Received May 5, 1983, from the *Department of Pharmacokinetics and Biopharmaceutics, ‡Department of Biochemistry and Drug Metabolism, and §Department of Clinical Pharmacology, Hoffmann-La Roche Inc., Nutley, NJ 07110. Accepted for publication August 22, 1983.

Abstract □ The pharmacokinetics of bumetanide was studied in 12 normal subjects after 1-mg intravenous, intramuscular, oral solution, and tablet administrations in a random four-treatment crossover design. Plasma and urine concentrations of intact bumetanide were analyzed by a sensitive and specific RIA. The pharmacokinetics of bumetanide after intravenous administration was characterized by a biexponential equation, including an initial disposition phase ($t_{1/2,\alpha}$ = 5.1 min), followed by a slower elimination phase ($t_{1/2,\beta}$ = 44 min). Bumetanide pharmacokinetics after intramuscular and oral administration could be described by a biexponential equation with first-order absorption and elimination. Bumetanide is rapidly absorbed *via* the intramuscular and oral routes, with mean ± *SD* maximum plasma concentrations of 38.2 ± 9.8 (intramuscular), 34.0 ± 10.6 (oral solution), and 30.9 ± 14.6 ng/mL (tablet) achieved within 0.34 ± 0.23, 0.76 ± 0.27, and 1.8 ± 1.2 h after dosing, respectively. The drug is rapidly eliminated from the body after intravenous, intramuscular, oral solution, and oral tablet administrations, with half-lives ranging from 24–86, 47–139, 27–71, and 26–99 min, respectively. Approximately 70% of a parenteral dose and 60% of an oral dose are excreted as intact drug in urine taken 0–24 h after administration. The extent of bioavailability of bumetanide from the tablet and oral solution dosage forms are equivalent, and the absolute bioavailability of the intramuscular and oral preparations are ~100 and 80%, respectively. This is consistent with the predicted limited extent of first-pass metabolism after complete absorption of an oral dose. The pharmacokinetic and pharmacodynamic data support the conclusion that bumetanide is galenically available from the tablet dosage form and that comparable cumulative diuretic activity is obtained, regardless of the route and mode of administration.

Keyphrases □ Pharmacokinetics—bumetanide, intravenous, intramuscular, and oral administration □ Bumetanide—pharmacokinetics, intravenous, intramuscular, and oral administration, □ Diuretics—bumetanide, pharmacokinetics following intravenous, intramuscular, and oral administration □ Bioavailability—bumetanide, intravenous, intramuscular, and oral administration

Bumetanide, 3-(butylamino)-4-phenoxy-5-sulfamoylbenzoic acid, a new potent sulfonamide diuretic, produces a rapid diuretic response with a short duration of action in humans. The major site of action is on the ascending limb of Henle's loop, in addition to further action on the proximal tubule (1–3). The diuretic effects of bumetanide are as extensive as those of other "loop" diuretics but at oral doses of 1 mg, as compared with 40–60 mg of furosemide (4–8). Although pharmacokinetic studies in humans after intravenous and oral administration of bumetanide have been reported (6, 9–12), the pharmacokinetics and bioavailability of intramuscularly administered bumetanide have not.

The purpose of this study was to determine primary pharmacokinetic parameters of bumetanide following intravenous, intramuscular, and oral administrations and to assess the bioavailability of the intramuscular, oral tablet, and oral solution preparations of bumetanide relative to intravenous administration.

EXPERIMENTAL SECTION

Clinical Protocol—Twelve healthy adult male and female volunteers [23–40 years old (mean 30); weight, 54–96 kg (mean 70)] were selected for the study. Subjects were considered normal by medical history, physical examination, and blood and urine laboratory tests. An informed written consent was obtained from each volunteer before the study.

Single 1-mg doses of bumetanide were administered to each subject as intravenous, intramuscular, oral solution, and tablet preparations. Subjects were randomly assigned to the four treatments, and there were at least 2 weeks between dosage administrations. The drug was supplied in 0.25-mg/mL ampules for parenteral and oral solution administrations. The intravenous dose was administered over a 2-min period, and the intramuscular dose was injected into the lateral thigh with an intramuscular administration needle. The oral solution dose was administered in a 4-mL solution given with 250 mL of water, and the oral tablet was given with 250 mL of water.

Subjects fasted for 8 h prior to drug administration and remained fasting until the 4-h blood sample was collected. A hospital-prepared lunch, supper, and a bedtime snack were served. No additional salt or highly salted foods were permitted. Water was permitted *ad libitum*.

Blood samples (10 mL) were drawn through an indwelling cannula or by separate venipuncture into oxalated tubes prior to drug administration and at 0.1, 0.25, 0.5, 0.75, 1, 1.5, 2, 2.5, 3, 4, 5, 6, 7, 8, 10, 12, and 24 h after drug administration. Plasma was separated and stored at −17°C until assayed. All urine voided over 12 h before dose and 0–2, 2–4, 4–6, 6–8, 8–12, and 12–24 h after drug administration was collected, and 50-mL aliquots were stored at −17°C until assayed.

Analytical Procedures—Plasma and urine samples were assayed for intact bumetanide using a slight modification of the sensitive and specific RIA procedure of Dixon *et al.* (13). In the present study, the precipitated antibody-bound fraction was quantitated rather than the unbound fraction, and the data were calculated as outlined by Rodbard (14), with a digital computer used for iterative weighted linear regression analysis of logit B/B_0 *versus* log dose. The RIA had a limit of sensitivity of 3 ng/mL of bumetanide with 0.1 mL of plasma or urine.

Pharmacokinetic Analysis—Plasma concentrations following intravenous administration were curve-fitted as follows (15):

$$C_p(t) = Ae^{-\alpha t} + Be^{-\beta t} \quad \text{(Eq. 1)}$$

and concentrations after intramuscular and oral administration were fitted with the following (15):

$$C_p(t) = A'[e^{-\beta(t-t_0)} - e^{-k_a(t-t_0)}] \quad \text{(Eq. 2)}$$

where $C_p(t)$ is the plasma concentration of bumetanide at time t; A, A', and B are coefficients; α is the initial disposition rate constant; β is the terminal elimination rate constant; k_a is the apparent absorption rate constant; and t_0 is the lag time preceding initiation of absorption. A weighted ($1/C_p$) nonlinear regression program [NONLIN (16)] was used to calculate the best estimates of the pharmacokinetic parameters.

The model-estimated parameters were used to calculate the theoretical area under the plasma concentration–time curve (AUCTh), the apparent volume of the central compartment (V_c), and volume of distribution in the postdistributive phase (Vd_{area}) as follows:

$$\text{AUCTh (intravenous)} = A/\alpha + B/\beta \quad \text{(Eq. 3)}$$

$$\text{AUCTh (intramuscular, oral)} = A'/\beta - A'/k_a \quad \text{(Eq. 4)}$$

$$V_c \text{ (intravenous)} = \text{Dose}/(A + B) \quad \text{(Eq. 5)}$$

$$Vd_{area} \text{ (intravenous)} = \text{Dose}/(\text{AUCTh}\cdot\beta) \quad \text{(Eq. 6)}$$

The maximum plasma concentration (C_{max}) and the time (t_{max}) of its occurrence following intramuscular and oral administrations were read directly from the observed plasma concentration–time data. The area under the plasma concentration–time curve from time zero to infinity (AUCTr) were calculated as follows:

$$\text{AUCTr} = \text{AUC}_{0\to t} + C_p(t)/\beta \quad \text{(Eq. 7)}$$

where $\text{AUC}_{0\to t}$ is the area calculated by trapezoidal summation from time zero to the time, t, of the last measurable plasma concentration, $C_p(t)$. For

intravenous administration, the plasma concentration at time zero was extrapolated graphically.

The volume of distribution at steady-state (Vd_{ss}), systemic plasma clearance (CL_p), apparent oral clearance (CL_o), renal clearance (CL_r), and nonrenal clearance (CL_{nr}) were calculated by model-independent methods from the following relationships:

$$Vd_{ss}\text{ (intravenous)} = \text{Dose (AUMCTr)}/(\text{AUCTr})^2 \quad \text{(Eq. 8)}$$

$$CL_p\text{ (intravenous, intramuscular)} = \text{Dose}/\text{AUCTr} \quad \text{(Eq. 9)}$$

[a] Parameters are defined in the text. Values are mean ±*SD*; n = 12.

$$CL_o = F\cdot\text{Dose}/\text{AUCTr} \quad \text{(Eq. 10)}$$

$$CL_r = Ae(0\text{–}24\text{ h})/\text{AUCTr} \quad \text{(Eq. 11)}$$

$$CL_{nr} = (CL_p - CL_r) \text{ or } (CL_o - CL_r) \quad \text{(Eq. 12)}$$

where AUMCTr is the area under the first moment of the plasma concentration–time curve, *i.e.*, the area under the curve when the product of time and plasma concentration are plotted against time (17); F is the fraction of the dose that is available for absorption as intact drug (F = 1, assuming complete absorption of the oral dose); and Ae(0–24 h) is the amount of intact bumetanide excreted in the urine over 0–24 h, assuming complete elimination during this interval.

Assessment of the absolute bioavailability of intramuscularly and orally administered bumetanide relative to intravenously administered bumetanide and the relative bioavailability of the oral tablet compared with the oral solution were determined by area ratios and urinary excretion ratios as follows:

Absolute bioavailability

$$= \frac{(\text{AUCTr})\text{ im, oral}}{(\text{AUCTr})\text{ iv}}, \frac{Ae(0\text{–}24\text{ h})\text{ im, oral}}{Ae(0\text{–}24\text{ h})\text{ iv}} \quad \text{(Eq. 13)}$$

Relative bioavailability

$$= \frac{(\text{AUCTr})\text{ tablet}}{(\text{AUCTr})\text{ solution}}, \frac{Ae(0\text{–}24\text{ h})\text{ tablet}}{Ae(0\text{–}24\text{ h})\text{ solution}} \quad \text{(Eq. 14)}$$

RESULTS AND DISCUSSION

Intravenous Administration—The mean observed plasma concentration–time profile and the fitted curve following intravenous administration of bumetanide are shown in Fig. 1a, and the pharmacokinetic parameters estimated by curve-fitting plasma concentration to Eq. 1 are presented in Table I. The mean ±*SD* model-independent pharmacokinetic parameters are presented in Table II. The plasma concentration–time data after intravenous administration were fitted well with a biexponential equation, including disposition and elimination phases in all the 12 subjects. The goodness of fit of the individual data to the equation is shown by correlation coefficients of 0.998–1.000 and the close agreement between the theoretical area [mean ±*SD* = 84 ± 29 ng·h/mL (Table I)] and the model-independent trapezoidal area [mean ± *SD* = 89 ± 30 ng·h/mL (Table II)].

The biphasic plasma concentration–time curve is characterized by a rapid α-phase with a harmonic mean half-life of 5.1 min, followed by a slower β-phase with a harmonic mean half-life of 44 min (Table I; Fig. 1a). Following intravenous administration, bumetanide is rapidly distributed into a small central compartment with a mean volume of 4.7 L ± 1.8 (*SD*) which is roughly comparable to the blood volume in an adult. The mean ±*SD* values for Vd_{area} and Vd_{ss} were 14.3 ± 3.9 and 9.8 ± 3.4 L, respectively. The disposition of intravenously administered [^{14}C]bumetanide in humans has been described by a triexponential equation in an earlier study (11). The mean values reported for $t_{1/2,\alpha}$ (5.9 min), $t_{1/2,\beta}$ (46 min), and V_c (5.5 L) are comparable to the mean values in our present study. However, the reported mean Vd_{area} value of 62.5 L is much higher than the mean Vd_{area} of 14.3 L determined in our study. In the study with labeled drug, the reported Vd_{area} represented the volume of distribution during the terminal phase (γ), which accounted for only 17% of the AUC for bumetanide. In a recent study (12), in which a two-compartment model was shown to adequately fit the data following intravenous administration of bumetanide, the mean values reported for $t_{1/2,\alpha}$ (5.75 min), V_c (3.53 L), and Vd_{ss} (9.45 L) were of the same magnitude as the values obtained in the present study. Their reported mean elimination half-life of 64 min, however, is slightly longer than the mean value of 44 min determined in our study.

Bumetanide is ~96%[1] bound to plasma protein in humans over the therapeutic plasma concentration range. High plasma binding contributes to the relatively small volume of distribution for bumetanide and may contribute to its high renal clearance. Although glomerular filtration is restricted to the free concentration of drug in the blood, active tubular secretion has been shown to act on both free and bound drug concentrations (18, 19). Therefore, binding decreases the volume of distribution of bumetanide, resulting in larger concentrations of drug being delivered to the kidney for possible secretion.

The mean ±*SD* plasma clearance and renal clearance of bumetanide were 208 ± 65 and 146 ± 59 mL/min, respectively (Table II). Lower renal clearance values relative to plasma clearance have been observed in other intra-

venous studies (6, 11, 12) and have been attributed to nonrenal elimination of the drug. The absolute values reported in a recent study (12), however, are much lower than the values in our present study. Evidence that hepatic metabolism and biliary excretion contribute to the total clearance of bumetanide have been reported in previous studies with ^{14}C-labeled bumetanide. After intravenous administration, metabolites of bumetanide accounted for ~30–35% of the total radioactivity excreted into the urine (10, 11), whereas ~14% of an oral dose was recovered in the feces, mostly in the form of metabolites identical to those found in bile (9).

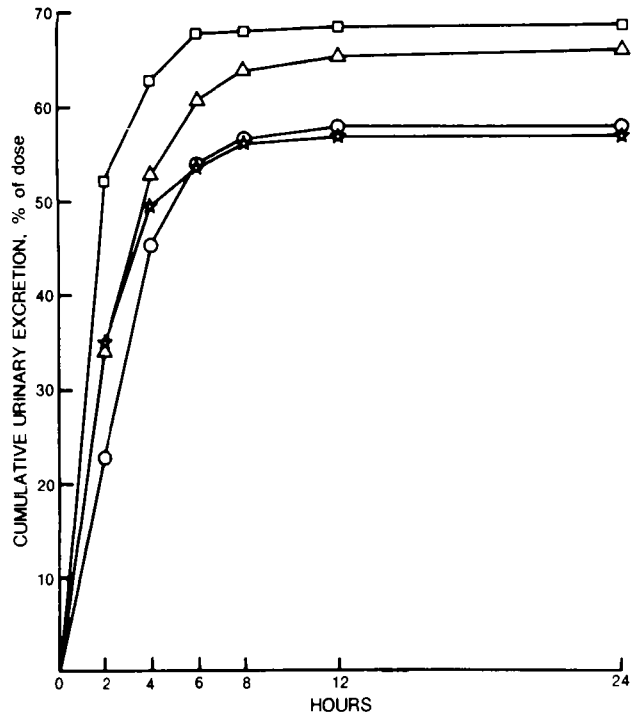

Figure 2—*Mean cumulative urinary excretion of intact bumetanide following administrations of 1 mg of bumetanide to 12 normal subjects. Key: (□) intravenous; (△) intramuscular; (★) oral solution; (○) oral tablet.*

The cumulative urinary excretion of intact bumetanide is shown in Fig. 2. The mean 0–24 h urinary recovery of intact drug following intravenous administration was 69 ± 11%. As shown in Fig. 2, more than one-half of the dose was excreted within 2 h of dosing, and urinary excretion was virtually complete 8 h after drug administration. This rapid excretion of intact drug is consistent with the short duration of action of bumetanide.

Intramuscular Administration—The mean observed plasma concentration–time profile and fitted curve following intramuscular administration are shown in Fig. 1b, and the pharmacokinetic parameters estimated by curve-fitting the plasma concentration–time data to Eq. 2 are presented in Table III. Fits of the intramuscular data to a biexponential equation, including first-order absorption and elimination were good in all 12 subjects, as shown by r values of 0.990–1.000. The goodness of fit of the individual data is supported by the virtually identical mean ±*SD* model-dependent and -independent AUC values (81 ± 25 and 80 ± 25 ng·h/mL, respectively).

Bumetanide was rapidly absorbed following intramuscular administration, with measurable concentrations of intact drug observed in the plasma within 6 min after drug administration. In all but one subject, there was no lag time in the onset of absorption (Table III). The large absorption rate constant (k_a = 21.8 ± 25.5 h^{-1}) further indicates the rapid absorption of bumetanide when administered intramuscularly. After reaching maximum plasma concentrations of 22.5 to 55.4 ng/mL (mean 38.2) within 0.1–0.75 h (mean 0.34) after dosing, plasma concentrations declined rapidly, with a harmonic mean elimination half-life of 68 min. This mean value is longer than the mean of 44 min observed after intravenous administration (Table I). The elimination of bumetanide from the body after intramuscular administration may be absorption rate limited, resulting in a slower apparent elimination rate relative to that after intravenous administration.

The observed mean ±*SD* values for CL_p, CL_r, CL_{nr}, and percentage for the dose recovered as intact drug in the urine were 223 ± 59 mL/min, 146 ± 32 mL/min, 78 ± 37 mL/min, and 66 ± 9%, respectively. These values agree closely with corresponding values observed after intravenous administration (Table II), suggesting that bumetanide is, in fact, completely absorbed into the systemic circulation after intramuscular injection. The absolute bioavailabilities after intramuscular administration were 0.94 ± 0.25 and 0.98

[a] Parameters are defined in the text. [b] Values in parentheses are for zero-order fit. [c] Harmonic mean.

± 0.16 (based on the trapezoidal AUC and the 0–24-h urinary excretion, respectively), indicating that intramuscularly administered bumetanide is completely available relative to intravenously administered bumetanide.

Oral Administration—The mean observed and fitted plasma concentration-time curves following administration of the oral solution and the oral tablet are shown in Fig. 1c and d, respectively. The respective pharmacokinetic parameters estimated by curve-fitting the plasma concentration-time data to Eq. 2 are presented in Tables IV and V. The plasma concentration-time data after administration of both oral formulations were fitted with a biexponential equation, including first-order absorption and elimination. Good fits were obtained in all 12 subjects for the oral solution and in 9 subjects for the tablet. Although the oral tablet data from the other three subjects were also fitted with Eq. 2, there was a slight improvement in the fits when the plasma concentration-time data were fitted with a monoexponential equation with zero-order absorption (Table V). The goodness of fit of the data to the equation selected is shown by r values ranging from 0.971 to 0.999 and 0.983 to 0.999 for the oral solution and tablet, respectively. The good agreement of the model-independent AUC values (Table II) and the AUC values estimated from the curve-fitted parameters (Tables IV and V) further supports the reliability of the equation to fit the data.

After lag times of 0–26 and 4–89 min following administration of the oral solution and tablet, respectively, the harmonic mean half-lives of absorption ($t_{1/2,k_a}$) were 8.5 and 12.6 min, respectively. Mean ±*SD* C_{max} and t_{max} values for the oral solution were 34.0 ± 10.6 ng/mL and 0.76 ± 0.27 h, respectively, whereas the corresponding values for the tablet were 30.9 ± 14.6 ng/mL and 1.8 ± 1.2 h. The mean C_{max} and t_{max} values observed for the tablet are in good agreement with the values for C_{max} of 30 ng/mL and t_{max} of 1.5 h observed in a previous study following a 1-mg oral dose of bumetanide (6). Comparable mean t_{max} values (1.4 h) but higher mean C_{max} values (48 ng/mL) have been reported for a 1-mg oral dose of bumetanide in another study (12). Although absorption from the GI tract was rapid for both formulations, the later mean peak time observed for the tablet reflects the longer lag time, as well as a somewhat slower rate of absorption from the tablet relative to the oral solution. The plasma concentrations declined rapidly after reaching maximum concentrations, with harmonic mean elimination half-lives of 42 min for the oral solution and 51 min for the tablet. The mean half-lives observed after oral administration are comparable to the mean half-life observed after intravenous administration, indicating that the apparent elimination rate of bumetanide from the body is independent of this route of administration, *i.e.*, it is not absorption rate limited.

The mean ±*SD* AUC, CL_o, and percent urinary recovery of intact bumetanide for the oral solution were 64 ± 27 ng·h/mL, 299 ± 100 mL/min, and 57 ± 12%, respectively (Table II). The corresponding values for the tablet were 66 ± 28 ng·h/mL, 310 ± 165 mL/min, and 58 ± 7%. Comparison of the respective areas and urinary excretion values between the two oral formulations showed a mean (tablet-solution) ratio of 1.0 (Table II), indicating that the extent of absorption of bumetanide from the tablet and solution oral dosage forms are equivalent, and that galenic availability was not a problem for the oral tablet. The similar apparent oral clearance values for both oral formulations further supports the assumption of complete absorption of bumetanide from the tablet. However, urinary excretion of intact bumetanide indicated absolute bioavailabilities of 0.84 and 0.86 for the oral solution and tablet, respectively, when compared with the intravenous dose. The respective bioavailabilities calculated from the AUCTr values were 0.74 and 0.78. Since the fraction of the dose excreted in the urine as intact bumetanide is large and the elimination of the drug from the plasma is fast, the urinary excretion method of estimating bioavailability is probably a more reliable method for bumetanide. A recent study (12), however, showed that there was no difference in the bioavailability values calculated by either the AUC or the urinary excretion method (0.90 and 0.89, respectively).

The diminished availability of intact drug to the systemic circulation following oral admninistration tends to suggest that bumetanide undergoes first-pass clearance. In support of this observation, the first-pass metabolism

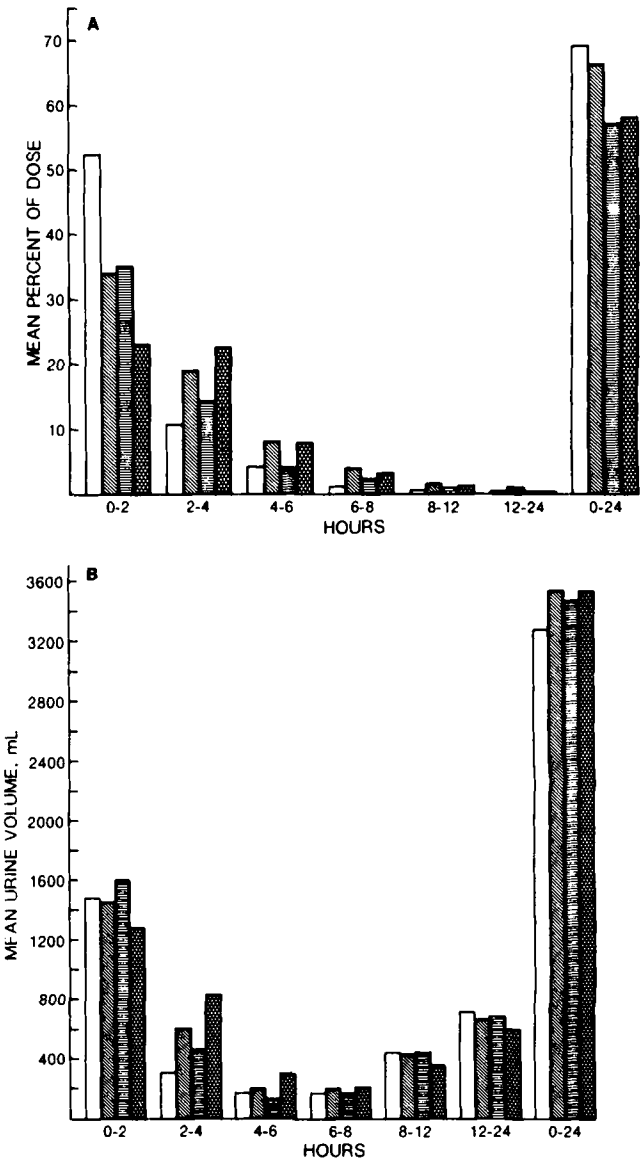

Figure 3—*Mean urinary excretion of intact bumetanide (A) and mean urine volume (B) following administrations of 1 mg of bumetanide to 12 normal subjects. Key: (□) intravenous; (▨) intramuscular; (▤) oral solution; (■) oral tablet.*

predicted for an oral dose, assuming linear kinetics, would be 10–20% (20). First-pass metabolism would also account for the higher mean oral clearance observed for both solution and tablet relative to the mean plasma clearance after intravenous and intramuscular administrations. Since ~70% of a parenteral dose and 60% of an oral dose are excreted as intact drug in the 0–24-h urine samples, the 10% difference as a function of the oral route of administration is consistent with the predicted limited extent of first-pass metabolism of the oral dose. These findings are consistent with the results of previous studies (10, 12), which have reported urinary recoveries for intact bumetanide of 60 ± 3% (10) and 66 ± 3% (12) from the intravenous dose, but only 49 ± 5% (10) and 59 ± 3% (12) from the oral dose.

The mean urinary excretion of intact bumetanide and the corresponding mean urinary volume following the four treatments are shown in Fig. 3. The diuretic effect of bumetanide following 1-mg iv, im, oral solution, and oral tablet doses was clearly evident in the first 2-h period, with mean urine volumes ranging from 1270 mL (tablet) to 1600 mL (oral solution). The diuretic activity lasted for ~4–8 h for all treatments, and the mean cumulative diuresis after 24 h was the same for the four treatments. The diuresis profile of bumetanide parallels the urinary excretion profile of intact bumetanide in that the major portion of intact bumetanide was excreted during the first 2 h following drug administration (Fig. 3). This confirms previous observations (9, 21) that the diuretic activity of bumetanide is closely associated with the concentration of intact drug in the kidney. The fact that the oral formulations are as effective diuretics as the parenteral preparations presumably reflects the maintenance of a minimum effective plasma or renal tubule concentration of bumetanide (22).

Determination of Total Captopril in Human Plasma by Gas Chromatography–Mass Spectrometry with Selected-Ion Monitoring After Reduction of Disulfides

EUGENE IVASHKIV *, DORIS N. McKINSTRY ‡, and ALLEN I. COHEN *x

Received January 10, 1983, from the **Department of Analytical Research, The Squibb Institute for Medical Research, New Brunswick, NJ 08903* and ‡*Department of Clinical Pharmacology, The Squibb Institute for Medical Research, Princeton, NJ 08540.* Accepted for publication August 19, 1983.

Abstract □ Captopril is liberated from covalently protein-bound disulfides and other disulfide metabolites in human plasma by reduction with tri-*n*-butyl-phosphine. The captopril is then treated with *N*-ethylmaleimide, purified on XAD-2 resin, eluted with ethyl acetate, and methylated prior to its determination by gas chromatography–mass spectrometry with selected-ion monitoring. The limit of detection is 20 ng/mL of plasma.

Keyphrases □ Captopril—reduction of disulfides, GC–MS, selected-ion monitoring □ GC MS—selected-ion monitoring, total captopril in human plasma, reduction of disulfides

Captopril (I), an orally active angiotensin I-converting enzyme inhibitor (1, 2), is currently marketed for the treatment of hypertension (3, 4). Because of the extreme reactivity of thiols in biological systems, captopril is quantitatively converted to a derivative, such as the *N*-ethylsuccimide derivative (II), prior to analysis (5). The reaction product was determined by a gas chromatographic–mass spectrometric (GC–MS) method (6, 7) with selected-ion monitoring for captopril in whole blood and by a radiometric-thin-layer chromatographic (RTLC) procedure for establishing the biological disposition of captopril (8, 9). The latter method has been used in various metabolism and pharmacokinetic studies (10–12). Other reported methods for the determination of captopril employ GC (13), HPLC (14–17), and most recently GC–MS with selected-ion monitoring (18).

Metabolites of captopril identified so far include captopril disulfide (III), the mixed cysteine and glutathione disulfides of I (IV and V, respectively), and the *S*-methyl (VI) and *S*-methyl sulfoxide (VII) metabolites (9, 10, 12, 19). A substantial proportion of the captopril radioactivity in human blood after oral administration of radioactively labeled I was associated with the plasma fraction (8), which was covalently bound as plasma protein disulfides. It is believed that the plasma proteins and mixed disulfides with endogenous thiol-

predicted for an oral dose, assuming linear kinetics, would be 10–20% (20). First-pass metabolism would also account for the higher mean oral clearance observed for both solution and tablet relative to the mean plasma clearance after intravenous and intramuscular administrations. Since ~70% of a parenteral dose and 60% of an oral dose are excreted as intact drug in the 0–24-h urine samples, the 10% difference as a function of the oral route of administration is consistent with the predicted limited extent of first-pass metabolism of the oral dose. These findings are consistent with the results of previous studies (10, 12), which have reported urinary recoveries for intact bumetanide of 60 ± 3% (10) and 66 ± 3% (12) from the intravenous dose, but only 49 ± 5% (10) and 59 ± 3% (12) from the oral dose.

The mean urinary excretion of intact bumetanide and the corresponding mean urinary volume following the four treatments are shown in Fig. 3. The diuretic effect of bumetanide following 1-mg iv, im, oral solution, and oral tablet doses was clearly evident in the first 2-h period, with mean urine volumes ranging from 1270 mL (tablet) to 1600 mL (oral solution). The diuretic activity lasted for ~4–8 h for all treatments, and the mean cumulative diuresis after 24 h was the same for the four treatments. The diuresis profile of bumetanide parallels the urinary excretion profile of intact bumetanide in that the major portion of intact bumetanide was excreted during the first 2 h following drug administration (Fig. 3). This confirms previous observations (9, 21) that the diuretic activity of bumetanide is closely associated with the concentration of intact drug in the kidney. The fact that the oral formulations are as effective diuretics as the parenteral preparations presumably reflects the maintenance of a minimum effective plasma or renal tubule concentration of bumetanide (22).

Determination of Total Captopril in Human Plasma by Gas Chromatography–Mass Spectrometry with Selected-Ion Monitoring After Reduction of Disulfides

EUGENE IVASHKIV *, DORIS N. McKINSTRY ‡, and ALLEN I. COHEN *x

Received January 10, 1983, from the **Department of Analytical Research, The Squibb Institute for Medical Research, New Brunswick, NJ 08903* and ‡*Department of Clinical Pharmacology, The Squibb Institute for Medical Research, Princeton, NJ 08540.* Accepted for publication August 19, 1983.

Abstract □ Captopril is liberated from covalently protein-bound disulfides and other disulfide metabolites in human plasma by reduction with tri-*n*-butyl-phosphine. The captopril is then treated with *N*-ethylmaleimide, purified on XAD-2 resin, eluted with ethyl acetate, and methylated prior to its determination by gas chromatography–mass spectrometry with selected-ion monitoring. The limit of detection is 20 ng/mL of plasma.

Keyphrases □ Captopril—reduction of disulfides, GC–MS, selected-ion monitoring □ GC MS—selected-ion monitoring, total captopril in human plasma, reduction of disulfides

Captopril (I), an orally active angiotensin I-converting enzyme inhibitor (1, 2), is currently marketed for the treatment of hypertension (3, 4). Because of the extreme reactivity of thiols in biological systems, captopril is quantitatively converted to a derivative, such as the *N*-ethylsuccimide derivative (II), prior to analysis (5). The reaction product was determined by a gas chromatographic–mass spectrometric (GC–MS) method (6, 7) with selected-ion monitoring for captopril in whole blood and by a radiometric-thin-layer chromatographic (RTLC) procedure for establishing the biological disposition of captopril (8, 9). The latter method has been used in various metabolism and pharmacokinetic studies (10–12). Other reported methods for the determination of captopril employ GC (13), HPLC (14–17), and most recently GC–MS with selected-ion monitoring (18).

Metabolites of captopril identified so far include captopril disulfide (III), the mixed cysteine and glutathione disulfides of I (IV and V, respectively), and the *S*-methyl (VI) and *S*-methyl sulfoxide (VII) metabolites (9, 10, 12, 19). A substantial proportion of the captopril radioactivity in human blood after oral administration of radioactively labeled I was associated with the plasma fraction (8), which was covalently bound as plasma protein disulfides. It is believed that the plasma proteins and mixed disulfides with endogenous thiol-

containing compounds (*e.g.*, glutathione) may act as a reservoir from which captopril is liberated over time to exert pharmacological effects (12, 20). It would not be practical to measure each metabolite separately, nor would it be possible to adequately measure the protein-bound levels by a nonradiometric method. Consequently, a method for measuring total captopril in plasma has been developed by treating the plasma fraction with the disulfide-reducing agent tri-*n*-butylphosphine (21), followed by reaction with *N*-ethylmaleimide to form II, which is then methylated and measured by GC–MS with selected-ion monitoring (7).

EXPERIMENTAL SECTION

Apparatus—A mass spectrometer[1] with a data acquisition system, gas chromatograph, and an interface was used as reported by Cohen *et al.* (7). A centrifuge[2] with stainless steel adapters, drug-screen columns[3], a water bath[4] set at 50°C, two sample concentrators[5], dry-block heating baths[6,7], a column mounting plate[8], an aspirator trough[8], 1-mL reaction vessels[9], vial seals[10], 100-μL micropipets[11], and 1-, 3-, 5-, and 10-mL dispensers[12] were used. Samples were agitated on a heavy-duty shaker[13]. Screw-capped 150-mm culture tubes with polytef-faced liners, 20-mL scintillation vials, 21-gauge syringe needles, a vial crimper, a desiccator, 15-cm disposable Pasteur pipets, a vortex mixer, 13 × 100-mm disposable glass tubes, and 1- and 5-mL disposable serological pipets were obtained commercially[13].

Reagents—Acetone, ethyl acetate, hydrochloric acid, phosphoric acid, *N*-ethylmaleimide, dimethylformamide, Tris, urea, dibasic sodium phosphate, sodium chloride, EDTA (disodium salt), neutral alumina Brockman Activity I (80–200 mesh), and sodium bicarbonate were reagent grade. An *N*-ethylmaleimide solution was prepared daily by dissolving 0.5 g of reagent in 1.5 mL of dimethylformamide. A 20% v/v solution of tri-*n*-butylphosphine was prepared with redistilled reagent[14] and acetone. A buffer was prepared by dissolving 12.1 g of Tris in 980 mL of distilled water, and the pH was adjusted to 8.2 with phosphoric acid. To 26 g of urea, was added 65 mL of the pH 8.2 buffer. This solution was prepared each day as required. A pH 7.0 buffer was prepared by dissolving 40 g of dibasic sodium phosphate heptahydrate in 1960 mL of distilled water, adjusting the pH with phosphoric acid. A diluted column activator solution[3] was prepared by diluting 35–500 mL with distilled water. The solution was refrigerated and used for not more than 1 week. The plasma used for experiments was prepared from commercially obtained blood[15]. Methanolic hydrochloride was prepared as described previously (6, 7). Captopril (I), captopril disulfide (III), and the fluoro analogue internal reference (VIII) were pharmaceutical-grade materials[16].

Standard Solutions—Captopril disulfide (III) solutions were prepared at concentrations of 10 and 40 μg/mL in methanol and stored in a refrigerator. A solution of II was prepared by treating 50 mg of I with 250 mg of *N*-ethylmaleimide in 10 mL of pH 7.0 buffer for 15 min, diluting to 100 mL with acetone, and filtering through a fine-porosity sintered glass filter. An unextracted control solution was prepared from II and IX, with respective final concentrations equivalent to 40 μg of I and VIII per mL of solution. The solution was stored in a refrigerator. For calibration, appropriate solution concentrations of III in methanol were prepared.

Preparation of Standard Curves—To each of six 20-mL scintillation vials, was added 1 mL of plasma. With 100-μL syringes, varying amounts (between 0 and 1 μg) of III and 1 μg of internal reference standard VIII were added. To another set of six 20-mL scintillation vials containing 1 mL of plasma, between 0 and 8 μg of III and 4 μg of VIII were added. These standards were immediately reduced or stored in a freezer with the samples until required.

Reduction—Aliquots (1 mL) of a thawed, well-mixed plasma sample were transferred to separate 20-mL scintillation vials and 5 mL of urea pH 8.2 buffer solution was added to each vial. To vial 12, 1 mL of blank plasma and the appropriate amount of control solution containing III and VIII were added. To plasma samples collected from 0.25 to 6 h after oral administration of a 100-mg tablet of captopril, was added 4 μg of VIII; 1 μg of VIII was added to all other plasma samples. The respective additions to controls were 4 μg of III and VIII and 1 μg of III and VIII. To each vial (located under a hood), 0.1 mL of 20% v/v tri-*n*-butylphosphine solution was added. The vials, covered with tin foil-lined caps, were mixed on a vortex mixer. These samples and standards were allowed to stand in the dark at 50°C for 1 h.

Reaction of Reduced Captopril with *N*-Ethylmaleimide—The aforementioned vials were cooled in the hood for 15 min and uncapped; to each vial, was added 25 mg of *N*-ethylmaleimide in 0.1 ml of dimethylformamide, and the vials were recapped. The samples were vortexed for 10 s, the vials were set aside for 5 min, and then the samples were treated with 5 mL of 0.67 M H_3PO_4.

Isolation and Purification of Samples—Prior to use, the required number of XAD-2 columns were activated with 5 mL of diluted activator solution, treated with 5 mL 0.1 M HCl, and 21-gauge syringe needles were attached. Each sample solution was decanted into an individual column, and the solution was allowed to percolate through the column; 5 ml of 0.1 M HCl was added to a scintillation vial, mixed, and decanted to the column after the original solution had eluted. The syringe needle was removed, and the column was washed first with a 10-mL aliquot and then with a 20-mL aliquot of 0.1 M HCl[17]. The columns were placed on a column mounting plate and dried under reduced pressure for 1 h; this was followed by eluting II and the fluoro analogue (IX) first with 10 mL and then with 15 mL of purified ethyl acetate. To each test tube containing the ethyl acetate eluant was added 3 mL of 5% sodium bicarbonate solution; this was shaken for 5 min to effect the transfer of II and IX into the aqueous layer, followed by centrifugation at 2000 rpm for 5 min. The upper ethyl acetate layer was discarded and 1 mL of 2 M phosphoric acid and 3 g of sodium chloride were added and the sample was mixed for 5 min. The sample was reextracted into ethyl acetate by adding 5 mL of the purified solvent, shaking, and centrifuging for the required times as indicated above. The entire contents of each test tube were decanted to new 13- × 100-mm test tubes, and the upper ethyl acetate layer (~4.8 mL) was transferred to a 20-mL scintillation vial with a 5-mL serological pipet. The solvent was then evaporated with a sample concentrator set at 65°C. The sample was transferred quantitatively, first with 0.5 mL and then with 0.2 mL of purified ethyl acetate, to a 1-mL reaction vial with a Pasteur pipet. An unextracted control solution containing 4 μg each of II and IX was added to a clean reaction vial and evaporated to dryness with a concentrator, along with extracted samples and the control. The vials were then dried under reduced pressure in a desiccator for 15 min. Samples were redissolved and methylated to X and XI as previously described (6, 7).

Tris buffer–propanol, 3:1	8.2	97.8
(~0.1 M NaOH)	12.5	64.0

Selected-Ion Monitoring—Approximately 1–2 μL of solution added to the tip of a GC solids injector[18] was allowed to evaporate. The appropriate ion profiles (m/z 230.1, m/z 248.1) were obtained by selected-ion monitoring. The maximum peak heights were measured by using a program written especially for the batch processing of the data (7). The program selects the baseline-corrected maximum peak heights of the requested ions. The mean ratio (R_n^*), and standard deviation for three to five injections of the control sample bracketing the samples were determined for subsequent use in correcting the data for differences in response from the calibration slope (k_n). The adjustment factor (A) is related to the calibration slope and the measured ratio of the control (R_n^*), by:

$$A = \frac{R_n^*}{I_n + k_n}$$

The data were processed as previously described (7).

RESULTS AND DISCUSSION

Captopril undergoes extensive biotransformation to form covalently protein-bound disulfides (21) in addition to the disulfides III, IV, and V (9, 10, 12, 21). When captopril is added to plasma and stored at either 5°C or −20°C, 62 and 87% of I is bound to protein (Table I). The greater binding at the lower temperature may result from an increase in protein thiols from freezing and thawing of the plasma. Approximately 43% of the disulfide III was bound to the protein, presumably due to interchange and disulfide formation with protein. The only captopril-related product not bound was *S*-methyl captopril (VI), a potential metabolite. The use of *N*-ethylmaleimide as a thiol alkylating agent in whole blood, plasma, and urine is the most effective method of preventing the formation of protein-bound captopril (5–7). It is not feasible to measure unbound captopril, because a significant amount of captopril is converted to protein-bound compound during the production of serum or plasma from whole blood and during storage prior to analysis.

Plasma or serum was subsequently processed to liberate I bound to proteins and mixed disulfides by reduction with tri-*n*-butylphosphine[19]. This reagent was previously used to reduce captopril disulfides in urine (14, 21). The great depot of protein disulfides required a tri-*n*-butylphosphine concentration of 20 mg/mL of plasma to achieve 98% reduction. Only 85 and 50% reduction could be obtained at tri-*n*-butylphosphine concentrations of 10 and 2 mg/mL, respectively. Nearly complete reduction is obtained in solutions more basic than pH 8 (Table II). The rate of reduction and the yield are also influenced by temperature. At 50°C, it takes ~30 min to reduce III with 20 mg/mL of tri-*n*-butylphosphine and 45 min to reduce protein-bound I. At temperatures greater than 60°C, III is reduced in <15 min, but some sample decomposition occurs. Up to 10 mL of urea buffer, used as a plasma-solubilizing agent, did not effect the reduction efficiency when 1 mL of plasma was used. When >1 mL of plasma was used, the yield decreased. Only 90% disulfide reduction could be achieved with whole blood samples, but decreased whole blood volumes yielded satisfactory reduction efficiency. Although excellent reductions have been obtained from 50% propanol solutions (22), the solvent causes interferences in the isolation procedure. When added to plasma, I, III, IV, and V are essentially quantitatively converted and subsequently measured as the methyl ester of II by the GC–MS procedure with selected-ion monitoring (Table III). Plasma samples of I, III, and IV stored for 4 weeks either at 5°C or −20°C yield substantially all of the available reducible compound (Table IV).

The precision of measurement was improved by adding 1000 ng of internal reference to the samples with lower concentrations (within a range of 0–1000 ng/mL); 4000 ng was added to those samples expected to have >1000 ng of reducible captopril. Samples collected from human subjects at 0.25 to 6 h after administration of a single 100-mg tablet of captopril were treated as high-concentration samples, whereas the 0-h samples and those collected at ≥8 h were treated as low-concentration samples. The methylated sample extracts were measured by essentially the same methods as used for free I (6, 7). Calibration curves of standard disulfide III, extracted from plasma, demonstrated a linear response–concentration relationship for reduction and extraction. The slope and intercept, 2.084 and 0.0667, respectively, are identical to the values reported for free I in whole blood (6). The extracted control was used as a single-point calibration (6, 7). The mean of three to five values was

[a] Single oral administration of 100 mg of captopril; nine healthy male subjects were treated. [b] ± *SEM* for nine healthy male subjects. [c] One-half total volume for plasma (blood equivalent). [d] Difference is equivalent to disulfides in blood.

used to adjust for the small variation in the response (6, 7). The data for total captopril are of the same quality as those for free captopril in whole blood (7). For total captopril values, the estimated precision from 0 to 100 ng/mL of plasma is 20 ng/mL; between 100 and 1000 ng/mL the precision is ~50 ng/mL; and at >1000 ng/mL the precision is 3%. The distribution of the measured total plasma levels of 27 plasma samples taken at 0, 12, 16, and 24 h is a demonstration of the sensitivity of the method (Fig. 1). Recorded to the nearest decade, 90% of the 0-h samples were determined to have 0 ng/mL, whereas the range of the 24-, 16-, and 12-h samples fell into groups of 40–100, 110–210, and 180–370 ng/mL, respectively. The mean values were also nearly equally spaced, with respective values of 70 (σ_n = 20), 130 (σ_n = 25), and 240 (σ_n = 50) ng/mL. A limit of detection of 20 ng/mL more than adequately reflects these data, and a sensitivity of 30 ng/mL appears to be readily achievable.

The mean bioavailability of I in whole blood and the total reducible captopril plasma levels of nine healthy subjects given a single oral 100-mg dose of captopril is shown as a typical example (Table V). The maximum concentration occurs at 1 h for free captopril, which is 900 (±140) ng/mL of whole blood, and at 1.5 h for total captopril in plasma, which is nearly 3000 ng/mL. To relate the total captopril levels in plasma to the whole blood equivalent, the plasma values were divided by 2 to adjust for the volume difference between the whole blood and plasma fractions. The difference between one-half the total captopril value and the free captopril value is the reducible captopril in whole blood. This parameter peaks at 2 h after drug administration. In a recent kinetic study of captopril in humans (20), it was suggested that captopril bound to plasma proteins and mixed disulfides with endogenous thiol-containing compounds may act as a reservoir from which captopril is slowly released. This possibility has also been cited in a captopril binding study (12). Future studies in which the total captopril method combined with the method for free captopril (7) are used should help in the refinement of the pharmacokinetics of captopril.

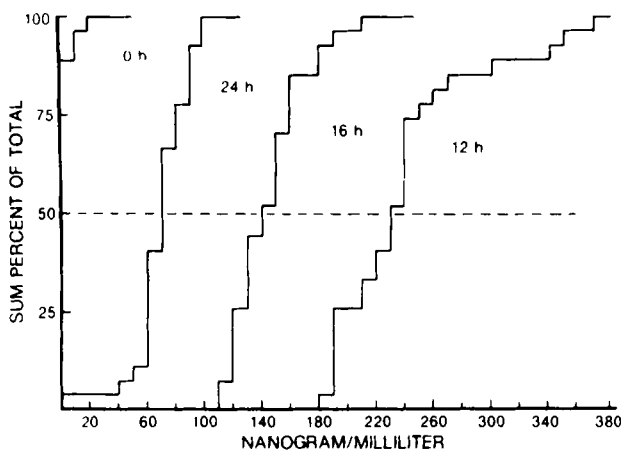

Figure 1—*Distribution and concentration range of total captopril in 0-, 24-, 16-, and 12-h plasma samples.*

Pharmacokinetics of Pentobarbital, Quinidine, Lidocaine, and Theophylline in the Thermally Injured Rat

RICHARD J. FRUNCILLO ˣ and G. JOHN DIGREGORIO

Received February 2, 1983, from the *Department of Pharmacology, Hahnemann Medical College and Hospital, Philadelphia, PA 19102.* Accepted for publication August 4, 1983.

Abstract □ Previous studies have shown that rats with 15% third-degree burns show a severe depression in various *in vitro* hepatic drug-metabolizing enzymes. This effect was assessed *in vivo* by measuring the disposition of four liver-metabolized drugs in 16% third-degree burned rats at 7 d postburn. Compared with pair-fed control rats, pentobarbital demonstrated a significantly prolonged clearance and elimination half-life without a change in volume of distribution. Quinidine demonstrated a significantly increased volume of distribution and a significantly decreased clearance without a change in elimination half-life. Lidocaine showed a significantly increased volume of distribution. Theophylline, which is only 50% metabolized in the rat, showed no changes in any pharmacokinetic parameters. The free drug fractions of quinidine and lidocaine were found to be significantly decreased at 1 d postburn and normal at 7 d postburn. These results warrant pharmacokinetic studies in human burn patients.

Keyphrases □ Pentobarbital—pharmacokinetics in thermally injured rats □ Quinidine—pharmacokinetics in thermally injured rats □ Lidocaine—pharmacokinetics in thermally injured rats □ Theophylline—pharmacokinetics in thermally injured rats □ Thermal injury—phramacokinetics of pentobarbital, quindine, lidocaine, and theophylline, rats

Thermal injury can produce numerous pathophysiological alterations in an organism which may modify the absorption, distribution, metabolism, and renal excretion of therapeutic agents (1). Such changes would be directly reflected in the derived pharmacokinetic parameters for a given drug (2). Recently, our laboratory has presented evidence of a generalized depression in various *in vitro* liver drug-metabolizing enzymes in rats subjected to 15–16% third-degree burns (3–5). Also, this phenomenon may occur in human thermal injury, as demonstrated by significantly decreased levels of D-glucaric acid in human burn victims (6). However, such data on drug metabolism in which *in vitro* liver homogenates and D-glucaric acid are used may not reflect the pharmacokinetic characteristics of a drug in an intact organism. Besides the activity of hepatic microsomal drug-metabolizing enzymes, other factors such as alterations in hepatic blood flow and changes in drug binding by plasma proteins may significantly contribute to the overall process of hepatic drug clearance (7). Thus, the present study was undertaken in a rodent model with a 16% third-degree burn to assess the effects of thermal injury on the *in vivo* disposition of four liver-metabolized drugs commonly used for burn patients.

EXPERIMENTAL SECTION

Animals—Adult male Sprague-Dawley rats[1] (weight, 220–250 g) received 16% full-thickness burns as described below. They were housed in plastic cages in groups of one or two over corncob bedding in a room maintained at 24 ± 0.5°C with a constant 12-h light and dark cycle. Pharmacokinetic experiments were done 7 d after the burning. Control rats housed alone were carefully pair-fed[2] daily with the burned rats to adjust for the slight anorexic effect of the burn wound.

Burn Procedure—A full-thickness burn was produced on the rats by the method of Arturson (8). This type of burn completely destroys all dermal appendages and epithelial elements, including sensory nerve endings, resulting in a virtually pain-free preparation (9). The animals were anesthetized with sodium pentobarbital (50 mg/kg) and shaved with electric clippers. Each rat was placed in a plastic mold with a hole cut out that corresponded to ~16% of the total body surface area. This value was arrived at by skinning burned rats and measuring the area of the burn and the total body area by tracing these areas onto graph paper and counting the squares. It was found that this particular mold consistently delivered an approximate 16% burn for animals in the weight range of 220–250 g. The burns were inflicted by placing the mold (containing the bare rat skin protruding through the hole) in 90 ± 1°C water for 20 s. This procedure produced a burn with sharp edges that did not impair the mobility of the animals. The animals awoke from the procedure in no apparent distress and did not require analgesics. At no time during the study did any burned animal exhibit gross signs of infection. Control animals were shaved and anesthetized but not immersed in water.

Biochemical Parameters—Estimations of the serum levels of proteins, enzymes, and other constituents were done on six 16% burned and six pair-fed control rats by sending 5 mL of serum from the pooled blood of two rats to a commercial laboratory[3]. The serum was analyzed with a standard serum multiple analyzer, with normal rat serum used as standards. Serum was ob-

tained 7 d postburning or pair-feeding by needle puncture of the surgically exposed jugular veins in rats anesthetized with sodium pentobarbital (50 mg/kg ip).

Quinidine, Lidocaine, and Theophylline Pharmacokinetics—Both burned and pair-fed rats were anesthetized with 1.7 g/kg of urethane, an anesthetic that does not inhibit drug metabolism (10) and which has been reported to maintain hepatic blood flow at a level equal to that of an awake animal (11). The right and left jugular veins were surgically exposed by superficial skin incisions in the areas of both clavicles, and 25 mg/kg of quinidine (free base), 15 mg/kg of lidocaine hydrochloride, or 15 mg/kg of theophylline (18.75 mg/kg of aminophylline) was injected intravenously through the right jugular vein. Blood samples (0.4 mL) were taken at 0.5, 1, 2, 3, and 4 h postinjection for quinidine; at 10, 20, 30, 40, and 50 min postinjection for lidocaine; and at 1, 2, 3, 4, and 5 h postinjection for theophylline. Samples were obtained by venipuncture of the left jugular vein through the pectoris major muscle with a 1-mL heparinized tuberculin syringe.

Pentobarbital Pharmacokinetics—Both 16% burned and pair-fed rats were lightly anesthetized with ether, and their ventral tail veins were cannulated with a piece of heparinized polyethylene tubing[4]. After securing the tubing in the vein with silk ligatures, the animals were placed in restraint cages and allowed to become fully awake. The rats were kept in the restraint cages for at least 3 h before the pharmacokinetic experiment was run, since it has been shown that brief exposure to ether can inhibit drug metabolism in the immediate postexposure period (10). After this 3-h recovery period, 40 mg/kg of sodium pentobarbital was injected intravenously through the tail vein cannula. Once the rats were in deep anesthesia, they were removed from the restraint cages, and the right jugular vein was exposed as described above. Blood samples were taken at 0.5, 1.0, 1.5, 2.0, and 2.5 h postinjection by venipuncture of the jugular vein with a 1-mL heparinized tuberculin syringe. Samples ranged in volume from 0.6 to 1.0 mL and did not exceed 3.0 mL of blood before the withdrawal of the last sample. After the 2.0-h sample was taken, 1.0 mL of saline was injected into the rat through the tail vein cannula in an attempt to partially restore some of the blood volume.

Drug Analysis—Quinidine, lidocaine, and theophylline plasma concentrations were measured by commercially available enzyme immunoassay kits[5] as described previously (12). The plasma concentrations of pentobarbital were determined by a modification of the GC method of Watson and Kalman (13). A gas chromatograph[6] equipped with a hydrogen flame-ionization detector was used for this study. Glass columns (~183 cm × 4 mm i.d.), packed with 3% OV-17 Gas Chrom Q, were used under the following conditions: injection port temperature, 200°C; column temperature, 180°C; detector temperature, 215°C; carrier gas, nitrogen at a flow rate of 20 mL/min. The sensitivity settings were 2 × 1.

The extraction procedure was as follows. Into a 13-mL glass centrifuge tube with a ground glass stopper were placed 0.3–0.6 mL of unknown plasma and 100 μL of barbital standard (200 μg of barbital/mL of distilled water). Saturated potassium dihydrogen phosphate (0.6 mL) was added, and the tubes were shaken lightly. Dichloromethane (0.5 mL) was then added, the stopper was replaced, and the tube was inverted manually 40 times. The layers were separated by centrifuging at 4000 rpm for 5 min, and the protein-containing aqueous layer was removed by aspiration. The organic layer (3.0 mL) was then transferred to a second 13-mL glass centrifuge tube, and the solvent was evaporated under a stream of nitrogen in a water bath at 45–50°C. The sides of the tube were washed with 0.5 mL of dichloromethane, and the solvent was again evaporated off. Chloroform (50 μL) was added and swirled around the tube, and 2 μL of the reconstituted sample was injected into the gas chromatograph.

Equilibrium Dialysis Experiments—A modification of the method of Woo and Greenblatt (14) was employed. Sixteen percent burns were inflicted as described above, and serum from 1- and 7-d postburn rats was compared with pair-fed controls. Whole blood was obtained by allowing decapitated rats to bleed into a large beaker without anticoagulant. The serum obtained after centrifugation was stored at −20°C and thawed just before dialysis.

Quinidine and lidocaine were dialyzed against pH 7.4 potassium phosphate buffer with added sodium chloride, prepared by dissolving 14.11 g of K_2HPO_4, 2.59 g of KH_2PO_4, and 1.99 g of NaCl in distilled water to make 1 L of solution. Lengths (19 cm) of cellulose dialysis tubing[7], with a molecular weight cut off of 10,000–14,000, were boiled in distilled water for 4 h and then rinsed with cold distilled water. Serum (1 mL) was added to the tubing, and both ends were sealed with double knots. The resultant dialysis bags were then placed in culture tubes holding 10 mL of buffer containing either 1.6 μg/mL of quinidine (free base) or 1.6 μg/mL of lidocaine (free base). The culture tubes were placed in a shaking water bath at 37°C for 20 h to reach equilibrium. Serum and buffer quinidine and lidocaine concentrations were determined by the enzyme immunoassay method[5], and the free drug percentage was calculated by:

$$\text{percent free drug} = \frac{\text{drug concentration in buffer} \times 100}{\text{drug concentration in serum}}$$

Mathematical Calculations—Pharmacokinetic parameters were calculated by utilizing the one-compartment open model which assumes very rapid initial distribution of the drug (15). The plasma disappearance of all four drugs was considered to follow the exponential function $C_p(t) = Ae^{-\lambda t}$, where $C_p(t)$ is the plasma concentration at time t, A is the zero-time intercept, and λ is the elimination rate constant. The elimination half-life ($t_{1/2}$) was calculated by $t_{1/2} = 0.693/\lambda$, the volume of distribution (Vd) was calculated by Vd = dose/A, and the clearance (CL) was calculated by $CL = Vd \cdot \lambda$. The parameters were calculated for each animal by linear regression analysis of a semilogarthmic plot of drug concentration *versus* time. All data were compared by the unpaired Student's t test, with $p > 0.05$ being statistically insignificant.

Table I—Biochemical Parameters in 16% Burned *versus* Pair-Fed Control Rats[a]

Parameters	Control	Burn
Serum glutamic oxaloacetic transaminase, IU/L	175 ± 30	200 ± 18
Serum glutamic pyruvic transaminase, IU/L	57 ± 8	59 ± 11
γ-Glutamyltransferase, IU/L	3.5 ± 2.1	6 ± 3
Total Bilirubin, mg/dL	0.59 ± .25	0.52 ± .25
Albumin, g/dL	2.80 ± .10	1.96 ± .06[b]
Total Protein, g/dL	6.0 ± 0.3	4.8 ± 0.2[b]
Blood urea nitrogen, mg/dL	13.7 ± 0.6	14.6 ± 1.1
Creatinine, mg/dL	1.5 ± 0.3	1.3 ± 0.1
Blood urea nitrogen–creatinine	9.1 ± 0.4	11.2 ± 1.2

[a] Values are means ± *SD* of six burned and six control animals compared at 7 d postburn. [b] $p < 0.0005$.

RESULTS

Biochemical laboratory parameters for pair-fed control rats and 16% burned rats 7 d postburn are listed in Table I. The serum albumin and total protein concentrations were significantly lower in the burned rats as compared with

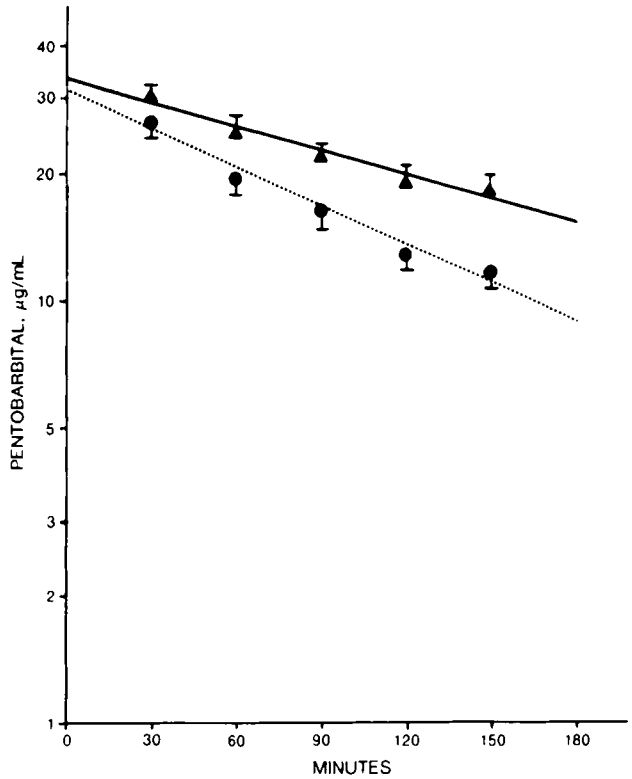

Figure 1—*Plasma disappearance curves of pentobarbital after a 40-mg/kg iv administration in 16% burned male rats at 7 d postburn (▲) and pair-fed control rats (●). Values are mean ± SE, with n = 5 or 6 at each point.*

[4] PE-50 tubing; Becton, Dickinson and Co., Parsippany, N.J.
[5] EMIT system; Syva Co., Palo Alto, Calif.

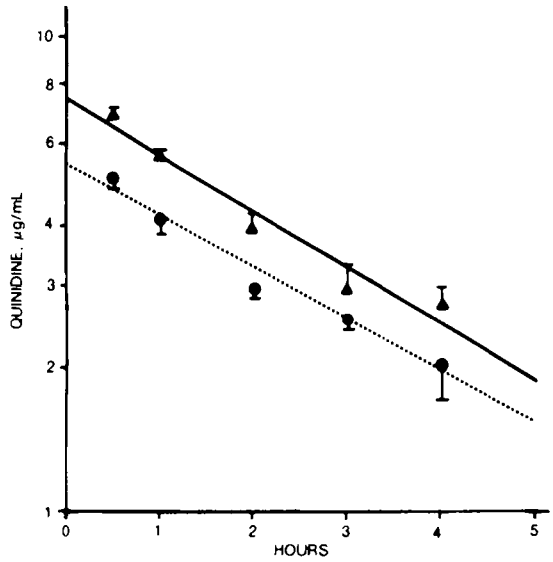

Figure 2—*Plasma disappearance curves of quinidine after 25 mg/kg (free base) iv administration in 16% burned male rats at 7 d postburn (▲) and pair-fed control rats (●). Values are mean ± SE, with n = 4 at each point.*

the control groups. There was no significant difference in the concentrations of the various liver enzymes measured between the two groups or in the concentrations of total bilirubin, creatinine, or blood urea nitrogen.

Figures 1–4 illustrate the respective average plasma disappearance curves for pentobarbital, quinidine, lidocaine, and theophylline for pair-fed controls and 16% burned rats 7 d postburn, and Table II shows the derived pharmacokinetic parameters and weight changes for these same animals. For each drug group tested, the burned rats gained a significantly lower amount of weight over the 7-d period than their corresponding controls, even though each control animal received the same amount of food daily as its paired burned animal. Thermal injury produced a significant 69% prolongation in pentobarbital elimination half-life and a correspondingly significant 43% reduction in total pentobarbital clearance. There was no significant difference in the volume of distribution observed for pentobarbital. For quinidine, the burned animals exhibited a significant reduction (24%) in total clearance and a significant reduction (25%) in volume of distribution, with an unchanged elimination half-life. The burned rats receiving lidocaine demonstrated a significant decrease (27%) in volume of distribution without significant changes in either total clearance or elimination half-life. For theophylline, thermal injury did not significantly alter total clearance, volume of distribution, or elimination half-life.

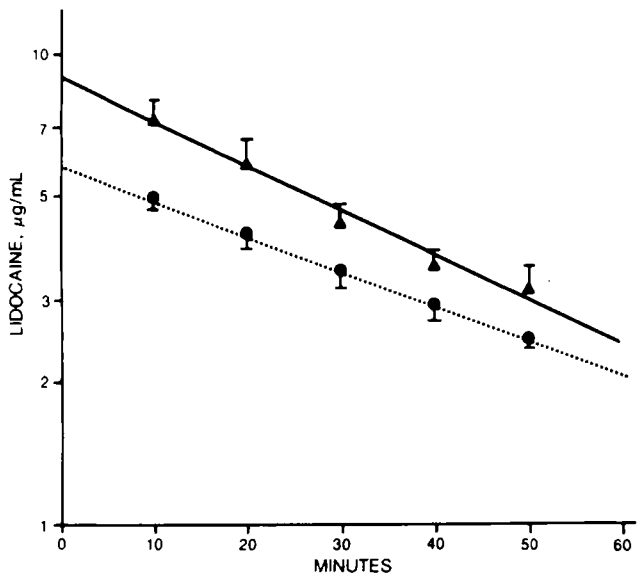

Figure 3—*Plasma disappearance curves of lidocaine after a 15-mg/kg (free base) iv administration in 16% burned male rats at 7 d postburn (▲) and pair-fed control rats (●). Values are mean ±SE, with n = 5 at each point.*

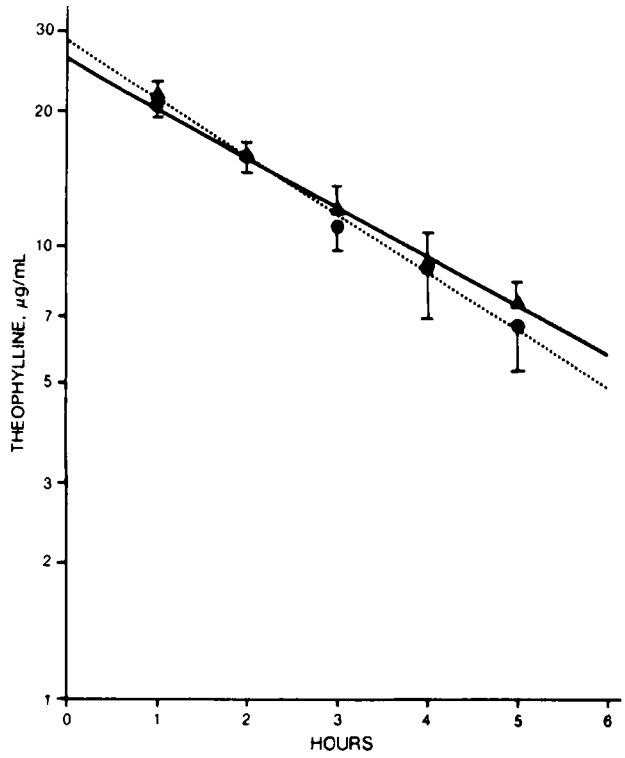

Figure 4—*Plasma disappearance curves of theophylline after a 15-mg/kg iv administration in 16% burned male rats at 7 d postburn (▲) and pair-fed control rats (●). Values are mean ± SE, with n = 4 at each point.*

To determine whether changes in drug protein binding contributed to the observed alterations in the volumes of distribution of quinidine and lidocaine at 7 d postburn, equilibrium dialysis studies were performed with quinidine and lidocaine in 16% burned and pair-fed control rats at 7 d postburn and also at 1 d postburn to serve as a comparison. At 7 d postburn, there was no significant difference in free drug percentages or total drug concentrations of either quinidine or lidocaine compared with controls (Table III). However, at 1 d postburn, there was a significant decrease (18%) in the free drug percentage of quinidine and a significant decrease (27%) in the free drug percentage of lidocaine, which resulted in a significant increase (20%) in total quinidine concentration and a significant increase (37%) in total lidocaine concentration.

Table II—Pharmacokinetic Parameters of Various Drugs in 16% Burned *versus* Pair-Fed Control Rats[a]

Parameter	Control	Burn
	Pentobarbital (40 mg/kg iv)[b]	
$t_{1/2}$, min	102.9 ± 27.8	173.9 ± 40.1[c]

Table III—Equilibrium Dialysis Results in 16% Burned *versus* Pair-Fed Control Rats [a]

	Control	Day 1 Postburn	Day 7 Postburn
	Percent Free Drug		
Quinidine	29.9 ± 5.1	24.4 ± 2.3[b]	31.1 ± 2.4
Lidocaine	52.5 ± 6.0	38.1 ± 1.8[c]	52.5 ± 4.8
	Total Drug Concentration, μg/mL		
Quinidine	4.13 ± 0.71	4.96 ± 0.45[b]	3.98 ± 0.48
Lidocaine	2.46 ± 0.24	3.38 ± 0.23[c]	2.48 ± 0.18

[a] Mean ± *SD*; $n = 6$. [b] Significantly different from the controls at $p < 0.05$. [c] Significantly different from the controls at $p < 0.0005$.

DISCUSSION

In this study, it has been demonstrated that thermal injury can alter pharmacokinetic parameters for various liver-metabolized drugs in rats. Previous studies in this laboratory have shown that third-degree burns can depress various components of the hepatic mixed-function oxidase system in rats (3-5) and D-glucaric acid excretion in humans (6). A manifestation of this effect *in vivo* would be a decrease in the total clearance of a drug. However, as stated previously, in addition to levels of hepatic drug-metabolizing enzymes, total clearance can also be affected by changes in hepatic blood flow and free drug fraction (7).

The significant reduction (43%) in pentobarbital clearance can probably be attributed to a reduction in the level of liver enzymes that metabolize pentobarbital. Although a decrease in the free fraction of pentobarbital could also cause a decreased total clearance (7), this event was unlikely since albumin is the main serum protein that binds pentobarbital (16), and it has been shown that the serum albumin concentration is decreased in the burned rats (Table I). This decrease in serum albumin should cause, if anything, an increased and not a decreased free drug concentration (7). Also, the observed total plasma pentobarbital clearance of 8.59 mL/min/kg in control rats is considerably less than the estimated literature values for hepatic plasma flow of ~40 mL/min/kg in similar rats (17). Thus, it can be assumed that pentobarbital clearance is relatively independent of hepatic blood flow changes in the rat (7).

For quinidine, there was a significant decrease (24%) in total clearance ($p < 0.05$), and for lidocaine there was a 20% reduction in total clearance ($p < 0.1$). Although these two drugs have total clearances in humans which are dependent on liver blood flow and drug-metabolizing enzyme activity (7), the relationship of total clearance to renal clearance, liver blood flow, and enzyme activity is unknown in rats. Thus, it is not possible to attribute the observed differences in total clearance for these drugs in the burned rats to any one particular factor. However, changes in drug protein binding did not play a part, as both drugs demonstrated unchanged free drug fractions at 7 d postburn (Table III).

For theophylline, the unchanged total clearance may not be due to a lack of effect of thermal injury on drug-metabolizing enzymes, since the disposition of theophylline differs markedly in rats as compared with humans, in that 46% of the drug is excreted unchanged by the kidneys in rats (18), as compared with less than 10% in humans (19). Thus, the renal route in rats may compensate for any reduction in hepatic clearance.

Since the concentrations of quinidine, lidocaine, and theophylline were measured by enzyme immunoassay, the possibility exists that certain metabolites in rat plasma may cross-react with the parent compounds in the assay and, thus, cause falsely higher values for intact quinidine, lidocaine, or theophylline to be reported. If such a situation were present, the values for drug concentrations and pharmacokinetic parameters in both burned and control rats would be altered slightly from their true values. However, any difference in these values would still be preserved. The only situation that could occur which would make the observed differences between burned and control rats artifactual would be that in which the burned rats metabolized the parent compound through a different metabolic pathway, producing different metabolites from the controls with a higher cross-reactivity for intact drug. Although such a situation cannot be completely ruled out, its occurrence seems unlikely.

For both the basic drugs, quinidine and lidocaine, there were significant decreases in volume of distribution in the burned animals at 7 d postburn (Table II). Increased plasma protein binding of these drugs was not the causative factor for these changes (Table III). A possible explanation is a displacement of drug from tissue-binding sites by substances released at the burn site. For these same drugs, there was a significant decrease in the free drug fraction and a significant increase in total drug concentration when serum taken from rats 1 d postburn was used for equilibrium dialysis studies. Quinidine and lidocaine are examples of drugs that bind more strongly to a specific plasma protein, α_1-acid glycoprotein, than to albumin (20). A number of inflammatory conditions, including burns, have been shown to elevate α_1-acid glycoprotein levels in humans (21) and to increase the plasma protein binding of various drugs (20). The results shown in Table III are consistent with the observation of a rapid rise in α_1-acid glycoprotein levels 24 h postburn in the male rat and a fall to normal levels by 7 d postburn.

In recent years, it has become increasingly apparent that various methodological artifacts could cause errors in the interpretation of data from protein binding experiments with equilibrium dialysis (22). Of particular relevance to this study is the possibility that the free drug fractions reported here after an 18-h dialysis may be larger than those after a shorter dialysis period due to possible deterioration of α_1-acid glycoprotein with time or dilution of this protein by an osmotic influx of water during the dialysis. Although no dialysis experiments were done at shorter time intervals, the control free drug fraction of quinidine reported here (30%) compares favorably with a literature value of 31% in the rat done over a shorter dialysis interval (23). However, the control free fraction of lidocaine (53%) is higher than an estimated literature value of 44% in the rat based on saliva-plasma lidocaine levels (24) and, thus, may have been influenced by the aforementioned factors.

Despite careful daily pair-feeding of burned animals with control animals, all of the burned rats in the four drug groups had a significantly slower rate of weight gain compared with the pair-fed controls (Table II). This finding is consistent with the hypermetabolic response and increased basal metabolic rate found previously both in burn patients and experimental animals (25).

The pathophysiological alterations caused by thermal injury can produce variable changes in the kinetic and dynamic behavior of drugs in humans. An increased elimination rate was found for the renally eliminated aminoglycosides gentamicin (26), tobramycin (27), and amikacin (28). This effect was probably due to a burn-induced increase in the glomerular filtration rate (27). For the nondepolarizing neuromuscular blocking agents tubocurarine (29) and metocurine (30), two- to fivefold increases in plasma drug concentrations were required to give normal muscle relaxation in burn patients. This effect could not be explained by increased drug protein binding and was probably related to a burn-related change in the neuromuscular junction receptors (31). The liver-metabolized drug diazepam has recently been shown to have a reduced free clearance in burn patients (32); however, all patients in this study received cimetidine, a drug known to inhibit diazepam clearance (33). Thermal injury in humans has also been shown to lower plasma protein concentrations (34) and to alter the protein binding of a number of drugs (35). A pharmacokinetic study in 15% burned rats has shown that thermal injury can increase the free phenytoin fraction with a corresponding increase in total phenytoin clearance (36). However, no calculation of free phenytoin clearance was done.

In conclusion, the results of this study and previous investigations suggest that the complex dynamic state of thermal injury can affect numerous aspects of drug disposition and action. Further pharmacokinetic studies with liver-metabolized drugs in burn patients are needed to determine whether altered hepatic drug metabolism plays a part in the disposition of drugs in human thermal injury.

Comparative *In Vivo* and *In Vitro* Studies of Phenytoin Protein Binding and *In Vitro* Lipolysis in Plasma of Pregnant and Nonpregnant Rats

RUBY C. CHOU and GERHARD LEVY ˣ

Received June 17, 1983, from the *Department of Pharmaceutics, School of Pharmacy, State University of New York at Buffalo, Amherst, NY 14260.* Accepted for publication October 3, 1983.

Abstract □ This investigation was designed to determine the cause of the changes in drug protein binding that occur in rat plasma, particularly in plasma from pregnant animals, during *in vitro* drug-protein binding measurements. *In vivo* estimates of phenytoin binding in plasma were obtained from steady-state CSF-plasma concentration ratios in pregnant and nonpregnant rats. Immediate ultrafiltration of heparin- or EDTA-anticoagulated plasma yielded phenytoin free fraction values that were in good agreement with *in vivo* estimates for nonpregnant rats but that were about one-third higher than *in vivo* estimates for pregnant animals. *In vitro* free fraction values tended to increase during incubation of plasma and/or during equilibrium dialysis. The concentrations of the four major endogenous free fatty acids were similar in plasma of pregnant and nonpregnant rats if determined immediately after blood collection. Six hours of incubation at 37°C caused fatty acid concentrations to increase about fivefold and twofold in heparin-anticoagulated plasma from pregnant and nonpregnant animals, respectively. The corresponding increases in EDTA-anticoagulated plasma were only about twofold and 1.14-fold, respectively. These changes were associated with decreased plasma protein binding of phenytoin. The *in vivo* differences between pregnant and nonpregnant rats with respect to phenytoin binding in plasma are not due to differences in fatty acid concentrations, but the *in vitro* differences are due primarily to corresponding differences in free fatty acid concentrations if extensive *in vitro* lipolysis occurs.

Keyphrases □ Phenytoin—plasma protein binding, lipolysis, pregnant and nonpregnant rats □ Lipolysis—*in vitro* and *in vivo* comparisons, plasma protein binding, pregnant and nonpregnant rats □ Anticoagulants—heparin, EDTA, plasma protein binding, *in vitro* and *in vivo* comparisons, pregnant and nonpregnant rats

Pregnancy is known to be associated with quantitative changes of drug biotransformation (1) and drug-protein binding in plasma or serum (2). Properly designed studies of the effect of pregnancy on the pharmacokinetics of drugs, therefore, require measurement of unbound drug in plasma, to differentiate between pharmacokinetic changes due solely to drug binding alterations and those due to altered intrinsic clearance or to a combination of both types of effects. Unfortunately, the drug-protein binding characteristics of plasma from pregnant rats and, to a lesser extent, from pregnant women are quite unstable (3, 4). A lack of appreciation of this problem can lead to serious misinterpretations in pharmacokinetic studies, particularly in the assessment of intrinsic drug clearance and drug concentration–pharmacological activity relationships.

This investigation was designed to determine the causes of *in vitro* alterations in protein binding of drugs in plasma from pregnant and nonpregnant rats and to assess the effects of the *in vitro* anticoagulant and of the methodology used for protein binding determinations. The study protocol also permitted a comparative determination of the effect of pregnancy on the total clearance and *in vivo* plasma protein binding of phenytoin in rats.

EXPERIMENTAL SECTION

Pregnant (day 20 of gestation) and nonpregnant Lewis rats[1] (the latter ≃ 200 g) received a loading dose of phenytoin, 14.7 mg/kg, by rapid injection

Comparative *In Vivo* and *In Vitro* Studies of Phenytoin Protein Binding and *In Vitro* Lipolysis in Plasma of Pregnant and Nonpregnant Rats

RUBY C. CHOU and GERHARD LEVY ˣ

Received June 17, 1983, from the *Department of Pharmaceutics, School of Pharmacy, State University of New York at Buffalo, Amherst, NY 14260.* Accepted for publication October 3, 1983.

Abstract □ This investigation was designed to determine the cause of the changes in drug protein binding that occur in rat plasma, particularly in plasma from pregnant animals, during *in vitro* drug-protein binding measurements. *In vivo* estimates of phenytoin binding in plasma were obtained from steady-state CSF-plasma concentration ratios in pregnant and nonpregnant rats. Immediate ultrafiltration of heparin- or EDTA-anticoagulated plasma yielded phenytoin free fraction values that were in good agreement with *in vivo* estimates for nonpregnant rats but that were about one-third higher than *in vivo* estimates for pregnant animals. *In vitro* free fraction values tended to increase during incubation of plasma and/or during equilibrium dialysis. The concentrations of the four major endogenous free fatty acids were similar in plasma of pregnant and nonpregnant rats if determined immediately after blood collection. Six hours of incubation at 37°C caused fatty acid concentrations to increase about fivefold and twofold in heparin-anticoagulated plasma from pregnant and nonpregnant animals, respectively. The corresponding increases in EDTA-anticoagulated plasma were only about twofold and 1.14-fold, respectively. These changes were associated with decreased plasma protein binding of phenytoin. The *in vivo* differences between pregnant and nonpregnant rats with respect to phenytoin binding in plasma are not due to differences in fatty acid concentrations, but the *in vitro* differences are due primarily to corresponding differences in free fatty acid concentrations if extensive *in vitro* lipolysis occurs.

Keyphrases □ Phenytoin—plasma protein binding, lipolysis, pregnant and nonpregnant rats □ Lipolysis—*in vitro* and *in vivo* comparisons, plasma protein binding, pregnant and nonpregnant rats □ Anticoagulants—heparin, EDTA, plasma protein binding, *in vitro* and *in vivo* comparisons, pregnant and nonpregnant rats

Pregnancy is known to be associated with quantitative changes of drug biotransformation (1) and drug-protein binding in plasma or serum (2). Properly designed studies of the effect of pregnancy on the pharmacokinetics of drugs, therefore, require measurement of unbound drug in plasma, to differentiate between pharmacokinetic changes due solely to drug binding alterations and those due to altered intrinsic clearance or to a combination of both types of effects. Unfortunately, the drug-protein binding characteristics of plasma from pregnant rats and, to a lesser extent, from pregnant women are quite unstable (3, 4). A lack of appreciation of this problem can lead to serious misinterpretations in pharmacokinetic studies, particularly in the assessment of intrinsic drug clearance and drug concentration–pharmacological activity relationships.

This investigation was designed to determine the causes of *in vitro* alterations in protein binding of drugs in plasma from pregnant and nonpregnant rats and to assess the effects of the *in vitro* anticoagulant and of the methodology used for protein binding determinations. The study protocol also permitted a comparative determination of the effect of pregnancy on the total clearance and *in vivo* plasma protein binding of phenytoin in rats.

Table I—Plasma Protein Binding of Phenytoin in Pregnant and Nonpregnant Rats: Effect of Methodology and *In Vitro* Anticoagulant on Free Fraction Determination [a]

	Pregnant Rats		Nonpregnant Rats	
	EDTA	Heparin	EDTA	Heparin
Total phenytoin in plasma, μg/mL	15.8 ± 1.7	16.9 ± 3.6	12.3 ± 4.7	12.4 ± 3.0
CSF-plasma conc. ratio × 100	19.1 ± 2.3	17.0 ± 0.9[b]	12.6 ± 2.3	13.8 ± 0.9[b]
Free fraction × 100				
Immediate ultrafiltration	25.5 ± 4.2	23.4 ± 7.3[e]	12.4 ± 1.5	13.7 ± 1.8
Ultrafiltration after 6 h	31.9 ± 4.9[d]	39.4 ± 12.9[d, e]	12.5 ± 1.8[c]	13.9 ± 1.9[c]
Equilibrium dialysis	26.2 ± 3.2	28.5 ± 7.3[d, e]	15.2 ± 1.4[d]	17.5 ± 1.9[c,d]

[a] Mean ±*SD*, $n = 6$ except pregnant-heparin group where $n = 5$. [b] $n = 4$ since CSF could not be obtained from one or two animals. [c] $n = 5$ due to loss of sample or inadequate plasma volume. [d] The method of protein binding measurement had a significant effect on free fraction values, as determined by two-way ANOVA for pregnant and nonpregnant rats considered separately. The superscript indicates that the free fraction value differs significantly ($p < 0.05$ by Newman-Keuls test) from the CSF-plasma concentration ratio × 100. [e] One rat had only three fetuses and yielded unusually low free fraction values. Without that animal, the free fraction × 100 values for immediate ultrafiltration, ultrafiltration after 6 h, and equilibrium dialysis were 25.9 ± 4.3, 44.4 ± 4.5, and 31.3 ± 2.6, respectively.

[a] Mean ±*SD*, $n = 6$ except pregnant-heparin group where $n = 5$. All concentrations are expressed as μM/L. [b] Assayed immediately after blood collection (0 h) or after 6 h incubation of the plasma at 37°C, before ultrafiltration (6 h). [c] Based on the sum of the concentrations of the four individual free fatty acids.

and then a continuous infusion of phenytoin, 195 μg/min/kg, through a jugular vein cannula. Only saline solution without anticoagulant was used to maintain cannula patency before the experiment. CSF and blood (for plasma) from the abdominal aorta were obtained at 2 h after the beginning of the infusion and were assayed for phenytoin by HPLC. Details of these procedures have been described previously (5). The blood was collected in a plastic syringe[2] containing either heparin[3] or EDTA in amounts such that their concentrations in the blood were ~20 U/mL or 2 mg/mL, respectively. The syringes had been dried overnight at 37°C to remove the solvent from the anticoagulant solutions. Plasma was separated immediately after blood collection by centrifuging at 15,600×*g* for 1 min. Two microliters were ultrafiltered (3) immediately at 37°C to yield ≃ 90 μL of filtrate, and another portion of the plasma was similarly ultrafiltered after 6-h incubation (in a capped glass vial) in a waterbath at 37°C. A third portion of the plasma was used for equilibrium dialysis at 37°C for 6 h against an equal volume of isotonic sodium-potassium phosphate buffer, pH 7.4 (5). The cellophane membrane[4] used for these procedures had a pore permeability cut-off of between 12,000 and 14,000 Da. Phenytoin concentrations in the protein binding experiments were measured by an HPLC method, with a detection limit of ~1 μg/mL (5).

One hundred-microliter portions of plasma were taken before and after incubation for analysis of free fatty acid concentrations. The "before incubation" sample was extracted into hexane within 5 min after blood collection to minimize *in vitro* lipolysis. Fatty acid concentrations were determined by GC after extraction and derivatization as described by others (6) except that *n*-heptadecanoic acid was used as the internal standard and sample volumes were reduced.

To determine the effect of *in vitro* addition of free fatty acids to serum on phenytoin protein binding, 200 μL of an ethanolic solution of fatty acids (palmitic, ≃40 mM; stearic, ≃8 mM; oleic, ≃60 mM; linoleic, ≃25 mM) was added to 20 mL of pooled rat serum (from 10 nonpregnant female animals) containing added phenytoin, 23 μg/mL. Another portion of that serum with only ethanol added was used as a control. Protein binding of phenytoin was determined by ultrafiltration at 37°C of seven aliquots of each pooled serum portion.

RESULTS

The results of the phenytoin infusion studies on pregnant and nonpregnant rats are summarized in Table I. Based on the plasma concentrations, which should be at steady state under the experimental conditions (5), the total clearance of phenytoin was significantly lower in the pregnant rats (12.2 ± 2.0 mL/min/kg; mean ±*SD*) than in the nonpregnant rats (17.1 ± 4.9 mL/min/kg; $p < 0.01$). This was also the case for the total clearance of free drug (70.0 ± 14.9 *versus* 136 ± 35 mL/min/kg; $p < 0.001$) which was calculated on the basis of the *in vivo* free fraction of phenytoin (*i.e.*, CSF concentration–plasma concentration ratio). These results represent the combined data obtained from the EDTA and heparin experiments because of their excellent replication and the identical *in vivo* experimental conditions, and were analyzed statistically by the unpaired *t* test.

The CSF-plasma concentration ratio of phenytoin was significantly higher in pregnant than in nonpregnant rats ($p < 0.001$ by *t* test for the combined EDTA and heparin data). There was excellent agreement between this ratio and the *in vitro* phenytoin free fraction in plasma from nonpregnant rats that was ultrafiltered within 5 min after blood collection (Table I). On the other hand, the *in vitro* free fraction of phenytoin in plasma from pregnant rats, determined under the same conditions, was about one-third higher than the CSF-plasma concentration ratio in these animals. Free fraction values of phenytoin determined by ultrafiltration after incubating plasma from pregnant rats for 6 h at 37°C were even higher. Equilibrium dialysis for 6 h at 37°C also yielded appreciably higher free fraction values than the *in vivo* estimates (CSF-plasma concentration ratio), for both pregnant and nonpregnant rats. The statistical significance of these differences are indicated in Table I.

Table II contains a summary of the results of the assays of the plasma samples for palmitic, stearic, oleic, and linoleic acids. The concentrations of these endogenous free fatty acids in plasma assayed within 5 min after blood

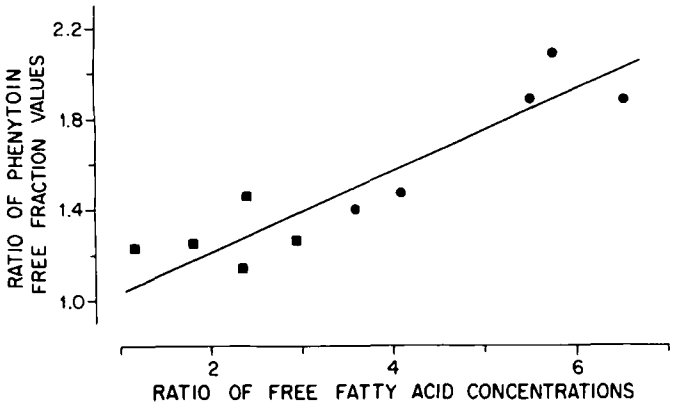

Figure 1—*Relationship between the ratios of the phenytoin free fraction values obtained by ultrafiltration (after 6 h incubation at 37°C-immediately, without incubation) and the ratios of the total free fatty acid concentrations (measured concomitantly in plasma of rats at day 20 of gestation) when either EDTA (■) or heparin (●) was used as the* in vitro *anticoagulant (r = 0.90, p < 0.001).*

collection were similar in pregnant and nonpregnant animals, irrespective of the anticoagulant used. However, heparin-anticoagulated plasma underwent pronounced lipolysis during 6 h of incubation, particularly plasma from the pregnant rats. Total free fatty acid concentrations increased by an average of 410% in plasma from pregnant rats and 95% in plasma from nonpregnant rats during incubation. These changes were much smaller in EDTA-anticoagulated plasma: 108% and 14%, respectively. The relative increase in fatty acid concentrations was associated with a corresponding relative increase in the free fraction of phenytoin in plasma from pregnant rats (Fig. 1). Addition of a mixture of the four free fatty acids, similar in proportion to that found *in vivo*, to serum from nonpregnant rats caused an increase of phenytoin free fraction values similar in relative magnitude to that found on lipolysis (Fig. 2).

DISCUSSION

The therapeutic management of pregnant patients with seizure disorders is difficult (7). The most frequently used drug for this purpose is phenytoin. Pregnancy may be associated with alterations in the pharmacokinetics of phenytoin and in the phenytoin concentration–effect relationship. Investigations of these possibilities in patients and in intact animals must be designed to distinguish between apparent effects referable to pregnancy-associated

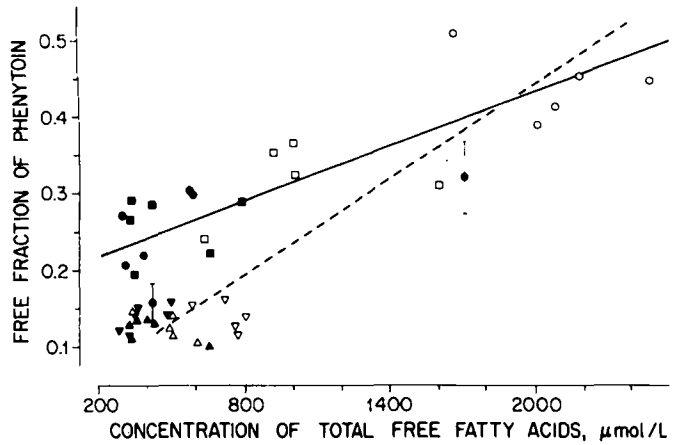

Figure 2—*Relationship between free fraction values of phenytoin and concentration of total free fatty acids in plasma. The lines were determined by bivariate linear regression. The two closed circles with the vertical bars (±SD) are the free fraction values obtained with serum from nonpregnant rats with and without addition of a physiological mixture of free fatty acids. Key: (——) relationship for pregnant rats at day 20 of gestation (r = 0.85, p < 0.001); (- - -) relationship for both nonpregnant and pregnant rats after incubation of plasma for 6 h at 37°C (r = 0.86, p < 0.001); (■,□) plasma from pregnant rats with EDTA as anticoagulant; (●,○) plasma from pregnant rats with heparin as anticoagulant; (▲,△) plasma from nonpregnant rats with EDTA as anticoagulant; (▼,▽) plasma from nonpregnant rats with heparin as anticoagulant. decreased plasma protein binding of phenytoin and actual changes in intrinsic clearance of the drug and in the relationship between biophasic drug concentration and pharmacological response. It became evident in the course of such an investigation (8) that the protein binding of phenytoin in plasma from pregnant rats undergoes rapid and pronounced alterations *in vitro* during the time between blood collection and plasma protein binding determination (3). The present study was designed to determine the cause of these alterations and to explore possibilities for minimizing them.

An important, although incidental, result of this investigation is the demonstration of a decreased steady-state plasma clearance of phenytoin by pregnant as compared with nonpregnant rats. The clearance of free (unbound) phenytoin in nonpregnant (control) animals was about twice as high as that in pregnant rats when both groups of animals received infusions of the drug at the same rate per unit of body weight. Since phenytoin pharmacokinetics are nonlinear and subject to product inhibitory effects in rats (9, 10), quantitatively different results may have been obtained if the clearance determinations had been made at comparable plasma concentrations rather than at comparable infusion rates. The results of more detailed and extensive studies of the effect of pregnancy on phenytoin elimination kinetics in rats will be presented in another report and a discussion of the subject will, therefore, be deferred.

Unbound phenytoin in plasma equilibrates readily with phenytoin in CSF; the CSF–plasma concentration ratio of the drug represents, therefore, its free fraction value in plasma under *in vivo* conditions (5). It was found that the free fraction of phenytoin in rat plasma is substantially (≃50%) increased in late pregnancy. This result is not a consequence of the higher phenytoin concentrations in the pregnant animals, since the protein binding of phenytoin in rat serum is independent of concentration over a wide range (11). Nor are these *in vivo* results subject to uncertainties due to the technical problems and possible artifacts associated with *in vitro* protein binding determinations.

The ability of nonesterified (free) fatty acids to affect (usually decrease) the plasma protein binding of drugs is well established (12). Recent research emphasis has been on the elevation of fatty acid concentrations in plasma after systemic administration of heparin; this elevation is now recognized to be largely an *in vitro* artifact due to continuing lipolysis in plasma during the time between blood collection and the determination of fatty acid concentrations (13, 14). While injected heparin mobilizes and activates lipases which then cause formation of free fatty acids from triglycerides in plasma, even plasma from individuals (humans and rats) who have not received heparin contains appreciable lipolytic activity (15–17). Consequently, the concentrations of free fatty acids increase *in vitro* even in plasma of individuals who have not been treated with heparin (4, 18–22), albeit at a much lower rate than in post-heparin plasma.

The free fatty acids that accumulate in plasma *in vitro* derive from triglycerides as well as from lecithin (19, 23, 24). The plasma concentrations of these sources of fatty acids increase substantially during pregnancy (25), thereby increasing both the absolute rate and the extent of *in vitro* free fatty acid formation in pregnancy plasma. Such increase apparently does not occur to any significant extent *in vivo*, probably due to distribution of the formed free fatty acids from blood to extravascular sites and metabolic clearance. Neither distribution nor clearance occur *in vitro* so that accumulation of free fatty acids in plasma can be substantial under *in vitro* conditions.

The four fatty acid concentrations quantitatively determined in this investigation (palmitic, stearic, oleic, and linoleic acids) account for most (≃90%) of the fatty acids in human plasma (20, 26), and the sum of their concentrations is probably a reasonable estimate of total fatty acid concentration in rat plasma. It is desirable, however, to determine the concentrations of these fatty acids individually, because they may have quantitatively different displacing effects on drugs bound to plasma proteins. By the same token, confirmatory protein binding experiments involving *in vitro* addition of free fatty acids to plasma should be carried out with fatty acid mixtures with a composition and ratio of concentrations similar to that found *in vivo*. The effect of free fatty acids on the plasma protein binding of different drugs is a function of the capacity of the binding sites, the relative concentrations and affinity of the ligands, and other variables. Consequently, the rate and extent of protein binding alterations of phenytoin reported here apply to that drug only.

The results of this investigation show that the concentrations of free fatty acids in plasma from nonpregnant rats increase about twofold within 6 h at 37°C, *i.e.*, under conditions typical of equilibrium dialysis, if heparin is used as the *in vitro* anticoagulant. This lipolysis is almost prevented by use of EDTA instead of heparin. Total free fatty acid concentrations in heparinized plasma from pregnant rats increase about fivefold during 6 h at 37°C; use of EDTA instead of heparin reduces this increase to twofold. When EDTA and heparin are used together, the extent of lipolysis is similar to that in heparinized plasma[5]. This is consistent with reports that EDTA is not a good lipoprotein

[5] Unpublished results.

lipase inhibitor (14, 27) and indicates that *in vitro* heparin increased lipolytic activity, particularly in pregnancy plasma, under our experimental conditions. According to the literature, heparin may activate or inhibit lipases, depending on its concentration (28, 29). To significantly reduce the *in vitro* accumulation of free fatty acids in plasma, it will be necessary to inhibit not only the lipolysis of triglycerides but also the formation of fatty acids from phospholipids (23, 24).

The rapid and pronounced *in vitro* lipolysis in the plasma of pregnant rats can easily lead to artifactual overestimation of *in vivo* free fatty acid concentrations. One group of investigators reported total plasma free fatty acid concentrations of $\simeq$360, 565, and 848 μM in heparinized plasma from nonpregnant rats, rats at day 19 of gestation, and rats at day 21 of gestation, respectively (30). The control value is similar to that in this study ($\simeq$400 μM), but the values for the pregnant rats are substantially higher than that for rats on day 20 of gestation determined in this study ($\simeq$430 μM) under conditions that minimize *in vitro* lipolysis. When proper precautions are taken to avoid artifacts, there appears to be no appreciable difference in plasma free fatty acid concentrations of pregnant and nonpregnant rats. This is also true for humans (26).

While plasma free fatty acid concentrations are of direct biochemical and physiological interest, their significance in pharmacology and pharmacokinetics relates principally to their effect on the plasma protein binding of drugs (12, 31). This effect is clearly evident in the strong correlation between the relative increase in the phenytoin free fraction and the relative increase of total free fatty acid concentrations in plasma found in the present investigation (Fig. 1). Moreover, direct addition of a physiological mixture of fatty acids to serum from nonpregnant rats, thereby duplicating the elevation of fatty acid concentrations found in the plasma of pregnant rats after 6 h of incubation at 37°C, results in an increase of the phenytoin free fraction to a value similar to that of the incubated pregnancy plasma (Fig. 2).

It is easy to come to the erroneous conclusion that pregnancy-associated changes of *in vivo* plasma protein binding of phenytoin (or other drugs) are due to the displacing effect of increased concentrations of free fatty acids. The dashed regression line in Fig. 2 represents the relationship between phenytoin free fraction value and total free fatty acids concentration in plasma from both pregnant and nonpregnant rats when that plasma had been incubated for 6 h at 37°C (*i.e.*, under conditions typical of equilibrium dialysis). The correlation is strong ($r = 0.86$) and highly significant ($p < 0.001$), but the conclusion is incorrect because it is based on inappropriate experimental conditions.

The solid symbols in Fig. 2 demonstrate that, when *in vitro* lipolysis is minimized, the protein binding of phenytoin is much less pronounced in plasma of pregnant rats than in plasma of nonpregnant controls at comparable free fatty acid concentrations. Viewed from another perspective, *in vivo* plasma protein binding of phenytoin is much less in pregnant than in nonpregnant rats (Table I), even though fatty acid concentrations are similar in the two groups when measured under conditions that minimize *in vitro* lipolysis (Table II). The notion that the diminished *in vivo* plasma protein binding of drugs during pregnancy is due to elevated fatty acid concentrations is, therefore, untenable. Lower plasma albumin concentrations during pregnancy (2, 32), possible accumulation of endogenous displacers other than fatty acids, and possible conformational changes of albumin are more likely causes of decreased plasma protein binding of albumin-bound drugs during pregnancy (11).

The *in vitro* lipolysis and corresponding changes in drug–protein binding demonstrated here with respect to plasma from rats in late pregnancy have also been investigated in humans (4, 33). The degree of *in vitro* lipolysis in plasma obtained from pregnant women during 6 h of equilibrium dialysis was, generally, somewhat less pronounced than in plasma from pregnant rats while the protein binding changes associated with the increased fatty acid concentrations ranged from negligible (phenytoin), to modest (salicylate, ibuprofen), to pronounced (diazepam). Rapid *in vitro* lipolysis may also occur in plasma from other species and in other states of altered physiology. It will be necessary to identify or rule out these factors in investigations of drug kinetics and dynamics in disease states.

Unfortunately, an *in vivo* estimation of plasma protein binding based on the steady-state CSF-plasma concentration ratio is not always feasible, because not all drugs equilibrate to equal concentrations in CSF and plasma water (5). Rapid separation of plasma after blood collection (which is facilitated by use of a high speed centrifuge), use of EDTA (or other suitable compounds) rather than heparin as the *in vitro* anticoagulant (provided that EDTA does not interfere with the drug–protein binding), and rapid ultrafiltration will minimize *in vitro* lipolysis and thereby reduce the likelihood of artifactual protein binding estimates. Particularly, if ultrafiltration is not feasible due to membrane binding or other technical problems and equilibrium dialysis must be used, determinations of fatty acid concentrations in plasma immediately after blood collection and again after dialysis (33) will provide an indication of the magnitude of *in vitro* lipolysis under the experimental conditions.

Systematic Error Associated with Apparatus 2 of the USP Dissolution Test V: Interaction of Two Tableted Prednisone Formulations with Glass and Plastic Vessels

DON C. COX ˣ and WILLIAM B. FURMAN

Received June 17, 1983, from the *Food and Drug Administration, National Center for Drug Analysis, St. Louis, MO 63101.* Accepted for publication September 22, 1983.

Abstract □ Recently marketed glass vessels that are uniform and pass USP specifications were compared with uniform plastic vessels that also pass USP specifications. Two lots of prednisone tablets, Tablet 1 and Tablet 2, were tested in both types of vessels. Tablet 1 gave higher results (+12.7% of label claim) in glass vessels at 50 rpm but gave equivalent results in either vessel at 75 rpm. Tablet 2 gave equivalent results in either vessel at 50 rpm but gave higher results (+22% of label claim) in glass vessels at 75 rpm. The type of vessel used to obtain dissolution results for tablets should be specified.

Keyphrases □ USP Dissolution Apparatus 2—error associated with use of glass and plastic vessels □ Dissolution—systematic error associated with USP dissolution Apparatus 2, use of glass and plastic vessels

In a previous report (1), it has been shown that glass and plastic vessels may give different results when dissolution of prednisone tablets is measured with USP Apparatus 2. In the earlier work, the glass vessels[1] used had nonuniform inside bottom curvatures and did not conform to the USP specification (2) of spherical curvature; the inside bottom curvatures of the plastic vessels[2] were more uniform and approximated spherical curvature. It was thus concluded (1) that use of the plastic vessels would reduce systematic error in the USP Apparatus 2.

Glass vessels[3] advertised to meet USP specifications were recently introduced, and five were purchased for evaluation. To permit direct comparisons, the previously used techniques and tablet lots were employed to evaluate the suitability of the new glass vessels in the USP dissolution test for prednisone tablets (3), and the results are reported here.

EXPERIMENTAL SECTION

Tablets—In this laboratory, two commercial lots of prednisone tablets that originally gave wide ranges in dissolution results with Apparatus 2 have been used extensively. The dissolution rates of Tablet 1 (5-mg prednisone tablets) and Tablet 2 (10-mg prednisone tablets) are affected to an unusual degree by minor variations in the test. In this respect, they are not typical of prednisone tablets currently available to the public but are very useful for measurement of apparatus variations. The dissolution rate of Tablet 1 responds to variations in the physical alignment of the equipment (4) and vessel curvature (1). The dissolution rate of Tablet 2 is less affected by these variations but is increased considerably if gas concentrations in the dissolution medium exceed a critical value (5, 6). Tablet 2 has been collaboratively studied in 11 laboratories (7). Both lots exhibit similar physical dissolution behavior; disintegration takes place within 2 min, and the disintegrated tablet material stays on the bottom of the vessel, where it gathers into a dynamic conical mass. Undesirable changes in test conditions alter the fluid flow in the vicinity of the conical mass; the conical mass is displaced or dispersed, and higher dissolution results are obtained. In this laboratory, the dissolution results from Tablet 2 are currently used as an indicator to determine whether the dissolution equipment and medium are suitable for testing tablets by the procedure with the USP Apparatus 2.

Apparatus—A six-spindle dissolution drive[4] was used. The drive was mounted on an acrylic water bath equipped with levelers. A circulator-heater[5], mounted externally to the bath, maintained the bath temperature at 37.5 ± 0.1°C. The base of the drive was leveled[6], and the paddle shafts were aligned vertically[6]. A specially designed tool (8) was used to center the vessels around the paddle shafts[7]. Each vessel was held in place with three cam lugs. Each paddle was adjusted with a depth gauge[8] to provide 25 mm of clearance above the bottom of the vessel. Paddle rotation was maintained within ±1.7% of the nominal value.

Procedure—A 20-L carboy was filled with deionized water. To achieve the desired equilibrium of gases, air was drawn through the water for 15 min at 145 mm Hg (6). The water was siphoned into 500-mL volumetric flasks[9], which were placed in a water bath at 37.5°C until their contents had reached that temperature. The contents were then transferred to the dissolution vessels in a 37.5°C water bath. The tablets were dropped into the vessels with the paddles rotating. After 30 min, aliquots were taken and filtered. (The water temperatures were 37.0 and 36.5°C in the glass and plastic vessels, respectively.) The absorbance of each filtrate was measured at 242 nm in a 1-cm cell.

Reevaluation of Glass and Plastic Vessels—Dissolution data for Tablet 1 were obtained with the same six glass vessels[1] previously evaluated (1). A different set of six plastic vessels was used, however, because the plastic vessels used in the previous evaluation were not available for this study.

Evaluation of New Glass Vessels—The new glass vessels[3] have graduations from 500 to 1000 mL in 50-mL increments. Inside diameters were measured with inside calipers. The bottom curvatures were measured with a mechanic's depth gauge and plaster of Paris (1). The glass vessels were numbered 1 through 5 and placed in the dissolution drive with one plastic vessel. Two sets of six tablets each were subjected to the dissolution test. The vessels were then moved one position in a clockwise direction, and two more sets of six tablets each were subjected to the test. This procedure was continued until each vessel had been tested twice in each position of the dissolution drive for a total of 72 results. Twelve results were associated with each vessel, which were sequentially placed in all six positions. Likewise, 12 sets of results were associated with each position in which all six vessels had been sequentially placed. The experiment was conducted only with Tablet 1.

Plastic-Coated Glass Vessels—Ten grams of plastic from a broken plastic vessel was dissolved in 100 mL of chloroform. This solution was poured into a clean, dry, glass vessel[3]. The vessel was tilted and rotated until its inside surface was brought in contact with the solution. The solution was poured from the vessel, and the vessel was inverted and placed on a cork ring in a draft hood overnight. The inside of the glass vessel was coated with a thin layer of plastic. The vessels had to be recoated after each dissolution test because the plastic did not adhere to the glass. Tablet 1 and Tablet 2 were tested in these coated vessels.

Glass Vessels with Different Bottom Curvatures—Dissolution results for Tablet 1 were taken from a glass vessel[10], in which the bottom curvature came to a blunted point (1), and from a flat-bottom glass vessel[11] that was positioned in the dissolution apparatus in a manner similar to that for the other vessels.

Dissolution Results at Different Stirring Rates—Three plastic vessels and three glass vessels[3] were placed in alternating positions in the dissolution apparatus. The dissolution test was conducted at stirring rates from 25 to 100 rpm for Tablet 1 and Tablet 2.

Dissolution Results from One or More Tablets Per Vessel—Three plastic vessels and three glass vessels[3] were placed in alternating positions as before.

[a] Percent of label claim dissolved at 30 min. [b] Mean ± *SD* of 12 individual tablets.

One or several tablets were dropped into each vessel. The test was conducted at 50 and 75 rpm for Tablet 1 and Tablet 2, respectively.

RESULTS AND DISCUSSION

Physical Dimensions—The five glass vessels[3] had inside diameters that ranged from 103.0 to 103.5 mm. The bottom curvatures of the vessels corresponded to those of spheres of diameters from 102.4 to 105.2 mm. Plaster of Paris casts of the bottom curvatures revealed no irregularities. The depth of the vessels was 165 mm. The vessels thus met USP specifications.

The dimensions of the glass vessels[3] differ from those of the plastic vessels in two respects. For the glass and plastic vessels, the outside diameters of the flanges are ~122 and 135 mm, respectively. The outer edge of the flange is lopsided with respect to the outer wall of the glass vessel, but is symmetrical with the outer wall of the plastic vessel. This difference in flange dimension required larger cam lugs on the dissolution apparatus to hold each glass vessel centered around its paddle axis. The flanges were marked so that they could always be oriented in the same configuration before use.

The glass vessels[3] have parallel sides, but the plastic vessels are tapered toward the bottom. Both types of vessel have essentially the same inside diameter at the top (103 mm), but the plastic vessel has a diameter of 101 mm just above the start of its bottom curvature. This difference in internal dimension causes the glass vessel to have a slightly flatter bottom curvature and to hold a slightly larger volume of liquid at a specified depth.

Selection of Tablets for Evaluation—With Tablet 1, significant differences among glass and plastic vessels (1) were revealed when the amount of dissolved drug, expressed as a percentage of the amount purported to be in the tablet, was measured at 30 min. The difference between mean results from the two types of vessels was dramatic for Tablet 1 but slight for Tablet 2. Tablet 1 was therefore selected to be used to detect differences among the five new glass vessels[3].

Tablet 1 had not been tested for 3 years. New dissolution results were collected from the six glass vessels[1] evaluated previously (1) and from six plastic vessels. The mean results obtained for 12 tablets were 54.7 and 41.2% of label claim in glass and plastic vessels, respectively. The corresponding standard deviations were 1.68 and 2.23% of label claim. These results compare favorably with the results previously obtained from the four positions of the dissolution drive that had vertical shafts[12]. Thus, Tablet 1 had not deteriorated, and direct comparisons could be made between the results collected 3 years ago and those from the new glass vessels[3].

