexylcarbodiimide or 1,1′-carbonyldiimidazole as the condensing agent. Most of the phenyl esters were potent inhibitors of γ-aminobutyric acid uptake. The uptake inhibition appeared to involve specific and nonspecific (detergent-like) mechanisms. The *m*-nitrophenyl and *p*-nitrophenyl esters were particularly potent against bicuculline-induced seizures in mice.

Keyphrases □ Nipecotic acid esters—synthesis, anticonvulsant activity □ Anticonvulsant agents—potential, nipecotic acid esters, synthesis

γ-Aminobutyric acid appears to act as a major inhibitory neurotransmitter in the central nervous system (1–3). Impairment in γ-aminobutyric acid neurotransmission may contribute to the symptoms of Huntington's disease, Parkinsonism, and epilepsy (4). Thus, compounds that potentiate γ-aminobutyric acid neurotransmission have considerable therapeutic potential.

(±)-Nipecotic acid (I) has been found to be a potent inhibitor of γ-aminobutyric acid uptake into rat cerebral cortex (5) and mouse whole brain mini-slices (6). The *R*-(−) enantiomer of nipecotic acid (I) has approximately five times greater affinity for the γ-aminobutyric acid uptake carrier than the *S*-(+) enantiomer (7).

As with several other compounds (8) having the potential of interacting with the γ-aminobutyric acid system, (±)-nipecotic acid (I) does not readily penetrate the blood–brain barrier (9). However, prodrug esters of nipecotic acid (I) that pass into the central nervous system have been evaluated for anticonvulsant activity (10–13) and γ-aminobutyric acid uptake inhibition (13, 14).

sulting in an increase in disintegration time, the effect increasing as the additive content of the tablet increases. For example, conventional tablets (Table III) typically disintegrate within ~10 s, but tablets with additives present at 1% of the tablet weight require 20–30 s for all additives except povidone. Tablets formulated with 2% of either additive V or additive VIII require ~100 s for disintegration. These times refer to tablets aged 2 years at 25°C. While 100 s is near the UPS limit for 2 min, a reduction in tablet density will significantly reduce the disintegration time. The data quoted above refer to a fixed tablet density (1.16 g/mL). Thus, it may be possible to reduce the tablet density by using less lactose, thereby reducing the disintegration time to a more acceptable level.

With the exception of tablets containing additive I (povidone), the disintegration times for fresh tablets are essentially the same as for aged tablets. Fresh tablets containing 1% povidone typically disintegrate within 20 s, but after prolonged aging (more than 2 years at 25°C) they may require 1–2 min for disintegration. Evidently the povidone cross-links to some extent which retards disintegration. When these tablets are left undisturbed in water for some time, a "ghost" of insoluble material in the shape of the tablet remains. Thus, with the exception of severely aged povidone-containing tablets, excessive disintegration time is not a problem for the tablet systems studied (Table III), at least for ≤1% additive.

CONCLUSIONS

A number of nitroglycerin-soluble additives sufficiently lower the vapor pressure of nitroglycerin to stabilize the content uniformity of molded nitroglycerin tablets. In general, an additive–nitroglycerin weight ratio, R, of 1 is adequate for this purpose. Tablet potency losses in open-dish evaporation tests are roughly proportional to the vapor pressure of nitroglycerin in the tablet, and higher levels of additive (R = 2) are normally needed to achieve a significant improvement in open-dish stability. However, with few exceptions (VII and XV) high additive levels lead to reduced chemical stability, particularly at high temperature, and a compromise must be made between chemical stability and open-dish stability. For packaging in sealed glass bottles, open-dish potency loss is of little importance, and a compromise of chemical stability is not necessary. For example, additives VII and XV stabilize content uniformity with no measurable loss of chemical stability and several other additives (V in particular) do not seriously affect chemical stability when used at R = 1[10].

[10] Only two stabilized nitroglycerin tablet products are available in the U.S. market. Parke-Davis' formulation uses polyethylene glycol 4000 as the additive while the Lilly formulation currently uses povidone.

γ-Aminobutyric Acid Uptake Inhibition and Anticonvulsant Activity of Nipecotic Acid Esters

A. MICHAEL CRIDER *§x, J. D. WOOD ‡, KATHRYN D. TSCHAPPAT *, CHRISTINE N. HINKO *, and KAREN SEIBERT *

Received May 16, 1983, from the **College of Pharmacy, The University of Toledo, Toledo, OH 43606* and the ‡*Department of Biochemistry, University of Saskatchewan, Saskatoon, Saskatchewan, Canada.* Accepted for publication October 5, 1983. Present address: § School of Pharmacy, Northeast Louisiana University, Monroe, LA 71209.

Abstract □ *n*-Alkyl esters of nipecotic acid were prepared by Fischer esterification, and the esters were evaluated against bicuculline-induced seizures in mice. Evaluation of the alkyl esters for inhibition of γ-aminobutyric acid uptake into mouse whole brain mini-slices revealed that the order of potency was proportional to chain length. The octyl ester inhibited γ-aminobutyric acid and β-alanine uptakes by apparently nonspecific mechanisms. A variety of phenyl esters of nipecotic acid were also synthesized utilizing either dicyclohexylcarbodiimide or 1,1′-carbonyldiimidazole as the condensing agent. Most of the phenyl esters were potent inhibitors of γ-aminobutyric acid uptake. The uptake inhibition appeared to involve specific and nonspecific (detergent-like) mechanisms. The *m*-nitrophenyl and *p*-nitrophenyl esters were particularly potent against bicuculline-induced seizures in mice.

Keyphrases □ Nipecotic acid esters—synthesis, anticonvulsant activity □ Anticonvulsant agents—potential, nipecotic acid esters, synthesis

γ-Aminobutyric acid appears to act as a major inhibitory neurotransmitter in the central nervous system (1–3). Impairment in γ-aminobutyric acid neurotransmission may contribute to the symptoms of Huntington's disease, Parkinsonism, and epilepsy (4). Thus, compounds that potentiate γ-aminobutyric acid neurotransmission have considerable therapeutic potential.

(±)-Nipecotic acid (I) has been found to be a potent inhibitor of γ-aminobutyric acid uptake into rat cerebral cortex (5) and mouse whole brain mini-slices (6). The *R*-(−) enantiomer of nipecotic acid (I) has approximately five times greater affinity for the γ-aminobutyric acid uptake carrier than the *S*-(+) enantiomer (7).

As with several other compounds (8) having the potential of interacting with the γ-aminobutyric acid system, (±)-nipecotic acid (I) does not readily penetrate the blood–brain barrier (9). However, prodrug esters of nipecotic acid (I) that pass into the central nervous system have been evaluated for anticonvulsant activity (10–13) and γ-aminobutyric acid uptake inhibition (13, 14).

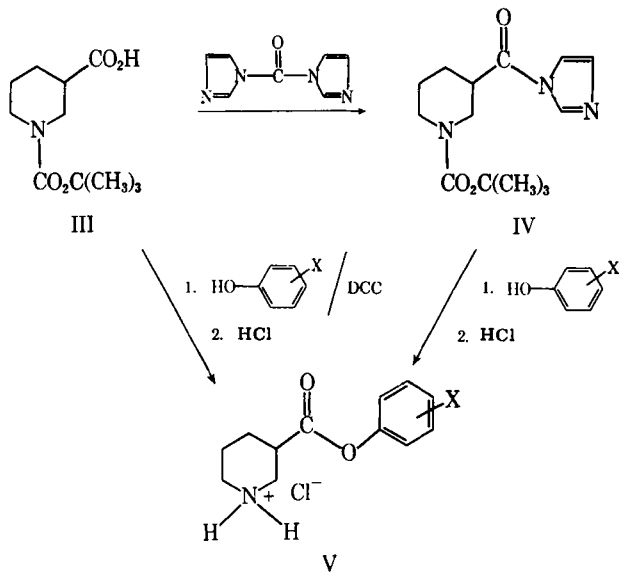


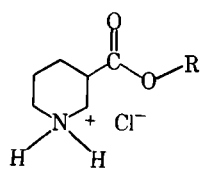
Scheme I

In a previous report, the *p*-nitrophenyl ester Vc was found to exhibit potent anticonvulsant activity and γ-aminobutyric acid uptake inhibition. The octyl ester IIc was also a strong inhibitor of γ-aminobutyric acid uptake (13). The results of this preliminary study indicated that Vc inhibited γ-aminobutyric acid uptake into mouse whole brain mini-slices by a combination of specific and nonspecific (detergent-like) effects. The specific effect is due to the hydrolysis product, nipecotic acid (I), while the nonspecific effect is caused by the intact ester. The octyl ester IIc apparently is not hydrolyzed under the assay conditions of the γ-aminobutyric acid uptake and the inhibition is entirely due to the intact ester.

Based on the activity of Vc, it was of interest to examine the structure-activity relationships of substituted-phenyl esters of I. Specifically, the lipophilicity and the electronic character of the phenyl substituent were varied in order to determine the effect on anticonvulsant activity and γ-aminobutyric acid uptake inhibition. An additional objective of this study was to evaluate the γ-aminobutyric acid uptake inhibition of the heptyl IIb and nonyl IId esters to determine if their action was nonspecific, as was the case with IIc.

RESULTS AND DISCUSSION

The alkyl esters (IIa-d) were synthesized by Fischer esterification of I with an appropriate alcohol in the presence of dry hydrogen chloride (13). Phenyl esters (Va-q) of nipecotic acid were prepared by utilizing either dicyclohexylcarbodiimide or 1,1′-carbonyldiimidazole as the condensing agent (Scheme I); the physical properties of these compounds are given in Table I.



IIa, R = C_6H_{13}
IIb, R = C_7H_{15}
IIc, R = C_8H_{17}
IId, R = C_9H_{19}

Termination of γ-aminobutyric acid with its postsynaptic receptor is brought about by high-affinity uptake systems in nerve terminals and glial cells (3). These carriers exhibit different substrate specificities for γ-aminobutyric acid and its derivatives (15, 16). The results of Breckenridge *et al.* (16) have confirmed that both neuronal and glial uptake processes prefer a folded conformation in the molecule. These same workers found that neuronal γ-aminobutyric acid uptake is markedly influenced by compounds having long alkyl chains. In contrast, inhibition of β-alanine uptake was more strongly affected by compounds having shorter alkyl chains. The speculation was that the glial uptake carrier has a more shallow hydrophobic bonding site.

Based on the work by Breckenridge and co-workers (16), we were interested in evaluating homologues of IIc for γ-aminobutyric acid uptake inhibition. The nonyl ester IId completely inhibited γ-aminobutyric acid uptake, while the heptyl ester IIb and hexyl ester IIa were less potent uptake inhibitors (85 and 53%, respectively). The results of IIc on β-[^{3}H]alanine uptake, a measure of glial uptake inhibition (16), are given in Table II. Since 1 mM nipecotic acid (I) only inhibits β-alanine uptake by 85%, the 100% uptake inhibition by IIc strongly suggests a nonspecific cationic detergent effect. Such a mechanism is further supported by the fact that IIc more potently inhibits γ-aminobutyric acid (100 *versus* 96%) and L-proline (13) (99 *versus* 21%) uptake than the parent amino acid I. Although IIc apparently inhibits both γ-aminobutyric acid and β-alanine by nonspecific mechanisms, it is rather difficult to explain the differences in uptake inhibition of γ-aminobutyric acid and β-alanine on dilution of the inhibitor (16 *versus* 50%) at 0.5 mM, respectively.

All of the phenyl esters, with the exception of Vd, were potent inhibitors of γ-aminobutyric acid uptake (Table III). As was the case with *p*-nitrophenyl ester Vc (13), these derivatives probably inhibit γ-aminobutyric acid uptake by a combination of specific and nonspecific effects. The phenyl substituents vary considerably in terms of lipophilic and electronic character. However, no readily apparent correlation exists between these parameters and either γ-aminobutyric acid uptake inhibition or anticonvulsant activity.

The esters were also evaluated for their ability to protect against bicuculline-induced seizures (Table IV). A single dose (150 mg/kg sc) of each compound was tested, with this dose being administered 60 min prior to bicuculline challenge. The dose and pretreatment time were chosen on the basis of preliminary testing of other compounds in the series (13). A subcutaneous route of injection was used to reduce peripheral hydrolysis. Currently, individual compounds are being evaluated at a variety of doses and pretreatment times in an effort to calculate specific ED_{50} values and times of peak effect.