Analysis of Variance—The data collected in the test of five glass vessels[3] and one plastic vessel were rearranged for an analysis of variance (Tables I and II). The data in the rows are associated with the individual vessels, and the data in the columns are associated with the individual positions in the dissolution apparatus.

[12] The Hanson dissolution drive used in the previous study (1) had two paddle shafts that were nonparallel with the other four shafts; results from the two nonparallel (nonvertical) positions were considered to be anomalous.

Table III shows the ANOVA. The *F* ratios indicate that at the 95% confidence level, there were no significant differences among the positions on the dissolution apparatus. However, the chance that Tablet 1 would give the same results in each of the glass[3] vessels is only ~1 in 40. The maximum range of the 12-tablet means associated with the glass vessels[3] is only 1.5% of label (Table I). The maximum ranges obtained previously (1) were 4.1% of label for six glass vessels[1] and 4.9% of label for six plastic vessels. Therefore, the dissolution data from Tablet 1 indicate that the new glass vessels[3] are more uniform than either type of vessel previously evaluated.

The overall mean of dissolution results for Tablet 1 in the new glass vessels[3] (52.7% of label claim; Table I) agrees well with the mean from the previously evaluated glass vessels[1] (54.7% of label claim). Neither of these means agree with the mean from plastic vessels (~41% of label claim; Table II), yet both the glass[3] and plastic vessels met USP specifications.

Results from Coated Vessels—It has been observed in this laboratory that at the beginning of the dissolution test, certain tablets seem to become more centered in glass vessels than in plastic vessels, which suggests that friction between a tablet and the wetted vessel surface may be greater for plastic than glass. Also, certain tablets become more centered in glass vessels cleaned with soap and water than in those rinsed with water and 95% ethanol, which suggests that a tablet may interact with residual films on the glass surface. Thus, certain tablets may interact differently with wetted plastic and glass surfaces.

The glass vessels[3] were coated with the material from which the plastic vessels were made. Five tablets of Tablet 1 were individually tested in plastic-coated vessels. A mean of 55.1% of label claim with an *SD* of 1.05% of label claim was obtained. These results indicate that the plastic coating had little or no effect.

Vessel Curvature—A correlation has been established between the dissolution data obtained for Tablet 1 and the shape of the bottom curvature of glass vessels (1). A glass vessel with an oblate deformation produces a higher dissolution result than one with a prolate deformation. Tablet 1 was used to estimate a maximum magnitude of this curvature effect; a single tablet was tested in a molded glass dissolution vessel[10] that possessed a bottom curvature that came to a blunted point, and a single tablet was tested in a flat-bottom glass vessel[11] similar to those used in the spinning-filter dissolution apparatus (9). Results were 38.9 and 70.3% of label claim, respectively. The extreme difference in vessel curvature gave a difference of ~31% of label claim which supports the idea that the difference in curvature between the glass[3] and the plastic vessels may have an effect. This supposition could not be further investigated because of the lack of glass vessels that have exactly the same dimensions as the plastic vessels.

Different Stirring Rates—Unlike Tablet 1, Tablet 2 does not give a large difference in dissolution results in glass and plastic vessels at 50 rpm. Results reported earlier (5) suggest that Tablet 2 would respond differently at 100 rpm. Tablet 1 and Tablet 2 were tested in glass and plastic vessels at stirring rates from 25 to 100 rpm (Table IV). For Tablet 1, the largest divergence in results between glass and plastic vessels occurred at 50 rpm, and the results converged at higher stirring rates. For Tablet 2 the dissolution results did not begin to diverge until stirring rates >50 rpm were attained.

Individual tablets from Tablet 2 were tested simultaneously at 75 rpm in three plastic-coated glass vessels[3] and three plastic vessels. The mean dissolution results (±*SD*) as percentage of label claim were 55.4 (4.68) and 60.7 (4.30) from plastic and plastic-coated glass vessels, respectively. Comparison of these results with those in Table IV (Tablet 2, 75 rpm) indicates that the plastic surface does interact with Tablet 2.

Volume of Disintegrated Tablet Material—The higher dissolution results obtained for Tablet 1 and Tablet 2 in glass vessels suggest that these tablets are subjected to higher fluid flow rates in glass vessels. During the dissolution

Tablets/Vessel	Percent of Label Claim for Tablet 1[b]		Percent of Label Claim for Tablet 2[c]	
	Glass	Plastic	Glass	Plastic
1	53.3	41.0	87.2	55.2
2	56.2	43.9	84.0	62.1
4	54.5	45.0	66.6	66.9
8	55.9	43.5	—	—

[a] Percent of label claim per tablet at 30 min. [b] At 50 rpm. [c] At 75 rpm.

test of a single tablet, the volume of the conical mass of disintegrated tablet material on the bottom of the vessel from Tablet 2 is about three times that from Tablet 1. It was speculated that this difference in volume could cause Tablet 1 to be more sensitive to slight differences among vessels because there might be less tendency for the tablet material to pack together at a specified stirring rate, *i.e.*, fewer particles would have greater freedom of movement in a given space.

The data in Table V show that this speculation is false for Tablet 1, but true for Tablet 2. For Tablet 1 at 50 rpm, the amount of drug dissolved per tablet remains relatively constant as the number of tablets per vessel is increased. For Tablet 2 at 75 rpm, the amount of drug dissolved per tablet decreases for the glass vessels[3] and increases for the plastic vessels until the amounts converge at about four tablets per vessel.

CONCLUSIONS

The glass vessels[3] are uniform and comply with USP specifications. At a given stirring rate, certain tablets may give higher dissolution rates in glass[3] than in plastic vessels. Although the results from Tablet 1 indicate that the vessel material is not important, the results from Tablet 2 indicate that tablets may significantly interact with the plastic or glass surface. Tablet 1 and Tablet 2 are affected to an unusual degree by minor changes in the test. However, if reproducible results are to be obtained for a wide range of products, it is important to specify which type of vessel was used in the dissolution test.

Sulpiride Pharmacokinetics in Humans After Intramuscular Administration at Three Dose Levels

FRANÇOISE BRESSOLLE *x, JANINE BRES *, MARIE DOMINIQUE BLANCHIN *, and ROBERTO GOMENI ‡

Received June 21, 1982, from the *Groupe de Recherche en Pharmacocinétique, Laboratoire de Chimie Analytique, Faculté de Pharmacie, Université de Montpellier, Montpellier 34060 and the ‡Laboratoires d'Etudes et de Recherches, Synthélabo-58, rue de la Glacière, Paris 75013, France. Accepted for publication July 1, 1983.

Abstract □ Pharmacokinetics of the disinhibitory psychotropic agent sulpiride was investigated in 9 healthy male subjects after intramuscular administrations of 50, 100, and 200 mg in a 3 × 3 Latin square design. Plasma and urine concentrations were measured by HPLC for 36 and 48 h, respectively. The lowest detectable concentration was 10 ng/mL. Plasma concentration *versus* time and urinary excretion rate *versus* time curves were consistent with an open two-compartment body model, where mean ±*SD* apparent half-lives of the absorption from muscle, λ_1 distribution, and λ_2 elimination phases were 6.96 ± 2.64 min, 0.220 ± 0.120 h, and 6.74 ± 2.67 h, respectively. The initial volume of distribution was 0.145 ± 0.063 L/kg, the steady-state volume of distribution was 0.639 ± 0.184 L/kg, and the total clearance was 89.8 ± 22.3 mL/min. The microscopic rate constants were $k_{12} = 2.53 \pm 1.13\ h^{-1}$, $k_{21} = 0.674 \pm 0.197\ h^{-1}$, and $k_{10} = 0.635 \pm 0.298\ h^{-1}$. Comparison of total clearance (89.8 mL/min), renal clearance (83.0 mL/min), and renal clearance of unbound drug (97.6 mL/min, $f = 0.15$) indicated that sulpiride is mainly excreted unchanged by the renal route, 93.1 ± 6.6% of the administered dose being recovered unchanged in urine. Statistical evaluation of all the above parameters, determined at the three dosage levels, did not show any variations related to dose; the pharmacokinetics of sulpiride, over the dose range tested, was therefore linear and independent of dose. The two-compartment body model proposed was validated by digital computer simulation on a small digital computer (32K).

Keyphrases □ Sulpiride—intramuscular administration, pharmacokinetics, humans □ Pharmacokinetics—intramuscular sulpiride, humans, HPLC

Sulpiride, 5-(aminosulfonyl)-*N*-[(1-ethyl-2-pyrrolidinyl)-methyl]-2-methoxybenzamide, a disinhibitory psychotropic drug belonging to the *o*-anisamide or substituted benzamide class of antipsychotic agents, is rapidly becoming an important psychotherapeutic agent in many parts of the world. Sulpiride is indicated mainly for the treatment of psychiatric disorders, peptic ulcers, and vertigo. At high dosage levels, it is a major nonsedative neuroleptic for use in acute psychosis, obsessional neurosis, and behavioral disorders. Sulpiride is characterized by its low incidence of extrapyramidal side effects, although it can induce endocrine effects, amenorrhea, or galactorrhea, probably as a result of direct interaction with prolactin cells. Benakis *et al.* (1) and Stefan *et al.* (2) demonstrated that the drug is specifically distributed into the pituitary.

Optimization of treatment with sulpiride requires knowledge of its bioavailability, pharmacokinetics, and metabolism in humans. The pharmacokinetic parameters determined after a single dose can then be used for adjustment of the dosage regimen and individualization of therapy.

The model which best describes the pharmacokinetics of a drug is that determined after intravenous administration or, when this is not possible, after administration by another route if absorption by this route is known to be rapid and total. Only then will the pharmacokinetic parameters determined be relevant. Sulpiride pharmacokinetics was investigated in humans after intravenous administration by Wiesel *et al.* (3, 4) and after intramuscular administration by Bres *et al.* (5–7) in order to choose the most appropriate model to describe the fate of sulpiride in humans and to determine the absolute bioavailability of several sulpiride preparations for oral administration. In bioavailability studies (5, 6), the intramuscular route was selected as the reference, following demonstration by the authors of bioequivalence between the intravenous and the intramuscular routes in the dog (8). All of these studies were conducted at one dose level only [1.5 mg/kg (3, 4), 6 mg/kg (5, 6), or 2.6 mg/kg (6)] and the linearity of the kinetics in humans was never truly demonstrated, as it had been in the dog (8). In the study presented here, the pharmacokinetics of intramuscularly administered sulpiride was evaluated at three dose levels (50, 100, and 200 mg) in nine healthy volunteers to determine the relationships between plasma levels, areas under the curve, rate constants, volumes of distribution, clearances, amounts of sulpiride recovered unchanged in urine, and the administered doses, and to ascertain whether all data deduced from sulpiride plasma levels and urinary excretion rate data were consistent with the two-compartment model with first-order transfer among compartments and first-order elimination.

Plasma and urine concentrations of sulpiride were determined by an original HPLC technique (7), since it has been shown that HPLC is a valid method for assay of benzamides in biological fluids (3, 4, 9–11). This technique has an increase in specificity compared with the spectrofluorometric determination of Kleimola *et al.* (12–14) and an increase in sensitivity compared with the quantitative TLC method developed for our earlier studies (5, 6, 8, 15–17).

EXPERIMENTAL SECTION

Drug Products and Materials—Sulpiride[1], sulpiride ampules[2] for intramuscular injection (100 mg/2 mL) were furnished. Nicotinamide[3] (used as an internal standard) was purchased. All chemicals and solvents were of analytical grade. Methanol and chloroform were twice-distilled in an all-glass apparatus before use. These solvents and distilled water were filtered through a 0.45-μm filter[4] before use.

Subjects—The study was conducted with nine male Caucasian subjects (25.6 ± 3.2 years) in good health as determined by screening, laboratory tests including hematology, urinalysis, blood chemistry (SMA-12), electrocardiogram, history, physical examination, and creatinine clearance. They were within the normal range for height (179 ± 6 cm) and weight (68.7 ± 5.0 kg) and had no history of recent drug intake or allergy. All laboratory parameters were monitored before and once during the study. The subjects were fully informed of study design and were given all available data on sulpiride clinical and toxicological studies.

Study Design—Each subject received three different treatments, randomly allocated according to three series of 3 × 3 Latin squares (Table I); at least 7 d were allowed between treatments. Each person received no medication for at least 48 h before the drug administration. They fasted for 12 h prior to and 4 h after each drug administration. Food and water were then taken as usual. Water (300 mL) was taken before each dosage administration.

Each subject received a single dose of 50, 100, or 200 mg im of sulpiride into the upper outer quadrant of the gluteus muscle. A catheter was placed in a forearm vein and a continuous drip was maintained for the first 6 h after

[a] Randomized with a 3 × 3 Latin square design.

drug administration, during which time the subjects were nonambulatory.

Blood samples were obtained by venipuncture immediately before and 5, 10, 15, 20, 25, 30, 35, 40, 45, 60, 90 min, 2, 3, 4, 5, 6, 8, 10, 12, 16, 24, 30 and 36 h after each injection. Urine specimens were collected before drug administration and for the following intervals after the injection: 0-1, 1-2, 2-3, 3 4, 4-5, 5-6, 6-8, 8-10, 10-12, 12-16, 16-24, 24 28, 28-32, 32-36, and 36-48 h.

Sample Collection—Blood samples were collected in heparinized tubes and immediately centrifuged; the plasma was removed and immediately frozen. The voided urine was collected, the total volume recorded, and an aliquot was placed in vials and stored frozen until analysis.

Assay Method—*Instrumentation*—The chromatograph[5] was connected to a 10-μL automatic loop injection system, a multiple-wavelength detector[6], and a computing integrator[7]. Chromatography was performed on a reverse-phase column[8] (filled in-house) with a precolumn[9], to extend column life.

The mobile phase contained 30 parts of methanol and 70 parts of 0.1 M ammonium acetate. The temperature was ambient, and the flow rate was 1.0 mL/min. The detector was set at 0.002 AUFS (197 nm), and the chart speed was 0.25 cm/min.

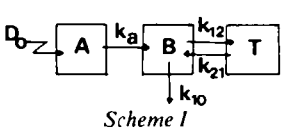
Sample Preparation—Plasma or urine (1-4 mL) was treated with 0.5 M NaOH (0.2 mL) and the pH was adjusted to 10. After extraction with 15 mL of chloroform for 20 min and centrifugation, a 15-mL aliquot of the organic phase was retained. After further extraction with 5 mL of chloroform, an additional 5 mL of the organic phase was retained. An internal standard was added (0.4 mL of nicotinamide at 1 mg/L in methanol for plasma and 1.0 mL of nicotinamide at 10 mg/L in methanol for urine) to the combined organic phases, and the extracts were evaporated to dryness. Before HPLC analysis, 0.3 mL of the mobile phase was added. After ultrasonic mixing[10], 10 μL of this solution was injected into the column by the automatic loop injection system.

The peak area ratio of sulpiride to nicotinamide (internal standard) was used as the assay parameter. Calibrations curves in control plasma (4 mL) were prepared for each two experiments from spiked pooled plasma samples of two subjects at concentrations of 20, 40, 50, 100, and 150 ng/mL. Calibration curves in control urine (2 mL) were prepared for each experiment from spiked urine samples of each subject at the concentrations of 0.5, 1.25, 6.25, 12.5, and 25 μg/mL. They were processed in the same manner as the *in vivo* samples.

Data Analysis—The plasma concentration of sulpiride for each subject was modeled using a two-compartment open model (Scheme I) with first-order absorption after intramuscular administration. The structural model describing the serum concentration C_p at time t is given by (18, 19):

$$C_p = \frac{k_a F D}{Vd_1}\left[\frac{(k_{21}-\lambda_1)e^{-\lambda_1 t}}{(k_a-\lambda_1)(\lambda_2-\lambda_1)} + \frac{(k_{21}-\lambda_2)e^{-\lambda_2 t}}{(k_a-\lambda_2)(\lambda_1-\lambda_2)} + \frac{(k_{21}-k_a)e^{-k_a t}}{(\lambda_1-k_a)(\lambda_2-k_a)}\right] \quad \text{(Eq. 1)}$$

where Vd_1 is volume of distribution in the central compartment, F is fraction



Scheme I

of dose D absorbed, λ_1 and λ_2 are first-order disposition rate constants in the distribution and elimination phases, k_{21} is the first-order transfer rate constant from the tissue compartment to the central compartment, and k_a is the first-order absorption rate constant from the muscle. Equation 1 is equivalent to:

$$C_p = -C_1' e^{-k_a t} + C_1 e^{-\lambda_1 t} + C_2 e^{-\lambda_2 t} \quad \text{(Eq. 2)}$$

The coefficients and exponents of the exponential terms were determined by an extended least-squares method..

The dispersion error on the measured concentrations was not known, so we decided to estimate the structural model parameters minimizing the log-likelihood function:

$$L = \sum_{i=1}^{N} \frac{(y_i - C_{pi})^2}{V_i} + \ln V_i \quad \text{(Eq. 3)}$$

where V_i is the error variance of the ith observation C_{pi}. Note that usually weighted least squares are appropriately used when it is assumed that the error variance is known up to a proportional factor. In our case the error variance is not known, so according to Sheiner (20) the following variance model was assumed:

$$V_i = a \times C_{pi}^b \quad \text{(Eq. 4)}$$

where a and b are variance model parameters. This is a reasonable model because it generalizes the usual weighting scheme applied to the weighted regression analysis, *e.g.*, for $a = 1$ and $b = 1$ the variance model becomes $V_i = C_{pi}^2$ and the weight is $1/y^2$. The exponential parameters as well as the error model parameters were estimated using the AUTOMOD II program (21-23) using a computer[11].

The microscopic rate constants k_{12} (first-order transfer rate constant from the central compartment to the tissue compartment), k_{21} (as previously determined), and k_{10} (first-order elimination rate constant from the central compartment) were determined from the coefficients and exponents of Eq. 2 (20). The total area under the plasma drug concentration-time curve (AUC_∞) was calculated from $AUC_{36\,h} + C_{36\,h}/\lambda_2$; $AUC_{36\,h}$ was calculated by the trapezoidal rule. Total body clearance, CL_{tot}, of sulpiride was calculated from the ratio of the dose of sulpiride and AUC_∞. The renal clearance, CL_r, of sulpiride was estimated either from the ratio of the amount of sulpiride eliminated unchanged in urine and the total area under the curve or from the slope of the plot of excretion rate *versus* plasma drug concentration at the midpoint of the drug excretion intervals.

The volume of distribution in the central compartment was evaluated by $Vd_1 = D \times k_a/[C_2 \times (k_a - \lambda_2)] + [C_1 \times (k_a - \lambda_1)]$; the volume of distribution in equilibrated tissues was evaluated by $Vd = CL_{tot}/\lambda_2$, and the steady-state volume of distribution was evaluated by $Vd_{ss} = Vd_1 \times (1 + k_{12}/k_{21})$. A pharmacokinetic analysis of the urinary excretion rate of sulpiride *versus* time curves (rate plot) and of amount of sulpiride remaining to be excreted *versus* time curves (σ^- plot) was undertaken for each subject using the GPHARM (24) computer program[12]. In some subjects three rate constants could then be determined for the absorption from muscle (phase 1), distribution (phase 2), and elimination (phase 3) processes, but in most of the subjects only the two latter phases could be measured with accuracy.

Digital Computer Simulations—Multicompartmental simulations on a small digital computer (32K)[12] was performed employing the GPHARM computer program (18, 24). The dose is introduced into an absorption compartment ($A = 5$). It then reaches the central compartment ($B = 1$), is distributed between the central and tissue compartments ($T = 2$), and is eliminated in urine ($U = 3$) or by another route of elimination ($E = 4$) (Scheme II).

The experimentally obtained sulpiride concentrations (in μg/mL) in plasma were expressed as percent of administered dose per milliliter of plasma and multiplied, for the three doses studied, by the mean initial volume of distri-

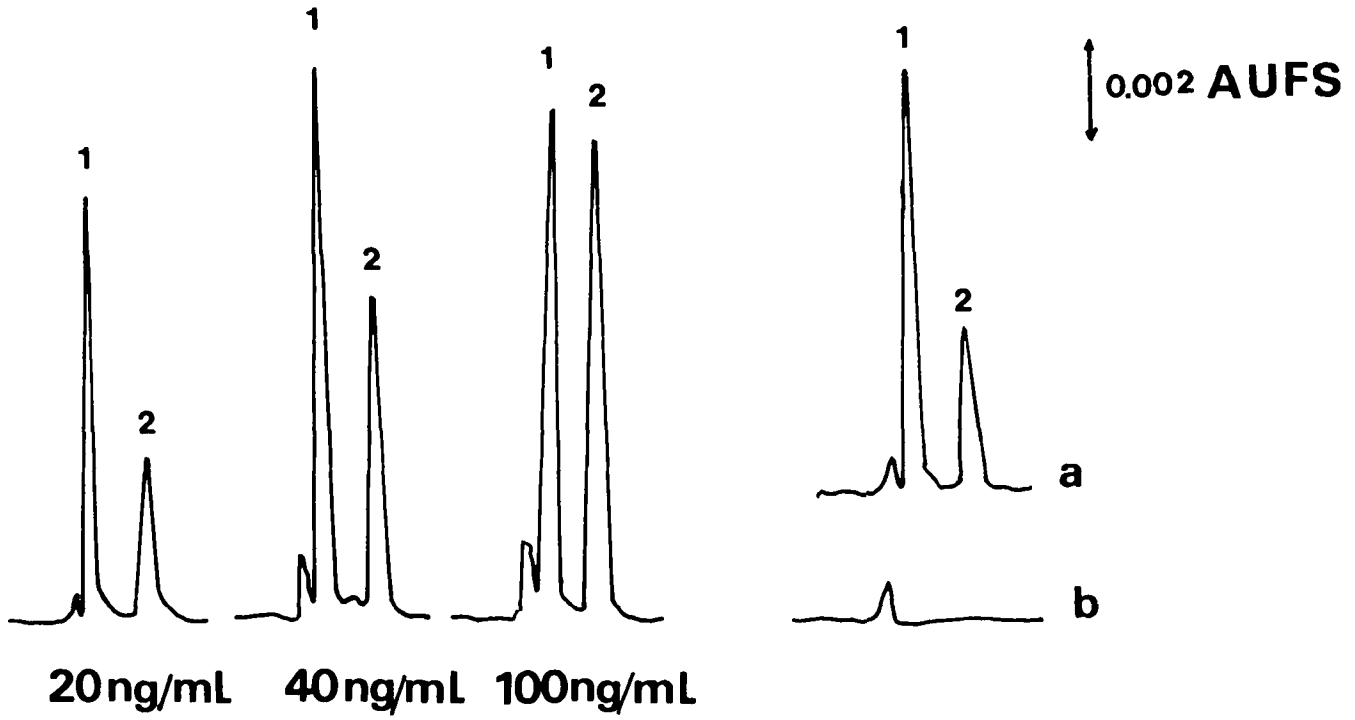

Figure 1—*Typical chromatograms obtained after injection on a Hypersil ODS column of 10-μL aliquots of the chloroform extracts of 4 mL of plasma spiked with sulpiride (20, 40, and 100 ng/mL) or taken from subject 3 before (b) and after (a) intramuscular administration of 96 mg of sulpiride.*

bution Vd_1 in order to obtain sulpiride amounts in the central compartment in terms of percent of administered dose (with the assumption that $F = 1$). For each subject, and for the three doses studied, these values and the experimentally obtained amounts of sulpiride excreted in urine as percent of administered dose were plotted against time. To account for the elimination of the remaining dose, another route of elimination from the central compartment was introduced into the model, so that at all times the mass balance was 100% of the dose.

For each subject, the mean microscopic rate constants obtained after pharmacokinetic analyses at the three dosage levels were taken as a first estimate for the simulations. They were then slightly modified to obtain the best fit between the curves generated with these values for plasma and urine and the experimentally obtained sulpiride amounts in plasma and urine at all times for the three doses.

Statistical Analysis—An analysis of variance on a randomized 3 × 3 Latin square design was performed on all the pharmacokinetic parameters determined to test variability between sequence of administrations, between doses, and between subjects.

RESULTS

Sensitivity and Reliability of the Analytical Method—Retention times were 12 min for sulpiride and 6.8 min for the internal standard nicotinamide. There were no major interfering peaks in control plasma and urine samples at the retention times of the aforementioned compounds (Fig. 1). To improve the reliability of the assay, each sample was injected in triplicate. Detection limits, evaluated by the amounts of samples yielding a detector response equal to twice the detector noise, was 10 ng/mL. Recovery after extraction from the plasma and urine was 98%. A five-point calibration curve was run with every set of 50 samples, and the method was validated with spiked samples every 10 samples throughout the duration.

In plasma, the peak area ratio (R) of sulpiride over the internal standard varied linearly with concentration over the range used. These calibration curves passed through the origin with a slope $\pm SD$ of $146.4 \pm 0.54 \times 10^{-4}$ ng^{-1} mL and a coefficient of the linear regression analysis of 0.9998 ± 0.0001 ($n = 10$) (Fig. 1). The intercept was not significantly different from zero ($13.8 \pm 4.48 \times 10^{-3}$). For the urine samples the reliability of the assay was of the same magnitude, with a slope of $579 \pm 1.9 \times 10^{-3}$ ng^{-1} mL, an intercept of $12.7 \pm 10.1 \times 10^{-3}$, and a correlation coefficient of 0.999979 ± 0.000013 ($n = 10$).

A stability study of plasma and urine samples stored at −20°C showed that sulpiride was stable over 3 months. Storage of samples during the present studies did not exceed 3 months.

Pharmacokinetic Analysis—After the maximum, sulpiride plasma concentration follows a biexponential decay. For each subject, the three curves obtained after 50-, 100-, and 200-mg im administrations were parallel when concentration units were μg/mL (Fig. 2), and superimposable when concentrations are expressed as percent of administered dose per milliliter of plasma (Fig. 3). These results are consistent with a two-compartment body model with first-order transfers among compartments and first-order elimination (Scheme I). All the pharmacokinetic parameters included in this model were first evaluated by the residual method or "exponential stripping" using the GPHARM program (24), and their values have been reported by Blanchin

(7). The parameters so estimated were used as starting values for the more refined extended least-squares maximum-likelihood method to obtain the best possible evaluation (20-23) (Table II).

Absorption from muscle is fast and complete, but an important inter- and intrasubject variability was observed. The lag time determined in each case with the program used was always negligible. The mean half-lives of the λ_1 distribution and λ_2 disposition phases were 0.220 ± 0.120 and 6.74 ± 2.67 h, respectively; these values are in good agreement with those reported by Imondi *et al.* (25) and Wiesel *et al.* (3), but they differ from those we reported previously (5, 6).

Distribution in peripheral tissues was rapid (k_{12} = 2.53 ± 1.13 h^{-1}), with a rate of transfer from tissue to plasma of the same order of magnitude (k_{21} = 0.674 ± 0.197 h^{-1}) as the elimination rate constant (k_{10} = 0.635 ± 0.298 h^{-1}). The apparent volume of distribution of the central compartment, Vd_1 = 0.145 ± 0.063 L/kg, was very close to the extracellular water volume (from 0.15 to 0.20 L/kg in humans), while the apparent volume of distribution at steady state, Vd_{ss} = 0.639 ± 0.184 L/kg, seemed to correspond to total water, which varies in humans from 0.45 to 0.65 L/kg. Total plasma clearance was 89.8 ± 22.3 mL/min. For each subject the cumulative urinary excretion curves as percent of administered dose were superimposable; the rate and extent of sulpiride elimination in urine in the form of unchanged drug does not, therefore, seem to depend on the dose administered (Table II).

Elimination of sulpiride after intramuscular administration was mainly *via* the renal route, since 93.1 ± 6.6% was recovered unchanged in the urine. Renal clearance, evaluated from total amount of sulpiride eliminated unchanged in urine divided by AUC_∞, was 83.0 ± 19.8 mL/min, while the renal clearance evaluated from the slope of the plot of urinary excretion rate *versus* plasma concentration at the midpoint of the drug excretion interval was 62.3 ± 22.3 mL/min. Sulpiride renal clearance was 83.0 mL/min when total sulpiride (free and bound) was assayed in plasma. If the fraction bound to plasma protein was f = 0.15 (26), free sulpiride clearance would be 97.6 mL/min.

The apparent rate contants of the absorption, distribution, and elimination phases, determined from the variations with time of the urinary excretion rate (rate method) or from the variations with time of the amount remaining to be excreted (σ^- method), were close to those determined from plasma data (Fig. 4, Table II). Mean elimination half-lives determined by these two methods were 5.58 ± 1.41 and 5.68 ± 1.52 h, respectively.

Linearity—To test the linearity of sulpiride pharmacokinetics all the individual data were normalized by the dose administered and fitted to the full model of data (structural and error model). Using 3 × 3 Latin-square analysis of variance, the following parameters were then compared: time to peak and peak plasma levels, area under the time concentration curve, amount of drug excreted unchanged in the urine, λ_1, λ_2, k_a, k_{12}, k_{10}, total clearance, and renal clearance. The analyses did not show any sequence nor dose effects. While the interindividual variations with dose of all parameters are small, large variations are observed between subjects (Table III). Of all the parameters tested, clearance was the most variable within subjects and for a same subject within administration (Fig. 5). The system is linear and time invariant, because all the pharmacokinetic parameters are independent of drug concentration and time. It would appear that distribution and elimination kinetics of sulpiride in humans are linear over the dose range tested.

Validation of the Proposed Model by Digital Simulation—The two-compartment model was validated by digital simulation employing the mean microscopic rate constants determined for each subject after intramuscular administration at the three dosage levels. The good fit obtained between the simulated curves (percent of dose in the central compartment) and the experimental points after the maximum, at the three dosage levels, allowed a single value for each parameter to be given for each subject.

These values were for all subjects in the study (Table IV): k_a = 9.36 ± 1.84 h^{-1}, k_{12} = 1.36 ± 0.47 h^{-1}, k_{21} = 0.61 ± 0.15 h^{-1}, k_{10} = 0.53 ± 0.13 h^{-1}, Vd_1 = 0.18 ± 0.02 L/kg, and Vd_{ss} = 0.57 ± 0.08 L/kg. Simulated curves for the peripheral compartment showed that marked distribution in tissues did not occur. At the maximum tissue level, 40-60% of the administered dose was present in tissues (Fig. 6); after this maximum and up to 10 h, the total amount of sulpiride in the tissues was ~1.5-2 times higher than that in the central

[a] The administered dose was determined by weighing the syringe before and after the injection. [b] Renal clearance estimated from slope of the plot of excretion rate *versus* plasma drug concentration at midpoint of the drug excretion intervals is indicated in parentheses.

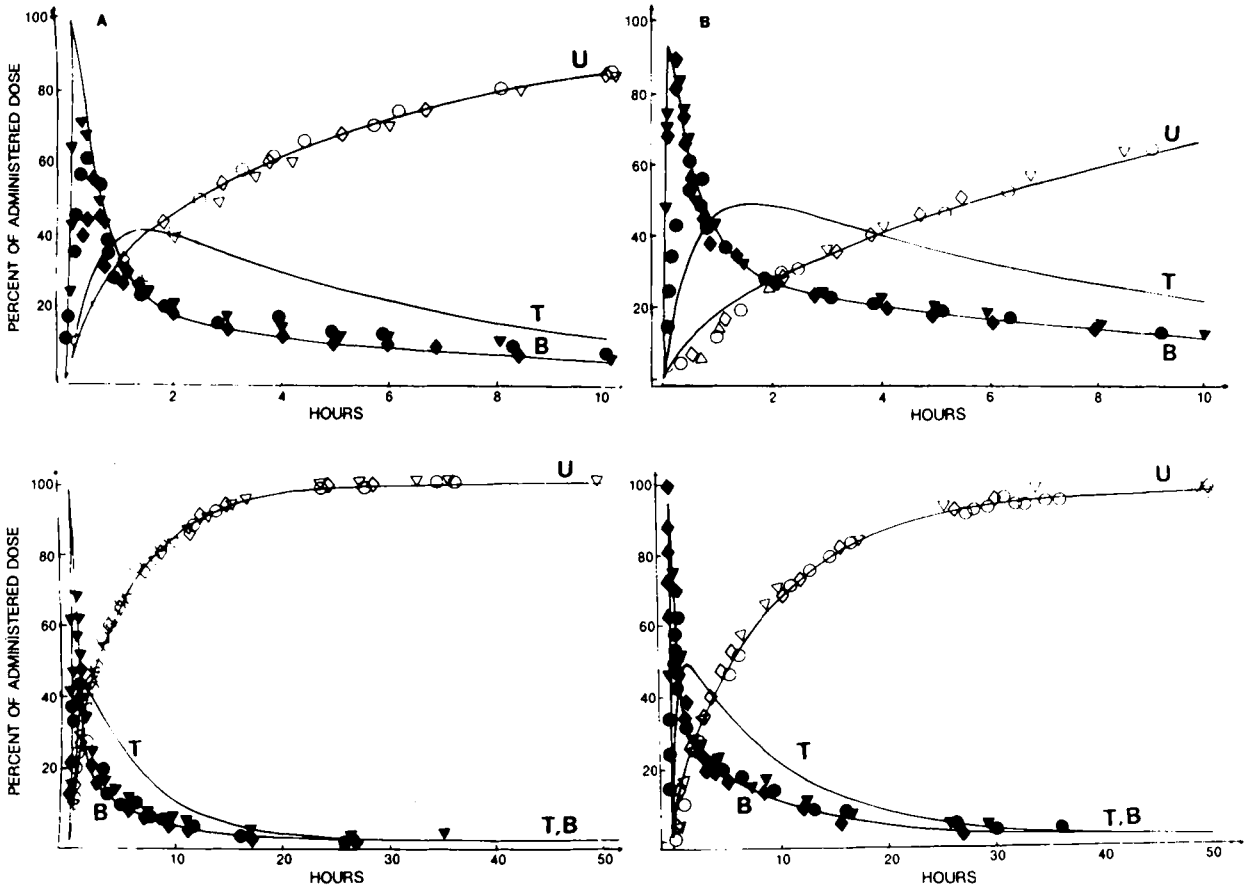

Figure 6—*Digital computer-fitting of sulpiride plasma (B) and urine (U) data following intramuscular administration of sulpiride, 50 (♦, ◇), 100 (▼, ▽), 200 mg (●, ○), to subjects 6 (A) and 5 (B). The curves labeled T are computer-generated amounts of sulpiride in the tissues in accordance with an open two-compartment model with first-order rates of transfer and elimination.*

compartment. The good fit obtained between the experimental points for urine and the curves generated from plasma data, at the three dosage levels, validates the proposed model.

DISCUSSION

Distribution in Peripheral Tissues—Distribution in the peripheral tissues can be estimated from the pharmacokinetic model consistent with sulpiride fate in humans. After intravenous (3) or intramuscular administration (5–7), plasma sulpiride levels follow a biexponential decay in most of the subjects. Two apparent rate constants can be determined for the λ_1 distribution and λ_2 elimination phases (Table V), since after intramuscular administration, absorption from the muscle is rapid and total. These results are consistent with a two-compartment open model with first-order transfer between compartments and first-order elimination from the central compartment. In four subjects (one male and three female), Bres *et al.* (5, 6) reported that only one phase of elimination was apparent since the distribution was too rapid to be detectable and the data were consistent with a one-compartment body model. Wiesel *et al.* (3) reported for two subjects, after intravenous administration, a triexponential decay consistent with a three-compartment body model. The terminal log-linear phase had half-lives of 11 and 13.9 h for the two subjects, respectively. The deep compartment added to fit the data in these cases did not modify the distribution rate constants between the central compartment and the shallow compartment (k_{12} and k_{21}).

[a] NS = not significant.

Rate Constants of Transfer Between Compartments—The microscopic rate constant of transfer from the central compartment to the peripheral tissues (k_{12}), which regulates the amount going to tissues, had a values of 2.19 h^{-1} (5, 6), 2.29 h^{-1} (3), and 2.53 h^{-1} (Table V). The rates of transfer from tissues to plasma (k_{21}), which regulates output from tissues, were 1.24 h^{-1} (5, 6), 0.703 h^{-1} (3), and 0.674 h^{-1} (in this study). These values were of the same magnitude as the elimination microscopic rate constant, k_{10}. The values found in this study were consistent with those found in our earlier study and the values reported by Wiesel *et al.* (3) with different routes of administration and final sampling times.

In our earlier studies (5, 6), the large number of samples taken up to 10 h allowed good determination of k_{10}, even if the value of λ_2 was overestimated. The differences for k_{10} reported in these three studies, 0.73, 0.686, or 0.635 (mean) h^{-1}, were smaller than the differences reported for λ_2 (0.22, 0.103, or 0.103 (mean) h^{-1}; Table V).

[a] Blood (0-10 h) and urine (0-24 h) were collected from 1 male and 11 female subjects; the amount of drug was determined by quantitative TLC with UV detection (plasma). The data were fit to a one- or two-compartment model (5, 6). [b] Blood and urine were collected for 0-36 h from three male and three female subjects; the amount of drug was determined by HPLC with fluorometric detection (serum). The data were fit to a two- or three-compartment model (3). [c] Blood (0-30 h) and urine (0-48 h) were collected from nine male subjects; the amount of drug was determined by HPLC with UV detection (plasma). The data were fit to a two-compartment model (this research).

Volumes of Distribution—Large variations were apparent in the values reported by the authors for the volume of distribution of the central compartment and for the volume of distribution at steady state (Table V). The apparent volume of distribution of the central compartment (Vd_1) was very close to extracellular water (0.15 to 0.20 L/kg) in humans; the apparent volumes of distribution at steady state (Vd_{ss}) of 1.06 and 0.639 L/kg seemed to correspond with total body water, which ranges from 0.45 to 0.65 L/kg in humans. The slightly higher value reported by Imondi *et al.* (25), 1.8 L/kg, is overestimated. Since sulpiride was administered orally, the calculated volume of distribution (Vd/F), would give a value of 0.6 L/kg for Vd if the absorption coefficient F were 0.30.

These results are in accordance with the very low lipophilic properties of sulpiride, which should lead to a poor distribution in tissues and thus to a volume of distribution close to total body water volume. The high value of Vd_1 (0.53 L/kg) and Vd_{ss} (2.7 L/kg) found by Wiesel *et al.* (3) are related to the low plasma levels found either after oral or intravenous administration by these authors. It could be that within-subject variations of the distribution parameters gave rise to these differences between the populations studied. In our earlier study (5, 6), all the subjects but one were females and the volume of distribution was significantly higher than in the recent study conducted exclusively in male subjects. In three female and one male subject, the distribution phase was not apparent after intramuscular administration (5, 6). There could be sex-related variations in the distribution pattern of sulpiride in humans.

Total Elimination from Plasma—*Half-Life of Elimination*—The half-life of sulpiride elimination from the body was evaluated either from plasma data by the slope of the log-linear terminal part of the plasma concentration *versus* time curve (Table V), from the urinary excretion rate *versus* time curve plot (rate plot), and the amount remaining to be excreted *versus* time plot (σ^- plot) (Table VI). The mean values obtained by these three methods were very close and ranged from 6 to 8 h.

Wiesel *et al.* (3) obtained elimination half-lives of 6.75 h (λ_2) and 7.15 h (dU/dt) after intravenous administration. In this study, we report elimination half-lives after intramuscular administration of 6.87 h (λ_2), 5.58 h (dU/dt), and 5.68 h ($U_\infty - U$). These values, obtained either after intramuscular or intravenous administration, with a sample collection lasting up to 36 h, should be the closest values to the true ones. When plasma and urine samples were collected for a shorter period than in these studies, the terminal log-linear part of the curves was not reached and the half-life was underestimated (the rate constant was overestimated). Bres *et al.* (5, 6) reported elimination half-lives after intramuscular administration of 3.11 h (λ_2), 3.73 h (dU/dt), and 3.33 h ($U_\infty - U$), while after oral administration these values were 3.0, 3.6, and 3.0 h, respectively (Table VI).

Total Clearance—Total plasma clearances, estimated from the ratio of dose/AUC were 415 mL/min after intravenous administration (3) and 220 mL/min (5, 6) or 89.8 mL/min (this study) after intramuscular administration. The large differences observed in these three studies were related to variations in the volumes of distribution at steady state (Table V).

Excretion in Urine in the Form of Unchanged Sulpiride—*Extent of Sulpiride Elimination in Urine*—Sulpiride is mainly eliminated from plasma by the renal route. After intravenous administration of the drug, Wiesel *et al.* (3) found 72.3 ± 8.9% of the administered dose in urine over a 36-h period. After intramuscular administration, Bres *et al.* (5, 6) found 82.9 ± 7.4% of administered dose in urine (24-h collection). In this study, 93.1 ± 6.6% was found in urine, almost all the administered dose (48-h collection; Table VI).

Rate Constant of Elimination—The rate of elimination of sulpiride in urine was identical to the rate of disappearance of sulpiride from the plasma. The fraction of administered dose eliminated unchanged in urine is close to 1.0; nevertheless, another route of elimination had to be introduced for the simulations (Scheme II, with $k_{10} = k_{13} + k_{14}$).

Renal Clearance—The renal clearances of sulpiride were 310 mL/min after intravenous administration (3) and 190 mL/min (5, 6) or 83.0 mL/min (this study) after intramuscular administration. The large variations observed in these studies and the interindividual variations, estimated from the standard deviations, are mainly related to changes in the sulpiride apparent volume of distribution within subjects. The renal clearance of sulpiride, while slightly lower than the total clearance, is a good reflection of the sulpiride total

Table VI—Sulpiride Elimination[a]

clearance from plasma. Since renal clearances of sulpiride and creatinine were simultaneously evaluated in all subjects in this study (Table I), we attempted to correlate these two values. With the large intraindividual variability (Table II, Fig. 5) in sulpiride renal clearance, it was not possible to find a positive correlation with creatinine clearance, but subjects 3 and 9 who had the highest sulpiride clearances also had the highest creatinine clearances.

Pulmonary Absorption and Excretion of Compounds in the Gas Phase: Theoretical Pharmacokinetic and Toxicokinetic Analysis

PETER VENG-PEDERSEN

Received September 1, 1982, from *Division of Pharmacokinetics, School of Pharmacy, Purdue University, West Lafayette, IN 47907.* Accepted for publication July 29, 1983. Present address: College of Pharmacy, University of Iowa, Iowa City, IA 52242.

Abstract □ Kinetic equations were derived that describe the plasma concentration of an inhaled compound during and following single or repeated regular and irregular pulmonary exposures. The equations are based on a diffusional type of input function and assume a linear disposition with a biexponential unit-impulse response. The use of linear system analysis avoids the complexity of modeling the disposition processes; yet, the effect of these processes is still accounted for mathematically. The approach, therefore, appears to be more general and rational than approaches based on linear compartmental modeling. The ways in which the kinetic equations can be readily applied in pharmacokinetic or toxicokinetic analyses to obtain valuable parameters that enable kinetic predictions of the cumulation during prolonged exposure are discussed. The toxicokinetic problem of comparing the effect of different work schedules in occupational environments with air contaminants is discussed. Formulas derived from considerations of the blood plasma kinetics are presented for the calculation of an adjustment factor for the adjustment of the contaminant threshold limit value for abnormal work weeks. The use of these formulas appears to be more rational than that of similar formulas that have been proposed.

Keyphrases □ Absorption—pulmonary, excretion, theoretical pharmacokinetic and toxicokinetic analyses □ Pharmacokinetics—pulmonary absorption and excretion, toxicokinetics □ Toxicokinetics—pulmonary absorption and excretion, pharmacokinetics

Little attention has been given to the pharmacokinetic-toxicokinetic characterization of the pulmonary absorption and excretion of compounds in the gas phase. The kinetic investigations of the volatile drugs used in general anesthetics has been limited mainly to empirical quantitative analysis of uptake, metabolism, and pulmonary excretion (1–3), without a formal mathematical, pharmacokinetic analysis of the plasma level-time profile (4, 5).

The study of pulmonary absorption kinetics is also of particular interest in environmental toxicology (6–9). Special attention has been given to the risk assessment of work place exposures to vaporous air contaminants. Of particular concern

has been the effect of the work schedule on the toxicokinetic effect (10–15). It is recognized that an assessment of the toxic effect cannot simply be determined on the basis of exposure level and total exposure time. Two different work schedules with the same exposure level and the same total hours of exposure may give substantially different plasma and tissue levels resulting in different toxic effects. Therefore, attempts have been made to predict and compare the biological effect of different work schedules by using the exposure limits established by the U.S. government, since these limits are based on exposures of a normal work week schedule (16, 17). However, the formulas that have been proposed are based on a one-compartment kinetic model, despite the fact that most gases show definite biphasic kinetics (10–14). The shortcomings of conceiving the body as exhibiting properties of a single compartment are well recognized (18). The formulas that have been proposed inappropriately deal with "the body burden" (the total amount of substance in the body) instead of plasma concentration (10, 11). Not only is it virtually impossible to experimentally determine "the body burden," but it is also misleading and inaccurate to conceive the body as a "homogeneous box," ignoring the pronounced tissue distribution of volatile lipophilic substances. The formulas presented are essentially "one-point comparisons" that only consider the peak "body burdens" (10, 11). No attempts have been made to describe the complete kinetics (10, 11).

The work presented here should overcome the shortcomings of previous analyses through a rigorous pharmacokinetic analysis that is based on more realistic and rational kinetic assumptions. A linear system-analysis approach is used to account for the disposition kinetics. This model-independent system approach requires fewer assumptions and is more general than conventional classical compartmental approaches and, therefore, should provide a more rational toxicokinetic basis for the development of exposure guidelines. By giving a complete pharmacokinetic description of the plasma level–time profile during and following multiple daily or weekly exposures, the analysis allows criteria other than peak plasma levels to be considered in a toxicokinetic assessment. By using this analysis, the daily and weekly accumulation effects are isolated and considered, thereby facilitating the assessment of prolonged exposures.

THEORETICAL SECTION

Single-Exposure Kinetics—The mass transfer rate $f(t)$ of a gas into the blood plasma from inhaled air containing a gas at a concentration C_g can be described by:

$$f(t) = K_1[C_g - K_2 \cdot c(t)] \qquad (0 \le t > T) \qquad \text{(Eq. 1)}$$

during the exposure period and:

$$f(t) = 0 \qquad (t \ge T) \qquad \text{(Eq. 2)}$$

in the postexposure period.

K_1 is a positive constant, and K_2 is the air/plasma partition coefficient of the gas. The plasma concentration of the gas [$c(t)$] depends on the input rate $f(t)$, as well as the disposition (distribution, metabolism, and excretion) of the gas in the body. It is assumed that the disposition processes result in a linear kinetic system in the sense that the superposition principle holds, so that the plasma response $c(t)$ is related to the systemic input rate, $f(t)$, by[1]:

$$c(t) = \int_0^t f(u)c_\delta(t-u)du \qquad \text{(Eq. 3)}$$

where $c_\delta(t)$ is the unit impulse response.

[1] See references 19–22 for a discussion of linear system analysis in pharmacokinetics.

The pulmonary excretion of gases appears to be well characterized by a biexponential decay, indicating that the unit-impulse response can be described by a biexponential expression:

$$c_\delta(t) = Ae^{-\alpha t} + Be^{-\beta t} \qquad (A, B, \alpha, \beta > 0) \qquad \text{(Eq. 4)}$$

The choice of Eq. 4 is also supported by the fact that most volatile drugs show a biexponential response to a bolus input.

Insertion of Eqs. 1 and 4 into Eq. 3 yields:

$$c(t) = \int_0^t K_1[C_g - K_2c(u)][Ae^{-\alpha(t-u)} + Be^{-\beta(t-u)}]du \qquad (t < T)$$

$$\text{(Eq. 5)}$$

Equation 5 is recognized as a Volterra integral equation of the second kind with a convolution-type kernel and can therefore be solved by Laplace transforms giving:

$$c(t) = K_1C_g[A'(1 - e^{-\alpha' t}) + B'(a - e^{-\beta' t})] \qquad (t < T) \qquad \text{(Eq. 6)}$$

where $-\alpha'$ and $-\beta'$ are the roots of the polynomial:

$$P(s) = (s + \alpha)(s + \beta) + K_1K_2[A(s + \beta) + B(S + \alpha)] \qquad \text{(Eq. 7)}$$

[$P(-\alpha') = P(-\beta') = 0$], and A' and B' are given by:

$$A' = \frac{A(\beta - \alpha') + B(\alpha - \alpha')}{\alpha'(\beta' - \alpha')} \qquad \text{(Eq. 8)}$$

$$B' = \frac{A(\beta - \beta') + B(\alpha - \beta')}{\beta'(\alpha' - \beta')} \qquad \text{(Eq. 9)}$$

Equation 6 describes the plasma level of the gas during the exposure period only. The plasma level in the postexposure period is subsequently obtained from the following:

$$c(t) = \int_0^T K_1[C_g - K_2c(u)][Ae^{-\alpha(t-u)} + Be^{-\beta(t-u)}]du \qquad (t \ge T)$$

$$\text{(Eq. 10)}$$

where the $c(u)$ term is given by Eq. 6 by substituting t with the dummy integration variable u.

Equation 10 then gives:

$$c(t) = K_1C_gAe^{-\alpha t}\left[\frac{K_1K_2A'}{\alpha - \alpha'} \cdot e^{(\alpha-\alpha')T} + \frac{K_1K_2B'}{\alpha - \beta'} \cdot e^{(\alpha-\beta')T} + \frac{\beta}{\alpha'\beta'} \cdot e^{\alpha T}\right] + K_1C_gBe^{-\beta t}\left[\frac{K_1K_2A'}{\beta - \alpha'} \cdot e^{(\beta-\alpha')T} + \frac{K_1K_2B'}{\beta - \beta'} \cdot e^{(\beta-\beta')T} + \frac{\alpha}{\alpha'\beta'} \cdot e^{\beta T}\right] \qquad \text{(Eq. 11)}$$

where $t \ge T$. The exposure solution (Eq. 6, $t < T$) and the postexposure solution (Eq. 11, $t \ge T$) can be combined to yield the following final equation, which describes the plasma concentration of the gas at any time during or after a single pulmonary exposure:

$$c(t) = A_T(t) \cdot e^{-\alpha(t-T)_+} + B_T(t) \cdot e^{-\beta(t-T)_+} \qquad \text{(Eq. 12)}$$

where:

$$A_T(t) = K_1C_gA\left(\frac{K_1K_2A'}{\alpha - \alpha'} \cdot e^{-\alpha' t'} + \frac{K_1K_2B'}{\alpha - \beta'} \cdot e^{-\beta' t'} + \frac{\beta}{\alpha'\beta'}\right) \qquad \text{(Eq. 13)}$$

$$B_T(t) = K_1C_gB\left(\frac{K_1K_2A'}{\beta - \alpha'} \cdot e^{-\alpha' t'} + \frac{K_1K_2B'}{\beta - \beta'} \cdot e^{-\beta' t'} + \frac{\alpha}{\alpha'\beta'}\right) \qquad \text{(Eq. 14)}$$

and

$$t' = t \text{ (for } t < T) \qquad \text{(Eq. 15)}$$

$$t' = T \text{ (for } t \ge T) \qquad \text{(Eq. 16)}$$

$$(t - T)_+ = 0 \text{ (for } t < T) \qquad \text{(Eq. 17)}$$

$$(t - T)_+ = t - T \text{ (for } t \ge T) \qquad \text{(Eq. 18)}$$

$A_T(t)$ and $B_T(t)$ are constants [$A_T(T)$, $B_T(T)$] in the postexposure phase ($t \ge T$); thus, Eq. 12 predicts a simple biexponential decay in this phase. The time coefficients in the decay are equal to those of the unit-impulse-response function (Eq. 4).

If the unit-impulse-response function is described by a single-exponential expression, $Ae^{-\alpha t}$, then Eq. 12 simplifies to:

$$c(t) = A_T'(t) \cdot e^{-\alpha(t-T)_+} \qquad \text{(Eq. 19)}$$

where:

$$A_T'(t) = \frac{K_1 C_g A}{\alpha + K_1 K_2 A} \cdot (1 - e^{-(\alpha + K_1 K_2 A)t'}) \quad \text{(Eq. 20)}$$

Multiple-Exposure Kinetics—*Regular Dosing Cycle*—Consider a repeated exposure cycle consisting of an exposure period of length T followed by a postexposure period of length H. The plasma kinetics during the first cycle are described by Eq. 12. At the start of the second cycle, there is a residual concentration of gas in the plasma equal to:

$$c_2(0) = A_T(T) \cdot e^{-\alpha H} + B_T(T) \cdot e^{-\beta H} \qquad (t_r = 0) \quad \text{(Eq. 21)}$$

The notation $c_n(t_r)$ is introduced here to denote the plasma concentration of the gas in the nth exposure cycle at a time t_r, measured relative to the start of the cycle (*i.e.*, relative to the start of the most recent exposure period).

Due to the superposition principle of linear systems, the plasma concentration of the gas in the second cycle is given by:

$$c_2(t_r) = A_T(T) \cdot e^{-\alpha(H+t_r)} + B_T(T) \cdot e^{-\beta(H+t_r)} + A_T(t_r) \cdot e^{-\alpha(t_r-T)+} + B_T(t_r) \cdot e^{-\beta(t_r-T)+} \quad \text{(Eq. 22)}$$

Thus, the residual plasma concentration at the start of the third exposure cycle is:

$$c_3(0) = A_T(T) \cdot e^{-\alpha(H+L)} + B_T(T) \cdot e^{-\beta(H+L)} + A_T(T) \cdot e^{-\alpha H} + B_T(T) \cdot e^{-\beta H} \quad \text{(Eq. 23)}$$

where L is the length of the exposure cycle:

$$L = T + H \quad \text{(Eq. 24)}$$

By deduction from Eqs. 21–23, it is concluded that:

$$c_n(t_r) = A_T(T) \cdot e^{-\alpha(H+t_r)} \sum_{j=0}^{n-2} e^{-jL\alpha} + B_T(t) \cdot e^{-\beta(H+t_r)} \sum_{j=0}^{n-2} e^{-jL\beta} + A_T(t_r) \cdot e^{-\alpha(t_r-T)+} + B_T(t_r) \cdot e^{-\beta(t_r-T)+} \quad \text{(Eq. 25)}$$

Equation 25 simplifies to the following final equation that describes the plasma concentration of the gas at any time (t_r) in any exposure cycle (n) during (or any time after) a regular repeated pulmonary exposure:

$$c_n(t_r) = \frac{1 - e^{-(n-1)L\alpha}}{1 - e^{-L\alpha}} A_T(T) \cdot e^{-\alpha(H+t_r)} + \frac{1 - e^{-(n-1)L\beta}}{1 - e^{-L\beta}} B_T(T) \cdot e^{-\beta(H+t_r)} + A_T(t_r) \cdot e^{-\alpha(t_r-T)+} + B_T(t_r) \cdot e^{-\beta(t_r-T)+} \quad \text{(Eq. 26)}$$

To simplify the notation and better conceptualize the cumulative effect of multiple exposures, it is convenient to introduce and define the function:

$$\phi_i(x) = \frac{1 - e^{-ix}}{1 - e^{-x}} = \sum_{j=0}^{i-1} e^{-jx} \quad \text{(Eq. 27)}$$

It can be seen in Eq. 26 that the first two terms of this equation represent the cumulation from the previous $(n-1)$ exposure cycles. Therefore, it appears to be more descriptive to present Eq. 26 in the following simplified form:

$$c_n(t_r) = A_T(t_r) \cdot e^{-\alpha(t_r-T)+} + B_T(t_r) \cdot e^{-\beta(t_r-T)+} + P_{n-1}(t_r) \quad \text{(Eq. 28)}$$

$P_{n-1}(t_r)$, the cumulation from the previous exposure cycles can, according to Eqs. 26 and 27, be simplified as:

$$P_{n-1}(t_r) = \phi_{n-1}(L\alpha) \cdot A_T(T) \cdot e^{-\alpha(H+t_r)} + \phi_{n-1}(L\beta) \cdot B_T(T) \cdot e^{-\beta(H+t_r)} \quad \text{(Eq. 29)}$$

Irregular Dosing Cycle Case.—In the context of occupational exposure to toxic substances, Eq. 28 is limited to a description of the kinetics during and following exposure to a gas for a single work week (or any fraction thereof). If there is a significant residual concentration left after the exposure-free weekend, then Eq. 28 should not be used for the second or subsequent work weeks. The following derivation includes cumulations from previous work weeks.

Consider a work schedule consisting of N working days (*i.e.*, N exposure cycles) and M nonworking days ($N + M = 7$). On each working day, the subject is exposed for T hours to a constant concentration (C_g) of a gas in the air. There are H hours between the exposure periods ($T + H = L = 24$), except for the period of nonworking days where there are ($H + M \cdot L$) hours without exposure. According to the superposition principle of linear systems, the plasma gas concentration at time t_r in the nth exposure cycle[2] in the mth work week is:

$$c_{n,m}(t_r) = c_n(t_r) + Q_{m-1}(t_r) \quad \text{(Eq. 30)}$$

where $c_n(t_r)$ is given by Eq. 28, and $Q_{m-1}(t_r)$ is given by Eq. 38. The function $Q_{m-1}(t_r)$ in Eq. 30, which is given by:

$$Q_{m-1}(t_r) = \sum_{i=1}^{m-1} c_N[(M+1)L + (m-i-1)7L + (n-1)L + t_r] \quad \text{(Eq. 31)}$$

represents the cumulations from the $(m-1)$ previous weeks. The residue from the exposure in week i ($i = 1, \ldots, m-1$) is derived as follows. The concentration left from this exposure is $c_N(t_i)$, where t_i is the time elapsed since the start of the last exposure cycle of the ith work week, and $c_N(\ )$ is given by Eq. 28 substituting n with N where N is the total number of exposure cycles in the work week. The time span t_i can be considered to consist of the following three components:

1. $(M+1)L$ is the time from the start of the last exposure cycle of week i to the start of the first exposure cycle of week $(i+1)$.
2. $(m-i-1)7L$ is the time from the start of the first exposure cycle of week $(i+1)$ to the start of the first exposure cycle of week m.
3. $(n-1)L + t_r$ is the time from the start of the first exposure cycle of week m to the current time t_r, where t_r as previously defined is measured relative to the start of the current exposure cycle, *i.e.*, cycle n. Thus:

$$t_i = (M+1)L + (m-i-1)7L + (n-1)L + t_r \quad \text{(Eq. 32)}$$

which is in agreement with Eq. 31.

The time span t_i stretches beyond the last exposure period of week i. Thus, according to Eqs. 28, 29, and 16, $c_N(t_i)$ becomes:

$$c_N(t_i) = A_T(T) \cdot e^{-\alpha(t_i-T)} + B_T(T) \cdot e^{-\beta(t_i-T)} + \phi_{N-1}(L\alpha) \cdot A_T(T) \cdot e^{-\alpha(H+t_i)} + \phi_{N-1}(L\beta) \cdot B_T(T) \cdot e^{-\beta(H+t_i)} \quad \text{(Eq. 33)}$$

According to $L = T + H$, Eq. 33 can be written:

$$c_N(t_i) = [1 + e^{-L\alpha} \cdot \phi_{N-1}(L\alpha)] A_T(T) \cdot e^{\alpha T} \cdot e^{-\alpha t_i} + [1 + e^{-L\beta} \cdot \phi_{N-1}(L\beta)] B_T(T) \cdot e^{\beta T} \cdot e^{-\beta t_i} \quad \text{(Eq. 34)}$$

This equation can be further simplified[3]:

$$c_N(t_i) = \phi_N(L\alpha) \cdot A_T(T) \cdot e^{-\alpha(t_i-T)} + \phi_N(L\beta) \cdot B_T(T) \cdot e^{-\beta(t_i-T)} \quad \text{(Eq. 35)}$$

To simplify the expression for the cumulation function $Q_{m-1}(t_r)$, it is convenient to rewrite the summation in Eq. 31 so that the formula in Eq. 27 can be employed:

$$Q_{m-1}(t_r) = \sum_{i=0}^{m-2} c_N(x_i) \quad \text{(Eq. 36)}$$

where:

$$x_i = (M-n)L + (m-2)7L - i7L + t_r \quad \text{(Eq. 37)}$$

When t_i is substituted by x_i in Eq. 35 and this equation is subsequently inserted in Eq. 36, the following final expression for the cumulation term in Eq. 30 is obtained:

$$Q_{m-1}(t_r) = \phi_N(L\alpha) \cdot \phi_{m-1}(7L\alpha) \cdot e^{-(M+n)L\alpha} \cdot A_T(T) \cdot e^{-\alpha(t_r-T)} + \phi_N(L\beta) \cdot \phi_{m-1}(7L\beta) \cdot e^{-(M+n)L\beta} \cdot B_T(T) \cdot e^{-\beta(t_r-T)} \quad \text{(Eq. 38)}$$

In deriving Eq. 37, the following property of the ϕ function was used:

$$e^{-(i-1)x} \cdot \phi_i(-x) = \phi_i(x) \quad \text{(Eq. 39)}$$

RESULTS AND DISCUSSION

The analysis described above is based on certain kinetic assumptions. It is assumed that the compound is present in the inhaled air at a constant concentration during the exposure. It is also assumed that the transport of the agent into the pulmonary blood plasma is proportional to the difference between the partial pressures of the agent in the inhaled air and in the blood plasma. It is assumed that the compound shows a linear disposition in the body in the sense that the linear superposition principle holds, so that input and plasma level response are functionally related through a convolution. Furthermore, it is assumed that the system is time invariant with a unit-impulse response that is well approximated by a biexponential expression. These assumptions that form the basis for the fundamental Eqs. 1–4 appear fairly well justified. The kinetics of gas diffusion is well understood, and many drugs and compounds have been shown to exhibit a linear disposition. In fact, a linear disposition is expected most often for compounds that are only slightly me-

[2] Note that the nth working day usually contains part of exposure cycle $(n-1)$ and cycle n, so it would be misleading in general to define n as the nth working day.

[3] Note that the ϕ function has the simple progression formula $e^{-x}\phi_{i-1}(x) = \phi_i(x) - 1$.

tabolized, such as the volatile, lipophilic compounds used in general anesthetics. The choice of a biexponential expression to represent the unit-impulse response appears to be appropriate, since this leads to kinetic equations that agree with the typical biexponential pulmonary excretion decay that is often observed. A biexponential expression also agrees with the elimination behavior most frequently seen in pharmacokinetic studies. The very distinct advantages of using a linear system approach instead of a classical compartmental approach have been discussed previously (19–22).

Three main equations have been derived that describe the plasma concentration of a gas at any time during or after (*a*) a single pulmonary exposure (Eq. 12), (*b*) a series of regular, constant exposures (Eq. 28), and (*c*) 1 or more weeks of exposures to a gas during the working days of the week (Eq. 30).

Single-Exposure Kinetics—The kinetic equation for a single pulmonary exposure (Eq. 12) is of particular pharmacokinetic interest, as it deals with the type of drug exposure found in general anesthetics. The equation also forms the basis for the multiexposure equations (Eqs. 28 and 30) that are of special toxicokinetic interest. An important use of the equation is in nonlinear regression analysis of single exposure data to obtain useful pharmacokinetic parameters. The data can be obtained either from a blood gas analysis or from excretion data obtained from the postexposure phase by analyzing the expired air for the gas.

Kinetic Analysis Based on Sampling of Expired Air—Pulmonary excretion data are typically in the form of the cumulative amount of gas excreted at various times, $M(t)$. According to Eq. 1, the rate of pulmonary excretion in the postexposure phase is $K_1K_2 \cdot c(t)$. Integration of Eq. 12 gives:

$$M(t) = \int_T^t K_1K_2 \cdot c(t)dt = K_1K_2 \frac{A_T(t)}{\alpha}[1 - e^{-\alpha(t-T)}] + K_1K_2 \frac{B_T(T)}{\beta}[1 - e^{-\beta(t-T)}] \qquad (t \geq T) \quad \text{(Eq. 40)}$$

In its simplest form, this equation is uniquely defined by only four quantities [$\alpha, \beta, K_1K_2 \cdot A_T(T)$, and $K_1K_2 \cdot B_T(T)$]. Therefore, it is not possible to determine all of the six basic parameters (*Appendix*) from pulmonary excretion data alone. However, Eq. 40 allows the two important parameters, α and β, to be accurately determined.

Although general kinetic predictions require that all six basic parameters (see *Appendix*) be determined, a closer analysis of Eq. 40 reveals that some important predictions can still be made from pulmonary excretion data alone. For example, it can be predicted how much the plasma concentration in the postexposure phase increases in multiple exposures relative to that resulting from a single exposure, *i.e.*, the ratio $c_n(t_r)/c(t_r)$, where $t_r > T$, can be predicted. To prove this, it is convenient to rewrite Eq. 28 in the following form[3]:

$$c_n(t_r) = \phi_n(L\alpha) \cdot A_T(T) \cdot e^{-\alpha(t_r-T)} + \phi_n(L\beta) \cdot B_T(T) \cdot e^{-\beta(t_r-T)} \qquad (t_r \geq T) \quad \text{(Eq. 41)}$$

By multiplying this equation and Eq. 12 ($t \geq T$) by K_1K_2, the following ratio is obtained:

$$\frac{c_n(t_r)}{c(t_r)} = \frac{\phi_n(L\alpha) \cdot [K_1K_2A_T(T)] \cdot e^{-\alpha(t_r-T)} + \phi_n(L\beta) \cdot [K_1K_2B_T(T)] \cdot e^{-\beta(t_r-T)}}{[K_1K_2A_T(t)] \cdot e^{-\alpha(t_r-T)} + [K_1K_2B_T(T)] \cdot e^{-\beta(t_r-T)}} \qquad (t_r \geq T) \quad \text{(Eq. 42)}$$

Fitting Eq. 40 to pulmonary excretion data yields values for $\alpha, \beta, K_1K_2 \cdot A_T(T)$, and $K_1K_2 \cdot B_T(T)$, so that Eq. 42 can be calculated at any time $t_r > T$ for any values of n and L. Thus, excretion data from a single exposure provide quite extensive and valuable information about the plasma accumulation of the compound. In particular, such data allow a comparison of the maximum plasma concentration by letting $t_r = T$ in Eq. 42:

$$\frac{\max c_n(t_r)}{\max c(t_r)} = \frac{c_n(T)}{c(T)} = \frac{\phi_n(L\alpha) \cdot [K_1K_2 \cdot A_T(T)] + \phi_n(L\beta) \cdot [K_1K_2 \cdot B_T(T)]}{[K_1K_2 \cdot A_T(T)] + [K_1K_2 \cdot B_T(T)]} \quad \text{(Eq. 43)}$$

A comparison of the minimum values is achieved by letting $t_r = L = (T + H)$ in Eq. 42, noting that $\min c_{n+1}(t_r) = c_{n+1}(0) = c_n(L)$:

$$\frac{\min c_{n+1}(t_r)}{c(L)} = \frac{\phi_n(L\alpha) \cdot [K_1K_2 \cdot A_T(T)] \cdot e^{-\alpha H} + \phi_n(L\beta) \cdot [K_1K_2 \cdot B_T(T)] \cdot e^{-\beta H}}{[K_1K_2 \cdot A_T(T)] \cdot e^{-\alpha H} + [K_1K_2 \cdot B_T(T)] \cdot e^{-\beta H}} \quad \text{(Eq. 44)}$$

Although the above analyses (Eqs. 42 and 43) are limited to the postexposure phase ($t \geq T$), the characterization is complete enough to get an adequate assessment of the accumulation tendency of the compound. It is particularly valuable to be able to determine the relative change in the maximum (Eq. 43) and minimum (Eq. 44) plasma level concentrations.

Kinetic Analysis Based on Blood Sampling—Plasma level data in the exposure phase provide a more comprehensive kinetic characterization than pulmonary excretion data. All six basic kinetic parameters are determined by fitting Eq. 6 to the plasma level data[4]. Thus, once these parameters are determined by a suitable nonlinear regression technique, then predictions can be made as to which plasma-time profiles or accumulations can be reasonably expected from other single or multiple exposures (Eqs. 12, 28, and 30).

If the plasma level data are obtained only in the postexposure phase ($t \geq T$), then it is not possible to determine more than two (α and β) of the six basic parameters. However, despite this, some useful predictions can still be made.

The postexposure phase, according to Eq. 12, is described by:

$$c(t) = A_T(T) \cdot e^{-\alpha(t-T)} + B_T(T) \cdot e^{-\beta(t-T)} \qquad (t \geq T) \quad \text{(Eq. 45)}$$

By fitting this equation to the data, values for $\alpha, \beta, A_T(T)$, and $B_T(T)$ are obtained which, according to Eqs. 42 and 43, permit the following predictions to be made from the single exposure response, $c(t)$:

$$c_n(t_r) = \left[\frac{\phi_n(L\alpha) \cdot A_T(T) \cdot e^{-\alpha(t_r-T)} + \phi_n(L\beta) \cdot B_T(T) \cdot e^{-\beta(t_r-t)}}{A_T(T) \cdot e^{-\alpha(t_r-T)} + B_T(T) \cdot e^{-\beta(t_r-T)}}\right] c(t) \qquad (t \geq T) \quad \text{(Eq. 46)}$$

$$\max c_n(t_r) = c_n(T) = \left[\frac{\phi_n(L\alpha) \cdot A_T(T) + \phi_n(L\beta) \cdot B_T(T)}{A_T(T) + B_T(T)}\right] c(t) \quad \text{(Eq. 47)}$$

$$\min c_{n+1}(t_r) = \left[\frac{\phi_n(L\alpha) \cdot A_T(T) \cdot e^{-\alpha H} + \phi_n(L\beta) \cdot B_T(T) \cdot e^{-\beta H}}{A_T(T) \cdot e^{-\alpha H} + B_T(T) \cdot e^{-\beta H}}\right] c(L) \quad \text{(Eq. 48)}$$

Thus, although pulmonary excretion data in the postexposure phase allow only relative comparisons (Eqs. 42–44), plasma data obtained in the same phase permit absolute predictions (Eqs. 46–48). In both cases, the predictions can only be made for exposure duration(s) of the same length, T, as in the single-exposure experiment. This limitation is not found when data are obtained during the exposure. Equations analogous to Eqs. 42–48 are readily obtained from Eq. 30 to extend the analysis to irregular exposures.

The single-exposure equation (Eq. 12) shows an interesting, unusual kinetic behavior. The exponential time coefficients in the exposure phase (α' and β') are different from those in the postexposure phase (α and β). This is in contrast to the equations of classical linear compartmental modeling, which have constant time coefficients (the eigenvalues). The different kinetic behavior is due to the use in pharmacokinetics of input functions that do not depend on the concentration or the amount of drug in the blood. Such input functions are likely to be encountered during oral absorption, because the GI concentration is much greater than the plasma concentration. However, in pulmonary absorption, the plasma concentration cannot be ignored in defining the input function. The concentration (partial pressure) gradient in the absorption path is considerably smaller because of an often very low concentration of the gas, a slow nonpulmonary elimination, and a rapid tissue equilibration.

The simple diffusional pulmonary absorption and excretion of a gas is intrinsically very regular and much less erratic and complex than the GI absorption and metabolism and renal excretion of regular drugs. A much smaller intra- and intersubject variability is expected. Kinetic predictions and estimations such as those described above should, therefore, be considerably more accurate than those made in general pharmacokinetic practice.

Multiple-Exposure Kinetics with Regular Dosing Cycle—Similar to the above (Eq. 40), the cumulative amount of gas excreted in the postexposure phase can be determined by integration of Eq. 41:

$$M_n(t_r) = \int_T^{t_r} K_1K_2 \cdot c_n(t)dt = \phi_n(L\alpha) \cdot \left[K_1K_2 \frac{A_T(T)}{\alpha}\right]\left[1 - e^{-\alpha(t_r-T)}\right] + \phi_n(L\beta) \cdot \left[K_1K_2 \frac{B_T(T)}{\beta}\right]\left[1 - e^{-\beta(t_r-T)}\right] \qquad (t_r \geq T) \quad \text{(Eq. 49)}$$

[4] Equation 6 is the explicit $c(t)$ function obtained directly from the implicit relationship in Eq. 5 which contains all six basic parameters. Equation 6, therefore, contains the exact same basic parameters as Eq. 5. The basic parameters are related to the macroparameters A', α', B', β' (introduced for simplification) through Eqs. 7–9. Determination of the macroparameters and their basic parameters by least-squares regression of Eq. 6 poses no real problem. The procedure is completely analogous to the determination of macroparameters and micro-rate constants in classical linear compartmental modeling, which is routinely done with well-established computer programs.

By fitting this expression to pulmonary excretion data, the same quantities [α, β, $K_1K_2 \cdot A_T(T)$, and $K_1K_2 \cdot B_T(T)$] as in the single-exposure case (Eq. 40) can be determined. Thus, the same predictions (Eqs. 42-44) can be made as before. Similarly, if plasma level data are obtained in the postexposure phase ($t_r \geq T$), then by fitting Eq. 41, the quantitites α, β, $A_T(T)$, and $B_T(T)$ are obtained and predictions can be made as before (Eqs. 46-48).

Irregular Dosing Cycle—By combining Eqs. 30, 41, and 38, the following expression for the plasma level in the postexposure phase is obtained:

$$c_{n,m}(t_r) = [\phi_n(L\alpha) + \phi_N(L\alpha) \cdot \phi_{m-1}(7L\alpha) \cdot e^{-(M+n)L\alpha}]A_T(T) \cdot e^{-\alpha(t_r-T)} + [\phi_n(L\beta) + \phi_N(L\beta) \cdot \phi_{m-1}(7L\beta) \cdot e^{-(M+n)L\beta}]B_T(T) \cdot e^{-\beta(t_r-T)} \quad (t_r \geq T) \quad \text{(Eq. 50)}$$

By integrating this equation, the cumulative amount of gas excreted in the postexposure phase can be described as:

$$M_{n,m}(t_r) = [\phi_n(L\alpha) + \phi_N(L\alpha) \cdot \phi_{m-1}(7L\alpha) \cdot e^{-(M+n)L\alpha}] \left[K_1K_2 \frac{A_T(T)}{\alpha}\right] [1 - e^{-\alpha(t_r-T)}] + [\phi_n(L\beta) + \phi_N(L\beta) \cdot \phi_{m-1}(7L\beta) \cdot e^{-(M+n)L\beta}] \left[K_1K_2 \frac{B_T(T)}{\beta}\right] [1 - e^{-\beta(t_r-T)}] \quad (t_r \geq T) \quad \text{(Eq. 51)}$$

In analogy to the regular dosing cycle case, the quantities α, β, $K_1K_2 \cdot A_T(T)$, and $K_1K_2 \cdot B_T(T)$ can be determined by fitting Eq. 51 to pulmonary excretion data. Similarly α, β, $A_T(T)$, and $B_T(T)$ are obtained from plasma level data by Eq. 50.

Thus, a kinetic analysis of data in the postexposure phase(s) of multiple exposures provides the same basic kinetic information as an analysis of postexposure data from a single exposure.

Occupational Exposure Limit Adjustment in Unusual Work Schedules—The regulatory threshold limit values (TLV) for exposure in air contaminants administered by the Occupational Safety and Health Administration are based on exposure during a normal work week of five 8-h days (16). If a person with a non-normal work week is not going to be exposed to a greater toxic burden than allowed, if may be appropriate to consider a different TLV. There is no general consensus of how to best compare the toxic burden from different exposure schemes. One approach that seems to have received particular interest is based on a comparison of the predicted maximum amount of the contaminant in the body (10). Such an approach appears to be unsatisfactory because of the experimental difficulties of estimating such a quantity and because of the kinetic misconception of treating the body as a homogeneous "box."

A more appropriate approach would be based on a comparison of peak plasma levels predicted from kinetic equations based on rational assumptions. In the comparison of two exposure schemes (denoted with superscripts I and II), it is of interest to determine a TLV adjustment factor, F, defined as follows. The maximum plasma level of the contaminant predicted for exposure scheme II with contamination level C_g^{II} is the same as that predicted for scheme I with contamination level C_g^{I} when:

$$C_g^{II}F \cdot C_g^{I} \quad \text{(Eq. 52)}$$

An analysis of Eq. 30 reveals that $c_{n,m}$ is directly proportional to the contamination level C_g. The adjustment factor F can therefore be calculated from the relationship:

$$F = \frac{\max c_{n,m}{}^{I}}{\max c_{n,m}{}^{II}} \quad \text{(Eq. 53)}$$

where

$$\max c_{n,m} = c_{N,m}(T) \quad \text{(Eq. 54)}$$

The predicted maximum plasma level, max $c_{n,m}$, can be calculated by Eq. 50:

$$\max c_{n,m} = \phi_N(L\alpha) \cdot [1 + \phi_{m-1}(7L\alpha) \cdot e^{-(M+n)L\alpha}] \cdot A_T(T) + \alpha_N(L\beta) \cdot [1 + \alpha_{m-1}(7L\beta) \cdot e^{-(M+n)L\beta}] \cdot B_T(T) \quad \text{(Eq. 55)}$$

If there is no more than one work week exposure ($m = 1$), Eq. 55 reduces to the regular dosing cycle case:

$$\max c_{n,1} = \phi_N(L\alpha) \cdot A_T(T) + \phi_N(L\beta) \cdot B_T(T) \quad \text{(Eq. 56)}$$

Although the above equations used to calculate the adjustment factor may appear complex and demanding in kinetic terms, F can be determined most simply from two sets of pulmonary excretion data; one set can be determined from a single or multiple exposure with an exposure period T^{I}, and another set can be determined with an exposure period T^{II}. By fitting a simple biexponential expression to the two sets of data, values for α, β, $K_1K_2 \cdot A_T(T)^{I}$, $K_1K_2 \cdot A_T(T)^{II}$, $K_1K_2 \cdot B_T(T)^{I}$, and $K_1K_2 \cdot B_T(T)^{II}$ can then be determined as previously discussed. In calculating F, it is important to realize that it is not necessary to know $A_T(T)$ and $B_T(T)$. It is sufficient to know the products $K_1K_2 \cdot A_T(T)$ and $K_1K_2 \cdot B_T(T)$, since in forming the ratio in Eq. 53, it makes no difference if $A_T(T)$ and $B_T(T)$ are replaced with the products.

The above analysis of the pulmonary kinetics is for the non-steady-state case. The steady-state cases are easily considered by letting n or $m = \infty$ and by noting that:

$$\phi_\infty(x) = \frac{1}{1 - e^{-x}} \quad \text{(Eq. 57)}$$

For most practical purposes, it is adequate to approximate the unit-impulse response by a biexponential equation (Eq. 4). However, the analysis can be readily extended to consider any number of exponential terms in the approximation.

APPENDIX: GLOSSARY

Basic Kinetic Parameters:

K_1	Mass transfer constant for transport of the inhaled gas into the blood plasma (Eq. 1)
K_2	Partition coefficient between air and blood plasma for the inhaled gas; $K_2c(t)$ is the partial pressure of the gas in plasma (Eq. 1)
A,B,α, β	Parameters defining the unit-impulse response of the gas in the subject, *i.e.*, the parameters describing the plasma concentration-time profile if a unit amount of the gas was introduced momentarily into the plasma (Eq. 4)

Parameters Defining the Exposure:

C_g	Concentration of gas in the inhaled air (Eq. 1)
T	Duration of single or multiple exposures (Eq. 1)
H	Duration between regular exposures (T) (Eq. 22)
t_r	Time elapsed since the start of the most recent exposure for multiple exposures (Eq. 21)
n	Number of the current exposure cycle (n runs from 1 to N each week for exposure for multiple weeks) (Eq. 25)
m	Number of the current week ($m = 1$ for exposure for the first week) (Eq. 30)
N	Total number of exposure periods in each week for exposure for multiple weeks (Eq. 31)
M	Number of exposure-free periods in each week for exposure for multiple weeks (Eq. 32)
L	$T + H$

Auxilliary Functions and Parameters:

α', β'	Parameters calculated from the fundamental parameters K_1, K_2, A, B, α, and β according to Eq. 7
A',B'	Parameters calculated from the fundamental parameters K_1, K_2, A, B, α, and β; A' and B' are calculated according to Eqs. 8 and 9 after α' and β' are calculated
$(x)_+$	Truncation function equal to x for $x \geq 0$ and 0 for $x < 0$ (Eqs. 17 and 18)
$A_T(t)/B_T(t)$	Functions introduced to simplify the mathematical notation [note that these functions are constant ($A_T(T)$,$B_T(T)$) for $t_r \geq T$ (Eqs. 13-16)]
t'	min (t,T) (Eqs. 15 and 16)
$\phi_i(x)$	Function introduced to simplify the mathematical notation (Eq. 27)
$P_{n-1}(t_r)$	Function describing the plasma accumulation of gas at time t_r resulting from the previous ($n - 1$) exposure periods (Eq. 29)
$Q_{m-1}(t_r)$	Function describing the plasma accumulation of the gas at time t_r resulting from the previous ($m - 1$) weeks of exposure (Eq. 38)

Synthesis of 4-Substituted Aminoquinoline-3-carboxylates as Potential Antimicrobial Agents

PAUL E. MARECKI *x and RONALD E. BAMBURY

Received March 7, 1983, from *SDS Biotech Corporation, World Headquarters, Concord Township, Painesville, OH 44077.* Accepted for publication July 19, 1983. *Present address: Ohio Medical Anesthetics, AIRCO Central Research Laboratories, Murray Hill, NJ 07974.

Abstract □ A series of 4-substituted aminoquinoline-3-carboxylates was prepared and evaluated for antimicrobial activity. Four of the compounds (VIII, XIII, XV, and XXIII) exhibited low activity against *Staphylococcus aureus*.

Keyphrases □ 4-Substituted aminoquinoline-3-carboxylates—synthesis, antimicrobial activity □ Antimicrobial agents—potential, 4-substituted aminoquinoline-3-carboxylates

The structural similarity between the coccidiostat buquinolate (I) (1) and the antimalarial 4-aminoquinolines (*e.g.*, chloroquin; II) (2) raised the question as to whether combination of the major functional groups of each class might lead to useful agents. This work sought to determine if the quinoline-3-carboxylate moiety of the coccidiostats could be successfully combined with 4-amino substituents, some of which have shown promise in antimalarial quinolines. A series of 4-aminoquinoline-3-carboxylates (III) was necessary, and a search of the literature revealed that these compounds had not previously been synthesized. To determine if antibacterial properties were associated with this new substituent pattern, the synthesis of several examples was undertaken.

RESULTS AND DISCUSSION

Ethyl 4-chloroquinoline-3-carboxylate, IV (3), was the key intermediate from which the target compounds were prepared (Scheme I). The immediate precursor to IV, ethyl 4-hydroxyquinoline-3-carboxylate V, was prepared in satisfactory yield by the method of Gould and Jacobs (4) as modified by Price and Roberts (5) and by Riegel *et al.* (6). The importance of short reaction times in the preparation of V was noted (7); yields of V decrease for reaction times exceeding 30 min. Reaction of V with phosphorus oxychloride smoothly led to IV (3).

Nucleophilic displacement of the 4-chloro substituent occurred in high yield after a few hours in refluxing toluene; several cases were noted where the reaction started while still at room temperature. The relative ease of displace-

Synthesis of 4-Substituted Aminoquinoline-3-carboxylates as Potential Antimicrobial Agents

PAUL E. MARECKI *x and RONALD E. BAMBURY

Received March 7, 1983, from *SDS Biotech Corporation, World Headquarters, Concord Township, Painesville, OH 44077.* Accepted for publication July 19, 1983. *Present address: Ohio Medical Anesthetics, AIRCO Central Research Laboratories, Murray Hill, NJ 07974.

Abstract □ A series of 4-substituted aminoquinoline-3-carboxylates was prepared and evaluated for antimicrobial activity. Four of the compounds (VIII, XIII, XV, and XXIII) exhibited low activity against *Staphylococcus aureus*.

Keyphrases □ 4-Substituted aminoquinoline-3-carboxylates—synthesis, antimicrobial activity □ Antimicrobial agents—potential, 4-substituted aminoquinoline-3-carboxylates

The structural similarity between the coccidiostat buquinolate (I) (1) and the antimalarial 4-aminoquinolines (*e.g.*, chloroquin; II) (2) raised the question as to whether combination of the major functional groups of each class might lead to useful agents. This work sought to determine if the quinoline-3-carboxylate moiety of the coccidiostats could be successfully combined with 4-amino substituents, some of which have shown promise in antimalarial quinolines. A series of 4-aminoquinoline-3-carboxylates (III) was necessary, and a search of the literature revealed that these compounds had not previously been synthesized. To determine if antibacterial properties were associated with this new substituent pattern, the synthesis of several examples was undertaken.

[q] Calc. for N, 8.60; found, 9.24. [r] See Ref. 10; lit. mp 32–34°C. [s] See Ref. 6; lit. mp 269–270°C. [t] See Ref. 3; lit. mp 46–47°C, bp 128–129°C (0.2 mm Hg).

ment is presumably due to the activating effect of the carboxylic ester adjacent to the reaction center. A similar effect has been observed for halogen displacement of 3-nitro-4-chloroquinolines (8). Table I lists the ethyl 4-aminoquinoline-3-carboxylates obtained in this manner. Preparation of VI required a slight modification. When the normal reaction conditions were employed with a constant, steady stream of ammonia passing through the reaction solution, no VI was obtained; however, when the reaction was carried out in liquid ammonia at 115–130°C a good yield of VI resulted.

Several of the amino esters were viscous oils which could not be purified either by evaporative distillation or by chromatography. These compounds were converted to the corresponding hydrochloride salts (XXII–XXVI) which, in some cases, could be purified by crystallization. Some of the salts, notably XXV and XXVI, were hygroscopic and did not give satisfactory microanalysis results after several attempts.

Ester hydrolysis using an equivalent amount or a slight excess of potassium hydroxide in ethanol afforded salts XXVII–XLII (Table I). The potassium carboxylates were hygroscopic, making acquisition of microanalytical data difficult. In the extreme cases of XXXVIII and XLI, the compounds were deliquescent. The remaining salts were also hygroscopic, but most could be equilibrated with atmospheric moisture to yield a hydrate of constant, although often nonstoichiometric, composition. The method of Donleavy (9) for preparation of solid derivatives of waxy fatty acids was helpful in some cases. Formation of the pseudouronium salt of the quinoline carboxylates in some instances gave nonhygroscopic salts suitable for microanalysis, but this method was by no means applicable to each compound. Structural assignments were confirmed by ^{1}H-NMR and IR spectrometry, and each ester showed one spot on TLC.

Nucleophilic displacement of the halogen in IV also readily occurred when IV was treated with a sodium thiolate to give XLIII and with ethoxide anion to give XLIV (10). In addition, the *N*-oxide XLV was prepared by treating IV with *m*-chloroperoxybenzoic acid.

Each compound was tested in an *in vitro* assay against a range of microorganisms to determine a general activity profile. The organisms used were *Escherichia coli* ATCC 23540, *Salmonella choleraesuis* ATCC 13312, *Streptococcus faecalis* ATCC 19433, *Staphylococcus aureus* (Smith) Merck 2949, *Pseudomonas aeruginosa* PS-44, *Proteus mirabilis* PR-91, and *Clostridium perfringens* ATCC 3624. Dimethyl sulfoxide was used to aid the dissolution of test compounds in Mueller-Hinton broth at 50 ppm. Inoculated broths, prepared with a semiautomated dispenser and inoculator[1], were incubated for 18 h at 37°C, then examined and assigned a general rating of active, slightly active, or inactive. Measurement of the minimum inhibitory concentrations (MIC) was accomplished by the same method using successive twofold dilutions of the test compound, starting at a concentration of 62.5 ppm.

The target compounds showed no remarkable *in vitro* antibacterial activity, although small amounts of growth inhibition by several members of the series

[1] Model MIC 2000; Dynatech.

was observed. Four of the active compounds (X, XVIII, XXV, and XLIII) were slightly active against *C. perfringens* with minimum inhibitory concentrations of ≥62.5 ppm. Another subgroup of four compounds showed general activity against *Staph. aureus*.

The four compounds active against *Staph. aureus* were examined further by measurement of the MIC values (Table I). Since XXIII is the salt of VIII, it is not surprising that both species have the same order of activity. However, the presence of XIII and XV, which bear no structural relationship to the tertiary amines VIII and XXIII, makes it difficult to draw a structural relationship with the *in vitro* antimicrobial activity.

EXPERIMENTAL SECTION[2]

Ethyl 4-Aminoquinoline-3-carboxylate (VI)—A solution of 23.5 g (0.1 mol) of IV, 250 mL of toluene, and 21 mL (1.0 mol) of liquid ammonia was scaled in a high-pressure reaction vessel, then heated at 120–125°C for 4 h. The vessel was cooled, opened, and the ammonia was allowed to evaporate. The residue was suction-filtered, and the solid was partitioned between chloroform and water. The organic phase was dried (Na_2SO_4), and the solvent was removed under reduced pressure to give 17.4 g of white needles. Recrystallization from ethyl acetate afforded 14.9 g (69%) of VI as white needles, mp 205.0–207.5°C. IR (KBr): 1669 cm^{-1} (C=O); ^{1}H-NMR (Me_2SO-d_6): δ 8.90 (s, 1, quinoline C-2 H), 7.33–8.50 (m, 6, ArH and NH), 4.33 (q, 2, J = 7 Hz, OCH_2), and 1.36 ppm (t, 3, J = 7 Hz, CH_3).

General Procedure for Preparation of Ethyl 4-Alkylamino- and Ethyl 4-Aralkylaminoquinoline-3-carboxylates (VII–XXI)—The general method is illustrated by the synthesis of VII. A solution of 5.89 g (25 mmol) of IV and 9.17 g (125 mmol) of diethylamine in 50 mL of toluene was stirred and heated at reflux for 35 h. The mixture was cooled to room temperature and the salt was removed by filtration. The solvent was removed under reduced pressure to give 7.5 g of a cloudy oil, which was chromatographed on silica gel (5 × 40 cm, ether) to give 6.59 g (96%) of VII as a clear yellow oil. IR ($CHCl_3$): 1698 cm^{-1} (C=O); ^{1}H-NMR ($CDCl_3$): δ 8.90 (s, 1, C-2 H), 7.25–8.22 (m, 4, ArH), 4.43 (q, 2, J = 7 Hz, OCH_2), 3.43 (q, 4, J = 7 Hz, CH_2NCH_2), 1.41 (t, 3, J = 7 Hz, ester CH_3), and 1.15 ppm (t, 6, J = 7 Hz, aminoethyl CH_3).

General Procedure for Preparation of Hydrochloride Salts (XXII–XXVI)—The general method is illustrated by the synthesis of XXII. To a stirred solution of 15.2 g (55.8 mmol) of VII in 250 mL of ether was added 200 mL of dry, ethereal hydrogen chloride. The resulting mixture was filtered, and the solid was recrystallized several times from dichloromethane–ether and then from ethyl acetate. The solid was sublimed to give 5.83 g (34%) of XXII as a fine yellow powder, mp 145–147°C. IR ($CHCl_3$): 1712 cm^{-1} (C=O); ^{1}H-NMR ($CDCl_3$): δ 8.93 (s, 1, C-2 H), 7.61–8.72 (m, 4, ArH), 4.50 (q, 2, J = 7 Hz, OCH_2), 3.87 (q, 4, J = 7 Hz, CH_2NCH_2), 1.47 (t, 3, J = 7 Hz, ester CH_3), and 1.40 ppm (t, 6, J = 7 Hz, aminoethyl CH_3).

General Procedure for Preparation of Potassium Salts (XXVII–XLII)—The general method is illustrated by the synthesis of XXVIII. A solution of 14.9 g (54.8 mmol) of VII and 5.37 g (82.2 mmol) of potassium hydroxide in 150 mL of ethanol was stirred and heated at reflux for 4 h. The mixture was cooled to room temperature, and the solid material was removed by filtration. The solvent was removed under reduced pressure to give 16.9 g of a tan solid. Recrystallization from ethyl acetate–acetone afforded 10.9 g (70%) of XXVIII as fine needles, mp 258–260°C; ^{1}H-NMR (Me_2SO-d_6): δ 8.76 (s, 1, C-2 H), 7.30–8.43 (m, 4, ArH), 3.61 (s, 2, H_2O), 3.33 (q, 4, J = 7 Hz, CH_2NCH_2), and 1.06 ppm (t, 6, J = 7 Hz, CH_3).

[2] Boiling and melting points are uncorrected. Melting points were measured with a Thomas-Hoover Unimelt capillary melting point apparatus. IR spectra were measured with a Perkin-Elmer model 137 spectrophotometer. NMR spectra were measured with a Varian 56/60D or a Hitachi Perkin-Elmer R-24B spectrometer in the stated solvent using tetramethylsilane as internal standard. Microanalyses were performed by the Analytical Department, Diamond Shamrock Corp.

Ethyl 4-Benzylthioquinoline-3-carboxylate (XLIII)—A mixture of 1.65 g (72 mg-atoms) of sodium and 75 mL of absolute ethanol was stirred at room temperature under an argon atmosphere. To the resulting solution of sodium ethoxide was added, over a period of 10 min, a solution of 8.7 g (70 mmol) of benzylmercaptan in 50 mL of absolute ethanol. The mixture was stirred at room temperature for 25 min, and then a solution of 16.5 g (70 mmol) of IV in 75 mL of absolute ethanol was added. The stirring was continued at room temperature for 27 h. The mixture was poured into 150 mL of water, the phases were separated, and the aqueous phase was extracted with ether (3 × 150 mL). The organic phases were combined, washed with water and then with brine, and dried (Na_2SO_4). Removal of the solvent under reduced pressure gave a solid-oil mixture. The oil was decanted, and the solid was recrystallized from hexane to afford 11.4 g (51%) of XLIII as pale yellow prisms, mp 34–36°C. IR ($CHCl_3$): 1724 cm^{-1} (C=O); ^{1}H-NMR ($CDCl_3$): δ 8.97 (s, 1, C-2 H), 7.33–8.62 (m, 4, ArH quinoline), 7.05 (s, 5, ArH), 4.43 (q, 2, J = 7 Hz, OCH_2), 4.12 (s, 2, SCH_2), and 1.42 ppm (t, 3, J = 7 Hz, CH_3).

Ethyl 4-Ethoxyquinoline-3-carboxylate (XLIV)—The method of Markees (10) was employed with slight modification. Dimethylformamide was not used as cosolvent, and the entire reaction was allowed to take place at room temperature rather than for a brief period at reflux. This gave a 53% yield of XLIV as colorless needles, mp 34–36°C, bp 125–128°C (0.1 mm Hg) [lit. (10) mp 32–34°C, bp 160–162°C (1.4 mm Hg)].

Ethyl 4-Chloroquinoline-3-carboxylate-*N*-oxide (XLV)—A solution of 22.3 g (0.11 mol) of *m*-chloroperoxybenzoic acid and 23.5 g (0.1 mol) of IV in 350 mL of dichloromethane was stirred in an ice bath for 1 h, then at room temperature for 66 h. The solution was then stirred with 50 mL of 10% Na_2HSO_3 until a negative starch–iodide test was observed. The phases were separated, and the organic phase was washed with 7.5% $NaHCO_3$ and then brine, and dried (Na_2SO_4). Removal of the solvent under reduced pressure gave 22.2 g of an orange solid, which was recrystallized from ether to give 12.4 g (49%) of XLV as pale yellow plates, mp 102–104°C. IR ($CHCl_3$): 1739 cm^{-1} (C=O); ^{1}H-NMR ($CDCl_3$): δ 7.55–9.00 (m, 5, ArH), 4.50 (q, 2, J = 7 Hz, OCH_2), and 1.47 ppm (t, 3, J = 7 Hz, CH_3).

Subnanogram Quantitation of Chlorpheniramine in Plasma by a New Radioimmunoassay and Comparison With a Liquid Chromatographic Method

K. K. MIDHA ˣ, G. RAUW, G. McKAY, J. K. COOPER, and J. McVITTIE

Received June 2, 1983, from the *College of Pharmacy, University of Saskatchewan, Saskatoon, Saskatchewan S7N 0W0 Canada.* Accepted for publication September 7, 1983.

Abstract □ A new radioimmunoassay (RIA) procedure for the quantitation of chlorpheniramine in plasma is described. The assay allows the determination of chlorpheniramine levels up to 96 h after oral administration of a single 4-mg tablet to healthy volunteers. This procedure was sensitive to a 156-pg/mL plasma concentration when a 100-μL plasma sample was used. The mean coefficient of variation over the linear range of the assay from 0.156 to 20 ng/mL was 3.79%. The specificity of the assay was investigated, and the antisera showed 7% cross-reactivity with the *N,N*-didemethyl analogue and 17% cross-reactivity with the *N*-demethyl analogue. This high degree of specificity was also evident from the findings that the plasma concentrations determined by this newly described RIA procedure in samples of two healthy male volunteers who were administered 4 mg of chlorpheniramine maleate orally gave a strong correlation (r^2 = 0.88) with values obtained by an HPLC-UV procedure. The antiserum cross-reacted 100% with brompheniramine and, thus, can be used for its analysis in plasma. The described RIA procedure is precise, simple, and capable of handling a large number of plasma samples with a minimal turnaround time.

Keyphrases □ Radioimmunoassay—chlorpheniramine, plasma, comparison with HPLC-UV □ Chlorpheniramine—subnanogram quantitation in plasma, RIA, comparison with HPLC-UV

Chlorpheniramine (2-[*p*- chloro -α-[2-(dimethylamino)ethyl]-benzyl]pyridine), a potent antihistaminic drug widely used for relief of symptoms of the common cold and other allergic reactions, is a common ingredient in nonprescription antihistamine preparations. It is generally recommended for use in relatively low doses (1). Recent studies have established that the assay methods of this drug should be sensitive at least to the low nanogram range to adequately follow the plasma concentrations for thorough, reliable pharmacokinetic investigations (2-6) in children.

The various methods for the quantitation of chlorpheniramine that have been used include TLC with liquid scintillation counting (7), TLC followed by chemical conversion to an azo dye and subsequent colorimetric analysis (8), GC (9-15), HPLC (16, 17), and GC-MS (18, 19). Most of the earlier methods were developed to assay the drug in dosage forms or in urine; only a few procedures (15, 17-19) have the necessary sensitivity to quantitate normal plasma levels of chlorpheniramine after single doses of the drug. The GC procedure using electron-capture detection (15) is complicated because it requires the liquid chromatographic separation of the drug from its metabolites and an oxidation reaction as preliminary steps. The HPLC (17) and GC-MS procedures (18, 19) have adequate sensitivity to determine 1-2-ng/mL plasma concentrations after single doses; however, they all require extraction of the drug from plasma and/or sophisticated instrumentation such as GC-MS and are generally cumbersome for routine analysis. Radioimmunoassay (RIA) procedures, on the other hand, are usually simple, sensitive, and readily applicable to routine analysis. They generally do not require either extraction of the drug from plasma or expensive instrumentation. Such an RIA method for chlorpheniramine, which is sensitive to 0.156 ng/mL and requires only a 100-μL plasma sample, has been developed and is reported here. This report also describes the comparison of the RIA with a new HPLC procedure.

EXPERIMENTAL SECTION

Materials—Chlorpheniramine maleate[1], prochlorperazine dimaleate[2], 2-[*p*-chloro-α-(2-aminoethyl)benzyl]pyridine (II)[3], 2-[*p*-chloro-α-[2-(methylamino)ethyl]benzyl]pyridine (III)[3], and brompheniramine maleate[4] were used. All solvents were HPLC grade, and all other chemicals were commercial analytical reagent grade. The tracer solution was tritiated chlorpheniramine with a specific activity of 14.6 Ci/mmol, prepared by catalytic exchange with tritium gas[5]. The following reagents were used without modification: 0.2 M phosphate buffer (pH 7.2) and dextran-coated charcoal suspension [prepared by the method of Powell *et al.* (20)]. A scintillation fluid[6] was used for liquid scintillation counting.

Apparatus—A liquid chromatographic pump[7] fitted with a valve-loop (500 μL) injector[8] was connected to a variable-wavelength detector[9] operated at 229 nm. A Spherisorb 5-μm cyano column (250 mm × 4.6 mm i.d.)[10] was used at ambient temperature with a flow rate of 3 mL/min. The mobile phase consisted of 30% 0.05 M ammonium acetate in acetonitrile. It was deaerated by filtration[11] before use. Scintillation counting was carried out with a liquid scintillation counter equipped with an automatic quench compensation[12].

Liquid Chromatographic Internal Standard—A stock solution of prochlorperazine dimaleate (100 μg/mL, calculated as free base) was prepared in double-distilled water and stored in the absence of UV light at 4°C; this was prepared fresh monthly. Dilutions of 200 ng/mL were prepared daily.

Preparation of Standard Curves—An aqueous solution of chlorpheniramine maleate (100 μg/mL, calculated as free base) was prepared monthly in double-distilled deionized water and stored at 4°C. Appropriate dilutions of the stock solutions were made in plasma. For RIA, this plasma was obtained from drug-free volunteers. For HPLC, outdated plasma[13] was used.

Table I—RIA Estimation of Chlorpheniramine Added to Plasma [a]

Concentration, ng/mL	n	Mean, B/B_0, %	SD, ng	RSD[b]
0.156	9	93.3	0.0016	1.05
0.313	7	86.8	0.0070	2.24
0.625	7	75.6	0.0137	2.19
1.25	8	59.2	0.0488	3.90
2.5	6	42.7	0.0608	2.43
5	8	25.8	0.2785	5.57
10	7	15.7	0.4560	4.56
20	6	9.7	1.672	8.36

[a] Composite standard curve where logit $y = M \cdot \log_{10} x + I$; $M = -2.329$, $I = 0.6686$, $r^2 = 0.999$. [b] Mean RSD = 3.79%.

For RIA, calibration curves were constructed by the following:

$$\text{Logit } y = \text{Log}_e \frac{B/B_0}{1 - B/B_0} = M \cdot \text{Log}_{10} C + I \qquad \text{(Eq. 1)}$$

where B is percentage bound, B_0 is the percentage bound at zero concentrations, M is the slope, C is the concentration (ng/mL), and I is the intercept.

Liquid Chromatographic Extraction of Samples—The extraction procedure was similar to that previously described for chlorpromazine (21, 22). To a 10-mL polytef-lined screw-capped centrifuge tube (13 × 100 mm) were added 2.0 mL of plasma (spiked or from dosed volunteers), 1.0 mL of prochlorperazine internal standard (100 ng/mL), and 0.5 mL of saturated sodium carbonate solution. The tube was mixed for 5 s, and 5 mL of 3% isopropyl alcohol in pentane was added. The tube was tightly capped and mixed[14] for 15 min and centrifuged[15] 10 min at 1725×g at ambient temperature.

The organic layer was transferred to a clean 10-mL tube, and the extraction was repeated with another 5.0 mL of 3% isopropyl alcohol in pentane. The combined organic extracts were evaporated at 65°C in a dry bath[16]. The dried residue was dissolved in 200 μL of acetonitrile, and 100 μL was injected into the chromatograph.

Synthesis of Drug Protein Conjugate and Production of Antisera—Antisera were raised in New Zealand White rabbits to an immunogen synthesized by covalent linkage of bovine serum albumin to *N*-(2-carboxyethyl)demethylchlorpheniramine employing the mixed anhydride condensation reaction (23, 24). A blank was prepared in the same manner without demethylchlorpheniramine. The number of hapten residues per mole of bovine serum albumin was determined to be 4 by a UV method (23, 24).

The hapten *N*-(2-carboxyethyl)demethylchlorpheniramine was prepared by alkaline hydrolysis of *N*-(2-methoxycarbonylethyl)demethylchlorpheniramine, a compound synthesized by refluxing equimolar amounts of methyl acrylate and III (25). The addition of III to methyl acrylate was monitored by GC, in which the absence of the peak due to III indicated completion of addition.

Four rabbits were each given one intradermal injection of 1.0 mg of the immunogen emulsified with 0.5 mL of Freund's complete adjuvant and 0.5 mL of isotonic saline. The rabbits were given four injections at 2-week intervals with the same amount of immunogen emulsified with Freund's incomplete adjuvant. Four intravenous boosters of 1.0 mg of immunogen dissolved in 0.25 mL of isotonic saline were given. After the second booster, titers of 1:500 were produced in three of the rabbits, and titers of 1:1000 were produced in the fourth. Subsequent injections did not increase the titer. The antiserum from each of the rabbits was characterized for its cross-reactivity and sensitivity. The antiserum employed in the present study was lyophilized and stored at −20°C. An aliquot of 25 mg was weighed out and reconstituted with 31.25 mL of phosphate buffer (pH 7.2). The cross-reactions (50% inhibition of binding at zero drug concentration) for the metabolites and other drugs were determined by the criteria of Abraham (26).

Radioimmunoassay—The assay was done in subdued light and an ice water bath so as to maintain the temperature at 4°C. To a 12 × 75-mm polystyrene tube containing 100 μL of plasma sample (standard or from dosed volunteer) was added 250 μL of tritiated chlorpheniramine (22,000 dpm) diluted in 0.2 M phosphate buffer (pH 7.2). The tube contents were mixed[17] for 5 s. An aliquot of 250 μL of the antiserum (80 mg in 100 mL) was added, and the tube contents were mixed[17] once more for 5 s and incubated at 4°C for 60 min. To this incubated solution was added 1.0 mL of a cold dextran-coated charcoal suspension (4°C). The tube contents were mixed[17] again for 5 s and incubated for 30 min at 4°C. The sample was then centrifuged[15] at 1720×g for 10 min at 4 °C. The supernatant was decanted into a scintillation vial containing 10 mL of cocktail[6] and then counted.

Table II—Cross-Reactivity of Chlorpheniramine Antiserum

Compound Tested	Cross-Reactivity, %
Brompheniramine (I)	100
2-[*p*-Chloro-α-(2-amino ethyl)benzyl]pyridine (II)	7
2-[*p*-Chloro-α-[2-(methylamino)ethyl]benzyl]pyridine (III)	17
Chlorpheniramine (IX)	100
N-(2-Carboxyethyl)demethylchlorpheniramine (V)	—

Plasma Level Study—A 4-mg dose of a commercial preparation of chlorpheniramine maleate[18] was given orally with 250 mL of water to each of two volunteers (weight, 56 and 60 kg, respectively). Blood samples were collected from each of the volunteers over a 96-h period in evacuated glass tubes[19] and centrifuged, and separated plasma was stored at 4°C for a maximum of 7 d. During collection of the venous samples, care was taken to avoid contact of the blood with the rubber stopper of the evacuated tube. For three of these blood samples for each volunteer, one extra tube of blood was collected in the conventional manner in which blood was allowed to come into contact with the rubber stopper.

Recovery Study for Liquid Chromatography—For the determination of chlorpheniramine recovery, blank plasma was spiked with 5 or 20 ng of chlorpheniramine/mL. The tritiated chlorpheniramine (10,400 dpm/mL) was also added to the spiked plasma. This brought the total concentration of chlorpheniramine added to 5.25 or 20.25 ng/mL. The samples were extracted as previously described, except that the organic layers were transferred to a 20-mL borosilicate glass scintillation vial and dried. Cocktail[6] (10 mL per vial) was also added, mixed, and then counted. Recovery of chlorpheniramine was determined by counting the radioactivity recovered *versus* the amount added.

Analytical Recovery for Radioimmunoassay—Tritiated chlorpheniramine was added to plasma samples containing chlorpheniramine and incubated with buffer in accordance with the procedure described above. The solutions were then decanted into scintillation fluid, and the radioactivity was measured. The recoveries of 0.156–20 ng were ~95%, which are similar to the values reported for another basic drug, trifluoperazine (27). It should be emphasized that during the decanting technique, small amounts of the sample adhere to the sides of the tube; thus, actual recoveries may be greater. When the tracer was added directly to the polystyrene tube without using plasma, >40% of the tracer was lost, probably due to adsorption onto the surface of the tube. Thus, all standards at a low nanogram range of chlorpheniramine were prepared in plasma.