As indicated in Table IV, all compounds (with the exception of Vd and Vn) demonstrated a significant degree of protection against clonic convulsions, tonic convulsions, or death induced by bicuculline. Although complete protection from clonic spasms was not observed with any of the compounds tested at this dose, IIb, IId, and Vb provided protection from clonic convulsions in seven of eight mice and IIb, Vc, and Ve protected all eight animals in each group from tonic convulsions and death. In addition, IIc, IId, Vb, Vk, Vp, and Vq prevented tonic convulsions and death in at least seven of eight animals. Antagonism of convulsions induced by bicuculline, a putative γ-aminobutyric acid receptor antagonist, suggests that these nipecotic acid esters may be producing their effects by interaction with the γ-aminobutyric acid system.

EXPERIMENTAL SECTION[1]

***n*-Heptyl 3-Piperidinecarboxylate Hydrochloride (IIb)**—This compound was prepared according to conditions previously described (13) in 21% yield, mp 74-75°C; IR (KBr): 2500 (NH_2^+), 1760 (C=O), and 1225 cm^{-1} (C—O); ^{1}H-NMR ($CDCl_3$): δ 0.90 (t, 3, CH_3), 1.07-3.80 (m, 19, aliphatic CH_2, ring CH, and ring CH_2), 4.10 (t, 2, OCH_2), and 9.45 ppm (br s, 2, NH_2^+).

Anal.—Calc. for $C_{13}H_{26}ClNO_2$: C, 59.17; H, 9.95; N, 5.31. Found: C, 59.43; H, 9.87; N, 5.01.

***n*-Nonyl 3-Piperidinecarboxylate Hydrochloride (IId)**—Compound IId was synthesized following the general method (13) in 51% yield, mp 85-86°C; IR (KBr): 2500 (NH_2^+), 1760 (C=O), and 1225 cm^{-1} (C—O); ^{1}H-NMR ($CDCl_3$): δ 0.87 (t, 3, CH_3), 1.03-3.77 (m, 23, aliphatic CH_2, ring CH, and ring CH_2), 4.07 (t, 2, OCH_2), and 9.43 ppm (br s, 2, NH_2^+).

Anal.—Calc. for $C_{15}H_{30}ClNO_2$: C, 61.71; H, 10.38; N, 4.80. Found: C, 61.79; H, 10.27; N, 5.02.

1-(1-*tert*-Butyloxcarbonyl-3-piperidinocarbonyl)imidazole (IV)—A mixture of III (13) (3.00 g, 0.013 mol) and 1,1′-carbonyldiimidazole (2.10 g, 0.013 mol) in 150 mL of tetrahydrofuran was heated at reflux overnight. Removal of the solvent gave a yellow oil, which was dissolved in 50 mL of chloroform

[1] Melting points were determined on a Fisher-Johns melting point apparatus and are uncorrected. IR spectra were recorded as potassium bromide pellets with a Perkin-Elmer spectrophotometer. ^{1}H-NMR spectra were recorded on a Varian EM 360A spectrometer. Chemical shifts are reported in parts per million (δ) relative to tetramethylsilane (1%) or, in the case of D_2O (1%), sodium 2,2-dimethyl-2-silapentane-5-sulfonate. Analytical data were obtained from Micro-Analysis Inc., Wilmington, Del.

$-\overline{N-CH=N-CH=C}H$), and 8.23 ppm (s, 1, $-\overline{NCH=N-CH=CH}$).

Anal.—Calc. for $C_{14}H_{21}N_3O_3$: C, 60.18; H, 7.59; N, 15.04. Found: C, 60.06; H, 7.58; N, 14.87.

Representative Procedures for the Synthesis of the Phenyl 3-Piperidinecarboxylate Hydrochlorides (V)—*Method A*—The synthesis of *m*-nitrophenyl 3-piperidinecarboxylate hydrochloride (Vb) is representative of the general procedure. A solution of III (3.00 g, 0.013 mol) and *m*-nitrophenol (1.82 g, 0.013 mol) in acetonitrile (150 mL) was treated in one portion with dicyclohexylcarbodiimide (2.70 g, 0.013 mol). A white precipitate of dicyclohexylurea formed immediately. Stirring was continued for 48 h, the dicyclohexylurea was removed by filtration, and the filtrate was saturated with hydrogen chloride at 0–5°C. The solvent was evaporated under reduced pressure and the resulting solid was recrystallized from absolute ethanol to yield 1.65 g (44%) of light-yellow crystals, mp 190–192°C; IR (KBr): 1785 cm^{-1} (C=O, ester); ^{1}H-NMR (D_2O): δ 1.65–4.00 (m, 9, ring CH and CH_2) and 7.55–8.45 ppm (m, 4, ArH).

Anal.—Calc. for $C_{12}H_{15}ClN_2O_4$: C, 50.26; H, 5.28; N, 9.77. Found: C, 50.49; H, 5.42; N, 9.63.

Method B—The synthesis of *m*-fluorophenyl 3-piperidinecarboxylate hydrochloride (Vi) is representative of the general method. A solution of IV (2.90 g, 0.010 mol) and *m*-fluorophenol (1.17 g, 0.010 mol) in acetonitrile (200 mL) was heated at reflux for 48 h, and the solvent was removed under reduced pressure. The resulting oil was dissolved in chloroform (200 mL) and washed three times with 25-mL portions of water. The organic phase was dried (sodium sulfate) and saturated with dry hydrogen chloride at 0–5°C. Evaporation of the solvent gave a light-yellow oil which solidified after trituration with ether. Recrystallization from ethanol–ether gave 1.30 g (48%) of analytically pure product, mp 124–126°C; IR (KBr): 1785 cm^{-1} (C=O, ester); ^{1}H-NMR (D_2O): δ 1.67–4.00 (m, 9, ring CH and CH_2) and 6.90–7.80 ppm (m, 4, ArH).

Anal.—Calc. for $C_{12}H_{15}ClFNO_2$: C, 55.49; H, 5.83; N, 5.39. Found: C, 55.76; H, 5.83; N, 5.53.

Table IV—Antagonism of Bicuculline-Induced Convulsions by Esters of Nipecotic Acid

[a] Compounds (150 mg/kg sc) were administered 60 min prior to bicuculline (3.00 or 3.75 mg/kg sc). Compounds Vh and Vl were also tested but limited solubility and stability of the compounds prevents the reporting of reproducible data. [b] The animal was considered protected from clonic convulsions if it failed to exhibit an episode of clonic spasms for at least 5 s. The animal was considered protected from tonic convulsions if it failed to exhibit hind limb extension. [c] Previously reported (13). [d] Not significantly different from saline controls. [e] Significantly different from saline controls ($p < 0.05$). All other values in the table are significantly different from saline controls ($p < 0.01$).

Biological Testing—Male Sprague-Dawley mice[2] received an injection of 3.0 or 3.75 mg/kg sc of bicuculline in a volume of 0.01 mL/g. The bicuculline was prepared by dissolving the solid in 0.1 M HCl and adjusting to pH 5 with 0.1 M NaOH (13). Each compound was evaluated for its ability to protect against bicuculline-induced seizures at a dose of 150 mg/kg sc injected 1 h prior to bicuculline administration. Groups of eight mice per compound were tested. Groups of four control mice were pretreated with 0.9% NaCl and tested before and after each experimental group to ensure maximal convulsant potency of the bicuculline.

The incidence and onset of clonic and tonic convulsions and fatality induced by bicuculline were recorded for each of the animals. A clonic convulsion was defined as a single episode of clonic spasms of at least a 5-s duration. A tonic seizure was defined as a brief period of hind limb flexion followed by a prolonged period of hind limb extension. The animals were observed for at least 45 min after the injection of bicuculline. The uptakes of γ-[^{3}H]aminobutyric acid and tritiated β-alanine were carried out following reported procedures (6, 17).

Accurate, Wide-Range, Automated, High-Performance Liquid Chromatographic Method for the Estimation of Octanol/Water Partition Coefficients I: Effect of Chromatographic Conditions and Procedure Variables on Accuracy and Reproducibility of the Method

J. E. GARST ˣ and W. C. WILSON

Received March 7, 1983, from the *Department of Animal Science, University of Illinois, 126 Animal Sciences Laboratory, 1207 West Gregory Drive, Urbana, IL 61801.* Accepted for publication November 29, 1983.

Abstract □ A high-performance liquid-chromatographic (HPLC) procedure is reported for estimation of the logarithm of the octanol/water partition coefficient, log P(o/w). This automated log P(o/w) measurement (ALPM) circumvents many inherent difficulties with the shake-flask method, yet gives high reproducibility and excellent overall correlation with shake-flask results. Partition coefficients for numerous structurally diverse chemicals, ranging from ~0 to ~8 log P(o/w) units, can be determined; however, values for zwitterionic compounds cannot be obtained. Additional advantages of ALPM include lower cost and greater safety when compared with other HPLC or shake-flask procedures. Chromatographic conditions (*i.e.*, flow rate and temperature) and variables (*i.e*, column length and solvent composition) affecting this method are discussed in detail. ALPM may also find application in quality control of HPLC columns, qualitative-quantitative analysis, and in computer-controlled method development and analysis.

Keyphrases ◻ HPLC-octanol/water partition coefficients □ Partition coefficients-octanol/water, HPLC

The logarithm of the octanol/water partition coefficient of a compound, log P(o/w), often parallels the biological effects of that substance (1, 2). Although log P(o/w) correlations are commonly used to optimize a specific biological response, they can also be a valuable predictor of adverse effects from chemical agents (3, 4). Consideration of this parameter in structure-toxicity as well as structure-activity studies might substantially reduce drug development costs (1). Furthermore, the increasing cost of animals and animal care, combined with growing public discontent over the use of animals in scientific research, will inevitably make prediction of toxicological responses much more important (5, 6).

Ideally, determination of the partition coefficient, P(o/w), requires measurement of the equilibrium ratio of the concentrations of a single component, X, dissolved in nonpolar and polar layers using simple separatory funnel shake-flask procedures (2):

$$P(o/w) = [X]_{octanol}/[X]_{water} \qquad \text{(Eq. 1)}$$

Although the polar phase is nearly always water, the choice of nonpolar phase is arbitrary; chloroform, hexane, and other solvents have been used, but octanol is the most common choice (2). There is, however, nothing unique about biological correlations using octanol/water as opposed to another solvent/water system. In 1954, Collander showed that partition data can be converted between solvent/water systems by least-squares regression (7), but Leo has described limitations in the use of this relationship (8).

Many economic and scientific problems occur with shake-flask log P(o/w) measurements. Since analytical procedures differ with each compound, the traditional method is time consuming and expensive (3). Log P(o/w) measurements may have only limited reproducibility among laboratories. For example, the seven reported shake-flask log P(o/w) values for naphthalene range from 3.01 to 3.59 (2). Analysis error is always a concern, but microemulsions can also alter distribution of the compound between the two phases (9). Formation of other components in the shake-flask could also alter phase equilibrium. The physical difficulties of measurement may be minimized by improved analytical techniques and sample centrifugation, but chemical interactions (changing the number of components) could affect the accuracy of even reproducibly obtained partition coefficients.

While measurement is always preferred, approximate values can be obtained by calculations based on the concept that the overall log P(o/w) reflects the summation of hydrophobic contributions from each constitutive group (π-approach) or fragment (f-approach) (2, 10, 11). Although calculated values often afford good estimates of log P(o/w), additivity of such constants may not always be observed (3). Problems of reproducibly and accurately measuring the shake-flask log P(o/w), knowledge of the increment for a particular molecular unit, and limitations in the additivity of such groups often re-

strict correlation analysis to academic research or the most rewarding industrial compounds.

There have been numerous attempts to employ high-performance liquid chromatography (HPLC) to estimate log P(o/w). Mirrlees *et al.* described the theory behind these efforts, most of which utilize the linear relationship between log P(o/w) and the logarithm of the capacity factor, log k', where $k' = [(t - t_0/t_0)]$ and t and t_0 refer to the elution times of compound and void volume marker, respectively (12):

$$\log P(o/w) = (m \times \log k') + b \qquad \text{(Eq. 2)}$$

Henry *et al.* modified Eq. 2 so that higher log P(o/w) values could be determined by defining log V_r, the logarithm of the retention volume, as a function of the flow rate, FR, according to (13):

$$\log V_r = \log [(t - t_0) \times FR] \qquad \text{(Eq. 3)}$$

They argued that since $\log k' = \log [(t - t_0/t_0)] = \log (t - t_0) - \log t_0$, the log t_0 term could be incorporated into the constant b. Since this value differs from column to column, the separate constant, c, is justified:

$$\log P(o/w) = (m \times \log V_r) + b + c \qquad \text{(Eq. 4)}$$

Equation 4 describes a proportionality between the retention volume of a compound and its partitioning between mobile and stationary phases. The constants m, b, and c reflect the chromatographic process, the conversion from stationary/mobile phase to octanol/water phase partitioning, and the difference between columns.