RESULTS

Radioimmunoassay—The amount bound at zero concentration of chlorpheniramine was determined at incubation times of 30, 60, and 90 min and at temperatures of 4°C and 37°C for the first incubation step in the assay. From the results of these experiments, the optimal conditions for the assay were found to be an incubation time of 60 min at 4°C, and B_0 was 23%. The concentrations of unknown samples were estimated by running a calibration curve with each set of unknown samples.

Table I shows a composite standard curve covering the range of 0.156 to 20 ng/mL, which is definable by:

$$\text{Logit } y = -2.329 \cdot \log_{10} x + 0.6686 \; (r^2 = 0.999) \qquad \text{(Eq. 2)}$$

Specificity—The cross-reactivity of the available metabolites of chlorpheniramine, as well as the related drug brompheniramine, as assessed by the criteria of Abraham, is recorded in Table II. Brompheniramine, as expected, did cross-react 100%. Thus, this antiserum can be used for the development of an RIA for brompheniramine. The *N*-demethyl and *N*,*N*-didemethyl metabolites of chlorpheniramine cross-reacted 17 and 7%, respectively. The significant cross-reactivity of the pharmacologically active *N*-demethyl metabolite (17%) was not surprising since the antisera were raised to a drug–protein conjugate prepared by coupling to this secondary amine. This also may explain the 7% cross-reactivity of the *N*,*N*-didemethyl metabolite. This relative cross-reactivity of 7% of the *N*,*N*-didemethyl metabolite was the same as that observed in the case of the chlorpromazine RIA (28). In the chlorpromazine RIA, the antisera raised in New Zealand White rabbits to the bovine serum

[18] Chlor-Tripolon; Schering Inc., Canada.
[19] Vacutainers, each containing 143 USP units of sodium heparin; Becton, Dickinson and Co., Mississauga, Ontario, Canada.

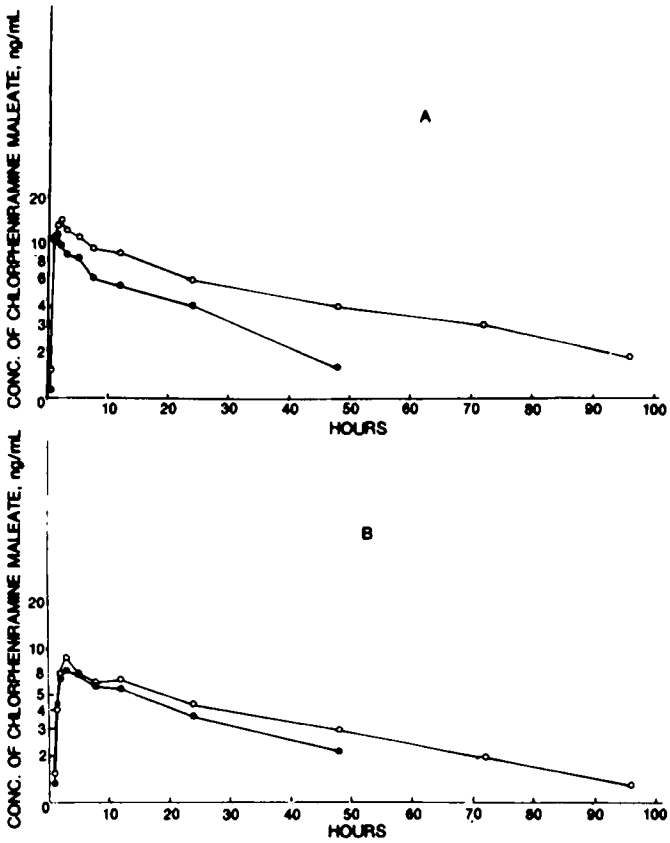

Figure 1—*Plasma concentrations* versus *time profiles obtained by RIA (○) and HPLC (●) for two healthy volunteers (A and B) weighing 56 and 60 kg, respectively, each of whom received a 4-mg dose of chlorpheniramine maleate.*

albumin conjugate of *N*-(2-carboxyethyl)demethylchlorpromazine cross-reacted 7% with the *N*,*N*-didemethyl metabolite.

The detection limit is <15.6 pg, which corresponds to 0.156 ng/mL if a 100-μL plasma sample is used. This sensitivity is greater than any method reported for chlorpheniramine. Thus, this RIA should be ideal for samples from infants and children, as the plasma volume needed does not exceed 0.2 mL for duplicate analyses of each sample.

Precision—The coefficient of variation for the replicate analyses of various concentrations of chlorpheniramine from 0.156 to 20 ng/mL is shown in Table I. The coefficient of variation of 0.156 ng/mL (n = 9) was ~1.05%.

Influence of Plasma Volume on Standard Curves—Standard curves were prepared by use of 50-, 100-, and 200-μL volumes of plasma. The slopes and intercepts derived were identical, thereby suggesting that plasma volumes did not affect the assay.

Capacity and Application of the Procedure—One technician can assay 50 samples in triplicate in a normal working day. Concentrations in plasma measured in two healthy volunteers (weight, 56 and 60 kg) after oral administration of a single 4-mg dose of the maleate salt of the drug are illustrated in Fig. 1. Note that the assay can easily quantitate the drug and/or its *N*-dealkylated metabolites in specimens collected as late as 96 h after a single oral dose.

Effect of Rubber Stoppers of the Evacuated Glass Tubes on Plasma Concentration Determination—To establish whether the measurement of the weakly basic lipophilic compound, chlorpheniramine [pK_a 8.99, (29)], is affected by contact with the rubber stoppers of the evacuated glass tubes, the duplicate samples of blood from the two dosed subjects were collected at three different times as described above. In each case, the first sample was collected with the evacuated tube held vertically so that the blood did not touch the rubber stopper at any time, whereas the second sample was collected immediately, with the tube held horizontally so that the blood did touch the stoppers. Plasma was prepared from the duplicate samples, which were analyzed in parallel by the RIA procedure. There was substantial reduction (18–30%) of the apparent plasma concentration of chlorpheniramine in all six samples when the blood was allowed to touch the stoppers. This significant lowering of apparent plasma concentration in chlorpheniramine is similar to that reported for other weakly basic lipophilic drugs (30). Therefore, for chlorpheniramine, during blood collection procedures, contact with the rubber stoppers should be avoided.

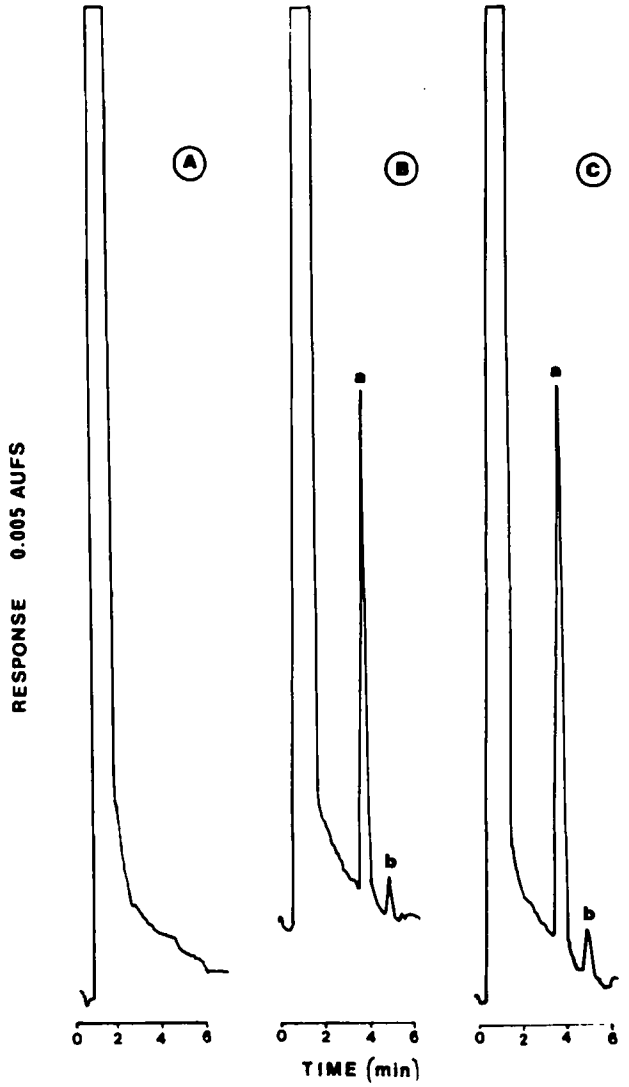

Figure 2—*Chromatograms of extracts from 2.0 mL of plasma. Key: (A) blank plasma; (B) plasma spiked with chlorpheniramine (b, 5.0 ng/mL) and internal standard prochlorperazine (a, 100.0 ng/mL); (C) plasma sample from a volunteer (56 kg) 7.5 h postdose (chlorpheniramine maleate, 4 mg), estimated to contain 6.1 ng of the drug per mL of plasma.*

High-Performance Liquid Chromatography—Under the HPLC conditions described above, chlorpheniramine and the internal standard prochlorperazine gave sharp and symmetrical peaks that eluted in 6 min (Fig. 2). No interference from endogenous plasma constituents was observed. Figure 2B shows a chromatogram of a spiked plasma sample containing 5.0 ng of chlorpheniramine/mL and 100 ng of prochlorperazine/mL. Figure 2C shows a chromatogram of a 7.5-h postdose plasma sample (2 mL) from a volunteer (56 kg) who received 4 mg of chlorpheniramine maleate orally, with the chlorpheniramine concentration estimated as 6.1 ng/mL. *N*-Demethylchlorpheniramine and *N*,*N*-didemethylchlorpheniramine do not interfere in the assay, as they are eluted at 4.2 and 3.1 min, respectively, as compared with chlorpheniramine and the internal standard, which elute with retention times of 5.7 and 4.7 min, respectively. Brompheniramine may also be amenable to analysis by the described HPLC assay, as it elutes at a retention time of 5.4 min.

Table III shows a composite standard curve for the quantitation of chlorpheniramine by HPLC from plasma. The curve is linear with a negligible intercept over the concentration range of 5–25 ng/mL. The ratios of chlorpheniramine to prochlorperazine peak heights plotted against chlorpheniramine concentrations gave a straight line passing through the origin (r^2 = 0.999). A mean slope value of 0.0102 ± 0.00089 was obtained. The sensitivity at 229 nm for chlorpheniramine (Fig. 2) is such that the HPLC assay can quantitate 2.5 ng/mL of the drug in plasma. This sensitivity is comparable

Table III—HPLC Estimation of Chlorpheniramine Added to Plasma [a]

Concentration, ng/mL	n	Mean Peak Height Ratio	SD	RSD, %[b]
5	6	0.0517	0.0017	3.39
10	6	0.1024	0.0060	5.90
15	6	0.1552	0.0085	5.47
20	7	0.2051	0.0054	2.64
25	8	0.2555	0.0130	5.08

[a] $y = mx$, where $m = 0.0102 \pm 0.00089$ and $r^2 = 0.99996$. [b] Mean $RSD = 4.5\%$.

with that reported for chlorpheniramine by a reverse-phase system with UV detection at 254 nm (17).

The overall recoveries of chlorpheniramine obtained from seven determinations, each at two concentrations (5.25- and 20.25-ng/mL of plasma) were 78.15 ± 2.71 and 78.43 ● 5.92, respectively. A mean percent recovery of 78.29 ± 4.32 was considered satisfactory.

Application of the described HPLC procedure to plasma concentration determinations in two healthy volunteers (56 and 60 kg), each of whom received a single oral dose of a commercial preparation[19] containing 4 mg of chlorpheniramine maleate, is shown in Fig. 1. As can be seen, the method is of sufficient sensitivity to analyze specimens obtained up to 48 h after this low oral dose, whereas the RIA procedure could measure the plasma concentrations in the specimens up to 96 h.

DISCUSSION

Sensitive, specific, and reproducible procedures are essential in order to carry out pharmacokinetic investigations of drugs which are given in small doses. Rapidity, high sample turnover, and low cost would be advantageous in encouraging clinicians to monitor plasma levels in individuals who do not respond to a certain dose of a drug.

For chlorpheniramine, two such methods are described here. The RIA procedure has the simplicity and sensitivity to measure plasma concentrations of chlorpheniramine and/or its *N*-dealkylated metabolites in specimens collected as late as 96 h after administration of single low doses, such as 4 mg. Because of its sensitivity, the RIA procedure is well suited to determine plasma chlorpheniramine levels in infants and children where the available plasma volume may not be large. The described HPLC procedure could measure concentrations up to 48 h after administration of single low doses in the two volunteers studied here. The plasma half-lives of chlorpheniramine after the single oral dose of 4 mg of the maleate salt in these two volunteers were estimated by the HPLC method to be 17 and 23 h, which are comparable with previous reports (2, 3). However, these half-lives were estimated by the RIA procedure for these volunteers as 35 h in each case. This over-estimation in half-lives is probably due to the cross-reactivity (17%), especially of the active *N*-demethyl metabolite with the antiserum used. Similarly, area under the plasma concentration time curves up to 48 h (AUC_0^{48}) by RIA for the two subjects were 330 and 222 ng·h/mL, respectively, whereas these values by HPLC were 205 and 187 ng·h/mL, respectively. This overestimation of AUC_0^{48} and 1.5–2.0-fold increase in half-life values between RIA and HPLC suggest that the RIA may not be useful in pure pharmacokinetic studies of chlorpheniramine.

The increases of 61 and 19% in the AUC_0^{48} value when measured by RIA probably represent the contributions due to the *N*-demethyl and, to a lesser extent, the *N*,*N*-didemethyl metabolites. The *N*-demethyl and *N*,*N*-didemethyl metabolites could not be detected by Huang *et al.* (2) in plasma after single oral doses. After both single and multiple doses of chlorpheniramine, the *N*-demethyl and *N*,*N*-didemethyl metabolites constitute 22 and 3%, respectively, of the total administered dose of the drug excreted in urine. This raises the possibility that there may be other unknown metabolites, which are responsible, at least in part, for the difference in results from RIA and HPLC. In spite of the cross-reactivity of the antiserum to the *N*-demethyl metabolite (17%), the RIA procedure, when compared with the HPLC method, gave a slope of 1.21 with a positive intercept of 0.46 and a correlation coefficent of 0.88 in plasma samples from the two healthy volunteers, who were each given orally a single dose of chlorpheniramine maleate.

The described RIA procedure is simple, precise, and capable of handling a large number of samples. This RIA may be useful for comparative bioequivalency studies of different formulations and for monitoring compliance. The HPLC method is reliable and should be well suited for pure pharmacokinetic studies.

Studies on the Formation of Electrostatic Complexes Between Benzethonium Chloride and Anionic Polymers

EDWARD A. TAVSS ˣ, ABDUL GAFFAR, and WILLIAM J. KING *

Received April 20, 1983, from the *Colgate-Palmolive Research Center, Piscataway, NJ 08854.* Accepted for publication September 7, 1983. * Present address: Department of Dental Research, Fairleigh Dickinson University School of Dentistry, Hackensack, NJ 07601.

Abstract □ The chemistry of a mixture of benzethonium chloride and a copolymer of methoxyethylene-maleic anhydride was investigated. This mixture was of interest because it was effective in reducing dental plaque, calculus, and gingival inflammation *in vivo*. Evidence from dialysis, pH measurements, and stoichiometry demonstrated that the benzethonium cation and the anion of the hydrolyzed copolymer formed an electrostatic complex. An emulsion was produced when a stoichiometric excess of either component was present, but this mixture coacervated at stoichiometric quantities. The stability of the complex was pH dependent, and it did not form in 50% acetone. The complex was decomposed by simulated saliva, mainly due to calcium and magnesium ions, but was unaffected by salivary proteins. Other anionic polymers also formed this type of complex.

Keyphrases □ Electrostatic complexes—reaction of benzethonium chloride and methoxyethylene-maleic anhydride copolymer □ Polyanions—complex formation with long-chain quaternary ammonium ion □ Benzethonium chloride—electrostatic complex with methoxyethylene-maleic anhydride copolymer

The antibacterial compound benzethonium chloride has been shown to be an effective inhibitor of dental plaque formation in humans (1). In a subsequent study, a mixture of benzethonium chloride and a copolymer of methoxyethylene-maleic anhydride (mol. wt. 500,000) was evaluated *in vitro* for antibacterial activity and *in vivo* (beagle dogs) for inhibition of plaque, gingivitis, and calculus formation (2–4). The results demonstrated that the combination was as effective as benzethonium chloride alone in antibacterial activity and in the reduction of plaque and gingivitis. A difference did exist, however, in the effect on calculus. Benzethonium chloride significantly increased calcified deposits on teeth as compared with the water control group, whereas the mixture showed significantly less calculus. Hence, the mixture was as effective as benzethonium chloride for the inhibition of plaque and gingivitis and had the advantage of inhibiting calculus formation rather than enhancing it. It was, therefore, of interest to elucidate the chemistry of the complex.

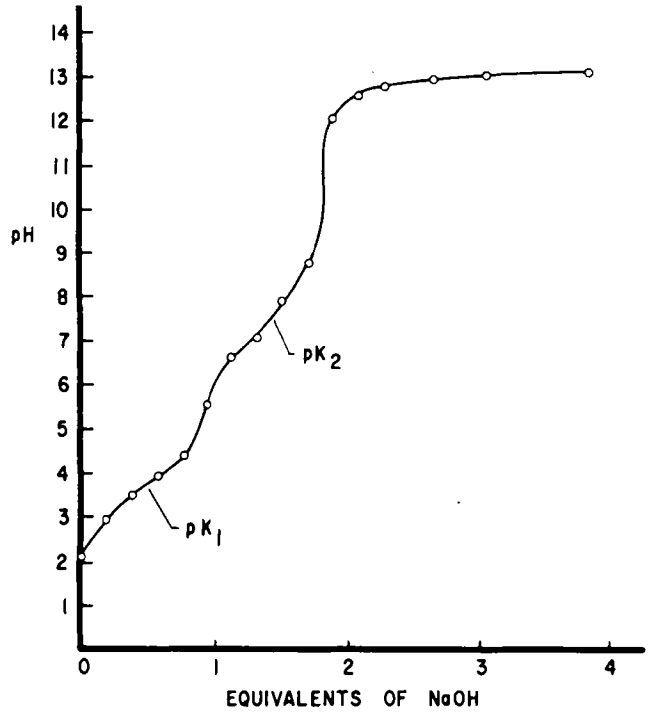

Figure 1—*Titration curve of the methoxyethylene-maleic anhydride copolymer.*

A number of investigators have studied the interactions of cations with polymers. Ackart *et al.* have investigated carboxyl-containing copolymers, such as the copolymer of ethylene-acrylic acid, and quaternary ammonium compounds, such as benzalkonium cations (5). They have suggested that the carboxyl-containing copolymer can be neutralized directly by the benzalkonium hydroxide or that the partial sodium salt of the copolymer could be ion-exchanged with benzalkonium chlorides. No evidence was presented, however, for the formation of electrostatic complexes. Rölla *et al.* have demonstrated interactions of another cationic antibacterial agent, chlorhexidine, with acidic salivary proteins (6). They hypothesized that this precipitate was an insoluble salt of the negatively charged protein and the positively charged chlorhexidine cations. Saito has studied interactions of tetra-alkyl ammonium chlorides with polyacrylic acid (7). By measuring the surface tension, he demonstrated that the quaternary compound became bound to the negatively charged polymer, neutralizing the surface and causing precipitation. Further addition of the quaternary cation coated the neutral surface of the coagulum, causing it to become charged and water soluble. Interactions of the alkaloid cation with the negatively charged ionized group of biocolloids were determined by coagulation observations and measurements of the direction of electrolytic transport by Jong and Meer (8). They demonstrated that there was an increase in interaction with increasing charge density on the colloid anion. Michaels and Miekka studied the interaction between sodium polystyrene sulfonate and polyvinylbenzyltrimethyl ammonium chloride (9). They have demonstrated that when the two were mixed in water, a precipitate formed which contained almost exactly stoichiometric proportions of the component polyions and, furthermore, contained virtually none of the sodium and chloride counterions associated with the individual polymers.

[a] Calculated as benzethonium chloride. [b] Calculated as ammonia.

Studies have been done on the degree of binding of negatively charged polymers with small positively charged ions (10). Increased binding at a particular polymer carboxylate site resulted in decreased negative charge density at that site. This resulted in reduced energy requirements for nearby carboxylic acid groups to ionize and, therefore, in a lowering of the pH (11). This decrease in pH has, in fact, been used to establish the magnitude of binding of counterions to polyanions (12–15).

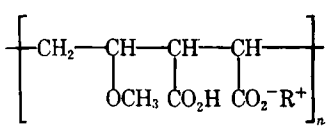
The studies described above, taken together, strongly suggest the formation of electrostatic complexes between polyanions and cations. The evidence for interaction with long-chain quaternary ammonium salts such as benzethonium chloride, however, is nonexistent. Furthermore, evidence of this kind of interaction with a type of copolymer such as methoxyethylene–maleic anhydride is lacking. Therefore, an investigation was undertaken to determine the nature of the mixture of benzethonium chloride and methoxyethylene–maleic anhydride copolymer.

EXPERIMENTAL SECTION

Preparation of Benzethonium Chloride–Polymer Mixtures in Water—Methoxyethylene–maleic anhydride copolymer[1] (100 mg) was added to deionized, distilled water at 50°C. The pH was adjusted with 3 M NH_4OH to 5.0, and the solution was diluted to 100 mL. An equal volume of a 0.2% solution of benzethonium chloride[2] in water was slowly added while maintaining the pH at 5.0–5.1 with 3 M NH_4OH. The final concentration was 0.0023 M NH_4^+, 0.0022 M benzethonium chloride, and 0.0032 M methoxyethylene–maleic acid repeating units. A 5% solution of the polymer was used for titration studies with 4 M NaOH (Fig. 1). Copolymer and benzethonium chloride were used as received.

Other benzethonium chloride–polymer mixtures were prepared in the same manner, but without pH adjustment, to provide the same concentrations of repeating units as described above. The complex was also prepared in 50% acetone by mixing equal volumes of 0.2% benzethonium chloride in acetone with 0.016–0.4% aqueous solutions of the copolymer at room temperature.

Dialysis—Cellulose acetate dialysis tubing[3], with a molecular weight cutoff of 12,000, was washed with distilled, deionized water. Equilibrium dialysis was performed at room temperature, with solvent inside and outside of the bag identical in composition and pH, under the following conditions: (*a*) equal volumes outside and inside the bag; (*b*) four times the volume outside as inside the bag; and (*c*) 19 times the volume outside as inside the bag.



I: $R^+ = NH_4^+$

II: $R^+ = (CH_3)_3CCH_2C(CH_3)_2$—C$_6H_4$—$(OCH_2CH_2)_2\overset{+}{N}(CH_3)_2$ with $CH_2C_6H_5$

[2] Hyamine 1622; Rohm and Haas, Philadelphia, Pa.
[3] Arthur H. Thomas Co., Philadelphia, Pa.

Advantages of the high ratio were that it allowed more unbound ions to dialyze out of the bag and there was a reduction of the Donnan effect. The disadvantage, however, was that any material of interest outside the bag was diluted. The ratio used depended on the optimum requirement for a particular experiment.

Dialysis was performed for 18–24 h with constant stirring. Before analysis of components under condition *c*, the volume of solution was concentrated to the volume found inside the bag.

Effect of Salivary Components—Four solutions, each containing some of the salivary components from simulated saliva (16, 17), were prepared (Table I). The solutions were: (A) calcium and magnesium salts, (B) potassium and sodium salts, (C) all saliva salts included in A and B; (D) proteins. For the salt reactions, 1 volume of these solutions or water was added to 3 volumes of 0.1% benzethonium chloride–polymer mixture and dialyzed. On the outside of the dialysis bag was a mixture of the salts with the same concentration as inside the bag. Dialysis proceeded according to condition *c*.

For the protein reactions, 1 volume of protein solution was added to 3 volumes of benzethonium chloride or the benzethonium chloride–polymer mixture and dialyzed according to condition *a*.

Analysis of Benzethonium Chloride—Benzethonium chloride was determined by anionic titration with sodium lauryl sulfate, using disulphine blue–dimidium bromide as an end point indicator (18).

Analysis of Ammonia—Ammonia was determined with an ammonium ion-selective electrode[4].

RESULTS AND DISCUSSION

Equilibrium Dialysis—An aqueous mixture of benzethonium chloride and ammonia-adjusted hydrolyzed methoxyethylene–maleic acid copolymer contained 0.0023 M ammonia, 0.0022 M benzethonium chloride, and 0.0032 M copolymer repeating units. This mixture was equilibrium dialyzed by using dialysis condition *c*. If all the benzethonium cations formed an electrostatic complex with the polymer anions, which by virtue of its molecular weight (500,000) would not pass through the membrane, then one would have expected to find all the benzethonium cations (0.0022 M) and only 0.05% of the ammonium ions (0.0001 M) inside the dialysis bag. On the other hand, if there was no selective binding of the benzethonium cation to the polymer counterion, then half of the benzethonium cation (0.0011 M) and half of the ammonium cation (0.0012 M) would have remained inside the bag to maintain charge neutrality with that portion of the polymer which is ionized (0.0023 M).

The results (Table II) show that approximately all the benzethonium cations (0.0024 M) and only 0.0001 M ammonium ions remained inside the dialysis bag. Virtually no benzethonium cations and most of the ammonium ions were found outside the bag. The ammonium ion concentration outside the bag would probably have been even higher if not for the likely loss of ammonia during the concentration step. These results indicate selective electrostatic binding of the benzethonium cations to the copolymer anions, *i.e.*, formation of an electrostatic complex.

pH Drop—The pH of a 0.20% benzethonium chloride concentrate rose slightly after being diluted to 0.10%, as would be expected for a twofold dilution. Similarly, after a 0.10% ammonia-adjusted copolymer concentrate was adjusted to 0.05%, the pH also rose slightly. When the two concentrates were diluted by mixing together, however, the pH decreased to below that of the individual components (Table III). This could be due to the fact that the benzethonium cation had a higher affinity than NH_4^+ for the polymer anion. This, in effect, reduces the amount of negative charge on the neutralized carboxylate group, permitting the adjacent carboxylic acid group to ionize, thus lowering the pH.

Stoichiometry—In Table IV, a study of precipitation conditions for the mixture is presented. It shows that when one equivalent of benzethonium chloride was mixed with one equivalent of active carboxylic acid (pK_a 3.7),

Table III—pH Drop in Mixing Benzethonium Chloride and Methoxyethylene–Maleic Anhydride Copolymer

Mixture Composition	pH
0.10% Benzethonium chloride	6.38
0.05% Ammonia-adjusted methoxyethylene-maleic anhydride copolymer	5.82
0.10% Benzethonium chloride and 0.05% ammonia-adjusted methoxyethylene-maleic anhydride copolymer (from respective stock solutions)	5.37

Table IV—Stoichiometry of Precipitation of Benzethonium Chloride and Active Methoxyethylene–Maleic Acid Copolymer Carboxylic Acids

Mixture Composition	Ratio of Equivalents of Mixture to Active Carboxylic Acid	Appearance
0.1% Benzethonium chloride + 0.050% polymer	1:1.5	Emulsion
0.1% Benzethonium chloride + 0.033% polymer	1:1	Precipitate
0.1% Benzethonium chloride + 0.025% polymer	1:0.75	Emulsion
0.1% Benzethonium chloride + 0.017% polymer	1:0.50	Emulsion
0.1% Benzethonium chloride + 0.009% polymer	1:0.25	Emulsion
0.1% Benzethonium chloride	1:0	Clear Solution

a precipitate formed, but an excess of either reactant resulted in formation of an emulsion. This can be explained by formation of an electrostatic complex between the reactants, which would tend to reduce the effective charge on each of the components, thereby decreasing water solubility. At the same time, a large, hydrophobic molecule is produced, which would also tend to have minimal water solubility.

Formation of an emulsion at any other ratio is readily explainable. With an excess of copolymer, the surplus negative charge keeps the material partially suspended in water. With an excess of benzethonium chloride, the positively charged, surface-active benzethonium chloride acts an an emulsifying agent.

Other Anionic Polymers—The effect of polymer molecular weight was investigated as a possible parameter of interaction with benzethonium chloride; dialysis condition *c* was used. The methoxyethylene-maleic anhydride copolymers used all have the same structure but average molecular weights of 250,000[5] (A), 500,000[1] (B), and 1,250,000[6] (C), respectively. Table II shows the theoretical results expected for 100 and 0% electrostatic complexation of benzethonium chloride with copolymer B (used throughout this research). These values also apply for copolymers A and C. The observed results (Table V) show that in all three cases, approximately all of the benzethonium cation stayed inside the membrane and approximately all of the ammonium ion was released. That is, within the limits investigated, formation of an electrostatic complex proceeded to completion independent of molecular weight.

The possibility of electrostatic complex formation was also investigated for benzethonium chloride and other polycarboxylic acids. Benzethonium chloride was mixed with several different types of anionic polymers. Two changes were observed (Table VI) which are similar to those observed with benzethonium chloride and copolymer B. These changes were marked increases in turbidity and, generally, decreases in pH to below that of either of the individual components. The pH of the benzethonium chloride solution was 6.38. The pH of the polymer solutions are listed in Table VI.

These two effects are consistent with formation of an electrostatic complex. Production of turbidity was explained above. Decrease in pH by formation of an electrostatic complex is also easily explained. Methoxyethylene-maleic anhydride copolymer, polyacrylic acid, and ethylacrylate-methacrylic acid copolymer yield hydrochloric acid, a relatively strong acid, as a by-product of the reaction. (As explained above, for copolymer B the decrease in the pK_a of the less active acid should also contribute to the decrease in pH.) For the diisobutylene-maleic acid and vinyl alcohol-acrylic acid copolymers, in which sodium chloride rather than hydrochloric acid would be expected to be released during the formation of an electrostatic complex, no decrease in pH was observed. One of these polymers, the disodium salt of the copolymer of diisobutylene-maleic acid, was further investigated by equilibrium dialysis. After equilibrium was attained, 98% of the benzethonium cation remained inside the membrane, demonstrating electrostatic complex formation. Dialysis was not attempted with the sodium salt of the vinyl alcohol-acrylic acid copolymer because of difficulties anticipated due to the precipitate.

Table V—Equilibrium Dialysis of Aqueous Mixture of Ammonia, Benzethonium Chloride, and Three Copolymers of Different Molecular Weights

Cation	Mol. Wt. 250,000	Mol. Wt. 500,000	Mol. Wt. 1,250,000
Benzethonium[a]	0.105[b]	0.107	0.108
Ammonium	0.0002[b]	0.0002	0.0002

[a] Calculated as benzethonium chloride. [b] Inside membrane, %.

Effect of Acetone—To elucidate the driving force of the reaction, it was of interest to determine the effect of other solvents on the benzethonium-copolymer complex. The reaction mixture was made with water-acetone (50:50) as solvent. The ratios of equivalents of benzethonium chloride-active carboxylic acid groups ranged from excess benzethonium chloride (1:0.25, for 0.1% benzethonium chloride and 0.008% copolymer) to excess carboxylic acid groups (1:6.00, for 0.1% benzethonium chloride and 0.200% copolymer). The solutions were dialyzed according to condition *b*. The degree of complexation was determined by analysis of the benzethonium cation inside and outside the membrane. The observed values were compared with theoretical values calculated *via* Donnan's equilibria.

The results (Table VII) show very good agreement between the observed ratio and that calculated for 0% complexation, indicating that, surprisingly, reaction did not occur, which is in contrast to the corresponding situation in water in which the reaction went to completion. This would suggest that a driving force of the reaction in acetone is different than in water. It has been suggested that in water, charged species (polyanions and polycations) show an increase in entropy (9). Molecules tend to occupy as much space as possible. Movement of the polymer microions is restricted due to the limited movement of the polyelectrolyte chain. Therefore, there is an "escaping tendency" of the microions. This escaping tendency is overcome by two oppositely charged polyions coming together, thereby liberating the microions from the polyelectrolyte. One would expect the reaction also to occur in aqueous acetone because the same escaping tendency should be present. However, the reaction did not occur in aqueous acetone.

This suggests a second possibility with respect to the driving force of the reaction. Benzethonium chloride forms micelles in water due to the incompatibility of the hydrophobic tails with water. The extent of this micelle formation is limited because of the repulsion among the positively charged benzethonium head groups. This can be overcome, however, by the oppositely charged field exerted by the polyanion. That is, strong attraction of the positively charged head groups on the benzethonium cation with the negatively charged field exerted by the polyanion tends to reduce the repulsion of the benzethonium cations with each other, allowing increased formation of micelles. This could be the driving force for the reaction in water. In acetone, however, there is no incompatibility between the benzethonium hydrophobic tails and the solvent and, therefore, no micelle formation. The reaction, therefore, should not, and did not, take place in acetone. Hence, a driving force for the reaction that is consistent with the facts is increased hydrophobic interactions of the long chains rather than increased freedom of the microions. Both could cause an increase in entropy.

Influence of pH—The effect of pH on the stability of aqueous benzethonium-copolymer complex was studied (Table VIII). The mixture was treated with either dilute hydrochloric acid or ammonium hydroxide to achieve the desired pH. Virtually no difference in appearance was observed at pH 4.0, 5.0, and 8.0. A decrease in pH to 3.6, however, by slow addition of hydrochloric acid led to complete clarification of the supernatant and concomitant formation of a precipitate. On the other hand, when hydrochloric acid was rapidly added to the pH 5.0 emulsion until it was at pH 2.0, a clear solution resulted without ever going through a precipitate stage. At pH 1.0, the clear solution separated into an oil and a clear supernatant.

Analysis of the dispersions or clear supernatants before dialysis showed the theoretical amount of benzethonium cation at pH 2.0, 4.0, 5.0, and 8.0, but not at pH 1.0 and 3.6. This suggests that there was a meaningful amount of benzethonium cation in the oil (pH 1.0) and solid precipitate (pH 3.6).

The mixtures of pH 2.0, 4.0, 5.0, and 8.0 were treated according to dialysis condition *b*. The results demonstrate that at pH $\geq$ 4.0, approximately all of the benzethonium cation is retained inside the membrane; however, at pH 2.0, within experimental error, the benzethonium cation is evenly distributed on both sides of the membrane. The formation of a precipitate at pH 3.6 can be explained by the fact that protons react with any excess negatively charged

Table VI—Comparison of pH and Appearance of Polymers Before and After Addition of Benzethonium Chloride

Polymer	pH of Polymer		Appearance of Polymer

[a] Calculated as benzethonium chloride. [b] Virtually only the supernatants were analyzed.

groups on the complex, thereby making the complex less water soluble. Formation of a clear solution at pH 2.0, in which the benzethonium cation was approximately evenly distributed inside and outside of the membrane, can be explained by the fact that the hydrogen and chloride ions of the hydrochloric acid successfully compete with the reactants for the charged sites on the complex. Hence, at pH 2.0, the benzethonium-polymer complex dissociated to form the soluble protonated polymer and soluble benzethonium chloride, and the benzethonium chloride passed through the dialysis bag. At pH 1.0, the same situation as at pH 2.0 existed, except that benzethonium chloride was insoluble at low pH. The results of the studies at pH 4–8 demonstrated that at these pH values, stable emulsions formed.

Effect of Saliva—Since the ultimate use of the benzethonium-copolymer complex was for a mouth rinse or dentifrice, it was important to determine whether it remained intact in the presence of saliva. Saliva contains mainly salts and glycoproteins. Due to experimental difficulties in working with whole saliva containing both salts and proteins, simulated saliva was made containing either one or the other.

Salivary Salts—After it was shown in a preliminary experiment that, indeed, the complex dissociated considerably in the presence of saliva salts under exaggerated conditions (in terms of contact time and concentrations of salts), it was of interest to determine which salts in the saliva were responsible for this dissociation. The reaction of the benzethonium-copolymer complex with salivary salts was studied by equilibrium dialysis condition *c*. The composition inside the dialysis tube roughly simulated in-use conditions, *i.e.*, dilution of a mouth wash by 25% with the saliva salt solution. This saliva salt solution had approximately the same composition as found in saliva. Benzethonium chloride and the benzethonium-copolymer complex diluted by 25% with water, were used as controls.

Table IX—Effect of Salivary Salts on Decomposition of Benzethonium-Copolymer Complex[a]

Reaction Mixture	Benzethonium Cation Inside of Bag After Dialysis, %[b]
Benzethonium chloride[a]	0.004
Benzethonium-copolymer complex	0.079
Benzethonium-copolymer complex and potassium and sodium salts	0.071
Benzethonium-copolymer complex and calcium and magnesium salts	0.064
Benzethonium-copolymer complex and all saliva salts	0.023

[a] 0.075% with respect to benzethonium chloride. [b] Calculated as benzethonium chloride.

The data (Table IX) show that the 0.075% benzethonium chloride was not held back by the dialysis membrane and was diluted ~20-fold by the dialysis solution. The 0.075% benzethonium-copolymer control was essentially maintained completely (0.079%) inside the membrane. In the presence of either the monovalent or divalent salts, little effect was apparent, with final concentrations of 0.071 and 0.064%, respectively. But when the monovalent and divalent salts were combined, a marked dissociation of the complex resulted. It appeared that a combination of calcium and magnesium salts and high ionic strength had a synergistic effect, giving a significant dissociation of the benzethonium-copolymer complex.

The contribution of calcium and magnesium ions was also studied by atomic absorption (Table X). The data show that the number of moles of calcium and magnesium ions which became bound to the copolymer was approximately equal to the sum of the carboxylate groups which contained sodium and am-

Table X—Relationship Between Available Copolymer Carboxylates and Binding of Calcium and Magnesium Ions

	Available Carboxylate[a], mol × 10^{-5}/100 mL	Bound Ca and Mg, mol × 10^{-5}/100 mL
Before salt reaction	8	—
After salt reaction	19	20

[a] Available carboxylate groups before the reaction are those containing sodium or ammonium counterions; available carboxylate groups after the reaction include the ones with sodium or ammonium counterions as well as those in which the benzethonium cations were displaced.

Table XI—Effect of Salivary Protein on Stability of the Benzethonium–Copolymer Complex

Mixture Composition	Benzethonium Cation After Dialysis, %[a]	
	Inside Bag	Outside Bag
Benzethonium chloride	0.038	0.038
Benzethonium chloride and mucin	0.034	0.032
Benzethonium chloride and α-amylase	0.038	0.038
Benzethonium-copolymer complex	0.071	0.000
Benzethonium-copolymer complex and mucin	0.074	0.001
Benzethonium-copolymer complex and α-amylase	0.071	0.002

[a] Calculated as benzethonium chloride.

monium ions and those groups which were freed of benzethonium cations. This suggests a direct relationship between the amount of benzethonium cation released from the polymer and the amount of divalent cations taken up.

The dissociation of the complex in the presence of saliva salts can be represented by Scheme I:

$$Bt^+G^- + M^+X^- \rightleftharpoons Bt^+X^- + M^+G^-$$

Scheme I

where Bt represents benzethonium, G represents the copolymer, M represents the saliva salt cations, and X represents the saliva salt anions.

These results provide a reasonable explanation for the mode of action of the benzethonium-copolymer complex in the oral cavity (2). Simply, the calcium-magnesium ions of the saliva displace the benzethonium cation in the benzethonium-copolymer electrostatic complex. Slow release of the benzethonium cations by the saliva salts explains the low plaque and gingivitis values since benzethonium chloride is an active antimicrobial compound. Complexation of calcium ions from the saliva by the copolymer explains the low calculus value.

Salivary Proteins—The stability of the benzethonium-copolymer complex with another type of salivary component, the proteins, was also studied by equilibrium dialysis (condition *a*). Benzethonium chloride and the benzethonium-copolymer complex were mixed with salivary proteins and dialyzed. The results (Table XI) show that the benzethonium cations from benzethonium chloride solutions were approximately evenly distributed inside and outside the dialysis bags, not being affected by the proteins, and the benzethonium cation from the benzethonium-copolymer emulsions remained inside the bag, not being released by the proteins.

If a complex formed between the proteins and the benzethonium cation, then the benzethonium cation would have been trapped with the protein inside the bag, since the molecular weight cutoff of the membrane is 12,000. The fact that in the benzethonium chloride-protein cells, the benzethonium cation was not trapped indicated that the salivary proteins had little or no affinity for the benzethonium cation. If the proteins formed some sort of complex with the copolymer, thereby dissociating the benzethonium-copolymer complex, then the benzethonium cation would have been found in the dialysate. It was not. Hence, although the complex dissociated in the presence of salivary salts, it did not dissociate in the presence of saliva proteins.

CONCLUSIONS

A mixture of benzethonium chloride and methoxyethylene-maleic anhydride copolymer formed an electrostatic complex of the benzethonium cation and the anion of the hydrolyzed polymer, as determined by dialysis, pH, and stoichiometric evidence. An emulsion of the complex was stable in the presence of an excess of either constituent and at pH > 4. The complex was unstable at pH < 4, precipitated at stoichiometric quantities, and did not form in 50% acetone. It was decomposed by simulated saliva because of calcium and magnesium ions in saliva and was unaffected by saliva proteins.

Increased Skin Permeability for Lipophilic Molecules

EUGENE R. COOPER

Received July 30, 1982, from *The Procter & Gamble Co., Miami Valley Laboratories, Cincinntai, OH 45247.* Accepted for publication August 25, 1983. Present address: Alcon Laboratories, Fort Worth, TX 76134.

Abstract □ Treatment of the epidermis with surfactants can markedly increase the transport of polar molecules but only marginally increases the transport of nonpolar (lipophilic) molecules. Thus, other vehicle systems are needed to increase the transport of lipophilic molecules. One method to accomplish this increased transport is to add small quantities of polar lipids to a base vehicle containing propylene glycol. The transport of nonpolar materials such as salicylic acid can be increased by an order of magnitude by the addition of small amounts of fatty acids or alcohols to a formulation. The effect of this mixed system is much greater than the effect of any of the agents alone.

Keyphrases □ Transport systems—increased skin permeability, lipophilic molecules □ Lipophilic molecules—transport systems, increased skin permeability

The stratum corneum, which is the main barrier to cutaneous transport (1), is structurally a complex membrane, and thus, transport probably takes place through a variety of pathways. It has been suggested in a study of the effect of temperature on the penetration of alcohols (2) that there are at least two pathways for transport across the skin: a polar pathway and a nonpolar pathway. The polar pathway is associated with the protein component of the stratum corneum and might be envisioned as aqueous channels in the protein; the nonpolar pathway is associated with the lipid component.

In recent studies (3), the attempt has been made to clarify and support the hypothesis that there are at least two parallel pathways for transport by using surfactant treatment, which greatly increases the transport of polar molecules but only slightly increases the transport of nonpolar molecules. For example, it has been found that treatment of the human epidermis with decylmethyl sulfoxide greatly increases the transport of salicylic acid at pH 9.9 (ionized or polar form) but only slightly increases salicylic acid transport at pH 2.65 (un-ionized or nonpolar form). Other studies have shown that the transport of 1-propanol is greater than that of propylene glycol or glycerol. That is, even though propylene glycol has a much higher oil–water partition coefficient than glycerol (4), its cutaneous flux from aqueous solution is only slightly greater than that of glycerol but much less than that of 1-propanol. Thus, as the polarity of a molecule is increased, *i.e.*, its oil–water partition coefficient decreases, a polarity exists for which the oil–water partition coefficient is not related to transport. These results differ noticeably from those obtained previously (2), in which even 1-pentanol is claimed to transport *via* a polar pathway.

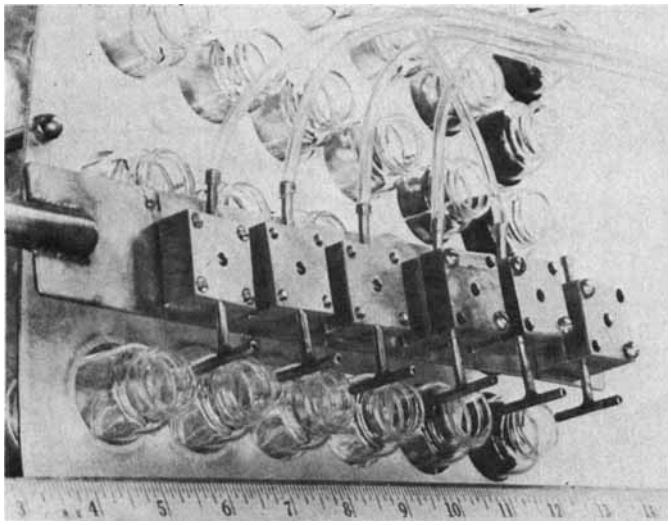

Figure 1—*Diffusion cell.*

The existence of multiple transport pathways in skin points to the possibility for design of vehicles to alter the permeability of the skin *via* the different pathways, as the surfactants seem to uniquely alter the polar pathway. Certain two-component systems have been found which alter transport differently from the way the components behave individually. The purpose of this report is to describe the effects of these vehicle systems on the transport of nonpolar molecules across skin. Salicylic acid was used as a prototype nonpolar compound, but similar results were obtained on many other nonpolar compounds. A model is proposed to interpret these findings, but the mechanism by which these vehicles alter transport is still unknown.

EXPERIMENTAL SECTION

Materials—Salicylic acid[1], [^{14}C-carboxylate]salicylic acid[2], the fatty acids and alcohols[3], propylene glycol[4], diethylene glycol[5], and the polyethylene glycols[6] were obtained commercially. The sulfoxides (purity >95%) were synthesized[7], and the dimethyl polysiloxane[8] rubber membranes were cast on a large stainless steel plate. All other chemicals used were of reagent grade.

Diffusion Studies—*Epidermis Preparation*—Full-thickness human ab-

dominal skin was obtained at autopsy and frozen until ready for use. The subcutaneous fat was removed with a scalpel, and the skin was placed in water at 60°C for 80 s. The epidermis was carefully removed and mounted (outer surface up) on aluminum foil before rinsing in 0°C hexane for 10 s to remove

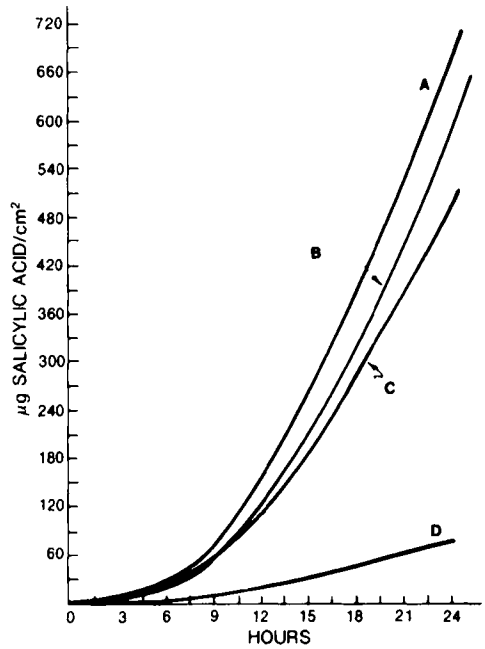

Figure 6—*Effect of the addition of* cis*-unsaturated fatty acids on the penetration of 1% salicylic acid in propylene glycol across human epidermis. Key: (A) 0.1 M myristoleic acid; 0.1 M palmitoleic acid; (C) 0.1 M oleic acid; (D) propylene glycol.*

any fat contamination. The epidermis was either used immediately or wrapped in a plastic sheet[9] and frozen.

Experimental Apparatus—The epidermis was mounted in diffusion cells as pictured in Fig. 1. The flat surfaces of the cell provide a pressure seal after the epidermis is placed between the two compartments, which are bolted together. Up to 100 µL of solution can be placed in the chamber above the skin. The area for transport is 0.122 cm². Water was pumped *via* a multichannel peristaltic pump through the lower compartment at 3.5 mL/h and collected in scintillation vials placed in a programmable rotating fraction collector. Figure 2 shows the entire assembly. The volume of water in the chamber beneath the skin is ~5 µL, so the volume beneath the skin is replaced ~100 times/h. The temperature of the experiments was that of the laboratory, 22 ± 1°C.

Assay for Penetration—Approximately 1 µCi of radioactive tracer was used for each diffusion cell. The quantity of radioactive tracer transported

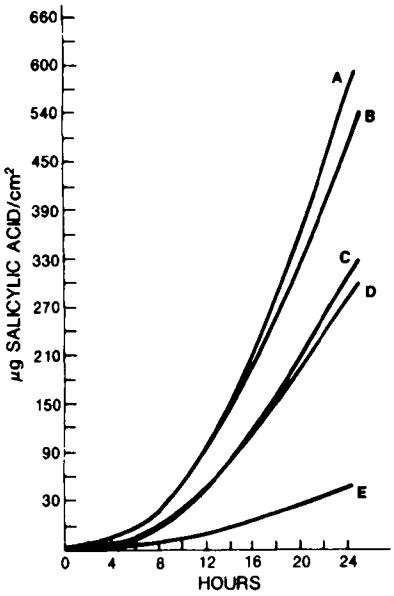

Figure 8—*Effect of the addition of polyunsaturated fatty acids on the penetration of 1% salicylic acid in propylene glycol across human epidermis. Key: (A) 0.1 M linolenic acid; (B) 0.1 M linoleic acid; (C) 0.1 M vaccenic acid; (D) 0.1 M linoelaidic acid; (E) propylene glycol.*

across the skin and collected in the scintillation vials was determined by liquid scintillation counting. The scintillation counting solution (10 mL), added to each 7-mL sample, consisted of cocktail stock solution. The latter consisted of 2,5-diphenyloxazole (8 g) and 1,4-bis(4-methyl-5-phenyloxazol-2-yl) benzene (0.16 g) per liter of toluene.

Variation in Data—The epidermal transport from each vehicle was determined in quadruplicate, and the variation in the data was ±25%. Data on each graph represent separate experiments run on different days with different epidermal samples.

RESULTS AND DISCUSSION

The vehicles described in this paper are two-component systems consisting of a polar solvent, such as propylene glycol, and a lipid, such as oleic acid. The choice of polar solvent is important, since there is a wide range in the effects of polar solvents. For example, it can be seen in Fig. 3 that propylene glycol and diethylene glycol support a high rate of transport of salicylic acid but that the flux drops off some as the number of ethylene oxide groups is increased. (Note that comparisons are made among saturated solutions to ensure equal thermodynamic activity.) Transport of salicylic acid across a dimethyl polysiloxane membrane (Fig. 4) was essentially the same from each of these

solvents. This result indicates that polar solvents interact differently with skin and that the variations in transport are not due to solution phenomena.

The addition of a small amount of oleic acid to propylene glycol provides for a rather large increase in salicylic acid transport (Fig. 5). (Similar increases

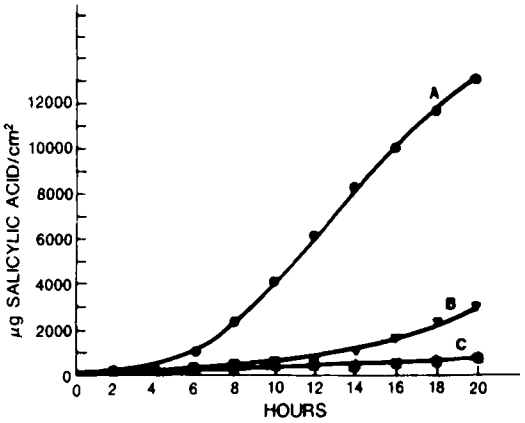

Figure 13—*Penetration of salicylic acid at saturation from oleic acid–propylene glycol or –1,2-butanediol vehicles across human epidermis. Key: (A) 15% salicylic acid in 0.25 mole fraction oleic acid–propylene glycol; (B) 15% salicylic acid in 0.25 mole fraction oleic acid–1,2-butanediol; (C) 23% salicylic acid in propylene glycol or 1,2-butanediol.*

in transport were also observed for the other polar solvents, but only the results for propylene glycol are presented.) Other unsaturated fatty acids give a similar result. Figures 6–8 show the effects of chain length and number and type of double bonds. The effect is reduced for saturated fatty acids (Fig. 9). Long-chain saturated fatty acids are too insoluble in propylene glycol for any effect on transport to be observed.

As the concentration of oleic acid (or oleyl alcohol) is increased, the transport of salicylic acid is also increased, up to a point. As the concentration of lipid is further increased, the flux of salicylic acid decreases (Fig. 10). Here, as mentioned above, transport from saturated solutions is compared to ensure equal driving force (chemical potential). The transport of salicylic acid from saturated solutions of propylene glycol (~22%) and oleic acid (~4%) [or water (0.2%)] are the same. However, use of a mixture of the two materials gives a ~20-fold increase in the transport rate.

The hydrocarbon chain seems to be the important factor as to whether a lipid will increase transport. For example, it can be seen (Fig. 11) that only the unsaturated methyl sulfoxide increases transport. Stearyl methyl sulfoxide also had no effect on transport. However, for alcohols, even the saturated chains can increase transport (Fig. 12). Here, the longer chains are more effective at increasing transport until the length of the chain exceeds 14. At this point, solubility of the alcohol becomes too small for an effect on transport to be observed. Other diols also exhibit this synergism with lipids, but the effect is less pronounced as the chain length is increased (Figs. 13 and 14).

The mechanism by which the epidermal barrier properties are altered is

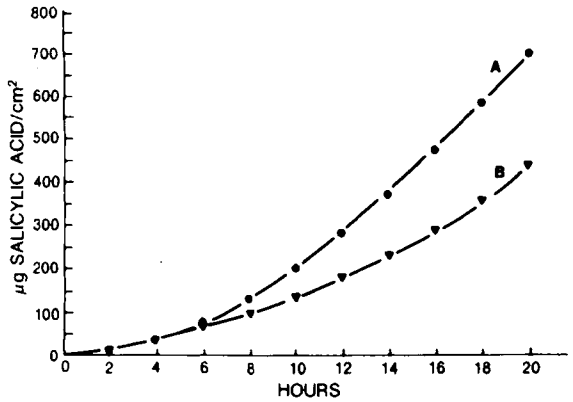

Figure 14—*Penetration of salicylic acid at saturation from oleic acid–1,2-hexanediol vehicles across human epidermis. Key: (A) 24% salicylic acid in 0.25 mole fraction oleic acid–1,2-hexanediol; (B) 14% salicylic acid in 1,2-hexanediol.*

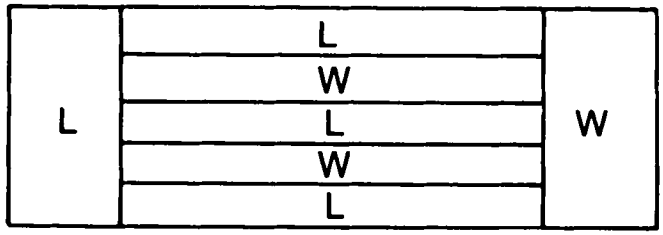

Figure 15—*Model for skin transport.*

not known, but differential scanning calorimetry studies of the stratum corneum[10] indicate that the two-component systems result in an increased fluidization of the stratum corneum lipids. This effect could then result in more rapid diffusion of the molecules across skin. The use of two different solvents to increase solute solubility has been known for some time as "cosolvency" and "blending" (5), and there might be a connection between cosolvency and the effects observed in this study on skin transport.

Regardless of the detailed mechanism by which these vehicles act, the results presented here open the door to the investigation of multicomponent systems to alter the barrier properties of skin. The penetration-aid guidelines obtained from this study and an earlier report (3) indicate that, for polar molecules, the head groups dominate (ionic > zwitterionic > nonionic) and for nonpolar molecules (polar solvent plus lipid), the hydrocarbon chains dominate. It was predicted that branched-chain lipids would be as effective as unsaturated lipids; this was, indeed, the case for isostearic acid.

A general way to categorize the pathways for transport in skin is depicted in Fig. 15, in which no attempt was made to assign a pathway to a particular morphological structure. J_s, the flux at steady state, can be written as:

$$J_s = a_w J_w + a_{Lw} J_{Lw} + (1 - a_w - a_{Lw}) J_L$$

where a_w is the area fraction of the aqueous pathway, a_{Lw} is the area function of the lipid–water pathway, J_w is the flux across the aqueous pathway, J_{Lw} is the flux across the lipid–water pathway, and J_L is the flux across the lipid pathway. It seems clear that there exists a continuous polar pathway, because the flux (at constant concentration) levels off with a decreasing oil–water partition coefficient and because surfactants act primarily to increase the transport of polar molecules. The pathway with the largest area fraction is probably the lipid–water pathway because molecules that have high solubility in both oil and water have the greatest transport. The lipid continuous pathway is included to account for the transport of very lipophilic molecules (such as benzyl salicylate), for which water becomes a major barrier to transport. The two-component systems described in this report act primarily on the lipid barriers, but they may have some effect on the polar pathway.

Fluorescence Determination of Microconcentrations of Chlorambucil after Photoactivation

L. G. BERNIER *x, R. C. GAUDREAULT ‡, M. PAGE *, and L. P. JOLY ‡

Received March 9, 1983, from the *Department of Biochemistry, Faculty of Medicine and the ‡School of Pharmacy, Université Laval, Québec, G1K 7P4, Canada. Accepted for publication May 20, 1983.

Abstract □ A fluorescence assay is described which measures the alkylating activity of chlorambucil or its isocyanate derivative after photoactivation in the presence of dimethyl sulfoxide. This assay has a lower limit of sensitivity of 100 ng/mL and *RSD* of <10% for chlorambucil. The method requires <5 μg of alkylating agent and the fluorophore produced is stable for at least 24 h.

Keyphrases □ Chlorambucil—isocyanate derivative, alkylating activity, fluorescence assay □ Nitrogen mustards—chlorambucil and its isocyanate derivatives, alkylating activity, fluorescence assay

Bifunctional alkylating agents are used extensively in the chemotherapeutic treatment of neoplastic and autoimmune diseases. Several colorimetric methods for the determination of specific nitrogen mustards have been described (1–5). These methods are based on the first report by Epstein *et al.* (6) who first showed the reaction of alkylating agents with nitrobenzylpyridine. A fluorometric method has also been described (7) which has a greater sensitivity, but it was not applicable to chlorambucil.

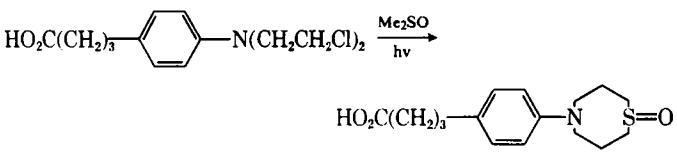
Gaudreault (8) reported that chlorambucil dissolved in dimethyl sulfoxide and exposed to UV light yielded a mixture of products. The fluorescence of the mixture was proportional to the amount of chlorambucil present. Perhydrothiazocine was the most important fluorophore; its structure was determined by mass spectrometry (8).

We describe here the use of this reaction (Scheme I) for the quantitative determination of chlorambucil. This method is sensitive while requiring little material.

EXPERIMENTAL SECTION

Chlorambucil[1] was dissolved in dimethyl sulfoxide[2]. The isocyanate of chlorambucil, 3-{4-[bis(2-chloroethyl)amino]phenyl}propyl-isocyanate, was produced in-house using a literature method (9).

A 200-W UV lamp[3] supplied by a power unit[4] was used for the photoactivation. A UV meter[5] was used to check the UV lamp periodically. Quartz cuvettes[6] (10-mm path length) were placed circularly at 10 cm around the lamp to expose the samples; the fluorescence was then read in the same cuvettes. A spectrophotofluorometer[7] was used to measure the fluorescence of the samples at 434 nm for emission after an excitation at 358 nm.



Scheme I

[7] Model 4-0202; Aminco-Bowmann, Silver Spring, Md.

Chlorambucil (1 mg/mL) was dissolved in dimethyl sulfoxide and stored at −20°C until use. Standards from 0.1 to 20 μg/mL were freshly prepared by dilution of the stock solution with dimethyl sulfoxide. Two milliliters of the standard was placed in quartz cuvettes and the background fluorescence was read. Samples were placed for 30 min in the UV illuminator (Fig. 1). They were then allowed to cool for 20 min and the fluorescence was read again. The difference in the fluorescence was plotted against the concentration of chlorambucil. The method was also applied to the isocyanate of chlorambucil.

RESULTS

Standard Curves—Following the assay procedure described above, we found a linear relationship between the fluorescence and chlorambucil concentrations varying from 0.1 to 1 μg/mL ($r = 0.986$) and from 1 to 20 μg/mL ($r = 0.999$). We also found a very good linear relationship using the isocyanate of chlorambucil ($r = 0.999$) for concentrations varying from 1 to 10 μg/mL. The lower

Table I—Intra- and Interassay Relative Standard Deviations for Two Concentrations of Chlorambucil and Isocyanate of Chlorambucil

Assay	Conc., μg/mL	Mean of Fluorescence	*RSD*, % Intra-assay	*RSD*, % Interassay
Chlorambucil				
1	2	11.9 ± 0.854	7.17	
2	2	11.6 ± 1.25	10.7	9.25
3	2	11.5 ± 1.08	9.39	
4	2	9.63 ± 0.479	4.97	
1	5	48.2 ± 1.41	2.92	
2	5	52.1 ± 1.93	3.70	8.79
3	5	58.0 ± 1.73	2.98	
4	5	57.8 ± 2.66	4.60	
Isocyanate of Chlorambucil				
1	2	20.3 ± 1.60	7.88	
2	2	20.3 ± 1.20	5.91	
3	2	13.6 ± 0.980	7.21	21.1
4	2	14.5 ± 1.17	8.07	
1	5	51.1 ± 1.65	3.23	
2	5	50.0 ± 1.73	3.46	
3	5	48.9 ± 1.03	2.11	5.25
4	5	45.2 ± 1.16	2.57	

limit of sensitivity of 0.1 μg/mL found with this method was 50-fold lower than the one obtained with the nitrobenzylpyridine method (5).

Reproducibility of the Assay—We found intra-assay *RSD* of 8.1 and 3.6%, respectively, at 2 and 5 μg/mL. The interassay *SD* was determined on four fluorescence measurements at 2 and 5 μg/mL and we found *SD* of 9.3 and 8.8%, respectively. The intra- and interassay relative standard deviations were also obtained with the isocyanate derivative of chlorambucil at the same concentrations (Table I).

Fluorophore Stability—Contrary to the nitrobenzylpyridine assay, the fluorescence could be read several hours after the photoactivation of the samples by UV. When the fluorophore produced was kept in the dark, it was stable for at least 24 h. We found a variation of only 5% in the fluorescence during the 24-h period at room temperature. This is an advantage over the nitrobenzylpyridine method, which yields a highly unstable chromophore.

DISCUSSION

The method presented above offers many advantages over the existing method for measuring alkylating activity. This fluorescence method is at least 50 times as sensitive as the nitrobenzylpyridine colorimetric procedure proposed by Balazs *et al.* (5). The interassay relative standard deviations given may represent the variations in the intensity of the UV lamp and the daily variations in the fluorometer light source; these deviations are much lower when a standard curve is used for each assay. This assay may be performed in protein-containing solutions, in contrast to the other assays available which require incubation at 85°C and cause protein precipitation.

Since alkylating activity is measured in this assay, it is essential that the assay is performed with an active alkylating agent; therefore, chlorambucil must be kept in a desiccator to prevent hydrolysis and formation of the hemimustard. The method proposed above measures the alkylating activity of chlorambucil; it should be useful for studying the metabolism of this compound in biological fluids.

Quantitation of Phenobarbital and Phenobarbital Sodium in Pharmaceutical Dosage Forms

V. DAS GUPTA

Received April 11, 1983, from the *Department of Pharmaceutics, University of Houston, Houston, TX 77030.* Accepted for publication July 29, 1983.

Abstract □ A reverse-phase high-performance liquid chromatographic method for the quantitation of phenobarbital and phenobarbital sodium in pharmaceutical dosage forms (elixir, injection, and tablets) was developed. The method is precise and accurate with percent relative standard deviations of 0.9 (without an internal standard) and 0.7 (with an internal standard) based on six injections. The method is stability indicating and is more sensitive than the revised USP–NF method. The products of decomposition showed two new peaks in the chromatogram.

Keyphrases □ Phenobarbital—quantitation with phenobarbital sodium in pharmaceutical dosage forms □ Phenobarbital sodium—quantitation with phenobarbital in pharmaceutical dosage forms

Phenobarbital (I) and phenobarbital sodium (II), extensively used as sedatives, are available in a variety of dosage forms, including capsules, elixir, injectable, tablets, *etc.* The literature for the quantitation of phenobarbital has been surveyed by Schmidt and Pennington (1). According to this report, investigations in which reverse-phase HPLC have been used without the addition of a counterion have not been successful. A reverse-phase HPLC assay procedure for phenobarbital with 0.01 M tetramethylammonium chloride as the counterion has been reported (1); however, the use of counterions usually shortens column life (2).

The revised USP–NF method for the quantitation of phenobarbital appeared in USP Supplement 3 (3), and use of a mobile phase of pH 4.5 is recommended.

The purpose of this investigation was to develop a stability-indicating assay method for the quantitation of phenobarbital and phenobarbital sodium in pharmaceutical dosage forms at neutral or weakly basic pH without the addition of a counterion to the mobile phase.

EXPERIMENTAL SECTION

Chemicals and Reagents—All chemicals and reagents were USP, NF, or ACS quality and used without further purification. The USP-quality powders of phenobarbital[1] and phenobarbital sodium[1] were used as received.

Table I—Intra- and Interassay Relative Standard Deviations for Two Concentrations of Chlorambucil and Isocyanate of Chlorambucil

Assay	Conc., μg/mL	Mean of Fluorescence	*RSD*, % Intra-assay	*RSD*, % Interassay
Chlorambucil				
1	2	11.9 ± 0.854	7.17	
2	2	11.6 ± 1.25	10.7	9.25
3	2	11.5 ± 1.08	9.39	
4	2	9.63 ± 0.479	4.97	
1	5	48.2 ± 1.41	2.92	
2	5	52.1 ± 1.93	3.70	8.79
3	5	58.0 ± 1.73	2.98	
4	5	57.8 ± 2.66	4.60	
Isocyanate of Chlorambucil				
1	2	20.3 ± 1.60	7.88	
2	2	20.3 ± 1.20	5.91	
3	2	13.6 ± 0.980	7.21	21.1
4	2	14.5 ± 1.17	8.07	
1	5	51.1 ± 1.65	3.23	
2	5	50.0 ± 1.73	3.46	
3	5	48.9 ± 1.03	2.11	5.25
4	5	45.2 ± 1.16	2.57	

limit of sensitivity of 0.1 μg/mL found with this method was 50-fold lower than the one obtained with the nitrobenzylpyridine method (5).

Reproducibility of the Assay—We found intra-assay *RSD* of 8.1 and 3.6%, respectively, at 2 and 5 μg/mL. The interassay *SD* was determined on four fluorescence measurements at 2 and 5 μg/mL and we found *SD* of 9.3 and 8.8%, respectively. The intra- and interassay relative standard deviations were also obtained with the isocyanate derivative of chlorambucil at the same concentrations (Table I).

Fluorophore Stability—Contrary to the nitrobenzylpyridine assay, the fluorescence could be read several hours after the photoactivation of the samples by UV. When the fluorophore produced was kept in the dark, it was stable for at least 24 h. We found a variation of only 5% in the fluorescence during the 24-h period at room temperature. This is an advantage over the nitrobenzylpyridine method, which yields a highly unstable chromophore.

DISCUSSION

The method presented above offers many advantages over the existing method for measuring alkylating activity. This fluorescence method is at least 50 times as sensitive as the nitrobenzylpyridine colorimetric procedure proposed by Balazs *et al.* (5). The interassay relative standard deviations given may represent the variations in the intensity of the UV lamp and the daily variations in the fluorometer light source; these deviations are much lower when a standard curve is used for each assay. This assay may be performed in protein-containing solutions, in contrast to the other assays available which require incubation at 85°C and cause protein precipitation.

Since alkylating activity is measured in this assay, it is essential that the assay is performed with an active alkylating agent; therefore, chlorambucil must be kept in a desiccator to prevent hydrolysis and formation of the hemimustard. The method proposed above measures the alkylating activity of chlorambucil; it should be useful for studying the metabolism of this compound in biological fluids.

Quantitation of Phenobarbital and Phenobarbital Sodium in Pharmaceutical Dosage Forms

V. DAS GUPTA

Received April 11, 1983, from the *Department of Pharmaceutics, University of Houston, Houston, TX 77030.* Accepted for publication July 29, 1983.

Abstract □ A reverse-phase high-performance liquid chromatographic method for the quantitation of phenobarbital and phenobarbital sodium in pharmaceutical dosage forms (elixir, injection, and tablets) was developed. The method is precise and accurate with percent relative standard deviations of 0.9 (without an internal standard) and 0.7 (with an internal standard) based on six injections. The method is stability indicating and is more sensitive than the revised USP–NF method. The products of decomposition showed two new peaks in the chromatogram.

Keyphrases □ Phenobarbital—quantitation with phenobarbital sodium in pharmaceutical dosage forms □ Phenobarbital sodium—quantitation with phenobarbital in pharmaceutical dosage forms

Phenobarbital (I) and phenobarbital sodium (II), extensively used as sedatives, are available in a variety of dosage forms, including capsules, elixir, injectable, tablets, *etc.* The literature for the quantitation of phenobarbital has been surveyed by Schmidt and Pennington (1). According to this report, investigations in which reverse-phase HPLC have been used without the addition of a counterion have not been successful. A reverse-phase HPLC assay procedure for phenobarbital with 0.01 M tetramethylammonium chloride as the counterion has been reported (1); however, the use of counterions usually shortens column life (2).

The revised USP–NF method for the quantitation of phenobarbital appeared in USP Supplement 3 (3), and use of a mobile phase of pH 4.5 is recommended.

The purpose of this investigation was to develop a stability-indicating assay method for the quantitation of phenobarbital and phenobarbital sodium in pharmaceutical dosage forms at neutral or weakly basic pH without the addition of a counterion to the mobile phase.

EXPERIMENTAL SECTION

Chemicals and Reagents—All chemicals and reagents were USP, NF, or ACS quality and used without further purification. The USP-quality powders of phenobarbital[1] and phenobarbital sodium[1] were used as received.

[a] With internal standard. [b] Without internal standard. [c] Not determined at this wavelength. [d] In aqueous solution containing 15% ethanol (v/v) and 45% glycerol (v/v).

Apparatus—The chromatograph[2] was equipped with a multiple-wavelength detector[3], a recorder[4], and a digital integrator[5]. A semipolar column[6] (30 cm × 4 mm i.d.) was used. The mobile phase contained 35% (v/v) of methanol in 0.02 M aqueous ammonium acetate. The flow rate was 2.0 mL/min, and the temperature was ambient. The sensitivity was set at either 0.2 (245 nm) or 0.1 (230 nm), and the chart speed was 30.5 cm/h.

Preparation of Stock and Standard Solutions—The stock solutions of phenobarbital (2.0 mg/mL in methanol), phenobarbital sodium (2.0 mg/mL in water) and the internal standard, mezlocillin sodium[7] (10.0 mg/mL in water) were prepared fresh daily. The standard solutions were prepared by diluting the appropriate quantities of stock solutions with water, methanol, or a mixture of both, as needed. All standard solutions of phenobarbital sodium were diluted with water. The standard solution of phenobarbital for assays at 230 nm contained 10% methanol (final concentration, v/v) in water, and pure methanol was used for diluting all solutions for assays at 245 nm. No internal standard was used for assays at 245 nm due to very poor absorbance at this wavelength. For assays at 230 nm, the concentration of the internal standard was 600.0 μg/mL.

Preparation of Assay Solutions—For assay at 230 nm, an appropriate quantity (3.75 mL) of phenobarbital elixir USP (4.0 mg/mL) was mixed with 10 mL of methanol and 6.0 mL of stock solution of the internal standard and brought to volume with water (100 mL). For assay at 245 nm, 6.25 mL of elixir was diluted to 25.0 mL with methanol.

Injections—An appropriate quantity of the injection of phenobarbital sodium was diluted with water to contain either 0.15 or 1.0 mg/mL of the drug for assays at 230 and 245 nm, respectively. The solution for assay at 230 nm also contained 0.6 mg/mL of mezlocillin sodium (internal standard).

Tablets—An appropriate quantity of the fine powder representing 200.0 mg of the phenobarbital powder was thoroughly mixed with 80 mL of methanol and shaken for 5 min. The mixture was brought to volume (100 mL) with methanol and filtered[8]. The first 15 mL of the filtrate was rejected and then collected for assay. For assays at 230 nm, 7.5 mL of the clear filtrate was mixed with 2.5 mL of methanol and 6.0 mL of the internal standard stock solution and brought to volume (100 mL) with water. For assays at 245 nm, a 12.5-mL quantity of the clear filtrate was diluted to 25 mL with methanol.

Assay Solutions of Decomposed Phenobarbital Sodium—A 30.0-mg sample of phenobarbital sodium powder was mixed with ~2 mL of ~1 M NaOH solution in a 150-mL beaker. The mixture was boiled on a hot plate for (*a*) ~4 min and (*b*) ~30 min; additional water was added as needed, and the mixture was cooled to room temperature and neutralized (pH ~6–8) with ~4 mL of ~0.5 M HCl. A 12.0-mL quantity of the stock solution of the internal standard was added, and the mixture was brought to volume (200 mL) with water. These solutions were assayed only at 230 nm.

Chromatographic Procedure—A 20-μL aliquot of the assay solution was injected into the chromatograph at the conditions described (solutions with internal standard, 230 nm; others, 245 nm). For comparison, an identical volume of the standard solution containing an identical concentration of the drug was injected after the assay solution was eluted.

Calculations—Since the peak heights (ratio of the peak heights when internal standard was added) were directly related to concentrations, the results were calculated by the equation:

$$100 \times \frac{R_{pha}}{R_{phs}} = \text{percent of the label claim}$$

where R_{pha} is the peak height (ratio of the peak height of drug to internal standard for assays at 230 nm) of the assay solution and R_{phs} is the peak height of the standard solution.

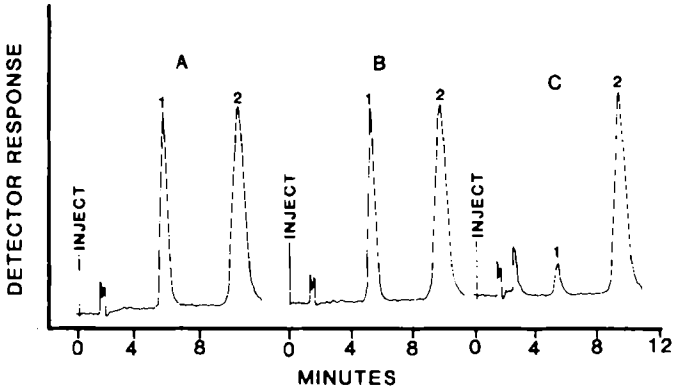

Figure 1—*Typical chromatograms at 230 nm. Peaks 1 and 2 are from phenobarbital sodium (II) and mezlocillin sodium (internal standard), respectively. Key: (A) standard solution; (B) injection containing 130 mg/mL of II; (C) decomposed solution (~30 min boiling, see text).*

RESULTS AND DISCUSSION

The assay results indicate (Table I) that the proposed HPLC method can be adopted for the quantitation of phenobarbital and phenobarbital sodium in pharmaceutical dosage forms. The method is accurate and precise. The percent relative standard deviations based on six injections were 0.9 and 0.7 at 245 and 230 nm (with internal standard), respectively. The internal standard was not used for assays at 245 nm due to poor absorption of mezlocillin at this wavelength. However, the results by both assay methods were similar (Table I). The concentrations *versus* peak heights were directly related in the 7- to 21-μg range at 245 nm. The ratio of peak heights (drug to internal standard) were directly related to drug concentrations at the 1.5- to 4.5-μg range at 230 nm. The method is ~1.7 times more sensitive at 230 than at 245 nm, as determined by using a standard solution (300 μg/mL in water) and a sensitivity of 0.1. Moreover, the method is at least two times more sensitive than the USP-NF method (3), as determined by UV spectrometry with the two mobile phases. The elixirs and injections can be simply diluted and assayed for phenobarbital and phenobarbital sodium. A simple preliminary extraction procedure is required to assay phenobarbital in tablets. There was no interference from excipients present in the tablets and the red colorant of the elixir (Table I).

The decomposed samples of phenobarbital sodium showed a new peak (peak 1, Fig. 1C) in the chromatogram, and the potency of the drug remaining intact was only 15.4% after ~30 min of boiling (see above). After ~4 min of boiling, there were two small peaks (side by side) in the chromatogram at about the same location as peak 1, Fig. 1C. The scheme of decomposition has been reported previously in the literature (4). It is interesting to point out that there were two additional peaks when the same lot of phenobarbital was assayed at 245 nm *versus* only one peak when assayed at 230 nm. It is perhaps due to the facts that (*a*) the concentration of excipients was 3.33 times higher (also considering AUFS of 0.2 at 245 nm and 0.1 at 230 nm) at 245 *versus* 230 nm and (*b*) there was poor or no absorption from one of the excipients at 230 nm. Furthermore, the same lot of phenobarbital sodium injection showed a small additional peak (Fig. 2B) when assayed at 245 nm *versus* almost none (Fig. 1B) when assayed at 230 nm.

Mesophase Formation During Cholesterol Gallstone Dissolution in Human Bile: Effect of Bile Acid Composition

C. C. SU ‡, W. I. HIGUCHI *x, I. T. GILMORE §, R. G. DANZINGER ¶, and A. F. HOFMANN §

Received February 14, 1983, from the **College of Pharmacy, University of Utah, Salt Lake City, UT 84112*, ‡*College of Pharmacy, University of Michigan, Ann Arbor, MI 48105*, §*University of California at San Diego, San Diego, CA 92103, and* ¶*St. Boniface General Hospital, Winnipeg, Manitoba, Canada.* Accepted for publication July 8, 1983.

Abstract □ Duodenal bile obtained from patients with gallstones who were acutely infused with chenodeoxycholic acid, ursodeoxycholic acid, or cholic acid were examined for the propensity toward the formation of a liquid crystalline mesomorphic phase when cholesterol gallstones were incubated in these bile acids. Bile taken from patients infused with ursodeoxycholic acid was found to be enriched in ursodeoxycholic acid; mesophase formation was detected in these samples but not in bile from patients infused with chenodeoxycholic acid or cholic acid.

Keyphrases □ Cholesterol—gallstone dissolution in human bile, effect of bile acid composition □ Gallstone dissolution—human bile, effect of bile acid composition □ Bile acids—mesophase formation during cholesterol gallstone dissolution

Clinical investigations have shown that ursodeoxycholic acid is as effective or more effective than chenodeoxycholic acid in gallstone dissolution. From the physicochemical standpoint, these results are interesting, because ursodeoxycholic acid (1) and its conjugates are generally not as effective as chenodeoxycholic acid and its conjugates in solubilizing cholesterol in the bile acid or the bile acid–lecithin solution (2). We have recently suggested (2, 3) that during *in vitro* dissolution of cholesterol monohydrate in the form of powder, compressed disks, single crystals, or in gallstones, a transition from the micellar phase to the liquid crystalline phase occurs when the dissolution media contain lecithin and predominantly ursodeoxycholic acid conjugates, but not chenodeoxycholic acid or cholic acid conjugates.

It was shown that mesophase formation and subsequent dispersion may contribute to the total dissolution/disintegration of cholesterol in the solid phase. To determine whether mesophase formation would occur during the *in vitro* disso-

Table I—Biliary Lipid Composition During Infusion with Chenodeoxycholic, Ursodeoxycholic, and Cholic Acid [a]

Bile Acid Infused	Bile Acid, mol %	Phospholipids, mol %	Cholesterol, mol %	Phospholipids-Cholesterol Molar Ratio
Chenodeoxycholic acid	87.2	8.3	4.5	1.84
Ursodeoxycholic acid	86.2	11.4	2.4	4.75
Cholic acid	89.2	6.7	4.1	1.63

[a] Averages of two samples are presented.

lution of cholesterol gallstones in human bile, we studied the mesophase formation tendency with gallstones in human bile samples which were selectively enriched with conjugates of ursodeoxycholic acid, chenodeoxycholic acid, or cholic acid by prior infusion of these bile acids into the jejunum of patients with gallstones.

EXPERIMENTAL SECTION

Materials—A triple-lumen orojejunal tube was placed into the patient with gallstones fluoroscopically[1], and synthetically prepared conjugates of chenodeoxycholic, ursodeoxycholic, or cholic acids were infused into the jejunum at 2 mmol/h for 8 h (3). Bile was aspirated from the duodenal port, beginning at 8 h, at which time replacement of the bile acid pool by the infused bile acid was 69–90% complete. Bile was collected in 60-min pools for the subsequent 28 h and frozen. Each bile acid was infused in random order in three consecutive 72-h periods. Before the experiments, the bile samples were freeze-dried, weighed, and reconstituted to predetermined concentrations by equilibrating in water at 37°C for 3 d. After inactivating the enzymes by heating at 60°C for 30 min, the reconstituted bile was filtered through a 0.45-μm filter[2]. The biliary lipid compositions were determined by enzymatic methods[3] (4, 5).

Gallstones were obtained at routine cholecystectomy from patients[1] who had not taken a gallstone-dissolving bile acid. Gallstones were washed free of bile and mucus and stored for short periods in normal saline solutions under nitrogen at 4°C in the dark.

Mesophase Detection—Two gallstones were placed in 2.5 mL of the filtered bile in a test tube. The test tube was flushed with nitrogen, capped, and then shaken with a wrist-action shaker in a water bath at 37°C. At predetermined intervals, samples of the dissolution media were taken and examined immediately under a polarizing microscope. The observation of birefringent spherules was interpreted to mean that the formation of a liquid crystalline phase had occurred.

RESULTS AND DISCUSSION

The effect of infused ursodeoxycholic acid on hepatic secretion of biliary lipids is shown in Table I. The better suppression of hepatic cholesterol output during ursodeoxycholic acid infusion than under the other experimental conditions has also been reported in healthy volunteers either acutely infused with (6, 7) or chronic enterally administered this bile acid and in patients with radiolucent gallstones (8). It is interesting to note that acute administration of ursodeoxycholic acid increased the amount of phospholipids secreted per mole of cholesterol (6). Table II indicates that during infusion with ursodeoxycholic acid, this bile acid increased to 73% of the bile, whereas chenodeoxycholic acid decreased to 11.5% of the total biliary bile acids. An even higher (>80%) enrichment of ursodeoxycholic acid in bile has recently been reported by others (6) in patients during the postreplacement phase of ursodeoxycholic acid studies.

Table III presents the results of the mesophase formation studies performed with the polarizing microscope. A transition from the micellar phase to the liquid crystalline phase was detected in the ursodeoxycholic acid-enriched bile samples but not in the chenodeoxycholic acids or cholic acid-enriched bile (Table III).

Table II—Bile Acid Composition in Reconstituted Duodenal Bile

Bile Acid Infused	Molar % Chenodeoxycholic Acid	Ursodeoxycholic Acid	Cholic Acid	Deoxycholic Acid	Lithocholic Acid
Chenodeoxycholic acid	51.1	37.4	10.5	0.6	0.4
Ursodeoxycholic acid	11.5	73.1	12.0	3.0	0.4
Cholic acid	1.3	—	98.2	0.5	—

Sample 6	90.4	6.4	4.6	—

[a] Not observed.

Although these bile samples were obtained from patients with acute infusion of bile acids and although ursodeoxycholic acid concentrations in these bile samples appear to be higher than those taken from patients taking ursodeoxycholic acid orally (8), these results provide the first insights regarding the possibility of mesophase formation during ursodeoxycholic acid administration *in vivo* in patients undergoing ursodeoxycholic acid therapy for gallstone dissolution. Mesophase formation is believed (3) to be the consequence of thermodynamics favoring the formation of a lecithin-cholesterol-rich mesophase from cholesterol monohydrate in the presence of aqueous bile acid–lecithin solutions when the bile acid is an ursodeoxycholic acid conjugate. The subsequent dispersion of the mesophase may then contribute to the total dissolution/disintegration of cholesterol in the solid phase (2, 3), and this process may effect mass transfer significantly beyond the micellar phase saturation limit. Thus, this finding that ursodeoxycholic acid conjugates, but not chenodeoxycholate conjugates, induced the formation of mesophases during the gallstone dissolution process in the conjugated ursodeoxycholic acid-enriched bile may relate to the equal or superior clinical efficacy of ursodeoxycholic acid compared with chenodeoxycholic acid.

Liquid Chromatographic Chiral Stationary Phases in Pharmaceutical Analysis: Determination of Trace Amounts of the (−)-Enantiomer in (+)-Amphetamine

IRVING W. WAINER ˣ, THOMAS D. DOYLE, and WILLIAM M. ADAMS

Received December 23, 1982, from the *Division of Drug Chemistry, Food and Drug Administration, Washington, DC 20204.* Accepted for publication June 8, 1983.

Abstract □ A rapid and accurate method was developed for the determination of the enantiomeric composition of amphetamine preparations. Amide derivatives of the amphetamine enantiomers are first formed by using achiral 2-naphthoyl chloride. The resulting enantiomeric amides are then chromatographed on a commercially available chiral stationary phase. The capacity factors (k') of (−)- and (+)-2-naphthoylamphetamine are 20 and 22, respectively, and the separation factor (α) for the two enantiomers is 1.08. The method allows detection of as little as 0.5% of the (−)-enantiomer in (+)-amphetamine and is applicable to both bulk drug and single-tablet analyses.

Keyphrases □ Enantiomers—(+)- and (−)-amphetamine, HPLC, trace amounts □ Chiral stationary phases—HPLC, determination of trace amounts of (+)- and (−)-amphetamine □ Amphetamine—(+)- and (−)-enantiomers, HPLC, trace amounts

Amphetamine (α-methylphenethylamine) is a pharmacologically active asymmetric molecule whose (S) and (R) enantiomeric forms, (+)- and (−)-amphetamine, respectively, have different biological activities (1). Accordingly, the resolution and quantification of the amphetamine enantiomers have received a great deal of attention.

The most common approach to this analytical problem involves the synthesis and separation by GC of diastereoisomeric amides of amphetamine (2–9). Although this technique has been successfully utilized, it suffers from a number of inherent problems which hinder the development of methods for the determination of trace amounts of one enantiomer in the presence of the other.

The most serious drawback is that the synthesis of diastereoisomers necessarily involves the use of a chiral derivatizing agent. Any isomeric impurity in this reagent will result in spurious results. Liu and Ku (9) have discussed this problem in detail for the case of L-prolyl-derivatives of amphetamine and were able to correct for it by resolving the diastereoisomers into their enantiomeric pairs on a GC chiral stationary phase. An additional complication is that enantiomers may have quite different rates and/or equilibrium constants when they react with another chiral molecule, resulting in the generation of two diastereoisomeric products in proportions that differ from the starting enantiomeric composition (10).

Both of these problems can be avoided by resolving the enantiomeric pair as enantiomers by utilizing chromatography on chiral stationary phases. In such a case, if a derivative is to be formed and if the derivatizing agent is not an optically active molecule, there is no question of trace isomeric contamination. Furthermore, all enantiomers react with an optically inactive reagent to the same extent, *i.e.*, they have the same rate constants and the same equilibrium constants (10). Therefore, complete reaction is not a requirement. Direct resolution of enantiomeric amphetamine derivatives has been accomplished by GC (9, 11) and most recently by Wainer and Doyle *via* high-performance liquid chromatography (HPLC) (12).

In this report the application of direct HPLC resolution (12) to the determination of the enantiomeric composition of bulk drug and commercial preparations of amphetamine is described. The method involves the synthesis of the 2-naphthoyl amide of amphetamine and its resolution by HPLC on a commercially available chiral stationary phase containing (*R*)-*N*-(3,5-dinitrobenzoyl)phenylglycine. It is rapid and accurate and can detect the presence of as little as 0.5% of the (−)-enantiomer in (+)-amphetamine.

EXPERIMENTAL SECTION

Apparatus—The liquid chromatograph[1] was equipped with a data system[2], a fixed-wavelength detector[3] (280 nm), a temperature-controlled column compartment, and a 20-μL fixed-loop injector[4]. All analyses were performed with a 25-cm × 4.6-mm i.d. stainless steel column packed with a covalently bonded chiral stationary phase[5] and a 50-mm × 4.6-mm i.d. stainless steel guard column packed with 35–50-μm silica.

Materials—Hexane[6], isopropyl alcohol[6], and acetonitrile[6] were HPLC grade and were used as purchased. The 2-naphthoyl chloride[7], (+)-amphetamine sulfate (reference standard)[8], and (+)-, (−)-, and (±)-amphetamine sulfate (bulk drug)[9] were also used as purchased. Pharmaceutical preparations of (+)-amphetamine sulfate as capsule[10] and syrup[11], (+)-amphetamine-(±)-amphetamine sulfate capsule[12], and (±)-amphetamine sulfate capsule[13] were purchased commercially.

Structural Determinations—Structural determinations were made with a 200-MHz NMR spectrometer[14], a gas chromatograph–mass spectrometer[15], and an IR spectrophotometer[16]. The ^{1}H-NMR spectra ($CDCl_3$) contained the following peaks: δ 1.24 (d, 3), 2.80–3.02 (m, 2), 4.44–4.58 (m, 1), 6.19 (d, 1), and 7.22–8.20 ppm (m, 12). The mass spectra contained a molecular ion peak at m/z 289 and a base peak at m/z 155. The IR spectra (CH_2Cl_2) contained a sharp peak at 1655 cm^{-1}. The following melting points for the derivatives were obtained: (+)-2-naphthoylamphetamine, 152–155°C; (−)-2-naphthoylamphetamine, 152–155°C; (±)-2-naphthoylamphetamine, 162–165°C.

General Procedure—The bulk drug (10 mg) or the pharmaceutical preparation (one 10-mg tablet or capsule or 10 mL of a 1-mg/mL syrup) was placed in 5 mL of 20% NaOH solution and ultrasonicated until dissolved. The solution was then transferred to a 30-mL separatory funnel. Ten milliliters of a 0.01 M solution of 2-naphthoyl chloride in dichloromethane was added, and the mixture was shaken for 1 min. The organic phase was transferred to another 30-mL separatory funnel. The aqueous phase was washed with a 5-mL

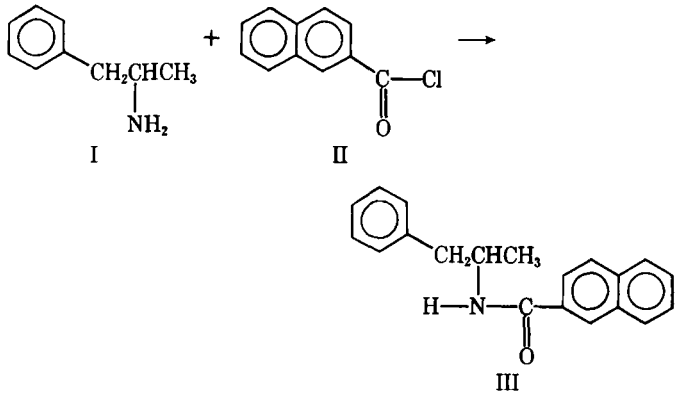

Scheme I—Reaction of amphetamine free base (I) and 2-naphthoyl chloride (II) to yield 2-naphthoylamphetamine (III).

portion of dichloromethane, and the organic layers were combined. The dichloromethane was extracted with two 5-mL portions of 0.01 M sulfuric acid, filtered through a cotton plug, and injected onto the HPLC column.

Chromatographic Conditions—The mobile phase was hexane–isopropyl alcohol–acetonitrile (97:3:0.5) at a flow rate of 2 mL/min. A column temperature of 20°C was maintained throughout the analyses.

Standard Curves—Two standard curves were constructed by combining (+)-amphetamine reference standard and (±)-amphetamine in various proportions by weight. The enantiomeric composition of one standard curve ranged from 50 parts (−)-amphetamine sulfate–50 parts (+)-amphetamine sulfate to 10 parts (−)-amphetamine sulfate–90 parts (+)-amphetamine sulfate. The other curve measured from 10 parts (−)-amphetamine sulfate–90 parts (+)-amphetamine sulfate to 0.5 parts (−)-amphetamine sulfate–99.5 parts (+)-amphetamine sulfate. The ratio of the integrated peak area of the (−)-isomer to the integrated peak area of the (+)-isomer was plotted *versus* the known enantiomeric composition.

RESULTS AND DISCUSSION

The reaction of amphetamine (I) with 2-naphthoyl chloride (II) proceeded rapidly under Schotten–Baumann conditions. When USP reference standard (+)-amphetamine sulfate was reacted under these conditions, a single product was isolated. The product was recrystallized from methanol and identified as the 2-naphthoylamide [III-(+)] by NMR, MS, and IR analyses (Scheme I). The amide was chromatographed on the chiral stationary phase; the chromatogram contained a single sharp peak with a capacity factor (k') of 22.

A series of five reactions with the USP reference standard and 2-naphthoyl chloride was carried out, and the crude reaction mixture was analyzed for amide concentration by using the crystalline product prepared as described above as an external standard. In this manner, the yield of the reaction was determined to be 82%. No attempt was made to increase the yield of the reaction, since the use of an achiral acid chloride ensures that both enantiomers react equally.

Table I—Enantiomeric Composition of Commercial Amphetamine Preparations

Sample	Assay 1, %	Assay 2, %	Average, %	Label, %
(+)-Amphetamine (bulk drug)				
(−)-Isomer	8.9	9.6	9.3	0
(+)-Isomer	91.1	90.4	90.8	100
(−)-Amphetamine (bulk drug)				
(−)-Isomer	98.4	99.3	98.9	100
(+)-Isomer	1.6	0.7	1.2	0
(+)-Amphetamine (timed-release capsule)				
(−)-Isomer	1.2	1.5	1.4	0
(+)-Isomer	98.7	98.5	98.9	100
(+)-Amphetamine (syrup)				
(−)-Isomer	1.4	0.8	1.1	0
(+)-Isomer	98.6	99.1	98.9	100
(+)-,(±)-Amphetamine (capsule)				
(−)-Isomer	25.4	25.5	25.5	25
(+)-Isomer	74.7	74.5	74.6	75
(±)-Amphetamine (capsule)				
(−)-Isomer	49.1	49.5	49.3	50
(+)-Isomer	50.8	50.4	50.7	50

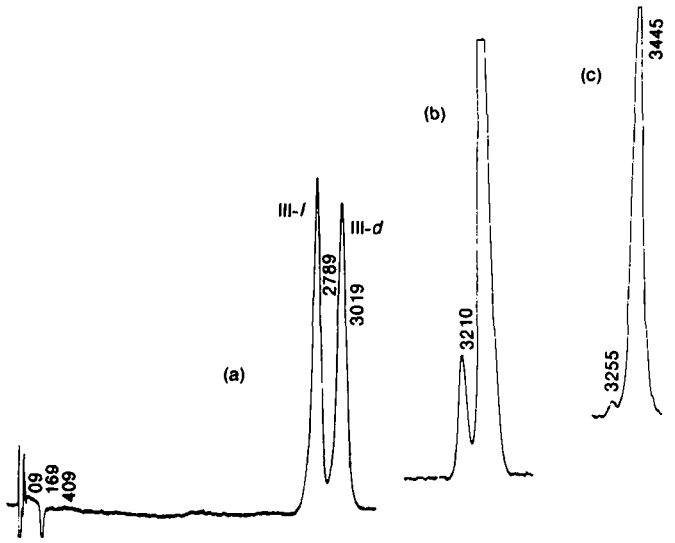

Figure 1—*Chromatograms of mixtures of (−)-2-naphthoylamphetamine [III-(−)] and (+)-2-naphthoylamphetamine [III-(+)]. Key: (a) III-(−)-III-(+), 50:50; (b) III-(−)-III-(+), 10:90; (c) III-(−)-III-(+), 1:99.*

The reaction of (−)-amphetamine bulk drug and 2-naphthoyl chloride afforded, on recrystallization, a product with the same NMR, MS, and IR spectral features as (+)-2-naphthoylamphetamine; this product was identified as the (−)-enantiomer [III-(−)]. The HPLC chromatogram of the recrystallized product contained two sharp peaks with capacity factors of 20 and 22, respectively. The first peak in the chromatogram, that of the (−)-enantiomer, contained 99% of the integrated area of the chromatogram, and the second peak, that of the (+)-enantiomer, contained 1% (Table I).

Two series of mixtures of (+)- and (−)-amphetamine were prepared by combining USP reference standard (+)-amphetamine sulfate and (±)-amphetamine sulfate in various proportions by weight. Enantiomeric proportions in the first series ranged from (±)-amphetamine sulfate (a 50:50 mixture of the two isomers) to a (+)-amphetamine sulfate–(−)-amphetamine sulfate mixture of 90:10. Proportions in the second series ranged from a (+)-amphetamine sulfate–(−)-amphetamine sulfate mixture of 90:10 to a 99.5:0.5 mixture. All solutions were derivatized and analyzed, and standard curves were constructed (Fig. 1). The curves were linear over both concentration ranges. The first standard curve (50:50–90:10) had a standard error of 0.0170 and a correlation coefficient of 0.998. The second curve had a standard error of 0.0077 and a correlation coefficient of 0.982. The separation factor (α) averaged 1.08.

Four pharmaceutical preparations of (+)-amphetamine and of (+)-amphetamine–(−)-amphetamine mixtures were purchased commercially and analyzed (Table I). A single 10-mg capsule or 10 mL of a 1-mg/mL syrup was used in the assays. By this method 1% of the (−)-isomer was detected in the (+)-amphetamine preparations; the expected enantiomeric ratios were detected in the other preparations.

The assay is a rapid (requiring no more than 2 h) and accurate method for the determination of the isomeric content of amphetamine bulk drug and commercial pharmaceutical preparations. It utilizes an achiral derivatizing reagent, 2-naphthoyl chloride, and a chiral stationary phase HPLC column which are both commercially available.

Dipole Moments and Conformational Equilibrium in Some Substituted 1-Phenyl-1-fluoro-2-halogenoethanes

C. CHARLON *, A.-M. GALY ‡, C. LUU DUC *, and J. BARBE ‡x

Received March 21, 1983, from the **Service de Chimie Pharmacie, UER des Sciences Biologiques et Pharmaceutiques, Domaine de la Merci, 38700 La Tronche* and the ‡*Service de Chimie Minérale, UER de Pharmacie, 27 Boulevard Jean-Moulin, 13385 Marseille Cedex 5, France.* Accepted for publication July 5, 1983.

Abstract □ Experimental dipole moments of substituted 1-phenyl-1-fluoro-2-halogenoethanes are compared with the vectorially and the theoretically calculated values using the CNDO/2 method. Results support the existence of a conformational mixture of these compounds as solutes; *gauche* structures are the prevailing conformations as in the related catecholamines.

Keyphrases □ Phenylfluorohalogenoethanes—substituted, dipole moments, conformations as solutes □ Dipole moments—substituted phenylfluorohalogenoethanes as solutes □ Conformations—phenylfluorohalogenoethanes as solutes

Potentially antiarrhythmic drugs can be prepared from substituted 1-phenyl-1-fluoro-2-halogenoethanes, because the latter are structurally related to catecholamines. However, conformations of these intermediates have to be portrayed. For this purpose, their experimental dipole moments and the vectorially as well as the theoretically calculated moments were compared in this report.

EXPERIMENTAL SECTION

Materials—The following compounds were studied: 1-phenyl-1-fluoro-2-chloroethane (I), 1-phenyl-(4′-bromo)-1-fluoro-2-chloroethane (II), 1-phenyl-(4′-chloro)-1-fluoro-2-chloroethane (III), 1-phenyl-(2′-bromo)-1-fluoro-2-bromoethane (IV), 1-phenyl-(2′-chloro)-1-fluoro-2-bromoethane (V), 1-phenyl-(2′,4′-dichloro)-1-fluoro-2-chloroethane (VI), 1-phenyl-(2′,-5′-dichloro)-1-fluoro-2-chloroethane (VII), and 1-phenyl-(2′,6′-dichloro)-1-fluoro-2-bromoethane (VIII). These compounds were prepared from the corresponding alcohols, in accordance with the process previously described (1).

Methods—The dipole moments of the compounds as solutes in anhydrous benzene were measured at 25.00 ± 0.05°C. The permittivity[1] and refractive index[2] of the solutions were extrapolated to infinite dilution according to Guggenheim (2) and Smith (3). The quantity $(\epsilon_{12} - n_{12}^2) - (\epsilon_1 - n_1^2)$ was plotted *versus* the molar concentration, C, of the solute. The slope of the curve at $C = 0$ was then used to calculate the dipole moment, μ, by:

$$\mu^2 = \frac{9kT}{4\pi N} \cdot \frac{3}{(\epsilon_1 + 2)(n_1^2 + 2)} \cdot \frac{(\epsilon_{12} - n_{12}^2) - (\epsilon_1 - n_1^2)}{C} \qquad \text{(Eq. 1)}$$

where k is the Boltzmann constant, N is Avogadro's number, T is the absolute temperature, and ϵ_i and n_i are the permittivities and refractive indexes, respectively, of the solutes (Index 1) and of the solutions (Index 12).

RESULTS AND DISCUSSION

The molecular geometry of the compounds studied is schematized in Fig. 1. Hence, six limit-conformers have to be considered, because of the presumable restricted rotation around the C_1—C_2 bond. These conformers, presented in Fig. 2, are noted (A) when bonds are staggered and (B) when bonds are opposed. The following bond increments were then used for vectorial calculations: H—$C_{sp}3$, 0.25 *D* (4); $C_{sp}3$—Br, 1.38 *D*; $C_{sp}3$—Cl, 1.46 *D*; $C_{sp}3$—F, 1.41 *D* (5); $C_{sp}3$—$C_{sp}2$, 0.4 *D*; $C_{sp}2$—Br, 1.54 *D*; and $C_{sp}2$—Cl, 1.58 *D* (6).

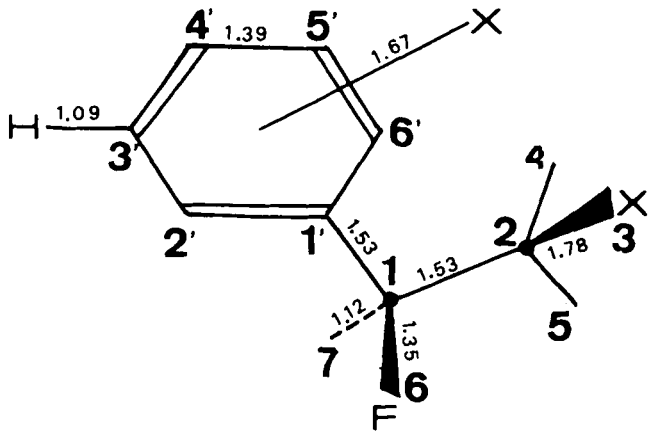

Figure 1—*Molecular geometry of the compounds studied.*

As regards the vectorial pattern of the molecules, it must be emphasized that spatial orientation of the phenyl ring *versus* the C_1—F bond is of no importance, except with the *ortho*-substituted derivatives. In the latter case, four possible orientations must be taken into account in accordance either with

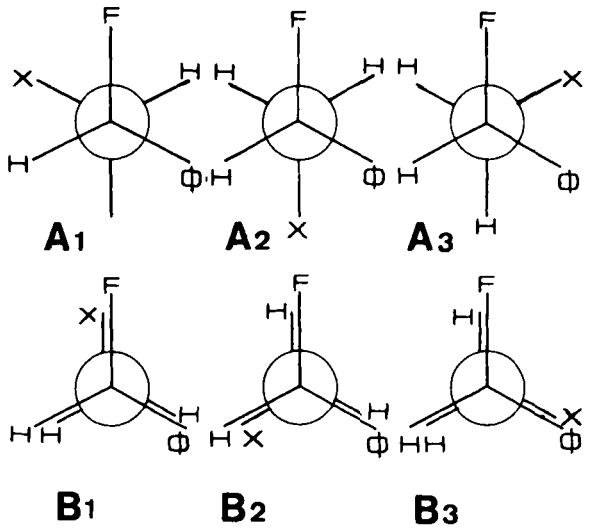

Figure 2—*Schemes of the staggered and the opposed limit-conformers used in the calculations.*

[a] In Debye units. [b] According to NMR data (17).

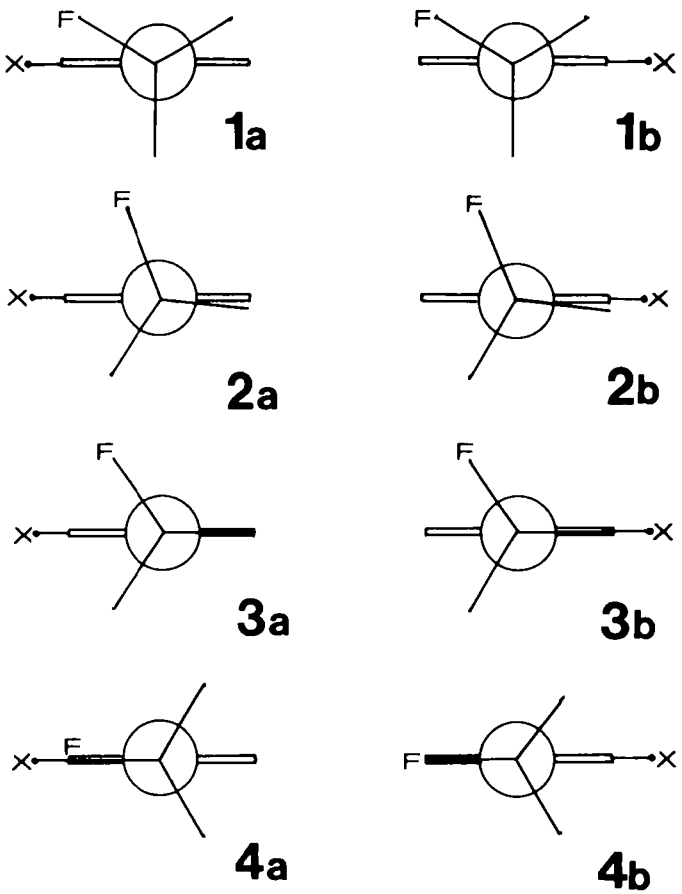

Figure 3—*Ring orientations* versus *the fluorine-carbon bond, in case of orthohalogeno(X)-substituted derivatives.*

experimental results concerning benzyl fluorides [Fig. 3, part 1 (7); Fig. 3, part 3 (8); Fig. 3, part 4 (9)] or crystallographic data about homologues of the compounds studied (Fig. 3, part 2)[3].

Experimental dipole moments and the vectorially calculated moments as well as some values theoretically calculated by means of the CNDO/2 (10) or PCILO (11) methods are given in Table I. On the one hand, all the calculated values are in satisfactory agreement, whatever are methods of calculation. The slight deviations noted are due to the bond increments herein used in the vectorial calculations instead of molecular increments. Under these conditions, atomic interactions through either bonds (12) or space (13) are neglected, although they lead to an inductive moment to be added or subtracted to the bond moments (14).