Despite problems with HPLC measurement of log P(o/w), Baker *et al.* and Henry *et al.* suggested that HPLC retention data may prove to be a better correlate of biological activity than the octanol/water partition coefficient (9, 13). In this paper, an automated log P(o/w) measurement (ALPM), based on further modification of Eqs. 3 and 4 is reported; it allows variable flow rates, temperatures, and column lengths, and compensates for column changes over time. This alteration affords a corrected retention volume proportional to log P(o/w) and enables estimation of the latter from 0 to nearly 8 units. The ALPM log P(o/w) displays high reproducibility and excellent general correlation with the shake-flask result. The subsequent paper of this series demonstrates the value of ALPM in predicting biological activities (14).

EXPERIMENTAL SECTION

Definitions—The procedure utilizes a temperature- and column-length-corrected retention volume, V_{cr}, in analogy to the definition of the retention volume (V_r) by Henry *et al.* (13). Specifically, the term $(t - t_0)$ in Eq. 3 is replaced by the value from Eq. 6, which is obtained from extrapolated measurements of percent alcohol (as the abscissa) *versus* log $(t - t_0)$ when the percent alcohol is 0, by taking the antilog of the linear relationship in Eq. 5:

$$\log (t - t_0) = [(\text{slope} \times \text{percent alcohol}) + \text{tci}] \qquad \text{(Eq. 5)}$$

$$(t - t_0) = 10^{[(\text{slope} \times \text{percent alcohol}) + \text{tci}]} \qquad \text{(Eq. 6)}$$

where: $t - t_0$ is the elution time of compound minus the elution time of the void volume marker (min); the percent alcohol is 0 (for 100% aqueous buffer); slope is the slope of log $(t - t_0)$ *versus* percent alcohol plot; tci represents the temperature-corrected intercept, i + [(CT − RT) × 0.015 per degree] where i is the intercept (0% alcohol); CT represents the column temperature; RT represents the reference temperature (for this work, RT = 25°C). Correction for different column lengths involves referencing the results to a 25-cm column. Since a shorter column would proportionally reduce V_{cr}, multiplication by the ratio (25/CL) restores V_{cr} to a constant value. Thus:

$$V_{cr} = \frac{10^{[(\text{slope} \times \text{percent alcohol}) + \text{tci}]} FR\ (25\ \text{cm})}{CL} \qquad \text{(Eq. 7)}$$

where CL is the column length (cm) and FR is the flow rate (mL/min)[1].

Log P(o/w) can be determined from Eq. 8 using the corrected retention volume, V_{cr}, from Eq. 7 and C_{cf}, a column correction factor measured in log P(o/w) units, which replaces c in Eq. 4:

$$\log P(o/w) = (m \times \log V_{cr}) + b + C_{cf} \qquad \text{(Eq. 8)}$$

Column changes are compensated by the column correction factor, C_{cf} (measurement is described below). With methanol as the alcoholic cosolvent and using a reference temperature of 25°C, two sets of constants are reported in Eqs. 9 and 10[2]. For 0.004 M trifluoroacetic acid and 0.035 M triethylamine[2]:

$$m = 1.118(\pm 0.010);\ b = -0.588(\pm 0.019);\ r^2 = 0.9988;\ SE = 0.0409 \qquad \text{(Eq. 9)}$$

For 0.015 M triethylamine[2]:

$$m = 1.169(\pm 0.032);\ b = -0.946(\pm 0.092);\ r^2 = 0.9993;\ SE = 0.0578 \qquad \text{(Eq. 10)}$$

Log V_{ccr} is defined as the C_{cf} and column-corrected equivalent to log V_{cr}:

$$\log V_{ccr} = \log V_{cr} + (C_{cf}/m) \qquad \text{(Eq. 11)}$$

Replacement of log V_{cr} in Eq. 8 by $[\log V_{ccr} - (C_{cf}/m)]$ from Eq. 11 affords a column-independent definition of chemical hydrophobicity, which can be related to log P(o/w) as in Eq. 12 with the same constants, m and b:

$$\log P(o/w) = (m \times \log V_{ccr} + b) \qquad \text{(Eq. 12)}$$

Instrumentation and Columns—All experiments were performed on a liquid chromatograph equipped with column-temperature control, automatic injector, automatic sample changer, and serial computer interface[3]. HPLC peaks were detected using either the fixed-wavelength detector at 254 nm or the variable-wavelength detector at 190–600 nm, as necessary. Retention times, computed by the HPLC hardware are independent of the volume and concentration injected from 1 to at least 30 μL for benzyl alcohol and quinoline using a 1-mg/mL solution[4]. Columns of 1, 3, 10, and 25 cm, packed with 10-μm, C_8-alkylated adsorbant, were used without modification[5].

Chemicals—HPLC-grade methanol[6] and deionized[7], distilled water were used as HPLC solvents. Nicotinic hydrazide *N*-oxide[8], pyridine *N*-oxide[8], triethylamine[8], trifluoroacetic acid[8], and tetrahydrofuran[8] were obtained commercially. The triethylamine or trifluoracetic acid, used as buffers, must be present only in the aqueous solvent reservoir to prevent rapid destruction of the HPLC ball valves. Although Mirrlees *et al.* chose pyridine *N*-oxide as the void volume marker, nicotinic hydrazide *N*-oxide elutes earlier under our conditions and is preferred (12). Chemicals were obtained from various sources[8,9] or were synthesized (15).

Procedures—Several milligrams of nicotinic hydrazide *N*-oxide and the compound to be measured were diluted to 1–2 mL with methanol. (To improve the solubility of agents with log P(o/w) values of >4.5, several microliters of saturated aqueous nicotinic hydrazide *N*-oxide can be substituted for the solid nicotinic hydrazide *N*-oxide and tetrahydrofuran can replace methanol in the injection solution.) Several microliters of the solution were injected for each analysis. The choice of organic injection solvent had no detectable effect on the log V_{cr}. Routine data analysis utilized a minicomputer and software written

[1] Although percent alcohol is zero for the determination of V_{cr} in Eq. 7, prior ALPM determinations of the log P(o/w) and the slope, and knowledge of the current value of t_0 enable Eqs. 7 and 8 to be solved for the theoretical elution time for that compound at any percent of the appropriate solvent where equilibrium conditions are maintained.

[2] Values for the constants m, b, and C_{cf} (Eq. 8) are valid only under the conditions stated here and only with Hewlett-Packard Model 1084B HPLC instruments manufactured before the June 1982 reduction in the injector system volume for narrower bore columns. Use of this procedure under the conditions stated, but with other HPLC instruments, will require the determination of new values for these constants.

[3] Model 1084B; Hewlett-Packard.

[4] Unpublished results.

[5] RP-8 Merck brand reverse-phase, silica columns; Brownlee Laboratories, Santa Clara, Calif. The RP-8 packing material used herein has been changed since this work was completed. As a result, identical columns are no longer available; but more efficient and pH-resistant C_8 types of packing could afford better results using these procedures. New regression constants must be determined, however.

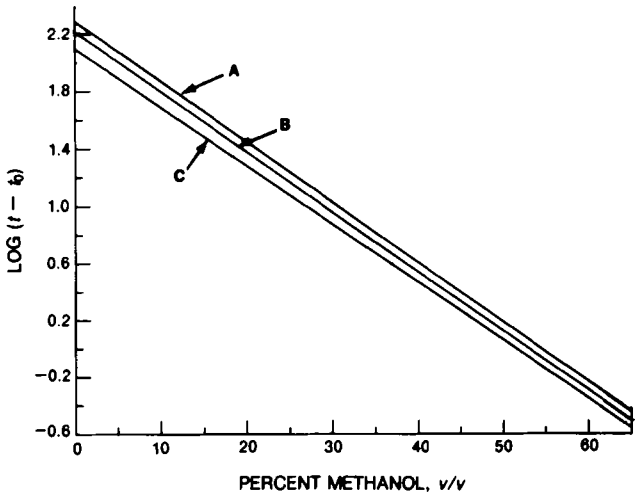

Figure 2—*Log* (t − t_0) versus *percent methanol for different temperatures. A parallel, linear relationship is apparent for temperatures from 17°C to 37°C for 1-(3-furyl)-4-methylpentan-1-one. Key: (A) 17°C; (B) 27°C; (C) 37°C.*

for this purpose[10]. When used, automatic data processing involved computer control of the chromatograph, data entry, and analysis steps[10].

Interpretation of Summary Data Tables—ALPM can produce considerable information that is helpful in evaluating the log P(o/w) results obtained for each compound. For example, some indication of HPLC equilibrium status, as discussed elsewhere, is given by these data (14)[11]. Equal values for n_0 and n indicate that all measured values were used in the linear regression process (*e.g.*, significant deviation from linearity over the measured range was not encountered). The greater the difference between n_0 and n, the more likely that curvilinearity, rather than simple statistical scatter, accounts for points being deleted from the linear regression (14). Where F_{calc} exceeds F_{set}, the data are indeed curved, but the low SE often suggests that the curve was randomly generated and need not be considered further. Increasing caution in accepting the data is urged when the SE exceeds 0.01 and/or the correlation coefficient falls below 0.999. However, the log P(o/w) may still be quite close to the literature value when high SE values and/or low correlations occur.

RESULTS

Figures 1 and 2 for 1-(3-furyl)-4-methylpentan-1-one typify log ($t - t_0$) *versus* percent methanol for different flow rates and column temperatures. The extrapolated intercept at 100% aqueous buffer was determined, corrected for measurement conditions by Eq. 7, and then converted to log P(o/w) according to Eq. 8, using the appropriate constants. The second paper in this series discusses the meaning of flow plot linearity and the extrapolation concept in greater detail (14).

Variable Flow Rates—Flow rates of 1-4 mL/min are statistically parallel for 1-(3-furyl)-4-methylpentan-1-one (Fig. 1). This is expected since flow rate and elution time are inversely related (16). All commercial HPLC instruments have some limitations. The HPLC used for these studies requires check valves to regulate the pumping process and requires at least a 10-bar column pressure to ensure correct seating of these values. The increased scatter and inaccuracy apparent at 1-mL/min flow rates for 1-(3-furyl)-4-methylpentan-1-one and naphthalene (*cf.*, Fig. 1, Table I) may arise from the low pressure generated with small columns by this low flow rate. Unrecognized instrumental limitations of this and/or other types may have contributed to past difficulties with other HPLC log P(o/w) determinations.

Temperature Variations—While temperature variations are probably not a major factor during a single run, they can affect the log V_{ccr} measurement and log P(o/w) reproducibility (Fig. 2, Table I). Data for several compounds suggest a consistent decrease in the intercept and a slight, but generally insignificant change in the slope as the temperature increases. As a result, an empirical intercept correction term, to restore the intercept to that expected at 25°C, is included in Eq. 6 and is supported by data in Table I. Column temperatures near 35°C are favored because temperature correction is empirical and valid only over a narrow range, elution times are faster, column pressures are lower, and the results are more reproducible. Once obtained, however, these data are referenced to 25°C for comparison with literature values; other reference temperatures could be used, but a new correction formula and regression constants would be needed.

Mobile Phase—The aforementioned findings have clarified the role of HPLC instrumental variables on the determination of log P(o/w), but the choice of mobile phase and column variables is also critical. The partition coefficient of most value in correlation work is that of the uncharged, neutral form, since this can exceed the ionized form by 1000-fold (2). To maintain the chemical in that form, dilute acid or base is required for acids or bases, respectively. Since halogen salts should be avoided when using stainless steel and concentrated salt solutions can ooze and block the very small-diameter tubing, miscible volatile organic acids and bases are preferred.

Although the log V_{cr} values for carboxylic acids and phenols were unaffected by concentrations of >0.004 M trifluoroacetic acid[4], base concentrations of ≫0.004 M were required. Elution of pyridine with 0.02 M Tris, trimethylamine, and triethylamine indicated that the strongest base gave the lowest log V_{ccr} measurement (*i.e.*, reduced tailing) ($r > 0.99$, Table II). As triethylamine elutes pyridine more quickly than the organic bases, it was chosen as the base modifier. Triethylammonium siloxide ion-pair formation was supported by the fact that the strongest base, NaOH, eluted pyridine slower than any of the organic bases. If a simple base interaction were involved, NaOH should have eluted pyridine before the organic bases. However, the determination with NaOH affected subsequent column performance.

The high pH of the triethylamine solution might have caused serious column degradation and only 0.015 M was used initially. However, column deterioration was less of a problem than anticipated, and the optimal concentration was determined. Triethylamine concentration *versus* log V_{cr} for pyridine (a compound very sensitive to base concentration) is shown in Fig. 3. It appears that concentrations at or somewhat above 0.06 M afford log V_{cr} values totally independent of base concentration; 0.035 M triethylamine affords greater independence of log V_{cr} from base concentration than does 0.015 M. However, the use of 0.035 M triethylamine probably offers increased column life. Although changes do occur as a result of base degradation, some columns have been used for many months by taking advantage of an external standard column factor (described below).