On the other hand, every vectorially calculated value can be alternately compared with the measured value of the dipole moments. In so doing, structures labeled "B" can be left out. This latter hypothesis directly proceeds from the conformational energy mapping (15), where energy minima only correspond to the "A" conformers. Under these conditions, it follows from the comparison that *gauche* structures (quoted as A-1 or A-3) prevail. However, existence of a conformational mixture cannot be ignored, because of the difference between experimental and calculated values. This is in agreement with the IR results (16). Nevertheless, relative populations cannot be then readily calculated using dielectric data, contrary to NMR data. Indeed, the coupling constants J^{t}_{HH}, J^{g}_{HF}, and J^{t}_{HF} calculated from the latter lead to values of conformational populations (17). Therefore, by using these values, theoretical dipole moments of each compound can be calculated according to the following:

$$\mu_{theor} = \sqrt{\mu^2_{A\text{-}1} \cdot P_1 + \mu^2_{A\text{-}2} \cdot P_2 + \mu^2_{A\text{-}3} \cdot P_3} \qquad \text{(Eq. 2)}$$

These results are also presented in Table I.

The conformational multiplicity is then confirmed by the good relationships noted between the theoretical and the experimental moments. Added to this, the spatial orientation of the phenyl ring can now be figured for IV, V, and VI. Indeed, experimental dipole moments of these molecules are pointed out in Fig. 4, referring to the theoretical moments calculated for the various orientations previously quoted. In the cases of IV and V, the geometrical structure intermediate between 2b and 3b is certainly favored because of the

[3] B. Chion, C. Charlon, and C. Luu Duc, unpublished results.

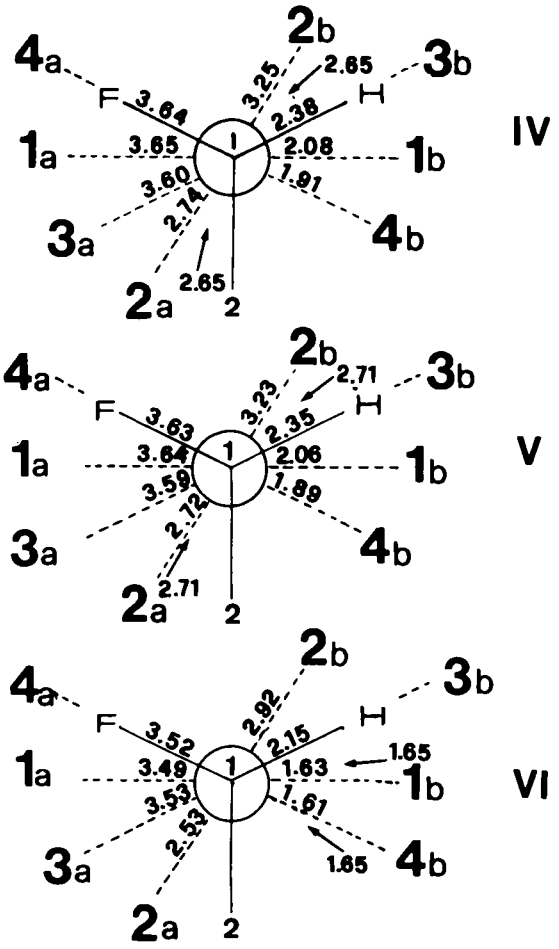

Figure 4—*Experimental dipole moments (values with arrows) and theoretical moments calculated for each ring orientation for IV, V, and VI.*

steric hindrances between halogens in the 2a structure. Conversely, structures 1b and 4b would have to be equally possible for VI, because the C_1—F and the C_2—X bonds are practically *anti* in each case. However, as steric hindrances between the halogen bonded to C-2 and the phenyl ring are minimized in position 1b, the latter will be more stable. These results are in close agreement with ^{13}C-NMR data (18).

Synthesis and Biological Evaluation of New 2,3-Dihydrothiazole Derivatives for Antimicrobial, Antihypertensive, and Anticonvulsant Activities

A.-MOHSEN M. E. OMAR ˣ and NABIL H. ESHBA

Received December 2, 1982, from the *Pharmaceutical Chemistry Department, Faculty of Pharmacy, University of Alexandria, Egypt.* Accepted for publication August 2, 1983.

Abstract □ A novel series of 2-arylimino-2,3-dihydrothiazole derivatives, substituted in the 3-position with a β-phenethyl moiety and the 4-position with substituted aryl functions, was synthesized as potential antimicrobial, antihypertensive and anticonvulsive agents. While no antimicrobial or significant antihypertensive activity was observed for the products, XII, XIII, and XXI displayed potent anticonvulsant activity.

Keyphrases □ 2,3-Dihydrothiazole derivatives—synthesis antimicrobial, antihypertensive, and anticonvulsant properties □ Antimicrobial activity—2,3-dihydrothiazole derivatives, antihypertensive and anticonvulsant properties

The synthesis and pharmacological properties of a variety of thioureas (1-3), thiosemicarbazones (4-6), thiosemicarbazides (1, 7, 8), thiazoles (2, 6, 7), and thiadiazines (9) derived from various biologically active nuclei (1-5, 8), aromatic (6), and heterocyclic compounds (7, 9) have been recently described in connection with our studies on the structure-activity relationships of certain thio compounds. The high bactericidal activity displayed by some 3,4-diarylthiazolin-2-oxo-(3-substituted 4-oxoquinazolin-2-yl)hydrazones (7) prompted the investigation of a novel series of 2-arylimino-2,3-dihydrothiazoles (VIII-XXXIII) which bear a structural similarity to such active thiazolines with respect to the substituents in the 4-position. This paper reports the synthesis and evaluation of these materials for antimicrobial, antihypertensive, and anticonvulsant activities.

RESULTS AND DISCUSSION

Chemistry—The *N*-substituted *N'*-(2-phenethyl)thiourea derivatives (II-VII), Scheme I, were synthesized (Table I) by treating 2-phenethylamine (I) with the appropriate aryl- or aralkylisothiocyanate in refluxing ethanol

[a] All compounds underwent elemental analyses for C and H. Compounds II VIII, XI, XIV-XVI, XXII, XXIII, XXVII, and XXIX-XXXI were also analyzed for N; II, V, VIII, X, XIII, XV-XVII, XX, XXI, XXIII-XXV, XXVIII, and XXX-XXXIII were analyzed for S; and IX, XIV, XXII, XXXI, and XXXII were analyzed for Br. All values were within ±0.4% of the theoretical values. [b] Percentages of protection for diazepam (5 mg/kg po) and chlordiazepoxide (10 mg/kg po) were +174 and +185, respectively. [c] Reported (13) mp 111 °C, without confirmation of elemental analysis. [d] Associated with symptoms of toxicity.

(10). The products were treated with either phenacyl bromide or the properly substituted phenacyl bromide in boiling ethanol to give the required 2,3-dihydrothiazole derivatives (VIII-XXXIII) as hydrobromide salts (see Table I).

Biological Screening[1]—*Antimicrobial Activity*—Using the serial dilution method in Mueller Hinton agar (6), VIII-XXXIII did not show antimicrobial effect against *Escherichia coli* NCTC 10418, *Klebsiella aerogene* A, *Pseudomonas aeroginosa* NCTC 10662, *Serratia marcescens* US32, *Staphylococcus aureus* Oxford, *Candida albicans* W97, and *Bacteroides fragilis* BC4, NCTC 8560, and B3.

Scheme I

Antihypertensive Activity—The 2-phenylimino-3-phenyl-4-phenyl-2,3-dihydrothiazole (XIII) caused a slight fall in blood pressure 6 h after administration of a dose of 100 mg/kg in spontaneously hypertensive rats. The 2,3-dihydrothiazoles XI and XX (at a dose of 5 mg/kg) and XXI (at a dose of 100 mg/kg), as the other selected examples of the series, did not exhibit antihypertensive activity.

Anticonvulsant Activity—The oral administration of VIII-XXXIII in doses of 100 mg/kg in mice 60 min prior to induction of convulsions by pentylenetetrazol[2] (8 mg/mL in saline), gave variable anticonvulsant activities ranging from +162 to −22% protection (Table I). The 2,3-dihydrothiazoles XIII and XXI were the most potent, causing +162 and +94% protection, respectively. The +91% protection exhibited by XII was accompanied by symptoms of toxicity.

Such results, as compared with those recently reported for the thiazoline-2-hydrazonoquinazolones (7), are indicative of the effect of the bulky phenethyl group, which is a constant substituent, on the supression of the antimicrobial activity of all products (12). The insignificant antihypertensive effect displayed by XIII as well as the general lack of anticonvulsant activity, despite the observed potency of XII, XIII, and XXI, could not lead to reliable structure-activity relationships in these 2,3-dihydrothiazoles.

EXPERIMENTAL SECTION[3]

N-Aryl-N'-(2-phenethyl)thiourea Derivatives (II-VII)—A mixture of 2-phenethylamine (I) (1.2 g, 0.01 mol) and the appropriate aryl- or aralkylisothiocyanate (0.01 mol) in ethanol (20 mL) was heated at reflux for 1 h. The mixture was concentrated under reduced pressure, and the material which separated on cooling was removed by filtration, washed with 10% HCl, dried, and recrystallized from ethanol. The yields and physical constants of the products (II-VII) are presented in Table I. IR (mineral oil) ν: 3370 and

[2] Metrazol; Sigma, U.K.

[3] All melting points are uncorrected. IR spectra were measured on a Beckman 4210 IR Spectrophotometer. ^{1}H-NMR spectra were measured on a Varian A-90, and mass spectra on a Finnigan 3200.

3250-3160 (NH), 1550-1525, 1345, 1320-1305, and 945-910 cm^{-1} (NCS I, II, III, and IV amide bands, respectively) (11); ^{1}H-NMR of II ($CDCl_3$): δ 2.82 (t, 2, J = 7.5 Hz, $C_6H_5CH_2CH_2$—), 3.68 (q, 2, J = 7.5 Hz, $C_6H_5CH_2CH_2$—), 4.41 (d, 2, J = 5 Hz, $C_6H_5CH_2$—), 5.64 (s, distorted, 1, 2-phenethyl-NH, exchangeable), 6.07 (s, distorted, 1, benzyl-NH, exchangeable), and 7.13 ppm (m, 10, ArH).

2-Arylimino-4-aryl-3-(2-phenethyl)-2,3-dihydrothiazole Hydrobromides (VIII–XXXIII)—A mixture of *N*-aryl-*N'*-(2-phenethyl)thioureas (II–VII) (0.001 mol) and phenacyl bromide or the appropriately substituted phenacyl bromide (0.0011 mol) in absolute ethanol (10 mL) was heated at reflux for 4 h. Some of the products separated during the heating, while others crystallized after cooling the mixture. The products were removed by filtration, dried, and recrystallized from benzene containing a few drops of absolute ethanol. The yields and physical constants of the products (VIII–XXXIII) are listed in Table I. IR (mineral oil) ν: 2780–2670 (—NH) and 1610–1590 cm^{-1} (C=N); ^{1}H-NMR of XXIII (Me_2SO-d_6): δ 2.41 (s, 3, CH_3), 2.94 (t, 2, J = 7.5 Hz, $C_6H_5CH_2CH_2$—), 4.46 (t, 2, J = 7.5 Hz, $C_6H_5CH_2CH_2$—), 7.26 (m, 10, ArH and C_5—H of the thiazoline ring), 7.70 (d, 2, J = 9 Hz, ArH, *meta* to nitro group), and 8.44 ppm (d, 2, J = 9 Hz, ArH, *ortho* to nitro group); ^{1}H-NMR for XXVIII: δ 2.41 (s, 3, CH_3), 2.87 (t, 2, J = 7.5 Hz, $C_6H_5CH_2CH_2$—), 4.34 (t, 2, J = 7.5 Hz, $C_6H_5CH_2CH_2$—), 6.87 (s, 1, C_5-thiazoline proton), and 7.25 ppm (m, 13, ArH); ^{1}H-NMR for XXX: δ 2.81 (t, 2, J = 7.5 Hz, $C_6H_5CH_2CH_2$—), 4.27 (t, 2, J = 7.5 Hz, $C_6H_5CH_2CH_2$—), 6.80 (s, 1, C_5-thiazoline proton), and 7.29 ppm (m, 14, ArH). MS, *m/z* (relative abundance %) for XXIII: M^+ at 415(7), 312(22), 311(100), 310(20), 134(19), 105(47), 104(22), 103(26), 91(49), and 89(28). For XXVIII: M^+ at 404 and M + 2 at 406(8), 302(36), 301(22), 300(100), 299(15), 149(27), 148(51), 147(74), 134(27), 118(31), 115(28), 105(52), 104(21), 103(29), and 91(48). For XXX: M^+ at 435 and M + 2 at 437(0.9), 332(57), 331(17), 330(50), 139(22), 135(31), 134(100), 105(41), 104(49), 103(32), 102(23), 91(86), 90(24), 89(20), and 82(16).

Antihypertensive Testing—Rats, maintained in an incubator (32–35°C) for 20–40 min, were restrained to measure systolic blood pressure and heart rate indirectly by the tail cuff method[4]. Each determination was the mean of at least six recordings. Groups of four animals were used, and measurements were made predose (time zero) 1, 2, 4, and 6 h after administration of the products, with occasional readings at 24 h.

Anticonvulsant Testing—The compounds suspended in 1% methylcellulose were administered orally (1 mL/100 g) to CD-1 male mice (18–25 g), 10 per group, 1 h before intravenous infusion of 8 mg/mL of pentylenetetrazol in saline at a rate of 0.5 mL/min. The time of infusion required to elicit a tonic extensor spasm was noted, and the dose of pentylenetetrazol administered was calculated. The results (Table I) are expressed as the percentage change compared with controls treated with vehicle only. Statistical significance was determined using the Student's t test.

Abstract □ A simple method for obtaining the title compounds was found in the alkaline rearrangement of *S*-2-aminoethylisothiouronium salts, which were obtained from the condensation of thiourea or substituted thioureas with 2-bromoethylamine hydrobromide. No activity was found for the substituted guanidines against P388 lymphocytic leukemia in mice, or as H_2-receptor antagonists.

Keyphrases □ *N,N'*-Disubstituted *N''*-2-(2-quinolinylmethylthio)ethylguanidines—anticancer activity, potential H_2-receptor antagonist □ Anticancer agents—potential, *N,N'*-disubstituted *N''*-2-(2-quinolinylmethylthio)ethylguanidines, H_2-receptor antagonist activity

A number of strongly basic compounds have shown appreciable anticancer activity. Bis(guanidines) and guanylhydrazones are active in leukemia systems (1, 2), and bis(guanylhydrazones) of anthracene-9,10-dicarboxaldehydes (3) have a particularly broad spectrum of anticancer activity. Recently, synthesized bis(*S*-alkyl) (4), and *S*-alkyl cycloalkylamino (5) derivatives of *N*-methylquinolinium dithioacetic acid showed reproducible activity against P388 lymphocytic leukemia in mice, the best activity being shown by one of the basic (morpholino) derivatives. It appeared that further increase in basicity of this series was warranted. The basic side chain of the cimetidine molecule was selected for inclusion in the quinoline-2-methyl structure because of the reported cytostatic and immunosuppressive activities of some guanidine derivatives (6). Modification of the basicity by inclusion of electron-attracting or -releasing functions on the guanidine moiety was

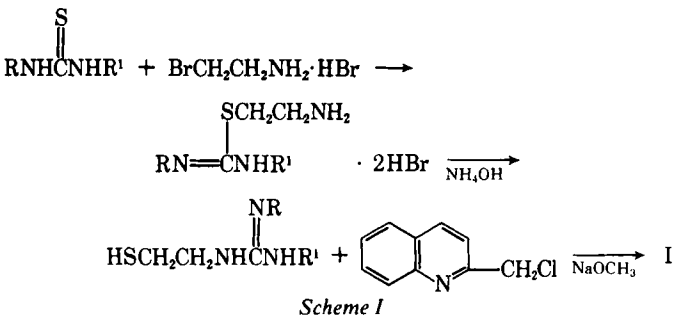
I

DISCUSSION

Chemistry—Most synthetic methods used for cimetidine analogues have involved the use of cyanamide (7, 8) or a derivative such as *N*-cyanoiminodithiocarbonic acid dimethyl ester (9) or *N*-methyldicyanodiamide (10) and treatment with appropriate amines or halides. It was found more convenient to synthesize the guanidinoethylmercapto moiety by alkaline rearrangement of *N,N'*-disubstituted *S*-2-aminoethylisothiouronium salts (11). These were prepared by condensation of *N,N'*-disubstituted thioureas with 2-bromoethylamine hydrobromide. When an electron-withdrawing function was present on the thiourea, salts were not formed, and rearrangement was carried out on the neutral molecule. The resulting mercapto compounds were converted to the sodium salts and condensed with 2-chloromethylquinoline. Yields of the *N*-2-(2-quinolinylmethylthio)ethylguanidines ranged from 42 to 93%, based on the isothiuronium compounds. Physical constants of the compounds obtained are recorded in Table I. This method of synthesis is shown in Scheme I. It may be considered an improvement over previously used methods for cimetidine analogues because of fewer synthetic steps and more stable starting materials.

^{1}H-NMR spectra of the products agreed with the proposed structures. Quinoline protons appeared at δ 8.46–8.60 ppm as salts and at δ 7.68–7.76 ppm as neutral molecules. The 2-quinolinylmethyl protons appeared as singlets at δ 4.52–4.64 ppm for the salts and at δ 3.90–3.99 ppm for the neutral molecules. The S—CH_2 protons were seen at δ 2.78–3.55 ppm for the salts and at δ 2.59–2.65 ppm for the neutral compounds. The N—CH_2 protons had chemical shifts at δ 3.50–3.55 ppm for the salts and at δ 3.41–3.43 ppm for the nonsalt forms. The N—CH_3 protons were found at δ 2.75–2.96 ppm for the salts and at δ 2.74–2.78 ppm for the nonsalts. The doublet of the N—CH_3 protons became a singlet in the presence of D_2O, indicating the proximity of N—H.



Scheme I

Biological Test Results—Antileukemia testing of the *N*-2-(2-quinolinylmethylthio)ethylguanidines was done at the National Cancer Institute in mice with P388 lymphocytic leukemia using the NCI protocol (12). Details regarding dose and survival of the treated animals are recorded in Table I. None of the compounds showed positive activity (a T/C × 100 ratio of ≥125), and all were appreciably toxic. Doses >100 mg/kg were generally fatal.

Screening of the compounds for possible H_2-receptor antagonism was carried out with guinea pig atria at doses of 10^{-4}–10^{-5} M. Cimetidine and tripelennamine were employed as H_2- and H_1-antagonists, respectively, and histamine was used as the H_2-agonist. None of the compounds had the ability to interact with the H_2-receptor, as determined by an isolated right atrial preparation from the guinea pig. The *N*-benzyl-*N'*-methylguanidine derivative slowed atrial rate but was not acting *via* an H_2-receptor.

EXPERIMENTAL SECTION[1]

***N*-Methyl-*S*-2-aminoethylisothiouronium Bromide Hydrobromide**—A mixture of *N*-methylthiourea (4.5 g, 0.05 mol) and absolute ethanol (50 mL) was refluxed for 30 min, 2-bromoethylamine hydrobromide (10.25 g, 0.05 mol) was added, and the mixture was refluxed for 2 h. The mixture was cooled, and the white precipitate was removed by filtration, dried at reduced pressure, and recrystallized from methanol to give 13.39 g (91%), mp 220–222°C; R_f 0.60. IR(KBr): 3300, 3260, 3080 (NH, NH_2^+, and NH_3^+), 1940 (amine·HBr), and 1648 (N—C=N) cm^{-1}; ^{1}H-NMR: δ 8.90 (br s, 6, NH, NH_2^+ and NH_3^+), 3.55 (t, 2, N—CH_2), 3.19 (t, 2, S—CH_2), and 2.99 ppm (s, 3, CH_3).

Anal.—Calc. for $C_4H_{11}N_3S\cdot 2HBr$: C, 16.28; H, 4.44; N, 14.24. Found: C, 16.43; H, 4.61; N, 14.37.

***N,N'*-Dimethyl-*S*-2-aminoethylisothiouronium Bromide Hydrobromide**—To a solution of *N,N'*-dimethylthiourea (5.20 g, 0.05 mol) in absolute ethanol (50 mL) was added 2-bromoethylamine hydrobromide (10.25 g, 0.05 mol) and the solution was refluxed for 2 h. The mixture was cooled (ice-bath), and the white solid was isolated and dried at reduced pressure. Recrystallization from methanol gave 12.59 g (82%), mp 215–216°C (dec.); R_f 0.59. IR(KBr): 3260, 3120, 3070 (NH_2^+, NH_3^+), 2020 (amine·HBr), 1630, and 1620 (N—C=N, NH_3^+) cm^{-1}; ^{1}H-NMR: δ 8.70 (br s, 5, NH_2^+ and NH_3^+), 3.68 (t, 2, N—CH_2), 3.18 (t, 2, S—CH_2), and 3.04 ppm (s, 6, $2CH_3$).

Anal.—Calc. for $C_5H_{13}N_3S\cdot 2HBr$: C, 19.43; H, 4.89; N, 13.60. Found: C, 19.65; H, 5.01; N, 13.46.

***N*-Benzyl-*N'*-methyl-*S*-2-aminoethylisothiouronium Bromide Hydrobromide**—*N*-Benzyl-*N'*-methylthiourea was prepared in 95% yield from benzylamine and methyl isothiocyanate in methanol, stirring for 20 h and recrystallizing from aqueous methanol to give white crystals, mp 71–73°C. The thiourea (9.01 g, 0.05 mol) was refluxed in absolute ethanol (50 mL) for 30 min, 2-bromoethylamine hydrobromide (10.25 g, 0.05 mol) was added, and

[1] Melting points were determined in capillary tubes with a Mel-Temp block and are uncorrected. ^{1}H-NMR spectra were obtained in Me_2SO-d_6 with a Varian T-60 spectrometer using Me_4Si as internal standard. IR spectra were obtained on a Perkin-Elmer 457A grating spectrophotometer using KBr pellets. TLC was carried out using Eastman silica gel plates with fluorescent indicator and a solvent system of 1-butanol–acetone–water (4:5:1). Elemental analyses were done by F. B. Strauss, Oxford, England. Organic reagents were supplied by Aldrich Chemical Co. and Fisher Scientific Co., and the hydrogen chloride by Matheson Gas Products.

the mixture was refluxed until it became homogeneous. It was cooled (ice-bath), and the white precipitate was removed by filtration and dried at reduced pressure. A second crop resulted on reducing the volume of the filtrate to 20 mL and cooling at −20°C. The combined solids were recrystallized from methanol to give 13.66 g (72%), mp 219–221°C; R_f 0.65. IR(KBr): 3330, 3230, 3100 (NH_2^+ and NH_3^+), 2020 (amine·HBr), 1620, and 1615 (N—C=N, NH_3^+) cm^{-1}; ^{1}H-NMR: δ 8.53 (bs, 5, NH_2^+ and NH_3^+), 7.93 (s, 5, ArH), 4.74 (s, 2, CH_2), 3.67 (t, 2, N—CH_2), 3.18 (t, 2, S—CH_2), and 3.09 ppm (s, 3, CH_3).

Anal.—Calc. for $C_{11}H_{17}N_3S{\cdot}2HBr$: C, 34.30; H, 4.97; N, 10.91. Found: C, 34.52; H, 5.18; N, 10.82.

***N*-Benzenesulfonyl-*N'*-methyl-*S*-2-aminoethylisothiourea**—To a solution of benzenesulfonamide (8.65 g, 0.055 mol) in dimethylformamide (30 mL) at 4°C was added a solution of sodium hydroxide (2.22 g) in water (3 mL) and methyl isothiocyanate (4.02 g, 0.055 mol), and the solution was stirred for 30 min. 2-Bromoethylamine hydrobromide (10.25 g, 0.05 mol) in dimethylformamide (20 mL) was added and stirring was continued at room temperature for 7 h. The mixture was added to water (500 mL) and extracted with 1-butanol (350 mL), and the extract was washed with water (2 × 250 mL). The organic phase was evaporated and the resulting syrup solidified on storage at −20°C. The white solid was recrystallized from methanol, to yield 4.23 g (28%), mp 114–116°C; R_f 0.50. IR(KBr): 3340, 3260 (NH and NH_2), 1570 (NH), 1200, and 1135 (SO_2) cm^{-1}; ^{1}H-NMR: δ 7.62 (m, 5, ArH), 7.20 (br t, 2, NH_2), 3.35 (m, 2, N—CH_2), 2.72 (d, 3, CH_3), and 2.60 ppm (m, 2, S—CH_2).

***N*-Cyano-*N'*-methyl-*S*-2-aminoethylisothiourea**—To a solution of cyanamide (2.31 g, 0.055 mol) in dimethylformamide (30 mL) at 4°C were added a solution of sodium hydroxide (2.2 g) in water (3 mL) and methyl isothiocyanate (4.02 g, 0.055 mol), and the solution was stirred for 30 min. 2-Bromoethylamine hydrobromide (10.25 g, 0.05 mol) in dimethylformamide (20 mL) was added, and the mixture was stirred at room temperature for 18 h. The solvent was evaporated at reduced pressure and the residue was extracted with 1-butanol (2 × 30 mL). The extract was washed with water (2 × 30 mL), and the organic phase was evaporated at reduced pressure to give 4.50 g (52%) of a syrup; R_f 0.81. IR(KBr film): 3350, 3240, 3170 (NH and NH_2), 2180 (CN), 1580; and 1540 (NH and NH_2) cm^{-1}; ^{1}H-NMR: δ 6.80 (br s, 3, NH and NH_2), 3.35 (m, 2, N—CH_2), 2.72 (d, 3, CH_3), and 2.60 ppm (m, 2, S—CH_2).

Representative Procedures for the Preparation of *N,N'*-Disubstituted *N''*-2-(2-Quinolinylmethylthio)ethylguanidines—*N-2-(2-Quinolinylmethylthio)ethylguanidine Dihydrochloride*—*S*-2-Aminoethylisothiouronium bromide hydrobromide (11) (28.10 g, 0.1 mol) in 50 mL of water was treated with concentrated ammonium hydroxide (15 mL, 0.25 mol) and stirred at room temperature for 2 h. The mixture was evaporated to dryness, and the residue was dried at reduced pressure. This material was dissolved in 25 mL of methanol, and a solution of sodium methoxide (5.40 g, 0.1 mol) in methanol (50 mL) was added. To the solution of the sodium salt of 2-mercaptoethylguanidine was added a solution of 2-chloromethylquinoline, prepared from the hydrochloride (21.41 g, 0.1 mol) and sodium methoxide (5.40 g, 0.1 mol), in methanol (50 mL). The mixture was stirred at room temperature for 18 h, the sodium chloride was removed by filtration, and the filtrate was evaporated to dryness. The residue was extracted with water (75 mL) and ether (75 mL), and the residual oil was reextracted with water (50 mL) and ether (50 mL). The aqueous extracts were evaporated to a syrup and dried at reduced pressure. The residue was treated with methanolic hydrogen chloride (75 mL), prepared by saturation at 0°C for 20 h. The methanol was evaporated, and the residue was recrystallized from methanol to give 14.59 g (44%) of beige crystals, mp 189–191°C; R_f 0.52. IR(KBr): 3380, 3300, 3120 (NH and NH_2), 2720–2600 (amine·HCl), and 1630 (N—C=N and NH_3^+) cm^{-1}; ^{1}H-NMR: δ 11.58 (br s, 1, quinoline·NH^+), 8.47 (m, 6, quinoline), 7.48 (br s, 5, NH, NH_2, and NH_2^+), 4.59 (s, 2, CH_2), 3.50 (q, 2, N—CH_2), 3.20 (s, H_2O), and 2.78 ppm (t, 2, S—CH_2).

N-Benzenesulfonyl-N'-methyl-N''-2-(2-quinolinylmethylthio)ethylguanidine Hydrobromide—*N*-Benzenesulfonyl-*N'*-methyl-*S*-2-aminoethylisothiourea (2.73 g, 0.01 mol) was added to 30 mL of methanol saturated with ammonia at 0°C, and stirred at 0°C for 18 h. The mixture was evaporated to dryness, and the residue was treated with acetone (20 mL) and sodium hydroxide (0.4 g) in water (10 mL). To the resulting solution was added 2-chloromethylquinoline (1.78 g, 0.01 mol) and stirring was continued at room temperature for 4 h. The mixture was evaporated to half volume, water (20 mL) was added, and the solution was extracted with 1-butanol (2 × 30 mL). The extract was washed with water (2 × 30 mL), evaporated to a syrup, and dried at reduced pressure to give 3.21 g (77%), which was converted to the hydrobromide, mp 68°C (color change), 80–90°C (dec.); R_f 0.84. ^{1}H-NMR ($CDCl_3$): δ 7.68 (m, 11, ArH), 6.60 (br s, 2, 2 NH), 3.90 (s, 2, CH_2), 3.41 (q, 2, N—CH_2), 2.74 (d, 3, CH_3), and 2.59 ppm (t, 2, S—CH_2).

N-Cyano-N'-methyl-N''-2-(2-quinolinylmethylthio)ethylguanidine—*N*-Cyano-*N'*-methyl-*S*-2-aminoethylisothiourea (3.35 g, 0.021 mol) was added to methanol (30 mL) saturated with ammonia at 0°C, and stirred at 0°C for 18 h. The mixture was evaporated to a syrup and dried at reduced pressure. The residue was added to a solution of sodium methoxide (0.81 g) in methanol (30 mL), 2-chloromethylquinoline (2.67 g, 0.015 mol) was added, and the solution was stirred at room temperature for 3 h. The mixture was filtered, and the filtrate was evaporated to a syrup which was dried at reduced pressure. The residue was extracted with 1,2-dichloroethane (50 mL), washed with water (2 × 30 mL), dried (Na_2SO_4), and filtered. The filtrate was evaporated to a syrup and dried at reduced pressure to give 4.18 g (93%); R_f 0.84. IR (film): 3280, 3160 (NH), and 2170 (CN) cm^{-1}; ^{1}H-NMR ($CDCl_3$): δ 7.76 (m, 6, quinoline), 6.18 (br s, 2, 2 NH), 3.99 (s, 2, CH_2), 3.43 (m, 2, N—CH_2), 2.78 (d, 3, CH_3), and 2.65 ppm (m, 2, S—CH_2).

H_2-Receptor Antagonist Test—Compounds were tested for H_2-receptor antagonist activity using the guinea pig right atrial preparation described by Yellen *et al.* (13) and Lumley and Broadley (14). The isolated atrium was placed in a 50-mL tissue bath at 30°C and filled with Krebs-bicarbonate solution oxygenated with oxygen-carbon dioxide (95:5). Connected to a Grass Force displacement transducer, a 750-mg tension was applied to the atrium, and the tissue was allowed to equilibrate for 60–90 min. Cumulative dose-response curves were constructed using 10^{-7} 10^{-4} M histamine[2] in the presence or absence of cimetidine[3], tripelennamine dihydrochloride[2], or propranolol hydrochloride[4]. None of the compounds tested was capable of shifting the cumulative dose-response curve to histamine.

Direct Chloride Measurement of [4-^{36}Cl]Chlorobiphenyl and [4,4′-^{36}Cl]Dichlorobiphenyl Dechlorination in the Rat

M. T. SCOTT * **and J. E. SINSHEIMER** ˣ

Received December 27, 1982 from the *College of Pharmacy, University of Michigan, Ann Arbor, MI 48109.* Accepted for publication August 4, 1983. *Present address: Analytical Research and Development, Du Pont Pharmaceuticals, Garden City, NY 11530.

Abstract □ A reverse-phase HPLC system was used for the determination of inorganic chloride liberated *in vivo* from two biphenyl compounds in the rat. Oral administration of [4-^{36}Cl]chlorobiphenyl resulted in a total yield of 27.6% of the original dose excreted over 10 d in the urine and included 1.7% of the dose as inorganic chloride. For [4,4′-^{36}Cl]dichlorobiphenyl, the radioactivity of the original dose in the urine was 39.8% after 10 d, which included 11.5% of the dose as inorganic chloride. These results appear to represent the first direct determination of dechlorination by measurement of the inorganic chloride and suggest that biodechlorination plays a greater role in the metabolism of these compounds than previously expected.

Keyphrases □ Dechlorination—chloride in rat urine, 4-chloro- and 4,4′-dichlorobiphenyl □ Chloride determination—rat urine, 4-chloro- and 4,4′-dichlorobiphenyl □ 4-Chlorobiphenyl—*in vivo* dechlorination in rats □ 4,4′-Dichlorobiphenyl—*in vivo* dechlorination in rats.

The metabolism of polychlorinated biphenyls (PCBs), the ubiquitous environmental pollutants, leading to macromolecular binding (1-3) and mutagenicity (3) has been reported. Although metabolic activation appears to involve arene oxides (1-3), biodechlorination may play a role in the formation of bound metabolites and subsequent toxicity. Metabolic dehalogenation has been noted for polychlorinated biphenyls (4-6), bromobiphenyls (4-6), and iodobiphenyl (7). This paper describes an extension of these *in vivo* dehalogenation studies to ^{36}Cl-labeled 4-chlorobiphenyl and 4,4′-dichlorobiphenyl in an effort to assess the extent of biodehalogenation by direct chloride measurement.

EXPERIMENTAL SECTION

Copper(II) [^{36}Cl]Chloride—[^{36}Cl]Hydrochloride[1] (1.4 M, 1.0 mL, 50 μCi) and copper(II) oxide (55.9 mg, 1.7 mmol) were slowly heated to 115-125°C in a closed flask. This temperature was maintained for 8 h and then the vessel was cooled, opened, heated to dryness at 150°C for 3 h, and then stored in a desiccator. The brown product was redried immediately before use at 25°C and 0.3 mm pressure for 12 h.

[4-^{36}Cl]Chlorobiphenyl—In a modification of the general procedure of Doyle *et al.* (8) unlabeled copper(II) chloride (1.1976 g, 8.9 mmol) and isoamyl nitrate (2.812 g, 24.0 mmol) were added to [^{36}Cl]$CuCl_2$. After anhydrous acetonitrile (20 mL) was added, the mixture was maintained at 0°C to −5°C with stirring for 25 min before 4-aminobiphenyl (1.3528 g, 8.0 mmol) in anhydrous acetonitrile (10 mL) was slowly added. The mixture was stirred for 2 h at 0°C to −5°C and then for 3 h at room temperature before it was poured into 150 mL of 20% HCl and extracted with ether (3 × 150 mL). The ether was dried over sodium sulfate and the solvent was removed under reduced pressure. The aqueous phase was neutralized (pH 6-7) with 40% NaOH and extracted with ether. The ether was dried and the solvent removed as before. The resulting solid was then combined with the original solid. The product was isolated by column chromatography using silica gel and hexane as the mobile phase. After removal of the solvent, 925 mg (61.3%) of product with a specific activity of 2.24 μCi/mmol was obtained (mp 76-77°C). The IR, melting point, and NMR data of the product (synthesized in the same manner but with unlabeled $CuCl_2$) were identical with spectra of a known, pure (>99%) sample of 4-chlorobiphenyl[2].

[4,4′-^{36}Cl]Dichlorobiphenyl—Copper(II) oxide (62.0 mg, 1.89 mmol) and 1.0 mL of 1.54 M [^{36}Cl]hydrochloride (61 μCi) were mixed as described to produce labeled copper(II) chloride. Unlabeled copper(II) chloride (1.0819 g, 8.0 mmol) and isoamyl nitrite (2.812 g, 24.0 mmol) were added to labeled copper(II) chloride with the aid of 20 mL of anhydrous acetonitrile. Benzidine (740.2 mg, 4.0 mmol) in 15 mL of anhydrous acetonitrile was added slowly to the mixture which was at 0°C to −5°C. The mixture was stirred for 5 h at that temperature. Workup was as described for [4-^{36}Cl]chlorobiphenyl with a yield of 502.1 mg (56.3%) of white solid, mp 144.5-147.0°C (reference compound[2], 147-148°C). The specific activity was 4.61 μCi/mmol. The chromatographic behavior of the product that was synthesized in the same manner, except using unlabeled copper(II) chloride, matched the behavior of the known, pure (>99%) reference sample of 4,4′-dichlorobiphenyl[2]. Both labeled chlorobiphenyl compounds were found to be free of inorganic chloride-36 by HPLC using a C_{18} column and methanol-water (90:10).

***In Vivo* Studies**—Male Sprague-Dawley rats weighing 250 300 g were quarantined for 2 d prior to administration of substrates by gastric intubation. The dosing regimens of substrates in corn oil were as follows: three rats were dosed with 0.5 mL of [4-^{36}Cl]chlorobiphenyl, containing 197,000 dpm of substrate; three rats were dosed with 0.9 mL of [4,4′-^{36}Cl]dichlorobiphenyl, containing 60,000 dpm; another rat was given twice the dose of the others. Rats were allowed food and water *ad libitum*. Urine was collected daily and stored frozen.

Chlorine-36 Analysis—*Total Activity*—Urine (100 μL) was measured for total radioactivity by scintillation counting[3]. A storage period of 24 h in the dark, after addition of the cocktail[4] (10 mL) and before counting, was required to avoid chemiluminescence.

Inorganic Chloride—Urine was acidified to pH 6-7 with dilute sulfuric acid and centrifuged. The supernatant was combined with the supernatant resulting from recentrifugation of the washed pellet (0.5 mL of water), and 1.0 mL was injected into a C_{18} HPLC system (9). The mobile phase consisted of methanol-water-glacial acetic acid (12.5:86.5:1.0) at a flow rate of 1 mL/min. Inorganic chloride-36 was determined in the eluant 2-6 min after injection; methanol (1.0 mL) and cocktail[4] (14 mL) were added with counting for 10 min. Between injections the HPLC system was flushed with methanol (30 mL) and reequilibrated with mobile phase.

RESULTS AND DISCUSSION

Analytical System—The metabolism of the chlorinated biphenyls was expected to yield phenols (5) and their glucuronides (10). Therefore, an HPLC procedure that would separate inorganic chloride prior to highly polar metabolites was desired. We used the system devised by Mitchell *et al.* (11) for the separation of metabolic conjugates which happened to be similar to a system we have used for the determination of inorganic halides (9). In a test mixture of chloride in the presence of the glucuronide and sulfate of *p*-nitrophenol, chloride was recovered quantitatively well before completely resolved peaks for these conjugates.

***In Vivo* Dechlorination**—*[4-^{36}Cl]Chlorobiphenyl*—Figure 1 outlines the excretion of total urinary radioactivity expressed as an average of the percentage of dose for three rats. The excretion of radioactive substances (17.7 ± 6.45%) after the first day constituted at least half the total radioactivity over 10 d and agreed with the data in the literature [25.8 ± 13.3% (12)] for oral administration. Excretion of total radioactivity after intravenous administration has been reported (12, 13) to be even more rapid, with 80% of the dose excreted within 24 h and almost total excretion after 2 d. In the present study, urinary excretion of radioactivity decreased to 2.5 ± 1.5% for the second day and remained relatively constant through day 10.

Injection of an aliquot of a composite urine sample from each of the three rats indicated that 1.7 ± 0.5% (mean for three animals, 11 injections) of the dose of [4-^{36}Cl]chlorobiphenyl was excreted as inorganic chloride-36 over a 10-d period. This was less than the *in vivo* deiodination of [4-^{125}I]iodobiphenyl (14), as expected, due to the stronger carbon-chloride bond. The low levels of total radioactivity in daily urine samples prevented determination of liberated chloride-36 on a daily basis.

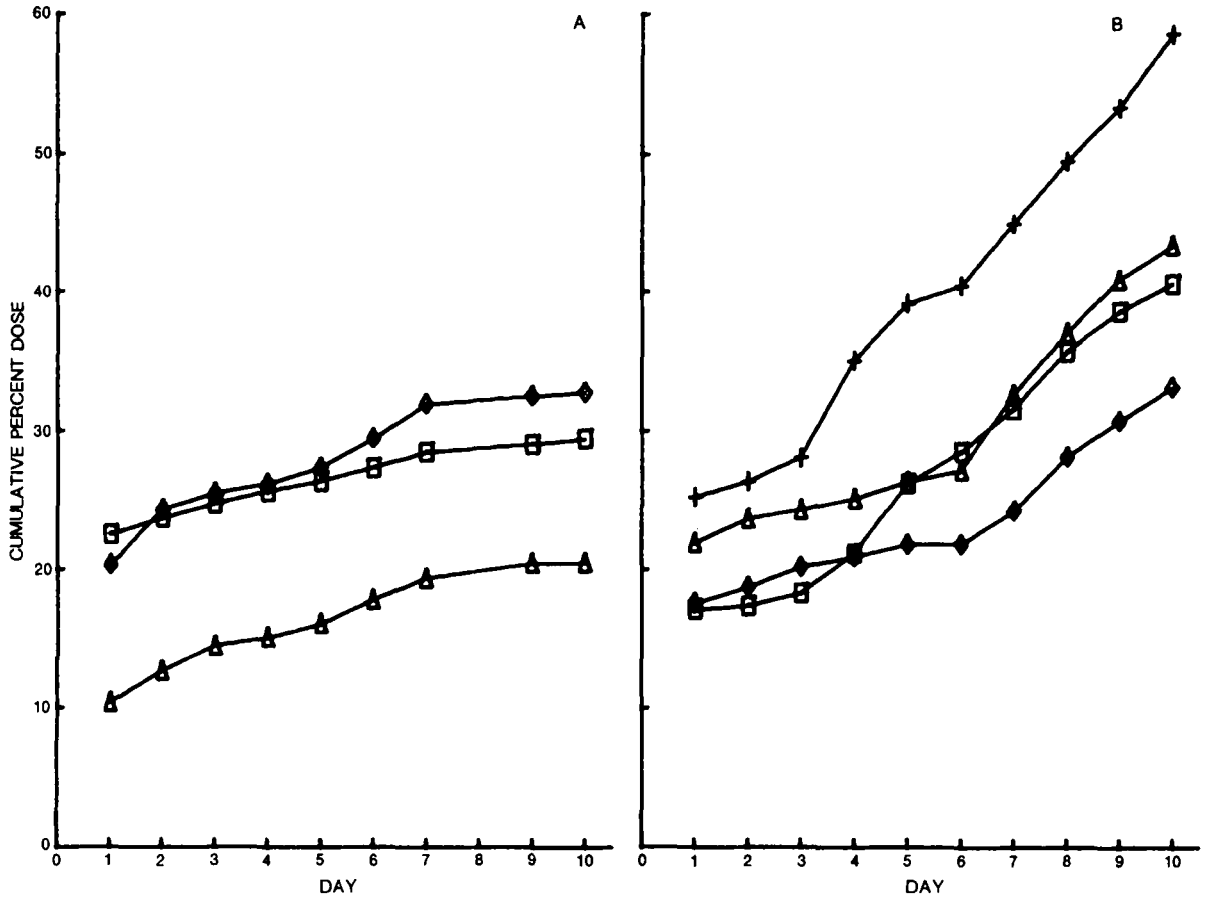

Figure 1—*Cumulative total urinary radioactivity expressed as a percentage of dose from [4-^{36}Cl]chlorobiphenyl (A) for 3 rats and [4,4'-^{36}Cl]dichlorobiphenyl (B) from 4 rats where the rat denoted with a "+" received twice the dose.*

These results appear to be the first to show dechlorination of 4-chlorobiphenyl and the first to follow dechlorination by direct determination of inorganic chloride. Previous studies in the rabbit (10) and in a variety of other species (5) reported no dechlorinated metabolites. The rapid excretion of total radioactivity coupled with the slow rate and low percentage of dechlorination may explain why no dechlorinated metabolites have been found in these *in vivo* studies.

[4,4'-^{36}Cl]Dichlorobiphenyl—The cumulative daily excretion of total radioactivity (percent of dose) for the four rats tested is summarized in Fig. 1. The total urinary radioactivity for the first day was 20.5 ± 3.9%, which agrees with the literature value of 22.9 ± 3.1% (12). Daily excretion of total radioactivity decreased rapidly, so that the day 2 through day 10 excretion ranged between 1 and 4.25% daily. This resulted in a small but continuous rise in the cumulative total urinary radioactivity for the dichloro compound in comparison to an earlier leveling off of radioactivity with 4-chlorobiphenyl for the 10-d period studied.

A composite urine sample for each of four rats was analyzed for chloride by HPLC, and the percentage of original dose was found to be 11.5 ± 2.7% (the mean of three measurements for each of four animals). This was 10-fold more dechlorination than found for [4-^{36}Cl]chlorobiphenyl. In addition to the twofold greater amount of original chloride, this increased dechlorination might have been a result of the increased importance of the dechlorination of an intermediate 3-hydroxy,4-chloro metabolite.

Tulp *et al.* (15) have shown that 4-chloro-3'-hydroxybiphenyl is an intermediate in the metabolism of 4,4'-dichlorobiphenyl and that the *ortho* hydroxy group in this metabolite and related compounds (16) activates dehalogenation. In the present study it is assumed that such activated dehalogenation would be more important in the 4,4'-dichlorobiphenyl than in the 4-chlorobiphenyl compound. In the former case there would be greater opportunity for the presence of a hydroxy group *ortho* to the increased number of chlorides. In the latter compound, there is the established (5, 10) hydroxylation of the unsubstituted ring with the elimination of the compound prior to the formation of 3-hydroxy-4-chlorobiphenyl.

The direct measurements of dechlorination for both 4-chloro- and 4,4'-dichlorobiphenyl would indicate that aromatic dechlorination plays a more important role in the metabolism of these compounds than previously noted.

Assay of Adinazolam in Plasma by Liquid Chromatography

GEOFFREY W. PENG

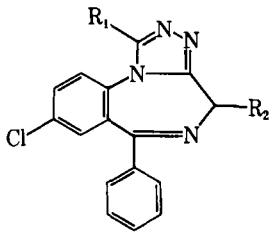
Received June 17, 1983, from the *Drug Metabolism Research, The Upjohn Company, Kalamazoo, MI 49001* Accepted for publication August 1, 1983.

Abstract □ A procedure for the quantitative determination of adinazolam in plasma was developed. The drug, an *N*-demethylated metabolite, and an internal standard were extracted from basified plasma into ethyl acetate. After evaporation, the residue was dissolved in toluene which was washed with sodium hydroxide. The toluene was evaporated and the residue was dissolved in a mixture of acetonitrile, methanol, and water for chromatography. The concentrations of the drug and the metabolite were determined using reverse-phase liquid chromatography with UV detection at 254 nm. The assay methodology showed good peak height ratio-concentration linearity, precision, and accuracy and has been used to analyze plasma samples collected from human subjects after oral administration of adinazolam mesylate in compressed tablets. The low plasma background interferences allowed the quantitative determination of concentrations as low as ~5 ng/mL.

Keyphrases □ Adinazolam and *N*-demethyl metabolite—liquid chromatographic assay in plasma □ Liquid chromatographic assay—adinazolam and *N*-demethyl metabolite in plasma

A number of compounds of the triazolobenzodiazepine class have been found to have important pharmacological properties (1, 2), *i.e.*, the antianxiety activity of alprazolam (3) and the hypnotic activity of triazolam (4) and estazolam (1, 5). More recently, adinazolam mesylate, the methanesulfonate salt of 8-chloro-1-[(dimethylamino)methyl]-6-phenyl-4*H*-*s*-triazolo[4,3-*a*][1,4]benzodiazepine (I), was shown to have both antidepressant and antianxiety properties (6–8).

Adinazolam mesylate is currently undergoing clinical testing for the treatment of depression in humans (9). Since little is known about the pharmacokinetic disposition of adinazolam, such an understanding would facilitate the design and evaluation of clinical efficacy studies. For this purpose, a liquid chromatographic method was developed for the separation and quantitative determination of adinazolam in human plasma samples. 8-Chloro-1-[(methylamino)-methyl]-6-phenyl-4*H*-*s*-triazolo[4,3-*a*][1,4]benzodiazepine (II) (8), an *N*-demethylated metabolite of adinazolam, found in abundant amounts in the plasma samples, were simultaneously analyzed.



I: $R_1 = CH_2N(CH_3)_2$, $R_2 = H$
II: $R_1 = CH_2NHCH_3$, $R_2 = H$
III: $R_1 = CH_2CH_3$, $R_2 = CH_2N(CH_3)_2$

EXPERIMENTAL SECTION

Materials—Adinazolam (I) mesylate, the *N*-demethyl metabolite (II), and the internal standard, 8-chloro-1-ethyl-4[(dimethylamino)methyl]-6-phenyl-4*H*-*s*-triazolo[4,3-*a*][1,4]benzodiazepine (III) (6) were used as received[1]. Acetonitrile and methanol were distilled-in-glass grade[2]. All other solvents and chemicals were reagent grade. Plasma samples were obtained from volunteer human subjects after oral administration of compressed tablets of adinazolam mesylate.

Sample Preparation—Aliquots of 1-mL plasma samples in 15-mL culture tubes equipped with polytef-lined screw caps[3] were supplemented with internal standard, basified with 1 mL of 0.1 M dibasic potassium phosphate[4], and extracted with 5 mL of ethyl acetate[2]. After shaking on a horizontal shaker for ~5 min and centrifuging at 2000 rpm for 5 min, these tubes were placed in a shallow bath of dry ice–acetone mixture to freeze the aqueous phase. The ethyl acetate was transferred to clean tubes and evaporated under a stream of nitrogen[5]. The residues were taken up in toluene[2], (2-mL aliquots) which were in turn washed with 2 mL of 2.0 M NaOH by shaking and centrifugation. After freezing the aqueous layer, the toluene extracts were transferred to clean tubes and evaporated under nitrogen at a temperature <50°C. The residues from the toluene extracts were dissolved in 0.1 mL of acetonitrile–methanol–water (1:1:2, v/v/v), mixed on a vortex mixer[3], and centrifuged prior to chromatography. Calibration standard samples were prepared by supplementing aliquots of blank human plasma with the drug, its metabolite, and the internal standard. These standard samples were similarly extracted and concurrently chromatographed with the plasma samples.

Chromatography—The liquid chromatographic system consisted of a solvent delivery pump[6], a fixed-wavelength UV absorbance detector[7], and a sample injection valve with a 100-μL loop[8]. The prepared plasma samples and the standard samples were chromatographed on a prepacked reverse-phase column[9] using acetonitrile–methanol–phosphate buffer (30:20:85, v/v/v) as the mobile phase. The phosphate buffer contained 0.06 M monobasic ammonium phosphate and 0.02% phosphoric acid. The mobile phase was filtered, deaerated, and pumped through the system at a flow rate of 2 mL/min. The chromatograms monitored by UV absorbance at 254 nm were recorded on a strip chart recorder[10]. The adinazolam–internal standard and *N*-demethyl metabolite–internal standard peak height ratios were measured for quantitative determination. The chromatography was carried out at ambient temperature (20–22°C).

RESULTS AND DISCUSSION

The recovery of adinazolam from the plasma samples by the extraction procedure was investigated by comparison of the chromatograms of the drug standards and the chromatograms of the extracts of plasma samples supplemented with the same quantities of adinazolam mesylate. The internal standard was added to these samples just prior to chromatography, and the peak height ratios measured from the resulting chromatograms were used to estimate the extraction recovery. The solvent extraction recovery of adinazolam from plasma was found to be ~82% in the concentration range of ~10–800 ng/mL of adinazolam mesylate and was essentially independent of the concentration. The extraction of the *N*-demethyl metabolite appeared to be less efficient than the parent drug because of the higher polarity of the metabolite. The extraction procedure was satisfactory for the preparation of the plasma samples for the chromatographic separation of the drug and the metabolite. Ethyl acetate extraction gave very good recovery of the drug and the metabolite from the plasma samples, but the high background interferences rendered the chromatographic separation unsuitable for quantitative determination of these compounds. Toluene extraction gave poor recovery of the metabolite, but the background interference was minimal. The two-step extractions using ethyl acetate and toluene were necessary to remove background interferences and to allow the quantitative determination of the drug and the metabolite at ~5 ng/mL levels.

Figure 1 shows the chromatograms of the extracts of plasma samples collected shortly before (Fig. 1A) and 4 h after (Fig. 1B) the administration of

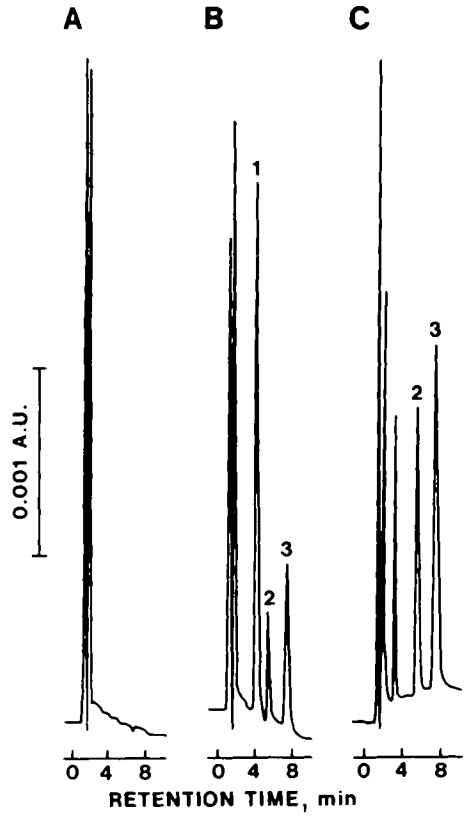

Figure 1—*Chromatograms of the extracts of plasma samples collected from a human subject shortly before (A) and 4 h after (B) the administration of a 20-mg dose of adinazolam mesylate in tablets, and the chromatogram of the extract of a blank plasma sample supplemented with adinazolam mesylate and internal standard (C). Key: (1) N-demethyl metabolite; (2) adinazolam; (3) internal standard.*

adinazolam mesylate. Both samples were obtained from the same human subject who received orally a single 20-mg dose of the drug in compressed tablets. Clinical studies showed that ≤30 mg of adinazolam mesylate three times a day for a total daily dose of 90 mg was efficacious in treatment of depression (9). Figure 1 also shows a chromatogram of the extract of a sample

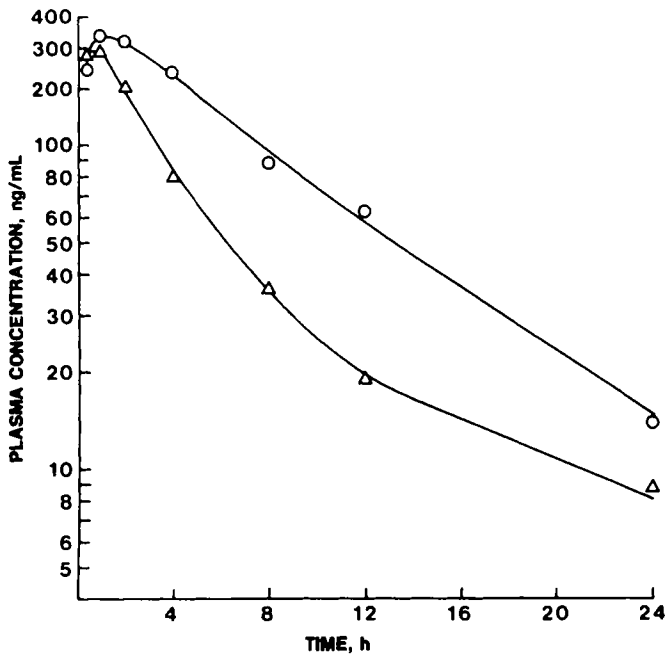

Figure 2—*Plasma concentration-time profiles of adinazolam (△) and the N-demethyl metabolite (○) after administration of a 30-mg dose of adinazolam mesylate in tablets to a human subject.*

of blank plasma with added adinazolam mesylate and the internal standard (Fig. 1C). Samples of blank plasma from several sources showed minimal interferences during the chromatographic separation. The chromatographic separation eluted adinazolam and the internal standard with retention volumes of ~11.2 and 16 mL, respectively. In the post-medication samples, an additional drug-related peak with a retention volume of ~8.8 mL was found (Fig. 1C). This peak was later identified as the *N*-demethyl metabolite of the parent drug. No other material could be identified as drug related in the chromatograms under the experimental conditions. The retention volumes of these sample components varied slightly from day-to-day and were especially sensitive to the changes in the proportions of acetonitrile, the concentrations of ammonium phosphate, and the pH of the buffer in the mobile phase. These compounds were more retentive on the column[9] using mobile phase with a lower proportion of organic solvents, a lower concentration of ammonium phosphate in the buffer, or a higher pH of the buffer. This knowledge was used to optimize the chromatographic separation by adjusting the mobile phase compositions. The limitations of these modifications were the excessive peak tailing and the prolongation of the retention times.

Like other benzodiazepines, the triazolobenzodiazepines undergo reversible ring-opening reactions in acidic media involving the hydrolysis of the azomethine linkage. These reversible reactions have been reported for triazolam (10) and estazolam (11). Adinazolam also showed similar ring-opening reactions in acidic solutions. At the pH of the buffer for the chromatographic mobile phase (pH 2.5–4.0), and in the mobile phase containing organic solvents, adinazolam was hydrolyzed to its ring-open form to a large extent. However, chromatographic separation using the acidic mobile phase indicated that essentially no ring-opening reaction took place by eluting adinazolam through the reverse-phase column as monitored by the UV detector. Under the same conditions, when an acidic solution of adinazolam was chromatographed, the intact drug and its ring-open form were separated: the ring-open form was much less retentive on the column than the intact drug. The reason for the discrepancy between the apparent stability of adinazolam during the acidic reverse-phase column separation and its instability in acidic solution was uncertain. It is possible that with the acid-catalyzed hydrolysis of the azomethine linkage, the environment inside the column was different from a simple acidic solution of a mixture of the buffer and organic solvents.

The adinazolam-internal standard and the *N*-demethylated metabolite-internal standard peak-height ratios showed good linear relationships with their corresponding concentrations. The linear regression of the peak height ratio-concentration data of both compounds usually resulted in calibration curves with correlation coefficients >0.998 and with positive or negative intercepts statistically zero, judging from 95% confidence limits. The slopes of the calibration curves were quite reproducible from day-to-day. For example, 12 sets of the calibration curves of adinazolam prepared over a period of three weeks showed a *RSD* of 4.3%, and eight sets of the calibration curves of the metabolite prepared over the same period showed a *RSD* of 9.7%. These data indicated the good interassay reproducibility for these compounds. The intra-assay reproducilibity and the accuracy of this methodology were also very good; *i.e.*, in the analyses of aliquots of blank plasma samples supplemented with 12, 74.5, 165, and 462 ng/mL of adinazolam mesylate, the concentrations found were 11.9 ± 0.38, 73.6 ± 1.0, 164.6 ± 17.24, and 462.5 ± 2.33 ng/mL, respectively. The relative *SD* of these replicate assays (N = 4) were from 0.5 to 10.5%.

The assay methodology has been used to analyze the plasma samples collected from human subjects after oral administration of adinazolam in compressed tablets. The plasma concentration of the parent drug reached its peak usually at ~1 h postdose and then declined following a biexponential pattern. In the same sample, the concentration of the *N*-demethyl metabolite was higher than the parent drug at most sampling times. A representative set of data, demonstrating the utility of the assay methodology, is shown in Fig. 2.

Potential Antitumor Agents X: Synthesis and Antitumor Activity of Two Nitrogen Mustard Derivatives Related to Ketocaine

ALDO ANDREANI *x, DANIELA BONAZZI *, MIRELLA RAMBALDI *, IRAKLIS GALATULAS ‡, and ROSARIA BOSSA ‡

Received July 19, 1982, from the **Istituto di Chimica Farmaceutica e Tossicologica, University of Bologna* and the ‡*Istituto di Farmacologia, University of Milan, Italy.* Accepted for publication May 23, 1983.

Abstract □ The synthesis of two nitrogen mustard derivatives (VIII and IX) related to the well-known local anesthetic ketocaine (III) is reported. These compounds were tested in mice implanted with Ehrlich ascites tumor cells, and the antitumor activity was compared with that of two previously synthesized analogues (I and II) lacking the nitro group and with that of doxorubicin. The monofunctional compound IX was inactive, but the bifunctional compound VIII showed potent antitumor activity (%T/C > 254 at 20 mg/kg).

Keyphrases □ Antitumor agents—potential, nitrogen mustard derivatives, Ehrlich ascites carcinoma screen □ Nitrogen mustard derivatives—antitumor agents, potential, Ehrlich ascites carcinoma screen

In a previous paper of this series (1), we reported the synthesis of I and II, two analogues of the well-known local anesthetic ketocaine (III). This work was based on the hypothesis that the *in vitro* antimitotic activity of ketocaine is related to its effect on oxygen consumption by tissues with prevailing anaerobic metabolism; this, in turn, demonstrates the ability of ketocaine to pass through the cell membrane (2). While ketocaine does not show antitumor activity, I and II were active (1). On the other hand, a series of butyrophenone derivatives showed that ketocaine and one of its nitro derivatives had analogous behavior to oxygen consumption (3). This study describes the nitration of *o*-hydroxybutyrophenone and the subsequent alkylation of the nitro derivative with tris(2-chloroethyl)amine hydrochloride, as previously described (1). The antitumor activity and the effect on oxygen consumption of these substances were compared with those of the previously described I and II.

RESULTS AND DISCUSSION

The nitration of *o*-hydroxybutyrophenone always gave a mixture of IV–VI. These materials were separated by column chromatography and identified by means of spectrometric data (see *Experimental Section*). The reaction between the nitro derivative (IV) and tris(2-chloroethyl)amine hydrochloride (VII) gave VIII and IX, as well as X (Scheme I). Compounds VIII and IX were tested, as the hydrochlorides, for antitumor activity.

The bifunctional compound VIII inhibited tumor growth and prolonged the life span of mice bearing Ehrlich ascites carcinoma beyond that of the untreated animals. The %T/C at 4 mg/kg ip was 144, and it was >254 at 20 mg/kg. The monofunctional compound IX was inactive. Table I reports the antitumor activity of VIII and IX compared with that of the previously reported I and II (1) and doxorubicin.

Compounds I, II, VIII, and IX also affected the oxygen consumption of tumor cells. Figure 1 shows a difference in the respiratory inhibition that may be related to the different lipophilicity of the four compounds: in fact respiratory inhibition is a linear function of lipophilicity in a series of 4-hydroxyquinoline-3-carboxylic acids (4). The potent antitumor activity of VIII under the experimental conditions employed is evident. From the results so far available it appears that VIII is also active against other experimental tumors.

EXPERIMENTAL SECTION[1]

Chemistry—*Nitration of o-Hydroxybutyrophenone*—A cold solution of 90% HNO_3 (5.2 mL, 110 mmol) in acetic anhydride (15 mL) was slowly added with stirring to a cold solution of *o*-hydroxybutyrophenone (14.8 g, 90 mmol) in 20 mL of acetic anhydride. The temperature was maintained below 15°C. The mixture was then stirred for 1 h at room temperature and poured onto ice. A densitometric TLC analysis of the precipitate gave the following percentages: 60% IV, 30% V, and 10% VI similar results were obtained by using acetic acid or sulfuric acid in place of acetic anhydride. The three compounds were isolated by means of column chromatography.

2-Hydroxy-5-nitrobutyrophenone (IV)—Compound IV was obtained as yellow needles, mp 108–110°C (petroleum ether). IR (nujol): 3080, 1638, and 810 cm^{-1}; ^{1}H-NMR: δ 8.85 (d, 1, J = 3.0 Hz, H-6); 8.43 (q, 1, J = 9.6 Hz, 3.0 Hz, H-4); 7.15 (d, 1, J = 9.6 Hz, H-3); and 3.15, 1.83, and 1.06 ppm (7, $—CH_2CH_2CH_3$).

Anal.—Calc. for $C_{10}H_{11}NO_4$: C, 57.41; H, 5.30; N, 6.70. Found: C, 57.70; H, 5.31; N, 6.69.

2-Hydroxy-3-nitrobutyrophenone (V)—Compound V was obtained as yellow needles, mp 43–45°C (petroleum ether). IR (nujol): 3080, 1642, and 1030 cm^{-1}; ^{1}H-NMR: δ 8.26 (q, 1, J = 8.0 Hz, 2.0 Hz, H-6); 8.20 (q, 1, J = 9.0 Hz, 2.0 Hz, H-4); 7.10 (q, 1, J = 9.0 Hz, 8.0 Hz, H-5); and 3.08, 1.83, and 1.03 ppm (7, $—CH_2CH_2CH_3$).

Anal.—Calc. for $C_{10}H_{11}NO_4$: C, 57.41; H, 5.30; N, 6.70. Found: C, 57.18; H, 5.35; N, 6.60.

2-Hydroxy-3,5-dinitrobutyrophenone (VI)—Compound VI was obtained as yellow needles, mp 118–120°C (ethanol). IR (nujol): 3070, 1645, and 1610 cm^{-1}; ^{1}H-NMR: δ 8.96 (d, 2, J = 2.4 Hz, H-4 + H-6) and 3.15, 1.83, and 1.06 ppm (7, $—CH_2CH_2CH_3$).

Anal.—Calc. for $C_{10}H_{10}N_2O_6$: C, 47.25; H, 3.96; N, 11.02. Found: C, 47.08; H, 3.76; N, 10.82.

Synthesis of VIII–X—Compound IV (6.3 g, 30 mmol), dissolved in 60 mL of absolute ethanol, was added to a solution of C_2H_5ONa (60 mmol) in absolute ethanol (50 mL). Tris(2-chloroethyl)amine hydrochloride (VII; 7.3 g, 30 mmol) was then added with stirring. The mixture was refluxed for 5 h, and then the solvent was removed under reduced pressure. The residue was extracted with chloroform. The organic phase was washed with water, dried (Na_2SO_4), and the solvent was removed under reduced pressure. A densitometric TLC analysis of the residue gave the following percentages: 35% (IV), 40% (VIII), 20% (IX), and 5% (X). The four compounds were separated by column chromatography and VIII and IX were converted into the corresponding hydrochlorides.

N-[2-(2-Butanoyl-4-nitro)phenoxyethyl]-N,N-bis(2-chloroethyl)amine Hydrochloride (VIII-HCl)—The compound was a white powder, mp 113–115°C (absolute ethanol); IR (KBr): 1695, 1610, and 1580 cm^{-1}.

[1] Melting points are uncorrected. Bakerflex plates (silica-gel IB2-F) were used for the TLC. For column chromatography Kieselgel 60 (Merck) was used, activated at 120°C for 2 h, in the proportion of 40 g/g of mixture; the eluant was petroleum ether (bp 60–80°C)/acetone (80:20). The IR spectra were recorded on a Perkin-Elmer 298 spectrometer. The ^{1}H-NMR spectra were recorded in $CDCl_3$ on a Varian XL-100 instrument using Me_4Si as internal standard.

Anal.—Calc. for $C_{16}H_{22}Cl_2N_2O_4 \cdot HCl$: C, 46.45; H, 5.60; N, 6.77. Found: C, 46.46; H, 5.70; N, 6.59.

N,N-*Bis*[*2-(2-butanoyl-4-nitro)phenoxyethyl*]-N-(*2-chloroethyl*)*amine Hydrochloride* (*IX·HCl*)—The compound was a white powder, mp 160–165°C (absolute ethanol); IR (KBr): 1685, 1605, and 1580 cm^{-1}.

Anal.—Calc. for $C_{26}H_{32}ClN_3O_8 \cdot HCl$: C, 53.25; H, 5.67; N, 7.16. Found: C, 53.49; H, 5.83; N, 7.05.

N,N,N-*Tris*[*2-(2-butanoyl-4-nitro)phenoxyethyl*]*amine* (*X*)—Compound X was a white powder, mp 87–90°C (ethanol); IR (KBr): 1670, 1605, and 1580 cm^{-1}.

Anal.—Calc. for $C_{36}H_{42}N_4O_{12}$: C, 59.82; H, 5.86; N, 7.75. Found: C, 59.56; H, 5.80; N, 7.63.

Pharmacology—*Antitumor Test*—Female Swiss mice (average weight 21 ± 1 g) were implanted on day 0 with 10^6 Ehrlich ascites tumor cells from donor mice. After 24 h the animals were treated with VIII (4, 20, or 100 mg/kg ip) or IX (20, 100, or 200 mg/kg ip) dissolved in dimethyl sulfoxide; the amount of dimethyl sulfoxide, previously used in analogous experiments, did not affect tumor growth. Doxorubicin (1 mg/kg ip) was used as a positive control. Deaths were recorded for a period of 60 d. The activity was measured as the ratio of the mean survival time of the test animals to that of the control expressed as a percentage (%T/C). Significant activity is achieved with an increased life span of 25% (T/C ≥ 125).

Respirometric Test—Oxygen consumption by Ehrlich ascites tumor cells was performed by placing in each flask of a Warburg's apparatus 4×10^7 Ehrlich carcinoma cells suspended in 1.8 mL of Ringer's solution and 0.2 mL of distilled water or the same volume of solution of the test compound (the final concentration in each flask was 1 mg/mL). Ehrlich ascites carcinoma cells were obtained from the ascitic fluid removed from mice 7–9 d after transplantation (female Swiss mice with weekly transplantations of 10^6 cells). Viability of cells was assayed by trypan blue dye test. Flasks containing the cell suspension were equilibrated for 10 min and respiration was measured for 60 min (temperature: 37°C; gas phase: air).

Gas Chromatographic–Mass Spectrometric Assay for the Ultra-Short-Acting β-Blocker Esmolol

CHECK Y. SUM ˣ and AVRAHAM YACOBI *

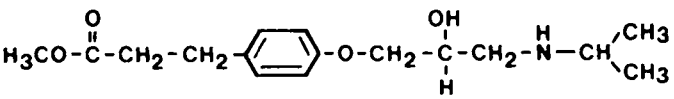
Received November 15, 1982, from *Research and Development, American Critical Care, McGaw Park, IL 60085.* Accepted for publication May 19, 1983. *Present address: Lederle Laboratories, Pearl River, NY 10965.

Abstract □ Esmolol is an ultra-short-acting β-blocker currently in Phase II clinical trials. The ester functionality in esmolol results in rapid metabolism of the β-blocker into an acidic metabolite and methanol. Dichloromethane was used to denature blood esterases and quantitatively extract esmolol from the blood. A deuterated analogue of esmolol was selected as the internal standard, and both compounds were chromatographed as the trimethylsilyl derivatives. Blood levels of esmolol were quantitated by gas chromatography–mass spectrometry with selective-ion monitoring, focusing on specific ions corresponding to esmolol and the internal standard. The lower limit of sensitivity of the assay was 2.5 ng/mL. Using the assay, blood samples from a dose-ranging study in humans were analyzed for concentrations of esmolol. Steady-state blood levels of esmolol after intravenous infusion rates of 40, 100, 200, 300, 450, and 650 μg/kg/min were 0.202, 0.464, 0.977, 1.31, 1.92, and 2.97 μg/mL of blood. The elimination $t_{1/2}$ and total body clearance were estimated to be ~10 min and 220 mL/kg/min, respectively. The high clearance of esmolol suggested that metabolism by blood esterase(s) was the primary determinant of the duration of action of the drug.

Keyphrases □ Esmolol—GC-MS, ultra-short-acting β-blocker □ Beta-blocker—ultra-short-acting, esmolol, GC-MS.

The concept and advantages of ultra-short-acting β-adrenergic receptor blockers have been presented recently (1). Briefly, in critical care settings like emergency rooms and intensive cardiac-care units, an ultra-short-acting β-blocker would be superior to conventional β-blockers with long durations of action, since therapeutic effects of the drug can be altered rapidly in either direction to meet changing cardiovascular responses.

Development of esmolol, methyl-3-[4-[2-hydroxy-3-(isopropylamino)propoxy]phenyl]propionate hydrochloride, as a novel ultra-short-acting β-blocker is based on the enzymatic instability of an ester function and incorporation of this functionality into a chemical structure that has β-blocking properties. Hydrolysis of the ester linkage in esmolol by blood and tissue esterases transforms the β-blocker into an acidic metabolite and methanol.



ESMOLOL

Esmolol has been shown to be cardioselective and to possess a duration of action of ~15 min in dogs (1). Since blood levels of esmolol were anticipated to decrease very rapidly after stopping administration of the drug, a sensitive assay was needed in order to conduct detailed preclinical and clinical pharmacodynamic and pharmacokinetic studies. This report describes a gas chromatographic–mass spectrometric (GC-MS) method for the quantitation of esmolol in whole blood. Application of the method to the analysis of blood samples from a dose-ranging study in humans is also presented.

EXPERIMENTAL SECTION

Chemicals—Esmolol and the deuterated internal standard, methyl-3-[4-[2-hydroxy-3-(isopropylamino)propoxy]phenyl][1,2-$^2H_2$]propionate hydrochloride, were synthesized in-house[1]. Dichloromethane[2] was spectro grade.

Dibasic potassium phosphate[3], hydrochloric acid[4], and bis(trimethylsilyl)-trifluoroacetamide[5] were reagent grade.

Instrumentation—Quantitation of esmolol was accomplished using a 2-m × 2-mm i.d. stainless steel column packed with 3% SP-2250 on 100–200-mesh Supelcoport[6]. The GC–MS system consisted of a gas chromatograph[7] coupled to a mass spectrometer[8]. The GC conditions were as follows: injector, column, and detector temperatures were set at 280°C, 230°C, and 290°C, respectively.

Electron-impact mass spectra were obtained at 70 eV, and the mass spectrometer was programmed in the selective-ion mode, focusing on ions at *m/z* 251 and 253 (corresponding to esmolol and the internal standard, respectively). The major fragments (>15% relative abundance) of esmolol were: *m/z* 101 (59.3), 103 (20.4), 107 (23.7), 116 (20.4), 120 (15.5), 131 (29.8), 145 (21.9), 147 (24.9), 188 (36.2), 251 (base peak, 100), 252 (20.4), 336 (16.4), 352 ($M^+ - 15$, 36.5), and 367 (M^+, 1.8). For the deuterated internal standard, the major fragments were: *m/z* 101 (72.6), 108 (23.4), 116 (22.8), 122 (15.2), 132 (30.1), 146 (21.1), 188 (36.5), 253 (base peak, 100), 254 (17.9), 338 (15.2), 354 ($M^+ - 15$, 36.7), and 369 (M^+, 1.7).

Clinical Protocol—Six healthy male subjects, 20–30 years old (mean 23.2 years) and weighing 67.5–82.5 kg (mean 73.4 kg), received constantly increasing intravenous infusions of 10, 40, 100, 150, 200, 300, 450, and 650 μg/kg/min of esmolol for 60 min on 8 consecutive days. The minimum period between treatments was 23 h. In each treatment, blood samples were collected into heparinized tubes 1 min before and 30 and 60 min after initiation of the infusion, and at 5 and 15 min after cessation of the infusion.

Blood Sample Processing and Analysis—Immediately after collection of blood, a 1.0-mL aliquot was transferred into a 20- × 150-mm extraction tube containing 10.0 mL of dichloromethane and an appropriate amount of the deuterated internal standard. The tube was then shaken vigorously by hand for 10 s and then placed into a mechanical shaker[9] for 10 min. The two phases were separated by centrifugation in a refrigerated table-top centrifuge[10] at 1700×*g* for 10 min. After centrifugation, the reddish aqueous phase, which contained the polar metabolites, was removed. After tilting the tube to loosen the protein plaque, a serological pipet was carefully inserted into the organic phase, and 9.0 mL of dichloromethane was removed and transferred into another extraction tube containing 2.0 mL of 0.02 M HCl. The tube was shaken and centrifuged to separate the phases. The resultant aqueous phase was transferred into another tube and the pH was raised to 8.0 by addition of 200 μL of a 1.0 M potassium phosphate buffer (pH 8.0). Five milliliters of dichloromethane was added to the tube, and the tube was shaken and centrifuged. The organic phase was quantitatively removed and concentrated to ~100 μL under a stream of dry nitrogen. Then, 50 μL of bis(trimethylsilyl)trifluoroacetamide was added and the resultant mixture was heated at 60°C for 30 min. Two microliters of the final solution was injected into the GC–MS system for analysis. Using the selective extraction steps, the resultant final solution was devoid of any biological contaminants and the final recovery was 73%.

Quantitation of esmolol in the samples was accomplished by adding varying amounts of esmolol and a constant amount of the deuterated internal standard to blank human blood samples prior to the addition of 10 mL of dichloromethane. The standard curve samples were then processed and analyzed according to the aforementioned procedures.

RESULTS

The mass spectrum of esmolol (data not shown) showed that the molecular ion (*m/z* = 367) was present at a relative abundance of 1.8% indicating that only one trimethylsilyl group was attached. Analysis of the mass fragments suggested that the trimethylsilyl group was attached to the amino nitrogen. In addition, the base peak at *m/z* = 251 contained the propionate portion of the molecule. Thus, an internal standard was prepared by substituting the hydrogen atoms at the 1,2-positions of the propionate portion of the molecule with deuterium. In the mass spectrum of the deuterated internal standard (data not shown), the molecular ion was shifted two mass units higher to *m/z* = 369 and the base peak was shifted to 253. Using selective-ion monitoring, focusing on *m/z* = 251 and *m/z* = 253, the contribution of esmolol to *m/z* = 253 was determined to be ~7% and the contribution of the deuterated internal standard to *m/z* = 251 was <1%. This finding indicated that the deuterium in the internal standard did not exchange with hydrogen during sample processing and analysis. By selecting the concentration of internal standard to be always greater than or equal to the highest esmolol concentration in the standard curve, the small "cross-talk" was neglected.

Table I—Standard Curve of Esmolol

Conc., ng/mL	Peak Area Ratio[a]	Mean ± *SD* *CV*
2.5	0.006, 0.009, 0.010, 0.007, 0.007	0.008 ± 0.002 25.0
5.0	0.012, 0.016	0.014 ± 0.003 21.4
10	0.029, 0.033	0.031 ± 0.003 9.6
25	0.063, 0.067, 0.051, 0.063, 0.064	0.062 ± 0.006 9.7
50	0.094, 0.101	0.098 ± 0.005 5.1
100	0.211, 0.205	0.208 ± 0.004 1.9

1,000	0.220, 0.223, 0.224, 0.223, 0.221	0.222 ± 0.002 0.9
2,500	0.546, 0.540	0.543 ± 0.004 0.7
10,000	1.99, 1.98	1.99 ± 0.0007 0.4

[a] Peak area ratio of *m/z* 251–253 (esmolol/esmolol-d_2). The first set contained 500 ng/mL of esmolol-d_2 and the second set contained 5000 ng/mL of esmolol-d_2.

Table I summarizes the reproducibility of the assay. At the lower limit of sensitivity (2.5 ng/mL of blood), the coefficient of variation of six different determinations was 25%; at 25 ng/mL blood, the coefficient of variation was 10%; and at 1.0 μg/mL blood, the coefficient of variation was 1%.

After establishing its validity, the GC–MS method was used to analyze blood samples from a dose-ranging study in humans. The blood concentration-time profile of esmolol is shown in Fig. 1. The concentration of esmolol was approaching or was at steady state after 60 min of intravenous infusion with all the doses that were examined. Blood levels of esmolol decreased very rapidly after stopping the infusion, so that in 15 min blood levels had decreased by >50%. Figure 2 shows the linear relationship between the average blood

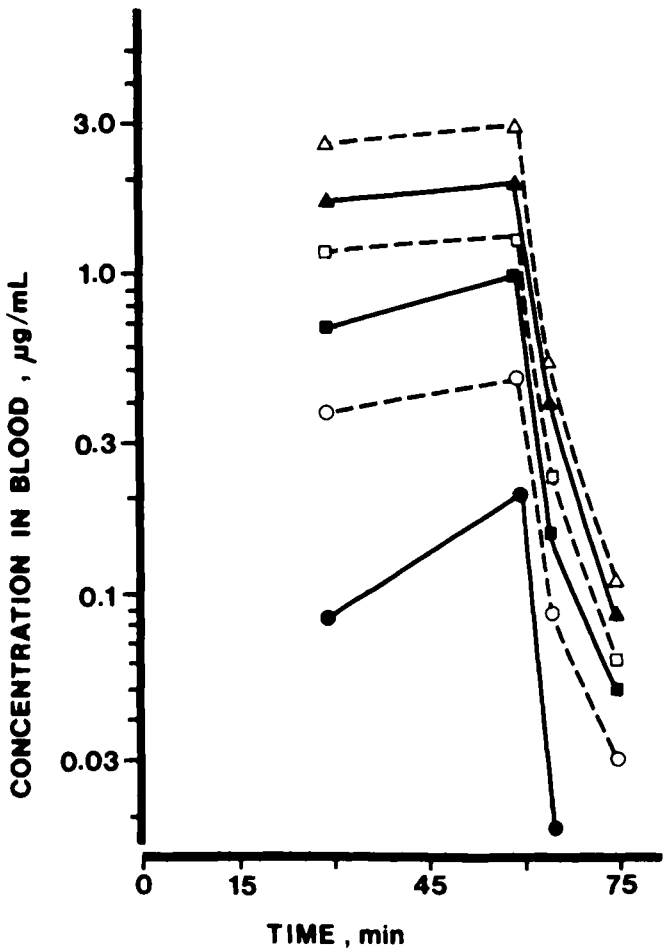

Figure 1—*Average blood concentration* versus *time profile of esmolol in normal subjects* (n = 1–6) *during and after a 1-h infusion of 40 (●), 100 (○), 200 (■), 300 (□), 450 (▲), and 650 (△) μg/kg/min.*

concentrations of esmolol at the conclusion of a 1-h infusion and the doses of esmolol. These results suggest that over the dose range examined esmolol appeared to follow linear pharmacokinetics.

Assuming that blood concentrations of esmolol had reached steady state, model-independent analyses of blood data indicated that the total body clearance (C_{ss}/infusion rate) averaged 220 mL/kg/min (Table II). A rough graphic determination indicated an extremely short elimination half-life for esmolol, averaging ~10 min.

Tble II—Summary of Estimated Pharmacokinetic Parameters of Esmolol in Humans

Dose, μg/kg/min	n^a	$C_{ss}{}^b$, μg/mL	Clearance^c, mL/kg/min	$t_{1/2}$, min
40	3	0.202 ± 0.038	198	≤10

200	6	0.977 ± 0.201	205	≤10
300	1	1.31	229	≤10
450	3	1.92 ± 0.500	234	≤10
650	1	2.97	219	≤10
Mean ± *SD*	—	—	217 ± 13.7	≤10

[a] *n* = number of subjects. [b] Concentration of esmolol observed in blood sample collected 60 min after the start of infusion at the indicated doses. [c] Clearance = dose/C_{ss}.

DISCUSSION

Most drugs are relatively stable in the presence of blood components for some time at room temperature. After removal of the drug from the body *via* blood sampling, there is reasonable assurance that levels of the drug in blood will not change until the sample is frozen or processed and analyzed. Even though blood does not appear to contain any of the oxidative enzymes which are abundant in the liver, it does contain high levels of esterases, which are found in red blood cells and plasma. Thus, drugs containing an ester functionality can potentially be rapidly metabolized by blood esterases.

Traditionally, very specific inhibitors were used to slow down or stop blood esterase activity. Assays for compounds such as chloroprocaine (2) were developed using this approach. Strong acids or bases have also been used to stop enzymatic activity, but the chemical lability of most ester linkages to high or low pH makes this approach undesirable. *In vivo* (1) and *in vitro* (3) studies with esmolol indicate that the compound is rapidly metabolized by blood esterase(s). To obtain reproducible results, blood esterases must be rapidly inactivated after blood sample collection. Dichloromethane was used to denature blood proteins, including esterase(s), and to partition esmolol into the organic layer away from the enzymatic activity.

The rapid decrease in blood levels of esmolol after stopping the infusion observed in the dose-ranging study in humans is consistent with results obtained in dogs (1). This rapid decrease in blood levels and concomitant dissipation of effects would be advantageous in critical-care settings. The high total clearance value of esmolol (220 mL/kg/min) in humans is three times greater than the cardiac output (5 L/min or 70 mL/min/kg in a 70-kg man) and 20 times greater than the hepatic blood flow (4). These results indicate that the primary determinant of the duration of action of esmolol in humans is blood esterases and not esterase activities in the liver and other tissues. The liver may still, however, play a role in the elimination of esmolol, since esterases and other plasma proteins which may bind esmolol are synthesized in the liver.

Effect of Folic Acid on the Pharmacokinetics of Acutely Administered Phenytoin in Pregnant and Nonpregnant Rats

RUBY C. CHOU and GERHARD LEVY ˣ

Received June 27, 1983, from the *Department of Pharmaceutics, School of Pharmacy, State University of New York at Buffalo, Amherst, N.Y. 14260.* Accepted for publication August 19, 1983.

Abstract □ The concentrations of both total and free phenytoin in the plasma of epileptic women tend to decrease during pregnancy, suggestive of a pregnancy-associated increase in the metabolic clearance of the drug. On the other hand, the metabolic clearance of free (unbound) phenytoin decreases during pregnancy in rats. One possible reason for this species difference is the routine dietary supplementation of folic acid in human pregnancy and the apparent ability of folic acid to lower phenytoin plasma concentrations even in nonpregnant humans. The purpose of this investigation was to determine the effect of treatment with folic acid on the pharmacokinetics of phenytoin in pregnant and female nonpregnant rats. In one experiment, the treated animals received folic acid in the drinking water, ~100–150 μg/kg/d, for 19 d. There was no apparent difference between the treated and untreated rats in the pharmacokinetics of a 10-mg/kg iv dose of phenytoin (which was administered to the pregnant rats on the 20th day of gestation), regardless of pregnancy status. In another experiment, pregnant and female nonpregnant rats received either folic acid, 400 μg/kg/d, or an equal volume of the solvent only, by gastric intubation for 19 d. The next day (which was the 20th day of gestation for the pregnant rats), the animals received an intravenous injection of phenytoin, 30 mg/kg. Again, pretreatment with folic acid had no apparent effect on the pharmacokinetics of phenytoin in both pregnant and nonpregnant rats. However, the results of this investigation confirm previous observations of dose-dependent phenytoin pharmacokinetics in rats and of decreased clearance of free phenytoin in late pregnancy. It is possible that the qualitative difference between humans and rats with respect to the effect of pregnancy on the pharmacokinetics of phenytoin may be due, at least in part, to a species difference in response to folic acid.

Keyphrases □ Pharmacokinetics—acutely administered phenytoin, folic acid, pregnant and nonpregnant rats □ Phenytoin—acutely administered, effect of folic acid on, pregnant and nonpregnant rats □ Folic acid—effect on acutely administered phenytoin, pregnant and nonpregnant rats

Long term use of phenytoin by epileptic patients is associated with decreased concentrations of folic acid or folate activity in serum, erythrocytes, and cerebrospinal fluid (1–3). Decreased folate activity has also been observed during pregnancy in nonepileptic women who are not taking phenytoin or other drugs (4, 5). Pregnant women taking phenytoin are, therefore, considered to be at particular risk of folate deficiency, and it is customary to give them supplementary folic acid.

Plasma concentrations of total and free phenytoin tend to decrease in women during pregnancy (6). The occurrence of decreased concentrations of free phenytoin suggests that the intrinsic metabolic clearance of the drug is increased in human pregnancy. The opposite is found in rats, *i.e.*, the metabolic clearance of free phenytoin is decreased during pregnancy (7). The reasons for this unusual, qualitative, apparent species difference are unclear (7), particularly since both humans and rats eliminate phenytoin primarily by the same metabolic pathway, *i.e.*, *p*-hydroxylation. One possibility is that it may be related to the dietary supplementation of folate in pregnant women. A number of studies on nonpregnant human subjects have shown that administration of folic acid can cause phenytoin plasma concentrations to decrease (8–11). The question arises, therefore, whether folate administration to rats will alter the pharmacokinetics of phenytoin in these animals, particularly during pregnancy.

EXPERIMENTAL SECTION

Female inbred Lewis rats were used in this investigation. Some of the animals were mated while others were designated as nonpregnant controls. The rats were then housed individually in suspended wire cages to prevent or minimize coprophagy. In one experiment, some of the pregnant and nonpregnant animals had folic acid and sodium bicarbonate, 1 μg/mL each, added to the drinking water while the others received drinking water containing only sodium bicarbonate. After 10 d, the folic acid concentration in the drinking water of pregnant animals was increased to 1.2 μg/mL in case these rats did not increase their water intake in proportion to their increased body weight. The total period of folic acid administration was 19 d; on the 20th day (day 20 of gestation of the pregnant rats) the rats received an intravenous injection of phenytoin, 10 mg/kg. Venous blood samples were collected periodically for determination of plasma phenytoin concentrations by HPLC. A large volume of blood was obtained from the abdominal aorta at the end of the experiment for determination of the plasma free fraction of phenytoin by immediate ultrafiltration at 37°C. The anticoagulant was heparin for the serial blood samples intended for phenytoin assay and EDTA for the large sample intended for plasma ultrafiltration.

In another experiment, some of the pregnant and nonpregnant rats received folic acid, 400 μg/kg as a 200 μg/mL freshly prepared aqueous solution containing 200 μg/mL sodium bicarbonate, daily for 19 d by gastric intuba-

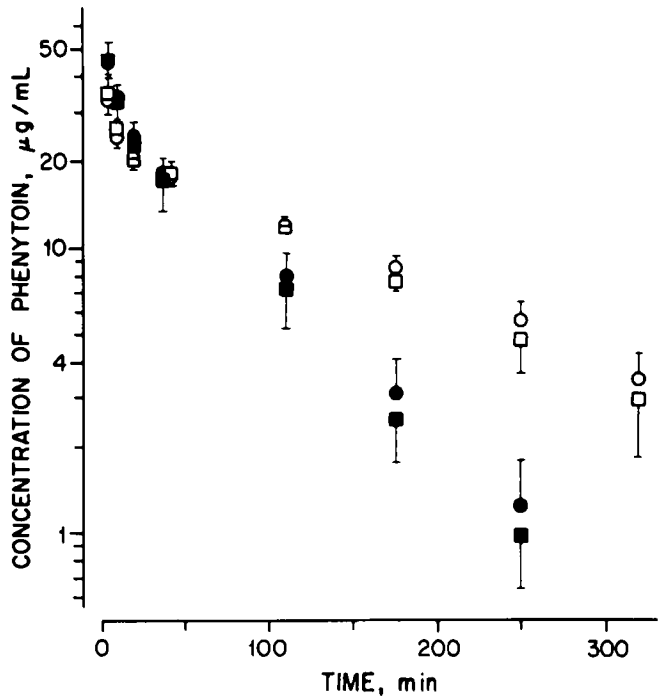

Figure 1—*Effect of pretreatment with folic acid (400 μg/kg/d orally for 19 d) on the pharmacokinetics of a 30-mg/kg iv dose of phenytoin in pregnant (day 20 of gestation) (open symbols) and nonpregnant (solid symbols) rats. Key: (□, ■) folic acid pretreated rats; (○, ●) rats that did not receive supplementary folic acid. Mean of 5 animals per group; vertical bars indicate + or − SD.*

mL/min/kg	32.3 ± 6.9	30.5 ± 5.3	81.0 ± 19.3	75.2 ± 11.6

[a] Results are reported as mean ±*SD*. The treated animals received 400 μg/kg/d of folic acid by gavage for 19 d before the experiment. There were no statistically significant differences between treated and untreated pregnant or nonpregnant animals.

tion. The other animals received only the solvent. On the 20th day (day 20 of gestation of the pregnant rats), a single intravenous injection of phenytoin, 30 mg/kg, was administered, and blood samples were collected periodically for assay and a large terminal sample was collected for ultrafiltration. All technical details of the pharmacokinetic study were identical to those already described (7).

RESULTS

The nonpregnant rats consumed 26.8 ± 2.8 (mean ± *SD*) mL/d of folic acid solution (equivalent to 109 ± 15 μg/kg/d of folic acid), 28.0 ± 2.4 mL/d of sodium bicarbonate solution, or 28.3 ± 3.3 mL/d of pure water (the latter determined in rats not used in the pharmacokinetic study). The pregnant rats consumed increasingly larger volumes of water with increasing gestation time: 16.3 ± 3.3, 23.5 ± 3.0, and 36.8 ± 6.3 mL/d on the 4th, 10th, and 15th day of gestation, respectively. These are combined figures for folic acid and sodium bicarbonate solutions since there were no apparent differences between the two. The average dose of folic acid ingested with the drinking water was 151 ± 21 μg/kg/d at the end of gestation.

The results of the pharmacokinetic study with the 10 mg/kg dose of phenytoin are summarized in Table I. There was no statistically significant difference between the folic acid treated and untreated rats in any of the parameters that describe the pharmacokinetics of phenytoin, including the plasma protein binding. This applies to pregnant and to nonpregnant rats, considered separately. A comparison of phenytoin pharmacokinetics in untreated pregnant and nonpregnant rats, with a larger number of animals per group, has been reported (7).

The results of the pharmacokinetic study with a 30 mg/kg dose of phenytoin are summarized in Table II, and the average plasma concentration *versus* time profiles are presented in Fig. 1. As already reported (7), the plasma clearance of the 30 mg/kg dose is considerably lower than that of the 10 mg/kg dose and is significantly decreased in pregnancy; but again, supplementation with folic acid had *no* apparent effect on the pharmacokinetics of phenytoin in either the pregnant or the nonpregnant animals. Nor did folic acid treatment affect body weight, hematocrit, or plasma protein binding of phenytoin.

One out of 10 folic acid treated and 4 out of 12 sodium bicarbonate treated impregnated (spermatozoa-positive vaginal smear) rats were not pregnant on the 20th day after mating, most likely due to resorption of fetuses. The difference between the two groups is not statistically significant by comparison of two success probabilities (12). Only the rats that were actually pregnant were used in the pharmacokinetic studies.

DISCUSSION

Female Sprague–Dawley rats fed a diet containing 1.6-mg folic acid per kg of feed[1] had 52% lower serum folate concentrations on the 21st day of pregnancy than did nonpregnant controls (13). The type of cages used to house these animals was not specified. The rats in the present investigation were fed a diet[2] containing 0.89-mg folic acid per kg of feed[1], and they were housed in suspended wire-mesh cages to minimize coprophagy, by which the animals could obtain folate synthesized by intestinal bacteria (14). It is not practical to put pregnant rats on a folate-deficient diet since this results in a high incidence of fetal resorption (15).

Blake *et al.* (16) have determined the effect of folic acid supplementation (100 μg/kg daily by gavage, from the 7th to the 20th day of gestation) on the *in vitro* activity of hepatic microsomal phenytoin hydroxylase in pregnant Sprague–Dawley rats on a diet containing 1.7 mg folic acid per kg of feed[1]. Enzyme activity per gram of liver increased fourfold relative to that of rats that did not receive folic acid supplementation. The authors concluded that this may explain the decreased plasma phenytoin concentrations observed when patients receive extra folic acid. Contrary to the *in vitro* findings by Blake *et al.* (16), the results of the present *in vivo* investigation indicate that

folic acid supplementation has no apparent effect on the pharmacokinetics of phenytoin in pregnant as well as in nonpregnant rats. Significantly, neither of these two studies involved prior or chronic administration of phenytoin.

The published clinical data concerning decreased phenytoin plasma concentrations during pregnancy were obtained, necessarily, from patients on a chronic oral regimen of the drug. While it would seem feasible to administer a single intravenous tracer dose of stable isotope labeled phenytoin to these individuals before, during, and after pregnancy, this has apparently not been done. In an acute (single dose) clinical study on nonpregnant individuals, pretreatment with 15- or 30-mg folic acid orally everyday for several weeks had no effect on the biological half-life of phenytoin (17). Plasma concentrations of phenytoin in male Wistar rats 1.5 and 5 h after a single intraperitoneal dose of phenytoin, were similar in animals given a single concomitant oral dose of folic acid, 5 mg/kg, and in controls (18).

One possibility not explored in the present investigation is that folic acid supplementation affects the *in vivo* clearance of phenytoin only in rats that have been treated chronically with phenytoin. If that possibility can be excluded, then the qualitative species difference between humans and rats, with respect to the effect of pregnancy on the pharmacokinetics of phenytoin, may be due, at least in part, to the difference in response to folate. If, however, increased dietary folic acid causes an increase in the metabolic clearance of phenytoin in both humans and rats on chronic phenytoin therapy, then the apparent species difference in the effect of pregnancy on phenytoin pharmacokinetics may be related to the common practice of supplementing the diet of pregnant women, but not of pregnant rats, with folate.

NOTE ADDED IN PROOF

Subsequent to the submission of this manuscript, Carl and Smith (19) reported that oral folate supplementation (20 mg/kg/d for 6 d, then every 12 h for 4 d) had no apparent effect on phenytoin concentrations in the liver, brain, and plasma of male Sprague-Dawley rats who received oral phenytoin (100 mg/kg/d) for 6 d, then every 12 h for 4 d) concomitantly. In a prospective study of epileptic women during pregnancy, Hiilesmaa *et al.* (20) found a negative correlation between folate and phenytoin concentrations in serum ($r = -0.56$, $p = 0.002$, $n = 39$) but no association between serum folate concentrations and the number of seizures during pregnancy.

bicyclo[2.2.1]hepta-2,5-diene-5,6-dicarboxylate (Ia) exhibited potent activity against L1210 leukemia in tissue culture assays, but failed to show any *in vivo* activity (2). The *bis*-carbamate (Ib) showed marginal activity against P388 lymphocytic leukemia *in vivo*, but this result was difficult to reproduce. This report describes an attempt to prepare derivatives of 2,3-*bis*(hydroxymethyl)-7-oxabicyclo[2.2.1]hepta-2,5-diene which show significant reproducible antineoplastic activity *in vivo*.

EXPERIMENTAL SECTION[1]

Ethyl 2,3-*bis*(hydroxymethyl)-5-phenyl-7-oxabicyclo[2.2.1]hepta-2,5-diene-6-carboxylate *bis*(*N*-methylcarbamate) (IIa) and its *p*-chloro (IIb) and *p*-nitro (IIc) analogues were prepared as follows. A mixture of 3,4-*bis*-(trimethylsilyloxymethyl)furan (2) (0.0147 mol), ethyl phenylpropiolate (0.0206 mol), and toluene (20 mL) was heated under reflux for 40 h. (Note, methyl *p*-methoxyphenylpropiolate failed to react under these conditions.) The mixture was concentrated under reduced pressure and the residue was treated with ethanol–water (1:1, 80 mL) at 60°C for 30 min. The hot mixture was filtered to remove the insoluble phenylpropiolate ester, and the filtrate was concentrated under reduced pressure. The residue was dried under high vacuum (P_2O_5) to give the unstable diol in 90–95% yield.

A solution of the diol (0.0059 mol) and triethylamine (0.2 mL) in dichloromethane (10 mL) was treated with methylisocyanate (2 mL), and the mixture was heated at reflux for 36 h. The reaction mixture was concentrated to dryness under reduced pressure and the residue was crystallized from ethyl acetate–isopropyl ether to give IIa in 60% yield, mp 140–143°C. IR: 3350, 2950, 1700, 1550, 1250, 1150, 1000, and 850 cm^{-1}; ^{1}H-NMR: δ 1.30 (t, 3, J = 8 Hz), 2.60 (d, 3, J = 6 Hz), 2.80 (d, 3, J = 6 Hz), 4.40 (q, 2, J = 8 Hz), 4.90 (s, 4), 5.70 (s, 2), and 7.20–7.80 ppm (m, 5).

Anal.—Calc. for $C_{20}H_{23}N_2O_7$: C, 60.56; H, 5.80; N, 6.72. Found: C, 60.45; H, 5.88; N, 6.69.

The chloro and nitro derivatives (IIb and IIc), as ethyl esters, were prepared in the same manner. Compound IIb, obtained in 72% yield, had mp 176–178°C (ethyl acetate–isopropyl ether). IR: 3350, 2950, 1700, 1540, and 1260 cm^{-1}; ^{1}H-NMR: δ 2.60 (d, 3, J = 6 Hz), 2.80 (d, 3, J = 6 Hz), 3.75 (s, 3), 4.85 (s, 4), 5.65 (s, 2), and 7.2–7.8 ppm (m, 4).

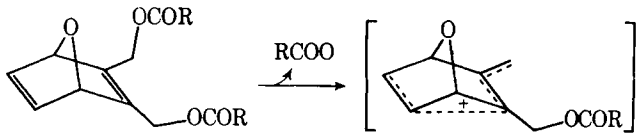
Anal.—Calc. for $C_{20}H_{22}ClN_2O_7$: C, 54.98; H, 4.84; N, 6.41; Cl, 8.11. Found: C, 54.92; H, 4.91; N, 6.35; Cl, 8.14.

Compound IIc (68%) had mp 172–176°C (ethyl acetate–isopropyl ether). IR: 3550, 2950, 1700, 1550, 1250, 975, and 850 cm^{-1}; ^{1}H-NMR: δ 2.60 (d, 3, J = 6 Hz), 2.80 (d, 3, J = 6 Hz), 3.75 (s, 3), 4.85 (s, 4), 5.65 (s, 2), and 7.2–7.8 ppm (m, 4).

Anal.—Calc. for $C_{20}H_{22}N_3O_9$: C, 53.69; H, 4.73; N, 9.39. Found: C, 53.74; H, 4.76; N, 9.34.

RESULTS AND DISCUSSION

The rationale for the design of I was based on two factors. These were, first, the electrophilicity of the allylic esters, which can react by an alkyl–oxygen cleavage mechanism (3, 4) and, second, the neighboring group participation



Scheme I

of C=C π-bonds in nucleophilic substitution reactions. These two factors are summarized in Scheme I.

The 5,6-double bond in I is substituted with two electron-withdrawing groups [for $-CO_2CH_3$ the Swain–Lupton resonance (R) and field (F) contributions are 0.552 and 0.140, respectively]. Compounds of the general structure II were designed to have a 5,6-double bond which was less electron-deficient than I (the phenyl substituent has F = 0.139 and R = −0.088). Thus, compounds of the general structure II should be more reactive than I.

These *bis*-carbamates were prepared in a reaction sequence which began with a Diels Alder reaction between 3,4-*bis*(trimethylsilyloxymethyl)furan (2) and the appropriate phenylpropiolic acid derivative. The trimethylsilyl-protected diol was used because it could be removed from the reaction mixture by distillation at a sufficiently low temperature to avoid decomposition of the product. The phenylpropiolic acid derivatives were prepared from the appropriate cinnamic acid by a bromination–dehydrobromination sequence (5–9).

The silyl blocking groups were removed from the Diels Alder adducts (ethanol–water), and the diols were converted to the *bis*-carbamates by treatment with methylisocyanate in the presence of triethylamine. The intermediate diols were unstable and attempts to purify these compounds led to extensive decomposition; thus, the diols were used directly in the next step.

Two of the compounds, selected as "lead" structures, were tested against P388 lymphocytic leukemia in mice under the auspices of the National Cancer Institute (10). The *p*-chloro compound (IIb) was inactive over the dose range of 1.56–200 mg/kg, and IIa was inactive over the dose range of 12.5–400 mg/kg. Compound IIa was toxic at the 400-mg/kg dose; three of the six test animals died before the fifth day of the test (the animals were given once daily intraperitoneal injections). Only one of six animals died before day 5 at the 200-mg/kg level with both IIa and IIb; however, IIb appeared to be more toxic as judged by the weight losses of the treated animals.

The reactivity of II was greater than I, as evidenced by the greater instability of II. Nevertheless, the reactivity is still not sufficient to confer *in vivo* antitumor activity to *bis*-carbamate derivatives in the oxabicyclic series.

Colorimetric Determination of Procainamide in Injectable Preparations

J. E. WHITAKER * and A. M. HOYT, JR. ‡x

Received October 13, 1981, from the *University of Oregon, Eugene, OR 97403 and the ‡Department of Chemistry, University of Central Arkansas, Conway, AR 72032. Accepted for publication August 30, 1983.

Abstract □ A simple, rapid colorimetric method is described which determines procainamide in commercially available, injectable solutions. It is based on complexing the drug with cupric ion and then measuring the absorption at 380 nm. The reaction is fast and the metal–drug ratio in the complex is 1:1. The pH optimum for maximum reaction is 4.0–4.5 which is maintained by an acetate buffer. Linear standard curves were obtained from 1.52 to 6.06 mg/mL. Analysis of 29 commercial samples resulted in an average of 97.3% of the label claim.

Keyphrases □ Procainamide—colorimetric determination, injectable preparations, cupric ion complexing □ Colorimetry—procainamide, injectable preparations, cupric ion complexing

Procainamide (I) is an antiarrhythmic agent used to treat cardiac disorders. Dosages and plasma concentrations as well as half-life and ultimate fate have been the subject of previous studies (1, 2). All of these studies require an analytical method for the analysis of I, and there exists an obvious need for such a method in manufacturing and quality control.

A large volume of literature exists on the determination of I in pharmaceutical and biological systems. One of the most favored techniques is HPLC (3–5), although gas chromatography (6), TLC (7), spectrophotofluorometry (8, 9), and even polarography (10) have been used. Some of the claimed advantages in specificity are not realized (11), and some of the methods are quite tedious and time-consuming.

Spectrophotometric procedures which involve diazotization and coupling reactions have been reported (12, 13). A colorimetric procedure for I that requires less manipulation and fewer reactions would be useful and more convenient. The text describes such a colorimetric method for I based on the formation of a complex between procainamide and cupric ion. This colorimetric method for the drug is shown to have sufficient sensitivity and adequate specificity, especially for relatively pure samples. The suitability of this colored complex for analytical purposes, and the application of this colorimetric method are also described.

EXPERIMENTAL SECTION

Materials—Procainamide hydrochloride[1] (II), *N*-acetylprocainamide[1], procaine hydrochloride[1], sulfuric and acetic acids[2] (reagent grade), sodium hydroxide[2] (50% solution), iron(III) nitrate[2], cobalt(II) chloride[2], and sodium acetate[2] (ACS grade), and chlorides[2] of copper(II), nickel(II), and chromium(III) were obtained commercially. The injectable vials[3] were obtained through local retail outlets.

Preliminary work was done on a recording UV-visible light instrument[4], but later analytical work was carried out using a single-beam spectrophotometer[5]. pH measurements were made on an instrument[6] which was standardized daily with commercially prepared biphthalate buffers.

Complex Formation—Screening of various metal ions for potential use was carried out by adding a few drops of ~2M solutions of the various metal ions (cobalt(II), nickel(II), chromium(III), copper(II) chlorides, and iron(III) nitrate) to ~1 mL of a 10-mg/mL solution of II in a spot plate. The only visible color change occurred with cupric ion; a green color became apparent on addition of the metal.

Spectra of solutions of II were obtained from 330–550 nm both in the presence and absence of the cupric ion, as shown in Fig. 1. Using the absorption generated at 380 nm, the formula of the complex was obtained by the continuous variations method (14). The absorption at 380 nm was maximized at $X_{Cu} = 0.5$, where X_{Cu} is the mole fraction of cupric ion.

pH Dependence of the Complex—The optimum pH for the complex was established by mixing 0.10 M solutions of II and cupric chloride, adjusting to a measured pH of 1.5 with concentrated sulfuric acid, and then gradually neutralizing the solution with dropwise addition of 10% NaOH, after measurement of absorbance at 380 nm. A plot of absorbance *versus* pH (Fig. 2) shows a maximum at pH 4. Increasing the pH >4.3–4.6 causes a white to light blue precipitate to form; therefore, a pH of 4.0 was selected for further studies.

Linearity Studies—A pH 4.0 acetate buffer (prepared by addition of sodium acetate to a 1 M solution of acetic acid) was used as the solvent for these studies. A series of solutions of the complex in acetate buffer were prepared; the solutions each contained a constant, excess level (10.5 mg/mL) of the cupric ion, and varying (1.52, 3.04, 4.55, and 6.06 mg/mL) amounts of II. This series of solutions was prepared by mixing three solutions in various ratios: 37.87 mg/mL II, 131.1 mg/mL cupric ion, and the buffer. Measurements of the absorbances of these solutions and their respective concentrations are shown in Table I.