[10] Hewlett-Packard Model 9845B desktop computer with 187 Kbytes internal memory, internal printer, I/O-, Graphics-, Advanced Programming-, and Structured Programming ROMS, and the necessary instrument interfaces were used for data acquisition and/or analysis. A more complete description of this copyrighted ALPM software, enabling multicomputer-controlled log P(o/w) determination, computation, and comparative analysis, complete with an example, is in preparation.

[11] Condition numbers 1-4 refer to organic solvents methanol, absolute ethanol, isopropyl alcohol, or acetonitrile, respectively. n_0 and n refer to the numbers of data points actually measured and those used in the linear regression. Low, high, intercept, slope, and r relate the lowest and highest solvent percentage measurements used in the regression line, its intercept, slope, and correlation coefficient r, respectively. F_{set} indicates that table F value above which a quadratic fit is indicated (or below which the points are accepted as statistically linear). F_{calc} represents the computed F value required for a linear fit of the measured number of points, all at the 96.9% confidence level. If F_{calc} is below F_{set}, the data are not statistically curved. Choice of the unusual 96.9% confidence level for a linear relationship was based on deviations encountered with benzene (14). SE refers to the standard error of estimate of log ($t - t_0$) by linear regression on percent methanol. V_{ccr} and C_{cf} are defined as the corrected column retention volume and the column correction factor, respectively. ALPM log P and log P range refer to the octanol/water partition coefficient as measured by ALPM and the range of shake-flask log P(o/w) literature values when present. Likewise, when present, Best indicates the single literature value closest to ALPM.

Table II—Log V_{ccr} of Pyridine *versus* 0.02 M Base

Base	Log V_{ccr}	pK_b
Organic		
Tris	1.69	5.92
Trimethylamine	1.38	4.13
Triethylamine	1.22	2.99
Inorganic		
Sodium hydroxide	1.83	~0

When 0.035 M triethylamine is used for bases and neutral compounds and 0.004 M trifluoroacetic acid is used for acidic compounds, the acid and base least-squares linear correlation equations become statistically indistinguishable in the range of 0.3–6 log P(o/w) units, and probably higher. This effect is dramatically exemplified by the relationship between log V_{ccr} and log P(o/w) (Fig. 4). The upper line in Fig. 4 represents the acidic and numerous basic or neutral compounds; the lower line depicts basic or neutral compounds measured in 0.015 M triethylamine. As triethylamine levels increase, the lower line in Fig. 4 merges with the upper line. Triethylamine at 0.06 M may prove statistically valuable for the most accurate determinations below 0.3 log P(o/w) units (Fig. 3). This is also evidenced by the very slight deviation of the overall column-corrected log P(o/w) *versus* literature correlation from a zero intercept as indicated in Fig. 5. Equations 8–12 describe the regression equations relating log P(o/w) and/or log V_{cr} for the different acid and base concentrations.

Several nonaqueous mobile phases were also studied. Figure 6 is a plot of percent cosolvent *versus* log $(t - t_0)$ using four different organic solvents and 0.015 M triethylamine to elute 1-(3-furyl)-4-methylpentan-1-one. Note that different slopes and extrapolated intercepts are obtained for these lines; this suggests that a solvent-strength-related intercept conversion factor could allow measurement of higher log P(o/w) values in other alcohols. Although methanol was chosen as the organic mobile phase for economic reasons, isopropyl alcohol may facilitate determination of even higher values, despite increased slopes and the resultant increase in the log P(o/w) error. Nonalcoholic solvents, such as acetonitrile, may distort the linear response of log $(t - t_0)$ *versus* percent solvent and complicate the conversion process (14).

Column Variables—The HPLC column is also critical to ALPM. The following column lengths afford an optimum elution time for the various log P(o/w) ranges: 0–~0.8, 50 cm; ~0.3–~1.5, 25 cm; ~1–~3, 10 cm; ~2.2–~5, 3 cm; and >~5, 1 cm. However, compounds run on different columns or the next longer or shorter column length give statistically the same results (Table I: obs. 15 and 16; Table III: obs. 22 and 23, 25 and 26, 39 and 40, and 62 and 63). These data indicate that only two or three column lengths are required. Despite the fact that ALPM has enabled measurements as high as 7.8 for hexabromobiphenyl (14), existing shake-flask methods cannot ensure that values of >6 log P(o/w) units are not low; therefore, some uncertainty does exist in fitting very high ALPM values (17). Although ALPM values for anthracene, 1,1,1-trichloro-2,2-bis(*p*-chlorophenyl)ethane (DDT), and diethylstilbesterol are only slightly higher than the shake-flask result, ALPM values for phenylphosphonothioic acid *O*-ethyl *O*-*p*-nitrophenyl ester (EPN), [2.2]paracyclophane, and progesterone are considerably higher (*cf.* Table V of Ref. 14).

Column-length differences are readily corrected by Eq. 7, except when using a 1-cm column or when the column has deteriorated. A packing error of 0.1 mm becomes important with a 1-cm column and requires the use of the column

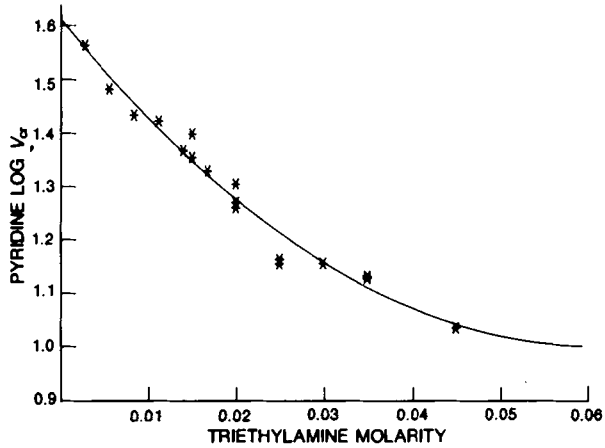

Figure 3—*Log* V_{cr} versus *triethylamine concentration. Dependence of pyridine log* V_{cr} *on triethylamine concentration becomes insignificant at* $\geq 0.06 M$.

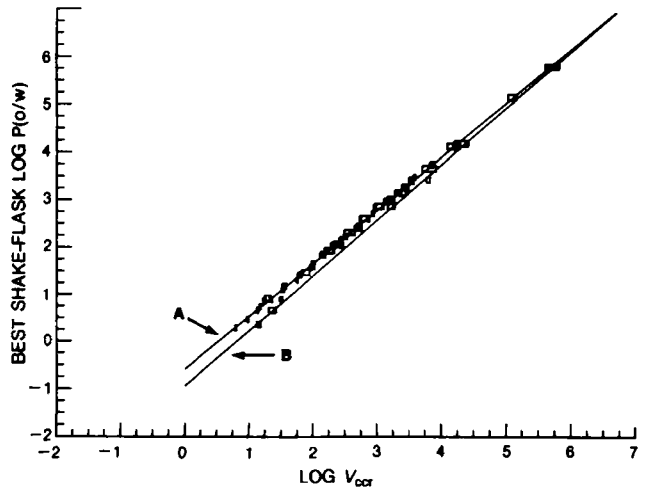

Figure 4—*Correlation between shake-flask log P(o/w) and ALPM log V_{ccr}. Although the correlation of acids is independent of concentration, the correlation of bases and neutral agents is dependent on triethylamine concentration. The boxes represent the 95% confidence limits (±2 SD) in ALPM log V_{ccr} (mean SE = ±0.049) and the mean 67% confidence limit (±SD) in log P(o/w). Key: (A) acidic compounds in 0.004 M trifluoroacetic acid; basic compounds in 0.035 M triethylamine (n = 58, r = 0.9994); (B) basic and neutral compounds in 0.015 M triethylamine (n = 8, r = 0.9996).*

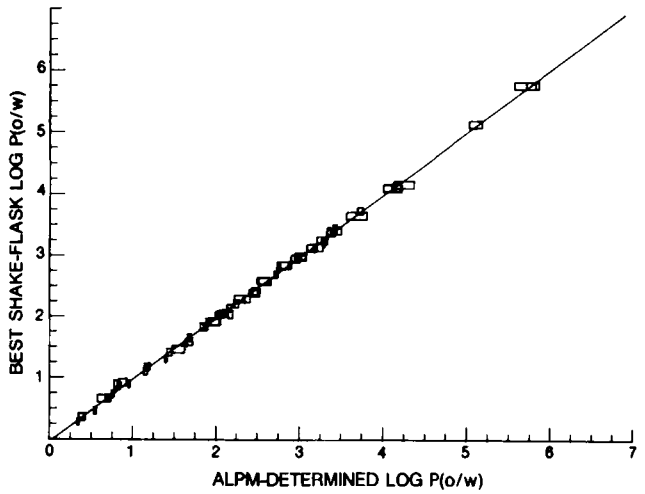

Figure 5—*Correlation between shake-flask and ALPM log P(o/w). Error boxes indicate the variable 95% confidence limits (±SD) (mean = 0.044) in shake-flask log P(o/w) as determined from the compounds shown in Table IV (n = 66, r = 0.9994). The SE of the estimate is 0.045.*

correction factor, C_{cf}. C_{cf} is determined by measuring the log P(o/w) of several agents with otherwise reproducible values. With these agents, any consistent error in log P(o/w) measured at essentially the same time is assigned to C_{cf}. Records normally include the time of C_{cf} assignment, which is checked and updated frequently. Column correction appears to be a valid technique as long as double peaks do not complicate the computation of retention times.

In early work, column deterioration frequently occurred when changing acid-base conditions. Although changing from organic acid to organic base posed few problems, changing from organic base to organic acid consistently destroyed columns. Hypothetically, changing from ion-paired triethylamine to trifluoroacetic acid could result in chemical reactions and/or heat liberation disrupting the column packing. Prior thorough washing with distilled, deionized water failed to prevent column deterioration. Therefore, columns of each length should be dedicated to each acid or base condition to maximize column life.

Changes in column C_{cf} values occur most under basic conditions. The greatest alterations occur when switching to a column that has not been used for an extended period, suggesting that base degradation may be a slow, continuous process. Nevertheless, such changes can be corrected using the C_{cf}; but, in contrast to the 1-cm columns, the C_{cf} for longer columns generally should not be negative, because overpacking is not a problem[12].

DISCUSSION

The value of the partition coefficient to pharmacology and toxicology arises from the dependence of Fick's permeability constant on the partition coefficient (18). As a result, the partition coefficient [*i.e.*, log P(o/w)] governs the absorption, distribution, metabolism, and excretion of chemicals (18-20). Many HPLC procedures that measure log P(o/w) have distinct advantages over shake-flask methods. HPLC procedures provide a continuous scale for measurement of both low and high partition coefficients and offer greater assurance that spectroscopic detection monitors component X, rather than highly absorbent trace impurities (9). In addition, HPLC measurement of elution times can be relatively fast and the conditions carefully controlled (12). HPLC procedures utilize lower concentrations of the agent of interest and may better avoid disequilibria (*e.g.*, multiple components), but HPLC elution time measurements, made as a function of solvent composition, may identify such disequilibria should they occur. The same assurance for shake-flask studies requires, at minimum, the repetition of log P(o/w) measurements at different concentrations and extrapolation to infinite dilution. HPLC methods can also enable partition coefficient determination when compounds are sufficiently unstable as to prevent their determination by conventional shake-flask techniques (21).

Despite these advantages, most available HPLC methods rarely cover much more than 3-3.5 log P(o/w) units (12, 13, 22, 23). Previous HPLC log P(o/w) methods have made use of C_{18} reverse-phase silica columns (9, 22) and/or packing materials coated with octanol to make the columns more "octanol-like" (12, 13, 23, 24). Some still gave poor correlations between elution data and literature or measured log P(o/w) values (13, 25). A relatively recent HPLC method by Veith *et al.* affords a large range of log P(o/w) (26). It uses a curvilinear fit between log P(o/w) and an elution parameter obtained from a programmed nonlinear increase in HPLC flow rate, but even this method gives substantial unexplained deviations from a smooth curve.

ALPM differs in several respects from the other HPLC procedures. ALPM uses C_8 reverse-phase columns, which contain greater hydrocarbon surface areas than either the equivalent C_2 or C_{18} packings (27). Besides using a different alkyl group length, ALPM gives greater assurance than shake-flask or other HPLC methods that the partitioning process achieves the equilibrium so essential to accurate determinations (14). Judicious choices of flow rate, column temperatures, and column lengths allow compounds of widely differing lipophilicities to elute within 10 min. Previously, only Henry *et al.* and Veith *et al.* utilized variable flow rates to expedite the elution process (13, 26). Rapid elution of peaks by ALPM retains excellent peak shapes, which facilitate accurate elution times.