Analysis of Injectable Solutions—A series of standards of II were prepared that are similar to those in the linearity studies; the absorbances were measured and a least-square line prepared from the data. Concurrently, 100 mg/mL commercial samples were analyzed by withdrawing 1 mL of the liquid, mixing with 4 mL of the 131.1 mg/mL cupric ion solution, and diluting to 50 mL with pH 4 acetate buffer. The absorbances of these solutions were also determined at 380 nm, and their concentrations calculated from the slope and intercept of the least-square line described above. As shown in Table II, recoveries varied from a low of 88.4% to a high of 107.9% based on label claims.

RESULTS AND DISCUSSION

Cupric ion complexed instantly with the procainamide molecule, the 1:1 coordination resulting in a visible absorption with a maximum at 380 nm. The complex formed most completely at a pH value of 4.0–4.5; a precipitate formed near the upper pH limit. Attempts to form the complex at pH 5.0 gave a dark blue precipitate which dissolved on long standing. The curve shape shown in Fig. 2 was reproduced by later experiments in which II in water (pH 4.5) was acidified, as opposed to the acid to neutral direction reported in the *Experi-*

mental Section. The anion present with copper did not affect complex formation and the sulfate salt was used routinely in later work.

An acetate buffer, pH 4.0, was found to be an excellent medium for analytical work; however, unbuffered solutions, as well as those buffered with biphthalate, were also tried and found to give linearly increasing absorbance at 380 nm with increasing levels of II. Biphthalate, however, repressed complex formation (as evidenced by the lower-than-expected absorbances), probably by competing with II for the cupric ion. Repetition of the above experiment showed that the concentration of acetate buffer was not critical; however, for reproducible results, the pH must be kept constant. This is most easily accomplished by preparing and using large quantities of buffer. It was also discovered, in later experiments, that the amount of excess copper was not critical; but, a minimum of two-threefold excess was used throughout. This observation indicates that the equilibrium constant for formation is very favorable and, thus, well-suited for an analytical technique.

The reported experiment on the analyses of injectable vials was carried out on four different days; each repetition gave a linear standard curve, and recoveries of the samples (all were guaranteed 100 mg/mL) varied from a low of 88.4% to a high of 107.9% on the results from 29 different samples. Between sets of samples there was a slight day-to-day variation in recovery; within a set the results were remarkably consistent (the highest *SD* within a set was 2.6%, the lowest was 0.5%, based on recovery figures). The variation between sets can be attributed to slight pH differences in different batches of buffer, therefore, it is suggested that large amounts of buffer be made to promote uniformity.

To address the question of the specificity of this procedure, a spot plate test of procaine hydrochloride and *N*-acetylprocainamide showed that the color is not unique to procainamide. Procaine gave the color, the *N*-acetylprocainamide did not. Procaine is the most chemically similar drug available, so the presence of color, not altogether surprising, was the most stringent test possible. *N*-Acetylprocainamide was selected because it is chemically similar to I, and, in addition, is the major metabolite in humans (15). The involvement of nitrogen atoms in coordination with copper is also suggested by the lack of color with the *N*-acetyl compound. The lack of absolute specificity was not viewed as a serious drawback, since use in laboratory was limited to the injectable sample only.

Table I—380 nm Absorbance Values of Varying Concentrations of the Copper–Procainamide Complex

Conc. of Procainamide, mg/mL	Absorbance
0	0.063
1.52	0.388
3.04	0.705
4.55	1.01
6.06	1.28

Table II—Concentrations of Pronestyl Injectables Calculated from Absorbance Data

Sample Number	Conc., mg/mL	Sample Number	Conc., mg/mL
1	102	16	89.5
2	91.2	17	96.8

Decrease in the Rate of Capsule Dissolution Due to Formaldehyde from Polysorbate 80 Autoxidation

Keyphrases □ Dissolution, capsule—rate decrease, formation of formaldehyde, polysorbate 80 autoxidation □ Polysorbate 80—autoxidation, formation of formaldehyde, decreased dissolution rate, capsules

To the Editor:

Dissolution studies on some stability samples of gemfibrozil capsules showed a significant decrease in dissolution rate with time of storage and exposure to humidity. Observations of these slowly dissolving samples during the tests showed that the capsule contents were held together by a thin, tough, water-insoluble film, the disruption of which was seen to be the dissolution rate-limiting factor for the drug product. A bioavailability study of such film-forming gemfibrozil capsules showed them to be bioequivalent to the readily dissolving product. Thus, the decrease in dissolution rate in the *in vitro* test is an anomaly because it does not correlate with *in vivo* results. This communication describes studies which established that film formation is due to denaturation of the inner surface of the capsule by formaldehyde, formed by trace autoxidation of the polysorbate 80 used as an excipient.

Polysorbate 80 had been useful in our laboratories as a wetting agent in capsule formulations of hydrophobic drugs. It was convenient to prepare a 1:2 dispersion by drying an alcohol solution of polysorbate 80 mixed with colloidal silica. The silica aided in powder flow, facilitating high-speed encapsulation. This dispersion was used in several capsule formulations of investigational drugs, all of which exhibited film formation when stored under high-humidity conditions. Studies on experimental capsule formulations (Table I) made with constituents of the gemfibrozil capsule formula and stored at 37°C, 37°C with 80% relative humidity (RH), and 45°C and tested after 1, 2, and 3 months showed that film formation occurred only when polysorbate 80 was present. All of the capsules containing polysorbate 80 showed film formation during testing after 1 month at 37°C with 80% RH.

The reaction of formaldehyde and other aldehydes with proteins is well known (1, 2). Cross-linking of the amino groups in gelatin results in its denaturation to an insoluble protein (3). Since formaldehyde could result from autoxidation of the end groups in polysorbate 80 and acetaldehyde could be produced by oxidation of alcohol used in preparation of polysorbate 80–silica dispersion, the hypothesis that one or both of these aldehydes was responsible for film formation was tested. Formation of aldehydes would be facilitated by the immense surface area of the silica, so the results in Table I are consistent with the hypothesis.

Table I—Experimental Capsule Formulations [a]

Ingredients, mg	Formulation a	b[b]	c	d[c]	e[d]	f[d]	g[e]	h[d]

Table II—Assay of Formaldehyde in Polysorbate 80 on Silica

Lot	Formaldehyde, μg/g of Sample Taken HPLC	Fluorometric	Colorimetric
1	20	163	260
2	13	55	170
3	13	—	75
4	18	—	100
5	27	111	200
6	36	163	110

Six lots of polysorbate 80–silica dispersion were analyzed for formaldehyde by three methods. The HPLC method (4) is based on the reaction of aldehydes with 2-diphenylacetyl-1,3-indanedione-1-hydrazone and afforded a separation of formaldehyde and acetaldehyde derivatives. The fluorometric method (5), based on the Hantzsch reaction, is much more sensitive for formaldehyde than for acetaldehyde. The same sample preparation was used for both; however, the fluorometric method provided significantly higher numbers. (This was determined later to be a result of lower reaction rate for the sample than the standard in the HPLC method.) The colorimetric microdiffusion method (6) was much simpler, with a weighed amount of dispersion in the outer ring of a microdiffusion chamber and chromotropic acid reagent in the inner ring. Table II shows results establishing that formaldehyde is present in all of the samples, half of which showed equivalent amounts of acetaldehyde by the HPLC method. For the purposes of this study, the qualitative results of the tests were much more important than the quantitative results. Obtaining reliable quantitative methods for the lower aldehydes in heterogeneous systems is difficult, owing to their volatility and reactivity; however, further work on this methodology has shown promise and may be reported elsewhere.

The highest estimate of formaldehyde content presented in Table II is <0.08% of the polysorbate 80 content of the dispersion. Thus, elucidation of the film-forming phenomenon provides a further example of the profound effect that trace decomposition may have on a drug product (7). Although the artifact has no bioavailability significance, it requires development of an alternative dissolution method for quality assurance, one where the film is digested or disrupted. Based on these studies, dissolution testing at 1 month of capsules stored at 37°C with 80% RH should provide a reliable indication of potential problems due to aldehydes. Whether film formation occurs in the presence of trace aldehydes likely depends on the reactivity of other constituents of the formulation, the internal moisture content, pH, and other factors. Certainly, the use of aldehyde-generating excipients in capsule formulations should be circumvented wherever possible.

Does Cimetidine Impair Nitroreduction?

Keyphrases □ Cimetidine—possible nitroreduction, nitrazepam □ Nitrazepam—nitroreduction, possible interference by cimetidine

To the Editor:

A recent report by Ochs *et al.* (1) demonstrated that cimetidine reduced the clearance of nitrazepam in human subjects from a mean of 1.41 mL/min/kg in the control state to 1.17 mL/min/kg during cimetidine treatment. Cimetidine had no effect on the absorption kinetics or on volume of distribution of nitrazepam. These observations, in conjunction with the belief that nitroreduction accounts for most of nitrazepam clearance, prompted Ochs and co-workers to conclude that cimetidine impairs the nitroreduction of nitrazepam. Furthermore, the authors suggested that such metabolic inhibition by cimetidine may interfere with the elimination of other drugs biotransformed by nitroreduction (1).

While the effect of cimetidine on nitrazepam clearance (1) is clear, we suggest that the above conclusion by Ochs *et al.* regarding the inhibition of nitroreduction by cimetidine may be premature. Our doubts are based on a review of published studies (2–5) of the metabolic fate of nitrazepam in humans. These studies reveal that while nitroreduction is an important biotransformation pathway for nitrazepam, it accounts for only a limited amount of the administered dose in humans. For example, Sawada and Shinohara found (2) that 17% of an oral dose of nitrazepam was excreted as nitro-reduced metabolites in the urine of human subjects in 5 d. Unchanged drug (1%) and a ring-opened metabolite (2%) were also detected, but 80% of the administered dose was not recovered (2). Kangas (3) isolated unchanged drug (1%) and nitro-reduced metabolites (52%) from the 7-d urine samples of human subjects administered nitrazepam, but could not account for nearly one-half of the administered dose. Nitro-reduced metabolites recovered from 72-h human urine samples represented only 6% of the administered nitrazepam dose in another study (4). Rieder and Wendt found (5) that ~7% of an administered oral radioactively labeled nitrazepam dose appeared in the 24-h urine specimen as nitro-reduced metabolites. Ring-opened metabolites accounted for an additional 9%, and traces of unchanged drug were also isolated. Other metabolites, which represented 21% of the administered dose, were also present but could not be identified. Thus, a total of 37% of the administered dose was excreted in the 24-h urine sample, and much of it was not identified (5). Although the recovery of total radioactivity increased to 65–70% after oral dosing and to 94% following intravenous administration during the subsequent 100 h, the proportion of the identified metabolites did not change significantly. Rieder and Wendt also demonstrated the accumulation of large amounts of unidentified metabolites in the plasma of human subjects after oral doses of this drug (5). Quantitative differences among the above-described studies may be due to differences in analytical methods and/or to inclusion *versus* omission of conjugated metabolites. Nevertheless, nitroreduction in humans has been shown to account, at most, for ~50% (3) of total nitrazepam elimination, and for much less in most studies (2, 4, 5). Since negligible amounts of unchanged drug are excreted (2–5), unidentified metabolites probably account (3, 5) for the remainder of nitrazepam elimination.

Cimetidine is known (6) to inhibit oxidative biotransformation of many drugs and, therefore, the following question must be raised: Is the effect of cimetidine on the clearance of nitrazepam due to the inhibition of some unidentified *oxidative* biotransformation rather than to inhibition of nitroreduction? This alternative explanation is supported by the isolation of small amounts of oxidized metabolites of nitrazepam from urine samples after the administration of the drug to humans (2, 5). Furthermore, oxidation may also be involved (7, 8) in the ring-opening biotransformation of benzodiazepines which may be an important metabolic pathway for nitrazepam (5).

Thus, it is clear that previous work has not accounted for a large fraction of the nitrazepam dose, and it appears that oxidative biotransformations may be responsible for a portion of nitrazepam clearance. There is insufficient data to determine whether nitrazepam nitroreduction or some hitherto unidentified oxidative metabolic pathway is impaired by cimetidine. Therefore, we feel that it is premature to suggest (1) that the ability of cimetidine to impair drug oxidation in humans should be extended to include inhibition of nitroreduction. There are several important drugs with a nitro group in their structure (*e.g.*, chloramphenicol, clonazepam, nitrofurantoin, and metronidazole), and some of these compounds have been shown to be metabolized *via* nitroreduction. We are concerned that the suggestion by Ochs *et al.* (1) may foster a general belief that cimetidine—a widely used agent—impairs the elimination of such drugs *via* nitroreduction, a belief for which there is, as yet, no firm evidence.

Perhaps cimetidine will be shown in the future to inhibit one or more of the several distinct nitroreductases known [*e.g.*, cytochrome P_{450}, whose oxidative function is inhibited by cimetidine (9), can also function as a nitroreductase (10)]. However, to demonstrate inhibition of nitroreduction, studies of the effects of cimetidine on specific biotransformations and on metabolite formation will be required. It will be interesting to watch developments in this area.

BOOKS

Review of Organic Functional Groups: Introduction to Medicinal Organic Chemistry. By THOMAS L. LEMKE. Lea and Febiger, Philadelphia, PA. 1983. 131 pp. 15 × 23 cm. Price $10.50.

The objective of this book is to provide a self-paced review of the nomenclature, physical properties, chemical properties, and metabolism of organic functional groups that are important in medicinal chemistry. The book is designed for use as supplemental material for a pharmacy course in medicinal chemistry as well as a concise reference for students and professional practitioners in pharmacy, medicine, nursing, dentistry, and veterinary medicine. After a general chapter on water solubility and chemical bonding, subsequent chapters focus on specific functional groups. Organic functional groups covered include alkanes, alkenes, aromatic hydrocarbons, halogenated hydrocarbons, alcohols, phenols, ethers, aldehydes, ketones, amines, carboxylic acids and their derivatives, sulfonic acids and sulfonamides, and heterocycles. A chapter on empirical and analytical methods of determining water solubility and an appendix on acidity and basicity are also included. Review questions are placed at the end of chapters to reinforce concepts presented in the text.

Chapters on individual functional groups are concise, and adhere to an outline format where the three major subheadings are Nomenclature, Physical-Chemical Properties, and Metabolism. There are adequate examples and tables of physical data given to illustrate the major points. The sections on nomenclature and physical-chemical properties are especially clearly written and complete. Most of the sections on metabolism are also clear and concise. However, the metabolism sections on aromatic hydrocarbons, halogenated hydrocarbons, and amines may be confusing since they contain several statements which contradict information found in drug metabolism chapters of current medicinal chemistry textbooks.

The major emphasis of this book is in areas of medicinal chemistry which many undergraduate pharmacy students find difficult. The sections on nomenclature and physical-chemical properties should be very helpful to those students who have difficulty extracting information from general organic chemistry textbooks that is directly pertinent to medicinal chemistry. Therefore, this book fills a distinct need in undergraduate medicinal chemistry instruction. As long as weaknesses in some metabolism sections are recognized, this book should be an excellent supplement to most undergraduate pharmacy courses in medicinal chemistry as well as a concise review for students and practitioners of other health professions.

Applied Clinical Pharmacokinetics. Edited by DENNIS R. MUNGALL. Raven Press, 1140 Avenue of the Americas, New York, NY 10036. 1983. 448 pp.

This book represents the most recent compilation of information related to the discipline of therapeutic drug monitoring. As stated in the preface, the major objective of this text is "to offer students and clinicians in pharmacy, medicine, pharmacology, and clinical chemistry a practical guide to clinical pharmacokinetics." Although a brief introductory chapter discusses general concepts and basic pharmacokinetic principles, students without previous pharmacokinetic course work may have difficulty applying the information presented in the remainder of the textbook. The subsequent chapter which examines protein binding and free drug concentrations is complete, reasonably well referenced, and a good review of the pertinent drug-protein binding literature. However, this chapter cannot be recommended for students because it contains several misleading statements and very minor yet bothersome errors.

The remaining chapters are primarily devoted to the discussion of individual therapeutic agents and include: procainamide, quinidine, digoxin, anticonvulsants, theophylline, aminoglycosides, warfarin, antihypertensives, lithium, tricyclic antidepressants, benzodiazepines, salicylates, and antineoplastics. The absence of a chapter addressing the pharmacokinetics of lidocaine is a limitation of the text and certainly would have proven more useful to the clinician than a chapter discussing antihypertensive agents.

Each of the drugs reviewed has a chapter to itself with the format designed to cover important aspects of clinical pharmacology, pharmacokinetics, plasma concentration and response relationships, dosage regimen design, and assay methods. The book is quite readable in this format and appears to be relatively free from errors. Most chapters contain practice problems along with detailed solutions. The information on each drug is, for the most part, well detailed and referenced. The concluding chapter is devoted to the use of programmable calculators in clinical pharmacokinetics. Included in this chapter is a group of calculator programs that may prove useful to those individuals who utilize such devices in their clinical practice.

On the whole, this book provides a reasonable compilation of the published literature in the areas addressed by the authors. However, this text is not unique in its area of emphasis and a more rigorous and comprehensive examination is available as a reference source. While the practicing clinician may find certain areas of this book of interest, (*e.g.* practice problems, calculator programs) its general appeal is limited; therefore, the student in either introductory or advanced courses will find currently available texts of greater benefit.

Decrease in the Rate of Capsule Dissolution Due to Formaldehyde from Polysorbate 80 Autoxidation

Keyphrases □ Dissolution, capsule—rate decrease, formation of formaldehyde, polysorbate 80 autoxidation □ Polysorbate 80—autoxidation, formation of formaldehyde, decreased dissolution rate, capsules

To the Editor:

Dissolution studies on some stability samples of gemfibrozil capsules showed a significant decrease in dissolution rate with time of storage and exposure to humidity. Observations of these slowly dissolving samples during the tests showed that the capsule contents were held together by a thin, tough, water-insoluble film, the disruption of which was seen to be the dissolution rate-limiting factor for the drug product. A bioavailability study of such film-forming gemfibrozil capsules showed them to be bioequivalent to the readily dissolving product. Thus, the decrease in dissolution rate in the *in vitro* test is an anomaly because it does not correlate with *in vivo* results. This communication describes studies which established that film formation is due to denaturation of the inner surface of the capsule by formaldehyde, formed by trace autoxidation of the polysorbate 80 used as an excipient.

Polysorbate 80 had been useful in our laboratories as a wetting agent in capsule formulations of hydrophobic drugs. It was convenient to prepare a 1:2 dispersion by drying an alcohol solution of polysorbate 80 mixed with colloidal silica. The silica aided in powder flow, facilitating high-speed encapsulation. This dispersion was used in several capsule formulations of investigational drugs, all of which exhibited film formation when stored under high-humidity conditions. Studies on experimental capsule formulations (Table I) made with constituents of the gemfibrozil capsule formula and stored at 37°C, 37°C with 80% relative humidity (RH), and 45°C and tested after 1, 2, and 3 months showed that film formation occurred only when polysorbate 80 was present. All of the capsules containing polysorbate 80 showed film formation during testing after 1 month at 37°C with 80% RH.

The reaction of formaldehyde and other aldehydes with proteins is well known (1, 2). Cross-linking of the amino groups in gelatin results in its denaturation to an insoluble protein (3). Since formaldehyde could result from autoxidation of the end groups in polysorbate 80 and acetaldehyde could be produced by oxidation of alcohol used in preparation of polysorbate 80–silica dispersion, the hypothesis that one or both of these aldehydes was responsible for film formation was tested. Formation of aldehydes would be facilitated by the immense surface area of the silica, so the results in Table I are consistent with the hypothesis.

Table I—Experimental Capsule Formulations [a]

Ingredients, mg	Formulation a	b[b]	c	d[c]	e[d]	f[d]	g[e]	h[d]
Gemfibrozil	171	171	171	171	171	171	—	—
Polysorbate 80 on Silica	5	10	—	—	—	—	150	—
Cornstarch NF	99	94	102	100	97	104	—	—
Polysorbate 80 NF	—	—	2	4	—	—	—	—
Silica Gel NF	—	—	—	—	7	—	—	90
Fill weight, mg	275	275	275	275	275	275	150	90

[a] No. 2 snap-fit white opaque 999 capsules, Lot 162 (Capsugel), were used for all formulations. [b] Questionable film formation at 3 months at 45°C. [c] Film formation 3 months at 37°C. [d] No film formation. [e] Film formation 1 month at 37°C.

Table II—Assay of Formaldehyde in Polysorbate 80 on Silica

Lot	Formaldehyde, μg/g of Sample Taken HPLC	Fluorometric	Colorimetric
1	20	163	260
2	13	55	170
3	13	—	75
4	18	—	100
5	27	111	200
6	36	163	110

Six lots of polysorbate 80–silica dispersion were analyzed for formaldehyde by three methods. The HPLC method (4) is based on the reaction of aldehydes with 2-diphenylacetyl-1,3-indanedione-1-hydrazone and afforded a separation of formaldehyde and acetaldehyde derivatives. The fluorometric method (5), based on the Hantzsch reaction, is much more sensitive for formaldehyde than for acetaldehyde. The same sample preparation was used for both; however, the fluorometric method provided significantly higher numbers. (This was determined later to be a result of lower reaction rate for the sample than the standard in the HPLC method.) The colorimetric microdiffusion method (6) was much simpler, with a weighed amount of dispersion in the outer ring of a microdiffusion chamber and chromotropic acid reagent in the inner ring. Table II shows results establishing that formaldehyde is present in all of the samples, half of which showed equivalent amounts of acetaldehyde by the HPLC method. For the purposes of this study, the qualitative results of the tests were much more important than the quantitative results. Obtaining reliable quantitative methods for the lower aldehydes in heterogeneous systems is difficult, owing to their volatility and reactivity; however, further work on this methodology has shown promise and may be reported elsewhere.

The highest estimate of formaldehyde content presented in Table II is <0.08% of the polysorbate 80 content of the dispersion. Thus, elucidation of the film-forming phenomenon provides a further example of the profound effect that trace decomposition may have on a drug product (7). Although the artifact has no bioavailability significance, it requires development of an alternative dissolution method for quality assurance, one where the film is digested or disrupted. Based on these studies, dissolution testing at 1 month of capsules stored at 37°C with 80% RH should provide a reliable indication of potential problems due to aldehydes. Whether film formation occurs in the presence of trace aldehydes likely depends on the reactivity of other constituents of the formulation, the internal moisture content, pH, and other factors. Certainly, the use of aldehyde-generating excipients in capsule formulations should be circumvented wherever possible.

Does Cimetidine Impair Nitroreduction?

Keyphrases □ Cimetidine—possible nitroreduction, nitrazepam □ Nitrazepam—nitroreduction, possible interference by cimetidine

To the Editor:

A recent report by Ochs *et al.* (1) demonstrated that cimetidine reduced the clearance of nitrazepam in human subjects from a mean of 1.41 mL/min/kg in the control state to 1.17 mL/min/kg during cimetidine treatment. Cimetidine had no effect on the absorption kinetics or on volume of distribution of nitrazepam. These observations, in conjunction with the belief that nitroreduction accounts for most of nitrazepam clearance, prompted Ochs and co-workers to conclude that cimetidine impairs the nitroreduction of nitrazepam. Furthermore, the authors suggested that such metabolic inhibition by cimetidine may interfere with the elimination of other drugs biotransformed by nitroreduction (1).

While the effect of cimetidine on nitrazepam clearance (1) is clear, we suggest that the above conclusion by Ochs *et al.* regarding the inhibition of nitroreduction by cimetidine may be premature. Our doubts are based on a review of published studies (2–5) of the metabolic fate of nitrazepam in humans. These studies reveal that while nitroreduction is an important biotransformation pathway for nitrazepam, it accounts for only a limited amount of the administered dose in humans. For example, Sawada and Shinohara found (2) that 17% of an oral dose of nitrazepam was excreted as nitro-reduced metabolites in the urine of human subjects in 5 d. Unchanged drug (1%) and a ring-opened metabolite (2%) were also detected, but 80% of the administered dose was not recovered (2). Kangas (3) isolated unchanged drug (1%) and nitro-reduced metabolites (52%) from the 7-d urine samples of human subjects administered nitrazepam, but could not account for nearly one-half of the administered dose. Nitro-reduced metabolites recovered from 72-h human urine samples represented only 6% of the administered nitrazepam dose in another study (4). Rieder and Wendt found (5) that ~7% of an administered oral radioactively labeled nitrazepam dose appeared in the 24-h urine specimen as nitro-reduced metabolites. Ring-opened metabolites accounted for an additional 9%, and traces of unchanged drug were also isolated. Other metabolites, which represented 21% of the administered dose, were also present but could not be identified. Thus, a total of 37% of the administered dose was excreted in the 24-h urine sample, and much of it was not identified (5). Although the recovery of total radioactivity increased to 65–70% after oral dosing and to 94% following intravenous administration during the subsequent 100 h, the proportion of the identified metabolites did not change significantly. Rieder and Wendt also demonstrated the accumulation of large amounts of unidentified metabolites in the plasma of human subjects after oral doses of this drug (5). Quantitative differences among the above-described studies may be due to differences in analytical methods and/or to inclusion *versus* omission of conjugated metabolites. Nevertheless, nitroreduction in humans has been shown to account, at most, for ~50% (3) of total nitrazepam elimination, and for much less in most studies (2, 4, 5). Since negligible amounts of unchanged drug are excreted (2–5), unidentified metabolites probably account (3, 5) for the remainder of nitrazepam elimination.

Cimetidine is known (6) to inhibit oxidative biotransformation of many drugs and, therefore, the following question must be raised: Is the effect of cimetidine on the clearance of nitrazepam due to the inhibition of some unidentified *oxidative* biotransformation rather than to inhibition of nitroreduction? This alternative explanation is supported by the isolation of small amounts of oxidized metabolites of nitrazepam from urine samples after the administration of the drug to humans (2, 5). Furthermore, oxidation may also be involved (7, 8) in the ring-opening biotransformation of benzodiazepines which may be an important metabolic pathway for nitrazepam (5).

Thus, it is clear that previous work has not accounted for a large fraction of the nitrazepam dose, and it appears that oxidative biotransformations may be responsible for a portion of nitrazepam clearance. There is insufficient data to determine whether nitrazepam nitroreduction or some hitherto unidentified oxidative metabolic pathway is impaired by cimetidine. Therefore, we feel that it is premature to suggest (1) that the ability of cimetidine to impair drug oxidation in humans should be extended to include inhibition of nitroreduction. There are several important drugs with a nitro group in their structure (*e.g.*, chloramphenicol, clonazepam, nitrofurantoin, and metronidazole), and some of these compounds have been shown to be metabolized *via* nitroreduction. We are concerned that the suggestion by Ochs *et al.* (1) may foster a general belief that cimetidine—a widely used agent—impairs the elimination of such drugs *via* nitroreduction, a belief for which there is, as yet, no firm evidence.

Perhaps cimetidine will be shown in the future to inhibit one or more of the several distinct nitroreductases known [*e.g.*, cytochrome P_{450}, whose oxidative function is inhibited by cimetidine (9), can also function as a nitroreductase (10)]. However, to demonstrate inhibition of nitroreduction, studies of the effects of cimetidine on specific biotransformations and on metabolite formation will be required. It will be interesting to watch developments in this area.

BOOKS

Review of Organic Functional Groups: Introduction to Medicinal Organic Chemistry. By THOMAS L. LEMKE. Lea and Febiger, Philadelphia, PA. 1983. 131 pp. 15 × 23 cm. Price $10.50.

The objective of this book is to provide a self-paced review of the nomenclature, physical properties, chemical properties, and metabolism of organic functional groups that are important in medicinal chemistry. The book is designed for use as supplemental material for a pharmacy course in medicinal chemistry as well as a concise reference for students and professional practitioners in pharmacy, medicine, nursing, dentistry, and veterinary medicine. After a general chapter on water solubility and chemical bonding, subsequent chapters focus on specific functional groups. Organic functional groups covered include alkanes, alkenes, aromatic hydrocarbons, halogenated hydrocarbons, alcohols, phenols, ethers, aldehydes, ketones, amines, carboxylic acids and their derivatives, sulfonic acids and sulfonamides, and heterocycles. A chapter on empirical and analytical methods of determining water solubility and an appendix on acidity and basicity are also included. Review questions are placed at the end of chapters to reinforce concepts presented in the text.

Chapters on individual functional groups are concise, and adhere to an outline format where the three major subheadings are Nomenclature, Physical-Chemical Properties, and Metabolism. There are adequate examples and tables of physical data given to illustrate the major points. The sections on nomenclature and physical-chemical properties are especially clearly written and complete. Most of the sections on metabolism are also clear and concise. However, the metabolism sections on aromatic hydrocarbons, halogenated hydrocarbons, and amines may be confusing since they contain several statements which contradict information found in drug metabolism chapters of current medicinal chemistry textbooks.

The major emphasis of this book is in areas of medicinal chemistry which many undergraduate pharmacy students find difficult. The sections on nomenclature and physical-chemical properties should be very helpful to those students who have difficulty extracting information from general organic chemistry textbooks that is directly pertinent to medicinal chemistry. Therefore, this book fills a distinct need in undergraduate medicinal chemistry instruction. As long as weaknesses in some metabolism sections are recognized, this book should be an excellent supplement to most undergraduate pharmacy courses in medicinal chemistry as well as a concise review for students and practitioners of other health professions.

Applied Clinical Pharmacokinetics. Edited by DENNIS R. MUNGALL. Raven Press, 1140 Avenue of the Americas, New York, NY 10036. 1983. 448 pp.

This book represents the most recent compilation of information related to the discipline of therapeutic drug monitoring. As stated in the preface, the major objective of this text is "to offer students and clinicians in pharmacy, medicine, pharmacology, and clinical chemistry a practical guide to clinical pharmacokinetics." Although a brief introductory chapter discusses general concepts and basic pharmacokinetic principles, students without previous pharmacokinetic course work may have difficulty applying the information presented in the remainder of the textbook. The subsequent chapter which examines protein binding and free drug concentrations is complete, reasonably well referenced, and a good review of the pertinent drug-protein binding literature. However, this chapter cannot be recommended for students because it contains several misleading statements and very minor yet bothersome errors.

The remaining chapters are primarily devoted to the discussion of individual therapeutic agents and include: procainamide, quinidine, digoxin, anticonvulsants, theophylline, aminoglycosides, warfarin, antihypertensives, lithium, tricyclic antidepressants, benzodiazepines, salicylates, and antineoplastics. The absence of a chapter addressing the pharmacokinetics of lidocaine is a limitation of the text and certainly would have proven more useful to the clinician than a chapter discussing antihypertensive agents.

Each of the drugs reviewed has a chapter to itself with the format designed to cover important aspects of clinical pharmacology, pharmacokinetics, plasma concentration and response relationships, dosage regimen design, and assay methods. The book is quite readable in this format and appears to be relatively free from errors. Most chapters contain practice problems along with detailed solutions. The information on each drug is, for the most part, well detailed and referenced. The concluding chapter is devoted to the use of programmable calculators in clinical pharmacokinetics. Included in this chapter is a group of calculator programs that may prove useful to those individuals who utilize such devices in their clinical practice.

On the whole, this book provides a reasonable compilation of the published literature in the areas addressed by the authors. However, this text is not unique in its area of emphasis and a more rigorous and comprehensive examination is available as a reference source. While the practicing clinician may find certain areas of this book of interest, (*e.g.* practice problems, calculator programs) its general appeal is limited; therefore, the student in either introductory or advanced courses will find currently available texts of greater benefit.

BOOKS

Review of Organic Functional Groups: Introduction to Medicinal Organic Chemistry. By THOMAS L. LEMKE. Lea and Febiger, Philadelphia, PA. 1983. 131 pp. 15 × 23 cm. Price $10.50.

The objective of this book is to provide a self-paced review of the nomenclature, physical properties, chemical properties, and metabolism of organic functional groups that are important in medicinal chemistry. The book is designed for use as supplemental material for a pharmacy course in medicinal chemistry as well as a concise reference for students and professional practitioners in pharmacy, medicine, nursing, dentistry, and veterinary medicine. After a general chapter on water solubility and chemical bonding, subsequent chapters focus on specific functional groups. Organic functional groups covered include alkanes, alkenes, aromatic hydrocarbons, halogenated hydrocarbons, alcohols, phenols, ethers, aldehydes, ketones, amines, carboxylic acids and their derivatives, sulfonic acids and sulfonamides, and heterocycles. A chapter on empirical and analytical methods of determining water solubility and an appendix on acidity and basicity are also included. Review questions are placed at the end of chapters to reinforce concepts presented in the text.

Chapters on individual functional groups are concise, and adhere to an outline format where the three major subheadings are Nomenclature, Physical-Chemical Properties, and Metabolism. There are adequate examples and tables of physical data given to illustrate the major points. The sections on nomenclature and physical-chemical properties are especially clearly written and complete. Most of the sections on metabolism are also clear and concise. However, the metabolism sections on aromatic hydrocarbons, halogenated hydrocarbons, and amines may be confusing since they contain several statements which contradict information found in drug metabolism chapters of current medicinal chemistry textbooks.

The major emphasis of this book is in areas of medicinal chemistry which many undergraduate pharmacy students find difficult. The sections on nomenclature and physical-chemical properties should be very helpful to those students who have difficulty extracting information from general organic chemistry textbooks that is directly pertinent to medicinal chemistry. Therefore, this book fills a distinct need in undergraduate medicinal chemistry instruction. As long as weaknesses in some metabolism sections are recognized, this book should be an excellent supplement to most undergraduate pharmacy courses in medicinal chemistry as well as a concise review for students and practitioners of other health professions.

Applied Clinical Pharmacokinetics. Edited by DENNIS R. MUNGALL. Raven Press, 1140 Avenue of the Americas, New York, NY 10036. 1983. 448 pp.

This book represents the most recent compilation of information related to the discipline of therapeutic drug monitoring. As stated in the preface, the major objective of this text is "to offer students and clinicians in pharmacy, medicine, pharmacology, and clinical chemistry a practical guide to clinical pharmacokinetics." Although a brief introductory chapter discusses general concepts and basic pharmacokinetic principles, students without previous pharmacokinetic course work may have difficulty applying the information presented in the remainder of the textbook. The subsequent chapter which examines protein binding and free drug concentrations is complete, reasonably well referenced, and a good review of the pertinent drug-protein binding literature. However, this chapter cannot be recommended for students because it contains several misleading statements and very minor yet bothersome errors.

The remaining chapters are primarily devoted to the discussion of individual therapeutic agents and include: procainamide, quinidine, digoxin, anticonvulsants, theophylline, aminoglycosides, warfarin, antihypertensives, lithium, tricyclic antidepressants, benzodiazepines, salicylates, and antineoplastics. The absence of a chapter addressing the pharmacokinetics of lidocaine is a limitation of the text and certainly would have proven more useful to the clinician than a chapter discussing antihypertensive agents.

Each of the drugs reviewed has a chapter to itself with the format designed to cover important aspects of clinical pharmacology, pharmacokinetics, plasma concentration and response relationships, dosage regimen design, and assay methods. The book is quite readable in this format and appears to be relatively free from errors. Most chapters contain practice problems along with detailed solutions. The information on each drug is, for the most part, well detailed and referenced. The concluding chapter is devoted to the use of programmable calculators in clinical pharmacokinetics. Included in this chapter is a group of calculator programs that may prove useful to those individuals who utilize such devices in their clinical practice.

On the whole, this book provides a reasonable compilation of the published literature in the areas addressed by the authors. However, this text is not unique in its area of emphasis and a more rigorous and comprehensive examination is available as a reference source. While the practicing clinician may find certain areas of this book of interest, (*e.g.* practice problems, calculator programs) its general appeal is limited; therefore, the student in either introductory or advanced courses will find currently available texts of greater benefit.

A Drug Is A Drug—Or Is It?

A matter of significant recent controversy is referred to by the public news media as "the use of prescription drugs in executions." Indeed, this subject has become so controversial that the matter is to be weighed by the U.S. Supreme Court this fall.

Capital punishment is also a controversial issue in itself, but the question of using "prescription drugs" to carry out the process of execution is a completely separate and distinct matter.

The current issue at hand was concisely summarized in a recent issue of APhA's weekly newsletter, *apharmacy weekly:*

"The court (U.S. Supreme Court) will hear oral arguments in a suit filed against the federal government by eight Texas and Oklahoma prisoners awaiting executions by lethal injection. The inmates are asking FDA to ban the use of prescription drugs for other than medical purposes.

"Currently, 14 states permit such executions, though only two (Texas and North Carolina) have carried any out. The executions typically involve the use of potassium chloride to stop the heart, a muscle relaxant to stop breathing, and a barbiturate to cause unconsciousness.

"To date, FDA has tried to sidestep the issue, saying it has an enforcement role only in instances which endanger the public health or involve fraud."

Other press reports have gone on to state that the prisoners have further claimed that FDA should not permit such use of these "drugs" because there has not been clinical demonstration of their effectiveness and safety for this particular use, as required by federal law for any new use of an otherwise approved and marketed drug.

Years ago, the *United States Pharmacopeia* and the *National Formulary* were faced with similar dilemmas. Substances such as sodium chloride, sucrose, rose water ointment, magnesium trisilicate, microcystalline cellulose, polysorbate, saccharin, carbon tetrachloride, and so on, all had multiple uses. They all had certain distinct uses as drug dosage form ingredients: either for the physiological activity they provided *per se*, or as pharmaceutical adjuncts that contributed to the overall suitability and activity of various drug dosage forms. But, in addition, they had certain other commercial uses that were clearly "non-therapeutic" or "non-drug" in nature: as foods, cosmetics, solvents, cleaning agents, and so on.

However, neither the drug laws nor the USP-NF made any distinction; in fact, the law as well as the official compendia appeared to specifically blanket all such substances under the broad obligation of meeting USP-NF standards and specifications. The wording in the General Notices section of both compendia read that: "The standards apply equally to articles bearing the official titles ... whether or not the added designation 'USP' (or 'NF') is used."

When the officials responsible for revising the compendia and maintaining their currency became aware of this unintended broad interpretation, they promptly introduced a clarifying new statement reading: "Articles listed herein are official and the standards set forth in the monographs apply to them only when the articles are intended or labeled for use as drugs or medical devices and when bought, sold, or dispensed for these purposes."

This means that a box of sodium chloride—whether it is labeled "USP" or not—must meet USP standards if it is intended for use as a drug or therapeutic agent. If, however, it is intended for use as a food, or as an agent in ice cream manufacture, or to melt road ice, then it is not obliged to meet the compendial standards.

Similarly, barbiturates are used as drugs and also as laboratory buffering agents; certain anticoagulants are used therapeutically and also as rat poison; and other examples might be cited as well. In each such case, it is the intended use of the substance—rather than what it is chemically—that determines whether it is a "drug," and therefore must meet the applicable drug requirements.

Applying this line of reasoning, the situation with regard to the substances used for execution *via* lethal injection seems quite obvious; namely, the substances are not drugs because their intended use is clearly otherwise, despite the fact that these same substances may also be labeled and used as drugs under another set of circumstances.

Ironically, however,the FDA itself is largely responsible for confusing what should be a clearly differentiated situation. Approximately 20 years ago, the FDA seized shipments of paper disks impregnated with various antibiotic agents which were intended for clinical laboratory use in determining whether cultures of isolated organisms were inhibited by one or more of the antibiotic agents. This FDA enforcement action was challenged by the manufacturer (Difco Laboratories), and the case went to trial.

In the personal view of this writer, the antibiotic-impregnated disks were only a diagnostic aid at most—they were not used in any therapeutic manner and, hence, were not drugs. Although they happened to contain trace amounts of antibiotic substances, their use made them no different than other reagents used in the clinical laboratory. On this basis, we testified as an expert witness in Federal District Court on behalf of Difco Laboratories and in opposition to the position taken by the FDA.

The case was a most difficult one, and was eventually decided by the U.S. Supreme Court in a landmark decision. The FDA had fought tenaciously to protect all aspects of its antibiotic certification program which was then in effect—but which has recently been abolished—and convinced the court of the necessity of "certifying" these test disks. In turn, this required the court to determine that the disks were "drugs" although they never came near the patient, and in themselves have no effect on the course of the patient's disease or condition of the patient.

It appears to us that the conclusion of the court was terribly erroneous and that many absurd interpretations mutually follow when the court's general conclusion is applied to other articles and to other situations that have subsequently arisen.

Perhaps the court, in reviewing the lethal injetion tissue, will see fit to review the Difco decision. If so, we believe that the wise course of action would be to reverse the unfortunate conclusion reached by an earlier panel of jurists some 15 years ago.

Alcoholism and Mortality Kinetics

HAROLD BOXENBAUM *x and DOMENIC CIRAULO ‡

Received March 31, 1983, from the *Pharmaceutics Section, School of Pharmacy, University of Connecticut, Storrs, CT 06268, and ‡Psychiatry Service, Veterans Administration Medical Center, Newington, CT 06111. Accepted for publication, September 8, 1983.

Abstract □ Gompertz plots of age-specific mortality rates *versus* age were compared in alcoholics and the general population. Alcoholism had a dual effect, apparently increasing vulnerability to death while slowing the aging rate (longevity is a two-dimensional function). It was hypothesized that the apparent slowing of the aging rate was an artifact, resulting from population heterogeneity in vulnerability. It is recommended that in future studies, attempts be made to categorize alcoholic subjects with respect to alcoholic habit. Longitudinal studies would also be useful.

Keyphrases □ Kinetics, mortality—effects of alcoholism □ Alcoholism—effects on mortality kinetics

It has long been recognized that alcoholism has serious consequences for health and longevity. Excess mortality in alcoholics has been reported for all major disease categories, particularly cirrhosis, cancers of the upper respiratory and digestive tracts, accidents, and suicide (1). The alcoholic environment probably promotes injury by exacerbating existing pathological tendencies, with the extent of deterioration being a weighted sum of the several kinds of injury produced in the constituent systems. The progressive and irreversible accumulation of informational entropy is hastened in alcoholism, and chances for survival are lessened. Death occurs when one or more subsystem is incapable of meeting the demands placed on it, producing a fluctuation in the physiological state of the organism of such magnitude as to exceed the limits within which homeostatic regulation can occur (2-6). The cybernetic failure or escape of one of these subsystems to a more likely configuration (death) is analogous to the transition of an activated complex over the activation energy barrier, implying an inherently stochastic component to the process. The situation is similar to a group of identical radioactive atoms, in which each atom has λdt probability of disintegrating in the interval dt. Alcoholic subjects are characterized by a hypothetical mean physiological state[1], which is more unstable than that in normal subjects and, therefore, more likely to undergo a biological fluctuation that produces death. This increased actuarial risk could result from two kinds of parameters governing longevity: rate of aging and vulnerability (7). These parameters are investigated in this report.

THEORETICAL SECTION

The measure of age-specific mortality rate is the actuary's q_x (7-10):

$$q_x = \frac{1}{h}\frac{L_x - L_{x+h}}{L_x} \qquad \text{(Eq. 1)}$$

where h is the length of the time interval, L_x is the number living at age x, and

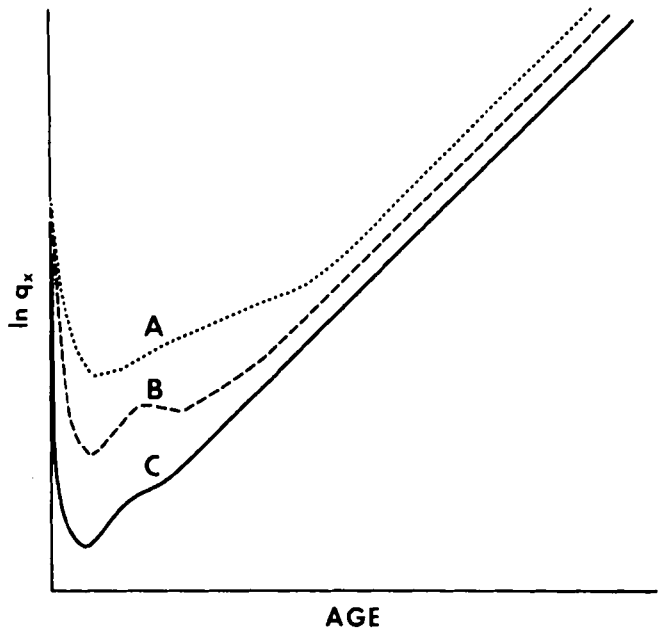

Figure 1—*Age-specific mortality rate plotted semilogarithmically against age for three populations; all populations have the same aging rate parameter but differ with respect to the vulnerability parameter (see text for discussion).*

[1] Mean physiological state can be described by specifying the mean values of certain essential physiological variables in a theoretical as opposed to an operational sense (see Refs. 3 and 5 for development of this concept).

[h] t Tests of slopes and intercepts for working class *versus* middle class populations failed to detect differences ($p > 0.8$). [i] t Tests of slopes and intercepts for male *versus* female alcoholics failed to detect differences ($p > 0.4$ and $p > 0.1$, respectively). [j] A t test of slopes for male *versus* female populations failed to detect differences ($p > 0.8$), whereas a t test of intercepts detected differences ($p < 0.005$).

L_{x+h} is the number living at age $x + h$. This is an estimate of the instantaneous mortality rate or force of mortality, $\rho(x)$ (5, 9):

$$\rho(x) = -\frac{1}{N(x)}\frac{dN(x)}{dx} \qquad \text{(Eq. 2)}$$

where $N(x)$ is the number of individuals surviving to age x. $\rho(x)$ is also the probability of an individual of age x dying over the interval from x to $x + dx$. Characteristically, q_x is high during infancy, falls to a minimum at ~10 years of age, and increases at an accelerated rate thereafter. Figure 1 illustrates typical semilogarithmic age-specific mortality curves for different populations. Goldman (11) has noted the similarity of these curves to failure curves for manufactured articles. High values of q_x occur during infancy and may be due to birth defects, immune deficiencies, incomplete gestation, *etc.* These are analogous to initial failures of manufactured products, resulting from faulty steps in the manufacturing process, defective parts, *etc.* After the curve bottoms out, but before it becomes exponential, chance failures predominate. In mortality curves and for manufactured goods, these chance failures are due to factors which are just as likely to be operative at any one time as at any other[2]. In mortality curves, this could be due to rare but fatal exposure to toxicants (chemicals, bacteria, *etc.*), accidents, *etc.* At some point in time, chance failures become exceedingly small relative to first-order wear-out failures, and the curve becomes exponential. Wear-out failures in manufactured articles are due to the effects of the duration of the service of the article. In mortality kinetics, wear-out failures are due to biological changes induced by processes we collectively lump under the heading of aging. In those Western societies with good standards of living, first-order mortality kinetics are generally first observed between the ages of 30 and 35 years. The appropriate mathematical relationship, termed the Gompertz equation, is (5, 7, 9, 12-17):

$$q_x = q_0 \cdot e^{\alpha x} \qquad \text{(Eq. 3)}$$

where q_x is the death rate at age x (age-specific death rate), q_0 is the extrapolated value of the death rate at age zero, and α is an aging rate parameter. The q_0 term is a measure of the initial vulnerability (7, 15) of the population to senescent-mediated causes of death in adults, *i.e.*, it measures the vulnerability of the population before the onset of aging. It is not an estimate of the death rate at birth, but rather is a theoretical parameter that is indicative of environmental influences and vigor of the genotype. Note in Fig. 1 that group A is more vulnerable than group B or C. The α term specifies the rate of increase of age-specific mortality; the doubling time (T_d) of age-specific mortality rates is equal to $(\ln 2)/\alpha$. In humans, T_d is ~8.5 years[3] (18). In a homogeneous population, an 8.5-year T_d means that a typical 50-year-old individual has twice the probability of dying during the course of one 24-h period than does a typical 41.5-year-old individual.

Sacher (7) has investigated the effects of various treatments (ionizing radiation, drugs, *etc.*) that contribute to the shortening and prolongation of life and has noted that although some treatments may affect both vulnerability (q_0) and rate of aging (α), most treatments affect predominantly one or the other (pharmacological agents usually affect q_0). In life prolongation, efficacious pharmacological therapies such as chronic procaine administration

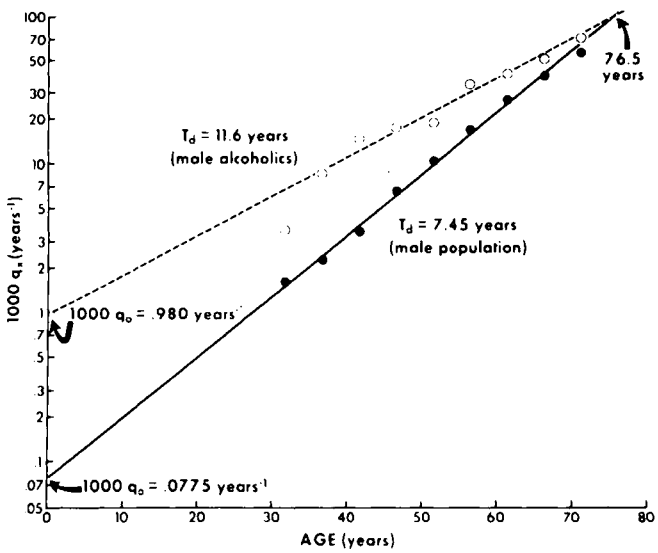

Figure 2—*Gompertz plots of age-specific mortality rates* versus *age for male alcoholics and the male general population in Ontario, Canada. See Fig. 3 for sample sizes and statistical weights in alcoholics (data are from Refs. 25 and 26).*

[2] This zero-order loss accounts for the age-independent term in the so-called Gompertz-Makeham equation (7, 12, 13), $q_x = q_0 e^{\alpha x} + A$, which characterizes age-specific mortality in this region and beyond; q_0 and α are defined with Eq. 3, and A is the zero-order component to mortality.

[3] In the data collated by Strehler and Mildvan (12), T_d ranged from 5.82 years in people from Trinidad and Tobago to 11.3 years for Algerian Moslems.

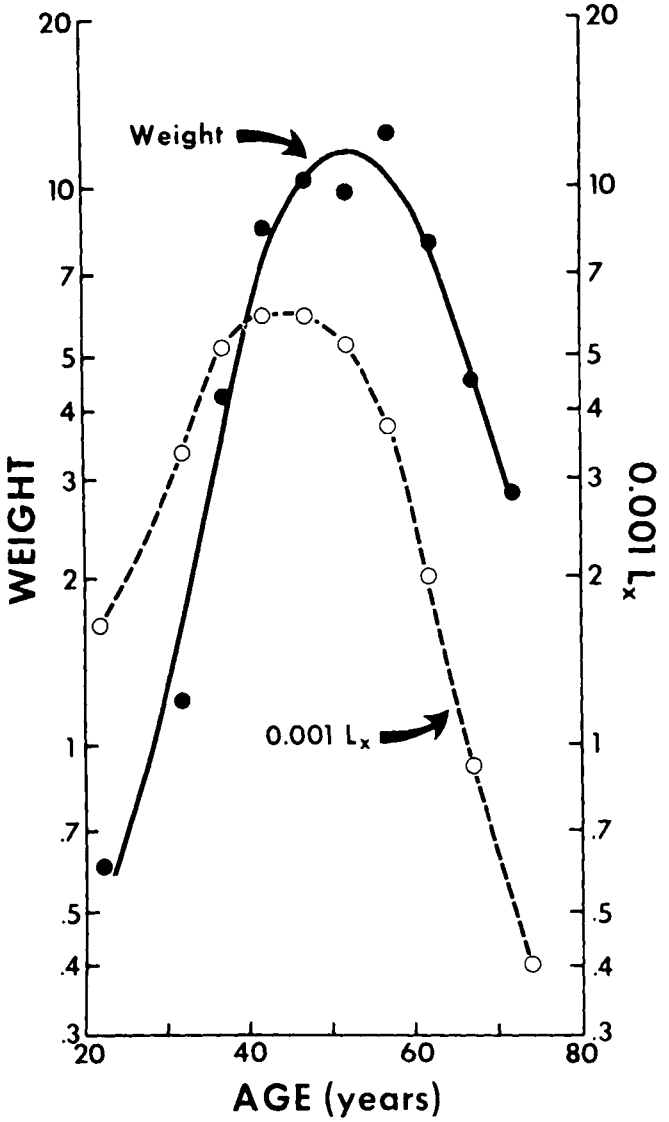

Figure 3—*Statistical weights and sample sizes (L_x) for alcoholic age-specific mortality data in Fig. 2 (data are from Refs. 25 and 26).*

achieve their effects by reducing q_0, whereas smoking in humans (7, 19) shortens life by increasing q_0. Strehler and Mildvan (12), on the other hand, have developed a general theory of mortality and aging which predicts an inverse relationship between q_0 and α.

Although the disease we term alcoholism is not generally regarded as a pharmacological treatment, mortality kinetics arising from it can be analyzed and discussed in that context; the results of such an analysis are reported.

EXPERIMENTAL SECTION

Mortality data in alcoholics was acquired by exhaustively searching the literature; this search ended in December 1982. In all cases, data were also presented on the general population as a whole[4], including all individuals of the same sex living in designated geographical areas.

Literature mortality data were generally collated for individuals in 5-year age groups; age-specific mortality rates were plotted semilogarithmically against age (Gompertz plot), where age was taken as the midpoint for the group. Data prior to the exponential phase were not used. Generally, this meant using only data obtained at or beyond the age of 32 years. A linear transformation of Eq. 3 is:

$$\ln q_x = \alpha x + \ln q_0 \qquad \text{(Eq. 4)}$$

Equation 5 was fitted to each set of data by the method of weighted, linear least-squares (21); parameter estimates and standard deviations were obtained for α and q_0. The weighting factor used for $\ln q_x$ was the reciprocal of its variance, and this was estimated by (9):

$$w = \frac{1}{v} \cong \frac{N_x P_x (\ln P_x)^2}{1 - P_x} \qquad \text{(Eq. 5)}$$

where w is the statistical weight, v is the sampling variance, N_x is the sample size, and P_x is the calculated probability of surviving the interval ($1 - P_x = q_x$). Differences between parameter estimates for alcoholics *versus* the general population were detected by t tests (Eq. 17 in Ref. 22).

[4] The population itself contains alcoholics, and a popular estimate of the point prevalence of alcoholism in Western societies is 7% (20). The lifetime prevalence rate is higher.

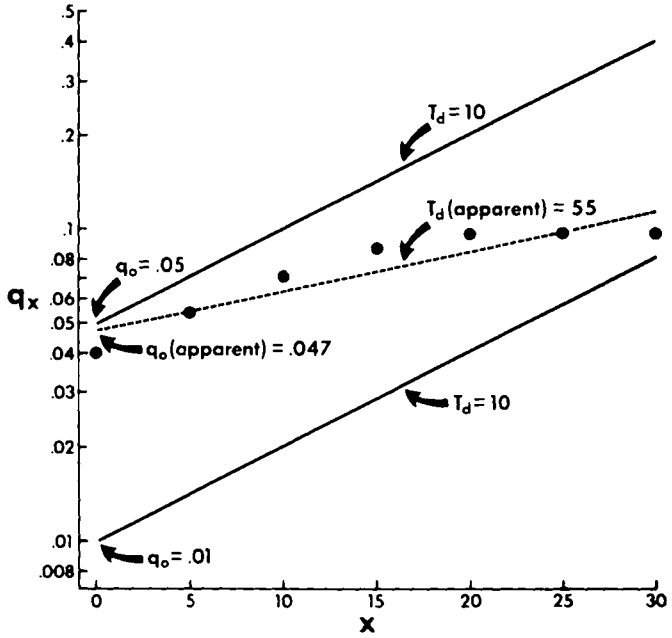

Figure 4—*Hypothetical Gompertz curves (—) for two strata of alcoholic subjects (arbitrary units). One group ($q_0 = 0.05$) is highly vulnerable to the mortality effects of alcohol, whereas the other group ($q_0 = 0.01$) mimics the general population; both groups have a T_d of 10. By taking the vulnerable group to comprise 75% of the alcoholic population and the invulnerable group to comprise 25%, pooling of the alcoholic subject data gives rise to the q_x data points between the two solid lines. The dashed line arises from a linear least-squares analysis of the pooled data. Note that the T_d (apparent) is considerably increased (see text for discussion).*

RESULTS AND DISCUSSION

Influence of Alcoholism on Vulnerability and Aging—Parameter estimates obtained from analysis of Gompertz plots are summarized in Table I. Curves for alcoholics and the general population from one representative study are shown in Fig. 2. Figure 3 depicts sample size and statistical weights for those data points from alcoholics in Fig. 2. A cursory examination of these data indicates two significant effects of alcoholism on the Gompertz parameters. First, the vulnerability parameter, q_0, is ~10-80 times higher in the alcoholic populations. Second, there appears to be a concomitant reduction in the aging rate parameter, α (see below). Although T_d in the general male population is ~7.7 years, an ostensible T_d of ~14.6 years is noted for male alcoholics.

The apparent increases noted for q_0 and T_d in male alcoholics are also seen in females. In the one study in which alcoholic subjects were categorized as either "working class" or "middle class," there were no differences in Gompertz plot slopes ($p > 0.8$) or intercepts ($p > 0.4$); in working class *versus* middle class general populations, slope ($p > 0.9$) and intercept ($p > 0.8$) values also did not differ.

Considerable variability exists between q_0 values in both normal male and female populations (an approximate threefold range). Aside from the genetic component, q_0 is affected by environmental factors (air and water quality, disease-carrying insects, *etc.*) and medical intervention (inoculations against disease, antibiotic therapy, *etc.*). Variability is also seen in a comparison of the influences of alcoholism on the T_d and q_0 parameters, particularly the latter. Values of q_0 are increased 12.6-fold over normal values in male alcoholics from Ontario, Canada, whereas there is a 67.8-fold increase in male alcoholics from England and Wales. Part of this diversity may be due to the variables mentioned above, as well as genetic factors predisposing individuals to alcoholism. In addition, several types of alcoholism do exist. Jellinek (29)

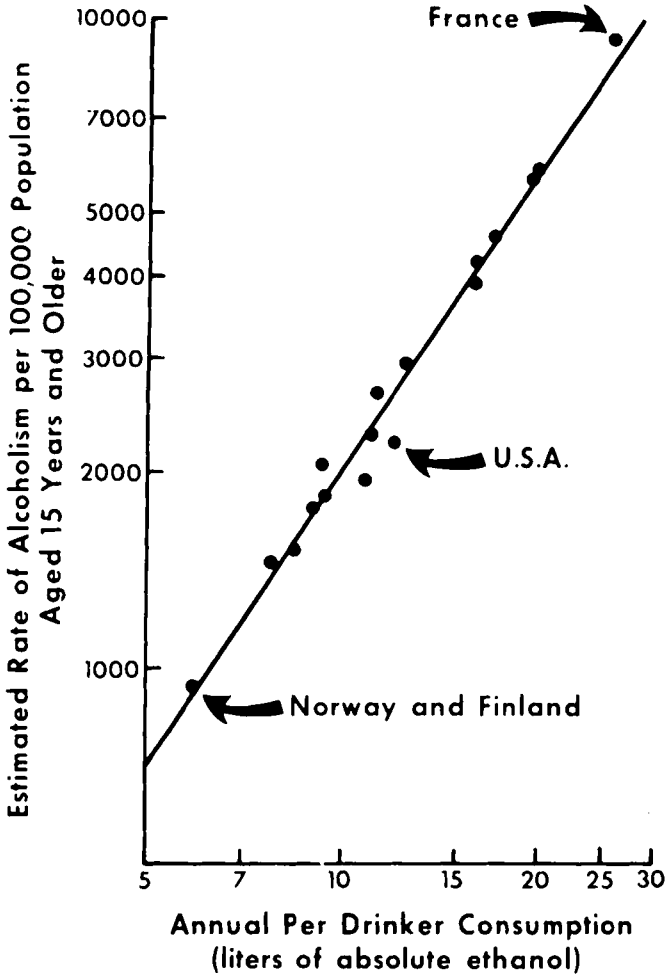

Figure 5—*Double logarithmic plot of the estimated rate of alcoholism in a country* versus *the annual per drinker consumption of alcohol. The equation consistent with this plot* ($y = \theta_1 y^{\theta_2}$) *was fitted by least-squares analysis (data from Ref. 30) and is* $y = 61.5\ x^{1.52}$; $r = 0.990$; $p < 0.01$.

has divided alcoholics into four major and several minor categories. The four major classifications are: (*a*) alpha alcoholism, a purely psychological continued dependence on the effects of alcohol to relieve bodily or emotional pain; (*b*) beta alcoholism, a condition in which alcoholic complications such as polyneuropathy, gastritis, and cirrhosis of the liver may occur without either physical or psychological dependence on alcohol; (*c*) gamma alcoholism, physical dependence and loss of control over the use of alcohol, a disease in and of itself; and (*d*) delta alcoholism, which is similar to gamma alcoholism, except instead of loss of control, there is inability to abstain (inveterate drinking)[5]. Therefore, alcoholics constitute a markedly heterogeneous group, with different drinking pattern and disease entities. Additionally, it is well known that the risk of getting cancer, cirrhosis of the liver, *etc.*, due to excessive alcohol use varies greatly among individuals. Those alcoholics who survive the age of, for example, 60 years in effect will be the least vulnerable, and their average vulnerability should be much lower than the average vulnerability in the general population at the same age. The range increases observed for q_0 in different populations probably reflects this heterogeneity[6].

To help explain this anomaly of an apparent slowing of aging in alcoholics, consider a hypothetical situation in which the alcoholic population consists of two strata, one highly vulnerable and one invulnerable to the effects of alcohol. In the latter group, the Gompertz curve is identical to that for the general population. In the former, the aging rate (α) is the same, but the vulnerability parameter is larger. For all alcoholics taken together, age-specific mortality rates will lie somewhere in between the two subgroups. This is illustrated in Fig. 4, in which q_0 for the invulnerable group is 0.01 (arbitrary units), and for the vulnerable group is 0.05. Note that the doubling times (T_d values) for the two subgroups are identical ($T_d = 10$ arbitrary units). If we take the vulnerable group ($q_0 = 0.05$) to comprise 75% of the alcoholic population and the invulnerable group ($q_0 = 0.01$) to comprise 25% of the alcoholic population, pooling of the data results in the q_x data points observed between the two Gompertz functions. Although the data points are best characterized by a curve, a linear function may be reasonably well fitted to the data, and this is indicated by the dashed line ($r = 0.92$) (Fig. 4). Note that the apparent T_d is now 55. After a number of years, the vulnerable alcoholics will become more or less extinct, and only the invulnerable ones will remain. At this age, the curve for all alcoholics would conicide with the one for the invulnerable group and, therefore, also for the general population. The larger the average vulnerability of the alcoholic group, as compared with the general population, the greater the apparent increase in T_d. This hypothetical illustration is no doubt simplistic (there are probably several strata), but it does serve to illustrate how an erroneously high T_d for alcoholics could be obtained. Although other possibilities exist to explain the increase in T_d, the grouping of heterogeneous alcoholic population is, by far, the most likely explanation.

If we assume the unlikely possibility that alcoholics are relatively homogeneous with respect to mortality parameters, we conclude that those factors causing or resulting from alcoholism also slow the aging rate. The Strehler–Mildvan theory of mortality and aging (12), mentioned above, interrelates the values of q_0 and α and predicts that a high initial mortality rate (q_0) should be associated with as low rate of increase of mortality rate (reduced α); this represents yet another interpretation of the data.

In future studies of alcoholic mortality, attempts should be made to categorize the various types of alcoholics. Another problem is that all studies have heretofore been based on age-group cohorts (not longitudinal data). Data from chronic, progressive alcoholics are therefore lumped with those from individuals who have a fluctuating course or a limited single alcoholic episode. This may have contributed to the postulated heterogeneity in vulnerability, producing the postulated artifactual increase in T_d. Longitudinal studies, therefore, would be very useful.

Drinking Habits, Alcoholism, and Aging—The fact that alcoholism affects apparent values of α and q_0 suggests that there might be some correlation between drinker consumption of alcohol in a given country and these parameters. Data from 16 countries (12, 30) were used to test this hypothesis. Correlation analyses were conducted on data for per drinker consumption *versus* α or q_0. Correlation coefficients were <0.02, indicating no correlations whatsoever. Similar results were obtained when rates of alcoholism in various countries were compared with α or q_0. This analysis implies that the drinking habits of a nation will not affect the overall Gompertz parameters for that nation. As expected, annual drinker consumption of alcohol did correlate with the rate of alcoholism (Fig. 5). For each twofold increase in per drinker alcohol consumption, alcoholism increases 2.87-fold.

Solubility and Complexation Behavior of Griseofulvin in Fatty Acid–Isooctane Mixtures

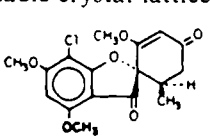
MEHDI MEHDIZADEH and DAVID J. W. GRANT ˣ

Received January 17, 1983, from the *Faculty of Pharmacy, University of Toronto, Toronto, Ontario M5S 1A1 Canada.* Accepted for publication August 1, 1983.

Abstract □ The influence of complex formation on the solubility behavior of griseofulvin in the straight-chain fatty acids was investigated by using phase solubility analysis in isooctane (2,2,4-trimethylpentane) at 25°C. The apparent molar solubility of the proton acceptor griseofulvin ($[A]_t$) was determined spectrophotometrically in the presence of various total molar concentrations ($[D]_t$) of each of the proton donors (acetic, propanoic, butanoic, hexanoic, and octanoic acids). Increasing $[D]_t$ caused a pronounced increase in $[A]_t$ according to a biphasic log-log relationship, suggesting the formation of two complexes, AD_m and AD_n. The data are in close agreement with a simple mathematical model which assumes that two complexes, AD_m and AD_n, are formed and that $[D]_t \approx 2[D_2]$, where D_2 refers to the fatty acid dimer. Linear regression analysis showed that the data best fit the complexation models with $n = 5$ or 6 and $m = 0$, 1, or 2, depending on the fatty acid. Assuming values of the dimerization constants of the fatty acids as reported in the literature, the stability constants of the complexes, K_n and K_m, were calculated and found to decrease with increasing chain length of the fatty acids. The proposed model was critically appraised. An alternative model, which takes into full account the fatty acid monomer while assuming that only one complex is formed, leads to unacceptable conclusions.

Keyphrases □ Molecular complexes—griseofulvin and straight-chain alkanoic acids, isooctane solution, solubility □ Carboxylic acid dimerization—influence on molecular complexation, griseofulvin and straight-chain fatty acids, isooctane solution □ Griseofulvin—solubility in isoocatane solution, straight-chain fatty acids

Complex formation, a valuable method for increasing the solubility, dissolution rate, and bioavailability of sparingly soluble drugs (1), also leads to a modification of the rate of transfer of certain drugs through lipid barriers (2). Griseofulvin (I) exhibits a poor bioavailability due to its low aqueous solubility (3). The stable crystal lattice of griseofulvin can, however, be broken down by proton-donating solvents, such as chloroform (4) and the fatty acids (5), which presumably form hydrogen-bonded complexes. Some of these complexes appear to exist in the solid state as solvates or inclusion compounds (6–8). Phenobarbital, a weak acid, also forms a solid complex with griseofulvin (9). Soluble complexes are formed between griseofulvin and phenols in carbon tetrachloride (10) and between certain steroidal drugs and organic solvents (11).



I

The purpose of the present work is to investigate further the complexation of griseofulvin with the straight-chain alkanoic acids. The solubility method of Kostenbauder and Higuchi (12) was employed, and isooctane (2,2,4-trimethylpentane) was used as the inert solvent.

EXPERIMENTAL SECTION

Materials—Griseofulvin[1] was >99% pure, as described previously (5). Chloroform[2], acetic acid[3], *n*-butanoic acid[3], and *n*-octanoic acid[3] were reported to be >99% pure. Propanoic acid[4] and *n*-hexanoic acid[3] were distilled by using a glass apparatus. Isooctane (2,2,4-trimethylpentane)[4] was ≥99% pure.

Solubility Determinations—A mixture of griseofulvin (in excess of its solubility) and 5 mL of isooctane–fatty acid was shaken at 25.0 ± 0.05°C. Aliquots of 0.1–1.0 mL were diluted with chloroform, and the concentration of griseofulvin was determined (in duplicate) spectrophotometrically[5] at λ_{max} = 289.5 nm[6]. Saturation equilibrium was attained in <24 h. Each value (*e.g.*, $[A]_t$) is the mean of three separate determinations.

Analysis of the Solid Phases—A sample of the solid was removed from the equilibrated saturated solution, and the crystals were immediately placed on filter paper. The following methods of analysis were applied to all samples: X-ray diffraction (9), hot-stage microscopy (9), thermogravimetry (8), and

[a] The molar solubility of griseofulvin in pure isooctane ($[A]_0$) is 9.358 μM.

differential scanning calorimetry[7] (DSC). For DSC, a 2–3-mg sample was encapsulated and heated at a rate of 10 mcal·s^{-1}, with alumina as the reference material, helium as the gas phase, and indium as the calibrating standard. The data indicated that the samples removed from the saturated solutions were essentially unsolvated crystals of griseofulvin.

THEORETICAL SECTION

Griseofulvin (I) contains two keto groups, four ether oxygen atoms, and an aromatic ring, each of which can accept protons to form a hydrogen bond. Since griseofulvin has no proton-donating groups, it acts only as a proton acceptor, A.

Fatty acids act as proton donors, D. Since each acid molecule has only one proton, whereas griseofulvin has multiple acceptor sites, the total molar concentration of acid ($[D]_t$) and griseofulvin ($[A]_t$) in solution can be expressed by the following mass balance equations:

$$[A]_t = [A]_0 + [AD] + [AD_2] + [AD_3] + \ldots + [AD_z] \quad \text{(Eq. 1)}$$

$$[D]_t = [D] + 2[D]_2 + [AD] + 2[AD_2] + 3[AD_3] + \ldots + z[AD_z] \quad \text{(Eq. 2)}$$

where $[A]_0$ is the molar concentration of uncomplexed griseofulvin and is equal to the solubility in isooctane, $[AD_n]$ is the molar concentration of a complex of stoichiometric number n, $[D]$ is the molar concentration of fatty acid monomers, and $[D_2]$ is the molar concentration of fatty acid dimers.

If the standard state of each dissolved species (X) is assumed to be a hypothetical 1 M solution, which is assumed to behave as if it were infinitely dilute, then the activity of X, $\{X\}$, is given by:

$$\{X\} = \gamma_x[X] \quad \text{(Eq. 3)}$$

where γ_x is the molarity-based activity coefficient.

The formation of each complex can be represented as follows:

$$A + nD \rightleftharpoons AD_n \quad \text{(Eq. 4)}$$

$$\{AD_n\} = K_{1:n}\{A\}\{D\}^n \quad \text{(Eq. 5)}$$

$$[AD_n] = (K_{1:n}\{A\}\gamma_D^n/\gamma_{AD_n})[D]^n \quad \text{(Eq. 6)}$$

$$[AD_n] = K_n[D]^n \quad \text{(Eq. 7)}$$

where $K_{1:n}$ is the thermodynamic stability constant (based on activity), and K_n is the apparent stability constant (based on concentration), such that:

$$K_n = K_{1:n}\{A\}\gamma_D^n/\gamma_{AD_n} \quad \text{(Eq. 8)}$$

Dimerization of the fatty acid donor may be represented as:

$$2D \rightleftharpoons D_2 \quad \text{(Eq. 9)}$$

$$\{D_2\} = K_D\{D\}^2 \quad \text{(Eq. 10)}$$

$$[D_2] = (K_D\gamma_D^2/\gamma_{D_2})[D]^2 \quad \text{(Eq. 11)}$$

$$[D_2] = K_d[D]^2 \quad \text{(Eq. 12)}$$

where K_D is the thermodynamic dimerization constant (based on activity) and K_d is the apparent dimerization constant (based on concentration), such that:

$$K_d = K_D\gamma_D^2/\gamma_{D_2} \quad \text{(Eq. 13)}$$

Equations 7 and 12 can be combined as follows:

$$[AD_n] = (K_n/K_d^{n/2})[D_2]^{n/2} \quad \text{(Eq. 14)}$$

Two-Complex Model—If the two complexes, AD_m and AD_n, are present, Eq. 1 becomes:

$$[A]_t - [A]_0 = [AD_m] + [AD_n] \quad \text{(Eq. 15)}$$

$$= (K_m \cdot K_d^{-m/2})[D_2]^{m/2} + (K_n \cdot K_d^{-n/2})[D_2]^{n/2} \quad \text{(Eq. 16)}$$

whereas Eq. 2 becomes:

$$[D]_t = [D] + 2[D_2] + m[AD_m] + n[AD_n] \quad \text{(Eq. 17)}$$

Expressing $[D]$, $[AD_m]$, and $[AD_n]$ in terms of $[D_2]$ using Eqs. 12 and 14 affords:

$$[D]_t = K_d^{-1/2}[D_2]^{1/2} + 2[D_2] + (m \cdot K_m \cdot K_d^{-m/2})[D_2]^{m/2} + (n \cdot K_n \cdot K_d^{-n/2})[D_2]^{n/2} \quad \text{(Eq. 18)}$$

Two-Complex Model with Predominance of the Fatty Acid Dimer—In the presence of all but the lowest concentrations of fatty acid in a hydrocarbon

[7] DSC-2C differential scanning calorimeter; Perkin-Elmer.

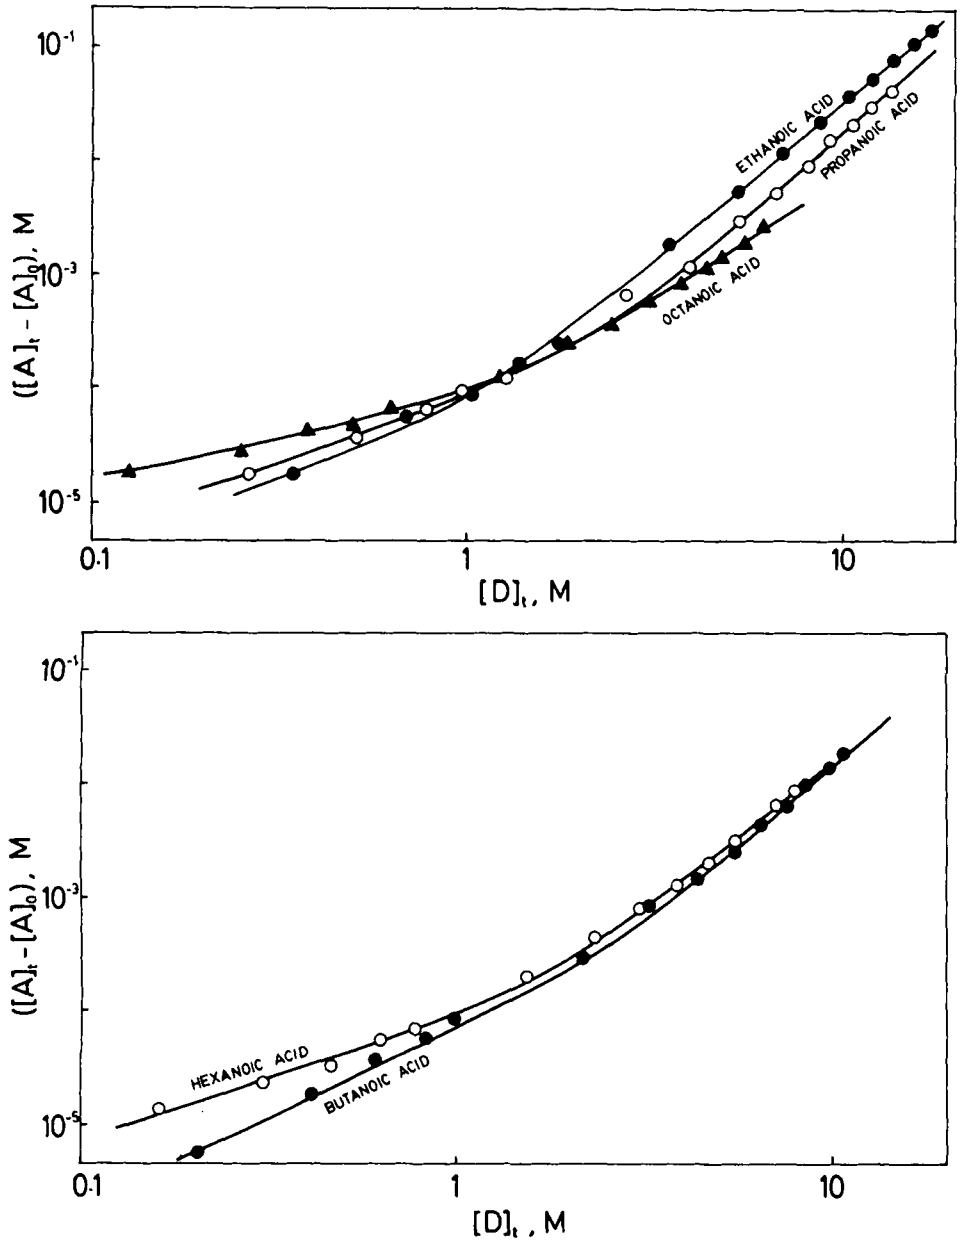

Figure 1—*Plots of log ([A]$_t$ − [A]$_0$) against log [D]$_t$, where ([A]$_t$ − [A]$_0$) is the increase in the apparent molar solubility of griseofulvin brought about by the presence of the following straight-chain alkanoic acids of total molar concentration, [D]$_t$, in isooctane at 25°C.*

solvent, $[D] \ll [D_2]$, because K_d in Eq. 12 has values of the order of 10^4 M^{-1}. Since the solubility of griseofulvin is always much smaller than the concentration of the fatty acid, $[AD_m] \ll [D_2]$ and $[AD_n] \ll [D_2]$. Equation 17 then simplifies to:

$$[D]_t \approx 2[D_2] \qquad \text{(Eq. 19)}$$

and Eq. 16 then becomes:

$$[A]_t - [A]_0 \approx (K_m \cdot K_d^{-m/2} \cdot 2^{-m/2})[D]_t^{m/2} + (K_n \cdot K_d^{-n/2} \cdot 2^{-n/2})[D]_t^{n/2} \qquad \text{(Eq. 20)}$$

Therefore:

$$[A]_t - [A]_0 \approx p[D]_t^{m/2} + q[D]_t^{n/2} \qquad \text{(Eq. 21)}$$

where:

$$p = K_m \cdot K_d^{-m/2} \cdot 2^{-m/2},\ q = K_n \cdot K_n^{-n/2} \cdot 2^{-n/2} \qquad \text{(Eq. 22)}$$

Therefore:

$$([A]_t - [A]_0)/[D]_t^{m/2} \approx p + q[D]_t^{(n-m)/2} \qquad \text{(Eq. 23)}$$

Thus, if two donor–acceptor complexes are present, $([A]_t - [A]_0)/[D]_t^{m/2}$ is expected to be a linear function of $[D]_t^{(n-m)/2}$. The slope q and intercept p afford the apparent stability constants, K_n and K_m, of the respective complexes, provided that the apparent dimerization constant, K_d, is known.

Single-Complex Model with Predominance of the Fatty Acid Dimer—If only one complex species, AD_m, is considered, Eqs. 1, 15, 20, and 21 reduce to:

$$[A]_t - [A]_0 = [AD_m] = (K_m \cdot K_d^{-m/2})[D_2]^{m/2} \qquad \text{(Eq. 24)}$$

$$\approx (K_m \cdot K_d^{-m/2} \cdot 2^{-m/2})[D]_t^{m/2} \qquad \text{(Eq. 25)}$$

$$[A]_t - [A]_0 \approx p[D]_t^{m/2} \qquad \text{(Eq. 26)}$$

The increase in solubility of the acceptor ($[A]_t - [A]_0$) is then expected to be proportional to the $m/2$ power of the total concentration of donor, $[D]_t^{m/2}$. The proportionality constant affords the apparent stability constant K_m of the complex if the apparent dimerization constant K_d is known. By taking logarithms, Eq. 26 yields:

$$\log([A]_t - [A]_0) \approx \log(K_m \cdot K_d^{-m/2} \cdot 2^{-m/2}) + (m/2) \cdot \log [D]_t \qquad \text{(Eq. 27)}$$

The linear regression of $\log([A]_t - [A]_0)$ against $\log [D]_t$ enables the stoichiometric number m of the complex to be determined from the regression coefficient (slope) and K_m to be determined from the intercept.

Single-Complex Model Allowing for all Donor Species Including the Monomer—Alternative models may be constructed which take into full account all species containing the fatty acid, including the monomer D. The approximate equation (Eq. 19) is clearly inappropriate here. For simplicity,

[a] Linear regression analysis of $([A]_t - [A]_0)/[D]^{m/2} = p + q[D]_t^{(n-m)/2}$ corresponding to the formation of two complexes of stoichiometry AD_m and AD_n, where $[D]_t$ is the total molar concentration of donor fatty acid in isooctane and $([A]_t - [A]_0)$ is the increase in the apparent molar solubility of the acceptor, griseofulvin, brought about by the presence of the donor in isooctane solution. It is assumed here that $[D_2] \approx 2[D]_t$. [b] Residual standard deviation per mean value of $([A]_t - [A]_0)[D]_t^{-m/2}$.

only one complex, AD_n, may be assumed, in which case the third term on the right in each equation (Eqs. 17 and 18) is ignored, so that:

$$[D]_t = K_d^{-1/2}[D_2]^{1/2} + 2[D_2] + (n \cdot K_n \cdot K_d^{-n/2})[D_2]^{n/2} \quad \text{(Eq. 28)}$$

Equation 24 is applied to AD_n instead of AD_m; thus:

$$[A]_t - [A]_0 = (K_n \cdot K_d^{-n/2})[D_2]^{n/2} \quad \text{(Eq. 29)}$$

Eliminating $[D_2]$ from Eqs. 28 and 29 affords:

$$[D]_t = c_1([A]_t - [A]_0)^{1/n} + c_2([A]_t - [A]_0)^{2/n} + n([A]_t - [A]_0) \quad \text{(Eq. 30)}$$

where:

$$c_1 = K_n^{-1/n} \text{ and } c_2 = 2K_n^{-1/n} \cdot K_d^{1/2} \quad \text{(Eq. 31)}$$

Rearranging Eq. 30 into a form suitable for linear regression analysis, we obtain:

$$\frac{[D]_t - n([A]_t - [A]_0)}{([A]_t - [A]_0)^{1/n}} = c_1 + c_2([A]_t - [A]_0)^{1/n} \quad \text{(Eq. 32)}$$

where c_1 is the intercept, and c_2 is the slope. This model, if valid, enables both the stability constant (K_n) and the dimerization constant (K_d) to be calculated directly from the intercept and the slope. Thus, from Eq. 31, we obtain:

$$K_n = (c_1)^{-n}, \quad K_d = (c_2/2c_1)^2 \quad \text{(Eq. 33)}$$

RESULTS AND DISCUSSION

UV Spectra and the Nature of the Griseofulvin–Fatty Acid Interactions—The choice of chloroform as the spectrophotometric solvent for the determination of dissolved griseofulvin was based on the UV absorption[6] data presented in Table I. Griseofulvin gave a high molar absorptivity which was unaffected by the presence of small amounts of fatty acids or isooctane. However, to measure the very low solubility of griseofulvin in isooctane alone, dilution with an equal volume of chloroform was preferable to optimize sensitivity and accuracy. In each determination, the linear (Beer's law) region of the appropriate absorbance–concentration calibration was employed.

Proton-donating solvents cause small but consistent red shifts to the UV spectrum of griseofulvin and increase the molar absorptivities about twofold, as compared with the noninteractive solvent, isooctane (Table I). These transitions are therefore $\pi \rightarrow \pi^*$ (15) and suggest that each protic solvent forms a hydrogen-bonded complex with the lone pair of electrons on the ether oxygen atom and/or the carbonyl oxygen atom, all of which are conjugated with the π electrons in an unsaturated or aromatic center in the griseofulvin molecule (I).

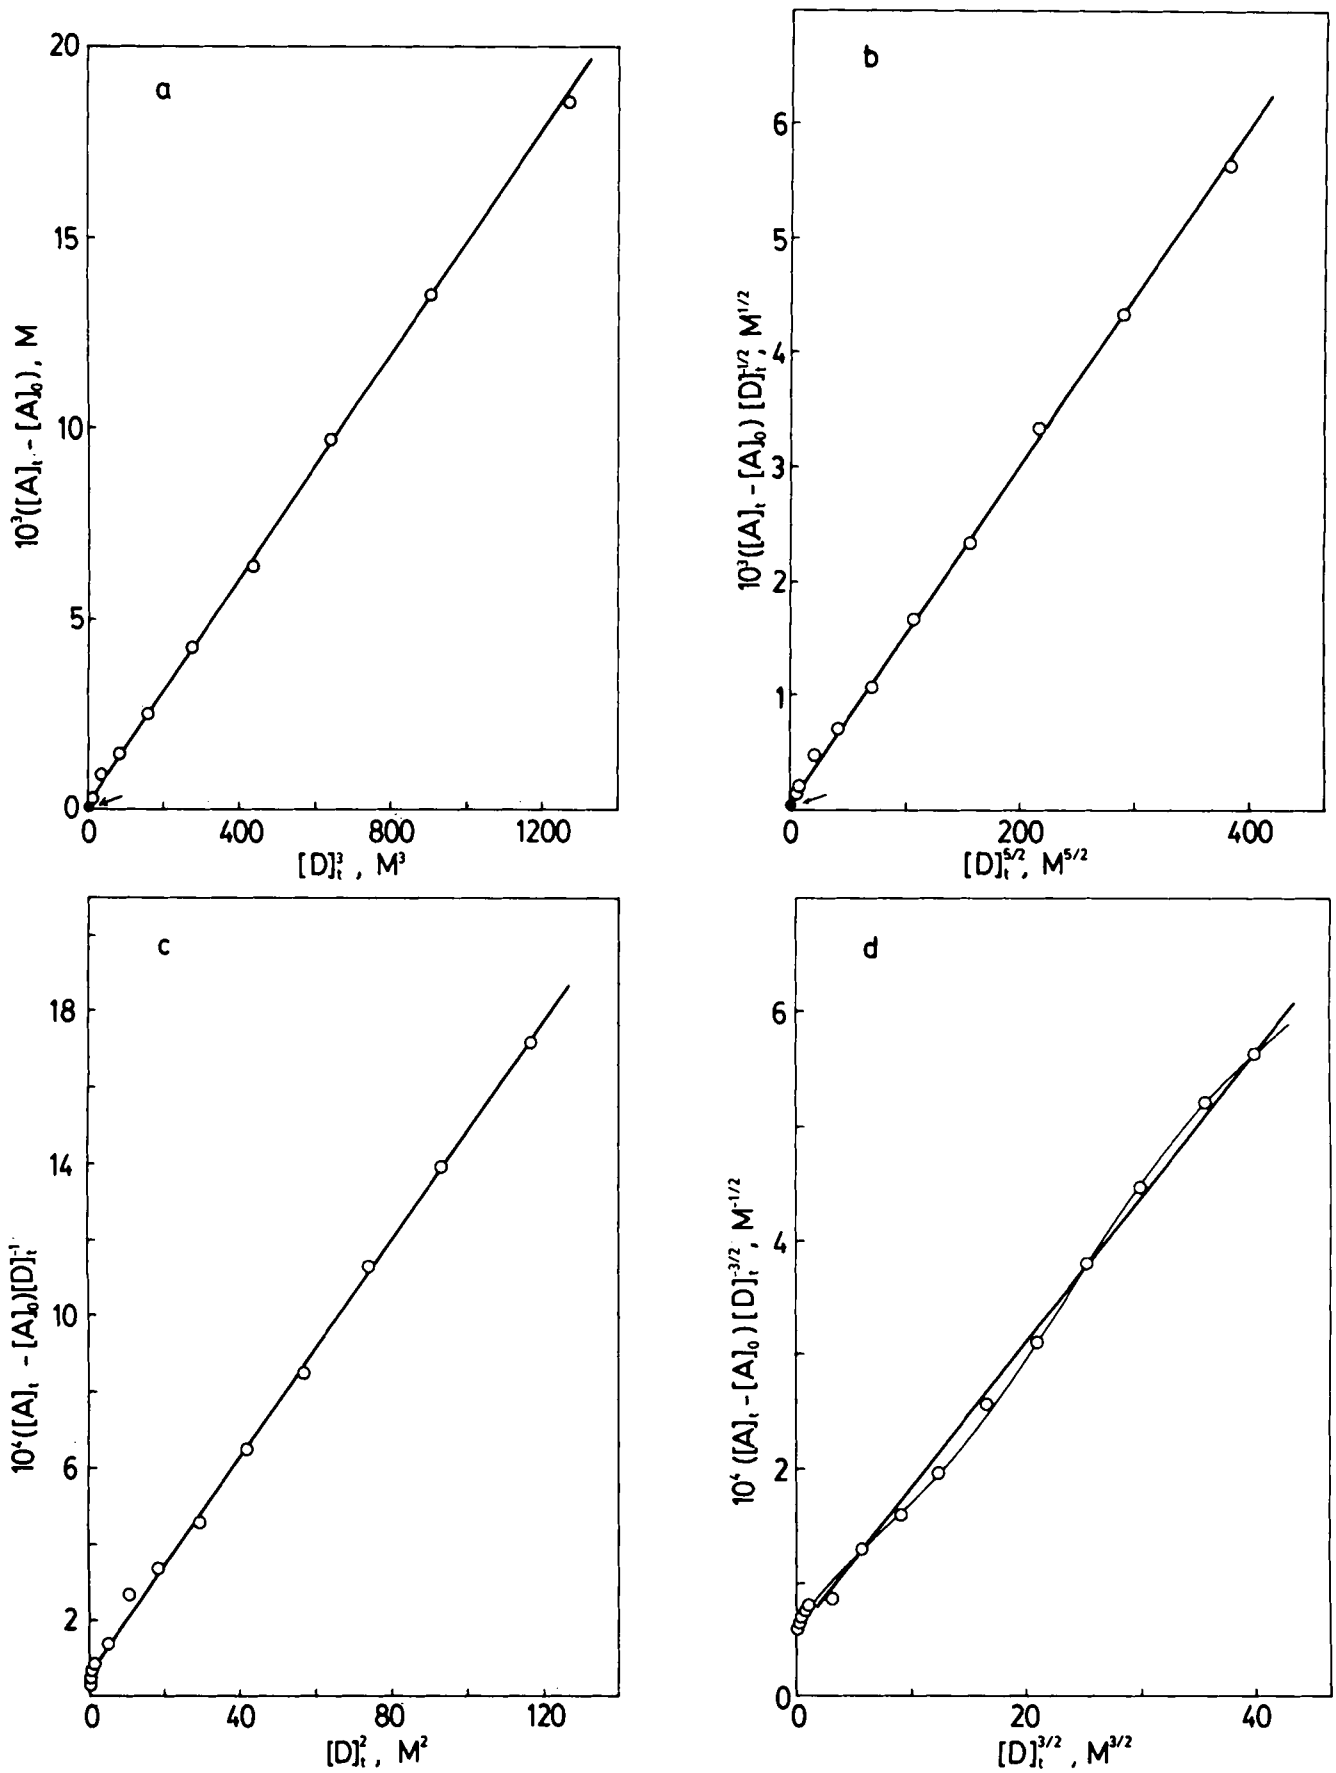

Figure 2—*Plots of various functions of* $([A]_t - [A]_0)$ *and* $[D]_t$, *where* $([A]_t - [A]_0)$ *is the increase in the apparent molar solubility of griseofulvin brought about by the presence of butanoic acid of total molar concentration* $[D]_t$, *in isooctane at 25°C. These plots correspond to linear regressions assuming the formation of the following complexes: (a)* AD_6 *alone; (b)* AD *and* AD_6; *(c)* AD_2 *and* AD_6; *(d)* AD_3 *and* AD_6.

Table IV—Stability Constants of Each of the Two Complexes Whose Stoichiometries Provide the Best Fit to the Solubility Data of Griseofulvin (A)[a]

Fatty Acid	K_d, M^{-1}	AD_m	K_m (Molarity Based)	AD_n	K_n (Molarity Based)
Acetic acid	37000[c]	AD	Very small[d]	AD_5	1.57×10^8
Propanoic acid	12000[b]	AD	0.0167	AD_6	2.38×10^8
Butanoic acid	9000[e]	AD	0.0106	AD_6	8.49×10^7
Hexanoic acid	6000[e]	AD_2	0.959	AD_6	2.76×10^7
Octanoic acid	5800[c]	AD	0.0068	AD_5	3.58×10^5

[a] In isooctane containing various concentrations of several fatty acids at 25°C. [b] Dimerization constant in cyclohexane at 25°C (from Ref. 19) is assumed to represent the corresponding value in isooctane at 25°C. [c] Dimerization constant in heptane at 23°C and 30°C (from Refs. 17 and 18) are assumed to represent the corresponding values in isooctane at 25°C. [d] Cannot be estimated from the negative intercept. [e] Determined by interpolation of the K_d values from Refs. 17–20.

Determination of the Stoichiometry of the Complexes—Table II presents the solubility data. The apparent molar solubility of griseofulvin in isooctane ($[A]_t$) increases rapidly with increasing molar concentrations of each acidic donor ($[D]_t$) from the value in isooctane, $[A]_0 = 9.358\ \mu M$. Plots of the logarithm of the increase in molar solubility, $\log([A]_t - [A]_0)$, against $\log [D]_t$ in Fig. 1 show two approximately linear regions: at $[D]_t < \sim 1$ M and at $[D]_t > \sim 2$ M. Each of these linear regions may be attributed to a complex between A and D, *e.g.*, AD_m or AD_n, according to Eq. 27. Regression analysis of the linear regions in Fig. 1 indicates high correlation coefficients ($r \geq 0.99$) and small residual standard deviations ($s < 1\%$). From each slope in Fig. 1, approximate values of the stoichiometric number, m or n, of fatty acid (D) molecules in each complex were calculated. Reference to Eq. 21 suggests that this is possible if m and n differ sufficiently such that at low $[D]_t$, the $[D]_t^{n/2}$ term is relatively small, whereas at high $[D]_t$, the $[D]_t^{m/2}$ term is relatively insignificant. Estimated stoichiometries are $m \simeq 1.7$–3.3 and $n \simeq 4.5$–5.9, depending on the fatty acid. However, the approximate nature of this treatment should be emphasized, especially with regard to the estimates of m for the lower-order complexes.

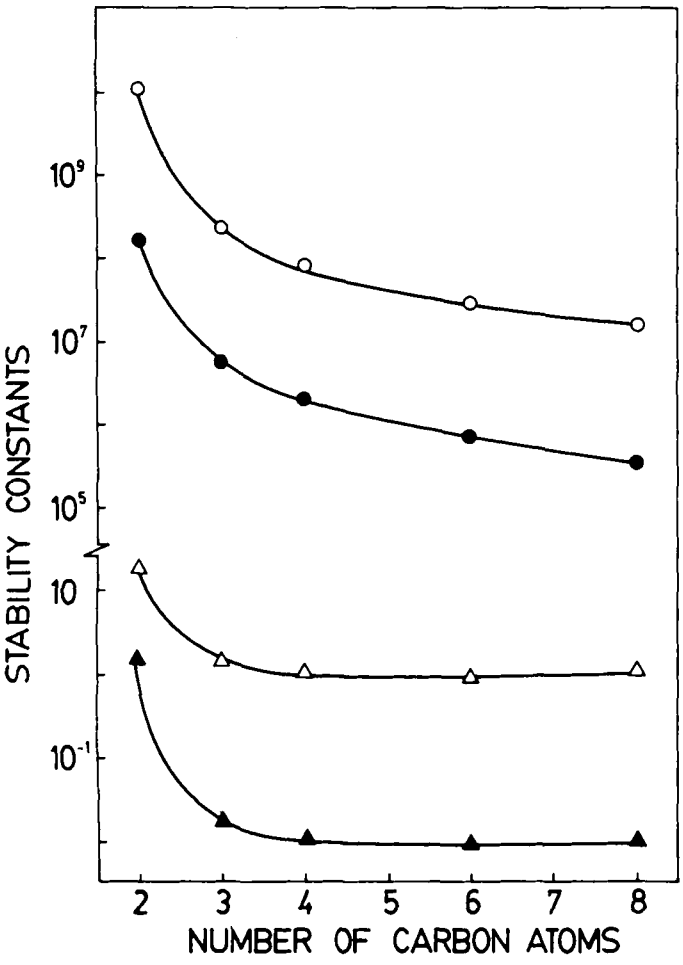

Figure 3—*Influence of the chain length of various straight-chain alkanoic acids on the molarity-based stability constants* K *of their complexes with griseofulvin. Key: (▲)* K_1 *for* AD *with* AD_6; *(△)* K_2 *for* AD_2 *with* AD_6; *(●)* K_5 *for* AD_5 *with* AD; *(○)* K_6 *for* AD_6 *with* AD.

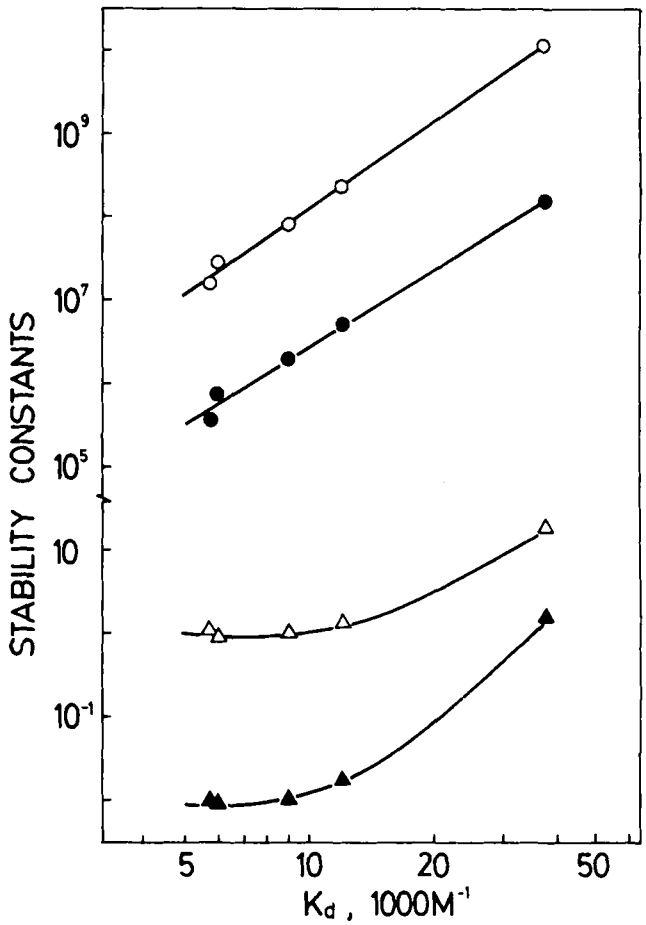

Figure 4—*Logarithmic relationships between the molarity-based dimerization constants* K_d *of various straight-chain alkanoic acids and the molarity-based stability constants* K *of their complexes* AD_n *with griseofulvin. Key: (▲)* K_1 *for* AD *with* AD_6; *(△)* K_2 *for* AD_2 *with* AD_6; *(●)* K_5 *for* AD_5 *with* AD; *(○)* K_6 *for* AD_6 *with* AD.

By using the approximate values of m and n as a guide, the solubility data were reanalyzed in terms of two stoichiometric complexes, AD_m and AD_n, by means of linear regressions represented by Eq. 23 (Table III). For this purpose, various probable and possible complexation models were assumed, with each corresponding to a certain pair of integral m and n values of greater or smaller magnitude than the approximate quantities, and the fatty acid dimers were generally assumed to predominate over all other species. For each acidic donor, the statistically most probable model (or pair of m and n values) corresponds to the linear regression with the highest correlation coefficient and the lowest residual standard deviation. Table III shows that these models are (m, n) 0,5 for acetic acid; 0,6 for propanoic and butanoic acids; 0,6 or 2,6 for hexanoic acid; and 1,5 for octanoic acid. When, however, the linear regressions were plotted (Fig. 2) for butanoic acid, the models for which $m = 0$ gave points that were crowded together at low $[D]_t$ and widely separated at high $[D]_t$ (Fig. 2a), whereas the models for which $m = 1$ or 2 gave points which were better separated (Fig. 2b–d). Therefore, the statistics of linear regression may be misleading at low $[D]_t$. Furthermore, the log-log plots in Fig. 1 clearly show two approximately linear regions, indicating $m > 0$. If, however, a value of m is selected that is too high, the correlation deteriorates (as shown by r and s in Table III), and the experimental points follow a sigmoidal curve on either side of the regression line. This is apparent in the case of the 3,6 model for butanoic acid (Fig. 2d) and is beginning to show in the 2,6 model (Fig. 2c). Bearing in mind all of these considerations, the preferred models (AD_m, AD_n) for each fatty acid donor with griseofulvin are summarized in Table IV.

To calculate the stability constants K_m and K_n of the complexes (Table IV) from the intercept (p) and slope (q) of each linear regression (Eqs. 20–22), the dimerization constant (K_d) of the fatty acid donor must be known.

Table V—Linear Regression Analyses [a]

[a] Linear regression analysis of $\{[D]_t - n([A]_t - [A]_0)\}([A]_t - [A]_0)^{-1/n} = c_1 + c_2([A]_t - [A]_0)^{1/n}$ corresponding to the single complex model allowing for all donor species, including the monomer, where $[D]_t$ is the total molar concentration of donor fatty acid in isooctane, and $[A]_t - [A]_0$ is the increase in the apparent molar solubility of the acceptor, griseofulvin, brought about by the presence of the donor in isooctane solution at 25°C. The single complex is represented by AD_n, where n corresponds to the stoichiometric number. [b] Residual standard deviation per mean value of ordinate. [c] $c_1^{-n} = K_n$, the stability constant of AD_n, if the model is correct. [d] $c_2/2c_1^2 = K_d$, the dimerization constant of D, if the model is correct.

Dimerization Constants of the Fatty Acid Donors—Equilibrium constants for hydrogen bonding, such as K_d, are usually largest in solvents of the saturated hydrocarbon type and do not differ much from one solvent to another within this group (16). They are not very dependent on temperature within a few degrees, because the negative enthalpies of hydrogen bonding are relatively small (<40 kJ·mol^{-1}, *i.e.*, <10 kcal·mol^{-1}). Consequently, the values of K_d for acetic, propanoic, and octanoic acids were taken to be the corresponding values in heptane and cyclohexane (17–19), whereas those for butanoic and hexanoic acids were obtained by interpolating the available data for six *n*-alkanoic acids (17–20) in these hydrocarbons (Table IV).

Although these values of K_d and the stability constants K_m and K_n (which are calculated from K_d and from the respective experimental quantities p and q) are only approximate (Table IV), the approximations will not affect the stoichiometry of complexation, since they are applied after the statistically favored complexation model has been selected from Table III.

Stability Constants of the Complexes—The stability constants of the various complexes plotted on a $\log_{10}$ scale against the chain length of the fatty acids are presented in Fig. 3. For the lower-order complexes AD and AD_2, the stability constants K_1 and K_2 are influenced by the stoichiometry of the accompanying higher-order complex and, for the purposes of comparison in Fig. 3, were calculated for the 1,6 and 2,6 models to form a self-consistent series. The values of K_1 and K_2 are, respectively, of the order 10^{-2}–10^{-1} M^{-1} and 1–10 M^{-2}, which are so small as to be accounted for by nonspecific, nonhydrogen-bonding interactions between D and A (21, 22). Values of $K_1 < \sim 1$ M^{-1} may be expected in nonbonding situations on a purely statistical analysis of the nearest neighbors (23, 24). K_1 and K_2 are preferably regarded as empirical quantities, reflecting an enhancement of the solubility of griseofulvin in isooctane by the presence of low concentrations of fatty acids interacting nonspecifically.

K_1 and K_2 are relatively independent of the chain length of the donor from propanoic to octanoic acid. The relatively high values of K_1 and K_2 for acetic acid may arise from deficiencies in the model, as reflected by the negative values of p, which have no physical meaning. The dimerization constants (K_d) also show relatively little dependence on the alkyl chain length (Table IV). Evidently, the flexible hydrocarbon chain has little effect on the stability of the smaller species (D_2, AD, or AD_2) derived from the fatty acids.

For the higher-order complexes AD_5 and AD_6, the values of the constants K_5 and K_6 are insensitive to the stoichiometry of the accompanying lower-order complex (AD_2, AD, or none) and are large, indicating powerful interactions between the fatty acids and griseofulvin. This reflects the strength of the donor and acceptor species and perhaps also the cooperative nature of hydrogen bonding. Griseofulvin has six obvious acceptor sites. The favored stoichiometries of the higher-order complexes suggest that these sites are saturated in AD_6 and not fully saturated in AD_5. Saturation of acceptor sites is probably accompanied by steric crowding, since K_6 decreases markedly with an increasing number of carbon atoms of the donor. This also reflects the increasing disruptive effect of the flexible hydrocarbon chain on the stability of the complex. The effect on K_5 is less pronounced, probably because one fewer acceptor site is occupied, thereby reducing the crowding and disruptive influences of the longer chains of the donor.

The concepts described above also explain why the relationships between $\log_{10} K_m$ or $\log_{10} K_n$ and the number of carbon atoms are not linear, as might be expected if a linear free energy relationship were obeyed (25). The gradient of the tangent to the curves in Fig. 3 represents the methylene-group contribution of the donor to the standard free energy of complexation; thus:

$$\Delta G_n^\theta = -RT \cdot \ln K_n \qquad \text{(Eq. 34)}$$

This contribution is not constant but decreases with increasing number of carbon atoms, reflecting the increasing disturbance to the griseofulvin–carboxyl group interactions by the longer hydrocarbon chains and perhaps the partial replacement of these interactions by weaker dispersion forces between the hydrocarbon chains and griseofulvin (5).

The statistically favored stoichiometry of the higher-order complex (Tables III and IV) for propanoic, butanoic, and hexanoic acids is AD_6; for octanoic acid it is AD_5, reflecting the steric crowding resulting from the larger size of the donor molecule in the latter case. The favored AD_5 stoichiometry for acetic acid is unexpected and is attributed tentatively to variations in the activity coefficients (γ in Eqs. 6, 8, 11, and 13), which are assumed to be constant.

In Fig. 4 are shown distinct linear free energy relationships between $\log_{10} K_5$ and $\log_{10} K_d$ and between $\log_{10} K_6$ and $\log_{10} K_d$. The linearity of these plots might result from the fact that the stability constants were calculated from K_d by Eq. 22. However, K_1 and K_2 were also calculated from K_d, but nonlinear relationships are found between their logarithms and $\log_{10} K_d$. Therefore, we suggest that the linear relationships between $\log_{10} K_6$ and $\log_{10} K_d$ and between $\log_{10} K_5$ and $\log_{10} K_d$ arise from the similarities of the intermolecular interactions, namely, hydrogen bonding, between D and A in the complexes AD_5 and AD_6 and between two fatty acid molecules in the dimer D_2. On the other hand, the nonlinearity of the relationships involving $\log_{10} K_1$, $\log_{10} K_2$, and $\log_{10} K_d$ probably reflect nonspecific interactions between A and D, in contrast to the specific interactions in the dimer.

Poor correlations are, however, found between $\log_{10} K_5$, $\log_{10} K_6$, $\log_{10} K_2$, $\log_{10} K_1$, and $\log_{10} K_d$, on the one hand, and the pK_a of the fatty acids (26) on the other hand. This is not unexpected, since ionization involves different intermolecular effects than interactions of the donor–acceptor type between D and A and two D molecules.