The logarithm of the corrected retention volume (V_{cr}) first obtained by ALPM is converted by linear regression to log P(o/w) values based on the shake-flask procedure. The discovery that two distinct lines (*e.g.*, Fig. 4)

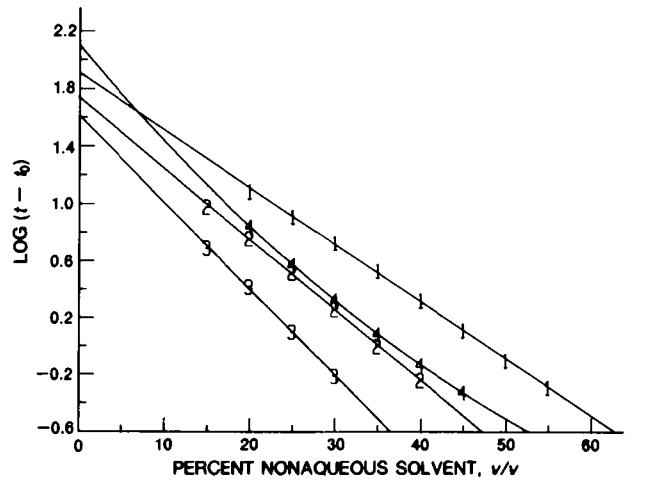

Figure 6—*Log $(t - t_0)$ versus cosolvent. Alcohols afford a linear relationship, although the slopes differ considerably for 1-(3-furyl)-4-methylpentan-1-one. Nonalcoholic solvents, however, do not always give a linear relationship. Key: (1) methanol; (2) absolute ethanol; (3) isopropyl alcohol; (4) acetonitrile.*

[12] Using one 10-cm column, however, it became apparent from several prior determinations using several different compounds, that the column C_{cf} had changed substantially from a positive (*i.e.*, needing a correction) to a negative (*i.e.*, being overcorrected) value. An explanation of this C_{cf} reversal is unclear, but its occurrence is noteworthy.

[a] See footnote 11 (in text) for definitions.

correlate acidic and basic chemicals has been previously reported (24, 25). However, conditions, in which reverse-phase columns offer a single linear correlation between log P(o/w) and HPLC data have not yet been elucidated. Hexabromobiphenyl afforded an ALPM log P(o/w) value of 7.8, the highest value yet measured (14). For neutral compounds, log P(o/w) measurement could be made under either acid- or base-elution conditions. Comparison of acid and base conditions for several neutral chemicals suggests occasional differences can occur (14). Base conditions seem favored for the measurement of the log P(o/w) of neutral compounds due to the substantial linearity already observed under these conditions, but this is currently under investigation.

ALPM reproducibility averages 1.06 ± 0.46% (*SD*) of the average HPLC measured value over 54 runs (Table IV). Errors in these measurements appear related to the slope of the individual log $(t - t_0)$ *versus* percent methanol lines. Although they increase as the log P(o/w) increases, they change little as a percentage of the log P(o/w) value. Reproducibility of the literature shake-flask values for virtually the same compounds averages 6.13 ± 2.76% (*SD*)

Table IV—Reproducibility of Log P(o/w) Measurements [a]

Compound	Runs	ALPM Average ± SD	Measurements	Shake-Flask Average ± SD
Acetanilide	15	1.18 ± 0.01	3	1.23 ± 0.11
Acetophenone	2	1.67 ± 0.01	2	1.66 ± 0.08
Biphenyl	2	4.12 ± 0.01	2	3.88 ± 0.41
4-Bromoaniline	8	2.07 ± 0.02	8	2.15 ± 0.15
4-Bromophenol	7	2.52 ± 0.04	7	2.60 ± 0.13
3-Chlorophenol	3	2.37 ± 0.02	3	2.49 ± 0.02
4-Chlorophenol	3	2.39 ± 0.06	3	2.42 ± 0.07
Naphthalene	9	3.42 ± 0.03	9	3.35 ± 0.19
1-Naphthol	2	3.01 ± 0.04	2	2.71 ± 0.35
Pentachlorobenzene	3	5.18 ± 0.06	3	4.94[b] —
Pentachlorophenol	1	5.11[b] —	1	5.33 ± 0.46
ALPM log P(o/w)		average error = 1.06% (±0.46%) for 54 values		
Shake-flask log P(o/w)		average error = 6.13% (±2.76%) for 40 values		

[a] The error in ALPM increases as the slope of log $(t - t_0)$ *versus* percent methanol becomes more negative. The average error is expressed as a percent of the log P(o/w) value for both the ALPM and shake-flask results. The shake-flask data are from Refs. 2, 3, and 26. [b] Not included in error determination.

of the measured value. Table III summarizes typical information obtained by ALPM for the standards used in Figs. 4 and 5.

In addition to high accuracy and excellent reproducibility, measurement of log P(o/w) by this procedure is less expensive and safer than by other methods. The shorter columns required for the majority of agents are 10–50% as expensive as 25-cm columns and generate much lower back-pressures. Neglecting the instrumentation cost, samples can be processed for ~$10.00 (which compares well with the cost of calculated values), yet the results provide as good or better a correlation with biological data (14). Even differences between isomers can be determined. All HPLC methods avoid the cumbersome use of often leaky separatory funnels and traditional UV-visible spectrophotometric analysis, with its manipulation of standards and analysis solutions; but ALPM also avoids exposure to toxicants. Samples can be prepared in a glove box and automatically injected under computer control, with wastes delivered directly into approved waste containers.

For maximal statistical validity and accuracy, ALPM requires numerous elution-time measurements. The error in ALPM log P(o/w) generally decreases as the number of measurements increase, so the needed number of determinations must be based on user requirements. An entire computer-operated run can generally be completed within 1 h for six measurements from ~55 to 30% methanol (5% increments) in descending order or within ~1.5 h for duplicate data measured first in descending, and then ascending, order. Facts pertinent to the choice of the methanol percentage range are presented in the following paper (14). Although somewhat more time is required for ALPM than for single-measurement HPLC procedures, labor expenses can be virtually eliminated by this computer-controlled analysis; it can automatically process up to 24 single or 12 duplicate runs while operating day and night.

The chemical need not be pure to use computer-data acquisition, but other components must provide smaller peak areas than either the void volume marker or the compound of interest. This purity limitation involves only the computer assignment of t and t_0. If the compound does not meet that requirement, log P(o/w) may still be measured, provided that the component peaks and times can be manually identified, but elution times must be entered into the computer *via* the keyboard. Less-obvious advantages of this desk-top-computer control include: routines for the unattended monitoring and response to HPLC-operational problems; recovery from power outages; versatile alphabetical data file listing (*e.g.* Table I); and a data format usable with commercial statistical and graphics packages.

Greater detection selectivity can be achieved for certain chemical by using variable-wavelength or fluorescence detectors. Refractive index (RI) or conductivity detectors should work, but as they measure changes instead of actual values, a given peak can be positive or negative. As a result, automated computer-data acquisition can become troublesome. Moreover, because of their enhanced sensitivity, these detectors also raise more questions about the identity of the eluting agent than do variable-wavelength detectors.

ALPM represents a major improvement in log P(o/w) measurement technology, especially for those requiring values for many compounds. It is not, however, without some problems. Other than the obvious requirements that the substance be stable in the injection solvent under the measurement conditions for the period of detection, only log P(o/w) values above zero may be measured currently. Second, log P(o/w) standards must be run externally before and/or after the compound of interest because no method is available to elucidate the peak of interest or a simultaneously measured standard. Third, ALPM fails for zwitterionic compounds which elute immediately in either acid or base and could afford incorrect values for compounds with complex, multiple pK values. Fourth, HPLC measurement of log P(o/w) values >~8 units becomes increasingly difficult. These compounds often have poor solubility even in tetrahydrofuran, and the high negative slopes encountered with these agents leads to peak broadening when higher percentages of aqueous buffer are used. This broadening diminishes the accuracy of HPLC-computed elution times and can even affect peak detection. As a result, high log P(o/w) compounds limit the range of percentages over which good data can be obtained and raise the absolute log P(o/w) error accordingly. The necessary use of the shortest columns and high flow rates for compounds with high log P(o/w) values also hastens elution of the void volume marker peak. This can cause computer-processing difficulties if that critical peak is missed or incorrectly assigned. Such problems are readily evident and, since the HPLC output is available, the data can be manually corrected often with no loss of information.

During the course of this study, several alternative uses of ALPM became apparent. Because elution times of organic acids are essentially independent of acid concentration, and 0.004 M trifluoroacetic acid has minimal effect on column life, this procedure should provide an excellent, reproducible, and automated method for quality control of RP-8, and likely all reverse-phase HPLC columns, once the necessary constants m, b, and C_{cf} are determined.

ALPM may also become a valuable addition to qualitative-quantitative analysis and structure assignment. For example, reaction of phenylmagnesium bromide with 3-cyanofuran gave two products after acid hydrolysis, which were not separable by simple vacuum distillation. We have found that treatment of other simple Grignard reagents with 3-cyanofuran gives no such problem. ALPM log P(o/w) analysis confirmed the suspected identity of the unwanted component as biphenyl, a well-known phenylmagnesium bromide degradation product.

Yet another use of ALPM technology may be automated method development and analysis. Specifically, overlap plotting of individual log $(t - t_0)$ *versus* percent solvent data for each compound can indicate the single percentage of solvent that allows easy separation of the compounds. Furthermore, once the log P(o/w) of a compound, the elution time (t_0) of the void volume marker, and the column correction factor (C_{cf}) are known, the elution time for a given agent may be computed for various aqueous-buffer methanol compositions.

Abstract □ Occasionally, results from the highly reproducible automated log P(o/w) measurement (ALPM) differ from those determined by shake-flask methods. Several specific examples affording different values are presented. One source of these differences may be curvilinearity in plots of log $(t - t_0)$ *versus* percent methanol, which complicate accurate intercept determinations and, thus, estimates of log P(o/w). Other sources of these differences are presented and discussed, although their cause remains unclear. Equilibrium ALPM log P(o/w) measurements of various phenyl-, methyl-, fluoro-, chloro-, and bromobenzenes, suggest substituent constants are not strictly additive. Moreover, the higher values indicate that calculated values may not be accurate for those compounds having multiple substituents or high log P(o/w) values. ALPM gives better predictability of the *in vivo* concentration process of 8 or 12 toxicants in fish than the shake-flask method, another HPLC method, or even calculated log P(o/w) values. However, it equally correlates the binding to bovine serum albumin by 34 chemicals as predicted by a combination of shake-flask and calculated log P(o/w) values reported elsewhere.

Keyphrases □ HPLC—octanol/water partition coefficient, equilibrium □ Partition coefficients—octanol/water, HPLC, equilibrium, biological correlation

An automated log P(o/w) measurement (ALPM) has been developed that utilizes high-performance liquid chromatography (HPLC) to accurately and reproducibly estimate the logarithm of the octanol/water partition coefficient at costs comparable with computation (1). ALPM differs from earlier HPLC procedures in that variable column lengths, flow rates, and temperatures have enabled determinations over the 0–8 log P(o/w) range (1). Most previous HPLC log P(o/w) procedures have involved measurement of the capacity factor, k', using a single determination at a fixed composition of water, buffer, or a low percentage of alcohol in water or buffer (2, 3):

$$k' = (t - t_0)/t_0 \qquad \text{(Eq. 1)}$$

where t and t_0 refer to the elution time of the compound of interest and void volume marker, respectively. From that data log P(o/w) has been calculated by:

$$\log P(o/w) = (m \times \log k') + b \qquad \text{(Eq. 2)}$$

Determination of log P(o/w) by shake-flask techniques requires that equilibrium be established between the aqueous and octanol phases for the single component being measured (1). Equilibrium is essential even when partitioning occurs between HPLC phases. To date, no HPLC log P(o/w) method has provided solid evidence that equilibrium is attained during the elution process. Theoretically, if HPLC equilibrium is attained at each percentage of mobile phase during such measurements, a linear relationship between percent mobile phase and log k' or log $(t - t_0)$ should be apparent. Yamana *et al.* did demonstrate a linear dependence of log k' on the percentage of methanol used for elution (3). However, despite lower error and a better correlation using the extrapolated intercept at 0% methanol, they opted to use data measured at 30% methanol for procedural uniformity. Unfortunately, they failed to consider fully the significance of linearity. Deviations from linearity suggest a departure from HPLC equilibrium caused by changing interactions between the chemical and either the mobile or stationary phase. Although linearity of such plots over a limited solvent range can not prove that HPLC equilibrium is attained, curvilinearity is contrary evidence.

Unlike most procedures, ALPM utilizes the extrapolated linear intercept from computer-assisted log $(t - t_0)$ *versus* solvent composition measurements. As such, ALPM not only makes many more measurements, but in doing so better establishes equilibrium HPLC behavior for the agent being

Keyphrases □ HPLC—octanol/water partition coefficient, equilibrium □ Partition coefficients—octanol/water, HPLC, equilibrium, biological correlation

An automated log P(o/w) measurement (ALPM) has been developed that utilizes high-performance liquid chromatography (HPLC) to accurately and reproducibly estimate the logarithm of the octanol/water partition coefficient at costs comparable with computation (1). ALPM differs from earlier HPLC procedures in that variable column lengths, flow rates, and temperatures have enabled determinations over the 0–8 log P(o/w) range (1). Most previous HPLC log P(o/w) procedures have involved measurement of the capacity factor, k', using a single determination at a fixed composition of water, buffer, or a low percentage of alcohol in water or buffer (2, 3):

$$k' = (t - t_0)/t_0 \qquad \text{(Eq. 1)}$$

where t and t_0 refer to the elution time of the compound of interest and void volume marker, respectively. From that data log P(o/w) has been calculated by:

$$\log P(o/w) = (m \times \log k') + b \qquad \text{(Eq. 2)}$$

Determination of log P(o/w) by shake-flask techniques requires that equilibrium be established between the aqueous and octanol phases for the single component being measured (1). Equilibrium is essential even when partitioning occurs between HPLC phases. To date, no HPLC log P(o/w) method has provided solid evidence that equilibrium is attained during the elution process. Theoretically, if HPLC equilibrium is attained at each percentage of mobile phase during such measurements, a linear relationship between percent mobile phase and log k' or log $(t - t_0)$ should be apparent. Yamana *et al.* did demonstrate a linear dependence of log k' on the percentage of methanol used for elution (3). However, despite lower error and a better correlation using the extrapolated intercept at 0% methanol, they opted to use data measured at 30% methanol for procedural uniformity. Unfortunately, they failed to consider fully the significance of linearity. Deviations from linearity suggest a departure from HPLC equilibrium caused by changing interactions between the chemical and either the mobile or stationary phase. Although linearity of such plots over a limited solvent range can not prove that HPLC equilibrium is attained, curvilinearity is contrary evidence.

Unlike most procedures, ALPM utilizes the extrapolated linear intercept from computer-assisted log $(t - t_0)$ *versus* solvent composition measurements. As such, ALPM not only makes many more measurements, but in doing so better establishes equilibrium HPLC behavior for the agent being

measured. The logarithm of the corrected retention volume, log V_{cr}, is converted by linear regression to the ALPM log P(o/w) (1). This paper describes the nature of this linearity and the ALPM linear extrapolation process. Several interesting discrepancies between ALPM and shake-flask log P(o/w) values are reported and discussed, and the ALPM-measured log P(o/w) values for certain phenylated, methylated, and halogenated benzenes are examined. This paper also compares equilibrium ALPM results with shake-flask and calculated log P(o/w) values used by Veith *et al.* to estimate the *in vivo* concentration process of chemicals in fish and by Helmer *et al.* to estimate the binding of chemicals to bovine serum albumin (4, 5).

EXPERIMENTAL SECTION

Definitions of terms, the equations for the calculation of ALPM log P(o/w), and a description of instrumentation, columns, conditions, and procedures are reported in the preceding paper (1).

RESULTS

Figure 1 illustrates that HPLC equilibrium [*i.e.*, linearity of log $(t - t_0)$ *versus* percent methanol] depends on the compound and not necessarily on the mechanical aspects of measurement. For instance, acetanilide, like the majority of compounds, gives a linear relationship between log $(t - t_0)$ and methanol percentage. Unlike acetanilide, but when run simultaneously, benzene seemingly interacts with the mobile phase, as demonstrated by the concave curvilinearity apparent at low percentages of methanol (Fig. 1). This increasingly rapid elution by water is pH independent; measurement using 0.004 M trifluoroacetic acid also affords a concave curvilinearity[1]. The benzene curve from ~60 to 35% MeOH is linear (*i.e.*, statistically, this region is not curved). Between these percentages, HPLC equilibrium is evidently maintained[2]. Extrapolation of the linear segment to 0% methanol and correction for conditions of measurement, as reported in the preceding paper for three separate determinations using 0.035 M triethylamine, indicates that the log P(o/w) for benzene is 2.00 ± 0.06 (*SD*); the relatively high standard deviation probably reflects the error in intercept measurement caused by curvilinearity. Although measurement using 0.004 M trifluoroacetic acid affords a concave curvilinearity, it yields a log P(o/w) of 2.15 ± 0.03 (*SE*), which is statistically identical to the benzene shake-flask value of 2.13. Regardless of the pH difference, either benzene curvilinear (*i.e.*, quadratic) intercept affords a log P(o/w) value substantially lower than that measured by extrapolation of the linear segment. This supports the midrange linear extrapolation approach.

In contrast with benzene, methylisobutylxanthine increasingly interacts with the stationary phase (indicated by the convex curvature in Fig. 1), but the cause for this phenomenon is not clear. Evaluation of this convex relationship is complicated by the unavailability of shake-flask results for methylisobutylxanthine. Future studies may be directed toward understanding these apparent disequilibria. For now, the results indicate that measurement of log $(t - t_0)$, particularly at a single, low alcoholic percentage (as is commonly practiced), could introduce substantial measurement error if HPLC equilibrium (*i.e.*, linearity) is not attained. This may have had considerable bearing on previous attempts to measure log P(o/w) by HPLC methods, regardless of column adsorbent.

While acids or bases can best be determined under acidic or basic conditions, respectively, ALPM measurement of neutral compounds can be performed in either acid or base (1). The data in Table I indicate that the extrapolated intercepts and log P(o/w) results for neutral compounds can be statistically the same (*e.g.*, iodobenzene) or they can differ (*e.g.*, benzene and acetanilide) depending on the measurement pH. These data are grouped primarily by compound name and secondarily by column serial number, but the results indicate column independence.

Figure 2 graphically illustrates results of ALPM log P(o/w) determinations of several benzene derivatives with phenyl, methyl, fluoro, chloro, and bromo substituents. Individual data for these compounds are listed in Table II. Figure 2 demonstrates that substituent additivity is generally invalid. Each substituent group appears to afford a concave relationship, although insufficient data are available for the fluoro and phenyl substituents to justify more than a linear

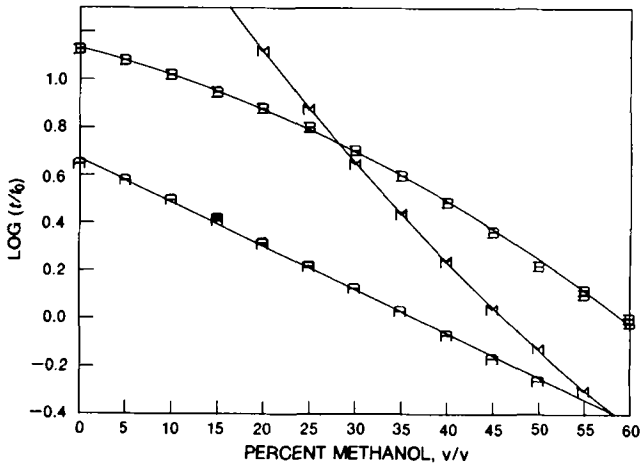

Figure 1—*Linearity of log* $(t - t_0)$ *data. Log* $(t - t_0)$ versus *percent methanol plots for acetanilide (A) and benzene (B) run simultaneously using 0.035 M triethylamine indicate that curvature depends on the compound. Methylisobutylxanthine (M) measured using 0.004 M trifluoroacetic acid gives a curvature opposite to that of benzene.*

[1] Unpublished results.

[2] Generally in ALPM, log $(t - t_0)$ values for methanol percentages of <25–30% are rarely measured. Not only do such measurements substantially increase the determination time, but the data often show greater statistical scatter (*e.g.*, Fig. 1, acetanilide between 8 and 15% methanol) or curvature (*e.g.*, Fig. 1, benzene and methylisobutylxanthine). Either condition requires that these points ultimately be excluded from the linear (*i.e.*, equilibrium) extrapolation. The results in Fig. 1 have been reproduced using several columns. Although not shown, high methanol percentages could also lead to curvature of log $(t - t_0)$. To maintain the greatest accuracy when measuring compounds with high partition coefficients, alcohol percentages of >60–65% should be used cautiously, and preferably with several points at and below 50% alcohol. Actually, use of these high percentages should be restricted to extremely high log P(o/w) compounds for which the lower values are difficult to obtain even on short columns. The difference $(t - t_0)$ should also exceed 0.3 min for greatest accuracy, although this empirical value actually depends on the accuracy of the elution-time measurements.

Table II—Partition Coefficient Summary for Various Substituted Benzenes

[a] Single literature value closest to ALPM log P.

fit. Table III lists ALPM-derived substituent constants, obtained by two different procedures, and shake-flask literature values (6). If the 0.035 M triethylamine value for benzene is used in the substituent constant calculation, the ALPM-derived constants are higher than those obtained by the octanol/water shake-flask method. These values closely resemble those obtained with the "hyperdiscriminating" solvents benzene or chloroform (7). If the monosubstituted benzene is used instead of benzene for the substituent constant calculation, the ALPM-derived value is lower and is closer to the shake-flask result. However, an average of these ALPM-derived values affords results close to the shake-flask substituent constant.

DISCUSSION

As a result of the potentially high error when using a single capacity factor measurement, many workers have begun to use the logarithm of the extrapolated intercept at 100% aqueous solvent in correlation work. For example, Butte *et al.* extrapolated data measured from 75–90% methanol to 0% methanol in their studies of various phenolic compounds eluting from an 10-μm octadecylsilane LiChrosorb RP-18 column (8). Bieganowska extrapolated values from 60–80% methanol (obtained using a 10-μm RP-18 column) in her investigation of the elution properties of *N*-phenylamides of benzoylacetic acid (9). In more extensive studies, Hafkenscheid and Tomlinson have examined 32 simple, but diverse, compounds over the range from 30 to

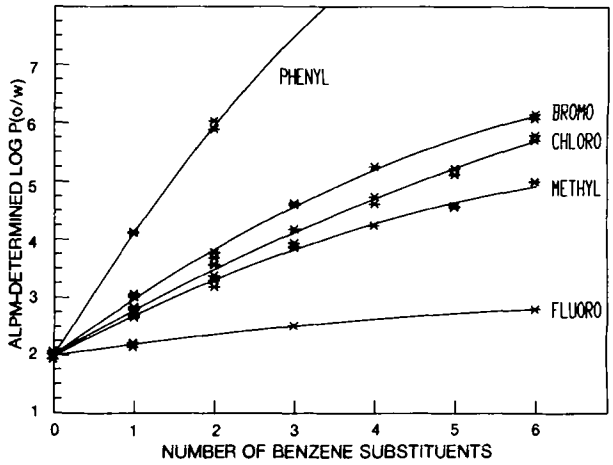

Figure 2—*ALPM log P(o/w)* versus *the benzene substituent number. This plot of ALPM log P(o/w) for various substituted benzenes* versus *the number of groups on the benzene ring reveals that strict substituent additivity is not the rule.*

90% methanol and extrapolated the RP-18 elution results to zero, generally obtaining a correlation coefficient of >0.999 (10). Braumann and Grimme used an extrapolated 0% methanol result obtained from 55 to 80% methanol with pyridazinones eluting over an RP-18 column (11). Close examination of the latter study reveals that correlation coefficients between 0.995 and 0.999 were often obtained, in contrast to the 0.999 minimum for ALPM (1), suggesting that curvature was perhaps unrecognized. Hanai and Hubert used acetonitrile/water from ≥30 to 90% in their study of urinary aromatic acids (12).

Questions arise as to the proper choice of solvent, solvent percentage range, and the extent of log $(t - t_0)$ *versus* percent solvent linearity for obtaining these extrapolated results. In this regard, an understanding of the way these factors can influence the log $(t - t_0)$ *versus* percent solvent relationship is pertinent. Acetonitrile, but not the alcoholic solvents, gave a curved plot of log $(t - t_0)$ as ordinate *versus* the percent of nonaqueous solvent for ALPM work with 1-(3-furyl)-4-methylpentan-1-one (1). The present study reveals, however, that curved plots can be obtained even in methanol. In their detailed studies, Schoenmakers *et al.* examined the elution behavior of 32 compounds from an RP-18 column using methanol, acetonitrile, or tetrahydrofuran; they also found plots of solvent fraction *versus* the logarithm of the capacity factor (as ordinate) were often curved, irrespective of the solvent (13). Although methanol afforded the greatest separation potential, it required such a long time for elution of highly nonpolar agents that it was useless. While other researchers have used higher methanol percentages to solve this problem, ALPM utilizes different column lengths for the less polar agents.