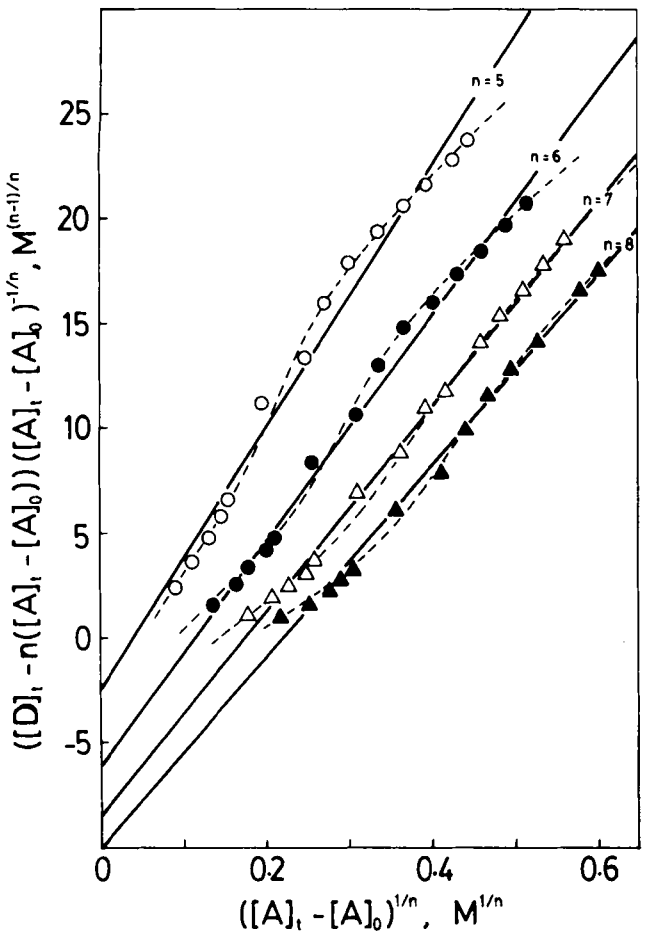

Figure 5—*Plots of* $\{[D]_t - n([A]_t - [A]_0)\}\{[A]_t - [A]_0\}^{-1/n}$ *against* $([A]_t - [A]_0)^{1/n}$, *corresponding to the single complex model allowing for all donor species, including the monomer. The stoichiometric number,* n, *of the single complex,* AD_n, *is as follows:* (○) n = 5; (●) n = 6; (△) n = 7; (▲) n = 8.

Critical Appraisal of the Proposed Models—The solubility behavior of griseofulvin in fatty acid–isooctane mixtures appears to conform to simple donor-acceptor models involving one or two complexes, AD_m and AD_n, which are summarized by Eqs. 20–27. These models are based on the following major assumptions: (*a*) the activity coefficient (γ) of each dissolved species (*e.g.*, in Eqs. 6, 8, 11, and 13) is constant and independent of the concentration terms, particularly $[D]_t$; (*b*) the activity of the solid which is in equilibrium with every saturated solution consisting of each fatty acid and isooctane (*e.g.*, in Eqs. 5, 6, and 8) is a constant equal to the activity of pure griseofulvin $\{A\}$; (*c*) the total amount of fatty acid is present almost exclusively as the dimer according to Eq. 19.

The assumption of constant activity coefficients becomes less reliable with increasing $[D]_t$, and the deviations become increasingly positive. In other words, with increasing concentrations of the highly polar fatty acid molecules in nonpolar isooctane solution, their activity or escaping tendency probably increases more rapidly than their concentration increases. Thus, although AD_6 is probably, for structural reasons, the real activity-based stoichiometry for the lower straight-chain alkanoic acids (C_2–C_6) as donors, the concentration-based stoichiometric number of D derived from the statistical treatment may be slightly less than the integral values of 6, as seen in Table III. When, however, acetic acid is present as the donor at volume fractions >60%, its molar concentration (>10 M; Table II) is so high that very large positive deviations from the ideal laws are expected, and the concentration-based stoichiometry which emerges from the statistical treatment is apparently AD_5 (Table III). The positive deviations, corresponding to $\gamma > 1$, may simply account for the negative values of p, which occur most commonly with acetic acid (Table III).

The activity of solid griseofulvin ($\{A\}$) depends on the nature of the solid phase which is in equilibrium with the saturated solution. When griseofulvin is allowed to crystallize from supersaturated solutions in each of the straight-chain alkanoic acids (except propanoic acid), new solid phases are obtained which contain both griseofulvin and the fatty acid (7, 8). Analysis of the excess of solid griseofulvin which stood in contact with each saturated solution in the solubility measurements, however, corresponded to that of the original griseofulvin crystals whose surface was moistened with liquid solution. The techniques used were DSC of five samples, which had previously been equilibrated with different mixtures of each fatty acid and isooctane, and differential thermal analysis and X-ray powder diffraction of one sample after equilibration with each neat fatty acid. This was confirmed by the inclusion of propanoic acid as a negative control which did not form solvates and which gave solubility data that were qualitatively no different from those of the other acids. We therefore conclude that $\{A\}$ was essentially constant in all the solubility measurements in the presence of each fatty acid and that solvates or inclusion compounds are not formed by allowing griseofulvin merely to stand in contact with each fatty acid.

The assumption that $[D]_t \approx 2[D_2]$ by Eq. 19 agrees with the experimental data. An alternative single-complex model in which $[D]_t$ accounts for the monomer, dimer, and complex leads to Eq. 32. The experimental data fit this equation also (Table V, Fig. 5 for butanoic acid), and it would appear that the statistically favored complexes correspond to $n = 6$, 7, or 8, depending on the fatty acid donor. However, except for statistically disfavored values of n for acetic acid, the data give negative values of c_1, which correspond to unacceptable negative values of the stability constant K_n (Eq. 33, Table V). In theory, this model should yield values of the dimerization constant K_d, but unacceptably small values are derived from the experimental data (*cf.* Table IV and V). Thus, this model, which accounts for the fatty acid monomer and a single complex, is totally unsatisfactory. Nevertheless, fatty acid monomers are undoubtedly present when fatty acids are dissolved in isooctane, and their relative concentration and influence increase as $[D]_t$ decreases. There is also evidence (27) that fatty acids in nonpolar solvents can form trimers, and perhaps also higher oligomers, in which the concentration is likely to increase with increasing $[D]_t$. If, however, all fatty acid species, with the exception of the dimer, are ignored, the solubility of griseofulvin in isooctane containing low concentrations of fatty acid can be explained by the presence of the lower-order complex, AD_m (in which $m = 1$ or 2). No doubt the most comprehensive model would involve a range or spectrum of AD_n complexes (Eq. 1) together with monomers, dimers, and perhaps even higher-order-associated species of fatty acids. Such a model would be algebraically complicated and would involve so many adjustable constants that it would be capable of fitting virtually any experimental data.

pH–Solubility Profile of Papaverine Hydrochloride and Its Relationship to the Dissolution Rate of Sustained-Release Pellets

ABU T. M. SERAJUDDIN ˣ and MORTON ROSOFF*

Received January 28, 1983, from the *Pharmacy Research and Development Department, Research and Development Division, Revlon Health Care Group, Tuckahoe, NY 10707.* Accepted for publication August 16, 1983. *Present address: Arnold and Marie Schwartz College of Pharmacy and Health Sciences, Brooklyn, NY 11201.

Abstract □ The pH–solubility profile of papaverine hydrochloride (I) was determined using the phase-solubility technique and equilibrium solubilities in buffers. The release of I from sustained-release pellets consisting of a shellac-based matrix was determined by the USP basket technique and was found to exhibit zero-order kinetics. Release rates at various pH values of the permeating solvent were compared with the pH–solubility profile and were directly proportional to the solubility below, but not above, the apparent pH_{max} (3.9). This lack of proportionality was also shown by the intrinsic dissolution rates. The effect was attributed to the self-buffering action of I and the metastability of the papaverine salt–base system in the vicinity of pH_{max}. It is postulated that the outer layer of polymer and filler on the surface of the pellets forms a barrier which determines the rate of release. The inner matrix serves as a drug reservoir in which the internal pH may not be the same as the bulk pH.

Keyphrases □ Papaverine hydrochloride—pH–solubility profile, supersaturation effect, common-ion effect, solubility–dissolution rate ratio, self-buffering effect □ Shellac-based matrix—sustained-release dosage forms, solubility–dissolution rate ratios, internal self-buffering effect □ Mechanism of release—matrix model, effect of filler

The solubility of a hydrochloride salt and its base may vary greatly in the GI pH range, depending on the solubilities of ionized and un-ionized forms and the pK_a of the compound (1). Kramer and Flynn (2) have investigated the solubility interrelationships of hydrochloride salts and their bases. They observed that instead of giving a smooth curve, the solubility curves of a salt and its base intersect at a sharp angle at the pH of maximum solubility (pH_{max}) of both forms. Chowhan (3) has also noticed a similar relationship between organic acids and their salts.

The release of papaverine hydrochloride (I) from commercial sustained-release preparations has been reported to be significantly affected by pH (1). A partial pH–solubility profile showed that the drug solubility reached a maximum at pH ~4.5, and a common-ion effect owing to the addition of excess chloride ion was noticed at low pH.

In the present investigation, the pH–solubility profile of I and the interrelationships betwen the solubility of its salt and base forms were studied. Experiments were then conducted to study the dissolution of I from sustained-release pellets[1] in relation to the pH–solubility profile.

EXPERIMENTAL SECTION

Materials—Papaverine hydrochloride[2] (I) was used as received. The papaverine base (II) was prepared by increasing the pH of an aqueous solution of I to at least 12.0, washing the resultant precipitate four to five times with water, and drying under reduced pressure over phosphorus pentoxide. The identity of II was established by elemental analysis.

Commercial sustained-release papaverine hydrochloride capsules were used as the dosage forms. Each capsule contained ~500 pellets. The diameter of each individual pellet was 0.9 ± 0.1 mm. The diameter of sugar granules around which I was embedded in a shellac-based matrix by a coating process in a conventional rotating pan (4) was ~0.6 mm. The outermost layers of pellets were formed by the addition of drug-free shellac and filler.

The citric acid–phosphate buffers (pH 2.2–7.8) were prepared by mixing 0.1 M citric acid and 0.2 M disodium phosphate. All other reagents used were of analytical grade.

pH–Solubility Profile—The solubility profile of I and its base was determined by the phase-solubility technique of Dittert *et al.* (5). The pH of I in saturated aqueous solution was 3.0. The solubilities at pH <3.0 were determined by titrating dropwise with 1 M HCl, stirring with an overhead stirrer for 1 h at 37°C in a water bath, recording the pH, and then collecting a suitable aliquot. To attain a higher pH, 1 M NaOH was similarly added. Throughout the titration, care was taken to maintain an excess of solid in equilibrium with the solution. The aliquots were filtered[3] immediately, diluted with 0.1 M HCl, and analyzed spectrophotometrically[4] at 310 nm. The solubility was calculated in terms of the hydrochloride salt. A preliminary study showed that the solubility did not change significantly if the equilibration of solution was continued for more than 1 h after each addition of titrant.

The solubility in a citric acid–phosphate buffer was determined by adding an excess of I to ~15 mL of the buffer in a 50-mL volumetric flask, shaking overnight with a wrist-action shaker[5] in a water bath at 37°C, and analyzing the aliquot as described above. The saturation solubility in 0.01 and 0.1 M HCl was determined in the same manner.

The solubilities at pH <3.0 were determined by titrating dropwise with 1 M HCl, stirring with an overhead stirrer for 1 h at 37°C in a water bath, recording the pH, and then collecting a suitable aliquot. To attain a higher pH, 1 M NaOH was similarly added. Throughout the titration, care was taken to maintain an excess of solid in equilibrium with the solution. The aliquots were filtered[3] immediately, diluted with 0.1 M HCl, and analyzed spectrophotometrically[4] at 310 nm. The solubility was calculated in terms of the hydrochloride salt. A preliminary study showed that the solubility did not change significantly if the equilibration of solution was continued for more than 1 h after each addition of titrant.

The solubility in a citric acid–phosphate buffer was determined by adding an excess of I to ~15 mL of the buffer in a 50-mL volumetric flask, shaking overnight with a wrist-action shaker[5] in a water bath at 37°C, and analyzing the aliquot as described above. The saturation solubility in 0.01 and 0.1 M HCl was determined in the same manner.

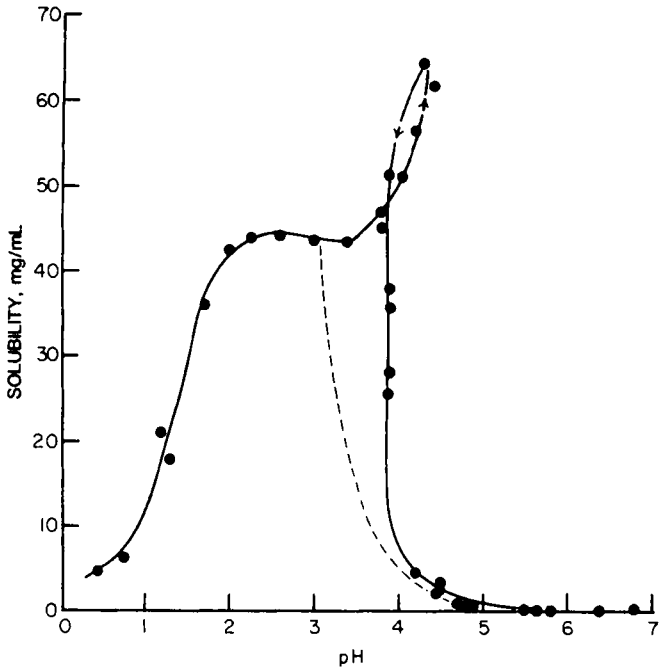

Figure 1—*Solubility of I in water at 37°C as a function of pH determined by adjusting the pH with 1 M HCl at pH <3.0 or with 1 M NaOH at pH >3.0. Each point represents one experimental value. All data were calculated in terms of hydrochloride salt equivalent. The broken line shows the theoretical solubility profile according to Eq. 3.*

The pH of the buffers with initial values >4 shifted to lower values on addition of I; consequently, the solubilities at these pH values were determined by using II, which gave no significant change in pH. The pH values of 0.01 and 0.1 M HCl media remained practically unchanged in the presence of I.

Analysis of Chloride Ion—During the determination of the solubility of I by the addition of 1 M HCl or 1 M NaOH, the analysis of chloride ion was made with selected aliquots. For the determination of chloride concentration, the aliquots were diluted 50 or 100 times with water, and 2 mL of 5 M $NaNO_3$ for each 100 mL of the diluted solution was added. The electrode potential in millivolts was measured with a pH meter[6] fitted with a chloride-sensitive electrode[7]. The standard calibration curve of log $[Cl^-]$ *versus* millivolts was obtained with sodium chloride solutions containing 2 mL of 5 M $NaNO_3$/100 mL.

Determination of pK_a—The apparent pK_a values of papaverine reported in the literature are 5.95 (6), 6.95 (7), and 6.40 (8). Since variations were noticed, the pK_a was determined in this study by recording the UV spectra of 0.015-mg/mL solutions of I in citric acid–phosphate buffer under various pH conditions. The average pK_a value obtained from the absorbances at 310 nm, using the following equation, was 6.5:

$$pK_a = pH - \log\left[\frac{A_{obs} - A_{BH^+}}{A_B - A_{obs}}\right] \qquad \text{(Eq. 1)}$$

where A_{BH^+} and A_B are the absorbances of the ionized and un-ionized species, respectively, and A_{obs} is the observed absorbance at the particular pH.

Dissolution from Papaverine Sustained-Release Pellets—A method using the USP dissolution apparatus[8] was developed for measuring the dissolution rates of papaverine hydrochloride-containing pellets. The contents of one capsule were placed in a dissolution basket, and the basket was immersed in 900 mL of dissolution medium previously warmed to 37°C. The basket was rotated at 100 rpm, and aliquots were taken from a point near the upper end of the basket and midway between the cylindrical edge of the basket and the wall of the vessel. The aliquots were analyzed spectrophotometrically at 310 nm, and the concentrations of the drug were determined from the extinction coefficients at the particular pH.

Intrinsic Dissolution of I—The intrinsic dissolution rates of I were determined using the dissolution apparatus described by Wood *et al.* (9). About 700 mg of the sample was compressed in a die with a hydraulic press[9] at a pressure of 4540 kg. The assembly was immersed in 300 mL of the medium at 37°C and stirred at 220 rpm. The surface of the pellet exposed to buffer had an area of 0.95 cm^2. The drug was assayed by removing suitable aliquots, diluting with 0.1 M HCl, and reading the absorbance spectrophotometrically at 310 nm.

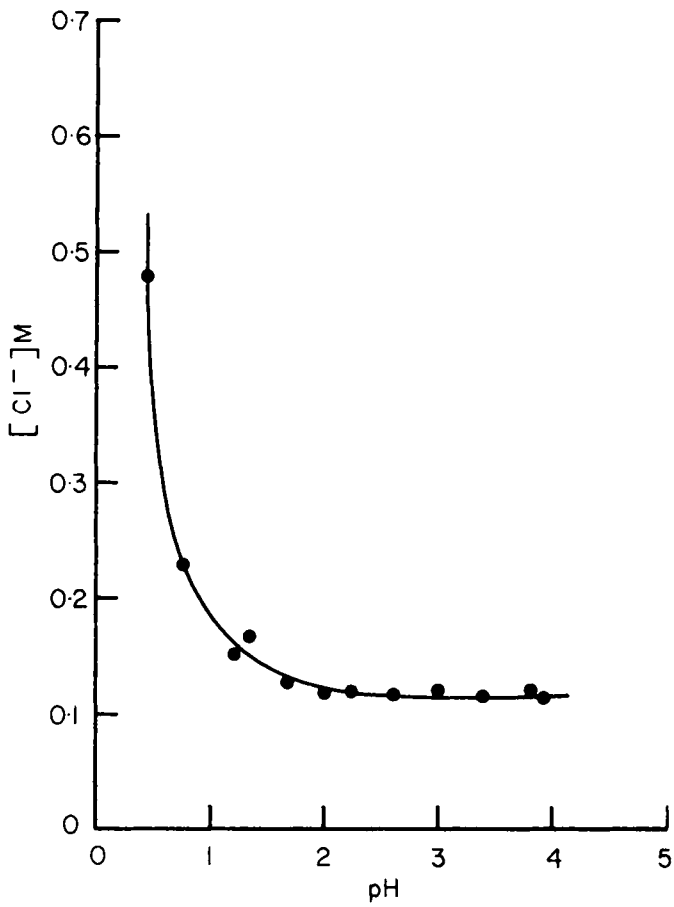

Figure 2—*The concentrations of chloride ion in the saturated solutions of I plotted as a function of pH (pH < apparent pH_{max}).*

Determination of the Effect of I on the pH of Buffers—The change in buffer pH in contact with I was determined in two ways. First, the citric acid–phosphate buffer, with pH 5, 6, or 7, was added to 1 g of I and stirred with a magnetic stirrer. The pH was recorded when stabilized, after the addition of 4 mL of the buffer and after 2-mL additions. Alternatively, the solid form of I was added in 0.1-g aliquots to 50 mL of a pH 6 buffer. The stabilized pH was recorded after each addition of solid.

Photomicroscopy of the Cross Sections of Pellets—The pellets were embedded in paraffin, and sections at a thickness of 10 μm were cut with a rotary microtome[10] using a diamond knife. The midsections of pellets were affixed to glass slides with egg albumin, and photomicrographs[11] were taken under UV light.

Determination of Density and Porosity—The densities of I and the sustained-release pellets were measured with a null pycnometer[12] using helium gas. Helium was purged through the samples for 12–15 min at the rate of 2–3 bubbles/s prior to the density measurement. The porosity of the pellets was determined by a mercury intrusion porosimeter[13].

RESULTS AND DISCUSSION

Solubility of I—The solubility of I at 37°C as a function of pH determined with the salt is shown in Fig. 1. It is observed from this figure that supersaturated solutions with a pH between 3.9 and 4.5 were formed; the pH of the supersaturated solution rose to 4.5 with the addition of 1 M NaOH before the precipitation of papaverine base (II) ensued; the pH finally stabilized at 3.9 (apparent pH_{max}). Elemental analysis of the solid phase precipitating at pH

	7.0	0.016	0.11	6.9	—	—

[a] Rate may have been affected by the deposition of a porous film on the dissolving surface.

3.9 revealed that the solid consisted of II only. The applicable equations (2) to express the total solubility (S_T) of salt and base at any pH are:

$$S_{T(pH < pH_{max})} = [BH^+]_s + [B] = [BH^+]_s\left(1 + \frac{K_a}{[H_3O^+]}\right) \quad \text{(Eq. 2)}$$

$$S_{T(pH > pH_{max})} = [BH^+] + [B]_s = [B]_s\left(1 + \frac{[H_3O^+]}{K_a}\right) \quad \text{(Eq. 3)}$$

where $[BH^+]$ and $[B]$ are the concentrations of the ionized and un-ionized species, respectively. The subscripts $pH < pH_{max}$ and $pH > pH_{max}$ indicate that the equations are applicable for pH values less than and greater than pH_{max}, respectively. The subscripts indicates a saturated species, and K_a is the apparent dissociation constant. Each of these equations describes an independent curve limited by the solubility of one of the two species, and pH_{max} is the juncture of the two curves. The solid phases in equilibrium with the solutions at a pH lower or higher than the pH_{max} are salt and base, respectively. By using the apparent pK_a of 6.5 and a solubility of 0.015 mg/mL for the base, the theoretical curve corresponding to Eq. 3 is also drawn in Fig. 1. The experimental values agree with Eq. 3 only at a pH >4.6. Below this pH, the experimental points are higher than the theoretical line, and the calculated pH_{max} (3.0) is lower than the apparent value (3.9).

The supersaturation at pH values of 3.9–4.5 in Fig. 1 is released by nucleation when the pH shifts to either side of the apparent pH_{max}. This was proven by the rapid precipitation observed when a supersaturated solution of salt was nucleated with solid base or *vice versa*.

According to Eq. 2, the total solubility below pH_{max} should remain constant,

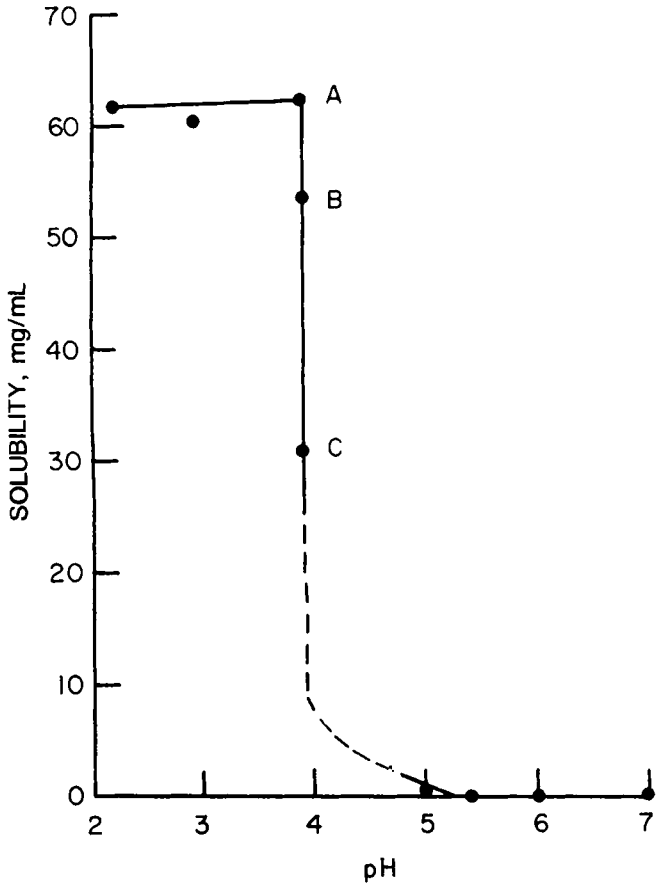

Figure 3—*The solubility of I in citric acid-phosphate buffers. A, B, and C were obtained when an excess of I was added to buffers of pH 4.0, 5.0, and 5.4, respectively. The solubility at pH ≥5 was determined with II. Each point represents one experimental value. All data were calculated in terms of hydrochloride salt equivalent.*

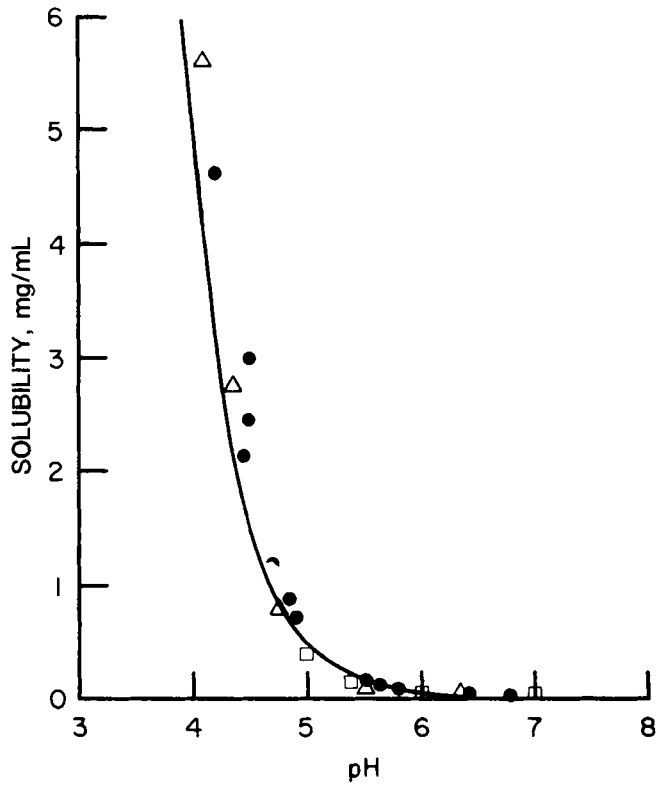

Figure 4—*The solubility of I and II at pH higher than pH_{max} shown with an expanded scale. The solubility was determined by increasing the pH of a solution of I with 1 M NaOH (●), by decreasing the pH of a solution of II with 1 M HCl (△), and by adding II to citric acid-phosphate buffer (□). The solid line was generated theoretically according to Eq. 3.*

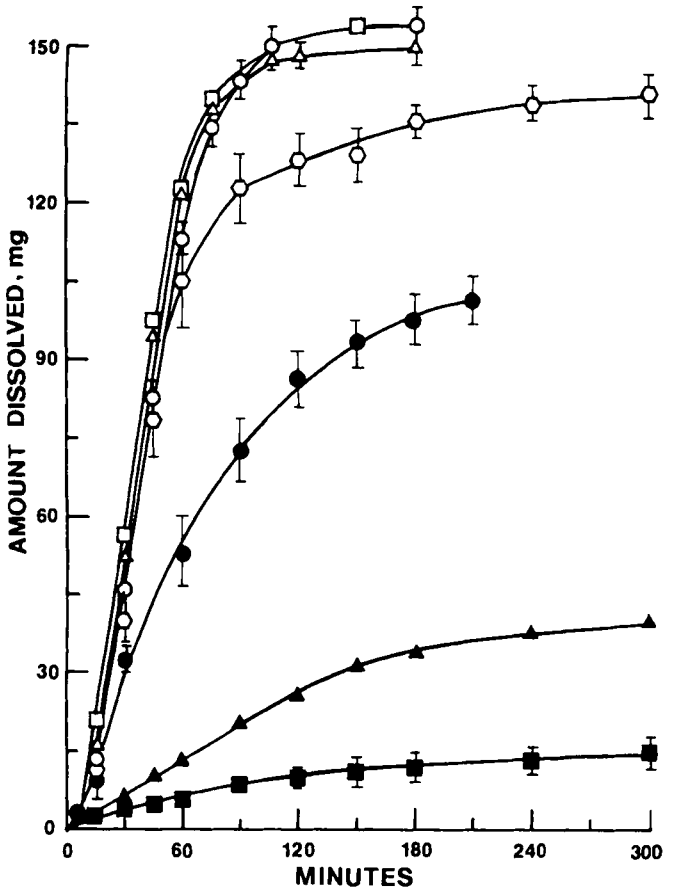

Figure 5 —*Dissolution of I from papaverine sustained-release pellets in citric acid–phosphate buffers. Key: (○) pH 2.2; (△) pH 3; (□) pH 4; (○) pH 5; (●) pH 5.4; (▲) pH 6; (■) pH 7. Each point represents mean ± SD of three experimental values, except for pH 6, for which the mean of duplicate determinations was plotted.*

i.e., equal to the solubility of the salt. The solubility of I, however, dropped gradually on lowering the pH below 2 with the addition of 1 M HCl. The chloride concentrations of solutions with pH values lower than pH_{max} are plotted in Fig. 2. Between pH 2 and 4, the chloride concentration remained constant, along with the constant solubility exhibited over this range (Fig. 1). A sharp increase in chloride ion concentration below pH 2 showed that the decline in solubility in Fig. 1 was due to a common-ion effect.

Solubility in Buffers— The pH–solubility of profile I in citric acid–phosphate buffers is presented in Fig. 3. As in Fig. 1, the apparent pH_{max} was 3.9 (higher than the theoretical pH_{max}), but the solubility of the salt at pH values between 2.2 and 3.9 was higher than that in the unbuffered solutions. Equilibrium solubility determinations in buffer showed no supersaturation effect around the apparent pH_{max}. The increase in solubility, however, over that obtained by the addition of acid or base between pH 3.3 and 3.9 may be due to salt formation with the buffer components. When an excess of I was added to the buffers with an initial pH higher than the apparent pH_{max}, the pH dropped to the latter value. The data points A, B, and C (Fig. 3) were obtained by adding an excess of I to buffers of pH 4, 5, and 5.4, respectively. Since the profile could not be extended below pH 2.2 in the citric acid–phosphate buffer system, no common-ion effect was noticed.

The solubilities above the apparent pH_{max} determined by (*a*) increasing the pH of a solution of I, (*b*) decreasing the pH of a solution of II, and (*c*) adding II to citric acid–phosphate buffer are shown with an expanded scale in Fig. 4. The line drawn is a theoretical value based on Eq. 3. As noted earlier, the solubility below pH 4.6 lies higher than the theoretical line.

Equilibrium solubility values determined by overnight shaking were plotted in Fig. 3, whereas Fig. 1 was generated by titration. An apparent pH_{max} of 3.9 in both cases, which is higher than the value of 3.0 derived theoretically, suggests that the positive deviation in solubility profile observed in Fig. 1 was not due to nonequilibrium conditions. Bogardus and Blackwood (10) have also observed similar nonideal behavior in the pH–solubility profile of doxycycline hydrochloride and have suggested that this might be due to self-association of the solute.

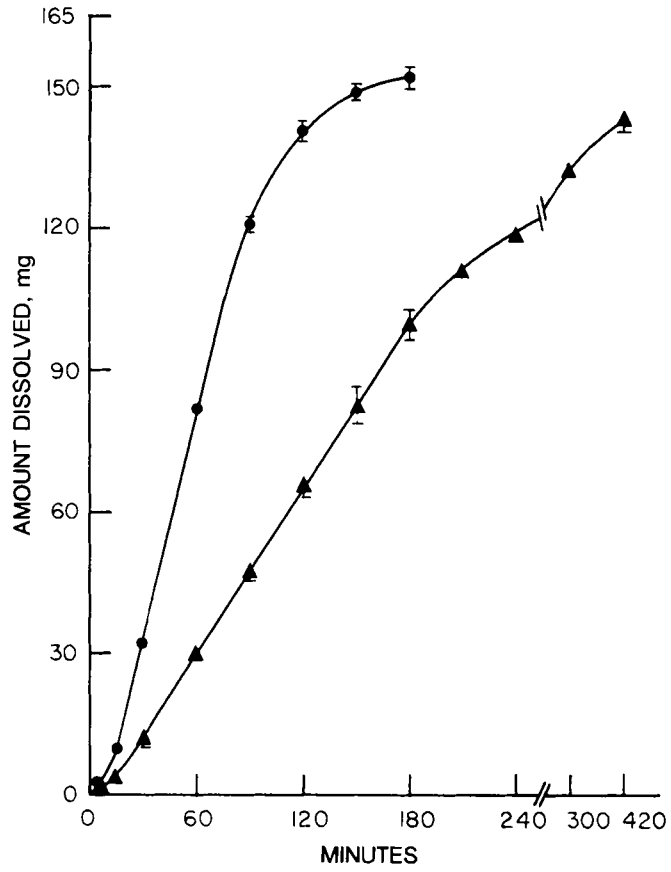

Figure 6—*Dissolution of I from papaverine sustained-release pellets in 0.01 M HCl (●) and 0.1 M HCl (▲). Each point represents mean ± SD of the three experimental values.*

Dissolution from Papaverine Sustained-Release Pellets— The dissolution of I from sustained-release pellets of I in citric acid–phosphate buffers at pH values of 2.2, 3.0, 4.0, 5.0, 5.4, 6.0, and 7.0 is shown in Fig. 5. The graphs in the pH region between 2.2 and 5.0 showed linearity after certain initial lag periods. This implies that the release rates were zero order for the periods corresponding to the linearity. At pH 2.2, 3.0, and 4.0, 100% of the drug was

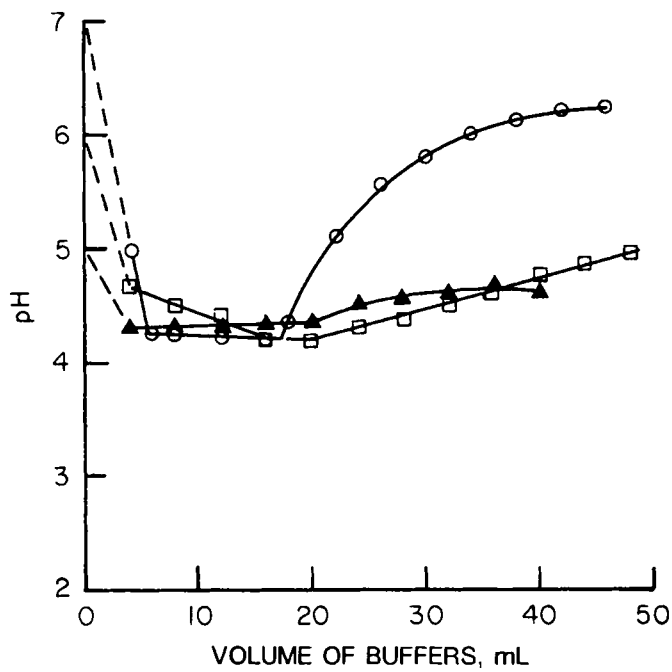

Figure 7— *Changes of pH of citric acid–phosphate buffers added to 1 g of I. Key: (▲) pH 5; (□) pH 6; (○) pH 7.*

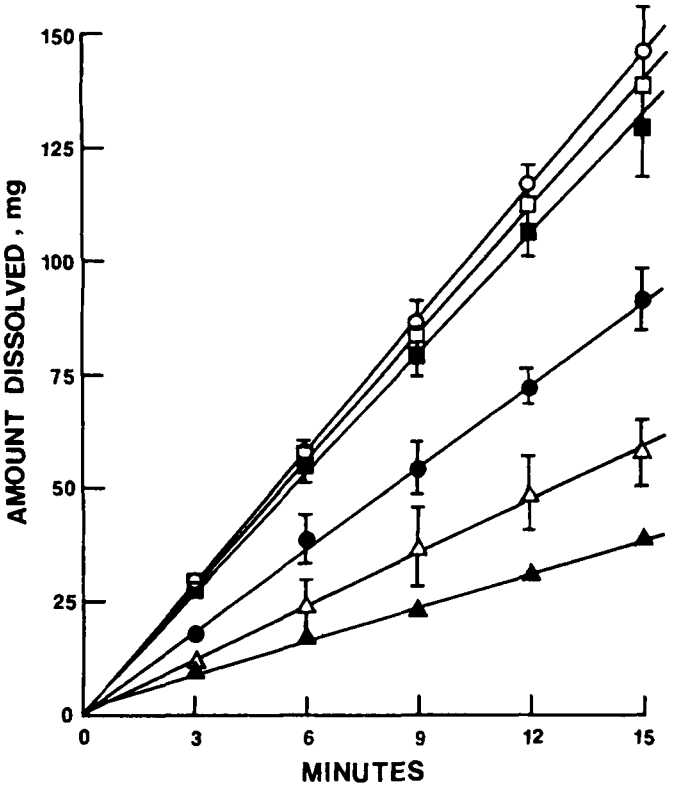

Figure 8—*Dissolution profiles of I from a constant surface area of 0.95 cm^2 at 37°C in various buffers. Each point represents mean ± SD of three experimental values. Key: (▲) pH 1.1; (●) pH 2.0; (○) pH 2.2; (□) pH 4.0; (■) pH 5.0; (△) pH 6.0. Deposition of a porous film of papaverine base was observed on the surface of I at pH 6.0.*

released from the pellets, whereas at pH ≥5.0, the dissolution profiles leveled off before complete release.

The zero-order rates in the pH range between 2.2 and 5.0 were calculated from the straight-line portions of the graphs. The release rates at pH 5.4, 6.0, and 7.0 were calculated from the initial portions of the graphs (<60 min) since sink conditions were not fulfilled. The rate constants, the solubilities, and their ratios at various pH are shown in Table I. According to Fig. 3, the saturation solubility between pH 2.2 and 3.9 was almost constant. This agrees with a similar constancy in dissolution rates at pH 2.2, 3.0, and 4.0. The dissolution of the pellets was also measured in 0.01 and 0.1 M HCl to study the effect of solubility on release rates (Fig. 6, Table I). In these two media, the saturation solubilities were 42 and 20 mg/mL, and the zero-order dissolution rates were 1.6 and 0.6 mg/min, respectively. Thus, at the apparent pH_{max} and lower, the dissolution rates were approximately proportional to the solubilities.

Similar proportional relationships between the solubility and the dissolution rate did not exist at higher pH. For example, although the solubilities at pH 5.0 and 5.4 were 152 and 390 times lower, respectively, than the solubility in the pH range of 2.2–3.9, the dissolution rates decreased only by factors of 1.1 and 2.3. This effect is further illustrated in Table I by the ratios of dissolution rate from pellets to solubility. At pH ≤4, the ratios were very small and almost constant, whereas at higher pH, the ratios were much larger. The discontinuity between the two sets of ratios occurred at the apparent pH_{max}.

Self-Buffering Action of I—The larger dissolution rate to solubility ratio at pH values higher than the apparent pH_{max} may be related to the effect of an excess of I on the pH of the buffer solutions. When buffers of pH 5.0, 6.0, and 7.0 were added to solid drug, the pH always dropped to a level between 4.0 and 4.5 and remained at this level until a considerable excess of buffer was added to raise the pH (Fig. 7). The same effect was also observed when an excess of I in solid form was added to pH 6 buffer, causing the pH to drop to 3.9. As long as an excess of I in solid form was present, the pH of the solution remained between 3.9 and 4.5, although the initial pH values of the buffers were higher. This pH range corresponds to the apparent pH_{max} and the supersaturation range of I (Fig. 1). The self-buffering action of I inside the pellets may increase the effective drug solubility, thus giving higher release rates at external pH values greater than the apparent pH_{max}. The increase in solubility due to the self-buffering action of I may not be identical when buffers of different pH values are used as the dissolution media. This is apparent from Fig. 3, in which points B and C represent the saturation solubilities of I in citric acid–phosphate buffers of pH 5.0 and 5.4, respectively.

The dissolution profiles of I from constant surfaces in selected media are shown in Fig. 8, and the results are tabulated in Table I along with those from sustained-release pellets. The profiles showed apparent linearity, although sink conditions should not exist at pH 5.0 and 6.0. According to the Noyes–Whitney equation (11), the dissolution rate (J) of a compound is proportional to the saturation solubility (C_s), and J/C_s is constant if the surface area, diffusion layer thickness, and diffusion coefficient are assumed to be constant. However, due to the self-buffering action in the diffusion layer (12, 13), the intrinsic dissolution rates of I at pH > pH_{max} were not proportional to the solubilities. This similarity with the dissolution from pellets confirms that the self-buffering action of I was involved in the dissolution from sustained-release pellets.

Mechanism of Release from Sustained-Release Pellets—The linearity of the drug release with time and the extended duration indicate zero-order kinetics for the dissolution rate. The structure of the pellets, consisting of I dispersed in a matrix of shellac with added filler, suggests a mechanism involving the leaching of the drug from the matrix (14). The equation describing the heterogeneous diffusion-controlled matrix model is:

$$Q = \left[\frac{D\epsilon C_s}{\tau}(2A - \epsilon C_s)t\right]^{1/2} \qquad \text{(Eq. 4)}$$

where Q is the amount of drug released per unit area from a matrix of porosity ϵ, tortuosity τ, and initial drug concentration A at the time t. D and C_s are the diffusion coefficient and solubility of the drug in the permeating solvent, respectively. Figure 9a and b show photomicrographs of the cross sections of pellets. The diameter of the core is ~0.6 mm, as compared with the diameter of 0.9 mm for the pellet. The outermost layer produced by the addition of shellac and filler cannot be clearly identified in Fig. 9a, because slight migration of I to this layer during spraying of the shellac solution obscures the distinction under UV light. However, the outermost barrier layer is distinguishable and remains intact after total leaching of I (Fig. 9b); the thickness of this layer is estimated to be 20–30 μm. From the core volume and papaverine hydrochloride charge, A was estimated at 700 mg/mL, and the condition $A \gg C_s$ was satisfied. Porosimetry measurements of pellets allowed computation of the average porosity of the penetrated portion of the matrix, which

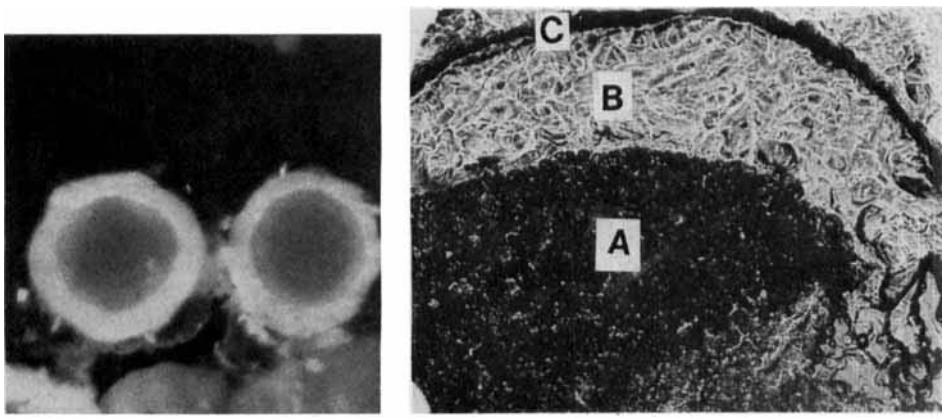

Figure 9—*Photomicrographs of (a) cross-sections of gross pellets (magnification, 30×) showing internal sugar beads and fluorescence of the papaverine hydrochloride annulus and (b) microtomed cross sections of leached-out pellets (magnification, 100×). Key: (A) sugar core; (B) leached-out annulus filled with paraffin; (C) outer shellac-filled layer.*

was ~0.6[14]. The tortuosity term must be high, particularly since additional shellac and filler were added in the final stages of pellet preparation. From the dissolution rate of pellets without added filler, a value of 30 was estimated for τ by Eq. 4. By assuming from the pellet core dimensions a matrix thickness of 150 μm and a boundary layer thickness of 100 μm, the ratio of resistances of matrix to unstirred layer is of the order of ~75, so matrix-controlled release proportional to $t^{1/2}$ would be predicted. The zero-order release rates that were observed, however, imply a constant activity of drug in a reservoir, due possibly to a barrier layer on the surface of the pellet where a constant concentration is maintained. Diffusion at constant concentrations through such a barrier layer may be the rate-determining step which results in release being linear with time. This mechanism was confirmed by dissolution from thick films of I dispersed in a shellac-based matrix in the same proportion as in the pellets but without the final drug-free layer. The release was found to be linear with $t^{1/2}$ and agreed with the heterogeneous matrix model. Moreover, the release from pellets made without the outer layer of shellac and filler also adhered to the $t^{1/2}$ relationship.

The sensitivity of the release rates to pH of the external solvent at pH < pH_{max} confirms that the leaching process takes place within a granular matrix. However, the expected decrease of release rate based on the decreased solubility at higher pH was not observed. These results were explained by the self-buffering action of the drug and the tendency to revert toward the apparent pH_{max} in the media of low buffer capacity.

The results of the present investigation indicate that the variability in the dissolution rate of a drug within the GI pH range due to differences in solubility may be reduced by designing controlled-release dosage forms. The importance of internal pH within the polymer matrices in controlling the solubility of drug and hence the dissolution rate has also been noted by Jambhekar and Cobby (15).

[14] The maximum porosity when all of the active drug is dissolved is given by $\epsilon + A(1 - \epsilon)$, where ϵ is the porosity of the pellet equal to 0.07, and A is the concentration of drug in the matrix.

Serum and Myocardial Kinetics of Amiodarone and Its Deethyl Metabolite After Intravenous Administration in Rabbits

R. KANNAN *x, N. IKEDA ‡, R. WAGNER ‡, M. DRACHENBERG ‡, and B. N. SINGH *

Received July 5, 1983, from the **Department of Cardiology, Veterans Administration Medical Center, West Los Angeles, CA 90073* and the ‡*Department of Medicine, UCLA School of Medicine, Los Angeles, CA.* Accepted for publication October 6, 1983.

Abstract □ The serum kinetics of amiodarone and its major metabolite the deethyl analogue were studied in rabbits after intravenous administration. The elimination of the drug and the metabolite from serum occurred as a biexponential function. Both compounds exhibited a rapid distribution phase (6.5 and 4.4 min, respectively) and had elimination half-lives of 136 and 235 min, respectively. There was a rapid uptake of both drugs by the myocardium, with maximal concentrations at 5 and 15 min. The myocardial concentrations were higher than the respective serum concentrations and declined with time. There was a wide scatter in myocardium-serum ratios, which ranged from 1 to 11 for amiodarone and 12 to 29 for the metabolite. Neither the drug nor the metabolite produced significant changes in the surface electrocardiogram after intravenous administration. These data suggest that accumulation of the metabolite does not account for the slow onset of action of amiodarone.

Keyphrases □ Kinetics—serum and myocardial, amiodarone and its metabolite, rabbits □ Amiodarone—serum and myocardial kinetics, rabbits □ Deethyl metabolite—amiodarone, serum and myocardial kinetics, rabbits

Plasma drug levels are commonly used to monitor the efficacy and toxicity of antiarrhythmic compounds. Such an approach is based on the assumption that the drug level in the myocardium, the presumed site of action of cardioactive agents, is in equilibrium with that in plasma. However, this assumption may not necessarily be valid under conditions of rapidly changing plasma levels of drugs (1). The significance of the myocardium–plasma drug ratios in the interpretation of the pharmacological responses of antidysrhythmic agents such as lidocaine (2), quinidine (3), verapamil (4), disopyramide (5), and *n*-acetylprocainamide (6) has been emphasized. Such studies are particularly relevant in the case of amiodarone, a potent class III antiarrhythmic drug (7), in light of our recent finding which demonstrates a lack of correlation between serum drug concentrations and suppression of premature ventricular contractions in patients with cardiac arrhythmias (8). Chronic amiodarone therapy results in the accumulation of a metabolite, the deethyl analogue, in serum (9). However, neither the pharmacokinetics nor the pharma-

was ~0.6[14]. The tortuosity term must be high, particularly since additional shellac and filler were added in the final stages of pellet preparation. From the dissolution rate of pellets without added filler, a value of 30 was estimated for τ by Eq. 4. By assuming from the pellet core dimensions a matrix thickness of 150 μm and a boundary layer thickness of 100 μm, the ratio of resistances of matrix to unstirred layer is of the order of ~75, so matrix-controlled release proportional to $t^{1/2}$ would be predicted. The zero-order release rates that were observed, however, imply a constant activity of drug in a reservoir, due possibly to a barrier layer on the surface of the pellet where a constant concentration is maintained. Diffusion at constant concentrations through such a barrier layer may be the rate-determining step which results in release being linear with time. This mechanism was confirmed by dissolution from thick films of I dispersed in a shellac-based matrix in the same proportion as in the pellets but without the final drug-free layer. The release was found to be linear with $t^{1/2}$ and agreed with the heterogeneous matrix model. Moreover, the release from pellets made without the outer layer of shellac and filler also adhered to the $t^{1/2}$ relationship.

The sensitivity of the release rates to pH of the external solvent at pH < pH_{max} confirms that the leaching process takes place within a granular matrix. However, the expected decrease of release rate based on the decreased solubility at higher pH was not observed. These results were explained by the self-buffering action of the drug and the tendency to revert toward the apparent pH_{max} in the media of low buffer capacity.

The results of the present investigation indicate that the variability in the dissolution rate of a drug within the GI pH range due to differences in solubility may be reduced by designing controlled-release dosage forms. The importance of internal pH within the polymer matrices in controlling the solubility of drug and hence the dissolution rate has also been noted by Jambhekar and Cobby (15).

[14] The maximum porosity when all of the active drug is dissolved is given by $\epsilon + A(1 - \epsilon)$, where ϵ is the porosity of the pellet equal to 0.07, and A is the concentration of drug in the matrix.

Serum and Myocardial Kinetics of Amiodarone and Its Deethyl Metabolite After Intravenous Administration in Rabbits

R. KANNAN *x, N. IKEDA ‡, R. WAGNER ‡, M. DRACHENBERG ‡, and B. N. SINGH *

Received July 5, 1983, from the **Department of Cardiology, Veterans Administration Medical Center, West Los Angeles, CA 90073* and the ‡*Department of Medicine, UCLA School of Medicine, Los Angeles, CA.* Accepted for publication October 6, 1983.

Abstract □ The serum kinetics of amiodarone and its major metabolite the deethyl analogue were studied in rabbits after intravenous administration. The elimination of the drug and the metabolite from serum occurred as a biexponential function. Both compounds exhibited a rapid distribution phase (6.5 and 4.4 min, respectively) and had elimination half-lives of 136 and 235 min, respectively. There was a rapid uptake of both drugs by the myocardium, with maximal concentrations at 5 and 15 min. The myocardial concentrations were higher than the respective serum concentrations and declined with time. There was a wide scatter in myocardium-serum ratios, which ranged from 1 to 11 for amiodarone and 12 to 29 for the metabolite. Neither the drug nor the metabolite produced significant changes in the surface electrocardiogram after intravenous administration. These data suggest that accumulation of the metabolite does not account for the slow onset of action of amiodarone.

Keyphrases □ Kinetics—serum and myocardial, amiodarone and its metabolite, rabbits □ Amiodarone—serum and myocardial kinetics, rabbits □ Deethyl metabolite—amiodarone, serum and myocardial kinetics, rabbits

Plasma drug levels are commonly used to monitor the efficacy and toxicity of antiarrhythmic compounds. Such an approach is based on the assumption that the drug level in the myocardium, the presumed site of action of cardioactive agents, is in equilibrium with that in plasma. However, this assumption may not necessarily be valid under conditions of rapidly changing plasma levels of drugs (1). The significance of the myocardium–plasma drug ratios in the interpretation of the pharmacological responses of antidysrhythmic agents such as lidocaine (2), quinidine (3), verapamil (4), disopyramide (5), and *n*-acetylprocainamide (6) has been emphasized. Such studies are particularly relevant in the case of amiodarone, a potent class III antiarrhythmic drug (7), in light of our recent finding which demonstrates a lack of correlation between serum drug concentrations and suppression of premature ventricular contractions in patients with cardiac arrhythmias (8). Chronic amiodarone therapy results in the accumulation of a metabolite, the deethyl analogue, in serum (9). However, neither the pharmacokinetics nor the pharma-

cological properties of the metabolite are known. The purpose of the present study was twofold: first, to make a comparative evaluation of the serum elimination kinetics of amiodarone and its major metabolite after intravenous administration in rabbits and, second, to determine the myocardial concentrations of amiodarone and its deethyl metabolite as a function of time after an intravenous dose and to correlate the tissue levels with the electrocardiographic changes.

EXPERIMENTAL SECTION

Experimental Design—The kinetic and electrophysiological studies were conducted using female New Zealand White rabbits. For the study of amiodarone kinetics, 15 rabbits [body weight, 1.9 ± 0.2 kg (mean ± *SD*)] were used. One rabbit died after the administration of amiodarone, and data from that rabbit were not included in the final analysis. The kinetics of the deethyl analogue were evaluated in 15 rabbits (2.42 ± 0.33 kg). However, three rabbits were excluded since they died from either anesthesia ($n = 1$) or drug ($n = 2$). All animals were anesthetized with pentobarbital[1] (20 mg/kg). Either 5% aqueous amiodarone hydrochloride[2] at a dose of 10 mg/kg or the deethyl analogue as the hydrochloride[2] in 50% ethanol (1.5% solution) at a dose of 10 mg/kg was injected as a single intravenous bolus dose in the marginal vein of the left ear. The total volume of injectant did not exceed 0.30–0.52 mL for amiodarone and 0.7–1.3 mL for the metabolite. Serial blood samples (1–1.7 mL) were drawn from the right ear vein. Up to eight serial blood samples were obtained at the following sampling times: 5, 10, 15, 30, 45, and 60 min and 1.5 h, 2, 4, 6, 8, and 10 h. Blood collected before the drug was injected served as the blank in drug assays. In some rabbits, blood samples were also taken at 2.5, 7.5, and 12.5 min. To obtain myocardial tissue samples, all 15 rabbits used in the amiodarone serum kinetics studies were sacrificed as groups of two to three rabbits each at 5 and 15 min and 1, 2, and 6 h. Similarly, groups of three to four rabbits were sacrificed at 15 min and 2, 4, 6, and 10 h in the metabolite studies. After dissection, the heart tissue was blotted dry, weighed, and kept frozen. Blood samples were spun at 10,000 rpm, after which the serum was separated and stored frozen until analysis. Electrocardiograms (ECGs) were recorded[3] with standard limb leads immediately before injection of the drug and at 15 and 30 min and 1, 3, 4, and 6 h postdose. ECGs of control rabbits that were injected with either equivalent volumes of sterile distilled water or 50% ethanol were recorded for up to 6 h.

Table I—Kinetic Parameters of Amiodarone and its Metabolite, the Deethyl Analogue, After Intravenous Administration in Rabbits [a]

	$t_{1/2,\alpha}$ min	$t_{1/2,\beta}$ min	Vd_{ss}, L/kg	CL, L/min/kg
Amiodarone	6.5 ± 1.2	136 ± 20	6.7	0.055
Deethyl analogue	4.4 ± 0.6	235 ± 7	34.4	0.116

[a] These data are derived from the serum elimination curves for amiodarone and the metabolite shown in Figs. 1 and 2.

Drug Analysis—Analyses were carried out in a liquid chromatograph[4] equipped with a solvent delivery system[5], a valve-type injector[6], a normal-phase silica column[7], and a variable-wavelength UV detector[8] set a 240 nm. Serum concentrations of amiodarone and its metabolite were determined by using a recent modification (10) of the procedure described by Flanagan *et al.* (11). The serum volumes for analysis varied from 0.25 to 0.75 mL, depending on the expected drug concentrations, with corresponding increase in the volume of the extracting solvent, methyl *tert*-butyl ether. The combined ether extract from two extractions was dried under a stream of nitrogen and reconstituted in 25 μL of methanol, of which 20 μL was injected into the liquid chromatograph.

For the measurement of myocardial concentrations of amiodarone and its metabolite, 100–250 mg of ventricular muscle was homogenized with 5 mL of deionized distilled water by sonication, and the homogenate was centrifuged

Table II—Mean Concentrations of Amiodarone and Its Deethyl Analogue in Serum and Myocardium after Intravenous Administration in Rabbits [a]

Time after Injection	Concentration		Myocardium-Serum Ratio (range) [b]
	Serum, ng/mL	Myocardium, ng/g	
		Amiodarone	
5 min	6050 ± 2200 (14)	8100 ± 4000 (3)	1.2 (0.3–1.7)
15 min	1990 ± 680 (11)	14,400 ± 2800 (3)	5.8 (4.9–7.6)
1 h	490 ± 170 (11)	7000 ± 1900 (3)	11.1 (9.6–12.0)
2 h	320 ± 120 (10)	530 ± 430 (2)	1.3 (0.5–2.1)
6 h	90 ± 30 (6)	362 ± 431 (3)	2.3 (0.7–5.5)
		Deethyl Analogue	
15 min	389 ± 64 (9)	10,800 ± 7850 (3)	28.8 (24.0–33.6)
2 h	136 ± 21 (8)	3444 ± 2910 (3)	26.9 (3.7–47.1)
4 h	95 ± 21 (6)	2590 ± 1150 (2)	25.9 (18.7–33.0)
6 h	58 ± 11 (6)	1006 ± 620 (3)	17.0 (8.6–28.7)
10 h	37 ± 1 (3)	445 ± 358 (4)	11.7 (1.8–24.4)

[a] Data are mean ± *SD*; number of rabbits is given in parentheses. [b] Ratios are presented only for those rabbits for which both serum and myocardial concentrations were available.

at 10,000 rpm for 10 min. Aliquots (2 mL) of the supernatant were extracted twice with 1 mL of methyl *tert*-butyl ether. Further processing of the sample was the same as described above for serum. The extraction efficiency of amiodarone and the metabolite from ventricular muscle of control rabbits was 71.2 ± 2.7% (n = 6), which did not differ from that found in serum (74.0 ± 9.8%; n = 8).

Data Analysis—Mean serum concentrations of amiodarone and the deethyl metabolite were fitted by nonlinear least-squares regression analysis (12). Clearance (CL) and volume of distribution at steady state (Vd_{ss}) were determined by using model-independent calculations (13). The ECG parameters were derived manually from records at 125-mm/s paper speed, and the resulting data were compared at each time point with an ANOVA program.

RESULTS

Serum Kinetics of Amiodarone and the Deethyl Analogue in Rabbits—In Figs. 1 and 2 are shown the serum elimination kinetics of amiodarone and the metabolite, respectively, in rabbits after intravenous administration. The data shown are from 14 rabbits administered amiodarone and 15 rabbits administered the metabolite; in both series of experiments, both serum and myocardial kinetics were studied. A biexponential fall in serum concentrations was observed for the parent drug and the metabolite. The serum concentrations 5 min after administration of the intravenous dose were 6050 and 2660 ng/mL for amiodarone and the metabolite, respectively, and fell to 30 and 38 ng/mL, respectively, in 10 h. The kinetic parameters of serum kinetics of amiodarone and the deethyl analogue are listed in Table I. Both drugs had a rapid distribution phase ($t_{1/2,\alpha}$ 6.5 and 4.4 min for amiodarone and the metabolite, respectively). The elimination half-lives ($t_{1/2,\beta}$) were 136 min for amiodarone and 235 min for the metabolite. The mean volumes of distribution and clearance for amiodarone were 6.7 L/kg and 0.055 L/min/kg, respectively. The corresponding values for the metabolite were 34.4 L/kg and 0.116 L/min/kg, respectively (Table I).

In Table II, the myocardial concentrations of amiodarone and the metabolite in rabbits as a function of time after intravenous administration are summarized. We used ventricular muscle as a representative tissue sample for the determination of the myocardial concentrations. The myocardial concentrations of the parent drug and the metabolite expressed as nanograms per gram of wet tissue were higher than the respective serum concentrations that were obtained throughout the time course of the study. In the postdistributive phase, myocardial concentrations of the metabolite declined approximately parallel to those of serum. Such a similarity was not apparent for amiodarone, partly due to the limited number of data points (2 and 6 h) for myocardial levels of amiodarone in the postdistributive phase. The myocardium-serum ratios (Table II) are derived from only those rabbits for which both serum and myocardial concentrations were available. Although the myocardium-serum ratios of amiodarone and the metabolite overlapped, the ratios for the metabolite (range, 11.7–28.8) were higher than for amiodarone (range 1.3–11.3). The large scatter in the ratios was a result of wide variations in myocardial concentrations.

Electrocardiographic Changes—Electrocardiographic changes accompanying intravenous administration of amiodarone and the metabolite were compared between rabbits injected with drug and a control group (n = 5) injected with the vehicle alone. All rabbits were mildly anesthetized with pentobarbital before administration of the appropriate drug or the vehicle and at other times during the study to obtain ECG recordings that were free of technical artifacts. An analysis of variance among the three groups showed that intravenous administration of either amiodarone or the metabolite did not cause any significant changes in RR, PQ, QRS, and QT_c intervals[9] as compared with the control group, except for an increase in the QRS intervals of the animals treated with the metabolite 15 min after administration of the drug (37.2 ± 4.0 *versus* 29.6 ± 2.8 ms in the controls). However, this increase is only of borderline significance. There were fluctuations in the values of the QRS intervals both in the control and drug-treated groups, although the values of the QRS intervals did not differ significantly from those of the controls at other time points studied.

DISCUSSION

We have determined the serum elimination kinetics and myocardial distribution of amiodarone in rabbits after intravenous administration. The pharmacokinetics of the major metabolite of amiodarone, the deethyl analogue, was compared with those of the parent drug for the first time. The short and long elimination half-lives of amiodarone in patients after acute and chronic oral administrations have been determined by us and others (9, 14, 15). It has been suggested that amiodarone equilibrates rapidly with tissues, such as the myocardium, after acute administration, and the rapid repartitioning between tissue and serum results in a short half-life. On the other hand, the long elimination half-life after chronic administration is attributed to the slowly equilibrating tissues, mainly adipose tissue and muscle. We found that amiodarone was rapidly eliminated from the serum of rabbits after intravenous administration, with an elimination half-life of 136 min, which is similar to that found in dogs (16, 17) but different from that found in rats (18). The disappearance of the intravenously administered metabolite from the serum of rabbits is also rapid ($t_{1/2,el}$ 235 min). There is a rapid uptake of both the drug and its metabolite by the myocardium. Although our limited data did not allow us to determine the precise time of maximal uptake of amiodarone and the metabolite by the myocardium, it can be estimated to be between 5 and 15 min. The myocardial concentrations of amiodarone and the metabolite decreased with time. This decline in myocardial concentrations was approximately parallel to that detected for the metabolite in serum but not for amiodarone. For both the drug and the metabolite, the myocardial concentrations were higher than the respective serum concentrations used throughout the study.

Latini *et al.* (16, 17) have recently reported a detailed investigation on serum kinetics and myocardial disposition of amiodarone in dogs. The mean serum elimination half-life of amiodarone after intravenous administration in dogs (3.01 h) was similar to that in rabbits, as determined in the present study. They observed a large interanimal variability in myocardium-serum ratios in dogs. The average ratio of myocardium-plasma amiodarone concentration was much higher in dogs (range, 34–134) than that in rabbits (range, 1.2–11.3). Whether this represents a species difference or differential binding characteristics of amiodarone is not certain at present. Interestingly, Latini *et al.* (17) have shown by computer simulation, that peak myocardial concentrations were achieved between 15 and 20 min after intravenous administration of amiodarone to dogs. Our limited data on rabbit myocardial levels appear to be in accord with their findings. In spite of high concentrations of amiodarone and the metabolite in the myocardium, no appreciable ECG changes were observed for up to 6 h after intravenous administration, suggesting a complex

[9] Definitions: (RR) duration between two successive heart beats; (PQ) time from the beginning of atrial depolarization to the beginning of ventricular depolarization; (QRS) duration of ventricular depolarization; (QT_c) duration of ventricular repolarization normalized or corrected for heart rate.

pharmacological action of the parent drug and possibly the metabolite. This finding is consistent with our previous observation of no significant alterations in the action potentials of rabbit sinoatrial node, atrioventricular node, and atrial fibers after a 1-h superfusion with therapeutically meaningful concentrations of amiodarone suspended in homologous plasma (19). Although similar studies with microelectrodes will be needed to establish the electrophysiological properties of the metabolite, our preliminary data on ECG changes suggest that the behavior of the metabolite is similar to that of the parent drug under acute conditions. However, this lack of the acute effect does not exclude the possibility that the accumulation of metabolite during chronic therapy may contribute significantly to the pharmacological and electrophysiological action of amiodarone. Thus, more definitive electrophysiological studies in rabbits treated chronically with amiodarone and its metabolite will be required to estimate the contribution of the metabolite to the observed pharmacological action of amiodarone during chronic administration.

In summary, both amiodarone and its major metabolite, the deethyl analogue, have similar serum kinetics after intravenous administration in rabbits and are rapidly taken up by the myocardium. Neither the parent drug nor its metabolite produces significant electrophysiological changes under acute conditions in concentrations that are therapeutically relevant. The data do not exclude the possibility that the metabolite exerts pharmacological effects that are similar to those of the parent compound during chronic dosing.

Analysis of Carprofen Dosage Forms and Drug Substance by High-Performance Liquid Chromatography

A. J. ROSS, M. D. DEL MAURO, H. K. SOKOLOFF, and D. L. CASEY ˣ

Received August 19, 1983, from the *Pharmaceutical Research Products Section, Quality Control Department, Hoffmann-La Roche, Inc., Nutley, NJ 07110.* Accepted for publication September 26, 1983.

Abstract □ A high-performance liquid chromatographic method for the analysis of carprofen in solid dosage forms and as the bulk drug substance was developed. The simple, accurate, reproducible, and stability-indicating method was shown to be applicable to drug substance and dosage form stability studies, as well as the quality control of carprofen dosage forms.

Keyphrases □ Carprofen—analysis of dosage forms and drug substances, HPLC □ HPLC—analysis of carprofen dosage forms and drug substance

Carprofen [(±)-6-chloro-α-methylcarbazole-2-acetic acid (I)], under development as a nonsteroidal anti-inflammatory agent (1–9), has been formulated as a solid oral dosage form. Analytical procedures for the analysis of carprofen in biological fluids have appeared in the literature (10–16). However, since carprofen is a relatively new drug entity, analytical procedures suitable for the analysis and control of carprofen drug substance and dosage forms have not appeared in the literature or the USP.

The purpose of this work was to provide specific, accurate, and reproducible liquid chromatographic (HPLC) methods which would be applicable to various quality control functions, *i.e.*, drug substance stability studies, potency and content uniformity assays of dosage forms, and dosage form stability studies. To satisfy these criteria, it was necessary to develop a method which would separate I from all known impurities and potential degradation products and separate the impurities and potential degradation products from each other.

Analysis of Carprofen Dosage Forms and Drug Substance by High-Performance Liquid Chromatography

A. J. ROSS, M. D. DEL MAURO, H. K. SOKOLOFF, and D. L. CASEY ˣ

Received August 19, 1983, from the *Pharmaceutical Research Products Section, Quality Control Department, Hoffmann-La Roche, Inc., Nutley, NJ 07110.* Accepted for publication September 26, 1983.

Abstract □ A high-performance liquid chromatographic method for the analysis of carprofen in solid dosage forms and as the bulk drug substance was developed. The simple, accurate, reproducible, and stability-indicating method was shown to be applicable to drug substance and dosage form stability studies, as well as the quality control of carprofen dosage forms.

Keyphrases □ Carprofen—analysis of dosage forms and drug substances, HPLC □ HPLC—analysis of carprofen dosage forms and drug substance

Carprofen [(±)-6-chloro-α-methylcarbazole-2-acetic acid (I)], under development as a nonsteroidal anti-inflammatory agent (1–9), has been formulated as a solid oral dosage form. Analytical procedures for the analysis of carprofen in biological fluids have appeared in the literature (10–16). However, since carprofen is a relatively new drug entity, analytical procedures suitable for the analysis and control of carprofen drug substance and dosage forms have not appeared in the literature or the USP.

The purpose of this work was to provide specific, accurate, and reproducible liquid chromatographic (HPLC) methods which would be applicable to various quality control functions, *i.e.*, drug substance stability studies, potency and content uniformity assays of dosage forms, and dosage form stability studies. To satisfy these criteria, it was necessary to develop a method which would separate I from all known impurities and potential degradation products and separate the impurities and potential degradation products from each other.

II: $R_1 = CH_3$, $R_2 = R_3 = CO_2C_2H_5$
III: $R_1 = CH_3$, $R_2 = CO_2C_2H_5$, $R_3 = H$
IV: $R_1 = CH_3$, $R_2 = OH$, $R_3 = H$
V: $R_1 = CH_3$, $R_2 = O$
VI: $R_1 = CH_3$, $R_2 = R_3 = H$

The dosage form assay procedure was designed to be amenable to either manual or automated injection. It was also designed so that quantification could be done either by a computer data acquisition system or by manual calculation of peak response.

EXPERIMENTAL SECTION

Materials—Benzophenone[1], anthraquinone[2], and glacial acetic acid[3] were all analytical reagent grade and were used as received. The methanol[4] and acetonitrile[4] used were distilled in glass. Water used in the preparation of mobile phases was doubly distilled.

Mobile Phase—The mobile phases used were prepared by mixing appropriately measured volumes of methanol and 1% acetic acid. The mobile phase selected for the assay was methanol-water (1% acetic acid) (65:35). All mobile phases were filtered before use.

Instrumentation—Portions of the present study were conducted with several different HPLC systems. The early developmental work on the dosage form assay was done with a constant-pressure single-piston pump[5], a fixed-loop injector[6], and a UV detector[7] set at 254 nm. The early developmental work on the drug substance stability assay was done with an HPLC system consisting of two constant-flow solvent-metering pumps[8], a solvent programmer[9], an injector[10], and an UV detector[11]. The major portion of the work was done with a 10-μm particle size octadecylsilane column[12]. Quantifications associated with developmental work on the dosage form assay were done with manual peak height measurements. Those associated with the drug substance stability study were done using peak area measurements obtained with an electronic integrator[13]. Subsequent to the earlier work, both dosage form and drug substance analyses were automated with an autosampler[14] and a more sophisticated computer data acquisition system[15].

Methods Development—Carprofen (I) and its known impurities (II and III) were chromatographed under various conditions until a suitable column–mobile phase combination was obtained that was capable of separating all compounds of interest. Samples from accelerated degradation studies were also chromatographed in this initial system to make certain that the system was also capable of separating potential degradation products. Compounds IV, V, and VI were isolated and identified as the major potential decomposition products[16]. These compounds were formed only under accelerated storage conditions. A study was also conducted in which the mobile phase composition was varied to determine the sensitivity of the separation to changes in mobile phase composition.

Dosage Form Assay Procedures—All solutions containing I were prepared by using low-actinic glassware and acetonitrile-water (50:50) as the diluent.

Internal Standard Solution—Benzophenone (380 mg) was accurately weighed into a 2-L volumetric flask and dissolved in 1 L of acetonitrile. Once dissolved, the resulting solution was diluted to volume with distilled water.

Standard Solution—Approximately 40 mg of carprofen reference standard was accurately weighed into a 100-mL volumetric flask. The standard was then dissolved and diluted to volume with the internal standard solution.

Sample Preparation for Potency Assay—Twenty tablets were combined and finely powdered with a mortar and pestle. From the composite, a tablet mass equivalent to 40 mg of I was accurately weighed into a 100-mL volumetric flask. The sample was dissolved in the internal standard solution by shaking for 15 min. After shaking, the sample was diluted to volume with the internal standard solution and filtered through a 5-μm filter[17].

System Suitability Test—Six injections of the standard solution were chromatographed, and the carprofen–internal standard response ratio was calculated for each injection. The system precision was considered to be adequate if the *RSD* for the six response ratio values did not exceed 1.5%.

The resolution factor (R^1) was calculated for the separation between the benzophenone and carprofen peaks according to the USP. The resolution was acceptable if R^1 was >3.5.

Potency Assay Procedure—The sample solutions were injected into the chromatograph using 20-μL injections. The carprofen content per tablet was then calculated by using the standard response ratio from the system suitability test, the respective peak heights in the sample chromatogram, the sample weight, and the appropriate dilution factor. Alternatively, peak areas obtained from a suitable computer system can be substituted for peak heights throughout the calculations.

Content Uniformity Sample Preparations—The same assay procedure as described above was applied to conduct content uniformity tests. For content uniformity measurements, the following sample preparation was substituted. One tablet was placed in each of ten 100-mL volumetric flasks. To each flask, 50 mL of the internal standard solution was added, and the flasks were shaken on a mechanical shaker for 1 h. Samples were then diluted to volume with internal standard solution and filtered as described above. Depending on the dosage strength, the samples were then appropriately diluted to obtain a final carprofen concentration of ~0.4 mg/mL. The final sample solutions were then chromatographed as described above, and the carprofen content per tablet was calculated.

Drug Substance Stability Assay Procedure—The same HPLC system was applied to drug substance stability testing. Several modifications in terms of sample preparation, amount of carprofen injected, and quantification techniques were necessary when the assay was to be used in bulk substance stability studies. For these assays, ~10 mg of carprofen was accurately weighed into a 10-mL volumetric flask, dissolved, and diluted to volume with the internal standard solution. Anthraquinone was used as an internal standard in some studies. During subsequent studies, it was discovered that use of benzophenone as an internal standard would shorten the analysis time. Either internal standard gave acceptable results. The carprofen concentration was determined by using an internal standard quantification technique, and the impurity and degradation product levels were estimated by using an area percent technique corrected for the presence of the internal standard in the chromatogram.

Validation—Both the dosage form assay and the drug substance stability assay were validated with respect to specificity, linearity, precision, and accuracy. The methods were also validated with both manual and automated

injection devices and by using both internal and external standard techniques.

RESULTS AND DISCUSSION

During preliminary methods development experiments, the carprofen peak exhibited marked tailing when chromatographed on a number of reverse-phase columns. This was believed to be due to partial ionization of the carboxylic acid function of the molecule in the mobile phase. Consequently, acetic acid was added to the mobile phase to suppress ionization and improve peak shape.

Since the intended purpose of the method was to supply a reliable and reproducible procedure suitable for assay, content uniformity, and stability studies, various columns and mobile phase compositions were carefully studied to achieve baseline resolution between carprofen, the internal standard, known impurities, and potential degradation products. The column[12] originally selected for the dosage form assay and used in the validation of the method was one that provided the desired separation within a reasonable analysis time and was commercially available at the time the method was developed. A chromatogram showing the separation between all possible components obtained with this column and the specified mobile phase composition is given in Fig. 1a. The sensitivity of that separation to variations in the mobile phase composition was studied with the same column (Fig. 1b–d). The data obtained were used to design an appropriate system suitability test for the dosage form assay. The separation most adversely affected by variations in mobile phase composition and most critical to the specificity of the dosage form assay is the separation between IV and carprofen (Fig. 1). Direct assurance of adequate separation between these two components could be obtained by specifying a minimum resolution factor between these two compounds in a system suitability test. However, this would require that all laboratories have access to a reference standard of IV. To make the method generally applicable for any laboratory and to eliminate the need for a reference standard of IV, an alternative approach was taken. The resolution factors R^1 (carprofen–internal standard) and R^2 (IV–carprofen) were obtained and plotted as a function of mobile phase composition (Fig. 2). For symmetrical peaks, minimum baseline resolution between two peaks should yield a resolution factor >1.0. By using the plot in Fig. 2, the appropriate resolution factor (R^1) which would simultaneously yield an R^2 value ≥ 1.0 was determined. The value for R^1 selected and included in the system suitability test was $R^1 \geq 3.5$. With the column specified, all mobile phase compositions which resulted in an R^1 value ≥ 3.5 also produced an R^2 value > 1.0 (Fig. 2). Therefore, by performing the system suitability test with the specified column and adjusting the mobile phase

composition to achieve a resolution factor $R^1 \geq 3.5$ between internal standard (commercially available) and carprofen, any laboratory can perform the assay and be assured of adequate resolution between all possible components.

The specificity of the method was examined in several ways. The method was shown to separate all known synthetic impurities. Solutions of carprofen subjected to accelerated degradation studies were chromatographed, and the method was shown to be capable of separating several potential degradation products. To establish the carprofen peak integrity in these accelerated degradation study chromatograms, several injections were made, and the carprofen peak was collected as it eluted from the column. After removal of the mobile phase under a stream of nitrogen followed by lyophilization, NMR analysis demonstrated that the peak assigned to carprofen appeared to be only one substance. The collected carprofen fractions also showed one spot on TLC.

The precision of the method was examined by repeating the entire assay procedure with several weighings of the same composite sample (Table I). The method was shown to be reproducible, with an *RSD* of 0.45%, by manual injection, manual peak height measurements, and the internal standard quantification technique. The system precision was evaluated by making several injections of the same standard solution. The *RSD* of the response ratios obtained was 0.31% (Table II). Subsequent to the initial validation, the method was automated. The system precision was examined using automated injection by both peak areas and peak height measurements and both internal standard and external standard quantification techniques (Table II). The system precision was acceptable by any of the quantification methods described above.

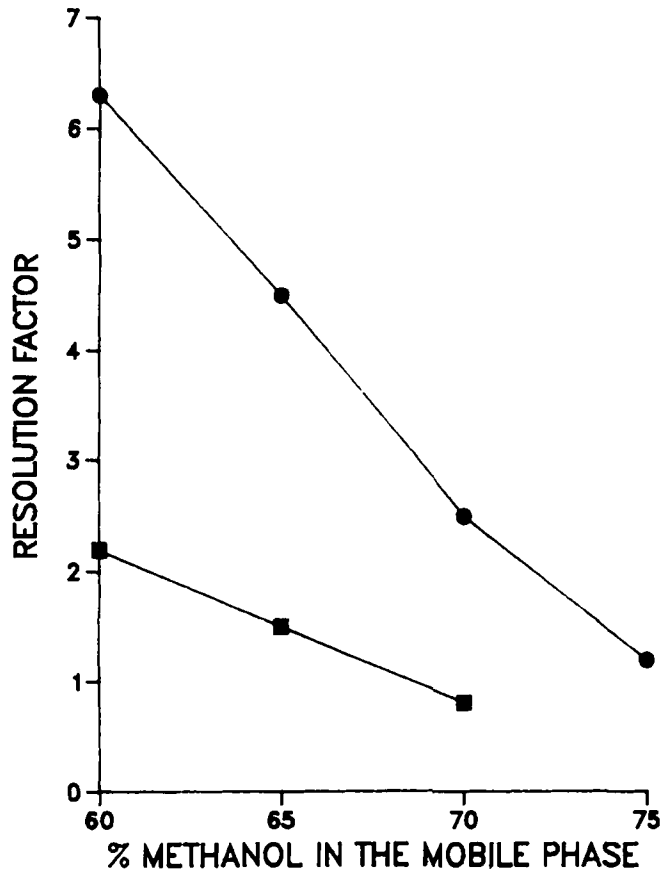

Figure 2—*Plot of resolution factors* versus *percent methanol in the mobile phase. Key: (●) resolution factor (R^1) between carprofen and internal standard; (■) resolution factor (R^2) between carprofen and IV.*

The linearity of the method was also studied. For the dosage form assay, samples containing carprofen concentrations spanning 50–150% of the expected working range were analyzed by the method. Plots of peak response ratios (carprofen–internal standard) *versus* carprofen concentration were generated. Similar plots were generated by using both peak heights (measured manually) and computer-calculated peak areas. The linearity of each plot was determined by using a computer program, LIN, to fit the observed data to a curve of the form $y = mx^n + b$. For perfect linearity, $n = 1.0$. The program also calculated the maximum error to be expected by the deviations from perfect linearity (17). When the observed data from the linearity plots was subjected to the LIN program, the value of n was between 0.95 and 1.0 in all cases. The maximum relative percent error due to nonlinearity over the assay range was also calculated by use of the LIN program and was found to be <0.3% in all cases.

The accuracy of the dosage form assay was also examined. Synthetic samples of carprofen tablets were prepared, covering 50–133% of the theoretical dosage range. The samples were prepared in such a way as to approach the average tablet weight of 365 mg. Appropriate weights of placebo tablet mass were mixed with known weights of carprofen spanning the range given above. These samples were analyzed by the described method. The recovery of carprofen from the tablet matrix is presented in Table III; the data show that excellent recoveries were obtained at all levels.

This HPLC system was also applied to drug substance stability testing, with several aforementioned modifications. For this application, emphasis was placed on the estimation of degradation products with reasonable accuracy, as well as quantification of intact carprofen in the stability study samples. Because of these joint objectives, the sample preparation was adjusted so that the concentration of carprofen in the sample injected was as high as possible without exceeding the linear range of the detector. This allowed accurate determination of the carprofen content and, at the same time, maximized the detector response for any impurities or degradation products present. For this purpose, a separate linearity study was conducted. The results show that carprofen concentrations as high as 2.0 mg/mL (20-μL injections) could be used while remaining within the linear range of the detector.

As mentioned above, various quantification techniques were studied for use with this method. The appropriate quantification technique depends both on the intended use of the method and on the instrumental and data acquisition systems available to the analytical laboratory.

Since the original developmental work on the dosage form assay was carried out by using manual injection and manual peak height measurements, it was believed that an internal standard quantification technique was appropriate. Since that time, state-of-the-art autosamplers and computer data acquisition systems have continually become more readily available. Because of this, the system precision of the dosage form assay was revalidated by other quantification techniques so that the assay procedure could be performed by any laboratory, regardless of the degree of sophistication of its automation and

Table III—Percent Recovery and Dosage Form Assay for Synthetic Tablet Mix

Placebo, mg	Carprofen, mg	Carprofen Found, mg	Recovery, %
340.35	26.08	27.02	103.6
314.90	49.80	50.26	100.9
264.45	101.45	101.88	100.4
214.70	150.36	145.92	97.0
165.42	203.25	203.93	100.3

data acquisition. The data with which the system precision of the dosage form analysis was compared by various quantification techniques is presented in Table II. The precision obtained by any of the quantification techniques was quite acceptable. Since external standard techniques require fewer calculations and are more convenient in terms of sample preparation, those laboratories in which automated equipment is used may select this as the preferred quantification technique.

Two different quantification techniques were used when the method was applied to drug substance stability studies. In such studies, the amount of carprofen in each sample was determined by using internal standard calculations similar to those used in the dosage form assay. However, the quantifications performed to estimate the impurity and degradation product levels were carried out by using an area percent calculation method corrected for the presence of the internal standard in the chromatogram. This technique has been found to be particularly useful when conducting drug substance stability studies on compounds in early phases of development. An underlying assumption with such a quantification technique is that potential degradation products and impurities have the same absorptivity as the parent compound at the chosen detector wavelength. Although this assumption may not always be valid, in many cases it is reasonable. It eliminates the need for reference standards of all impurities and degradation products, which are usually not available during the early stages of development. Considering this restriction, the technique described above is certainly acceptable for demonstrating stability trends. When reference materials become available, the data generated by using the area percent method can be refined or recalculated to take into account any differences in absorptivity. The area percent technique is also useful if an outside laboratory (without access to reference standards of potential impurities and degradation products) is conducting the assay.

The method described has been shown to be accurate, precise, and broadly applicable to all control and analysis laboratories and functions. The sample preparations are simple, and the method can easily be automated.

Development and Evaluation of Enteric-Coated Penicillamine Tablets

WALTER G. CHAMBLISS, DIANA A. CHAMBLISS, ROBERT W. CLEARY, ALAN B. JONES, ERNEST C. HARLAND, and ARTHUR H. KIBBE* ˣ

Received February 18, 1983, from the *Department of Pharmaceutics, University of Mississippi, University, MS 38677.* Accepted for publication September 26, 1983. * Present address: Chief, Pharmaceutical Development Services, Building 10, Room 1D37, Clinical Center, National Institutes of Health, Bethesda, MD 20205.

Abstract □ Commercially available 250-mg penicillamine tablets were converted into enteric-coated tablets. Based on *in vitro* dissolution and disintegration tests, tablets coated with five layers of a cellulose acetate phthalate formulation by a modified pan coating technique were judged to be superior to other coated tablets. These tablets resisted disintegration in simulated gastric fluid over a 4-h period and disintegrated in an average of 21 min in simulated intestinal fluid. Enteric-coated penicillamine tablets were tested *in vivo* in nine weanling pigs divided into three groups: a negative control group, a test group dosed with enteric-coated penicillamine tablets, and a positive control group dosed with uncoated tablets. The incidence of GI tract bleeding, as determined by daily occult blood tests of the stools, was significantly less in the animals receiving the enteric-coated tablets when compared with the positive control group. The enteric-coated dosage form appeared to decrease GI tract irritation caused by penicillamine. Plasma concentration–time curves for penicillamine in the pigs were similar in shape to those reported in humans. Atypical double peaks occur in both species. Relative bioavailability of the enteric-coated tablet was found to be 67% when compared with the uncoated tablet. This apparent reduction is probably due to a large intrasubject variation in areas under the plasma concentration–time curves and not to a dosage form effect.

Keyphrases □ Penicillamine—development and evaluation of enteric-coated tablets □ Formulations—penicillamine, development and evaluation of enteric-coated tablets

Penicillamine has been used for many years in the treatment of Wilson's disease and cystinuria. More recently, the drug has been approved for the treatment of rheumatoid arthritis. Due to severe adverse reactions, penicillamine therapy in the arthritic patient is normally limited to those who have been previously treated unsuccessfully by conventional therapy (1).

It has been estimated that up to one-third of the patients

Development and Evaluation of Enteric-Coated Penicillamine Tablets

WALTER G. CHAMBLISS, DIANA A. CHAMBLISS, ROBERT W. CLEARY, ALAN B. JONES, ERNEST C. HARLAND, and ARTHUR H. KIBBE* ˣ

Received February 18, 1983, from the *Department of Pharmaceutics, University of Mississippi, University, MS 38677.* Accepted for publication September 26, 1983. * Present address: Chief, Pharmaceutical Development Services, Building 10, Room 1D37, Clinical Center, National Institutes of Health, Bethesda, MD 20205.

Abstract □ Commercially available 250-mg penicillamine tablets were converted into enteric-coated tablets. Based on *in vitro* dissolution and disintegration tests, tablets coated with five layers of a cellulose acetate phthalate formulation by a modified pan coating technique were judged to be superior to other coated tablets. These tablets resisted disintegration in simulated gastric fluid over a 4-h period and disintegrated in an average of 21 min in simulated intestinal fluid. Enteric-coated penicillamine tablets were tested *in vivo* in nine weanling pigs divided into three groups: a negative control group, a test group dosed with enteric-coated penicillamine tablets, and a positive control group dosed with uncoated tablets. The incidence of GI tract bleeding, as determined by daily occult blood tests of the stools, was significantly less in the animals receiving the enteric-coated tablets when compared with the positive control group. The enteric-coated dosage form appeared to decrease GI tract irritation caused by penicillamine. Plasma concentration–time curves for penicillamine in the pigs were similar in shape to those reported in humans. Atypical double peaks occur in both species. Relative bioavailability of the enteric-coated tablet was found to be 67% when compared with the uncoated tablet. This apparent reduction is probably due to a large intrasubject variation in areas under the plasma concentration–time curves and not to a dosage form effect.

Keyphrases □ Penicillamine—development and evaluation of enteric-coated tablets □ Formulations—penicillamine, development and evaluation of enteric-coated tablets

Penicillamine has been used for many years in the treatment of Wilson's disease and cystinuria. More recently, the drug has been approved for the treatment of rheumatoid arthritis. Due to severe adverse reactions, penicillamine therapy in the arthritic patient is normally limited to those who have been previously treated unsuccessfully by conventional therapy (1).

It has been estimated that up to one-third of the patients

treated orally with penicillamine must discontinue use because of adverse reactions such as gastric distress (2). Gastric upset, which is normally decreased by coadministering food or antacids with the drug, is not possible in this case because the drug chelates magnesium, calcium, and iron (1). In previous work, it has been shown that plasma levels of the unchanged drug are reduced in humans when penicillamine is given with a meal (3).

Enteric-coated dosage forms release drugs in the intestine and have been shown to decrease gastric irritation (4). In this study, an enteric-coated penicillamine tablet is described, and this dosage form is evaluated *in vitro* and *in vivo* in weanling pigs.

EXPERIMENTAL SECTION

Materials– Penicillamine tablets[1], cellulose acetate phthalate[2], and polyvinyl acetate phthalate[3] were obtained commercially. Simulated gastric and intestinal fluids were made as directed in USP XX (5).

Coating Methods– *Dip Coating*—The capsule-shaped tablet was held at one end with tweezers and dipped a little over one-half way into 50 mL of 10% w/w cellulose acetate phthalate in acetone. The tablet was withdrawn after 10 s, and its free end was touched to the lip of the beaker to remove excess solution. The tablet was held in the air for 2 min to dry. The procedure was repeated until both halves of the tablet were coated three times. Twenty tablets were coated by this procedure. The tablets were placed in an evaporating dish and dried at 50°C for 16 h.

Pan Coating—A 15-cm diameter stainless steel coating pan was used. Two aluminum baffles were mounted in the pan to promote a smooth tumbling action of the tablets. The 11.4 × 0.64-cm baffles extended from the inside of the pan rim to 3.8 cm from the bottom center. They were equally spaced, 180° apart. The baffles were bent to fit the curvature of the pan and sloped in the direction of the pan rotation. The pan was rotated at 32 rpm.

5 coats	0.007	>60 (*d*)	13
10 coats	0.010	>60 (*c*)	16
15 coats	0.013	>60 (*c*)	17
20 coats	0.018	>60 (*b*)	21
25 coats	0.023	>60 (*b*)	14
30 coats	0.030	>60 (*a*)	18

[a] $n = 6$. [b] Key: (*a*), no damage to coat; (*b*), some softening of coat and slight pitting; (*c*), obvious coat damage, deep pits; (*d*), partial tablet core disintegration.

Table I contains the two formulations that were applied to the tablets by the pan coating procedure. The cellulose acetate phthalate formulations (200 g) were prepared by mixing 95.0 mL of ethyl acetate and 180.6 mL of isopropyl alcohol in a 600-mL beaker. The solution was vigorously stirred with a magnetic stirrer, and 24.0 g of cellulose acetate phthalate was dissolved in the solution followed by the addition of 2.7 mL of diethyl phthalate; the solution was continuously stirred for 20 min.

The polyvinyl acetate phthalate formulation was prepared by slowly adding 10.0 g of polyvinyl acetate phthalate to 75.0 mL of methanol over a 15-min period. The solution was vigorously stirred with a magnetic stirrer. After the polyvinyl acetate phthalate was added, 0.9 mL of polyethylene glycol 400 was added, and the solution was stirred for 10 min. The weight of the solution was adjusted to 100.0 g by the addition of methanol. The solution was stirred for an additional 10 min.

A typical batch of 90 tablets was placed in a 1000-mL beaker, and 3 mL of the formulation was added. The tablets were stirred by hand for 1 min and then transferred to the pan. The pan was rotated for 10 min at 32 rpm. The tablets were stirred by hand during the first 2 min of rotation to prevent clumping. When the coat was dry, the tablets were returned to the 1000-mL beaker. The procedure was repeated until the required number of coats were applied. After receiving the final coating, the tablets were placed on a drying tray in a 50°C oven for 16 h. The number of coats used were 5, 7, and 10 for the cellulose acetate phthalate formulation and 5, 10, 15, 20, 25, and 30 for the polyvinyl acetate phthalate formulation.

***In Vitro* Tests of Enteric-Coated Tablets**—*Uniformity Test*—Tablets from each batch were visually inspected for uniformity in appearance, smoothness of coat, and absence of cracks. Twenty tablets in each batch were individually weighed, and the mean weight and *SD* were determined.

A micrometer was used to determine the average length, width, and thickness of the 20 tablets from each batch. The mean thickness of the enteric coat was calculated by:

$$\text{Coat Thickness} = \frac{(L_c - L_n) + (W_c - W_n) + (T_c - T_n)}{(2) \cdot (3)}$$

where L_c is the length of coated tablet, W_c is the width of coated tablet, T_c is the thickness of coated tablet, L_n is the length of uncoated tablet, W_n is the width of uncoated tablet, and, T_n is the thickness of uncoated tablet. The numerator of the equation sums the differences between the coated and uncoated tablets in three dimensions (length, width, and thickness). The denominator contains two correction factors: the three dimensions and the two sides of the tablet contained in each measurement.

Disintegration Test—The USP XX (6) disintegration test for enteric-coated tablets was used to evaluate the penicillamine tablets coated by either the dip coating or pan coating procedure. A standard six-tube basket-rack assembly[4] was used for all the determinations. After 1 h of operation using simulated gastric fluid as the disintegration fluid, the basket was lifted from the fluid, and the tablets were inspected for signs of disintegration, cracking, or softening. The condition of the coated tablets was rated by the following scale: (*a*) no obvious damage, (*b*) some softening of the coat and slight pitting, (*c*) obvious coat damage, deep pits, (*d*) partial tablet core disintegration, and (*e*) total tablet disintegration. The medium was then changed to simulated

intestinal fluid and disks were added to each tube. The disintegration time for each of the six tablets was noted to the nearest minute.

Dissolution Test—A USP rotating-basket dissolution apparatus[5] was used for all dissolution studies. A single enteric-coated or uncoated tablet was placed into the 40-mesh basket and lowered into the specified medium such that the basket was 2.0 cm from the bottom of the vessel. The basket was rotated at 100 rpm. Each dissolution test was run in triplicate.

Three dissolution media were used. A pH 1.2 solution (0.063 M HCl) was used to simulate gastric fluid. A pH 6.0 sodium phosphate buffer was used to simulate intestinal fluid in the duodenum. A pH 8.0 sodium phosphate buffer was used to simulate intestinal fluid with a pH in the upper range.

A colorimetric assay developed by Mann and Mitchell (7) was used to quantitate penicillamine in the dissolution medium. The absorbance was determined at 412 nm with a spectrophotometer[6]. The amount of penicillamine contained in the sample was determined from a standard curve prepared for penicillamine in each of the dissolution solutions. A linear relationship held over the concentration range tested.

Stability of the Enteric Coat—The effect of storage at different temperatures on the enteric-coated tablet was investigated. Enteric-coated tablets with five layers of the cellulose acetate phthalate formulation, prepared by the pan coating procedure, were stored and tested along with uncoated tablets so that changes in the tablet core could be determined. Samples of each tablet were stored in ~118-mL amber glass prescription bottles at 4°C, 25°C, 37°C, or 50°C. Eighteen tablets were removed from each bottle at various times during a 75-d period for testing.

The USP disintegration test for enteric-coated tablets was performed on six tablets from the enteric-coated group at each sampling period. The tablets were inspected for signs of disintegration, cracking, or softening after 1 h in simulated gastric fluid. The disintegration time in simulated intestinal fluid was then noted to the nearest minute. The disintegration time of six uncoated tablets in simulated intestinal fluid was determined to the nearest minute.

The procedure described above was used to test the dissolution of the coated and noncoated tablets at pH 1.2 and 6.0. Samples were removed at 0, 10, 20, and 30 min from the pH 6.0 solution and at 0, 30, and 60 min from the pH 1.2 solution. The concentration of penicillamine in each dissolution medium was determined by colorimetry, as described above. Each test was performed on three tablets.

Experimental Animals—Nine disease-free, acclimated, Yorkshire pigs (5–8 weeks old) were randomly divided into three groups by using color-coded tags. Control pigs, pigs receiving uncoated penicillamine tablets, and pigs receiving enteric-coated penicillamine tablets were housed in separate pens and fed ~2.2 kg of commercial hog feed daily. Food was offered for at least 4 h after dosing and was removed at least 12 h before the next dose was given. Each pen was equipped with an automatic watering device which allowed water *ad libitum*.

A dosing syringe was designed to administer the tablets to the pigs. The device consisted of a 26.6-cm flexible plastic tube (0.7 cm i.d. and 1.1 cm o.d.), with a 31-cm, flexible polytef rod (0.6-cm diameter) which was inserted into the tube and used as a plunger. The entire apparatus was bent to promote insertion past the throat of the pig. Before dosing, the plunger and the outside of the tube were coated with a water-soluble lubricant. The penicillamine tablet was placed into the end of the dosing syringe, and the tube was inserted 10–15 cm down the esophagus of the pig, where the tablet was injected. Each pig received several milliliters of 50% w/v sucrose solution before dosing; the mouth was flushed with the sucrose solution after dosing, and a small slice of apple was then given to decrease the incidence of tablet regurgitation. Another tablet was administered if the first one was rejected.

[5] Erweka Dissolution apparatus (type DT); Chemical and Pharmaceutical Industry Co.

[6] Spectronic 20 colorimeter/spectrophotometer; Bausch and Lomb.

The control pigs were treated in an identical fashion except that no tablet was loaded into the dosing apparatus. Dosing occurred daily for a period of 2 months.

Bioavailability Study—The study was conducted on 2 d, 1 week apart. On the first day, one animal from each treatment group was used. The other pigs were dosed as usual for an additional week and then used in the study.

Each animal received an appropriate 250-mg penicillamine tablet (uncoated or enteric coated) and was prepared for surgery immediately after dosing. A catheter was surgically placed in the jugular vein such that the tip was in the anterior vena cava; the catheter was exteriorized behind the base of the ear and attached to a 15-gauge needle, which was taped to the neck to allow access.

Blood samples were obtained at 0.5-h intervals for 12 h. The catheter was aspirated until fresh blood entered the syringe. One milliliter of blood was collected with a fresh 3-mL syringe containing 100 U of heparin, and the catheter was flushed with 2–3 mL of heparinized saline (100 U/mL). The blood was centrifuged at 500×*g* for 10 min. Plasma (500 μL) was transferred to another centrifuge tube, 100 μL of 20% w/v trichloroacetic acid was added, and the contents of the tube were gently mixed. The sample was centrifuged at 500×*g* for an additional 10 min. The protein-free supernatant was decanted and stored at 20°C until assayed; all samples were analyzed within 7 d.

A procedure developed by Bergstrom *et al.* (8) to assay penicillamine in

plasma with a liquid chromatograph[7], which was equipped with a cation-exchange analytical column[8] and an electrochemical detector[9], was used. The detector consisted of a thin-layer electrochemical cell[10] containing a mercury-gold amalgam working electrode, a glassy carbon auxiliary electrode, and a silver-silver chloride reference electrode. The potential of the working electrode was set at +0.1 V *versus* the reference electrode. The range on the detector was varied from 5 to 20 nA, depending on the sample concentration. The mobile phase consisted of a 0.035 M citric acid–0.005 M disodium phosphate buffer. The buffer was filtered and deaerated before use. Penicillamine has an average retention time of 3.34 min at a flow rate of 2 mL/min.

A standard curve of peak height ratios, prepared with plasma samples obtained from the control animals, was linear. The plasma samples were treated as described above. One previously prepared standard was analyzed with each set of samples. A total of 20 μL of the standard was injected into the liquid chromatograph approximately every 0.5 h during sample analysis. The peak height of an unknown plasma sample was then compared with the average peak height of the standards injected before and after the sample. Duplicate 20-μL injections of each unknown plasma samples were made.

Occult Blood Tests—Stool samples were collected from each pen daily before drug administration. The stool samples were tested for occult blood with a commercially available kit[11]. The incidence of positive tests after 55 d of dosing was determined for each group.

Tissue Sample Collection—Immediately after sacrificing the animals, tissue sections were removed from the GI tract, including glandular and nonglandular stomach, duodenum, jejunum, colon, and a mesenteric lymph node. The tissues were preserved in buffered formalin, embedded in paraffin, sectioned, and mounted on slides. The slides were stained with hematoxylin and eosin for routine histological examination.

RESULTS AND DISCUSSION

Coating Method— Two methods of coating the penicillamine tablets were investigated. The dip coating procedure was slow and tedious, requiring approximately 2 h to coat 20 tablets. Although the coating solution overlapped at the center of the tablets, causing a nonuniform coat, these tablets performed well in the USP disintegration test. No damage to the coat was apparent after 1 h of testing in simulated gastric fluid, and six tablets disintegrated in an average of 20 min in simulated intestinal fluid.

The pan coating procedure provided an excellent method of coating the tablets. The procedure was easy and quick; it produced tablets with uniform coats and proved to be the method of choice.

Evaluation of Coated Tablets—The enteric-coated tablets prepared in this study were judged on ease of preparation, appearance, uniformity, and performance in disintegration and dissolution tests. Tablets coated with polyvinyl acetate phthalate and cellulose acetate phthalate by a pan coating procedure were evaluated.

The polyvinyl acetate phthalate formulation was much more difficult to work with than the cellulose acetate phthalate formulation. Polyvinyl acetate phthalate solutions are tacky and are more suited to a spray coating procedure. Tablets pan-coated with this formulation tended to clump together and to stick to the side of the pan. Tablet sticking can normally be controlled by the use of a dusting powder. Penicillamine, however, chelates with magnesium, calcium, and aluminum, which eliminates the possibility of using common dusting powders, such as magnesium stearate and talc. Tablets coated with cellulose acetate phthalate had clean coats with a high gloss. Due to the tackiness of polyvinyl acetate phthalate, the tablets coated with this polymer were not smooth.

Both formulations provided coated tablets of uniform size and weight. The average dimensions of 20 tablets from each batch had <1% variation in any dimension. The thickness of the coat increased with increasing number of coats.

The results of the disintegration tests are given in Table II. All of the enteric-coated tablets resisted disintegration in gastric fluid after 1 h of testing. Cellulose acetate phthalate coating was thicker than polyvinyl acetate phthalate for the same number of coats.

The condition of the coated tablets, as indicated by the alphabetical rating (Table II), varied with the polymer used for coating and the number of coats. Thirty coats of the polyvinyl acetate phthalate formulation were required to provide complete protection to the tablet. Only seven coats of the cellulose acetate phthalate formulation were required. The tablets with five coats of cellulose acetate phthalate showed some signs of coat softening after 1 h in the gastric fluid. Tablet core disintegration, however, did not occur in this group after testing for 4 h in the gastric fluid. All batches had an average disintegration time in intestinal fluid of ≤22 min. There appeared to be no relationship between the number of coats and disintegration times.

The following criteria were established to help in the selection of the best coating material and the ideal number of coats based on dissolution testing:

1. Less than 10% of the drug should be released after 4 h at pH 1.2.
2. The enteric coat should not alter dissolution of the tablet at pH 6.0. There should be no significant difference in percent remaining in the uncoated or enteric-coated tablets at selected sampling times.
3. The enteric coat should not alter dissolution of the tablet at pH 8.0. There should be no significant difference in percent remaining in the uncoated or enteric-coated tablets at selected sampling times.

The dissolution profiles for the uncoated tablets and five batches of enteric-coated tablets at pH 1.2 are given in Table III. All of the coated formulations, except for polyvinyl acetate phthalate with 25 coats, retained ≥90% of the drug in the dosage form after 4 h of dissolution testing at pH 1.2. Less than 40% of the drug remained in the uncoated tablets after 30 min of testing.

A *t* test ($p = 0.001$) was used to determine whether criteria 2 and 3 were met by any of the formulations. The results of the analysis for pH 6.0 and pH 8.0 are given in Tables IV and V, respectively. Differences between the groups were more evident with the pH 6.0 buffer. Only tablets coated with five layers of cellulose acetate phthalate showed no difference at each sampling time when compared with the uncoated tablet group. By using the pH 8.0 buffer, only the 5-min sample of tablets coated with 30 coats of polyvinyl acetate phthalate differed from the uncoated group.

Table VII—Relationship Between Animal Weight and t_{max}

Animal	Weight, kg	C_{max}, μg/mL	t_{max}, h
C26	24.0	10.18	2.0
B23	29.0	16.46	1.5
C28	19.8	12.55	4.0
B24	18.5	11.84	3.0

Selection of the Best Coat—In general, the formulation containing cellulose acetate phthalate was more suited to the pan coating procedure than was the formulation which contained polyvinyl acetate phthalate. The tablets coated with cellulose acetate phthalate did not stick together and required fewer applications. Tablets coated with 5 layers of this formulation were judged to be better than tablets coated with 7 or 10 coats. Five applications prevented disintegration after 4 h of testing in simulated gastric fluid, although some damage occurred after 1 h. This batch of tablets was the only one to meet the specifications set for the dissolution study. The addition of two more layers improved the performance in the disintegration test but drastically altered dissolution at pH 6.0.

Stability of the Coat—Disintegration and dissolution tests were used to determine whether storage at different temperatures altered the release of drug from uncoated and enteric-coated penicillamine tablets. All enteric-coated tablets resisted disintegration in simulated gastric fluid after 1 h of testing. The degree of coat damage during the disintegration test varied from no obvious damage to some softening of the coat. There was no relationship between temperature or storage time and the amount of coat damage.

Storage had no effect on the disintegration time of enteric-coated tablets in intestinal fluid (Table VI). These results compare favorably with those reported previously by Luce (9). In that study, tablets coated with cellulose acetate phthalate showed no change in disintegration time after storage at room temperature for 1 year.

No changes in dissolution of the uncoated or enteric-coated tablets was seen at pH 1.2. Changes did occur in the dissolution of both the coated and uncoated tablets at pH 6. As shown by a typical profile (Fig. 1), the changes in dissolution were random. No relationship could be established between storage time or temperature. The apparent changes in dissolution could not be attributed to the presence of the enteric coat.

Plasma Concentrations—The plasma concentration-time curves for four animals are shown in Fig. 2. Data from one animal in each group were not included because the samples were not assayed until 10 d after collection, and degradation of the samples was suspected.

The curves show atypical double peaks. Similarly shaped curves have been reported after oral administration of penicillamine in a mongrel dog (10) and in normal human subjects (3). The multiple peaks did not occur after intravenous administration of the drug in the dog (10) or when given with food in humans (3). Double peaks after oral administration of cimetidine (11) and phenytoin (12) have also been reported in the literature. Explanations for these types of curves have included a GI transit-time effect (3) and an enterohepatic cyclic-process effect (11).

Examination of the plasma concentration-time curves (Fig. 2) reveals two types of curves, which differ in the size and location of the double peaks. The curve shape was independent of the type of tablet administered. Although the number of subjects was low, it appears that the shape may be related to the weight of the animal. In Table VII, the relationship between animal weight and the time (t_{max}) to reach the maximum plasma concentration (C_{max}) is shown. The lag time seen in the group receiving the enteric-coated tablet group was ~1 h.

The same two types of plasma concentration-time curves have been observed by Bergstrom *et al.* (3) and appear to be related to the weight of the subject. The areas under the plasma concentration-time curves (AUC) from 0 to 6 h were calculated by the trapezoidal rule. The average AUC from pigs that received enteric-coated tablets was compared with the average AUC from pigs that received uncoated tablets. Since the drug was not given on a milligram per kilogram basis, each AUC was normalized to a body weight of 24.0 kg. Both the calculated and normalized AUC values are given in Table VIII.

The mean, normalized, AUC for animals that received uncoated tablets was 27.61 mg·h/mL, as compared with 18.36 μg·h/mL for the animals that received enteric-coated tablets. The relative bioavailability of the enteric-coated tablet as compared with the uncoated tablet was 66.5%. The overall difference in AUC between the two groups was due primarily to the large difference between animals C26 and B23. A study with a larger number of subjects and a crossover design would be necessary to determine whether the bioavailability is reduced by the enteric formulation.

Table VIII—AUC from Pigs Receiving Either Uncoated or Enteric-Coated Penicillamine Tablets

Animal	AUC, μg·h/mL	Weight, kg	Normalized AUC, μg·h/mL
B23	26.95	29.0	32.56
B24	29.40	18.5	22.67
C26	16.15	24.0	16.15
C28	24.93	19.8	20.57

Occult Blood Tests—Stool specimens from each group of pigs were checked for occult blood daily for 55 d. The incidence of positive tests in the control group was 13%. Pigs receiving uncoated penicillamine tablets had positive tests on 44% of the days. The group receiving enteric-coated penicillamine tablets had 24% positive tests. An outbreak of vibrionic dysentery during the middle of the study was probably responsible for some of the positive tests. The *Vibrio coli* organism can cause bleeding from the GI tract (13). If the 21 d in which the animals were treated for dysentery are omitted, the percentage of positive tests for the control group, animals receiving uncoated tablets, and animals receiving enteric-coated tablets become 5.8, 35.3, and 11.8%, respectively. The incidence of blood in the stool of the group receiving uncoated tablets was significantly higher using either set of data. It appears, therefore, that less GI bleeding occurred in the pigs which were given enteric-coated penicillamine tablets than those given the uncoated tablets.

Tissue Analysis—No significant mucosal damage was noted in any of the groups.

Pharmacokinetics of Mitomycin C in Dogs: Application of a High-Performance Liquid Chromatographic Assay

R. H. BARBHAIYA ˣ, E. A. PAPP, D. R. VAN HARKEN, and R. D. SMYTH

Received April 11, 1983, from the *Metabolism and Pharmacokinetics Department, Pharmaceutical Research and Development Division, Bristol-Myers Co., Syracuse, NY 13201.* Accepted for publication September 4, 1983.

Abstract □ A normal-phase high-performance liquid chromatographic (HPLC) assay was developed for the determination of mitomycin C in plasma and urine. The method involves extraction of mitomycin C from plasma or urine into ethyl acetate-2-propanol-chloroform (70:15:15) with UV detection at 365 nm. Quantitation was performed with an internal standard (porfiromycin) by the peak height ratio method. Excellent correlation was obtained between the HPLC assay and the established microbiological cup-plate bioassay. The pharmacokinetics of mitomycin C were investigated in beagle dogs following a 1-mg/kg iv (22-mg/m^2) bolus dose. The plasma mitomycin C concentration *versus* time data were analyzed by using an open three-compartment model. The average volume of distribution was 1.90 L or 17% of body weight for the central compartment and 7.7 L or 68% of body weight for the terminal elimination phase. The volumes of distribution at steady state, calculated by model-dependent and -independent methods, compared very well with each other and were 6.5 L or 58% of body weight. Total body clearance averaged 112 mL/min, and the mean terminal plasma half-life was 53 min. The 0–24-h urinary excretion of intact mitomycin C accounted for 19% of the dose. The terminal half-life and percent urinary recovery of mitomycin C in dogs is similar to that in humans. Based on these observations, the dog appears to be a good model for studying the disposition of mitomycin C.

Keyphrases □ Mitomycin C—pharmacokinetics in dogs, HPLC □ Pharmacokinetics—mitomycin C in dogs, HPLC

Mitomycin C, an anticancer antibiotic, was first introduced for clinical trials in the United States over two decades ago, but its use was limited due to bone marrow toxicity. The development of high-dosage, intermittent schedules and its use in combination with other anticancer agents has improved the therapeutic index of mitomycin C against a variety of tumors (1–3). The therapeutic index and toxicity are reported to be dependent on dose and schedule (4).

The pharmacokinetics of mitomycin C in animals and humans have not been fully described, mainly due to the lack of a sensitive and specific assay. Preliminary pharmacokinetics of mitomycin C have been reported in humans (5, 6) and rabbits (6). Recently, assay methodologies involving high-performance liquid chromatography (HPLC) (6, 7) and enzyme immunoassay (8) have been described for the determination of mitomycin C in serum.

The HPLC assays utilize reverse-phase columns with UV detection at 365 nm. One of the HPLC assays (7) has a sensitivity of 40 ng/mL in plasma, making it unsuitable for pharmacokinetic studies. In addition, the assay involves acidification of plasma prior to the extraction of mitomycin C into ethyl acetate. As mitomycin C is unstable in acidic and basic solutions (5, 9, 10), it may degrade before being extracted. A modified, stability-indicating HPLC assay involving extraction of mitomycin C at neutral pH in plasma has been reported (5). The disadvantage of this method relates to the fact that no internal standard is used in the assay. In a third HPLC assay (6), a nonionic exchange resin column is utilized for the extraction of mitomycin C and the internal standard. The assay has a sensitivity of ~5–10 ng/mL; however, it is expensive to run on a routine basis because of the cost of the resin columns. The enzyme immunoassay (8) may lack the necessary specificity for pharmacokinetic studies.

In the present study, a normal-phase HPLC assay for mitomycin C in plasma and urine was developed, compared with an established microbiological cup-plate assay (11), and applied to a study of the pharmacokinetics of mitomycin C after intravenous bolus administration in beagle dogs.

EXPERIMENTAL SECTION

Reagents—Mitomycin C[1], porfiromycin[2], tetrahydrofuran[3], dichloromethane[4] (glass distilled), ethyl acetate[3] (glass distilled), isooctane[5] (pesticide grade), 2-propanol[4] (glass distilled), methanol[5] (certified ACS), and chloroform[4] (glass distilled) were used as received from the suppliers.

Animals—Three healthy female beagle dogs (weight, 10.7–12 kg) were used in the study. Each dog was restrained in a sling; the urinary bladder was catheterized, and indwelling venous catheters were placed in the saphenous veins of both hind legs.

Dose Preparation and Administration—To each vial[6], containing 20 mg of mitomycin C and 40 mg of mannitol, was added 40 mL of sterile distilled water. The vials were gently shaken until a clear solution of mitomycin C was obtained. A 1-mg/kg dose was administered by a rapid bolus (1-min) injection through a saphenous vein catheter.

Sample Collection—Samples of venous blood (8 mL) were collected in heparinized tubes just before dosing and at 2, 5, 10, 15, 20, 30, and 45 min, and 1, 1.5, 2, 3, 4, 5, 6, and 7 h after drug administration. A venous catheter placed contralaterally to the one used for intravenous administration of the drug was used for all blood collections. Blood samples were centrifuged immediately after collection, and the plasma was separated and stored at −20°C. Urine samples were collected in a graduated cylinder and immersed in crushed ice before dosing and 1, 3, 5, 7, and 24 h after dosing. After each collection interval, the volume of urine was recorded, and 10 mL of urine was stored at −20°C.

Extraction of Mitomycin C from Plasma and Urine—The extraction solvent consisted of ethyl acetate-2-propanol-chloroform (70:15:15). The reconstitution solvent was chloroform-methanol (9:1). The internal standard was 1000-ng of porfiromycin/mL in methanol.

Plasma (2 mL) or urine (0.2 mL), 1.0 mL of distilled water, 7.0 mL of the extraction solvent, and 0.1 mL of the internal standard solution were transferred into a 16 × 125-mm screw-capped tube. The tube was capped with a polytef-lined screw cap and gently rotated[7] for 20 min. The tube was centrifuged[8] at 3000 rpm for 10 min and the upper organic phase was transferred into a clean 16 × 125-mm tube. The solvent was evaporated to dryness under nitrogen. The residue was dissolved in 50 μL of the reconstitution solvent, and 25 μL was injected on the liquid chromatograph.

Chromatography—The HPLC system was the same for mitomycin plasma and urine assays and consisted of a solvent pump[9], an injector[10], a 10-μm particle size normal-phase silica column[11], a fixed-wavelength UV detector[12]

with a 365-nm filter, and a guard column[13]. The mobile phase consisted of tetrahydrofuran-methanol-isooctane-dichloromethane (3:7:15:75). The solvent flow rate was maintained at 1.0 mL/min. HPLC analysis was performed at ambient temperature.

Data Processing—The peak heights were measured manually or with an automated laboratory data system[14], and the ratio of the mitomycin C to porfiromycin peaks for each chromatogram was calculated. After each series of injections, the regression of peak height ratio *versus* concentration of mitomycin C standard was calculated by least-squares analysis, and the concentration of mitomycin C in each plasma or urine sample was estimated by inverse prediction.

Comparison with Bioassay—Samples of plasma and urine from dogs have also been assayed by a cup-plate bioassay (11), with *Escherichia coli B* A22636 as the test organism. The assay was sensitive to 10 ng/mL of mitomycin C on plasma or urine.

Pharmacokinetic Calculations—After intravenous administration, unchanged mitomycin C concentration-time curves showed a triexponential decay on a semilogarithmic graph. Thus, an open three-compartment model, with elimination occurring from the central compartment, was proposed to describe mitomycin C kinetics (Scheme I).

The data were fitted according to:

$$C_p = Pe^{-\pi t} + Ae^{-\alpha t} + Be^{-\beta t} \qquad \text{(Eq. 1)}$$

where C_p is the concentration of mitomycin C in plasma at time t; π, α, and β are the exponential coefficients during the three phases; and P, A, and B are the concentrations of the exponential terms at time zero. Estimates of these parameters were first obtained by standard graphical analysis and then by computer program P-AUTOAN which is a combination of the programs

CSTRIP (12) and GUESS (13). For computer analysis, all plasma level data were squared, weighted according to their reciprocals, and fitted to mono-, bi-, tri-, and tetraexponential equations. The model equation with Akaike's minimum information criterion (14) was chosen as the best representation for the time course data. The values obtained for each parameter were then used to calculate other kinetic parameters, such as intercompartment rate constants (k_{12}, k_{21}, k_{13}, and k_{31}), the overall elimination rate constant (k_{el}), terminal elimination phase and central compartment volumes of distribution (Vd_β and V_c, respectively), and total (CL_{tot}) and renal (CL_r) clearances, using conventional methods (15). The steady-state volume of distribution (Vd_{ss}) was calculated by model-dependent (16) and -independent (17) equations (Eqs. 2 and 3, respectively):

$$Vd_{ss} = (1 + k_{12}/k_{21} + k_{13}/k_{31})V_c \qquad \text{(Eq. 2)}$$

$$Vd_{ss} = \frac{\text{Dose} \cdot \left(\int_0^\infty t\, C_p dt\right)}{\left(\int_0^\infty C_p dt\right)^2} \qquad \text{(Eq. 3)}$$

The areas under the plasma concentration-time curves (AUC) were calculated by the trapezoidal rule with extrapolation to infinite time.

RESULTS AND DISCUSSION

Assay—Mitomycin C and the internal standard (porfiromycin) can be readily extracted into organic solvent from plasma and urine at neutral pH. As mitomycin C and porfiromycin are very stable at neutral pH and are subjected to rapid decomposition in acid and base (5, 9, 10), extraction was carried out at neutral pH. The extraction efficiency of mitomycin C and the internal standard in plasma and urine was not significantly affected between pH 7.0 and 7.9 and was >90% with a phase volume ratio of plasma extractant of at least 1:3.5. The normal-phase chromatographic procedure was developed to separate mitomycin C from endogenous plasma and urine components, the internal standard, and possible metabolite(s). A mobile phase consisting of ethyl acetate–2-propanol–chloroform (70:15:15) was found to be most suitable for the selective determination of mitomycin C in plasma and urine. Mitomycin C has maximum UV absorbance at 365 nm (5); detection at 254 nm resulted in decreased sensitivity and increased interference at or near the mitomycin C or porfiromycin peaks. A 365-nm UV filter was therefore selected for the optimum sensitivity and specificity.

Typical chromatograms obtained from blank plasma samples and from

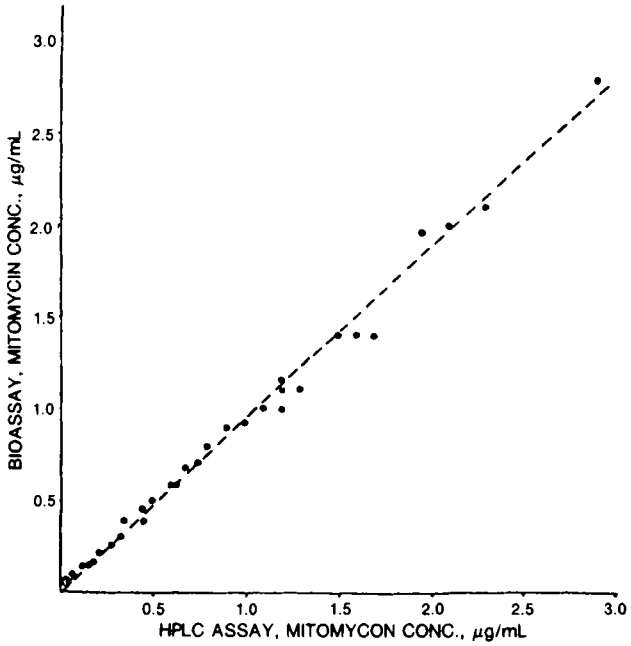

Figure 3—*Comparison of HPLC assay and bioassay of mitomycin C in plasma: slope 0.93; intercept, 0.008; r = 0.996.*

plasma samples containing mitomycin C and porfiromycin are shown in Fig. 1. Mitomycin C was completely separated from porfiromycin, and there was no interference from any endogenous substance in the plasma samples obtained from dogs. The retention times for mitomycin C and porfiromycin were 10.5 and 5.6 min, respectively, and the response (concentration *versus* peak height ratio) was linear in the range of 1–2000 ng of mitomycin C per mL. Standard curves obtained from repeated determinations of plasma standards were $y = 0.009x + 0.033$, $r = 0.999$. Typical chromatograms obtained from blank urine samples and from urine samples containing mitomycin C and porfiromycin are shown in Fig. 2. The retention times for mitomycin C and porfiromycin were the same as in the plasma assay. The urine assay for mitomycin C was linear in the range of 200–2000 ng/mL. Standard curves obtained from repeated determinations of urine standards were $y = 0.0008x - 0.027$, $r = 0.999$.

A set of 10 plasma samples was prepared to contain 5 ng of mitomycin C/mL and carried through the assay procedure for determining accuracy and precision of the assay. The estimated sample concentrations were then used to calculate the observed mean (5.3 ng/mL), *SD* (0.61), *RSD* (11.0%) and mean recovery (106%).

A set of 10 urine samples was prepared to contain 1000 ng of mitomycin C/mL and carried through the assay procedure for determining accuracy and precision of the assay. The estimated sample concentrations were then used to calculate the observed mean (1019 ng/mL), *SD* (35), *RSD* (3.39%), and mean recovery (102%).

Comparison of the Liquid Chromatographic Assay and the Bioassay—Since the lower limit of detection for the plasma bioassay was 10 ng/mL, values of <10 ng/mL found by the HPLC assay were excluded from the comparison of the two assays. The paired assay values of mitomycin C by HPLC assay and bioassay were highly correlated, with a correlation coefficient of 0.996 (Fig. 3). Excellent correlation between the HPLC assay and bioassay suggests that both assays are specific, and metabolite(s) of mitomycin C may not be microbiologically active. Pharmacokinetic calculations were performed by employing the values obtained from the plasma HPLC assay because of its greater sensitivity (1 ng/mL).

Pharmacokinetics of Mitomycin C in Dogs—Following the bolus intravenous administration of mitomycin C, a triexponential plasma level curve was observed in all three dogs (Fig. 4). The graphic and computer analyses of the data suggest that the pharmacokinetic evaluation would require a three-compartment open-model system (Scheme I), assuming that all processes are linear and that elimination occurs from the central compartment (plasma) which is connected to two peripheral compartments. The summary of pharmacokinetic parameters is shown in Table I.

The rate constants associated with the rapidly and relatively slowly equilibrating sites in the peripheral compartments ranged from 27.6 to 42.2 h^{-1} for π and from 3.73 to 7.86 h^{-1} for α, respectively. These values correspond to apparent half-life ranges of 1–1.5 and 5–11 min, respectively. The terminal elimination rate constant (β) ranged from 0.66 to 0.89 h^{-1}, corresponding to an apparent half-life range of 47–63 min. The magnitude of the three hybrid rate constants π, α, and β reflect an extremely rapid initial distribution of mitomycin C and a relatively slow elimination rate of the drug from plasma.

The individual rate constants k_{12}, k_{21}, k_{13}, and k_{31} reflect the rate of distribution into and out of the shallow and deep peripheral compartments. The mean ratio of k_{21}/k_{12} of 1.4, which reflects the return and entry of the drug within the shallow peripheral compartment, suggests rapid equilibration and free transfer of the drug between the central and shallow peripheral compartments. The mean ratio of k_{31}/k_{13} of 0.66, which reflects the return and entry of the drug within the deep peripheral compartment, suggests somewhat slower equilibration plus the possibility of drug binding to tissues or protein sites in this compartment, with a corresponding slower return of the drug to the central compartment. The mean ratio of β/k_{el} of 0.23 indicates that only 23% of the mitomycin C in the body is in the central compartment and available for elimination at any time (18).

The volume of distribution of mitomycin C in the central compartment (V_c) was calculated to be 16, 14, and 22% of body weight for dogs 17637, 17876, and 17516, respectively. The Vd_{ss} calculated by model-dependent (16) and -independent (17) methods were in agreement with each other and ranged from 35 to 62% of body weight in the three dogs. The values calculated for Vd_β were higher than Vd_{ss} and ranged from 58 to 78% of body weight.

The 24-h excretion of intact mitomycin C in urine ranged from 19.2 to 19.8% of the dose, most of which was excreted in the first 7 h. The total body clearance for mitomycin C ranged from 90 to 129 mL/min, and renal clear-

ance ranged from 17 to 23 mL/min in the three dogs. The large differences between renal and plasma clearances can be attributed to extensive biliary and/or metabolic clearances of mitomycin C. The terminal half-life and percent recovery of the mitomycin C dose in the urine of dogs is very similar to those values in humans (19).

The HPLC assay described for mitomycin C in plasma is sensitive to 1 ng/mL and should be suitable for elucidating the pharmacokinetics of mitomycin C in humans after therapeutic doses. There appears to be no interference from any metabolite in dogs. Drug-free human plasma and urine samples from different individuals do not have any interfering peak with mitomycin C or porfiromycin. However, possible interference from other drugs which may be coadministered with mitomycin C must be determined before use of this assay in humans. The pharmacokinetic data of mitomycin C in dogs are similar to preliminary pharmacokinetic data in humans (19). The dog may, therefore, be a good model for studying the disposition of mitomycin C.

Mass and Heat Transfer in Vial Freeze-Drying of Pharmaceuticals: Role of the Vial

M. J. PIKAL ˣ, M. L. ROY, and SAROJ SHAH

Received April 25, 1983, from the *Lilly Research Laboratories, Eli Lilly and Company, Indianapolis, IN 46285.* Accepted for publication June 8, 1983.

Abstract □ Flow of water vapor is impeded by three barriers or resistances: resistance of the dried-product layer, resistance of the semistoppered vial, and resistance of the chamber. The relationship between heat flow and temperature difference may be described by a vial heat transfer coefficient which has contributions from three parallel mechanisms: (*a*) direct conduction from the shelf to the vial *via* points of direct contact between the vial and shelf, (*b*) conduction through the vapor between the vial bottom and the shelf, and (*c*) radiative heat transfer. This report describes experimental studies of the resistance of semistoppered vials, the resistance of the chamber, and vial heat transfer coefficients. Mass transfer through the semistoppered vial has significant contributions from both Knudsen- and viscous-flow mechanisms. Stopper and chamber resistances are of the same magnitude and are about a factor of 10 less than the dried product resistance. All three heat transfer mechanisms are significant, the relative contributions depending on both the chamber pressure and the type of vial. Vial heat transfer coefficients are sensitive to the geometry of the vial bottom, and even vials of nominally the same specifications may differ significantly in heat transfer characteristics. Vials from the same lot are relatively uniform in their heat transfer characteristics, the relative standard deviation of the vial heat transfer coefficient being only ~4%. The temperature distribution in the frozen product is adequately described by a constant temperature gradient in the vertical direction and the thermal conductivity of ice.

Keyphrases □ Freeze-drying—vial heat transfer coefficients, measurement of resistance to mass transfer □ Heat transfer coefficients—freeze-drying, experimental measurement, mechanisms

Freeze-drying, or lyophilization, is the process by which the solvent, normally water, is removed from a frozen solution by sublimation. The freeze-drying process may be divided into three stages: freezing, primary drying, and secondary drying. For pharmaceutical products, the solution is normally filled into vials and then stoppers are partially inserted into the vial necks (semistoppered position), such that openings for vapor flow are present. Next, the vials are placed on temperature-controlled shelves in the freeze-drying chamber. After freezing, the chamber is evacuated to the desired pressure, normally in the range of 30–500 μm, and the shelf temperature is increased to provide energy for sublimation of ice during primary drying. Secondary drying, which is removal of water from the solute phase, begins in a local region of the sample when the ice has been removed from that region and normally continues for some time after all of the ice has been removed from the sample.

Due to high equipment costs, there is considerable economic motivation to minimize process times (1) while maintaining a low level of product loss arising from either eutectic melt or collapse (2). Optimization of the primary-drying stage requires a knowledge of the maximum allowable product temperature, which is either the eutectic temperature (for a crystalline solute) or the collapse temperature (for an amorphous solute), and also requires a determination of the optimum shelf temperature and chamber pressure–time profile required to maintain the product temperature slightly lower than the maximum allowable temperature during all of primary drying. In practice, the shelf temperature and chamber pressure–time relationship is often determined by trial and error. Since, in principle, optimization of this relationship is a problem in coupled mass and heat transfer, a better fundamental understanding of mass and heat transfer in primary drying would allow greater efficiency in process development and minimize problems encountered on scaleup to production operations.

Passing from the frozen product to the condenser, the flow of water vapor is impeded by three barriers or resistances: (*a*) resistance of the dried-product layer above the frozen product, which in addition to being product dependent is also dependent on the vial used (both the area of the ice–vapor interface and the thickness of the dried-product layer) (3), (*b*) resistance of the semistoppered vial, and (*c*) resistance in transfer from the drying chamber to the condenser. Heat for sublimation must be transferred to the product on the vial bottom from the surface upon which the vial rests and through the frozen solution to the subliming ice. For purposes of this discussion, it will be assumed that the vials are placed directly on the dryer shelf. The relationship between heat flow and temperature difference may be characterized by a vial heat transfer coefficient which has contributions from three parallel mechanisms for heat flow: direct conduction from the surface to the vial *via* points of direct contact between the vial and the shelf, conduction through the vapor between the vial bottom and the shelf, and by radiation heat transfer.

The resistance of the dried product was the subject of an earlier experimental study from this laboratory (3), while several aspects of heat transfer have been addressed by Nail (4). He demonstrated that, for a system of vials in a metal tray placed on a heated shelf, the sublimation rate increased as the chamber pressure was increased. Theoretical arguments were used to demonstrate that the temperature differences across the frozen product, across the glass at the vial bottom, and across the metal tray bottom are small and, therefore, the largest temperature differences, or thermal resistances, were across the vapor boundaries between surfaces. In this case, there were two vapor boundaries, one between the vial bottom and the tray surface upon which the vials rested, and the other between the tray bottom and the shelf. However, since Nail's methodology did not allow the thermal resistances for the two vapor boundaries to be evaluated separately, vial heat transfer coefficients could not be determined.

[a] These vials frequently show two concentric prints with the procedure used. The diameter given is the outer diameter of the largest print.

This research describes experimental studies which evaluate: (*a*) mass transfer coefficients (resistances) for several stoppers in the semistoppered configurations, (*b*) resistance of the chamber-to-condenser pathway in a laboratory dryer, and (*c*) vial heat transfer coefficients as a function of chamber pressure for seven types of vials, including examples of both tubing and molded vials. With the aid of a theoretical model for heat transfer, the relative contributions of the three mechanisms of heat flow are examined. Further, since variability in heat transfer coefficients within a given lot of vials is an important consideration in process development, the standard deviation of heat transfer coefficients is determined at selected chamber pressures for six of the seven types of vials studied.

THEORETICAL SECTION

Definition of Mass Transfer Coefficients—Mass transfer is discussed in terms of resistance offered by a given barrier. Resistance, rather than permeability, is used since the total resistance is the sum of component resistances in series. Assuming the usual proportion between flow rate through the barrier and driving force for the process, resistance is defined as the ratio of driving force to flow rate. Since the driving force for both sublimation at the ice-vapor interface and Knudsen flow (3–5)[1] of vapor through the small pores of a dried product is a difference in partial pressures of water (5), the difference between the equilibrium vapor pressure of subliming ice and the partial pressure of water above the dried product is taken as the driving force in the definition of the resistance of the dried product. For vapor flow through the semistoppered vial neck and through the chamber condenser pathway, the driving force is more appropriately taken as a difference in total pressure, to be consistent with the driving force for viscous flow of a fluid (5)[1].

The resistance of the dried-product layer, R_p, is defined by:

$$R_p = (P_0 - x_1^v P_v)/\dot{m} \quad \text{(Eq. 1)}$$

where P_0 is the equilibrium vapor pressure (mm Hg) of the subliming ice, x_1^v is the mole fraction of water vapor in the vial, P_v is the total pressure in the vial (mm Hg), and $\dot{m}$ is the sublimation rate (g/h/vial). As will be shown later, $x_1^v \approx 1$. The normalized product resistance, $\hat{R}_p$, is an area-normalized quantity (independent of product area) given by:

$$\hat{R}_p = A_p R_p \quad \text{(Eq. 2)}$$

where A_p is the geometric cross-sectional area of the product normal to the direction of water vapor flow (computed from the internal diameter of the vial).

The resistance of the semistoppered vial, R_s, is defined by:

$$R_s = (P_v - P_c)/\dot{m} \quad \text{(Eq. 3)}$$

where P_c is the chamber pressure (mm Hg). The resistance of the chamber to condenser pathway, R_c, is defined similarly:

$$R_c = (P_c - P_{cd})/\dot{m}N \quad \text{(Eq. 4)}$$

where N is the number of vials in the dryer and P_{cd} is the pressure in the condenser chamber.

Assuming $x_1^v = 1$, the combination of Eqs. 1–4 yields:

$$\dot{m} = R_T^{-1}(P_0 - P_{cd}) \quad \text{(Eq. 5)}$$

where the total resistance to flow from a given vial to the condenser chamber, R_T, is:

$$R_T = R_p + R_s + NR_c \quad \text{(Eq. 6)}$$

Thus, the contributions to total resistance offered by the dried product, stopper, and chamber are, respectively: R_p, R_s, and NR_c. The quantity NR_c, is a "scaled" chamber resistance and, in effect, is the chamber resistance per vial.

Since the mean free path of water vapor in the dried product is large compared with pore dimensions in the dried product, flow in this region is free molecular or Knudsen flow and the dried-product resistance (R_p) is, therefore, independent of pressure (3, 5). However, the mean free path is smaller than the channels in the stopper and the chamber through which vapor must flow and, hence, the flow mechanism is expected to be predominantly viscous flow with perhaps some contribution from Knudsen flow. Therefore, the stopper and chamber resistances should be pressure dependent and are expected (5) to be of the form:

$$R_i^{-1} = a_0 + a_1\bar{P}_i, \; i = s, c \quad \text{(Eq. 7)}$$

where R_i refers to either R_s or R_c and $\bar{P}_i$ is the mean pressure across the barrier. For example, for $i = s$, $\bar{P}_s = (P_v + P_c)/2$.

The form of Eq. 7 assumes that viscous flow may be described by Poiseuille's law. For viscous flow in short tubes, a correction to Poiseuille's law (5) leads to an additional term in Eq. 7 which is proportional to the product of the sublimation rate and the mean pressure. However, the equations presented by Dushman (5) indicate that the short tube correction is small for both closure resistance and resistance of the laboratory dryer chamber. A preliminary study of closure resistance data (3) suggests that the sublimation rate dependence of the closure resistance is negligible. Thus, although not rigorous, Eq. 7 should serve as a useful first approximation.

Definition of Heat Transfer Coefficients—A heat transfer coefficient is defined as the ratio of the area-normalized heat flow to the temperature difference between heat source and heat sink. For the case of vials resting directly on the freeze-dryer shelf, the vial heat transfer coefficient, K_v, is defined by:

$$\dot{Q} = A_v K_v (T_s - T_b) \quad \text{(Eq. 8)}$$

where $\dot{Q}$ (cal/s) is the heat flow from the shelves to the product in a given vial, A_v is the cross-sectional area of the vial calculated from the vial outer diameter, T_s is the temperature of the shelf surface, and T_b is the temperature of the product at the bottom center of the vial. If the vials are resting on a tray bottom, the temperature T_s refers to the tray surface temperature. Equation 8 assumes the surface above the vials is also at T_s and further assumes the normal situation of a small temperature differential between subliming ice and ice at the vial bottom.

The vial heat transfer coefficient may be expressed as the sum of three terms:

$$K_v = K_c + K_r + K_g \quad \text{(Eq. 9)}$$

[1] When the mean free path is large compared with the dimensions of the pores or tubes constituting the physical system responsible for resistance to flow, as is the case with flow through a dried product (3), collisions of water molecules with the pore or tube walls are responsible for resistance to flow, and the flow mechanism is said to be free molecular flow or Knudsen flow (5). Here, the driving force is the difference in partial pressure of the flowing gas under discussion. When the mean free path is small compared with pore or tube dimensions, collisions between gas molecules are much more frequent than collisions of gas molecules with pore or tube walls, and the resistance is due to momentum transfer between gas molecules, or viscous "forces." The flow mechanism is "viscous flow" (5), and the driving force is the difference in total pressure. The distinction between partial pressure and total pressure is obviously not important when the gas phase is essentially pure water. As data to be presented later will show, the mole fractions of water in the vial and in the chamber are close to unity. The mole fraction of water vapor in the condenser, however, is significantly less than unity. Thus, if flow from the chamber to the condenser were predominantly Knudsen flow, the chamber resistance, defined using the total pressure difference between chamber and condenser as the driving force, might behave anomalously with variations in chamber pressure. However, as will be demonstrated later, the pressure dependence of the chamber resistance is of the expected form, and, therefore, the selection of the driving force seems appropriate.

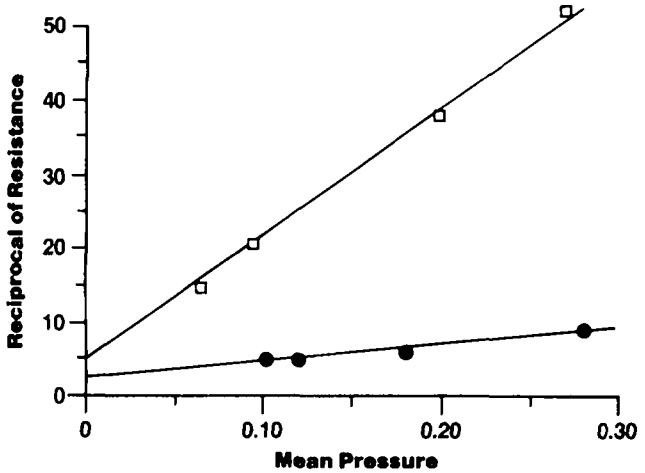

Figure 2—*Reciprocal of closure resistance* versus *pressure. Key: (□) 20-mm closure, (●) 13-mm closure.*

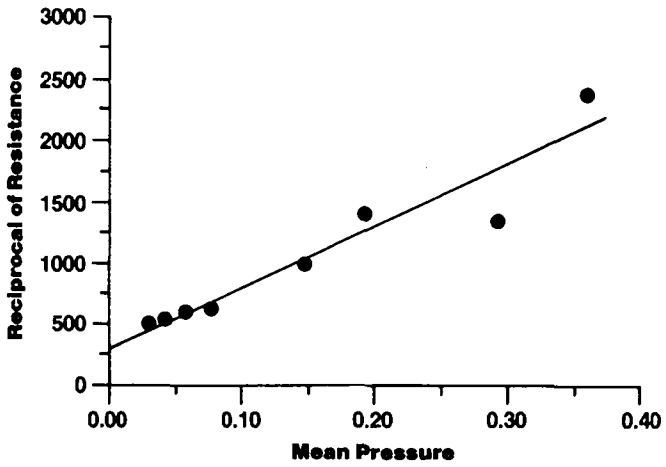

Figure 3—*Reciprocal of chamber resistance* versus *pressure.*

where K_c is the contribution resulting from direct conduction from shelf to glass at the points of contact, K_r is the contribution from radiative heat transfer, and K_g is the contribution from conduction through the gas between the shelf and the vial bottom. Both K_c and K_r are independent of pressure, but K_g increases with increasing gas pressure. Using the Smoluchowski theory as outlined by Dushman (5), and assuming the gap between the vial bottom and the shelf may be characterized by a constant "effective" distance, l, the gas conduction term may be written:

$$K_g = \frac{\alpha\Lambda_0 P}{1 + l(\alpha\Lambda_0/\lambda_0)P} \qquad \text{(Eq. 10)}$$

where Λ_0 is the free molecular heat conductivity of the gas at 0°C, λ_0 is the heat conductivity of the gas at ambient pressure, P is the gas pressure, and α is a function of the energy accommodation coefficient (a_c) and the absolute temperature of the gas (T):

$$\alpha = \frac{a_c}{2 - a_c} \cdot \sqrt{\frac{273.2}{T}} \qquad \text{(Eq. 11)}$$

The radiation term is a sum of two contributions, radiative heat transfer between the shelf and the vial bottom and radiative heat transfer between the shelf above the vial and the top of the vial. Radiative heat flow Q_r, depends on the difference in the fourth powers of the absolute temperatures of the two surfaces:

$$\dot{Q}_r = A_v \bar{e} \sigma (T_2^4 - T_1^4) \qquad \text{(Eq. 12)}$$

where σ is the Stefan-Boltzmann constant and $\bar{e}$ is the "effective" emissivity for the heat exchange, which depends on the relative areas of the two surfaces, their emissivities, and a geometrical view factor (4). For modest temperature differences between the two surfaces:

$$\dot{Q}_r \cong A_v \bar{e} \sigma 4\overline{T}^3 (T_2 - T_1) \qquad \text{(Eq. 13)}$$

where $\overline{T}$ is the mean temperature. For temperatures normally used in freeze-drying, the product, $\sigma 4\overline{T}^3$, is $\sim 1.0 \times 10^{-4}$. For radiation from the shelf upon which the vials rest (bottom radiation), the view factor is approximately unity, and since the emissivity of glass is near unity (4), the effective emissivity for bottom radiation is essentially the emissivity of the shelf surface, e_s, and T_1 is essentially the temperature at the vial bottom, T_b. For radiation from the top, the shelf area view factor of the vial top is much greater than the vial area, and one therefore expects (4) the effective emissivity to be essentially independent of the emissivity of the shelf above the vials. An exact evaluation of $\bar{e}$ for top radiation is not possible, and we treat the effective emissivity for top radiation, denoted e_v, as an experimental quantity to be evaluated by vial heat transfer experiments.

Since Q_r for top radiation is the heat transferred to the subliming ice, an empirically defined e_v should be based on an identification of T_1 as the temperature of subliming ice. In general, temperature differences within the product are small and, as a satisfactory approximation in most cases, T_1 may be taken as T_b. With the definitions of e_s and e_v given above, use of Eq. 13 and the approximation, $\sigma 4\overline{T}^3 \approx 1.0 \times 10^{-4}$, the radiative heat transfer coefficient, K_r, becomes:

$$K_r = 1.0 \times 10^{-4}(e_v + e_s) \qquad \text{(Eq. 14)}$$

In the case of vials resting on a tray bottom, an equation similar to Eq. 8 may be used to define a tray heat transfer coefficient, K_{TR}. Here the area, A_v, is replaced by the ratio of the tray area to the number of vials in the tray, and T_b is replaced by the temperature of the tray bottom. The meaning of $\dot{Q}$ and T_s is the same as in Eq. 8. The components of K_{TR} are given by the right side of Eq. 9, with the form of K_g identical to Eq. 10, although the value of the accommodation coefficient could differ from the value applicable to heat transfer between shelf and vial.

Since most of the heat input flows from the bottom of the vial to the subliming ice, the temperature of the product decreases as the distance from the bottom of the vial, X, increases. The usual proportionality between heat flow and temperature gradient may be used to define the effective thermal conductivity of the product, K_I:

$$\dot{Q}_B = -A_v K_I \cdot \frac{dT}{dX} \qquad \text{(Eq. 15)}$$

where $\dot{Q}_B$ is the heat flow (cal/s) through the bottom of the vial and T is the temperature of the frozen product in the vial. Since the total area available for heat transfer, A_v, is in part glass and in part frozen solution, one would expect K_I to be an area-weighted sum of the thermal conductivities of glass, κ_G, and frozen product, κ_p:

$$K_I \cong \frac{A_v - A_p}{A_v} \cdot \kappa_G + \frac{A_p}{A_v} \cdot \kappa_p \qquad \text{(Eq. 16)}$$

where A_p is the cross-sectional area of the frozen product calculated from the inner diameter of the vial. For dilute solutions, one would expect κ_p to be close to the value for pure ice (6, 7).

EXPERIMENTAL SECTION

Materials—Chemicals used were either reagent or USP grade and were used without further purification, except for filtration of the solutions prepared through a 0.45-μm filter to remove particulate matter. Solutions were prepared by weighing the appropriate quantities of distilled water and solute. Studies involving pure water used distilled water[2].

The rubber closures[3] have two openings for vapor passage in the semi-stoppered position. The 20-mm finish closure has two openings of ~0.4 cm in diameter, while the 13-mm finish closure has openings of ~0.2 cm in diameter.

The vials used were of commercial origin[4] and, except for the limited studies with 5304 vials, were selected to yield a representative cross section of vials produced during a given production run. All of the vials were type I glass; the 5303 and 5304 vials were molded and the others were tubing vials. The relevant vial geometric parameters are summarized in Table I. The contact-print parameters refer to the imprint created by first placing the vial bottom on an ink pad and then placing the vial on a sheet of paper resting on cardboard. Moderate pressure is applied by placing a 500-g weight on top of the vial. While reproducible, the thickness of the contact print is obviously procedure sensitive and does not represent, except in a relative sense, the actual area of physical contact between the vial and a hard surface. The entry in the last column, l_{max}, is the maximum separation distance between the vial bottom

[a] Calculated for a vial of 3.8 cm^2 internal area, a dried product thickness of 0.5 cm, a chamber pressure of 0.1 mm Hg, an ice temperature of −20°C, and the laboratory freeze-dryer with a load of 60 vials of 4.7 cm^2 external area. [b] Sublimation rate per vial. [c] System I is dobutamine hydrochloride (dobutrex) and mannitol in a 1.12:1 weight ratio with total solids being 53 mg/mL.

and a flat surface, obtained simply by direct measurement with a metric ruler. Thus, this parameter is subject to a measurement error of ± ~0.02 cm.

Freeze-Dryers—The laboratory freeze-dryer was a highly modified commercial unit[5] (3) illustrated schematically in Fig. 1. A stainless steel cylinder (A) constituted the drying chamber wall, and the top of the unit (B) was a transparent plastic lid which formed a vacuum-tight seal with the chamber walls *via* a rubber gasket. Temperature control of the shelf (C) was provided by rapid circulation of fluid (methanol) from a thermostat (not shown) into the shelf (D) and out of the shelf (E); the fluid flowed through channels in the shelf interior. The chamber walls and top were covered with 2 cm of rubber foam insulation. However, under the usual conditions of ice sublimation, the dryer walls and top run warmer than the shelf. With a 5°C shelf, the walls were ~15°C while the top was ~12°C. The shelf surface used in these experiments was a thin (1-mm) metal plate in good thermal contact with the original shelf *via* a thin coat of high-vacuum silicone grease impregnated with copper dust. Unless specifically indicated otherwise, the shelf surface was a polished 316 stainless steel plate with a measured emissivity, e_s, of 0.28[6].

The temperature of the shelf surface was measured by thermocouple sensors (30-gauge wire) designed for surface temperature measurements. A welded copper-constantan thermocouple junction was silver-soldered to a copper disk ~1 mm thick and 1.5 cm in diameter. A 2-mm thick disk of foam insulation was glued to the copper disk, and an empty 10-mL glass vial was then glued to the insulation, thus insulating the thermocouple junction from the vial. Good thermal contact between the copper disk and the shelf surface was obtained by applying a thin coat of high-vacuum silicone stopcock grease to the bottom of the copper disk. The shelf surface temperature readings were accurate within ±0.5°C.

Without grease at the interface between the copper disk and shelf surface, the shelf sensors gave readings that were dependent on chamber pressure and were 2–3°C lower than the greased sensors. The shelf surface temperature was normally independent of position on the shelf, within ±0.5°C. The difference between fluid temperature and shelf surface temperature increased as the total sublimation rate increased (*i.e.*, increased heat flow), but was in the 1–2°C range for most of the experiments.

A butterfly valve (F) separated the drying chamber from a tube (G) (2.3 cm diameter, 25 cm length) leading to the condenser chamber (H). A tube (I) connected the interior of a modified vial with a pressure sensor external to the drying chamber (M1 or M2) by suitable manipulation of valves (K1, K2, K3, K4, and K5). A pressure-tight seal between the vial and a glass tube (I1) was made with silicone rubber glue. The glass tube was connected to a flexible stainless steel tube (I3) with a high-vacuum union[7]. The flexible tube was then connected with tube I *via* another high-vacuum union. Temperature measurements were made at four locations within the frozen product using copper-constantan thermocouples (30-gauge wire) (I4). Ten additional thermocouple leads (J) were also available. Differential capacitance manometers (M1, M2)[8] were used for quantitative measurements of absolute pressure, although a thermocouple vacuum gauge (N) was also included in the apparatus. Pressures and temperatures in the vial and chamber were continuously displayed as a function of time on a 24-channel recorder[9].

Studies requiring a larger shelf area than that available in the laboratory dryer were carried out using a pilot scale dryer[10] with condensers in the drying chamber. The dryer contained three shelves of 2800 cm^2 area separated from the condensers by radiation shields. Only the middle shelf was used in the experiments. The shelf surface was painted black and the surface temperature was uniform within 3°C: several shelf temperature sensors were used and care was taken to locate the sensors at positions where the average recorded temperature represented the true average shelf temperature. The temperature of the surface above the vials was colder than the shelf surface upon which the vials rested. Temperature measurements taken near the center of the top shelf indicated a mean difference of 4.3°C for the experiments performed.

Procedures—*Calibrations*—The differential capacitance manometers were calibrated against a precision McCloud gauge[11]. Deviations were less than the stated accuracy of the McCloud gauge (±3%) and no corrections were used. The thermocouple temperature sensors were calibrated at the ice point and at −25°C against a mercury-in-glass thermometer (±0.1°C).

Vapor Composition Measurement—Vapor composition was measured by comparing the pressure of a fixed quantity of vapor at room temperature with the corresponding pressure at dry ice temperature (−78°C), where the pressure of water is negligible. For example, the vapor composition in the vial was measured by first determining the total pressure in the vial with pressure gauge M1 (Fig. 1). Valves K1 and K2 were opened, valve K3 was closed, and the cold finger (O) was at ambient temperature. Next, valve K1 was closed to isolate the sample of vapor, representing the composition of vapor in the vial, and a dry ice–acetone bath was placed around the cold finger. Within a few minutes essentially all water vapor was condensed, and the residual pressure was due only to air[12]. This residual pressure was slightly lower than the air pressure in the original vapor since the air in the cold finger was at a lower temperature. The original air pressure was obtained from the measured residual pressure, using an empirically determined correction factor (1.044). The correction factor was determined by measuring the pressure reduction after placing the dry-ice bath on the cold finger at high pressure in a "dry" system, where essentially all the vapor was air. With the total pressure and the air pressure determined, the water vapor pressure in the sample was obtained by difference. The mole fraction of water in the vapor sample was calculated as the ratio of water partial pressure to the total pressure. When the pressure measurements were complete, the dry-ice bath was removed, and, by appropriate manipulation of valves, the vapor sample was pumped directly into the condenser chamber. The valves were then returned to their normal operating position for pressure monitoring. This procedure was believed to result in more rapid equilibration of the system following a composition measurement.

Mass Transfer Coefficients—Closure resistance at given mean pressure was determined by measuring the average pressure difference across the closure during sublimation of a known quantity of ice at constant chamber pressure. The mean pressure, $\bar{P}$, is the mean of the vial pressure and chamber pressure over the time interval of the experiment. The mean sublimation rate was calculated from the mass of ice sublimed and the time required for sublimation. The closure resistance was then obtained from Eq. 3. Similarly, the chamber resistance was evaluated from the chamber pressure, P_c, pressure in the condenser chamber, P_{cd}, and the total sublimation rate (all vials), $N \cdot \dot{m}$, using Eq. 4. Since both chamber and closure resistance measurements are sensitive to small pressure measurement errors (the pressure differences were small), care was taken to ensure that the pressure sensors (M1 and M2, Fig. 1) gave the same reading when connected to the same source, and a number of replicate experiments were made at each mean pressure to obtain the final data sets.

Heat Transfer Experiments—Two types of vial heat transfer experiments were performed. Experiments where data were collected on a single vial over a wide range of shelf temperatures and chamber pressures in a single experiment were denoted "single vial experiments." Experiments designed to measure both the mean heat transfer coefficient for a set of nominally identical vials and their corresponding standard deviation in heat transfer coefficients were referred to as "multivial experiments." All experiments, except those multivial experiments that used larger vials, were carried out using a full shelf

of vials in the laboratory dryer. In both types of experiments, a small precision bore stainless steel tube (length 1.497 cm, 0.217 cm i.d.) was inserted in each stopper, and the stopper was inserted fully into the vial neck[13]. This procedure accomplished several purposes:

1. The pressure difference across the closure, which was needed to evaluate the sublimation rate in a single vial experiment, was increased over that found with stoppers in the usual semistoppered position, thereby decreasing the relative error in the pressure difference measurement.

2. The closure resistance was fixed by the geometry of the tube and the chamber pressure and, therefore, was not subject to variation arising from slight variations in stopper placement or geometry. Uniformity in resistance to mass transfer in a set of vials is critical when the standard deviation in heat transfer coefficient is measured.

The resistance of the metal tube used with the modified vial (Fig. 1) was determined as a function of mean pressure by a procedure identical to that used to determine closure resistance. The tube resistance, R_{TB}, is given by:

$$R_{TB}^{-1} = 0.2478 + 1.944\,\bar{P} \qquad \text{(Eq. 17)}$$

where $\bar{P}$ is $(P_v + P_c)/2$, and the numerical coefficients are a result of regression analysis of four data points over a range of $\bar{P}$ from 0.2 to 0.5 mm Hg, yielding a correlation coefficient of 0.9965. The numerical coefficients were in satisfactory agreement with the corresponding coefficients calculated strictly from theory[14].

A fill volume equivalent to a liquid depth of ~2 cm was used for all heat transfer studies. With pure water, a redistribution of ice within the vial occurred such that ice near the vial wall and ice near the thermocouple wire was preferentially removed. As a result of this phenomenon, measurements of temperature distribution in the ice had to be completed early in the experiment, before the assumption of a planar ice-vapor interface was seriously violated. Accurate temperature distribution data was obtained until ~15% of the ice had been removed. The vial heat transfer coefficient is defined assuming the ice at the vial bottom is in good thermal contact with the glass. Normally, with vials filled with pure water, partial loss of thermal contact occurs after sublimation of 35–50% of the ice. Thus, duration of a heat transfer experiment is limited to a time corresponding to sublimation of ~25% of the ice. Loss of thermal contact is rarely a problem when a frozen solution is dried.

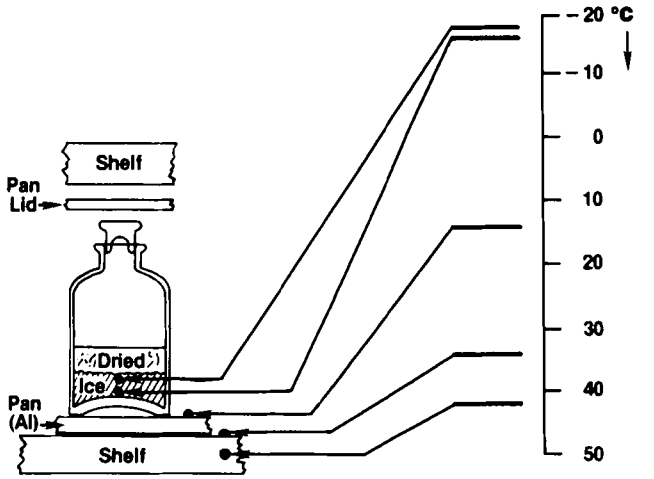

Figure 4—*Temperature profile in primary drying using dobutamine hydrochloride–mannitol (1:1) (10 mL) in 5304 molded vials (8.3 cm²) in an aluminum tray; heat flux = 42 cal/cm²·h, chamber pressure 0.10 mm Hg.*

[13] Experiments with the 5304 vials represented our first attempt at heat transfer coefficient measurement and used 13-mm freeze-drying stoppers in the semistoppered position.

[14] Using the theoretical relationships for gas flow in tubes (5), the resistance of the tube, in mm Hg·h/g, is given in terms of the tube cross-sectional area, A, tube radius, a, and tube length, l, by $R_{TB}^{-1} = [150 \cdot A\,(a/l)]/[1 + 8/3\,(a/l)] + 7965A\,(a^2/l)\bar{P}$. Substitution of the measured values of a and l (in cm) gives $R_{TB}^{-1} = 0.338 + 2.329\,\bar{P}$. While the agreement between theory and experiment is not quantitative, uncertainty in the measured value of a and uncertainty in the experimental coefficients could account for the difference.

Table IV—Evaluation of Heat Transfer by Top Radiation: Effective Emissivity, e_v

KCl (l = 0.2)	1	20.8	0.80
Mean			0.84

For single vial heat transfer studies, a representative vial from a given lot of vials was modified as shown in Fig. 1. After filling, normally with pure water, the modified vial and other vials of the same lot, all equipped with "identical" metal tubes, were loaded into the laboratory dryer, the liquid was frozen, and the chamber was evacuated. The procedure then involved a series of heat transfer measurements under steady-state conditions at selected shelf temperatures and chamber pressures. An operational definition of steady state is taken as constant temperatures (±0.2°C) and pressures (±2 μm) for a period of 10–15 min. The sublimation rate, $\dot{m}$, is calculated from the observed steady-state pressure readings using Eq. 3 with the closure resistance given by the tube resistance, Eq. 17. The heat transfer rate, $\dot{Q}$, is then calculated:

$$\dot{Q}\ (\text{cal/s}) = 0.1833\dot{m}\ (\text{g/h}) \qquad \text{(Eq. 18)}$$

where 660 cal/g is used for the heat of sublimation (8).

The first shelf temperature setting was adjusted to be equal to the ice temperature at the vial bottom. Heat transfer from the shelf to the vial was zero, and any residual heat transfer was due to radiative heat transfer from the dryer lid and/or possible contributions from conduction through the thermocouple wires and the pressure measurement tube (I, Fig. 1). Normally, shelf temperature settings of −10°C, 5°C, and 25°C were used in the balance of the experiment with four chamber pressures studied at each shelf temperature. The first pressure setting was the minimum pressure attainable with the leak valve closed (0.05–0.10 mm Hg). Higher pressures (0.2, 0.4, and 0.6 mm Hg) were obtained by manual adjustment of the controlled-leak valve (P, Fig. 1).

The advantages of the single vial experiment were that, during one ~6-h experiment, heat transfer could be studied over a wide range of shelf temperatures and chamber pressures, and the effect of radiation from the dryer lid could be directly measured. Since this procedure characterized the heat transfer for only one vial in a given experiment, the procedure was not designed to examine the variation in the heat transfer coefficient in a set of nominally equivalent vials. Moreover, it is difficult to select a "typical" vial and, even if this selection is successful, the presence of the pressure measurement tube makes it difficult to place the vial absolutely flat on the shelf with no downward force on the vial. Even a slight tilt of the vial would have decreased the area of actual contact between the glass and the shelf and would, therefore, decrease the contact conduction term, K_c (Eq. 9). The value of the separation distance, l (Eq. 10), may also be increased. Conversely, good contact with an excessive downward force on the vial may actually increase the value of K_c over that characteristic of a free-standing vial (9). Thus, particularly for the smaller vials where the contact problems were most severe, the single vial procedure was not the method of choice for determining the heat-transfer coefficient of an average vial in normal contact with the shelf.

Single vial data are, however, an accurate representation of the heat transfer for the vial used and the degree of vial–shelf contact experienced in the experiment performed. Thus, single vial data were used to efficiently and accurately investigate various assumptions in the defining equation for vial heat transfer coefficients (Eq. 8), to verify the theoretical form of the pressure dependence of K_v (Eqs. 9, 10), to characterize radiative heat transfer from the dryer lid, and to determine the effective thermal conductivity of the product (Eq. 15).

The equation defining the vial heat transfer coefficient, Eq. 8, assumes the

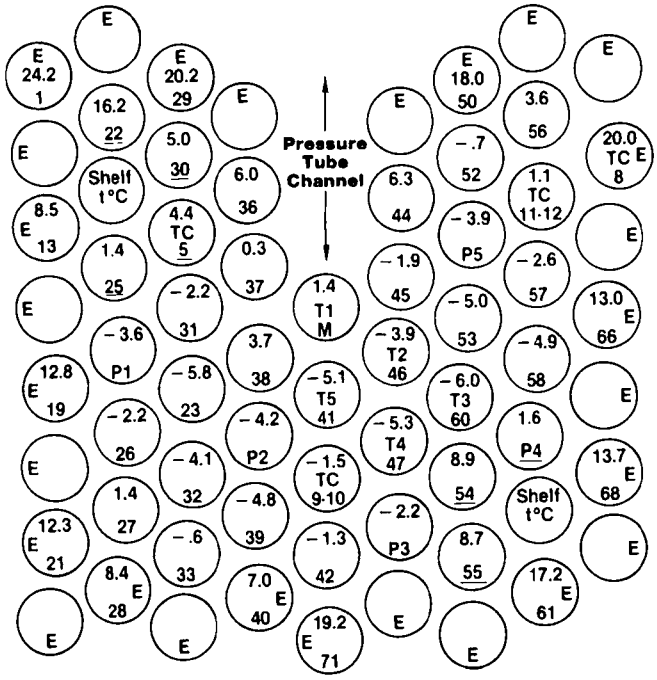

Figure 5—*Vial placement on the shelf and mean percent deviations in sublimation rates for components of the variance study. (See* Appendix I *for discussion.)*

temperature of the surface above the vials is the same as the temperature of the surface upon which the vials rest. While this assumption is valid for most freeze-dryers, the surface above the vials in the laboratory dryer (Fig. 1) was the chamber lid, which was not temperature controlled. Thus, the calculation of K_v from heat transfer data accumulated on the laboratory dryer involves a correction for the atypical radiative heat transfer from the dryer lid to the top of the vials. The heat transfer rate, $\dot{Q}$, for vials in the laboratory dryer may be written:

$$\dot{Q} = A_v(K_c + 1.10^{-4}e_s + K_g)(T_s - T_b) + A_v e_v \sigma(T_L^4 - T^4) \quad \text{(Eq. 19)}$$

where T_L is the lid temperature and T is the temperature of the subliming ice. The effective emissivity for top radiation (e_v) is assumed to be a property of the vial only. Thus, to convert heat transfer data from the laboratory dryer to K_v data defined by Eqs. 8 and 14, e_v must be evaluated.

Data for e_v were generated by using the single vial procedure and adjusting the shelf temperature so that $T_s = T_b$. Under these conditions, the heat transfer was due to the top radiation term only, and e_v data may be evaluated by determining $\dot{Q}$, T_L, and T. The value of T_L is obtained by direct measurement, $\dot{Q}$ is determined from P_v and P_c as outlined earlier, and T is calculated using one of the following procedures. When pure ice is in the vial, the resistance to mass transfer between the sublimation interface and the chamber is almost entirely due to the metal tube in the closure. The pressure in the vial, P_v, is essentially equal to the equilibrium vapor pressure of the subliming ice, and the temperature of the subliming ice, T, may be evaluated from the measured P_v data[15]. However, when a solution is freeze-dried, the vial pressure is much less than the equilibrium vapor pressure of ice, and the value of T is calculated using the measured product temperature near the sublimation interface[16].

Multivial heat transfer studies were used to determine the mean vial heat transfer coefficient as a function of pressure as well as to obtain the standard deviation in heat transfer coefficients for a set of nominally equivalent vials. All vials investigated were filled with pure water to a depth of ~2 cm, and each vial was weighed (±0.2 mg). After loading and freezing, the shelf temperature

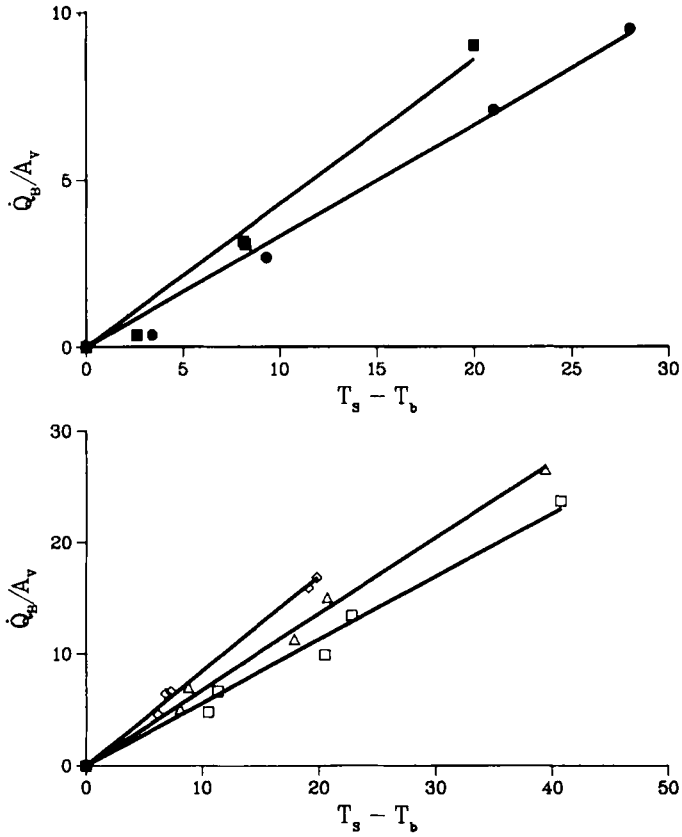

Figure 6—*Proportionality between heat transfer rate and temperature difference. Key: 5303 vials, (●) 0.1 mm Hg and (■) 0.2 mm Hg; W5800 vials, (□) 0.2 mm Hg, (△) 0.4 mm Hg, and (◇) 0.6 mm Hg.*

(and product temperature) were adjusted to the expected steady-state sublimation temperature for that experiment, and the chamber was quickly evacuated to the desired chamber pressure by manual adjustment of the leak valve. Once the pressure decreased below ~1 mm Hg and sublimation began, the shelf temperature was quickly increased to +5°C. The entire experiment was conducted under conditions of constant shelf temperature (5°C) and constant chamber pressure. After ~2 g of ice was sublimed, the dryer was vented, and each vial was weighed to obtain the mass loss for each vial. The average sublimation rate for each vial is calculated as the mass loss divided by the time period of sublimation. Calculations of the heat transfer coefficients and the corresponding standard deviation from the raw sublimation rate and temperature data are described in *Appendix I.*

RESULTS AND DISCUSSION

Closure Resistance—Two types of closures of similar design were studied. The smaller closure was designed for use with vials that had 13-mm o.d. necks, while the larger closure was used with vials that had 20-mm o.d. necks. Both closures had two openings in the semistoppered position with effective diameters of 0.2 cm for the 13-mm size and 0.4 cm for the 20-mm size. The experimental data (Fig. 2) demonstrate that the reciprocal of closure resistance is a linear function of mean pressure, as expected (Eq. 7). The mean pressure is the mean of the vial and chamber pressures. Each point is the mean of at least two replicate experiments, while the solid lines represent smoothed data from Eq. 7 with the coefficients determined by regression analysis:

$$R_s^{-1} = 2.3 + 22.4\bar{P} \text{ (13 mm)} \quad \text{(Eq. 20)}$$

$$R_s^{-1} = 4.8 + 169\bar{P} \text{ (20 mm)} \quad \text{(Eq. 21)}$$

The resistance of the 13-mm closure was roughly a factor of 5 higher than the 20-mm closure at corresponding pressures over the pressure range normally encountered in practice, a ratio close to that predicted theoretically[17]. The

[15] The vapor pressure of ice, in mm Hg, as a function of absolute temperature (8), may be expressed as $\ln P = -6144.96/T + 24.01849$.

[16] Although we cannot directly measure temperature at the sublimation interface, the temperature variation within the product is negligible between locations where temperature is measured (Fig. 1); thus, both methods of determining T should yield the same result when the product is pure water. However, we find that the value of T determined from P_v is systematically ~1.8°C lower than the corresponding measured product temperature. Evidently, a temperature gradient exists very near the sublimation surface, at least when the sample is pure water. However, a temperature error of 1.8°C produces an error in e_v of only 0.03, so even if the same error is present with a solution, the error introduced into the e_v data is slight.

[17] If each closure opening is approximated as a tube of radius a and length l, the same equation used to calculate resistance of the metal tubes[14] may be used to estimate the coefficients in Eq. 7. The estimated values of a and l are $a = 0.2$ cm, $l = 0.4$ cm (20 mm) and $a = 0.1$ cm, $l = 0.3$ cm (13 mm). Thus, the theoretical equivalents of Eqs. 20 and 21 are $R_s^{-1} = 1.7 + 17\bar{P}$ (13 mm) and $R_s^{-1} = 8.1 + 200\bar{P}$ (20 mm).

[a] Mean data from six replicate experiments; N = 36, A = 5; SD in calculated $10^4 \times K_v$ is ±0.14; N is the total number of vials in the sample and A is the number of vials located adjacent to a shelf temperature sensor (see *Appendix I* and Fig. 5). [b] N = 15, A = 6. [c] N = 35, A = 12.

intercept (Fig. 2) at $P = 0$ represents the contribution of Knudsen flow, and the ratio R_s^{-1} ($P = 0$) to R_s^{-1} at any given pressure represents the relative contribution of Knudsen flow to the total vapor flow at that pressure. Thus, at >0.03 mm Hg for the 20-mm closure and >0.1 mm Hg for the 13-mm closure, Knudsen flow was <50% of the total flow, and the flow mechanism became predominantly viscous flow or bulk-fluid flow.

Chamber Resistance—The reciprocal of the chamber resistance of the laboratory dryer is a linear function of the mean pressure (the mean of the chamber and condenser pressures) within the precision of the data (Fig. 3). Each data point is the mean of at least two, and usually more than four, replicate experiments. The solid line gives the best fit of the data to Eq. 7 with $a_0 = 320 \pm 230$ and $a_1 = 4960 \pm 650$, where the uncertainty represents the standard error in the coefficient. As with closure resistance, the intercept (Fig. 3) at $P = 0$ represents the contribution of Knudsen flow while the ratio R_c^{-1} ($P = 0$)/R_c^{-1} gives the relative contribution of Knudsen flow to total vapor flow. Due to the considerable uncertainty in the experimental value of a_0, it is not possible to make a definitive comment on the relative contribution of Knudsen flow.

Assuming that the chamber resistance is due entirely to the tube separating the chamber from the condenser, theoretical values of a_0 and a_1 may be calculated[14]: a_0 = 124 and a_1 = 28,639. While the experimental and theoretical values of a_0 agree within the uncertainty in the data, the experimental value of a_1 is a factor of ~6 less than the theoretical estimate. Thus, the pressure-dependent term in R_c^{-1}, which is due to the viscous flow mechanism, was much smaller than expected, and the resistance to viscous flow in the laboratory dryer appeared to be anomalously high.

Since the chamber resistance depends on the dryer dimensions, the chamber resistance of a production scale dryer obviously will be much less than the chamber resistance of the laboratory dryer. However, the total resistance to flow from a given vial (Eq. 6) depends on the scaled chamber resistance, NR_c, where N is the number of vials in the dryer. The pressure drop between chamber and condenser for a given sublimation rate per vial depends on the scaled chamber resistance (Eq. 4). If the laboratory dryer is a satisfactory model for a production scale dryer, the scaled resistances should be comparable for the two dryers. Although sparse, the production data available suggest that at a mean pressure of 0.1 mm Hg, the scaled chamber resistance (N = 30,000) is ~0.05 mm Hg·h/g, while the corresponding scaled resistance for the laboratory dryer (N = 70) is 0.086 mm Hg·h/g.

Comparison of Resistances—Using the data presented in Figs. 2 and 3 and dried product resistances generated from vial data in a previous study (3), the resistance to passage of water vapor from the sublimation surface in a given vial to the condenser chamber may be calculated for each barrier: dried product, closure, and chamber–condenser pathway. The mean pressures needed to evaluate closure and chamber resistances are evaluated by solving Eqs. 1, 3, and 7 or Eqs. 1, 4, and 7, with 0.1 mm Hg as the chamber pressure.

The dried-product resistance was the dominant resistance, accounting for nearly 80% of the mass transfer resistance even when the small (13-mm) closures were used (Table II). Closure and chamber resistances were of the same order of magnitude, the chamber resistance was less than the resistance of a 13-mm closure, but greater than the resistance of a 20-mm closure.

Vapor Composition—The gas present in the vial and the chamber was mostly water vapor under all conditions studied (Table III). Even when the chamber pressure was increased by a controlled air leak, the vapor in the chamber was predominantly water. These observations, which are in qualitative agreement with literature data (10), are a direct result of the low pumping speed of the system for air relative to the pumping speed for a considerable vapor (H_2O). An air leak increases the total pressure in the condenser chamber (mostly air) and, because the chamber pressure is related to the condenser pressure by Eq. 4, the chamber pressure also increases. However, even with an air leak sufficient to increase the condenser pressure significantly, the molar flow rate of air is still much smaller than the molar flow rate of water vapor, and the chamber gas is, therefore, predominantly water. Thus, as a first approximation, the heat conductivity parameters Λ_0 and λ_0 (Eq. 10) refer to water vapor.

Temperature Profile in Primary Drying—A temperature profile measured during primary drying in the pilot dryer is illustrated by Fig. 4. In this experiment, the vials were placed in an aluminum tray with a flat 5-mm thick bottom and a tray lid containing open channels for vapor passage. Only the middle shelf was used. The temperature data (Fig. 4) refer to mean temperatures recorded at 50% completion of primary drying, and the heat transfer rate is the average heat transfer rate calculated from the total amount of ice sublimed and the primary-drying time.

Heat transfer may be described in terms of four barriers or resistances to heat flow: (*a*) the shelf itself, with a temperature difference of 8°C between the shelf interior and the shelf surface; (*b*) the pan or tray, with a temperature

[a] Both W5303 and K5303 vials gave the same mean K_v (within 0.2%), and $\hat{\sigma}(\dot{m})$ is essentially the same for the pooled data set as for each data set considered individually.

difference of 20°C between the shelf surface and the top surface of the tray bottom; (*c*) the vial, with a temperature difference of 30°C between the pan surface and the product in the bottom of the vial; and (*d*) the frozen product, with a temperature difference of ~2°C between the ice at the vial bottom and the ice at the sublimation interface. The thermal resistance of a barrier may be defined as the ratio of temperature difference across the barrier and the area-normalized heat flow (4). Thus, the largest thermal resistance (50%) is the vial-tray interface, but both the tray-shelf interface and the shelf itself contribute significantly to the total resistance, 33.3 and 13.3%, respectively.

As defined here, the thermal resistance of the vial includes the thermal resistance of the glass in the vial bottom. Likewise, the tray resistance includes the thermal resistance of the aluminum in the tray bottom. However, as shown by Nail (4), the thermal resistance of the metal in an aluminum tray bottom is essentially zero. Therefore, the tray resistance is due to the tray-shelf interface resistance. The thermal resistance of the glass, even for molded vials where the glass is several millimeters thick, is generally less than the thermal resistance of the frozen product (4), and the vial thermal resistance is nearly all due to the tray-vial interface resistance. In Fig. 4, the thermal resistance of the glass (3.5 mm thick) is ~5% of the defined vial resistance and <3% of the total thermal resistance. For tubing vials, the glass thickness is usually ~1 mm, and the corresponding contribution of the glass to thermal resistance is even less. Consequently, the thickness of the glass is not a significant factor in vial heat transfer and the usual variations in glass thickness may be ignored.

Heat transfer coefficients for the tray, K_{TR}, and the shelf itself, K_S, may be defined by equations analogous to the defining equation for vial heat transfer coefficients (Eq. 8). Theoretically, the tray heat transfer coefficient may be described as a sum of contact, radiation, and gas conduction terms (Eq. 9), where the gas conduction term depends on pressure in the same manner as the corresponding term in the vial heat transfer coefficient (Eq. 10). For the aluminum tray studied, the tray temperature is uniform throughout the tray bottom, and the calculated value of $K_{TR} = 5.8 \times 10^{-4}$ cal/s²·cm²·°C at 0.1 mm Hg. Similar measurements with a stainless steel tray of the same geometry, but with a warped bottom (with ~4 mm maximum distance between the shelf and the tray bottom) showed significant tray temperature differences (≈5°C) between zones over a maximum warp and zones near a shelf-tray contact point. The mean tray heat transfer coefficient at 0.1 mm Hg is 3.3×10^{-4} cal/s·cm²·°C, but in a zone of maximum warp, the coefficient decreased to 2.4×10^{-4} cal/s·cm²·°C.

The shelf heat transfer coefficient, K_S, calculated from the temperature difference between shelf interior and shelf surface (Fig. 4) is 1.5×10^{-3} cal/s·cm²·°C. The reciprocal of K_S is the thermal resistance for flow of heat from the shelf interior to the surface and probably represents a combination of limited fluid flow through the shelf interior and a finite thermal conductivity of the shelf material itself. Thus, the shelf heat transfer coefficient is expected to be independent of chamber pressure and is probably quite sensitive to dryer design.

Vial Heat Transfer: Radiation Effects/Driving Force for Heat Flow—*Contribution of Radiation*- The parameter, e_v, represents the effect of radiation heat transfer from the surface above the vials. The e_v data obtained (Table IV) show no systematic trend as the vial size (value of A_v) increased[18]. The experiments with potassium chloride were carried out to determine whether the development of a dried-product layer above the sublimation interface would act as a thermal barrier and reduce the heat transfer *via* top radiation. Thus, measurements of e_v were made at the beginning of sublimation where the dried-product thickness, l, is essentially zero, and later in the same experiment after a dried product layer developed ($l > 0$). The data clearly do not show a decrease in e_v as l increases; indeed, there appears to be a small increase in e_v as l increases, a result for which we cannot offer a reasonable interpretation. In summary, the data appear to be adequately interpreted in terms of a value of e_v equal to 0.84, independent of vial size and thickness of the dried-product layer.

The definition of the vial heat transfer coefficient assumes the vial is completely surrounded by other vials. Clearly, this assumption is not valid for those vials forming the perimeter of a group of vials. Such "edge" vials may show a significantly higher sublimation rate than "interior" vials due to radiative heat transfer from the surface facing the vial perimeter. The additional heat transfer rate for edge vials, $\Delta\dot{Q}_E$, may be written:

$$\Delta\dot{Q}_E = A_c e_E \sigma (T_w^4 - T_b^4) \qquad \text{(Eq. 22)}$$

where A_c is the vial area exposed to the extra radiation effects, taken as one-half the cylindrical area of the vial, T_w is the absolute temperature of the heat source (*i.e.*, the chamber wall), and T_b is the absolute temperature of the product. The parameter, e_E, denotes the effective emissivity for radiative heat transfer between the edge vial and the heat source. Numerical analysis[19] of the experimental data (Appendix I; Fig. 5) yields, $e_E = 0.21$. Since edge vials are atypical, edge vial data are excluded from heat transfer data analysis.

Proportionality Between Heat Transfer Rate and Temperature Difference—The definition of the vial heat transfer coefficient assumes that the heat transfer rate is proportional to the temperature difference between the shelf surface and the temperature in the product at the bottom of the vial (Eq. 8). Thus, the driving force for heat flow is taken as the temperature difference, $T_s - T_b$. The corresponding assumption for heat transfer in the laboratory dryer is a direct proportion between heat transfer rate from the shelf, denoted $\dot{Q}_B$, and the same temperature difference. The value of $\dot{Q}_B$ is obtained from the total heat transfer rate by subtraction of the top radiation contribution. The top radiation contribution is calculated using the term in Eq. 19 involving e_v with $e_v = 0.84$. Data are obtained at constant pressure as a function of $T_s - T_b$ by varying the shelf temperature in single vial studies. Representative results for two types of vials are shown in Fig. 6 at selected chamber pressures. As expected, $\dot{Q}_B$ is directly proportional to $T_s - T_b$ within the uncertainty in the data. Further, the slopes of the plots were observed to increase as the chamber pressure increased, which is consistent with the expected increase in conduction through the vapor phase as pressure increases.

Vial Heat Transfer Coefficients *Phenomenological Results*—The results of the multivial studies (Tables V-VII) are identified by experiment number (first column), vial type (second column), and chamber pressure (third column). In general, two vial types were studied in the same experiment, thereby providing greater accuracy for the comparison of K_v between the two vial samples under identical conditions. Thus, while the precision in K_v for a given set of vials is ± ~2%, as measured by the standard deviation in a series of replicate experiments (laboratory dryer), the ratio of K_v data for the two sets of vials is precise within ± ~0.5%.

The vial number (*e.g.*, 5800) defines the vial specifications while the letter (*i.e.*, W or K) defines the supplier. Thus, although W5800 and K5800 vials are nominally identical, vial heat transfer coefficients for K5800 vials are significantly higher than K_v for W5800 vials at corresponding pressures (Table V). For the 5800 vials studied, the K_v ratio is 1.115, independent of pressure within ±0.5%. The analogous K_v ratios for 5816 vials (Table VI) increases smoothly from 1.092 at 0.068 mm Hg to 1.187 at 0.4 mm Hg. Again, although both W5816 and K5816 vials are nominally identical, the K vials have significantly higher vial heat transfer coefficients than the W vials. Contrary to the K *versus* W bias found for tubing vials (5800 and 5816), the large molded 5303 vials studied show no supplier bias in K_v (footnote *a* in Table VII). The mean K_v values are identical, within ±0.2%, for K5303 and W5303 vials at corresponding pressures.

The mean K_v data reported are evaluated using a finite number of vials

[18] If a significant amount of heat were conducted down the thermocouple wires or through the pressure measurement tube, a term in Eq. 19, independent of vial area, would be needed. The experimental value of e_v would include a term inversely proportioned to A_v, which would then result in the measured e_v data decreasing as A_v increases. Regression analysis of all the pure water data (13 experiments) gives: $e_v = 0.82 + 0.14/A_v$, with a correlation coefficient of 0.10. Thus, heat conduction through the thermocouple wires (30-gauge) and/or the pressure measurement tube is small and may be ignored.

[19] Under the conditions of the experiment (*Appendix I*), the 15.0% sublimation rate bias between edge vials and interior vials yields $\Delta\dot{Q}_E = 0.0106$ cal/s. The W5800 vial is a cylinder of height ~4 cm and radius 1.22 cm. The observed value of T_b is 254.7 K. Since the shelf is actually a shallow box with a height of 1 cm, the heat source is the shelf, 275.5 K, for the first 1 cm of vial height and is the chamber wall, 288 K, for the remaining 3 cm of vial height. Thus, $\Delta\dot{Q}_E = \pi(1.22)e_E \cdot \sigma[1\cdot(275.5^4 - T_b^4) + 3\cdot(288^4 - T_b^4)]$, and the calculated value of e_E is 0.21.

Table VIII—Vial Heat Transfer Parameters[a] with Accommodation Coefficient, a_c, of 0.67 and Effective Top Emissivity, e, of 0.84

Vial	Contact Parameter 10^4K_c	Separation Distance (l), cm
W5800[b]	1.24 ± .08[e]	0.0471 ± 0.0018[e]
K5800[b]	1.70 ± 0.11	0.0396 ± 0.0021
W5811[b]	1.58 ± 0.11	0.0395 ± 0.0021
W5816[b]	0.63 ± 0.08	0.0513 ± 0.0024
K5816[b]	0.87 ± 0.08	0.0372 ± 0.0013
5303[c]	0.4 ± 0.4	0.090 ± 0.028
5304[d]	0.7 ± 0.2	0.067 ± 0.008

[a] Parameters evaluated using heat conductivity values for pure water taken from the literature (5, 11): $\Lambda_0 = 6.34 \cdot 10^{-3}$ cal/s·cm²·°C·mm Hg; $\lambda_0 = 4.29 \times 10^{-5}$ cal/s·°C·cm. [b] Data from multivial studies (Tables V and VI). [c] Datum is mean of the multivial study ($10^4K_c = 0 \pm 0.6$, $l = 0.103 \pm 0.040$) and the single vial study ($10^4K_c = 0.8 \pm 0.1$, $l = 0.078 \pm 0.009$). [d] Datum from the single vial studies with two vials. [e] Uncertainty given is the standard error of the parameter as given by the MLAB program output and does not reflect absolute error. The value of K_c is sensitive to the choice of a_c and also depends on the mathematical form chosen for K_g.

(normally ~15) randomly selected from one lot of vials. Thus, the reported K_v value is an accurate representation of the mean of the lot within a standard error, $\sigma(K_v)/\sqrt{N}$, where N is the number of vials studied. Using the $\sigma(K_v)$ data reported, the corresponding standard error in the K_v ratio between K vials and W vials averages ~1.5%. Therefore, the K_v ratios calculated from the reported data are an accurate representation of the lots studied, within ~1.5%, and probably reflect differences in geometry of the vial bottoms (Table I). Vial heat transfer data for different lots from the same supplier are needed to verify that the lots investigated in this study are typical of the total output from a given supplier. At present, such data are not available, but the differences in vial bottoms noted in Table I appear to be consistent, suggesting that the K_v ratios determined in this study do indeed indicate a supplier difference rather than a lot-to-lot variation within a given product.

The differences in K_v between K and W vials are of no practical significance in freeze-drying, as long as vials from only one supplier are used for a given product. A slightly lower K_v simply requires a slightly higher shelf temperature in the freeze-drying process. The supplier bias is particularly important if circumstances can arise where both K and W vials are used for the same pharmaceutical product lot. Since the K *versus* W bias in K_v is significantly greater than nonuniformity in K_v for a given vial type, measured by $\sigma(K_v)$, a significant increase in nonuniformity of heat input would result whenever both K and W vials are used in the same freeze-drying run. The consequence could well be a large product loss arising from collapse or eutectic melt, although the severity of the problem encountered would depend on both the nature of the product and the process design.

The relative standard deviation in K_v, $\sigma(K_v)$, is a measure of the uniformity of heat transfer coefficients within a given lot of vials. Since the $\sigma(K_v)$ data are based on data from a relatively small number of vials (~15), one expects a sizable uncertainty in a given value of $\sigma(K_v)$[20]. Based on the differences in $\sigma(K_v)$ between replicate experiments (Tables V–VII), the uncertainty (SD) in a reported value of $\sigma(K_v)$ is ~1.2%.

While the $\sigma(K_v)$ data are only semiquantitative, several generalizations appear valid. First, all vial types have a surprisingly uniform heat transfer coefficient; the average value of $\sigma(K_v)$ is only 4%. Second, the uniformity in K_v is systematically slightly better for W tubing vials than for the corresponding K vials (Tables V and VI). The data for 5800 and 5816 vials show a mean $\sigma(K_v)$ of 3.4 ± 0.3% for W vials, while the corresponding value for K vials is 5.3 ± 0.3%. The uncertainties given are standard deviations of the means. Third, while a small but significant pressure dependence in $\sigma(K_v)$ could be obscured by the scatter of the data, the data are not consistent with a pressure dependence of more than a factor of ~2 over the pressure range studied. The pressure dependence in $\sigma(K_v)$ will be addressed later from a theoretical point of view.

While histograms constructed from the sublimation rate data do appear consistent with a normal distribution of K_v data in a set of vials, the data available are not sufficient for a critical test. Experiments involving a very large number of vials in a freeze-dryer with no significant position effects would be needed for a definitive study of the distribution function. Thus, one should exercise caution in assuming a normal distribution for the vial heat transfer coefficients.

Mechanisms of Heat Transfer—In principle, the contribution of each of the parallel mechanisms of heat transfer from shelf to vial may be evaluated by regression analysis of K_v data as a function of pressure using the mathematical model defined by Eqs. 9–11 and 14. The zero pressure intercept of K_v *versus* pressure defines the sum of the radiative and the contact conduction contributions. The radiative contribution (Eq. 14) is evaluated independently by evaluation of the effective emissivity for top radiation, $e_v = 0.84$ (Table IV), and by measurement of the emissivity of the shelf surface (0.28 for polished stainless steel, 0.95 for painted black shelf). The contact contribution, K_c, is calculated from the zero pressure intercept of K_v and the calculated value of the radiative contribution, K_r. Both heat conductivity parameters, Λ_0 and λ_0, are available from the literature (5, 11). The gas conduction term, K_g (Eq. 10), is therefore determined by the accommodation coefficient, a_c (Eq. 11) and the effective mean separation distance between the bottom of the vial and the shelf, l. Thus, three parameters, K_c, a_c, and l, are determined by regression analysis of the data. However, the multivial K_v data set for any type of vial consists of K_v values at only three or four different pressures, which is insufficient data to evaluate the three parameters with acceptable accuracy. In theory (12), the accommodation coefficient is a function of the natures of the gas, the shelf surface, and the vial surface. The gas is independent of the vial studied, the vial surface is always glass, and, with the exception of one study with the pilot dryer, the shelf surface is polished stainless steel. Therefore, the accommodation coefficient is assumed to be a constant and is evaluated by simultaneous regression analysis of all data sets, where K_c and l are vial specific, but the accommodation coefficient is independent of the type of vial. Both single vial-generated data, fit to Eq. 19, and multivial data, fit to Eqs. 9–11 and 14, were used to determine the accommodation coefficient. Although single vial data may yield inaccurate values of K_c and l (see *Experimental Section*), these data are suitable for evaluation of the accommodation coefficient.

Table IX—Vial Heat Transfer: Comparison of Heat Transfer Mechanisms for Vials on a Polished Stainless Steel Shelf

Vial	Contribution to Heat Flow, % of Total					
	P = 0.1 mm Hg			P = 0.4 mm Hg		
	Radiation	Contact	Gas	Radiation	Contact	Gas
K5800	21	32	47	13	19	68
W5816	27	16	57	16	9	75
5303	32	11	57	22	8	70

Single vial heat transfer data for the 5303, W5816, W5800, K5800, and W5811 vials are well represented by the theoretical model (Eq. 19) with a single accommodation coefficient of 0.72 ± 0.07. The uncertainty given is the standard error provided by the MLAB[21] fit program. The data are the result of replicated experiments consisting of 132 data points at chamber pressures from 0.06 mm Hg to 0.6 mm Hg and at shelf temperatures from −15°C to 25°C. The computer fit provided 11 parameters, including the accommodation coefficient, with a relative SD in $\dot{Q}$ of 7.7%, which is within the anticipated

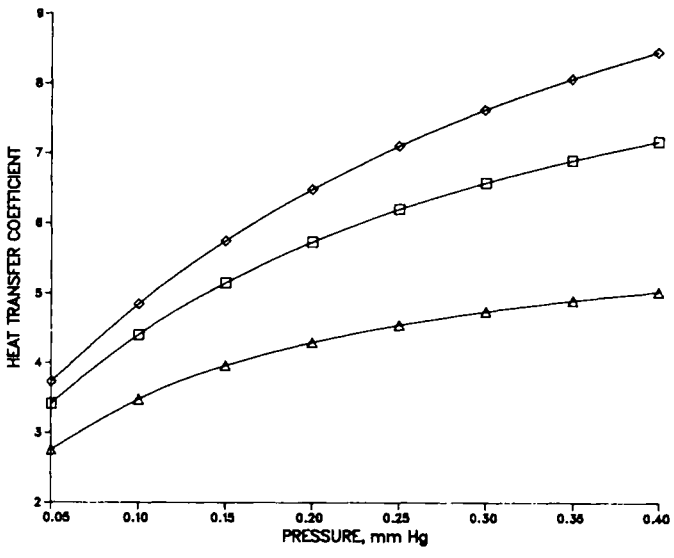

Figure 7—*Pressure dependence of vial heat transfer coefficients for selected vials. Key: (□) W5816, (◇) K5816, and (△) 5303.*

[20] The variance in a standard deviation estimate based on N measurements is approximately $\sigma^2/2N$ (14), where σ^2 is the variance in the measured quantity. Thus, the SD in $\hat{\sigma}(\dot{m})$ is $\approx \hat{\sigma}(\dot{m})/\sqrt{2N}$. Assuming that in the evaluation of $\sigma(K_v)$ from $\hat{\sigma}(\dot{m})$, the only uncertainty of consequence originates in the uncertainty in $\hat{\sigma}(\dot{m})$; numerical calculations give 1.6% for the average uncertainty (SD) in $\sigma(K_v)$.

[21] MLAB is a general purpose model fitting a computer program package available from the Division of Computer Research and Technology, National Institutes of Health, Bethesda, Md.

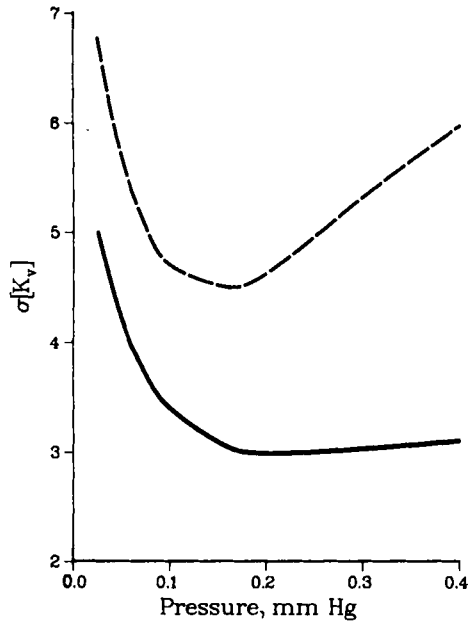

Figure 8—*Calculated pressure dependence of the relative standard deviation in vial heat transfer coefficients. Key: (—) mean of W tubing vials, and (- - -) mean of K tubing vials.*

experimental error. The multivial data set, consisting of 22 (K_v, P) data pairs, is also well represented by the theoretical model. Eleven parameters, including a single accommodation coefficient, $a_c = 0.62 \pm 0.05$, are obtained. The *SD* of the fit for 10^4K_v is ±0.10, which is within the precision of the data. The agreement between the single vial results and the multivial results for a_c is satisfactory, and the mean value, 0.67, is taken as the effective accommodation coefficient for vial heat transfer. When a_c is fixed at 0.67, and the regression analysis of single vial and multivial data are repeated, the quality of the fit obtained is essentially identical to that found when a_c is an adjustable parameter. The resulting K_c and l parameters are listed in Table VIII.

Since multivial data are generally a more accurate representation of the heat transfer characteristics of the mean of a set of vials, only multivial-derived parameters are listed for the tubing vials (5800, 5816, 5811). The parameters for the 5304 vials are derived from single vial studies with two "typical" vials since multivial results are not available. In general, K_v data from single vial studies are in satisfactory agreement with the correspondingly more accurate multivial data; the mean relative deviation in K_v is <6%. For the 5303 vials, the agreement between multivial and single vial data is less satisfactory, and this lack of agreement in K_v data is reflected in a comparison of the heat transfer parameters (K_c and l) obtained from the two data sets (Table VIII, footnote *c*). Moreover, the standard error in l derived from the multivial data is unusually large. Lacking a satisfactory explanation for these observations, the K_c and l parameters reported (Table VIII) for the 5303 vials represent means of the results of single vial- and multivial-derived parameters.

The values of l (Table VIII) correlate reasonably well with the l_{max} data from Table I, where l_{max} is the approximate maximum separation distance between the vial surface and a flat surface. Linear regression gives:

$$l = 0.023 + 0.273\, l_{max} \qquad \text{(Eq. 23)}$$

with a correlation coefficient of 0.958. The values of K_c might be expected to correlate with the ratio of the contact area to the total vial area, denoted f_c, where the contact area is calculated from the diameter and thickness of the contact print. As a rough approximation, $10^4K_c = 12f_c$, but the correlation coefficient is only 0.76.

The uncertainties given (Table VIII) are standard errors provided by the computer output and are a useful indication of uncertainty only when data in Table VIII are compared. The value of K_c is particularly sensitive to changes in a_c and may also depend on the mathematical form chosen for K_g. An increase of 0.05 in a_c results in a decrease in 10^4K_c of 0.20. With the mathematical form of K_g fixed by Eq. 10, the standard error in a_c is ± ~0.05, corresponding to an absolute uncertainty in 10^4K_c of ±0.2. Note, however, that if the value of a_c is really 0.72 instead of 0.67, all values of 10^4K_c in Table VIII decrease by 0.2. The mathematical form of K_g (Eq. 10) is derived for two surfaces separated by a constant distance, l. The separation distance between the vial and the shelf is not a constant, but generally decreases as the radial distance from the center of the vial increases, until the contact print region is reached. As the radial distance increases further, the separation distance

Table X—Variation in Vial Heat Transfer Coefficients: Components of $\sigma(K_v)$ Defined by Eq. 25

Vial	RSD	
	Constant Term, $\sigma(K_K)$	Separation Distance, $\sigma(l)$
W5800	5.0	8.9
K5800	8.8	14.4
W5811	6.7	5.5
W5816	7.9	3.6
K5816	8.9	13.8
5303	4.6	7.0

increases sharply up to a maximum value characteristic of the vial. An alternate mathematical model for K_g (denoted model II), based on the vial bottom geometry discussed above, produces an extremely complex mathematical form for K_g[22]. Regression analysis of single vial and multivial data using K_g from model II yields an accommodation coefficient of 0.84 ± 0.04 and gives contact parameters, 10^4K_c, which are in good agreement with the corresponding parameters given in Table VIII. The quality of the fit is the same as that found using Eq. 10 for K_g. The absolute value of the difference between the corresponding values of 10^4K_c averages 0.14, as the parameters from model II are systematically lower. Thus, it appears that as long as the form of K_g provides a good fit to the data, the values of the contact parameter obtained are not extremely sensitive to the precise form of K_g used. We conclude that the systematic error in 10^4K_c introduced by the combination of uncertainty in a_c and uncertainty in the form of K_g is > ± ~0.3.

The energy accommodation coefficient, a_c, measures the efficiency of energy transfer in a collision between a gas molecule and a surface. For an elastic collision no energy is transferred and $a_c = 0$, while for a perfect inelastic collision, the gas molecule "equilibrates" with the temperature of the surface and $a_c = 1$. Since both the vial and shelf surfaces are involved in energy transfer, the accommodation coefficient for vial heat transfer reflects an average accommodation coefficient for gas molecule collisions with the two surfaces. For freeze-drying, the gas is nearly pure water vapor (Table III), and the error in a_c introduced by assuming the vapor is 100% H_2O is negligible[23]. Thus, although the value of a_c determined from the data may depend slightly on the model chosen for K_g, 0.67 ± 0.05 for Eq. 10 *versus* 0.84 ± 0.04 for Model II, both models suggest incomplete energy transfer ($a_c < 1$) for the collision of a water molecule with one (or both) of the surfaces involved. Due to the difficulties in evaluating an accommodation coefficient from vial heat transfer data, the conclusion, $a_c < 1$, must be regarded as tentative. Unfortunately, the accommodation coefficient data in the literature (12), do not include data for water vapor or glass surfaces.

Theoretically, the accommodation coefficient could depend on the nature of the shelf surface; however, at least for the two surfaces investigated, polished stainless steel and black paint, the K_v data (Table V) suggest such a dependence is minimal. The increase in K_v obtained with a black painted shelf (experiment 7 *versus* experiment 5, Table V), $\Delta 10^4K_v = 0.57 \pm 0.14$, is fully consistent with the observed increase in shelf emissivity, $\Delta e_s = 0.67 \pm 0.10$.

The relative importance of the three heat transfer mechanisms (radiation, contact conduction, and gas conduction) are compared in Table IX. Although the contact contributions are somewhat uncertain due to the possible systematic errors in K_c discussed earlier, it does appear that all three heat transfer mechanisms can make significant contributions to the total heat flow in freeze-drying. The dominant mechanism depends on both the chamber pressure and the type of vial considered. At chamber pressures >0.1 mm Hg, the dominant mechanism is gas conduction, but even at 0.4 mm Hg, both radiation and contact conduction can be important for some vials.

[22] Model II assumes that the vial bottom curvature near the shoulder is described by a semicircle of radius k_s while the curvature in the middle of the vial may be approximated by the arc of a circle. The arc and semicircle meet at $r = a$ (near the contact print region). Thus, K_g is obtained by integration of Eq. 10 over the radial distance $0 \le r \le r_v$, where r_v is the vial radius, $\sqrt{A_v/\pi}$, and the separation distance, l, is a function of r. For $0 \le r \le a$, the equation for an arc is used to obtain $l(r)$, while for $a \le r \le r_v$, the equation of a semicircle is used to evaluate $l(r)$. The value of a is calculated from $r_v = a + k_s$, where k_s is measured from the vial geometry and found to be 0.25 cm (10-mL vials), 0.32 cm (20-mL vials), and 0.44 cm (5303 vials). The resulting expression for K_g may be written in the form: $K_g = [(\lambda_0/h)/(1 + k_s/a)^2] \cdot \ln [1 + (\Lambda_0/\lambda_0)\alpha hP] + [2(ks/a)\Lambda_0\alpha P/(1 + ks/a)^2] \int_0^1 [1 + (ks/a)x]dx/[1 + (ks\Lambda_0\alpha P/\lambda_0)(1 - \sqrt{1 - x^2})]$ where h is the distance between the shelf and the vial bottom at the vial center (r = 0), and x is a dummy variable. The remaining symbols are as previously defined. The definite integral is a function of pressure, P, which must be evaluated by numerical procedures. Regression analysis of the data using the model II function for K_g gives an excellent fit to the data, but the values of h determined from the regression analysis are consistently a factor of ~2 larger than the measured separation distances (Table I).

[23] The average mole fraction of air (Table III) is ~0.15. Assuming that the value of Λ_0 is a weighted average of the Λ_0 data for water vapor and air, with the mole fraction of each component as the corresponding weight, the value of Λ_0 is calculated as 5.98×10^{-3} (P in mm Hg), compared with 6.34×10^{-3} for pure H_2O. Using 5.98×10^{-3} for Λ_0 increases the value of a_c determined from the data by only 0.03.

Table XI—Variation in Sublimation Rate Attributable to Tube Variation

Tube/Vial	Percent Deviation from Run Mean M	46	60	47	41	Row Mean
1	−0.17	−3.40	−5.42	−4.26	−5.06	−3.66

Row effect (tube), σ_R^2	0.03[a]

[a] Excluding M vial: $\sigma^2 = 0.44$, $\sigma_R^2 = 0.05$.

The pressure dependence of K_v is illustrated in Fig. 7 for several vials. The data shown are evaluated from the parameters in Table VIII. The curvature is a reflection of the importance of the separation distance, l, which is highly vial specific. Thus, particularly at high pressure, the vial heat transfer coefficient is quite sensitive to the geometry of the vial bottom.

Intervial Variability in K_v*: Pressure Dependence*—While there is no obvious pressure dependence in the $\sigma(K_v)$ data, theoretical considerations suggest a small but significant pressure dependence may be obscured by the lack of precision in the data. Assuming the variation in K_v arises from both variation in the pressure-independent term, $K_r + K_c$, and from variation in the separation distance, l, the variance in K_v is written:

$$\sigma^2(K_v) = \left(\frac{\partial \ln K_v}{\partial \ln K_K}\right)^2 \cdot \sigma^2(K_K) + \left(\frac{\partial \ln K_v}{\partial \ln l}\right)^2 \cdot \sigma^2(l) \qquad \text{(Eq. 24)}$$

where K_K denotes the pressure independent part of K_v, $K_K = K_r + K_c$, and the sigmas represent *RSD* values. Equation 24 also assumes that the deviations in K_K and l are not correlated. Evaluation of the derivatives in Eq. 24 then gives:

$$\sigma^2(K_v) = \sigma^2(K_K)G1(P) + \sigma^2(l)G2(P) \qquad \text{(Eq. 25)}$$

where $G1$ and $G2$ are functions of pressure:

$$G1(P) = (1 + k_D \cdot P)^2/[1 + (k_D + k_p/k_K)P]^2 \qquad \text{(Eq. 26)}$$

$$G2(P) = (k_p/k_K)^2 \left[\frac{k_p \cdot P^2}{1 + k_D P}\right]^2/[1 + (k_D + k_p/k_K)P]^2 \qquad \text{(Eq. 27)}$$

where $k_D = (\Lambda_0/\lambda_0)\alpha \cdot l$, $k_p = \Lambda_0\alpha$, and the other symbols have their usual meanings. The functions, $G1$ and $G2$, depend on vial type as well as pressure, but at low pressure $G1 \gg G2$, and at 0.4 mm Hg, $G2$ is slightly larger than $G1$.

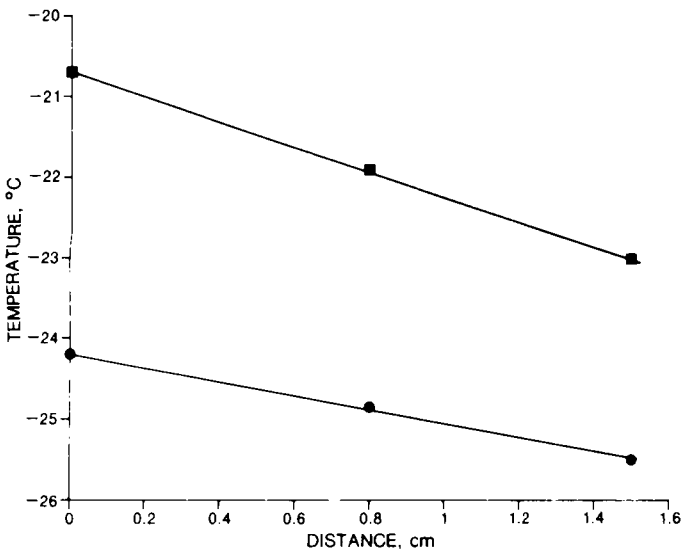

Figure 9—*Product temperature as a function of distance from the vial bottom. Key: (●) heat flux = 5.4 mcal/cm²·s, (■) heat flux = 10.6 mcal/cm²·s.*

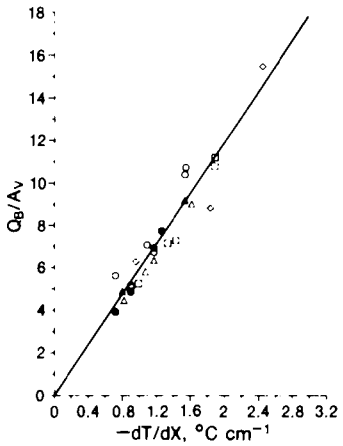

Figure 10—*Heat flux as a function of temperature gradient in the frozen product;* $\dot{Q}_B = \Lambda_r K_I[-dT/dx]$*;* $10^3 K_I = 5.9 \pm 0.4$*. Key: (○) W5800, (●) W5800 (5% KCl), (□) K5800, (△) W5811, (◇) W5816.*

Formally, Eq. 25 gives $\sigma^2(K_v)$ as a function of two variables, $G1$ and $G2$, with $\sigma(K_K)$ and $\sigma(l)$ as parameters. Regression analysis of the $\sigma(K_v)$ data, according to Eq. 25, produces "experimental" values for $\sigma(K_K)$ and $\sigma(l)$ (Table X). Presumably, variation in the contact term is the major contributor to $\sigma(K_K)$. The data are well represented by Eq. 25, but neither the precision nor the extent of the data is sufficient to establish the validity of Eqs. 25–27. Rather, provided one assumes the theoretical analysis in Eqs. 25–27 is valid, the data are sufficient to establish both $\sigma(K_K)$ and $\sigma(l)$ for each vial type with slightly better accuracy than the accuracy in the input $\sigma(K_v)$ data. The means of $\sigma(K_K)$ and $\sigma(l)$ for all W tubing vials are 6.5 and 6.0, respectively; the corresponding means for K tubing vials are 8.8 and 14.1, respectively. Thus, the K vials display somewhat greater relative variability, particularly in the separation distance. Calculated values of $\sigma(K_v)$, Eq. 25, for the average W and average K vials do show a pressure dependence (Fig. 8), the variability in K_v passing through a minimum at ~0.15 mm Hg. Particularly with K tubing vials where the minimum is relatively pronounced, primary drying will be more uniform if the chamber pressure is maintained between 0.1 and 0.2 mm Hg.

Intravial Temperature Distribution—The temperature of the frozen mass in the vial is routinely measured at four locations (Fig. 1) during all single vial experiments. No significant temperature difference is observed between the bottom center and bottom edge of the vial, suggesting that radial heat flow is minimal. As expected, however, the temperature decreases linearity with distance, X, from the vial bottom (Fig. 9), the slope increasing in magnitude as the heat flow through the bottom of the vial increases. Theoretically, the heat flow rate through the bottom of the vial, $\dot{Q}_B$, should be directly proportional to the temperature gradient, $\partial T/\partial X$ (Eq. 15). Evaluating $\dot{Q}_B$ as previously described yields the data shown in Fig. 10. Within the precision in the data, the heat flux, $\dot{Q}_B/A_v$, is directly proportional to the measured temperature gradient. The scatter in the data is largely a consequence of the uncertainty in temperature measurement. The slope appears to be independent of vial type; moreover, the data for KCl solutions do not deviate significantly from the data obtained using pure water. It appears that, independent of the vial type or product, the temperature distribution in a vial may be characterized by Eq. 15 with a constant value for the effective product thermal conductivity, K_I. Regression analysis yields $10^3 K_I = 5.9 \pm 0.4$. Theoretically, K_I contains contributions from both the frozen mass and the glass, Eq. 16. From the vial dimensions (Table I) and the thermal conductivity of glass (13), the thermal conductivity of the frozen product, κ_p, is calculated: $10^3\kappa_p = 6.6 \pm 0.5$ cal/s-cm-°C, in excellent agreement with literature data for ice (6, 7) at corresponding temperatures (−25°C).

CONCLUSIONS

The vial is an extremely important variable in the primary-drying stage of the freeze-drying process. Although the direct effect of the vial on mass transfer (*via* closure resistance) is slight, the nature of the vial does significantly affect the rate of heat transfer to the product and is a major factor in determining the product temperature and drying time for a given set of chamber pressure–shelf temperature settings. Vial heat transfer coefficients increase with increasing chamber pressure, but the pressure dependence is nonlinear. At high pressures, the coefficients are less sensitive to changes in pressure. The magnitude of the vial heat transfer coefficient is sensitive to the geometry of the vial bottom. While the thickness of the glass in the vial bottom

[a] Position 4 is class A (adjacent to shelf temperature sensor); all others are class H.

is not important, both the average separation distance between the vial bottom and the shelf and the degree of physical contact between the vial and the shelf are critical factors. The *RSD* in vial heat transfer coefficients, reflecting variability within a given lot of vials, is rather small (≈4%). However, large differences in vial heat-transfer coefficients exists between different types of vials. Even vials of nominally the same specifications, manufactured by different suppliers, differ significantly in their heat transfer characteristics. A freeze-drying cycle, optimized using one type of vial, cannot be expected to perform satisfactorily with a different vial. Indeed, circumstances may arise where a product is routinely freeze-dried with excellent yield, but a change of supplier for vial stock results in significant product loss arising from eutectic melt. Clearly, heat transfer characteristics must be given serious consideration when vial specifications are determined.

APPENDIX I: Data Analysis for K_v and $\sigma(K_v)$ Evaluation

Evaluation of Intervial Variability $\sigma(K_v)$—The multivial experiment directly yields the estimated variance in the sublimation rate for a given set of vials, $\hat{\sigma}^2(\dot{m})$. The desired parameter is the *RSD* in the vial heat transfer coefficients, $\sigma(K_v)$, and considerable data reduction is needed to extract $\sigma(K_v)$ from the raw data. First, components of variance in $\dot{m}$, due to causes unrelated to the vial heat transfer coefficient, must be subtracted from the estimated variance in $\dot{m}$, $\hat{\sigma}^2(\dot{m})$, to obtain the variance in $\dot{m}$ due to variation in the vials, σ_v^2. Second, the calculated value of σ_v must be converted into the corresponding value of $\sigma(K_v)$.

In addition to variation in vial heat transfer coefficients, three sources of variation in sublimation rate are possible: (*a*) variation in the mass transfer coefficients of the metal tubes, (*b*) variations due to location of the vial on the shelf originating from variations in shelf surface temperature and variations in radiation effects, and (*c*), measurement error or intrinsic variation in the procedure itself, probably resulting mostly from variability in the surface area and contour of the ice-vapor interface[24].

A series of six multivial experiments at a chamber pressure of 0.2 mm Hg were designed to evaluate the various components of variance in sublimation rate. The entire series of experiments were carried out with the same set of W5800 vials in the laboratory dryer. For most of the vials, the vial number, the metal tube used, and the shelf position were held constant throughout the series to allow evaluation of the intrinsic variation or "error" component of the variance, σ^2. For the first five experiments, a subgroup of five vials and corresponding positions were fixed, and the five metal tubes were rotated among the subgroup to determine the effect of variation in metal tube on the sublimation rate. A second subgroup of five vials, with corresponding metal tubes, were rotated among five selected shelf positions to determine the effect of shelf positions on the sublimation rate. The vial placement used in these studies is shown in Fig. 5, where each vial is shown as a circle. The term "pressure tube channel" denotes the space occupied by the tube connecting

[24] Particularly with pure ice, the ice-vapor interface does not remain perfectly planar during the entire experiment. While the mass transfer resistance of the solid to vapor phase transition is small, it is not zero (3), and variation in surface area will therefore have a small effect on the overall mass transfer resistance. Moreover, the effective thickness of the ice plug for heat transmission from the vial bottom may vary slightly between vials or between replicate experiments with the same vial. Thus, even for fixed K_v and fixed T_s, the sublimation rate will vary slightly within a given set of vials.

Table XIII—Sublimation Rate Variation in Pilot Dryer: Percent Deviation from Mean Sublimation Rate Related to Vial Position[a]

[a] 5303 vials, 0.2 mm Hg.

the interior of the modified vial to the pressure sensor. Vials on the edge of the shelf, which are exposed to the chamber walls, are marked with an E. All other (interior) vials are divided into two classes: class A, which represents those vials adjacent to a shelf temperature sensor, and class H, where the vial is in a hexagonal close-packed configuration with other vials, as would be found in normal loading of a freeze-dryer. Vials adjacent to the pressure tube channel are not rigorously in a hexagonal configuration, but the results of this series of experiments and subsequent multivial experiments indicate that vials adjacent to the pressure tube channel show no measureable position bias when compared with hexagonally packed vials. The vial identification number is given in the lower part of the circle, and the class A vials have a bar underlining the vial number. [The modified vial (Fig. 1) is denoted M.] The symbols P_1, P_2, P_3, P_4, and P_5, refer to the positions used in the position rotation study while the symbols T_1, T_2, . . . , refer to vials-positions used in the tube rotation study. Thermocouple-containing vials have the designation TC, followed by the thermocouple identification numbers, or numbers in the case of multiple-thermocouple vials. The number in the top part of the circle, containing a decimal point, is the percent deviation of the mean sublimation rate for that vial-position combination from the corresponding mean for the total interior set of vials. The deviations recorded for the P vials correspond to the mean deviation for that position as found in the position rotation study.

The edge vial deviations represent the results of a single experiment but clearly show a higher sublimation rate than the interior vials. The mean deviation in sublimation rate for the edge vials is 15.0 ± 1.5%, where the uncertainty is the *SD* of the mean. The higher sublimation rate for edge vials is undoubtedly due to radiation effects from the edge of the shelf and chamber wall. Since edge vials are atypical, edge vial data are excluded from the data analysis. It should also be noted that vial 22 (Fig. 5, upper left corner) behaves anomalously. The edge vials surrounding vial 22 displayed a tendency to move away from it during the course of the experiment, presumably due to vibrations, giving vial 22 some characteristics of an edge vial. Thus, vial 22 is also excluded from data analysis.