Hanai and Hubert, in their studies using an octadecylsilica column, found that curvature can occur at either high or low acetonitrile levels (12). Results obtained using methanol (Fig. 1) reveal that curvature can be either concave or convex, depending on the compound. A comparison of RP-8 ALPM findings for specific compounds with the results of Schoenmakers *et al.* using RP-18 columns reveals that compounds need not have the same concave or convex curvature; thus, curvature is also column dependent. Overall, HPLC equilibrium can depend on the organic solvent(s), the chemical, and/or the column, among other factors. Indeed, so many factors become important that one wonders if these relationships are ever really linear. In this regard, Schoenmakers *et al.* have theorized that these relationships should actually be qua-

Table III—Aromatic Substituent Constants[a]

Substituent	ALPM Constant: Mono-substituted[b]	ALPM Constant: Di-substituted[c]	ALPM Constant: Mean[d]	Shake-Flask Constant[e]

[a] All ALPM values determined using 0.035 M triethylamine (1). [b] ALPM constant computed from the difference between ALPM values for the log P(o/w) of the monosubstituted benzene and benzene. [c] ALPM constant computed from the difference between ALPM values for the log P(o/w) of the disubstituted benzene and that of the monosubstituted benzene. [d] Average of mono- and disubstituted values. [e] Derived from octanol/water data (6).

Table IV—"Bioconcentration Factor" (Log BCF) Predicted from Various Log P(o/w) Measurements [a]

	Measured log BCF	Calculated log BCF		
		Other HPLC	ALPM	Calculated
Acenaphthene	2.58	3.18 (4.49)	2.83 (4.02)	3.15 (4.45)
Butyl benzyl phthalate	2.89[b]	3.38 (4.75)	3.64 (5.09)	—
2-Chlorophenol	2.33	0.40 (0.83)	1.53 (2.32)	1.42 (2.17)
1,2-Dichlorobenzene	1.95	2.62 (3.75)	2.47 (3.56)	2.47 (3.55)
1,3-Dichlorobenzene	1.82[b]	2.77 (3.95)	2.48 (3.57)	2.47 (3.55)
1,4-Dichlorobenzene	1.78	2.64 (3.78)	2.33 (3.37)	2.47 (3.55)
Diethyl phthalate	2.07	1.80 (2.67)	2.02 (2.96)	—
Dimethyl phthalate	1.76	—	1.19 (1.87)	0.96 (1.56)
2,4-Dimethylphenol	2.18[b]	1.28 (1.99)	1.64 (2.46)	1.70 (2.54)
N-Nitrosodiphenylamine	2.34[b]	2.47 (3.55)	2.19 (3.18)	—
1,2,3,4-Tetrachlorobenzene	3.26	3.57 (5.00)	3.32 (4.67)	3.55 (4.97)
Pentachlorobenzene	3.53	3.79 (5.29)	3.69 (5.16)	4.09 (5.68)[c]

[a] Numbers in parentheses are log P(o/w) values used to calculate log BCF by the formula of Veith *et al.* (4): log BCF = 0.76 × [log P(o/w)] − 0.23. [b] Measured log BCF was better approximated using "Other HPLC" or "Calculated" values than by "ALPM" log P(o/w) values. [c] Calculated from values determined by this study.

dratic (13). While it is difficult to explain why results are so often linear, it is clear that equilibrium (*i.e.*, state of linearity) must now be considered in HPLC methods for hydrophobicity determination, if more meaningful data are to be obtained.

Unfortunately, it is difficult to know the status of such equilibria without a time-consuming measurement of all significant log $(t - t_0)$ results at incremental percentages from 0 to 100% solvent. Although ALPM software can achieve this, once these data are obtained, they are often of little use[2]. If they are linear, only a few points would be needed, and the time required could be greatly reduced. If they are curved, it may be unclear at which end or over which region the curvature occurs. The only answer is to understand the real cause of this curvilinear behavior. However, the use by ALPM of statistically valid log $(t - t_0)$ *versus* 55–35% methanol percentage data with linearity (or curvilinearity) testing, as for benzene, seems to afford the fastest and, by covering the range of maximum solvent independence, the best assurance of the actual equilibrium condition.

HPLC-determined hydrophobicity is generally considered to be a composite of partition and absorption processes (14). If absorption events could be eliminated from HPLC measurements, then data from the HPLC partition process could be compared with that from the shake-flask method to discern discrepancies. However, absorption processes probably cannot be prevented using octadecylsilane columns because of a structured methanol layer on the column packing surface (14). ALPM utilizes C_8 or octylsilylated columns, which are less likely to bind methanol. In this regard, the high correlations of ALPM data with the shake-flask results over such a wide range, as reported in the first paper (1) and in Table IV herein, suggest absorption processes are of minimal importance. As a result, unexplainable differences between ALPM and shake-flask log P(o/w) results should be rare. However, discrepancies warrant attention. In general, they could signify an absorption process with the ALPM partition column, another ALPM anomaly, or perhaps even shake-flask irregularities. ALPM discrepancies could indicate how the processes unique to individual chemicals alter simple partitioning phenomena. While such deviations could have considerable relevance to predicting biological activities, they affect only that isolated value. On the other hand, shake-flask irregularities could also identify improperly computed substituent constants and errors in calculated values.

One inconsistency between the ALPM and shake-flask log P(o/w) values occurs for benzene, a primary standard for the calculation of log P(o/w). ALPM measurement using the established 0.035 M triethylamine conditions does not give the reproducible and accepted shake-flask value of 2.13, but affords a mean of 2.00 ± 0.06 for three determinations. ALPM measurement in 0.004 M trifluoroacetic acid yields 2.15 ± 0.03, which is statistically the same as the shake-flask result. The data indicate a possible pH dependency of log P(o/w); however, no significant variation of shake-flask log P(o/w) with pH is evident with benzene[3].

ALPM estimates of log P(o/w) reflect the ratio of chemical on the stationary phase (SP) to that in the mobile phase (MP) (Eq. 3). If the ALPM result has the same value as the shake-flask approach, pure partitioning would be indicated. If not, the ALPM result can be evaluated to determine which changes would give the altered ratio (1):

$$\log P(o/w)_{ALPM} = m \times \log ([X]_{SP}/[X]_{MP}) + b \qquad \text{(Eq. 3)}$$

where $[X]_{SP}/[X]_{MP} = V_{ccr}$.

Assuming the ALPM acid result and the reproducible 2.13 literature shake-flask log P(o/w) for benzene are correct, the lower ALPM value in base suggests that benzene is eluting earlier in base than in acid. This could result from a reduced interaction between benzene and the stationary phase or an increased interaction between benzene and the mobile phase. Four facts argue against the former possibility and support the latter: (*a*) excellent correlations are obtained under basic conditions for many agents having higher or lower log P(o/w) values; (*b*) benzene is chemically unlikely to combine with column functionalities; (*c*) it has no substituents to hinder column interactions; (*d*) the log $(t - t_0)$ *versus* percent methanol plot is curved regardless of pH for benzene, but not for acetanilide. The well-known benzene-water azeotrope also supports occurrence of such an interaction.

The lower base log P(o/w) observation has some generality. Base-determined ALPM values for the smaller, more water-soluble, heterocyclic compounds pyrrole, furan, and thiophene, are similarly lower than their shake-flask counterparts (Table V, obs. 21, 45, and 46) (6, 15, 16). Increasing compound size appears to diminish the differences between ALPM and the shake-flask results. The 2.20 average ALPM value for fluorobenzene is lower than the 2.27 shake-flask result. Fluorobenzene, like benzene, affords a curvilinear relationship between log $(t - t_0)$ and percent methanol. However, no curvilinearity or deviation was apparent with chlorobenzene (Table II, obs. 10–12 and 19–22). Similarly, the ALPM value for the larger aromatics naphthalene and anthracene are statistically the same as their shake-flask values.

These data could support the existence of a hydrogen-bonded solvation shell about the smaller aromatic agent. Masking of lipophilic aromatics by a hydrophilic shell could impede their column binding; it would, however, decrease as the size of the aromatic chemical increases. Knowledge of whether the complete log $(t - t_0)$ *versus* percent methanol relationship for these heteroaromatic agents is curvilinear would be useful in evaluating this proposal, but their weak UV absorption (when compared with baseline triethylamine-methanol solutions) has precluded obtaining that information. The lower ALPM value for benzene in base, as opposed to acid, could arise from stronger hydrogen bonding caused by a greater electron density on the hydroxyl ion. Such a solvation shell, if formed, could also reduce penetration of these smaller π-excessive aromatic agents through lipid-like biomembranes, suggesting that the ALPM result may be more relevant than the shake-flask result in predicting biological properties. However, no comparative biological data are presently available to support that suggestion.

Different values for ALPM and shake-flask results can occur even when a linear relationship is evident, regardless of measurement pH. The 1.17 value for acetanilide obtained in base using ALPM is consistent with the pH-independent literature shake-flask result[4], requiring the higher ALPM value obtained in acid to be explained (Table I). The possibility of a fast trifluoroacetylation reaction was discounted by substitution of acetic acid (Table I, obs. 7). Since the acid plot of log $(t - t_0)$ *versus* percent methanol is also linear, the higher value can only be explained by increased column binding by acetanilide under acid conditions. In this regard, reversible Michael addition of a silanol residue to a multisubstituted and benzene-stabilized imine by the process in Scheme I is proposed. While occurrence of this base-catalyzed process in dilute acid may seem strange, the acid could represent a compromise between the needed tautomerization and sorbant-imine-catalyzed Michael reaction. The Michael reaction is a highly reversible process (17); its occurrence would statistically delay departure of the compound from the column. The present data are insufficient to determine that this reaction actually occurs on the column. Theoretically, it would be prevented if no free, unalkylated silanol residues were present. Future studies using spherical, extensively capped packing materials could conceivably eliminate this process. If such a chemical event could also occur with nucleophiles in membranes, the ALPM determi-

[a] Determined using the regression constants reported by Helmer *et al.* (5), the value of log P(o/w) given in parentheses, and: log (1/*C*) = 0.751 × log P(o/w) + 2.301. [b] Calculated log P(o/w) used by Helmer *et al.* (5). [c] ALPM log P(o/w) and Helmer *et al.* (5) data differ by more than ±3 *SD* based on the shake-flask error (*i.e.*, 6.13 ± 2.76%) reported in the preceding paper (1).

nation in acid might more adequately reflect biological activities than would either the pure solvent/water partition measurement or the new, improved end-capped, partition column packings.

Several other compounds have also given ALPM estimates of log P(o/w) that differ from the shake-flask result. In principle, if triethylamine (pK_a = 11.01) forms an ion-pair with silanol residues, as suggested in the preceding paper (1), an amine of comparable basicity would do the same, delaying its elution and raising its apparent log P(o/w) value. Amines of lower basicity would not be affected. Thus, little difference between shake-flask and ALPM values has been found for diphenylamine (pK_a = 0.79), 3-bromoquinoline (pK_a = 2.69), 4-bromoaniline (pK_a = 3.86), pyridine (pK_a = 5.25), and acridine (pK_a = 5.58) (1). Although the ALPM value of 4-aminopyridine (pK_a = 9.11) appears unaffected, phenethylamine (pK_a = 9.84) affords an ALPM value of 2.84, ~0.4 units higher than the shake-flask result (6). This discrepancy for phenethylamine could prove advantageous in studies of new column packings. The absence of unalkylated silanol groups on a particular packing should theoretically result in no deviation for this agent and provide an excellent experimental tool to examine silica gel alkylation.

Two other compounds studied appear inconsistent with shake-flask data. Both the reproducible shake-flask method and the octanol-saturated, kieselguhr-packed column of Mirrlees *et al.* indicate that the log P(o/w) for caffeine ranges from −0.07 to 0.01 (2, 6). These values differ considerably from the reproducible ALPM value of ~0.63 (Table V). A base-related explanation for the high ALPM value of caffeine is unlikely; however, literature shake-flask data also suggest inconsistencies in the xanthine series. While the −0.07 value of Anderson, cited by Hansch and Leo, is consistent with the findings of others, his report of −0.02 for theophylline and −0.80 for theobromine, two dimethylated xanthines which should have similar values, complicate evaluation of this matter (6).

ALPM also does not afford a result similar to the shake-flask literature for α-tropolone (Table V). Although some enhanced column-binding process cannot be discounted, the 1.54 ± 0.04 ALPM value is close to the 1.45 shake-flask value of the similar *p*-hydroxyacetophenone (6). Likewise, a value of 1.61, estimated from that of catechol (Table V) and the ALPM substituent constant for a methyl group, is closer to the 1.54 ALPM value than to the

0.53–0.75 range reportedly obtained by shake-flask (6). α-Tropolone shows no evidence of curvilinearity in its log $(t - t_0)$ *versus* percent methanol plot. Furthermore, this deviation occurs at a log P(o/w) value where other compounds give virtually identical shake-flask and ALPM results (Table V). The fact that α-hydroxy ketones in general, and α-tropolone specifically, readily hydrate and dimerize may be relevant to these discrepancies (18). Perhaps biological properties may be better predicted by the higher ALPM result, especially if the higher ALPM log P(o/w) value reflects partitioning of a stable dimer or unhydrated species.

In the course of these determinations various substituted benzenes were examined (Fig. 2). Concave curvature of their ALPM log P(o/w) values continues from 0 to 6 substituents seemingly without regard to the electron-donating or electron-withdrawing character of the substituent. Figure 2 also indicates that values for the various fluorobenzenes deviate the least from linearity when compared to methyl, phenyl, chloro, or bromo substituents. This near linearity for the smaller fluorine groups suggests that spatial rather than electronic factors influence ALPM log P(o/w). Other correlation parameters, such as molar refractivity, are known to have a major spatial component (6). Such factors may also explain results with [2.2]paracyclophane, which has a reported shake-flask log P(o/w) of 2.33 (6). ALPM yields the much higher value of 4.47 (Table V), yet even this value is significantly lower than that expected based on double the 3.29 ALPM value for *p*-xylene (Table II).

Since ALPM affords a continuous, wide-range estimation of log P(o/w) by a column-binding method and since considerable shake-flask data also indicate that these groups are not truly additive (6), perhaps strict additivity is simply fallacious. This would suggest clear limitations on the calculation of log P(o/w) values using various additivity schemes. However, even calculations should afford minimal error when one or two benzene substituents are present. In this case, ALPM often gives values very close to the calculated value (using benzene = 2.13). ALPM gives 3.56 and 3.57 for both the 1,2- and 1,3-dichlorobenzenes, respectively, but only 3.37 for 1,4-dichlorobenzene. The shake-flask procedure gives 3.40 and 3.44 for the 1,2- and 1,3-dichlorobenzenes, respectively, but 3.37 for 1,4-dichlorobenzene. Veith *et al.* reported 3.55 as the calculated value for all the dichlorobenzenes (4). Since ALPM gave that value for 1,2- and 1,3-dichlorobenzenes, but afforded the noticeably lower 3.37 shake-flask value for the *para* isomer, perhaps ALPM can detect real differences between isomers which are not evident in calculations. Occasionally, ALPM better supports the calculated value for compounds with sterically noninteracting substituents. For instance, the shake-flask log P(o/w) of mesitylene is 3.42 (6) and the calculated value is 3.81 (6), yet ALPM yields 3.87.

Attempts to calculate log P(o/w) values using various additivity schemes may lead to inaccurate values for interacting, multiply substituted, and high log P(o/w) compounds; these compounds have log P(o/w) values which are otherwise difficult to measure directly and, in part, prompted development of the additivity concept. Thus, ALPM gives interesting differences between shake-flask and/or calculated values for such compounds as 1,2,3,4-tetrachlorobenzene or pentachlorobenzene (Table IV), and hexamethylbenzene [ALPM, 5.00; shake-flask, 4.31 (6); calculated, 5.49 (6)]. These findings and interesting discrepancies for phenylphosphothioic acid *O*-ethyl *O*-*p*-nitrophenyl ester (EPN) and progesterone in Table V could suggest that the best way to determine log P(o/w) is ALPM measurement.

One clear comparison of method is the prediction of biological data. In this regard, ALPM log P(o/w) values seem to afford equal or better predictions. Table IV compares ALPM log P(o/w) data with those obtained from calculated values and another HPLC method in predicting the measured *in vivo* concentration process of various compounds in bluegill sunfish (4, 19). For 8 of 12 compounds having sufficient UV absorption to allow evaluation with the current detector system, ALPM measurement gave equal or better approximation of the "bioconcentration" factor (as log BCF) than did either the calculated or HPLC-determined values reported by Veith *et al.* (4, 19). Since, *in vivo* measurement of the concentration process may cost from $3000 to $10,000 (depending on the need for radiolabeled agents), this represents a significant savings (4).

Log P(o/w) data for 34 compounds, having sufficient availability and UV absorption to enable ALPM measurement, were compared with the combination of shake-flask and calculated log P(o/w) values reported by Helmer *et al.* with regard to prediction of bovine serum albumin binding (Table VI) (5). Correlation coefficients, standard errors, and other measures of similarity are shown in Table VII. Several major discrepancies occur between shake-flask and ALPM values. Although Helmer *et al.* measured a value of 1.22 (5) and Hansch and Leo cite 1.70 as the shake-flask value of 3-cyanophenol (6), ALPM measured an even higher 1.84. Calculations would suggest a value near 0.89; however, electron-withdrawing groups tend to greatly increase this value. Thus, the ALPM value for 3-cyanophenol is similar to both the ALPM and shake-flask result for 4-nitrophenol (Table V). In view of the measurement error in the binding term, log $(1/C)$, and the wide range of literature shake-flask log P(o/w) values cited for these compounds, these methods are judged indistinguishable.

In summary, any direct HPLC method is quicker and can ensure measurement of the correct component better than shake-flask techniques. But only ALPM, which measures considerable elution data, can easily offer considerable insight into whether equilibrium is obtained between the mobile and stationary HPLC phases. Examination of benzene suggests that if linearity (*i.e.*, equilibrium) is not attained, altered physical interactions between the chemical and the mobile or stationary phases may be responsible for deviations between ALPM and the shake-flask result. If linearity is attained, acetanilide data suggest that altered column-binding interactions may more satisfactorily explain deviations between these measurement methods. Full understanding of chemical-mobile phase and chemical-stationary phase interactions is required to elucidate chemical factors which could change the partition coefficient apparent in biological situations. In addition to providing a computer-operated method to expedite this data acquisition, ALPM estimation of log P(o/w) and of biological activities can offer improved or equal accuracy, a major cost reduction, and a speed greater than existing HPLC and shake-flask log P(o/w) determinations. In the few cases where ALPM and shake-flask results differ, more research is necessary to establish the exact nature of the discrepancy, with biological data affording the ultimate tool to determine the most suitable parameter. Future ALPM developments should further enhance accuracy by enabling the simultaneous measurement of the void volume marker, the compound of interest, and internal log P(o/w) standard, all under computer control.

Generic Tolbutamide Tablet Dissolution: Intralot and Interlot Variation

JAMES W. AYRES *[x], HUA-PIN HUANG *, and KENNETH ALBERT[‡]

Received August 8, 1983, from the **School of Pharmacy, Oregon State University, Corvallis, OR 97331* and the [‡] *Medical Bioavailability Unit, The Upjohn Company, Kalamazoo, MI 49001.* Accepted for publication October 26, 1983.

Abstract □ Dissolution profiles for 62 lots of tolbutamide tablets from six manufacturers have been characterized using the USP paddle-stirrer apparatus. Results of paddle-stirrer dissolution for percent drug dissolved at 10, 20, and 30 min correlated well ($r^2 = 0.7444$) with results from the USP rotating-basket test for 39 lots of tolbutamide. Interlot and intralot variability in tolbutamide dissolution was highly dependent on the manufacturer. For one product, the intralot range (for six paddle-stirred tablets) of percent drug dissolved after 30 min was 50–68% while the maximum interlot range for mean dissolution was 58–104%. One lot failed to meet both the rotating-basket and the paddle-stirrer dissolution specifications. Tablet response to aging at 60, 75, and 98% relative humidity over time was also highly manufacturer specific. The innovator's product repeatedly dissolved well when fresh or aged at all humidities. Dissolution from some generic tablets was dramatically depressed by humidity aging, even after only 3 d. Pretreatment of tablets with simulated gastric fluid modified the dissolution profile of one poorly dissolving lot of tablets. Results indicate that manufacturing quality control is highly variable among tolbutamide tablets.

Keyphrases □ Tolbutamide—dissolution, intra- and interlot variation, effect of humidity aging □ Dissolution studies—tolbutamide, intra- and interlot variation, effect of humidity aging

Tolbutamide tablets must meet United States Pharmacopeia (USP) dissolution requirements which are established because ". . . in many cases it is possible to correlate dissolution rates with biological availability of the active ingredient" (1). Dissolution testing is also recognized (2) as useful for quality control purposes.

Tolbutamide exhibits only limited solubility and the United States Food and Drug Administration (FDA) recognizes that tolbutamide products are prone to bioavailability problems. Currently, the FDA lists 12 manufacturers' products as "therapeutically equivalent to each other" (3). Large variations in lot-to-lot dissolution of tolbutamide products indicate variations in quality and possible variations in bioavailability since low tolbutamide bioavailability is sometimes related to poor tolbutamide tablet dissolution (4–6). If such variations occur for different lots of products which have been ruled "therapeutically equivalent" by the FDA, then satisfaction of current FDA regulations may not assure lot-to-lot equivalence of products on the FDA list.

Previous work has shown extensive lot-to-lot variation in dissolution of tolbutamide tablets for six lots of one manufacturer (7), while there was uniformity for the originator's product. Others have demonstrated that humidity "aging" of tolbutamide tablets differentially affected dissolution for two different brands of products (8). Also, the physiological exposure to acid of ingested tablets is not mimicked by the current USP dissolution test although exposure of tolbutamide tablets to gastric acid has been reported to be necessary for disintegration and dissolution of some formulations (9).

Therefore, the purposes of this study were: (*a*) to evaluate the dissolution characteristics of several fresh lots of tolbutamide listed as therapeutically equivalent by the FDA; (*b*) to evaluate many of the same lots after humidity "aging" of the tablets; (*c*) to determine the effect of tablet exposure to gastric acid on tolbutamide dissolution for both fresh and humidity-aged tablets.

EXPERIMENTAL SECTION

Products were obtained commercially, stored in tightly closed, opaque containers in the dark at room temperature for 1–3 months, and tested using the USP rotating-basket (10) or paddle-stirrer dissolution test (1). Samples (3 mL) were collected with a continuous flow (set at 5–10 mL/min) eight-channel peristaltic pump[1] fitted with stainless steel 20–30 μm in-line filters. Samples were collected for 6 tablets for 10, 20, 30, and 45 min for the rotating-basket test (150 rpm) and at 10, 20, and 30 min for the paddle-stirrer test (75 rpm) in order to establish a dissolution *versus* time profile (rather than single time point dissolution values). All samples were replaced with temperature-equilibrated dissolution medium.

Filtered samples were diluted, the UV absorbance was measured at 226 nm (1), and the concentration of tolbutamide was calculated based on a seven point standard curve prepared the same day as unknowns were collected. Standard curves were generated by preparing known concentrations of either USP reference standard or company-provided tolbutamide. The UV spectra from these sources were superimposable and the standard curves considered equivalent as the null hypothesis of equal slopes and intercepts could not be rejected ($\alpha = 0.05$). Standard curves were fit with parabolic regression and had coefficients of variation of <4%. The average inversely estimated percent

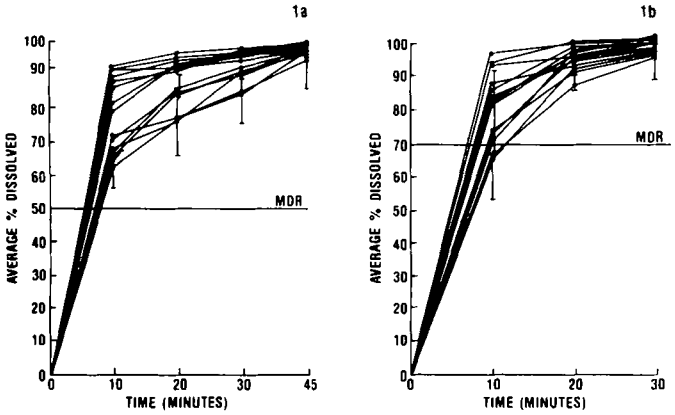

Figure 1—*Average percent of labeled tolbutamide dissolved from 500 mg of U tolbutamide tablets using the rotating-basket test (a) and the paddle-stirrer test (b). MDR is minimum dissolution requirement. Each data point is the average of six tablets and each line is for a different test (Table I). Data variation bars show the range of observed values for the slowest dissolving lots.*

of theory for standard concentrations was 100 ± 0.5% and all individual concentrations were estimated within 3% of theoretical values. The use of UV absorbance as a measure of dissolved tolbutamide was considered appropriate as HPLC analysis (11) of 37 different lots of tolbutamide resulted in only one absorption peak with a retention time equal to that of standard tolbutamide. Content analysis of these lots by HPLC also gave the same results as UV analysis which indicates that the only UV-absorbing material released was tolbutamide.