The raw data and corresponding analysis of variance for the metal tube rotation portion of the experiment (Table XI) show essentially zero variance in sublimation rate caused by variation in the mass transfer coefficient of the metal tubes. All standard deviations (σ) are relative standard deviations. The estimated or directly measured *SD* in the first three rows of the analysis of variance section are evaluated with $N - 1$ weighting from the raw data. The value of $\hat{\sigma}_{\bar{C}}$ is computed from the column means while the value of $\hat{\sigma}_{\bar{R}}$ is computed from the row means. The last three rows in the analysis of variance section are calculated variances for an infinite set of vials evaluated from the variances in the first three rows using the appropriate corrections for degrees of freedom (14). The measurement error component, σ^2, represents the intrinsic variability in the experiment while the column effect, σ_c^2, gives the variance originating from vial-position variability. The variance component giving the row effect, σ_R^2, represents the contributions to the variance in sublimation rate originating from variation in metal tubes. Clearly, variation in the mass-transfer coefficient of the metal tubes is negligible.

The results of the position rotation experiment (Table XII) indicate a significant position effect, but nearly all of this effect is due to a difference between class A and class H interior shelf positions. Indeed, when position 4 (class A) is excluded from the analysis, the remaining four positions yield a position variance of only 0.47. Thus, the shelf temperature uniformity appears to be excellent.

The mean bias between position 4 and the other positions is 5.1 ± 1.0%, where the uncertainty is the standard error in the bias estimate. Additional multivial experiments comparing class A positions with class H positions yield a bias of 3.6 ± 1.0%, in reasonable agreement with the value obtained from the data in Table XII. The higher sublimation rate for vials adjacent to a shelf sensor is probably a result of radiative heat transfer from the shelf sensor, at roughly the shelf temperature, to the vial. We write[25]:

$$\Delta\dot{Q}_A \cong A_v S_a \times 10^{-4} (T_s - T_b) \qquad \text{(Eq. 28)}$$

where $\Delta\dot{Q}_A$ is the extra heat flow coming from the shelf sensor. The parameter, S_a, evaluated from the data is 0.31.

The measurement error variance, σ^2, is estimated from the replication data for those vials where the vial position is held fixed for the series of six experiments. Using $N - 1$ weighting, the estimated variance is calculated for each vial, and the mean variance of each vial class is taken as the measurement error variance for that class. For class A vials $\sigma^2 = 4.3$, while for class H vials, $\sigma^2 = 2.6$.

For a set of N vials of which A vials are adjacent to a shelf temperature sensor, the total estimated variance in $\dot{m}$, $\hat{\sigma}^2(\dot{m})$, where $\hat{\sigma}(\dot{m})$ is the estimated *RSD* in $\dot{m}$, with $N - 1$ weighting, may be approximated by:

$$\hat{\sigma}^2(\dot{m}) = \sigma_v^2 + \sigma_{SP}^2 + (A/N)\sigma_{EA}^2 + (1 - A/N)\sigma_{EH}^2 + (A/N)(1 - A/N)r^2 \qquad \text{(Eq. 29)}$$

here, σ_v^2 is the variance component from variation in the vial heat transfer coefficient, σ_{SP}^2 is the variance component from shelf position variation for class H vials [0.47 (Table XII)], σ_{EA}^2 and σ_{EH}^2 are the measurement error components for class A (4.3) and class H (2.6) vials, respectively. The term in r gives the variance component originating in the class bias between class A and class H vials where:

$$r = 10^2 \frac{\Delta\dot{m}_A}{\langle\dot{m}\rangle} = \frac{0.0545\, A_v S_a (T_s - T_b)}{\langle\dot{m}\rangle} \qquad \text{(Eq. 30)}$$

The term, $\Delta\dot{m}_A$, is the difference in sublimation rate (g/h) between a class A vial and the mean sublimation rate for the entire set, $\langle\dot{m}\rangle$. From the variance data obtained in the series of preliminary experiments described in Tables XI, XII and Fig. 5, and the experimental value of $\hat{\sigma}^2(\dot{m})$ obtained for a given experiment, the corresponding variance due to variation in the vial transfer coefficient, σ_v^2, may be calculated. When A/N is ~0.5, the position bias term in Eq. 29 is large and may be the largest component of variance, thus limiting the accuracy with which σ_v^2 may be determined.

Equation 29 is an approximation where the most serious problem arises from the assumption that the measurement error variances and class bias do not vary between experiments. Clearly, the accuracy in σ_v^2 would be greatly improved with an experimental design where A/N is zero without decreasing N significantly. Originally, we were concerned with potential shelf temperature variation with position and chose to employ two shelf sensors at central locations on the shelf (A/N is ~0.4). However, experience has shown that shelf temperature variation is not a problem with the laboratory dryer, and our current experiment design uses only one shelf sensor at an edge vial location and does not use the modified (M) vial. Thus, the pressure tube channel is filled with vials. The net result is that only one vial from a set of ~15 is adjacent to the shelf sensor, and this vial is excluded from the data analysis. Only vials in a truly hexagonal packing arrangement are used in the data analysis.

The *RSD* in sublimation rate is slightly smaller than the corresponding *RSD* in the vial heat transfer coefficient. The sublimation rate is proportional to the product of K_v and the temperature difference, $T_s - T_b$. A given positive deviation in K_v produces a corresponding increase in T_b, thereby decreasing slightly the temperature difference, $T_s - T_b$, resulting in a net relative increase in $\dot{m}$ smaller than the relative increase in K_v. The *RSD* in K_v, $\sigma(K_v)$, may be related to the *RSD* in $\dot{m}$, σ_v by:

$$\sigma(K_v) = \sigma_v \cdot \frac{d \ln K_v}{d \ln \dot{m}} \qquad \text{(Eq. 31)}$$

where:

$$\frac{d \ln K_v}{d \ln \dot{m}} \cong 1.2 + 400\, K_v \qquad \text{(Eq. 32)}$$

Since K_v is of the magnitude 5×10^{-4}, the value of $\sigma(K_v)$ is ~50% greater than σ_v. The derivation of Eq. 32 is given in *Appendix II*.

Due to significant shelf position effects, evidently originating, at least in part, from nonuniformity of shelf temperature, the statistical analysis for data generated with the pilot dryer differs slightly from the analysis (Eq. 29) given data from the laboratory dryer. The procedure used with data from the pilot dryer is outlined in Table XIII. Here, the rows and columns represent vial locations on the dryer shelf. The numbers within the row-column matrix are percent deviations of the sublimation rate for a given vial-position from the mean sublimation rate of all interior vials. The *RSD* ($\hat{\sigma}(\dot{m})$, $\hat{\sigma}_{\bar{c}}$, and $\hat{\sigma}_{\bar{R}}$) are evaluated directly from the raw data as described previously in the discussion of Table XI. The last four rows in the analysis of variance section of Table XIII are calculated data (14)[26] using $\sigma^2 = 1.99$. This value of σ^2 is determined from a series of replication experiments with 5303 vials in the pilot dryer. Note that the column position effect, σ_c^2, and row position effect, σ_R^2, are major contributors to the total variance. The term of interest, the variance in $\dot{m}$ due to vial heat transfer variations, σ_v^2, is <50% of the total variance.

Evaluation of Vial Heat Transfer Coefficients From Multivial Data—The vial heat transfer coefficient is formally defined by Eq. 8 when the surface above the vials is at the temperature of the shelf. For both the laboratory and pilot dryers, the temperature of the surface above the vials differs somewhat from the shelf temperature. Moreover, although the average sublimation rate is measured, from which the mean heat transfer rate may be calculated, the temperature difference $T_s - T_b$ is measured for a limited number of vials, normally four. Therefore, the average temperature difference corresponding to the average heat-transfer rate is not directly measurable, and an indirect calculation procedure is used to evaluate the average heat transfer coefficient.

First, the mean heat transfer rate corresponding to heat flow through the vial bottom, $\langle\dot{Q}_B\rangle$, is evaluated from the mean heat transfer rate, $\langle\dot{Q}\rangle$, by subtraction of the top radiation contribution:

$$\langle\dot{Q}_B\rangle = \langle\dot{Q}\rangle - A_v e_v \sigma (T_L^4 - T^4) \qquad \text{(Eq. 33)}$$

where σ is the Stefan-Boltzmann constant, T_L is the temperature of the surface above the vials, and e_v is taken as 0.84 (Table IV). The value of $\langle\dot{Q}\rangle$ in cal/s is calculated from the mean sublimation rate in g/h by $\langle\dot{Q}\rangle = 0.1833\langle\dot{m}\rangle$. The temperature, T_L, is directly measured, and the temperature of subliming ice, T, is evaluated indirectly from the mean sublimation rate and the chamber pressure. Since the gas in the vial is essentially pure water vapor at the equilibrium vapor pressure of the subliming ice, the mean sublimation rate, mean vapor pressure, and chamber pressure are related (Appendix II, Eq. 41). Thus, the mean vapor pressure is determined from the mean sublimation rate, and the corresponding mean ice temperature, $\langle T\rangle$, is evaluated from the mean vapor pressure[15]. Equation 33 is used to evaluate the mean heat transfer rates for both the set of thermocouple-containing vials and the complete vial set.

That portion of the vial heat transfer coefficient representing heat transfer from the shelf to the vial bottom, denoted K_{vB}, is evaluated for the set of thermocouple-containing vials:

$$\langle K_{vB}\rangle_{TC} = \langle\dot{Q}\rangle_{TC}/A_v\langle T_s - T_b\rangle \qquad \text{(Eq. 34)}$$

where the subscript TC denotes the mean of the thermocouple vial set. The mean of K_{vB} for all vials, denoted $\langle K_{vB}\rangle$, is obtained indirectly. In general, the value of $\langle\dot{Q}_B\rangle_{TC}$ is slightly different from the corresponding mean of all the vials, $\langle\dot{Q}_B\rangle$. Treating this small difference as a differential, $d\langle\dot{Q}_B\rangle \cong \langle\dot{Q}_B\rangle - \langle\dot{Q}_B\rangle_{TC}$, the corresponding differential in $\langle K_{vB}\rangle$, $d\langle K_{vB}\rangle = \langle K_{vB}\rangle - \langle K_{vB}\rangle_{TC}$, may be evaluated from the value of the derivative, $d \ln K_{vB}/d \ln \dot{Q}_B$ (Appendix II, Eq. 45). Thus, the value of $\langle K_{vB}\rangle$ is given by:

$$\langle K_{vB}\rangle = \langle K_{vB}\rangle_{TC}\,[1 + (1.2 + 400\,\langle K_{vB}\rangle_{TC}) \cdot (\langle\dot{Q}_B\rangle/\langle\dot{Q}_B\rangle_{TC} - 1)] \qquad \text{(Eq. 35)}$$

The value of $\langle K_{vB}\rangle$ calculated from Eq. 35 refers to the mean of all vials and, therefore, includes the effects of atypical radiation heat transfer from the shelf sensor for the class A vials. The result of Eq. 35 is corrected to represent only class H (normal position) vials by subtracting the term, $S_a \times 10^{-4}\,(A/N)$, (see Eq. 28) from $\langle K_{vB}\rangle$. Finally, the total vial heat transfer coefficient, as defined by Eq. 8, is obtained by adding $e_v \times 10^{-4}$ to the corrected result from

[25] Heat flow from the shelf sensor to the vial is probably proportional to the "cylinder" area of the vial, A_c. However, for the vials studied, A_c is approximately proportional to the cross-sectional vial area, A_v.

[26] For a matrix of deviations containing p rows and q columns, where the rows and columns represent position effects, the random component of variance is the sum, $\sigma_v^2 + \sigma^2$, which may be evaluated from (14): $\sigma_v^2 + \sigma^2 = [(pq - 1)/(p - 1)(q - 1)]\hat{\sigma}^2(\dot{m}) - p/(p - 1)\hat{\sigma}_{\bar{c}}^2 - [q/(q - 1)]\,\hat{\sigma}_{\bar{R}}^2$.

Eq. 35 to provide for the correct top radiation term under the conditions of Eq. 8. Thus, the mean value of K_v for the vial set is:

$$K_v = \langle K_{vB} \rangle - S_a \times 10^{-4} (A/N) + e_v \times 10^{-4} \qquad \text{(Eq. 36)}$$

where $\langle K_{vB} \rangle$ is given by Eq. 35, S_a is taken as 0.31, and e_v is 0.84 (Table IV).

APPENDIX II: Relationship of Relative Standard Deviation in K_v with Relative Standard Deviation in $\dot{m}$

The relationship of $\sigma(K_v)$ to $\hat{\sigma}(\dot{m})$ depends on the derivative, $d\ln K_v/d\ln \dot{m}$ according to Eq. 31. This derivative may be evaluated with sufficient accuracy assuming the temperature of the source of top radiation is equal to the shelf temperature, T_s. With this assumption, the sublimation rate, $\dot{m}$ (g/h) may be written:

$$\dot{m} = \frac{3600\, A_v K_v}{\Delta \overline{H}_s} (T_s - T_b) \qquad \text{(Eq. 37)}$$

where $\Delta \overline{H}_s$ is the heat of sublimation and the factor, 3600, converts sublimation rate from g/s to g/h. Similarly, the sublimation rate may be related to the temperature difference between the bottom of the vial and the temperature of subliming ice using the approximation:

$$\dot{m} \cong \frac{3600\, A_v K_I}{\Delta \overline{H}_s} \frac{(T_b - T)}{l_i} \qquad \text{(Eq. 38)}$$

where l_i is the thickness of the ice plug and T is the temperature of the subliming ice. The relationship given by Eq. 38 is rigorous only when all heat flow comes through the vial bottom. However, the error introduced by using Eq. 38 does not seriously affect the results of this section. Differentiation of Eq. 37 yields:

$$\frac{d \ln K_v}{d \ln \dot{m}} = 1 + 3600 \frac{A_v K_v}{\Delta \overline{H}_s} \left(\frac{d\dot{m}}{dT} \cdot \frac{dT}{dT_b} \right)^{-1} \qquad \text{(Eq. 39)}$$

while differentiation of Eq. 38 gives:

$$\left[\frac{dT}{dT_b} \right]^{-1} = 1 + \left(\frac{l_i \Delta \overline{H}_s}{3600 A_v K_I} \right) \cdot \frac{d\dot{m}}{dT} \qquad \text{(Eq. 40)}$$

The sublimation rate may also be related to the pressure in the vial using Eqs. 3, 7, and 17. Since in multivial experiments with pure water, the pressure in the vial is approximately equal to the equilibrium vapor pressure of ice (P_0), one may write:

$$\dot{m} = a_0 (P_0 - P_c) + \frac{a_1}{2} (P_0^2 - P_c^2) \qquad \text{(Eq. 41)}$$

with $a_0 = 0.2478$ and $a_1 = 1.944$. Thus, since $d\dot{m}/dT = (d\dot{m}/dP_0)(dP_0/dT)$:

$$\frac{d\dot{m}}{dT} = (0.2478 + 1.944\, P_0) \frac{dP_0}{dT} \qquad \text{(Eq. 42)}$$

Combining Eqs. 39-42 and using $dP_0/dT \approx 0.1\, P_0^{1.5}$:

$$\frac{d \ln K_v}{d \ln \dot{m}} = 1 + \frac{l_i}{K_I} K_v + \frac{3.6 \times 10^4 A_v K_v}{\Delta \overline{H}_s (0.2478 + 1.944 P_0) P_0} \qquad \text{(Eq. 43)}$$

Numerical evaluation of the term involving P_0 demonstrates that this term is nearly constant at 0.2 for all multivial experiments conducted. Thus, with $l_i \approx 2.3$ cm and $K_I = 5.9 \times 10^{-3}$ (Fig. 9), Eq. 43 simplifies to:

$$\frac{d \ln K_v}{d \ln \dot{m}} = 1.2 + 400\, K_v \qquad \text{(Eq. 44)}$$

A derivation nearly identical to that given above may be given to evaluate the derivative $d \ln K_{vB}/d \ln \dot{Q}_B$, where K_{vB} is that portion of the heat transfer coefficient describing heat transfer from the shelf to the vial bottom, and $\dot{Q}_B$ is the heat flow from the shelf to the vial bottom. The result is also nearly identical to Eq. 44 and may be written:

$$\frac{d \ln K_{vB}}{d \ln \dot{Q}_B} = 1.2 + 400\, K_{vB} \qquad \text{(Eq. 45)}$$

Equation 45 is used in the evaluation of vial heat transfer coefficients from the raw data.

Determination of the Chemical Constituents and Spectral Properties of Commercial and NF Reference Standard Potassium Guaiacolsulfonate: Implications of the Findings on Compendial Analytical Methodology

PAKTIYA TANGTATSAWASDI and S. EDWARD KRIKORIAN ˣ

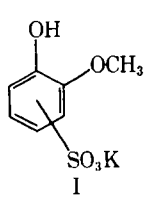
Received June 1, 1983, from the *Department of Medicinal Chemistry/Pharmacognosy, School of Pharmacy, University of Maryland, Baltimore, MD 21201.* Accepted for publication September 26, 1983.

Abstract □ HPLC analysis confirmed a difference in the chemical composition of commercial *versus* NF reference standard potassium guaiacolsulfonate. After separation by fractional crystallization, the two constituents comprising the former sample were identified by ^{1}H-NMR as potassium guaiacol-4- and -5-sulfonate, respectively. The former isomer predominated. The reference standard material was identified as the 4-sulfonate salt by HPLC, NMR, IR, and UV. This difference raises questions concerning the validity of the compendial identification tests and assay procedure for the drug, which are based on methods requiring direct comparison between it and the reference standard. In fact, the IR test has now been shown to be unreliable as a rigorous criterion for identification, in light of significant differences found in the fingerprint regions of the spectra of the two isomers. However, because the two isomers exhibit identical UV absorption characteristics in solutions of pH ≤7 (but not in alkaline solution), the compendial UV identification test and assay procedure appear to be valid under the conditions specified. The pK_a values of the isolated isomers were estimated by a spectrophotometric method to be 8.74 and 9.16 for the phenolic group of potassium guaiacol-4- and -5-sulfonate, respectively.

Keyphrases □ Potassium guaiacolsulfonate—chemical constituents, spectral properties, commercial and NF reference standard □ Isomers—potassium guaiacolsulfonate, determination of chemical constituents and spectral properties, commercial and NF reference standard

Since the first reported synthesis of potassium guaiacolsulfonate *via* sulfonation of guaiacol with concentrated sulfuric acid (1), there has been disagreement over product composition. Some workers have suggested that a single product is formed (2–4); however, others have described isomeric mixtures (1, 5–8). The identification of the mixture as the 1-hydroxy-2-methoxybenzene-4- and -5-sulfonic acid salts by Paul (5) has been accepted (9, 10) and confirmed by others who examined both commercial samples and formulated drug products (11–13).

However, discrepancies in several drug listings (14–16) have persisted. The National Formulary (NF) has failed to be specific about the composition of the officially recognized drug entity (I) with no reference to a mixture of isomers (17). The original analytical methodology introduced in NF XII appears to be based on methodology (18) which (*a*) failed to take into account the fact that the drug may be an isomeric mixture and (*b*) proposed a reference standard prepared by recrystallization of the commercial sample from water or alcohol, which could lead to a product of uncertain composition, since solubility differences between the isomeric components of the mixture of potassium guaiacolsulfonates are known to exist (9, 11).



I

Although potassium guaiacolsulfonate (I) is no longer included in the official compendium, its commercial use in cough and cold remedies as an expectorant is still widespread. In this study, a commercial sample and an NF reference standard of potassium guaiacolsulfonate are characterized, and the NF XIII methodology (17) is evaluated.

EXPERIMENTAL SECTION

Materials—Commercial[1] and NF reference standard[2] potassium guaiacolsulfonate were used as received. All solvents and standard chemicals employed were reagent grade.

High-Performance Liquid Chromatography—The apparatus consisted of a single-piston reciprocating solvent delivery pump with integral pulse dampener[3]; a valve injector[4] fitted with a 25-μL sample loop; a 30 cm × 4-mm stainless steel column packed with a chemically bonded octadecylsilane reverse-phase packing[5]; a variable-wavelength UV–visible spectrophotometer[6] operated at 278 nm and fitted with an 8-μL, 1-cm path length, quartz flow cell[7] as detector; and a recorder[8].

The mobile phase consisted of 0.005 M tetrabutylammonium hydroxide, adjusted to pH 7.15 with 86% H_3PO_4, and contained 10% (v/v) methanol. It was deaerated by stirring under reduced pressure. The flow rate was maintained at ~1.4 mL/min.

All solutions of potassium guaiacolsulfonate analyzed by HPLC were prepared at a concentration of ~1.3 mg/mL in water. Analysis of the commercial sample of I under the conditions described above resulted in a chromatogram with two baseline-resolved peaks (R_s = 1.7) at retention times (t_R) near 11 and 14 min, respectively, in the area ratio[9] 1.5:1 (Fig. 1). Analysis of the NF reference standard of I under identical conditions yielded a chromatogram containing only a single peak with a retention time of 11 min, which was shown by mixture analysis to be identical with the t_R of the earlier-eluting (major) peak of the commercial sample.

Spectrometric Measurements—^{1}H-NMR spectra were recorded[10] in D_2O[11] containing 1% sodium 3-trimethylsilyl-1-propanesulfonate (DSS)[12]. To generate the phenolate anions of the I isomers, a few drops of NaOD solution[13] were added to the D_2O solutions. Chemical shifts are reported as δ values in parts per million relative to DSS.

IR spectra[14] were run as KBr pellets. UV spectra[15] were recorded at a concentration of 0.02 mg/mL in water, 0.1 M HCl, and pH 7.0 potassium phosphate buffer and at 0.01 mg/mL in 0.1 M NaOH. Molar absorptivities (ε) of the isomers at the wavelengths of maximum absorption in the pH 7.0 phosphate buffer solution were determined from the slopes of Beer's law plots derived from absorbance measurements of seven solutions over the concentration range 8×10^{-5} to 3×10^{-4} M.

Preparative Isolation of the Constituents of Commercial I by Fractional Crystallization—The commercial sample (90 g) was dissolved in 120 mL of boiling water, and the solution was filtered while hot, cooled to room temperature, and refrigerated overnight. The resulting white crystals were removed by filtration and recrystallized from water to give isomer A (41 g), which has previously been described as the "less-soluble" salt (9).

To the mother liquor (80 mL) from the aforementioned first crystallization was added slowly with stirring 95 mL of absolute ethanol. A white solid precipitated (4 g), which was removed by filtration. This material was purified by suspending in boiling absolute ethanol (125 mL) and then adding sufficient aqueous ethanol (25% ethanol–water), while heating, to completely dissolve the solid. The solution was cooled and allowed to stand overnight. The resulting precipitate was removed by filtration and washed with aqueous ethanol, and then absolute ethanol, to give (after drying) 2 g of isomer B, the "more-soluble" salt.

1-*O*-Acetyl Derivatives of the Isomeric Potassium Guaiacolsulfonates—Each of the aforementioned isomers A and B (200 mg, 0.8 mmol) was refluxed with 10 mL of acetic anhydride and 2 mL of pyridine for 30 min and then cooled. The white crystals were removed by filtration, washed with acetone, and dried, to give 160 mg of potassium 4-(acetyloxy)-3-methoxybenzenesulfonate (acetylated isomer A) [IR(KBr): 1760 cm^{-1} (C=O); ^{1}H-NMR (D_2O): δ 2.36 (s, CH_3CO), 3.92 (s, CH_3O), 7.25 (d, ArH), 7.51 (d of d, ArH), and 7.55 ppm (d, ArH)] and 150 mg of potassium 3-(acetyloxy)-4-methoxybenzenesulfonate (acetylated isomer B) [IR(KBr): 1760 cm^{-1} (C=O); ^{1}H-NMR (D_2O): δ 2.36 (s, CH_3CO), 3.86 (s, CH_3O), 7.24 (d, ArH), 7.60 (d, ArH), and 7.79 ppm (d of d, ArH)].

Anal.[16]—Calc. for $C_9H_9O_6SK$: C, 38.02; H, 3.19; S, 11.28. Found for acetylated isomer A: C, 37.72; H, 3.47; S, 11.21. Found for acetylated isomer B: C, 37.75; H, 3.41; S, 10.99.

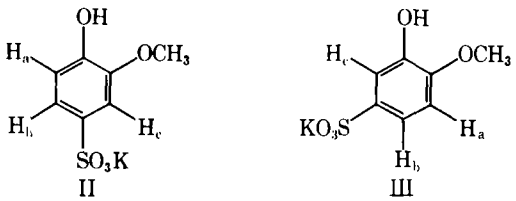
Spectrometric Estimation of the pK_a Values of the Isomers of I—Eleven solutions of each isomer were prepared (0.02 mg/mL), covering the pH range of 5.6–10.0, with 0.1 M potassium phosphate and sodium borate buffer systems. The analytical wavelengths employed were selected by comparison of the spectra of the free phenol and phenolate anion forms of the isomers in pH 5.6 buffer and 0.1 M NaOH solution, respectively, with 257 nm being chosen for isomer A and 296 nm for isomer B. From absorbance measurements of each of the 11 solutions and for the pure anion and free phenol form of each isomer at the selected wavelengths, the ratio $[A^-]/[HA]$ was calculated (19) at each pH[17]. The pK_a of the phenol group was then determined graphically (linear regression analysis) as the *y*-intercept of the linear plot of pH *versus* log $[A^-]/[HA]$ ($r > 0.99$, with unit slope for each determination).

RESULTS AND DISCUSSION

The results of paired-ion HPLC analysis of the commercial and NF reference standard samples of I clearly demonstrate the dissimilarity in their chemical compositions. Furthermore, determination of the retention times of the isolated pure isomers A and B show that the former represents the major constituent in the commercial sample and the sole constituent of the NF reference standard I, whereas isomer B represents the later-eluting peak in the chromatogram of the commercial sample. The structural identities of the two isomers then remain to be established.

Structure Determination of the Isomers of I by ^{1}H-NMR—The aromatic region of the ^{1}H-NMR spectra of isomers A and B both featured an upfield *ortho*-split doublet (H_a, δ 7.00, J = 9 Hz) and a lower-field doublet of doublets (H_b, J_{ortho} = 9 Hz, J_{meta} = 2 Hz) overlapping a *meta*-split doublet (H_c, J = 2 Hz). This pattern of absorption bands establishes that the three substituents on the aromatic ring of both isomers must be oriented asymmetrically [1,2,4 (II) and 1,2,5 (III)] rather than vicinally (1,2,3 or 1,2,6).

In order to assign structures II and III specifically to isomers A and B, respectively, the positions of the three ring protons relative to the ring substituents need to be differentiated for each compound. This was accomplished by determining the effect on the chemical shifts of the ring protons of changing the electronic character of the hydroxyl group of each of the isomers by converting it to its phenoxide ion and acetyl derivative. It is known that the chemical shifts of ring protons *ortho* and *para* to the hydroxyl group are most affected by such changes and *meta* protons are affected less (20). For the derivatives of isomer A, the greatest chemical shift changes were observed for the high-field doublet due to H_a (0.38 ppm upfield in the phenoxide ion, 0.25 ppm downfield in the acetate ester), with the corresponding changes for the absorptions due to H_b and H_c being approximately half as large. For the derivatives of isomer B, the greatest chemical shift changes were observed for the absorptions due to H_b and H_c (0.41 and 0.37 ppm upfield, respectively, in the phenoxide ion; 0.45 and 0.30 ppm downfield, respectively, in the acetate ester), with the corresponding changes in the high-field doublet due to H_a being much smaller (0.09 ppm upfield and 0.22 ppm downfield in the respective derivatives). These results leave no doubt that for isomer A, H_a must be *ortho* to the hydroxy group (*i.e.*, the 6-position) and that for isomer B, H_b and H_c must be *para* and *ortho*, respectively, to the hydroxy group (*i.e.*, the 4- and 6-positions, respectively) (20). Therefore, isomer A, the "less-soluble" salt which represents the earlier-eluting (major) HPLC peak from the commercial sample is potassium guaiacol-4-sulfonate (II) and isomer B is potassium guaiacol-5-sulfonate (III).



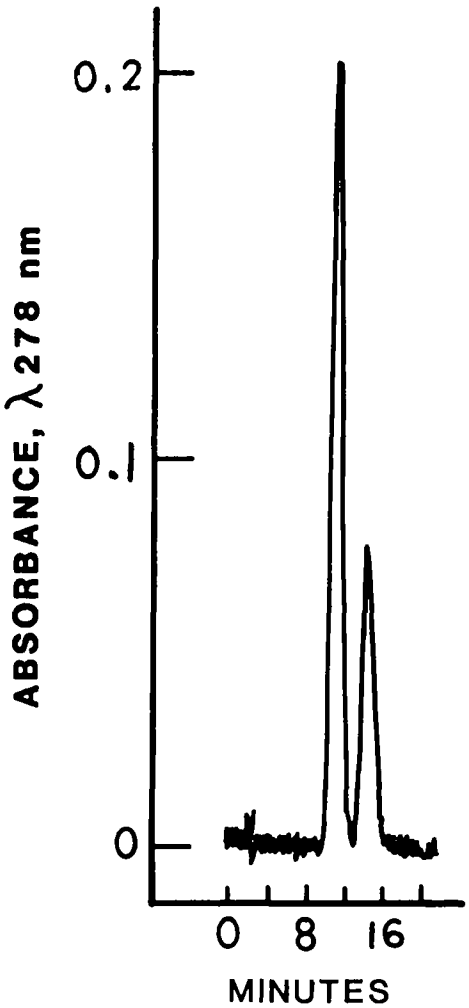


Figure 1—*Paired-ion high-performance liquid chromatogram of commercial sample of I. The major peak corresponds to isomer A (II), and the minor peak corresponds to isomer B (III), which were subsequently isolated from the sample by fractional crystallization.*

With the identity of the two constituents of the commercial sample of I established, it was concluded that the NF reference standard consisted solely of potassium guaiacol-4-sulfonate, inasmuch as its NMR and IR (see below) spectra were identical to those for II, and the retention time of its single HPLC peak coincided with that for II (see above).

The obvious difference in the compositions of the commercial sample of I and the NF reference standard raises some concern regarding the reliability of the identification tests and assay procedure described in NF XIII (17), since the methodologies involved rely on direct comparison of the drug with the reference standard. It was important, therefore, that the accuracy of these methods be reevaluated.

(B) UV spectra (1-cm path length cells) of 0.01-mg/mL solutions of II (- - - -), III (• • • •), and a commercial preparation of I (——) in 0.1 M NaOH.*

Evaluation of the NF IR Absorption Identification Test for I (17)—As expected, the IR spectra of KBr dispersions of pure II and the NF reference standard I proved to be superimposable, confirming the chemical identity of the standard as the single pure compound. However, the IR spectrum for the commercial preparation of I differed markedly from that of the reference standard in the fingerprint region (especially around 1100–1300 cm^{-1}) due to the contribution of absorption bands from its second constituent, III. Therefore, it must be concluded that comparison of the IR spectra of commercial and reference standard samples of I cannot be used as a rigorous criterion for the reliable identification of unknown samples of the drug.

Evaluation of the NF UV Absorption Identification Test and Assay Procedure for I (17)—Dabrowski and Patel (18), although not acknowledging that they were comparing different materials, claimed that their reference standard and commercial preparations of I exhibited the same UV behavior in aqueous solution at pH ≤ 7, and on this basis proposed an assay for the drug which was adopted by the NF. This methodology is only valid provided that isomers II and III have identical UV absorption characteristics.

Indeed, the UV spectra of II, III, and the commercial sample of I in aqueous solution all appear to be identical at pH ≤ 7 (Fig. 2A), with absorption maxima at 236 and 279 nm, as previously reported for the commercial preparation of I (18, 21, 22). However, in 0.1 M NaOH, the spectra for the two pure isomers differ substantially (Fig. 2B), with II exhibiting absorption at λ_{max} of 264 and 293 nm and III exhibiting absorption at λ_{max} of 249 and 296 nm. The spectrum for the commercial preparation of I (Fig. 2B) is clearly a composite of the contributions from its two isomeric constituents, with absorption maxima at 257 and 290 nm. Based on these results, it can be concluded that despite the difference in their compositions, comparison of the UV spectra of the commercial mixture and NF reference standard in pH 7.0 buffer solution (but not in alkaline solution), as specified in NF XIII, is a valid identification test. However, the same comparison for quantitation of I is only reliable provided that the absorptivities of the two isomeric constituents, II and III, are identical at the wavelength of analysis (279 nm).

Determination of the molar absorptivities of the two isomers from the slopes of the respective Beer's law plots ($r > 0.999$, with intercepts passing through the origin verified by t test) yielded values of ϵ of $3.07 \times 10^3 \pm 0.03 \times 10^3$ and $2.97 \times 10^3 \pm 0.01 \times 10^3$ L mol^{-1}-cm^{-1} for II and III, respectively, at λ_{max} of 279 nm in pH 7.0 buffer solution. Statistical comparison of these values by a two-tailed t test revealed that their difference is not significant at the $p = 0.05$ level but is significant at the $p = 0.1$ level. Thus, if a 95% or higher probability level of significance is acceptable, the two absorptivities can be considered to be not different, and therefore, the UV spectrometric quantitation of the commercial drug by direct comparison with the single-constituent NF reference standard appears to be justified under the specified conditions.

Spectrometric Estimation of the pK_a Values of the Isomers of I—The aforementioned differences in the UV spectra of the acidic and basic forms of II and III could be taken advantage of to determine their pK_a values (phenol group). The values obtained were 8.74 ± 0.05 for II and 9.16 ± 0.04 for III, which compare with a pK_a of 9.98 for guaiacol (23). The greater acidity of the 4-sulfonate *versus* the 5-sulfonate derivative is consistent with the relative acidities of *p*- and *m*-methylsulfonylphenol, which have pK_a values of 7.83 and 8.40, respectively (23).

CONCLUSIONS

The determination of the composition of the commercial preparation of I to be a mixture of the guaiacol-4- and -5-sulfonate salts, whereas the NF reference standard of I has been shown to be only pure potassium guaiacol-4-sulfonate, has raised questions concerning the reliability of direct comparison of the two materials for the identification and assay of the drug as specified in NF XIII. However, based on the present work, it appears that as long as the UV assay procedure is carried out in neutral or acidic solutions of the drug, valid quantitative results can be obtained. In contrast, comparison of the IR spectra of commercial *versus* reference standard I is not strictly reliable as an identification test for the drug, because significant differences in the fingerprint regions which distinguish the two pure isomers from each other also cause the commercial sample to present a composite spectrum which is different from that of the pure, single-component reference standard.

Synthesis of Bridged Catechol–Homocysteine Derivatives as Potential Inhibitors of Catechol *O*-Methyltransferase

O. WILLIAM LEVER, JR.ˣ, CLIFTON HYMAN, and HELEN L. WHITE

Received July 8, 1983, from the *Wellcome Research Laboratories, Burroughs Wellcome Co., Research Triangle Park, NC 27709.* Accepted for publication September 14, 1983.

Abstract □ Catechol derivatives, covalently joined to homocysteine by sulfide or sulfonium linkages, were synthesized as potential catechol *O*-methyltransferase multisubstrate inhibitors which might bridge the enzymatic binding sites for the catechol substrate and the amino acid portion of the methyl donor *S*-adenosylmethionine. These compounds were found to be less effective inhibitors than the product inhibitor *S*-adenosylhomocysteine.

Keyphrases □ Catechol homocysteine derivatives - bridged, synthesis, inhibition of catechol *O*-methyltransferase □ Catechol *O*-methyltransferase - potential inhibitors, bridged catechol-homocysteine derivatives

Catechol *O*-methyltransferase (COMT; EC 2.1.1.6) catalyzes methyl transfer from *S*-adenosyl-L-methionine (SAM, I) to catechol substrates and plays an important role in the inactivation of catecholamines (1, 2). COMT inhibitors offer opportunities for control of catecholamine levels and have potential for treatment of disorders thought to arise from catecholamine deficiencies (3). For example, by decreasing the formation of *O*-methylated metabolites of levodopa and dopamine, COMT inhibitors may enhance the effectiveness of levodopa therapy for Parkinsonism (3–5).

One approach to design of inhibitors of SAM-dependent methylases has focused on analogues of SAM or the product inhibitor *S*-adenosyl-L-homocysteine (SAH, II) (6–12). However, analogues of SAM and SAH may not be highly specific inhibitors for a single methylase since many methyltransferases utilize SAM as the methyl donor and are also subject to potent product inhibition by SAH (1). Although inhibitor specificity for COMT might be more readily achieved with catechol analogues, a number of potent *in vitro* inhibitors of this type are limited in clinical potential by poor *in vivo* activity and/or by unacceptable toxicity (3).

An intriguing alternative approach to COMT inhibitor design emanates from consideration of the proposed mechanism for methyl transfer by COMT. The mechanism appears to involve an S_N2-like nucleophilic attack by the catechol on the methyl group of SAM (13, 14) with a transition state which may be depicted as shown in III. This suggests that compounds such as IV and V, in which a catechol is covalently joined to homocysteine by sulfide or sulfonium linkages, might bridge the enzymatic binding sites for the catechol and for the amino acid portion of SAM and thus might function as multisubstrate (15), or rudimentary transition-state (16, 17), inhibitors of COMT.

The direct transition state analogue IV (n = 1) would not be expected to be sufficiently stable to permit study in an aqueous environment. In an earlier study (18), this problem was circumvented by isosteric replacement of one of the catechol oxygen atoms by a methylene group (*cf.* VI, n = 1). The adducts thus obtained were stable, but were not potent COMT

Although inhibitor specificity for COMT might be more readily achieved with catechol analogues, a number of potent *in vitro* inhibitors of this type are limited in clinical potential by poor *in vivo* activity and/or by unacceptable toxicity (3).

An intriguing alternative approach to COMT inhibitor design emanates from consideration of the proposed mechanism for methyl transfer by COMT. The mechanism appears to involve an S_N2-like nucleophilic attack by the catechol on the methyl group of SAM (13, 14) with a transition state which may be depicted as shown in III. This suggests that compounds such as IV and V, in which a catechol is covalently joined to homocysteine by sulfide or sulfonium linkages, might bridge the enzymatic binding sites for the catechol and for the amino acid portion of SAM and thus might function as multisubstrate (15), or rudimentary transition-state (16, 17), inhibitors of COMT.

The direct transition state analogue IV (n = 1) would not be expected to be sufficiently stable to permit study in an aqueous environment. In an earlier study (18), this problem was circumvented by isosteric replacement of one of the catechol oxygen atoms by a methylene group (*cf.* VI, n = 1). The adducts thus obtained were stable, but were not potent COMT

Table I—Inhibition of Catechol-*O*-Methyltransferase [a]

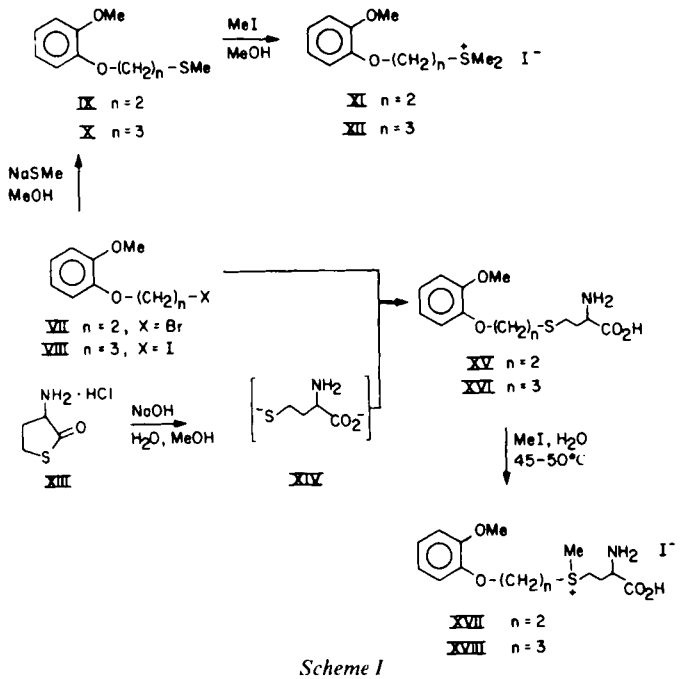
Compound	Percent Inhibition at 100 μM
XXIV	--[b]
XXV	14.9
XV	13.2
XVI	9.0
XVII	12.1
XVIII	5.6
IX	17.3
X	14.0
XI	5.9
XII	Stimulates[c]
XIX	4.7
II	72.2

[a] Rat liver COMT was incubated with 0.1 mM [^{14}C-methyl]*S*-adenosyl-L-methionine (0.3 Ci/mol), 0.25 mM 3,4-dihydroxybenzoic acid, 1 mM $MgCl_2$, 0.5 mM dithiothreitol, and 50 mM Tris-HCl buffer, pH 7.8, for 30 min at 37°C. [b] No significant inhibition observed. [c] Apparent stimulation of activity by 26.4% at 100 μM XII.

inhibitors (18), possibly because COMT is highly specific for the catechol functionality in substrates and in most inhibitors (2, 3). Retention of both catecholic oxygen atoms, for possible coordination at the catechol binding site, might facilitate multisubstrate binding. This could be accomplished by insertion of one or more additional methylenes in the briding chain. The bridging link would thereby be one or two units longer than required for an exact transition-state analogue (*cf.* III). However, a bridging length greater than that suggested by precise transition state mimicry led to increased potency in multisubstrate kinase inhibitors (19), and the expanded bridging chain in the present case might thus be an acceptable structural feature. Accordingly, sulfides and sulfonium salts of types IV and V were synthesized for *in vitro* evaluation as COMT inhibitors.

RESULTS AND DISCUSSION

Chemistry—The synthesis of the sulfides and sulfonium salts with *o*-methoxy substituents are outlined in Scheme I. The only salt obtained from reaction of iodide VIII with dimethyl sulfide was trimethylsulfonium iodide; none of the desired salt XII could be isolated. This type of reversion-ligand exchange process is well documented for sulfonium salts (20, 21), and has recently been adapted as a synthetic method for symmetrical and unsymmetrical organic sulfides (22). This problem was circumvented by preforming



Scheme I

sulfides IX and X followed by their alkylation with methyl iodide. The unsuitability of iodide VIII for direct formation of sulfonium salts was again noted in unsuccessful attempts to form bridged salt XVIII from VIII and methionine, although *S*-methyl methionine XIX was readily formed from methionine and methyl iodide under acidic (23) or neutral (24), *i.e.* zwitterionic amino acid, conditions. We then developed an alternative route to XVII and XVIII utilizing thiolactone XIII. Dianion XIV was generated from XIII by a method similar to those previously reported (25-27) and was alkylated with halides VII and VIII to provide sulfides XV and XVI. The resulting alkyl homocysteines were then alkylated with methyl iodide under neutral conditions (24), which led to specific methylation of the sulfide linkage in the presence of the unprotected amino acid moiety.

The *o*-hydroxy sulfides XXIV and XXV were prepared by similar methods to those in Scheme I. Alkylation of *o*-benzyloxyphenol with 1,3-dibromopropane followed by reductive debenzylation provided the phenolic bromide XXII, which afforded sulfide XXV on treatment with dianion XIV. In the preparation of dimethylene analogue XXIV, protection of the phenol as the acid-labile tetrahydropyranyl group (*cf.* XXIII) was required to avoid intramolecular cyclization (28) of the unprotected phenolic bromide to benzodioxane XX during the reaction with dianion XIV. The free phenol was liberated during acidic workup.

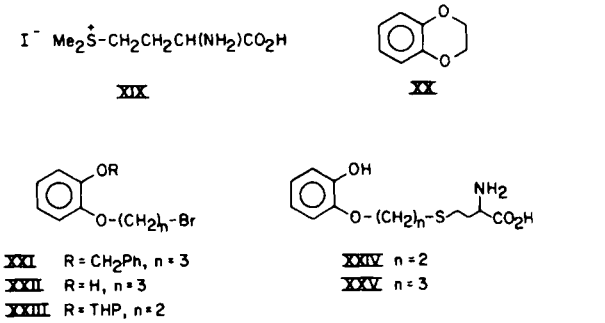
Enzyme Inhibition Studies—Sulfides and sulfonium salts prepared in this study were evaluated as COMT inhibitors by a radiochemical assay (29). The inhibition results listed in Table I indicate that these compounds are at least fourfold less effective inhibitors of COMT than the potent product inhibitor *S*-adenosylhomocysteine (II), and that the inhibition is not greatly affected by the type of bridging atom (sulfide or sulfonium), the length of the bridge (di- or trimethylene), or the nature of the *o*-substituent (hydroxy *versus* methoxy). Our goal was to enhance affinity and specificity of candidate COMT inhibitors by incorporation of portions of SAM (or SAH) into a catechol structure to increase the number of binding sites. Both the level and the narrow range of inhibition shown by the compounds in Table I, along with the results from the related study by Coward and co-workers (18), suggest that a multisubstrate approach to potentially clinically significant COMT inhibitors is likely to require a higher level of molecular complexity than that offered by bridged catechol-homocysteine structures. The additional presence of significant portions of the nucleoside moiety of SAM or SAH may be essential.

EXPERIMENTAL SECTION[1]

2-(2-Methoxyphenoxy)ethyl Bromide (VII)—A mixture of 2-methoxyphenol (124 g, 1.0 mol), 1,2-dibromoethane (379.7 g, 2.0 mol), and aqueous NaOH (48 g, 1.2 mol, in 300 mL of H_2O) was stirred overnight at 80°C. The product was extracted into $CHCl_3$ and the extracts were washed three times with 5% aqueous NaOH and then with water. The solvent was removed under reduced pressure, and the residue was distilled twice through a Vigreux column (15 cm). The fraction boiling at 125°C (0.25 mm) was dissolved in EtOH and the solution was cooled to provide crystals of VII as white needles (112.7 g, 49% yield), mp 45-46°C; ^{1}H-NMR ($CDCl_3$): δ 3.60 (t, 2, J = 7 Hz), 3.81 (s, 3), 4.30 (t, 2, J = 7 Hz), and 6.86 ppm (s, 4); UV (MeOH) λ_{max}: 271.5 (ε 2300) and 220.5 (ε 7400) nm; TLC (silica, $CHCl_3$): R_f 0.57.

Anal.—Calc. for $C_9H_{11}BrO_2$: C, 46.77; H, 4.80; Br, 34.58. Found: C, 46.75; H, 4.80; Br, 34.53.

3-(2-Methoxyphenoxy)propyl Iodide (VIII)—3-(2-Methoxyphenoxy)propyl bromide (51% yield; bp 110-118°C, 0.3 mm Hg) was prepared from 2-methoxyphenol and 1,3-dibromopropane in ethanolic aqueous sodium hydroxide essentially as described for VII. The bromide (51.5 g, 0.21 mol) was



[1] Melting points were determined with a Buchi melting point apparatus and are uncorrected. Elemental analyses were performed by Atlantic Microlab, Inc., Atlanta, Ga. ^{1}H-NMR spectra were determined with Varian T-60, XL-100, and CFT20 and Hitachi Perkin-Elmer R-24B spectrometers with tetramethylsilane as internal standard. COMT inhibition data were obtained by a radiochemical assay (29).

then refluxed with sodium iodide (44.4 g, 0.3 mol) in methyl ethyl ketone (350 mL) for 21 h. The mixture was filtered and the solvent removed under reduced pressure. The residue was dissolved in ether, and on addition of hexane there was deposited 31.4 g (51% yield) of VIII. A portion (6.9 g) of this product was chromatographed on silica gel (Et_2O) and then was recrystallized from ether–hexane to give 4.4 g of VIII as white needles, mp 39–41°C; ^{1}H-NMR ($CDCl_3$): δ 2.31 (quintet, 2, J = 6 Hz), 3.39 (t, 2, J = 6 Hz), 3.85 (s, 3), 4.08 (t, 2, J = 6 Hz), and 6.91 ppm (s, 4); UV (MeOH) λ_{max}: 273.5 (ε 2700, sh) and 224.5 (ε 7200) nm; TLC (silica, $CHCl_3$): R_f 0.58.

Anal.—Calc. for $C_{10}H_{13}IO_2$: C, 41.11; H, 4.49; I, 43.45. Found: C, 41.31; H, 4.53; I, 43.22.

2-(2-Methoxyphenoxy)-1-methylthioethane (IX)—A solution of bromide VII (23.1 g, 0.10 mol) in MeOH (60 mL) was added over a 0.5-h period to a cold (0°C) stirred solution of NaOMe (16.5 g, 0.30 mol) and methanethiol (25 g, 0.52 mol) in MeOH (125 mL). After 0.5 h, the mixture was concentrated under reduced pressure and the residue was extracted with ether. The extracts were concentrated and the residue was distilled (oven 95–115°C, 0.025–0.045 mm Hg) to give IX (18.7 g, 92% yield) as a colorless oil; ^{1}H-NMR ($CDCl_3$): δ 2.19 (s, 3), 2.89 (t, 2, J = 7 Hz), 3.83 (s, 3), 4.17 (t, 2, J = 7 Hz), and 6.88 ppm (s, 4); UV (MeOH) λ_{max}: 272.5 (ε 2600, sh) and 222.5 (ε 8200) nm; TLC (silica, $CHCl_3$): R_f 0.77.

Anal.—Calc. for $C_{10}H_{14}O_2S$: C, 60.57; H, 7.12; S, 16.17. Found: C, 60.52; H, 7.16; S, 16.11.

3-(2-Methoxyphenoxy)-1-methylthiopropane (X)—Sulfide X was prepared in 79% yield from iodide VIII by the same procedure as described above for IX. Sulfide X was isolated as a colorless oil, bp 155°C (oven), 0.32 mm Hg; ^{1}H-NMR ($CDCl_3$): δ 2.10 (m, 5), 2.72 (t, 2, J = 6 Hz), 3.85 (s, 3), 4.14 (t, 2, J = 6 Hz), and 6.92 ppm (s, 4); UV (MeOH) λ_{max}: 272.5 (ε 2400, sh) and 222.5 (ε 7500) nm; TLC [silica, $CHCl_3$–EtOAc (2:1)]: R_f 0.61.

Anal—Calc. for $C_{11}H_{16}O_2S$: C, 62.23; H, 7.60; S, 15.10. Found: C, 62.47; H, 7.67; S, 14.94.

[2-(2-Methoxyphenoxy)ethyl]dimethylsulfonium Iodide (XI)—A solution of sulfide IX (2.97 g, 0.015 mol) and methyl iodide (2.74 g, 0.019 mol) in MeOH (10 mL) was stoppered and allowed to stand in the dark at ambient temperature for 17 h. Addition of ether precipitated sulfonium salt XI as an off-white powder, mp 100–101°C; ^{1}H-NMR (D_2O): δ 2.93 (s, 6), 3.73 (s, 3), 3.61 (t, 2, J = 6 Hz), 4.37 (t, 2, J = 6 Hz), and 6.93 ppm (m, 4); UV (MeOH) λ_{max}: 271.5 (ε 2500, sh) and 219.0 (ε 21,200) nm; TLC [silica, $CHCl_3$–MeOH–NH_4OH–H_2O (40:30:10:3)]: R_f 0.79.

Anal.—Calc. for $C_{11}H_{17}IO_2S$: C, 38.83; H, 5.04; I, 37.30; S, 9.43. Found: C, 38.83; H, 5.06; I, 37.33; S, 9.43.

[3-(2-Methoxyphenoxy)propyl]dimethylsulfonium Iodide (XII)—Sulfonium salt XII was prepared from sulfide X in 72% yield by the procedure described above for preparation of XI. Salt XII was isolated as an off-white microcrystalline solid, mp 98–99°C; ^{1}H-NMR (D_2O): δ 2.34 (br quintet, 2), 2.94 (s, 6), 3.50 (t, 2, J = 7 Hz), 3.87 (s, 3), 4.22 (t, 2, J = 6 Hz), and 7.06 ppm (br s, 4); UV (MeOH) λ_{max}: 271.5 (ε 4200, sh) and 219.5 (ε 23,900) nm; TLC [silica, $CHCl_3$–MeOH–H_2O, (40:30:3)]: R_f 0.78.

Anal.—Calc. for $C_{12}H_{19}IO_2S$: C, 40.68; H, 5.41; I, 35.82; S, 9.05. Found: C, 40.59; H, 5.41; I, 35.70; S, 9.01.

2-Amino-4-[2-(2-methoxyphenoxy)ethylthio]butyric Acid (XV)—DL-Homocysteinethiolactone hydrochloride XIII (12.24 g, 0.08 mol) was heated for 1.5 h at 65°C under nitrogen with a solution of NaOH (9.6 g, 0.24 mol) in 11% aqueous MeOH (88 mL). A solution of bromide VII (19.4 g, 0.084 mol) in MeOH (60 mL) was then added dropwise during a 0.5-h period. After an additional 3.5 h at 65°C, the mixture was concentrated under reduced pressure, the residue was dissolved in hot water, and the mixture was filtered. After cooling, the aqueous solution was extracted twice with ether and then adjusted to pH 7 with concentrated HCl. The resulting precipitate was collected and treated with EtOH. The mixture was filtered, and the filtrate was cooled to provide amino acid XV (11.7 g, 51% yield) as a white powder, mp 221–224°C; ^{1}H-NMR (Me_2SO-d_6): δ 1.92 (m, 2), 2.83 (t, 4, J = 7 Hz), 3.28 (br t, 1, J = 7 Hz), 3.72 (s, 3), 4.09 (t, 2, J = 7 Hz), and 6.90 ppm (s, 4); UV (MeOH) λ_{max}: 272 (ε 2600, sh) and 222.5 (ε 8000) nm; TLC (silica, MeOH): R_f 0.41.

Anal.—Calc. for $C_{13}H_{19}NO_4S$: C, 54.71; H, 6.71; N, 4.91; S, 11.24. Found: C, 54.47; H, 6.77; N, 4.84; S, 11.17.

2-Amino-4-[3-(2-methoxyphenoxy)propylthio]butyric Acid (XVI)—In the same manner as described for preparation of XV, the dianion of DL-homocysteine thiolactone was formed in aqueous methanol at 70°C. Iodide VIII was added as a warm oil and after 0.5 h at 70°C the solution was evaporated, the residue was washed with ether, treated with isopropyl alcohol, and the mixture was filtered. The filtrate was evaporated and the residue was dissolved in water. The pH was adjusted to 7.9 and the resulting precipitate was recrystallized from ethanol to give a 23% yield of XVI as a pale-yellow powder, mp 221–224°C; ^{1}H-NMR (Me_2SO-d_6): δ 1.95 (m, 4), 2.37–2.85 (m, 4), 3.32 (m, 1), 3.74 (s, 3), 4.01 (t, 2, J = 6 Hz), 4.6–6.8 (v br, 3), and 6.93 ppm (s, 4); UV (MeOH) λ_{max}: 272.5 (ε 2500, sh) and 222.5 (ε 7600) nm; TLC (silica, MeOH): R_f 0.54.

Anal.—Calc. for $C_{14}H_{21}NO_4S$: C, 56.16; H, 7.07; N, 4.68; S, 10.71. Found: C, 55.87; H, 7.12; N, 4.73; S, 10.79.

(3-Amino-3-carboxypropyl)[2-(2-methoxyphenoxy)ethyl]methylsulfonium Iodide (XVII)—Methyl iodide (1.88 g, 13.2 mmol) was added to a warm solution of sulfide XV (1.71 g, 6 mmol) in water (40 mL). The mixture was stirred at 50°C for 4 h followed by 12 h at 25°C. A cold condenser (~5°C) was used throughout. The residue, after evaporation under reduced pressure, was dissolved in 50% aqueous ethanol. The solution was filtered and cooled to provide salt XVII (1.00 g, 39% yield) as a pale yellow powder, mp 131–133°C; ^{1}H-NMR (D_2O): δ 2.34 (q, 2, J = 7 Hz), 2.99 (s, 3), 3.36–3.88 (m, 8), 3.77 (s, 3), 4.46 (t, 2, J = 6 Hz), and 6.96 ppm (m, 4); UV (MeOH) λ_{max}: 272 (ε 4900, sh) and 219 (ε 40,000) nm; TLC [silica, $CHCl_3$–MeOH–NH_4OH–H_2O (40:30:10:3)]: R_f 0.71.

Anal.—Calc. for $C_{14}H_{22}INO_4S$: C, 39.35; H, 5.19; I, 7.50; N, 3.28; S, 29.70. Found: C, 39.07; H, 5.20; I, 7.44; N, 3.22; S, 29.51.

(3-Amino-3-carboxypropyl)[3-(2-methoxyphenoxy)propyl]methylsulfonium Iodide (XVIII)—Methyl iodide (1.69 g, 12 mmol) was added to a warm (45°C) mixture of sulfide XVI and water (40 mL) in an apparatus protected with a cold water (~5°C) condenser. After 2 h at 45°C, an additional quantity (1.69 g, 12 mmol) of methyl iodide was added and stirring was continued for 3 h at 45°C and 14 h at ambient temperature. The mixture was filtered and evaporated, and the residue was dissolved in water. Ethanol was added, and the resulting solid was collected and dried to provide 2.77 g (63% yield) of salt XVIII as an off-white powder, mp 126–130°C; ^{1}H-NMR (D_2O): δ 2.39 (m, 4), 3.00 (s, 3), 3.58 (m, 4), 3.86 (s, 3), 3.91 (t, 1, J = 6 Hz), 4.22 (t, 2, J = 6 Hz), and 7.06 ppm (s, 4); UV (MeOH) λ_{max}: 298 (ε 190, sh), 272.5 (ε 2700), and 219.5 (ε 20,000) nm; TLC [silica, $CHCl_3$–MeOH–NH_4OH–H_2O (40:30:10:3)]: R_f 0.61.

Anal.—Calc. for $C_{15}H_{24}INO_4S$: C, 40.82; H, 5.48; I, 7.27; N, 3.17; S, 28.76. Found: C, 40.71; H, 5.52; I, 7.26; N, 3.14; S, 28.65.

(L-Methionine)methylsulfonium Iodide (XIX)—In a manner similar to that described for the preparation of the methyl sulfonium salt from racemic methionine (24), a mixture of L-methionine (3.7 g, 0.025 mol), water (20 mL), and methyl iodide (3.9 g, 0.027 mol) was stirred at 40°C for 18 h. The mixture was taken to dryness under reduced pressure, and the residue was triturated with ethanol. The resulting solid was recrystallized from aqueous ethanol, and the product was washed with hot methanol to provide 5.0 g (68% yield) of XIX as a white microcrystalline solid, mp 185°C (dec.) [the mp for the corresponding salt from racemic methionine has been reported as 150°C (dec.) (23, 24) and 156–157°C (dec.) (30); we are unaware of a specific mp citation for the optically active form, although an elemental analysis has been reported previously (31)]; ^{1}H-NMR (D_2O): δ 2.28–2.50 (m, 2), 2.98 (s, 6), 3.42–3.60 (m, 2), and 3.91 ppm (t, 1, J = 7 Hz); UV (MeOH) λ_{max}: 217.5 nm (ε 61,800); $[\alpha]_D^{20}$ 17.70°; TLC [silica, $CHCl_3$–MeOH–NH_4OH–H_2O (40:30:10:3)]: R_f 0.63.

Anal.—Calc. for $C_6H_{14}INO_2S$: C, 24.75; H, 4.85; I, 43.59; N, 4.81; S, 11.01. Found: C, 24.78; H, 4.89; I, 43.59; N, 4.80; S, 11.00.

1-(2-Benzyloxyphenoxy)-3-bromopropane (XXI)—To a stirred solution of 2-benzyloxyphenol (30.0 g, 0.15 mol) and 1,3-dibromopropane (60.5 g, 0.30 mol) in ethanol (100 mL) was added a solution of NaOH (6 g, 0.15 mol) in water (150 mL). The mixture was refluxed for 9 h, allowed to stand overnight, and then extracted with $CHCl_3$. The organic layer was washed with aqueous NaOH and then with water. The extract was dried (Na_2SO_4) and concentrated, and the residue was distilled to provide an oil (bp 157°C, 0.002 mm Hg) which was crystallized with ether–hexane to give 20.5 g (42% yield) of the bromide as a white powder, mp 29–30°C; ^{1}H-NMR ($CDCl_3$): δ 2.30 (quintet, 2, J = 6 Hz), 3.60 (t, 2, J = 6 Hz), 4.15 (t, 2, J = 6 Hz), 5.10 (s, 2), 6.92 (s, 4), and 7.40 ppm (m, 5); UV (MeOH) λ_{max}: 275 nm (ε 2750); TLC [silica, $CHCl_3$–hexane (1:1)]: R_f 0.44.

Anal.—Calc. for $C_{16}H_{17}BrO_2$: C, 59.81; H, 5.33; Br, 24.89. Found: C, 60.01; H, 5.39; Br, 24.70.

3-(2-Hydroxyphenoxy)propyl Bromide (XXII)—A solution of the benzyloxy compound XXI (44.9 g, 0.14 mol) in ethanol (100 mL) was hydrogenated at 40 psi over 20% $Pd(OH)_2$ on charcoal until hydrogen uptake ceased. The catalyst was removed by filtration, and the solution was evaporated under reduced pressure to provide XXII as an oil, which was used directly in the preparation of sulfide XXV. In another experiment the oil crystallized to give long off-white prisms, mp 52–54°C [lit. (28) mp 57–58°C]; ^{1}H-NMR ($CDCl_3$): δ 2.27 (quintet, 2, J = 6 Hz), 3.52 (t, 2, J = 6 Hz), 4.13 (t, 2, J = 6 Hz), 5.46 (br s, 1), and 6.84 ppm (m, 4).

2-(2-(2-Tetrahydropyranyloxy)phenoxy)ethyl Bromide (XXIII)—A mixture of 2-(2-tetrahydropyranyloxy)phenol (19.4 g, 0.10 mol), NaOH (4.4 g, 0.11 mol), 1,2-dibromoethane (75.1 g, 0.40 mol), and 20% aqueous EtOH (100 mL) was heated at 80°C for 4.5 h. The solvent was removed under reduced pressure, and the residue was treated with $CHCl_3$. The extract was washed

with 5% aqueous NaOH, then water, and concentrated under reduced pressure. Distillation of the residue gave 10.2 g (34% yield) of XXIII as a colorless oil, bp 105–130°C, 0.2 mm Hg; ^{1}H-HMR ($CDCl_3$): δ 1.3–2.3 (m, 6), 3.56 (t, 2, J = 6 Hz), 3.90 (m, 2), 4.25 (t, 2, J = 6 Hz), 5.37 (br s, 1), and 6.2–7.2 ppm (m, 4).

2-Amino-4-[2-(2-hydroxyphenoxy)ethylthio]butyric Acid (XXIV)—A mixture of DL-homocysteinethiolactone hydrochloride (XIII, 4.59 g, 0.03 mol) and NaOH (3.6 g, 0.09 mol) in 20% aqueous MeOH (45 mL) was stirred under nitrogen at 25°C for 18 h, then heated at 65°C for 2 h. Bromide XXIII (9.90 g, 0.033 mol) was then added, and after 3 h at 65°C and 17 h at room temperature, the mixture was concentrated, the residue was treated with isopropyl alcohol, and the mixture was filtered. The filtrate was evaporated, and the residue was dissolved in water. The resulting aqueous solution was washed twice with ether. The aqueous phase was adjusted to pH 8 (1 M HCl), and the precipitate which formed was collected and then suspended in water. The aqueous solution was adjusted to pH 6 (1 M HCl), and the mixture was stirred for 0.75 h. The deprotected product, precipitated by adjustment to pH 7, was washed with a small amount of absolute EtOH followed by ether. This afforded 3.31 g (41% yield) of sulfide XXIV as a white powder, mp 206–209°C; ^{1}H-NMR (Me_2SO-d_6): δ 1.9 (m, 2), 2.68 (t, 2, J = 7 Hz), 2.83 (t, 2, J = 7 Hz), 3.33 (t, 1, J = 6 Hz), 4.05 (t, 2, J = 7 Hz), 6.5–7.0 (m, 4), and 7.9 ppm (v br, 4); UV (MeOH) λ_{max}: 274 (ε 2800, sh), and 215 (ε 7200) nm; TLC (silica, MeOH): R_f 0.51.

Anal.—Calc. for $C_{12}H_{17}NO_4S$: C, 52.25; H, 6.39; N, 5.08; S, 11.62. Found: C, 52.24; H, 6.34; N, 5.05; S, 11.67.

2-Amino-4-[3-(2-hydroxyphenoxy)propylthiobutyric Acid (XXV)—A mixture of DL-homocysteinethiolactone hydrochloride (XIII; 12.24 g, 0.08 mol) and NaOH (9.6 g, 0.24 mol) in 20% aqueous MeOH (60 mL) was stirred under nitrogen at 25°C for 18 h, then heated at 65°C for 2 h. Bromide XXII (15.0 g, 0.065 mol) was added, followed by a solution of NaOH (5.2 g, 0.13 mol) in 20 mL of 50% aqueous MeOH. After the addition of a second portion of XXII (15.0 g, 0.065 mol), the mixture was stirred at 25°C for 18 h and the solvent was removed under reduced pressure. The residue was dissolved in water, and the solution was extracted three times with $CHCl_3$. The aqueous phase was brought to pH ~2 with 6 M HCl and extracted twice with $CHCl_3$. The aqueous phase was brought to pH 7 with 1 M NaOH, and product XXV was collected as a white powder (8.93 g, 39% yield), mp 218–221°C; ^{1}H-NMR (Me_2SO-d_6): δ 1.90 (m, 4), 2.4–2.8 (m, 4), 3.25 (t, 1, J = 6 Hz), 3.96 (t, 2, J = 6 Hz), 6.55–6.95 (m, 4), and 7.9 ppm (v br, 3); UV (MeOH) λ_{max}: 274.5 (ε 2900), 279 (ε 2500), and 215 (ε 6800) nm; TLC (silica, MeOH): R_f 0.51.

Anal.—Calc. for $C_{13}H_{19}NO_4S$: C, 54.71; H, 6.71; N, 4.91; S, 11.24. Found: C, 54.56; H, 6.78; N, 4.91; S, 11.22.

Effects of Divalent Amino Acids on Iron Absorption

JOHN M. CHRISTENSEN ˣ, MUSA GHANNAM, and JAMES W. AYRES

Received May 2, 1983, from the *School of Pharmacy, Oregon State University, Corvallis, OR 97331.* Accepted for publication August 30, 1983.

Abstract □ Solutions of each of 10 amino acids or ascorbic acid were mixed with iron and orally administered to rats. Iron was absorbed to a statistically significantly greater extent ($p < 0.05$) when mixed with asparagine, glycine, serine, or ascorbic acid as compared with a control solution of iron. The largest effects were for asparagine and glycine, which also increased iron absorption to a significantly greater extent ($p < 0.001$) than did serine or ascorbic acid. No statistically significant increase in iron absorption occurred when any of the other amino acids was mixed with iron. The extent of iron absorption from each test solution, as measured by area under the concentration of iron-59 in the blood-time curve ($r^2 = 0.0002$), and the initial rate of iron absorption for each test solution ($r^2 = 0.01$) showed no correlation with the stability constant of the amino acid-iron complex.

Keyphrases □ Absorption—iron, effects of divalent amino acids □ Iron—absorption, effects of divalent amino acids □ Amino acids—divalent, effects on iron absorption □ Complexes—iron-divalent amino acids, effect on iron absorption

Some products are available on the market in which amino acids or protein are combined with iron[1] in the hope of promoting iron absorption. Amino acids chelate with iron (1–3), and under certain circumstances, the resultant chelate enhances iron absorption from the GI tract (4–9). Low molecular weight chelates have been postulated to be essential for iron absorption by keeping iron in solution and preventing hydrolysis or precipitation of iron (10–12).

It has been proposed (8, 9) that amino acids which form the most stable complexes with iron are the most effective in increasing iron absorption from the GI tract, and failure of certain amino acids to promote iron absorption *in vivo* is due to their inability to chelate iron strongly enough to compete with water. Thus, they do not prevent hydrolysis and subsequent precipitation of iron. These data also suggest that amino acids with high stability constants should enhance iron absorption better than amino acids with lower stability constants.

These conclusions were reached based on data obtained for trivalent amino acids only (8). In some previous experiments conducted to study the effects of amino acids on iron absorption (4–9), phosphate buffers were used which have been reported to decrease iron absorption both *in vivo* and *in vitro* (13, 14). The conclusion of these reports that amino acid–iron complexes administered in phosphate buffer increase iron absorption may not be quantitatively correct since iron is known to form insoluble phosphate salts which might result in decreased iron absorption. Also, Monsen and Page (15) have studied some "iron absorption promoting agents," including aspartic acid which is an amino acid that forms a high-affinity iron chelate, and reported no increase in iron absorption.

This study was initiated to define the effect of selected divalent amino acids on iron absorption and to determine whether increased iron absorption with amino acids is related to the stability constant of the amino acid–iron complex. Ascorbic acid, an agent which is reported to enhance iron absorption (16, 17), was also tested to compare its effect on enhancing iron absorption with that of amino acids.

EXPERIMENTAL SECTION

Determination of Stability Constants of 10 Amino Acid Complexes with Iron—Glycine, L-proline, D,L-tryptophan, L-asparagine, D,L-alanine, D,L-phenylalanine, D-serine, D,L-methionine, D,L-leucine, and L-isoleucine were obtained commercially. Stability constants were determined by using a standard method for the determination of chelation between amino acids and metals (1–3). The amino acids described above were all dried at 60°C under reduced pressure for 1 h. Each amino acid (50 mL of a 0.01 M aqueous solution) was titrated with 0.1 M KOH first in the absence of metals and then in the presence of one equivalent of the ferrous sulfate salt (0.005 M). Thus, the molar ratio of the complex-forming agent to metal was 2:1 for all bivalent ions. The amount of alkali used in each titration was 5 mL (*i.e.*, the equivalent of the amount of complex-forming agent), and this was added in 10 equal portions of 0.5 mL each.

Experiments were conducted by using a water bath maintained at 37°C, and the amino acid solution was stirred continuously with nitrogen to maintain an inert atmosphere above the solutions. Boiled water was used since air must be removed from the system to avoid change in base concentration. The pH was recorded after each addition.

Preparation of the Buffer—A potassium hydrogen phthalate–sodium hydroxide buffer solution was prepared with a final pH of 6.0. Such a buffer contained 50 mL of 0.1 M potassium hydrogen phthalate and 43.7 mL of 0.1 M NaOH diluted to 100 mL. This buffer system was used because it did not precipitate iron from solution as did the phosphate buffer.

The ferrous ion was the important ion, and the potassium hydrogen phthalate buffer system maintained the iron in the ferrous state. This was determined throughout the study by taking a small portion of the solution, filtering it, and counting the radioactivity (iron-59) in solution. The ferric ion eventually forms and precipitates at pH 6.0 and does not stay in solution. The iron never precipitated in potassium hydrogen phthalate buffer throughout the study. The ferrous ion did not hydrolyze to form the ferric ion in potassium hydrogen phthalate buffer, and the iron was administered as the ferrous ion.

Procedure with Rats—Sprague–Dawley rats were bred and raised at the Oregon State University Animal Resource Center. The rats were housed in

Soybean meal (44% crude protein)	240
Fish meal	100
Feather meal	40
Whey (dried)	200
Trace mineralized salt	10
Tricalcium phosphate	14
Vitamin A (1,000,000 IU/g)	3 g
Vitamin D (36,000 IU/g)	13.6 g

pairs in metal cages (~25.4 × 20.3 cm) for 3 months before use, with a 12-h light/12-h dark cycle. The rats were allowed food and water *ad libitum* prior to fasting. The rat food was a special feed developed at Oregon State University. The formula for the food is presented in Table I.

Solutions of iron (as $^{59}FeSO_4$)[2] as a control solution and complexed with each of 10 amino acids or ascorbic acid were administered orally to groups of six rats each. Male albino rats (weight, 250–270 g each) were used. Rats were fasted for 24 h before the start of the experiment to minimize the occurrence of extraneous complexing agents, present as food constituents in the intestinal lumen, which may affect iron absorption (4). All test solutions were prepared by adding an amino acid and $^{59}FeSO_4$ to aliquots of the buffer so that the resulting iron-59 activity was 10 μCi/mL. The amino acid concentration was 0.4 M. The ascorbic acid concentration was 0.5 M, and the ferrous sulfate concentration was 0.2 M (10 μCi/mL). A control solution was prepared by the same procedure, but it did not contain amino acid or ascorbic acid.

An oral intubation tube[3] was used to deliver 1 mL of test or control solution into the stomach. The tube was then removed, and the rat was kept under anesthesia (ether) during the entire experiment.

At 5, 10, 20, 30, 45, 60, 90, 120, 150, 180, 210, and 240 min after administration of the solution, 20-μL samples of blood were collected from a toe of the rat by clipping the skin and collecting blood in capillary tubes. The capillary tubes were then placed into counting vials. Each sample was counted for 10 min in a solid scintillation counter chamber[4].

At the end of 4 h, the animals were sacrificed by overdose of ether. Liver, kidney, heart, brain, and muscle samples were collected from the animals, weighed, and then counted for 10 min[4].

RESULTS AND DISCUSSION

The concentration of iron-59 in blood *versus* time curves of iron-59 absorbed from all amino acid–iron, ascorbic acid–iron, and control solutions are shown in Fig. 1. All test solutions of amino acid and ascorbic acid with iron produced concentrations of iron-59 in blood higher than that in the control solution. It is known that blood or serum iron *versus* time curves cannot be used alone for quantitative and reliable iron absorption measurements (15–17). Other tissue iron concentrations should be included with concentrations of iron-59 in blood so that the total iron absorbed can be measured or estimated from the tissues sampled. The concentration and amount of iron-59 in tissues sampled 4 h after administration of all the amino acid–iron solutions, the ascorbic acid solution, and the control solution are shown in Table II.

The concentration of iron-59 was highest in tissues of animals receiving asparagine–iron and glycine–iron solutions, whereas it was lower in the tissues of animals receiving the other amino acid–iron solutions or the ascorbic acid–iron solution. The fact that the concentrations of iron-59 in blood and tissue at the end of the experiment were higher in the animals receiving amino acid–iron solutions than control solutions indicates that the elevated concentrations of iron-59 in blood in these animals is an accurate reflection of increased absorption from the GI tract.

In the tissues, the iron-59 concentration was highest in the heart, and the largest amount was found in muscle (due to large muscle mass in the body). High concentrations of iron-59 were also found in the liver and kidney, and generally, there were very small concentrations in the muscle and brain. This was consistent for the control experiments as well as for all 10 amino acid–iron complexes and the ascorbic acid–iron solution. Stores of iron are mainly in reticuloendothelial cells and, thus, are found in organs rich in such cells, especially the liver (18, 19). The heart is also an organ that has been reported

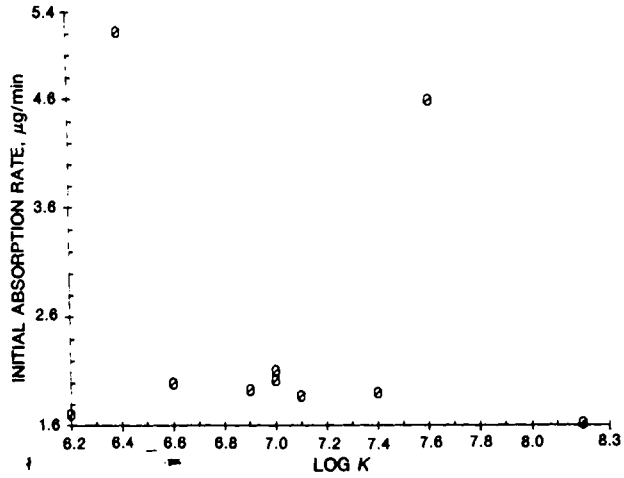

Figure 2—*Initial rate of absorption* versus *log* K *for each of the amino acids.*

(20, 21) to be high in iron content, which is most likely due to the heart being an organ high in iron sulfur proteins and cytochrome enzymes. Cytochrome *c*, for example, contains 1 g of iron/mol (20). The amount of stored iron varies with sources and also with demands made on it for hemoglobin formation. Glycine and asparagine increased iron-59 absorption to the greatest extent ($p < 0.001$) as compared with the control solution. Although the increase of iron-59 absorption over that of the control by serine and ascorbic acid was statistically significant (by ANOVA, $p < 0.05$), the increase was minimal, only 72.7 and 54.5%, respectively, compared with 309% for glycine and 345% for asparagine. These data are consistent with the data of Forth and Rummel, who observed a 300% increase in the amount of iron absorbed from the gut *in situ* in rats with glycine–phosphate buffer compared with iron–phosphate buffer (9) alone. Diets for chicks that were low in glycine but adequate in iron caused a marked reduction in the amount of iron absorbed *versus* diets in which glycine and iron were present in adequate amounts (22).

The concentration of iron-59 in tissues of animals receiving amino acid–iron solutions, control solution, or the ascorbic acid–iron solution was consistent with concentrations of iron-59 in the blood obtained from each test or control solution. Therefore, the concentration of iron-59 in blood *versus* time curves were used to compare the chelating affinity of the amino acid to iron (stability constant) with the ability of the amino acid to increase the rate or an approximated relative extent of iron absorption. This was done by comparing the initial rate of absorption with the stability constant of the amino acid–iron complex or by comparing the area under the concentration of iron-59 in blood *versus* time curve (0–4 h) with the stability constant of the amino acid complex. For all amino acid–iron complexes, the concentration of iron-59 in the blood *versus* time (Fig. 1) was fit to a trinomial equation (r^2 range, 0.9857–0.9991). Figure 1 shows the plot of the experimentally observed *versus* calculated concentrations of iron-59 in blood for each test solution. An empirical equation which describes the concentrations of iron-59 in blood curves, therefore, is:

$$y = B_0 + B_1 t + B_2 t^2 + B_3 t^3 \qquad \text{(Eq. 1)}$$

where t is time. This equation was used to fit the data so that the initial rate of absorption could be estimated.

The initial rate of absorption is approximated by the tangent to the concentration of iron-59 in blood curve at time zero and is equal to B_1 after differentiating dy/dt. The initial rates of iron-59 absorption, in decreasing order starting with the amino acid that increased the initial rate of absorption most, were: asparagine, glycine, serine, leucine, methionine, isoleucine, tryptophan, alanine, phenylalanine, and proline (Table III).

The effects of different amino acids on iron-59 absorption from time zero to 4 h were compared with the control by comparing the area under the concentration of iron-59 in blood *versus* time curve (AUC) for each amino acid–iron complex from time zero to 4 h. When integrating the above equation over the experimental period of 4 h, the area under the concentrations of iron-59 in blood time curve ($AUC_{0\text{-}240\ min}$) for each amino acid iron complex can be obtained as:

$$\int_{y_0}^{y_{240}} y\,dt = \int_{t=0}^{t=240} (B_0 + B_1 t + B_2 t^2 + B_3 t^3)\,dt \qquad \text{(Eq. 2)}$$

$$= 240\,B_0 + 28{,}800 B_1 + 4608 \times 10^3 B_2 + 82{,}944 \times 10^4 B_3$$

The values of B_0, B_1, B_2 and B_3 for each amino acid were obtained by curve

Table II—Iron in Tissues Sampled 4 h after Oral Administration of Test Solution to Rats

Test Solution	Average Concentration of Iron, μg/g of tissue					Conc. of Iron Remaining in GI Tract, μg/g of tissue[a]	Total Amount of Iron Absorbed, mg[b]

[a] After 4 h. [b] After 4 h. Calculations assume homogenous iron content throughout the tissues sampled. Also, the skeletal and adipose tissues are assumed to have the same iron content as the muscle tissue. Tissue mass was not determined in this study, but published (23) averages values for specific tissue masses, corrected for rat weights, were used in these estimations. Although these assumptions may not be totally accurate for estimating total iron absorbed, they are adequate because the actual values of iron absorbed would only be all scaled-up or -down in proportion to the relative values listed. The dose of iron administered was 11.2 mg. [c] $p < 0.001$. [d] $p < 0.005$.

fitting[5], and the area (Table III) under the concentrations of iron-59 in blood–time curve (0–4 h) was then calculated for each test solution.

Table III lists stability constants determined experimentally for each amino acid–iron complex, as well as the initial rate of iron absorption and the area under the concentration of iron-59 in blood *versus* time curves.

Figure 2 is a plot of the initial rate of iron absorption *versus* stability constant for each amino acid–iron complex, and Fig. 3 is a plot of AUC *versus* stability constant for each amino acid–iron complex. No useful correlation between either the initial rate of absorption ($r^2 = 0.01$) or area under the concentration of iron-59 in blood *versus* time curve ($r^2 = 0.000208$) (Fig. 2) and the stability constants of the appropriate amino acid–iron complex was observed (Fig. 3). This is contrary to the earlier hypothesis that amino acids which have larger amino acid–iron complex stability constants should increase iron absorption (8, 9). Although the amino acids reported to increase iron absorption had high stability constants, neither glycine nor asparagine have high stability constants, but both were effective in increasing iron absorption from the GI tract. What may have been measured in the earlier experiments was the ability of those amino acids that have large iron-complex stability constants to protect iron from precipitating with phosphates. It is interesting to note that EDTA forms a more stable complex than any of the amino acids tested, yet it does not facilitate increased iron absorption (9, 16, 17) and is even reported to negate any iron absorption enhancement produced by an iron absorption-promoting agent.

As another measure of the ability of the amino acid to increase iron absorption, the amount of iron-59 in gut tissue was determined after administration of phenylalanine–iron and methionine–iron complexes, in which the increase in iron absorption was lowest, and asparagine–iron complexes, in which it was highest. The amount of iron-59 in gut tissue (Table II) was much higher in the case of the phenylalanine–iron and methionine–iron complexes. This, too, is an indication that the elevated concentration of iron-59 in blood in the rats is a reflection of increased absorption from the GI tract. Conversely, when iron absorption is lower, the iron is retained in the gut tissue.

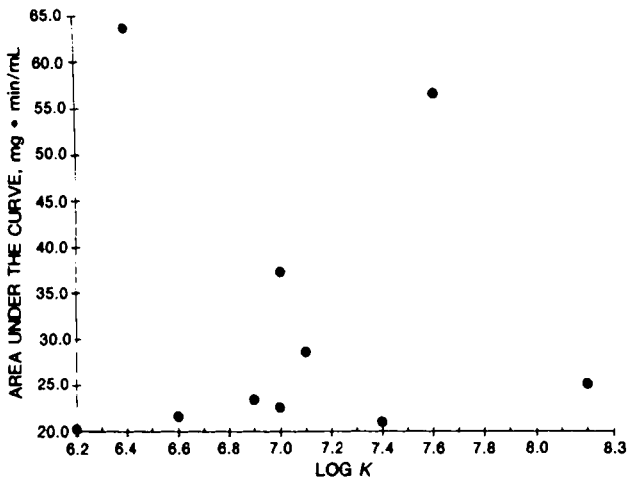

Figure 3—*AUC from time zero to 4 h of blood iron-59 concentration–time profile* versus *log K for each of the amino acids tested.*

Protein repeatedly has been reported to promote iron absorption (4–8, 24–26). This effect may account for the high fraction of iron in meat that is absorbed and for the enhancement of iron absorption from vegetables with simultaneous ingestion of meat (24–27). However, protein has also been reported to have a negative effect on iron absorption. Egg protein retards the absorption of iron (23, 27); it is not known whether the effect is related to its content of conalbumin. Conalbumin forms a stable complex with iron *in vitro* that drastically reduces the transfer of iron in jejunal segments of anemic rats (10). Egg yolk also contains phosphoproteins that form stable complexes with iron and prevent iron absorption (13, 23). The differential effects of proteins on absorption of iron may be attributed to the degree of proteolysis that occurs in the different experiments (23). All the data suggest that iron chelation does not always promote iron absorption.

Several products on the market have iron-chelating agents that are reported to promote iron absorption. These products, which contain agents reported to promote iron absorption, vary from protein hydrolysate to combinations of amino acids to a single amino acid. The iron absorption-promoting ability of these mixtures of agents needs to be investigated and compared with the ability of each one to promote iron absorption. It may be that only certain amino acids are responsible for enhanced iron absorption, and others can be omitted from iron product formulations; the result may be further increased iron absorption. A product containing only glycine and/or asparagine with iron may be sufficient to produce significantly increased iron absorption compared with other mixtures.

The amount of amino acids used in this study (or what would be used for an iron preparation for adult human use) is far too little to maintain a good nitrogen balance. Also, use of a single or a few selected amino acids as dietary supplements has caused significant shifts toward a negative nitrogen balance

Table III—Stability Constants, Initial Absorption Rates, and AUC for Each Amino Acid Tested

	log *K* Stability		Initial Absorption Rate, μg/min[b]	AUC, mg·min/mL[c]
	Experimental	Literature[a]		
Asparagine	6.4	6.5	5.21	63.59
Glycine	7.6	7.8	4.57	56.51
Serine	7.0	7.0	2.10	37.31
Leucine	7.0	6.9	2.02	22.60
Methionine	6.6	6.7	1.99	21.71
Isoleucine	6.9	7.1	1.93	23.48
Tryptophan	7.4	7.6	1.9	21.05
Alanine	7.1	7.3	1.87	28.64
Phenylalanine	6.2	6.3	1.70	20.24
Proline	8.2	8.3	1.62	25.22

[a] Values are from Refs. 1–3. [b] Calculated from Eq. 1. [c] Calculated from Eq. 2; time, 0–4 h.

[5] The organization and analysis of the data base associated with this investigation were carried out in part using the PROPHET system, a unique national resource sponsored by the National Institutes of Health. Information about PROPHET, including how to apply for access, can be obtained from the Director, Chemical/Biological Information-Handling Program, Division of Research Resources, National Institutes of Health, Bethesda, MD 20205.

in individuals (29). Therefore, individuals taking amino acid–iron complexes should be made aware that such products do not have value as protein supplements or replace the need for dietary protein. In addition, depending on the quantity and essentiality of the amino acids ingested from the supplement, protein metabolism may be adversely affected.

A consensus has been reached that amino acids considered to be essential are isoleucine, leucine, lysine, methionine, phenylalanine, threonine, tryptophan, and valine for children and adults. Histidine is an essential amino acid for infants, but it is not considered essential for children or adults (30). It is important to note that the amino acids that appear to increase the absorption of iron are not considered to be essential amino acids. Nitrogen balance is maintained by an adequate diet of protein and not by an iron supplement containing one or two amino acids in very low quantities (29, 30). Likewise, increasing the dosage of the amino acid by taking more tablets of an amino acid–iron preparation could cause iron toxicity.

Evaluation of High-Performance Liquid Chromatography and Gas Chromatography for Quantitation of Dextromethorphan Hydrobromide in Cough–Cold Syrup Preparations

V. GIBBS ˣ **and Z. ZAIDI**

Received May 27, 1983 from the *R & D Laboratories, Block Drug Co., Inc., Jersey City, NJ 07302.* Accepted for publication October 6, 1983.

Abstract □ A rapid and sensitive high-performance liquid chromatographic (HPLC) procedure is described for the analysis of the antitussive dextromethorphan hydrobromide in several cough–cold syrup preparations and compared with a gas chromatographic (GC) procedure. In the HPLC procedure, the active ingredient is analyzed as the hydrobromide salt by dilution in the mobile phase and separation on a reverse-phase cyano column. In the GC method, the active ingredient is analyzed as the free base, in which an aqueous solution of the antitussive is made alkaline and extracted with dichloromethane before injection onto the GC column. Excellent resolution of the antitussive agent was obtained by both systems; however, the HPLC assay is preferred for routine analysis (*RSD* 1%), as compared with the GC assay (*RSD* 4%).

Keyphrases □ Dextromethorphan hydrobromide—HPLC, GC □ Antitussive agents—dextromethorphan hydrobromide, HPLC, GC □ Formulations—cough–cold syrup, analyses by HPLC and GC

Dextromethorphan hydrobromide [(+)-3-methoxy-17 methyl-9α,13α,14α-morphinan hydrobromide monohydrate (I)] is commonly used an an antitussive agent in many commercial cough–cold syrup preparations. There are several clinically active compounds classified as morphinans. All have the drawbacks of morphine: its dependence liability and respiratory-depressant characteristics (1). However, the side effects of some morphinans are not as severe as those of morphine. As a result, dextromethorphan hydrobromide has gained wide acceptance as a nonaddictive antitussive agent because it is nearly devoid of any analgesic activity (2).

use of various chromatographic procedures when present alone (3) and in combination (4–10) with other active ingredients. Foremost in this category is high-performance liquid chromatography (HPLC), employing either ion-pair (6, 9) or buffer systems (8, 10). Since cough–cold syrups usually contain a combination of many active ingredients, the ability to analyze a full range of amine ingredients in cough–cold syrups by a single assay has been emphasized by most of these methods, as opposed to one single active ingredient in a range of multicomponent cough–cold syrup preparations. In our laboratory, the application of several of these HPLC procedures to various marketed cough–cold syrups containing dextromethorphan hydrobromide was unsuccessful in separating the active ingredient each time. In addition, excessive retention times and peak tailing were also experienced in some cases. To our knowledge, we are unaware of any reported chromatographic procedure which is broadly applicable to the analysis of dextromethorphan hydrobromide in a variety of cough–cold syrups containing several active ingredients, as well as various excipients, dyes, and/or sugar bases. Reported gas chromatographic (GC) methods usually involve an extraction step and prove to be better at resolving dextromethorphan hydrobromide from various excipients present in cough–cold syrups. However, sufficient recovery data have not been reported (4, 5).

The purpose of this study was to develop a rapid and sensitive method for analyzing dextromethorphan hydrobromide in several cough–cold syrup preparations, regardless of formula subtleties and, subsequently, to compare the efficiency of GC and HPLC for completing this task. In this paper, the application of HPLC and GC to several different cough syrups containing dextromethorphan hydrobromide as an active ingredient is described.

[a] 10 mL of placebo was spiked with the added amount of standard; I, contained no other active ingredients. [b] 5 mL of placebo was spiked with the added amount of standard; II, contained 12.5 mg of phenylpropanolamine hydrochloride and 20% alcohol.

EXPERIMENTAL SECTION

Chemicals and Reagents—Methanol, acetonitrile, and dichloromethane were distilled in glass[1] (HPLC grade). Perchloric acid (60% v/v), potassium nitrate, and anhydrous sodium sulfate were either ACS or analytical reagent grade[2].

High-Performance Liquid Chromatography—The liquid chromatograph[3] was fitted with an automatic injector[4] and a variable-wavelength UV detector[5] set at 280 nm. A microparticulate cyano column[6] (25 cm × 4.6 mm i.d.), containing 5-μm particles, was used.

Chromatographic Conditions—The mobile phase was 0.05 M potassium nitrate in acetonitrile–water (25:75), with the pH adjusted to 3.0 ± 0.1 with 60% v/v perchloric acid; the flow rate was 1.5 mL/min. The mobile phase was filtered[7] and deaerated before use. The inlet pressure was approximately 2900 psi. Detector sensitivity was 0.2 AUFS, the chart speed was 0.25 cm/min, and the injection volume was 10 μL.

Standard Preparation—Three working standard solutions were prepared by diluting 3, 5, and 8 mL of dextromethorphan hydrobromide[8] stock standard solution (1 mg/mL), respectively, to 100 mL with the mobile phase in volumetric flasks. Solutions were mixed and filtered[7].

Sample Preparation—Samples (2–10 mL, depending on label claim) were accurately transferred to 100-mL volumetric flasks and diluted to volume with the mobile phase. Solutions were mixed and filtered.

Gas Chromatography—The gas chromatograph[9] was a dual column modular system equipped with 1–10-mV recorder[10].

RSD, %		3.4			2.9

[a] 5 mL of placebo was spiked with the added amount of standard; II, contained 12.5 mg of phenylpropanolamine hydrochloride and 20% alcohol; III, contained 20% alcohol.

Chromatographic Conditions—A glass column[11] (~1.8 m × 2 mm i.d.) packed with 3% OV-17 on Chromasorb Q[12] (100–120 mesh) was used. The column temperature was maintained at 110°C for 2 min and programmed to 230°C for 4 min at 30°C/min. The flow rate of the helium carrier gas was 25 mL/min, with an inlet pressure of 30 psi. The injector port temperature was 220°C. The detector temperature was 260°C, with a hydrogen flow rate of 30 mL/min and an air flow rate of 300 mL/min. Detector sensitivity was 10^{-9} with a chart speed of ~0.5 cm/min. The temperature program was initiated with each 5-μL injection[13]. The column was allowed to condition overnight at 240°C before use.

Standard Preparations—Standard solutions of dextromethorphan hydrobromide were prepared by accurately weighing 1–15 mg of dextromethorphan hydrobromide standard into a 60-mL separatory funnel containing 25 mL of 0.1 M NaOH. The separatory funnel was stoppered and shaken gently to dissolve the solid, and the free base was extracted with three 15-mL portions of dichloromethane. After each addition of the organic solvent, the separatory funnel was stoppered and shaken vigorously for 15 min. The organic layer was transferred to a 50-mL volumetric flask *via* a funnel containing 200 mg of sodium sulfate supported by glass wool. Two milliliters of a 2.5-mg/mL solution of *O*-methoxyphenyl benzoate[14] in chloroform was added as internal standard to each flask before diluting to volume with dichloromethane.

Sample Preparations—Samples (5–10 mL, depending on label claim) were accurately transferred to 60-mL separatory funnels and extracted in the same manner as described above for the standards.

Assay Procedure and Quantitation—Under the chromatographic conditions described for HPLC and GC, injections of the sample and standard solutions were made. Results were calculated from the linear regression of the three standards, relating peak height ratios (standard-internal standard) and concentration.

[a] Formulation I, contains no other active ingredients; formulation II, contains 12.5 mg of phenylpropanolamine hydrochloride and 20% alcohol; formulation III, contains 20% alcohol.

RESULTS AND DISCUSSION

Preliminary studies involved testing of several mobile phase compositions for effective separation of dextromethorphan hydrobromide in a cough-cold syrup base. A 25:75 ratio of acetonitrile–water was finally found to be suitable for all the products analyzed. Peak tailing was minimized by using 0.05 M potassium nitrate and adjusting to pH 3.0. Several microparticulate reverse-phase columns with octadecylsilane (C_{18}) and cyano (CN) packings were tried from various manufacturers. In the past, C_{18} columns have been widely used by other workers for the separation of amines in cough-cold syrup preparations. In our experience, these columns (30 cm × 3.9 mm i.d. of 10-μm particle size) did not give suitable separation of dextromethorphan hydrobromide in some of the products analyzed. Finally, a cyano column (5-μm particle size; 25 cm × 4.6 mm i.d.) was used and was found to be more selective for the antitussive agent and, hence, provided better separation of the active ingredient from other excipients. Since the ultimate objective was to develop a method which would work for other commercially available products as well, column selection was considered to be an important factor.

Typical chromatograms of a placebo and sample run by HPLC are shown in Fig. 1. Construction of a standard curve from injections of dextromethorphan hydrobromide standard solutions ranging from 1 to 10 mg demonstrated the linearity of the HPLC procedure. The average peak height response was 8.98 cm for a 5-mg standard solution (*RSD* 1.6%). The limit of detection was 0.005 mg/mL for a steady baseline at 280 nm. The GC procedure offered comparable detection, and the standard curve was also found to be linear for solutions ranging from 1 to 15 mg. The average peak height response was 8.56 cm for a 5-mg standard solution (*RSD* 3.5%). Chromatograms of a GC run are shown in Fig. 2.

Data generated from the recovery studies by HPLC and GC are outlined in Tables I and II, respectively. The recoveries were performed by an external standard addition method. To evaluate the precision of the two methods, multiple injections of a single lot of cough syrup were made (Table III). For each formulation under investigation, the *RSD* was <1.5% for the HPLC assay and <4.0% for the GC assay. Although the HPLC assay is an external standard method, it was believed that the addition of an internal standard would not significantly improve the precision of the assay procedure. However, if an internal standard is desired, methaphenilene hydrochloride and promethazine can be used for this purpose. The retention times are 14.0 and 20.0 min, respectively, relative to dextromethorphan hydrobromide, which has a retention time of 10.0 min.

The second phase of the study involved the evaluation of both assay pro-

Table IV—Comparative Analysis of Dextromethorphan Hydrobromide in Commercial Products

		HPLC		GC	
Product[a]	Claim, mg	Found, mg[b]	Percent Label Claim	Found, mg	Percent Label Claim

C	10	9.99	99.9	10.82	108.2
D	30	29.08	96.9	30.31	101.0

[a] A, contained 100 mg of guaifenesin/5 mL and 1.4% alcohol; B, contained 5% alcohol; C, contained 100 mg of guaifenesin and 30 mg of pseudoephedrine hydrochloride/5 mL and 2.4% alcohol; D, contained 9.5% alcohol. [b] Results are the average of duplicate determinations.

cedures (HPLC and GC) for determining dextromethorphan hydrobromide from other commercially available cough syrups. Chromatograms obtained for these products were representative of the assay procedure and gave resolution and/or separation similar to that of dextromethorphan hydrobromide in the products under investigation. Typical chromatograms are shown in Figs. 3 and 4 for HPLC and GC, respectively, and the results are compared in Table IV.

The results obtained by the GC procedure were higher for all the products analyzed and, hence, reflected the difficulty in extracting the free base with organic solvents (10). This difficulty was experienced with the standard and sample solutions as well. It is believed that the partitioning behavior (11) of the antitussive agent is the major cause for this problem rather than the complexity of the cough syrup formulations. The GC procedure involved a lengthy sample preparation and required more analysis time as compared with the HPLC procedure. Finally, the HPLC procedure gave results that were in better agreement with label claims for all the products evaluated and was a more precise assay procedure.

CONCLUSION

Although excellent resolution of the antitussive agent was obtained by both the HPLC and GC systems, further examination of the applicability of either method for routine analysis of dextromethorphan hydrobromide revealed that the HPLC procedure described is simple, rapid, and precise for the quantitation of the antitussive agent in several commercially available cough-cold syrups. The GC procedure does not seem to be the method of choice for quantitation of dextromethorphan hydrobromide in cough syrups due to the difficulty in extracting the free base and the time involved in sample preparation.

Nasal Drug Delivery System of a Quaternary Ammonium Compound: Clofilium Tosylate

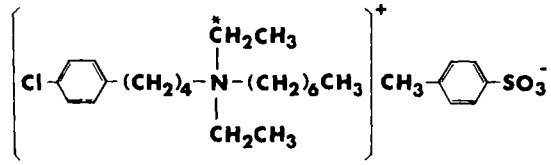
KENNETH S. E. SU ˣ, KRISTINA M. CAMPANALE, and CHRISTIAN L. GRIES

Received September 9, 1983, from the *Pharmaceutical Research Department and Pathology Division, Lilly Research Laboratories, Eli Lilly and Co., Indianapolis, IN 46285.* Accepted for publication October 12, 1983.

Abstract □ The blood levels of the [^{14}C]clofilium ion in rats after various routes of administration of clofilium tosylate were compared. The results indicate that the blood levels after nasal administration were not statistically different from levels after intravenous administration ($p > 0.05$). Administration by the oral route resulted in considerably lower blood levels. Nasal administration of clofilium tosylate appeared to be superior to oral administration. Histological examinations of nasal mucosa were conducted. At the lower concentration, mild necrosis was observed, and large areas of mucosa were unaffected. However, necrosis of large areas of mucosa occurred after exposure to the higher concentration. Levels of radioactivity in heart, liver, lung, and kidney tissue, as a function of time, were also studied. Unlike the blood levels after nasal administration, the levels of radioactivity were persistent in heart tissue. The data suggest that the [^{14}C]clofilium ion and/or metabolite concentrate in the heart and that blood levels of radioactivity may not be an accurate index of cardiac levels or biological response.

Keyphrases □ Clofilium tosylate—nasal drug delivery □ Drug delivery systems—clofilium tosylate, nasal administration

Clofilium tosylate, [4-(*p*-chlorophenyl)butyl]diethylheptylammonium tosylate, is a newly synthesized quaternary ammonium compound that has been shown to selectively increase refractoriness of cardiac tissue in dogs and humans (1-3). It is known that oral administration of quaternary ammonium compounds results in low and varied blood levels (4). Predictably, the oral absorption of clofilium tosylate in rats was poor (5). A total of 0.35% of the dose was excreted in the urine and 79% was excreted in the feces within 72 h after oral administration. All tissues had extremely low levels of radioactivity and low rates of absorption after oral administration of clofilium tosylate. The pharmacokinetics and bioavailabilities of quaternary ammonium compounds given by various routes have been studied previously (4-7). However, nasal administration of a quaternary ammonium compound has not yet been evaluated. It was the object of this study to report the results on the nasal absorption of clofilium tosylate in rats. The tissue disposition of radioactivity after nasal administration of [^{14}C]clofilium tosylate is also reported.



EXPERIMENTAL SECTION

Synthesis of [^{14}C]Clofilium Tosylate—[^{14}C]Clofilium tosylate was prepared in this laboratory by Dr. F. J. Marshall. *N*-[^{14}C]Acetyl-*N*-heptyl-(4-chlorophenyl)butylamine was prepared as follows: 104.4 mg (1.33 mmol) of [^{14}C]acetyl chloride was introduced by vacuum transfer into a flask containing 804.8 mg (2.86 mmol) of 4-(4-chlorophenyl)butylamine in 13 mL of dry toluene. The mixture was then stirred for 3 h and warmed gently for 1 h in a stoppered flask. The solution was washed with 10 mL of a 1 M HCl-water-saturated sodium chloride solution and then dried with magnesium sulfate and the organic phase was evaporated to dryness under reduced pressure. The resulting material was dissolved in chloroform and purified by preparative TLC (ethyl acetate, silica gel[1]). A total of 277 mg (64% yield) of the amide was obtained. This material was reduced to the tertiary amine as follows. With cooling in ice water, a solution of 277 mg (0.855 mmol) of the aforementioned

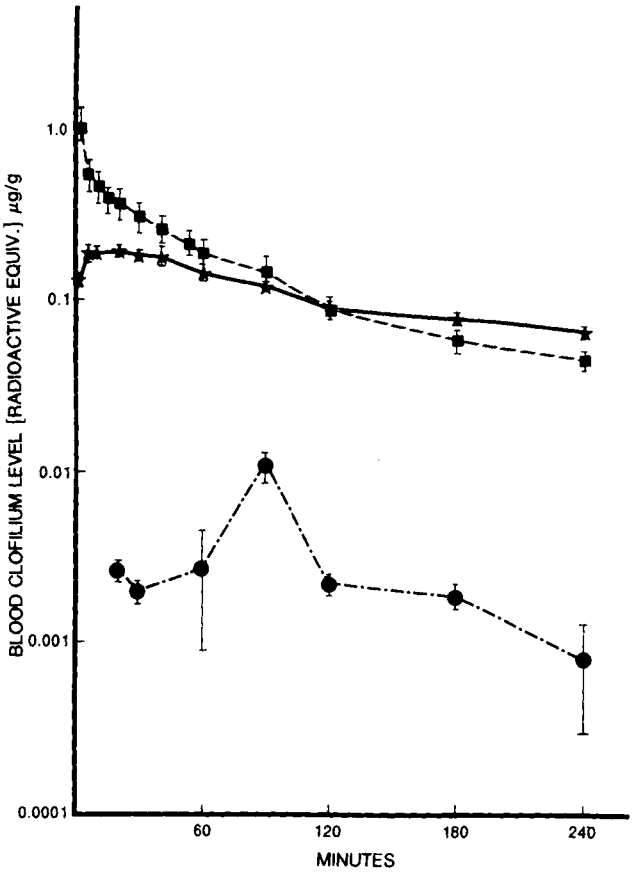

Figure 1—*[^{14}C]Clofilium ion in blood of male Sprague-Dawley rats after various routes of administration of a 1.2-mg/kg dose (n = 3). Key (1) intranasal administration; (2) intravenous administration; (3) oral administration.*

amide in 8 mL of tetrahydrofuran was added dropwise to 5.25 mL of a 1 M solution of diborane in tetrahydrofuran. The mixture was refluxed gently for about 20 h, cooled in ice water, and 7 mL of methanol was cautiously added. The mixture was stirred for a few minutes, and 11 mL of 1 M HCl and 3 mL of concentrated HCl were added. The mixture was heated for 3 h. After cooling in ice water, it was made strongly basic by the addition of 5 M NaOH. The product was extracted with ether, and the extract was washed with water-saturated sodium chloride solution and dried with magnesium sulfate. The ether was removed under reduced pressure. The tertiary amine was purified by preparative TLC as described above (ethyl acetate-triethylamine, 30:1) to give 206 mg (78% yield) of material which showed one spot on TLC. The quaternary tosylate was prepared as follows: 206 mg (0.665 mmol) of the ^{14}C-labeled tertiary amine was refluxed with 159.6 mg (0.797 mmol) of ethyl-*p*-toluenesulfonate in 3.2 mL of 1,2-dichloroethane for 96 h. The solvent was removed under reduced pressure, and the residue was recrystallized from acetone-ethyl acetate to give 226 mg of colorless crystals of [^{14}C][4-(*p*-chlorophenyl)butyl]diethylheptylammonium tosylate, mp 98–101°C. The product appeared to be 97.5% pure by TLC and autoradiography.

Formulation—[^{14}C]Clofilium tosylate was dissolved in NaCl for injection USP (8) and sonicated before administration to rats.

Animal Absorption Studies—Male Sprague-Dawley rats (average weight, 275 g) were anesthetized during the entire course of the intravenous and nasal absorption studies. For intravenous administration, the rats were anesthetized with pentobarbital by intraperitoneal injection, and the drug solution was administered by bolus injection into the femoral vein. For nasal administration, the surgical procedure conducted on the rats was that described previously (9, 10) with some modifications. The drug solution was delivered to the nasal cavity through the esophagus cannulation tubing by means of a syringe. For oral administration, the rats were not anesthetized, and the drug solution was administered by gavage. Blood samples were taken from the tail vein periodically and acid-digested in 0.2 mL of 70% $HClO_4$ and 0.4 mL of 30% H_2O_2 at 70°C for 1 h in scintillation vials. The samples were cooled and counted in scintillation fluid[2].

[2] Ready-Solv MP; Beckman.

Figure 2—*Nasal mucosa of necropsy A; control rat.*

Histological Examination of Nasal Mucosa in Rats—After the absorption phase of the study, the rats were killed, decapitated, and the nasal passages were flushed with 10% buffered formalin. After fixation by immersion, the heads were decalcified, and four cross sections of the nasal cavity of each rat were stained and examined (11).

Tissue Distribution of the [^{14}C]Clofilium Ion after Nasal Administration of [^{14}C]Clofilium Tosylate—At various times after nasal administration of the drug, tissues were dissected, rinsed, blotted, and weighed. Samples (100–260 mg) were digested in 0.2 mL of 70% $HClO_4$ and 0.4 mL of 30% H_2O_2 at 70°C for 1 h in scintillation vials. The samples were cooled and counted in scintillation fluid[2].

RESULTS AND DISCUSSION

The disappearance of radioactivity in the blood of rats administered [^{14}C]clofilium tosylate by the three administration routes is shown in Fig. 1. The variations in blood levels as well as the low absorption rate following administration of the oral dose are clearly demonstrated. Nasal administration of the drug resulted in much higher levels of radioactivity than levels after oral administration. The blood radioactivity levels of the clofilium ion after oral administration of the tosylate were ~1% of the levels obtained from the dose, whereas the radioactivity levels after nasal administration were 70% of those obtained from the dose (Table I). Furthermore, the difference in levels following intravenous and nasal administrations were statistically insignificant ($p > 0.05$).

The data on the effect of the clofilium ion concentration indicate that the area under the curve of the blood radioactivity level increased with dose in a nonlinear manner when administered nasally (Table II). However, a linear dose-response relationship appeared in the lower ranges. The nonlinear portion of the curve and good absorption rate at the concentration of 1.2 mg/kg were possibly attributable to damage to the nasal mucosa with exposure of the submucosal vasculature to the quaternary ammonium compound. Inspection of the blood kinetics of the radioactivity levels (Table III) suggested that, even at this lower dose, the drug was slowly absorbed and/or diffused through epithelial cells into the systemic circulation. At 0.3–0.6 mg/kg, the absorption

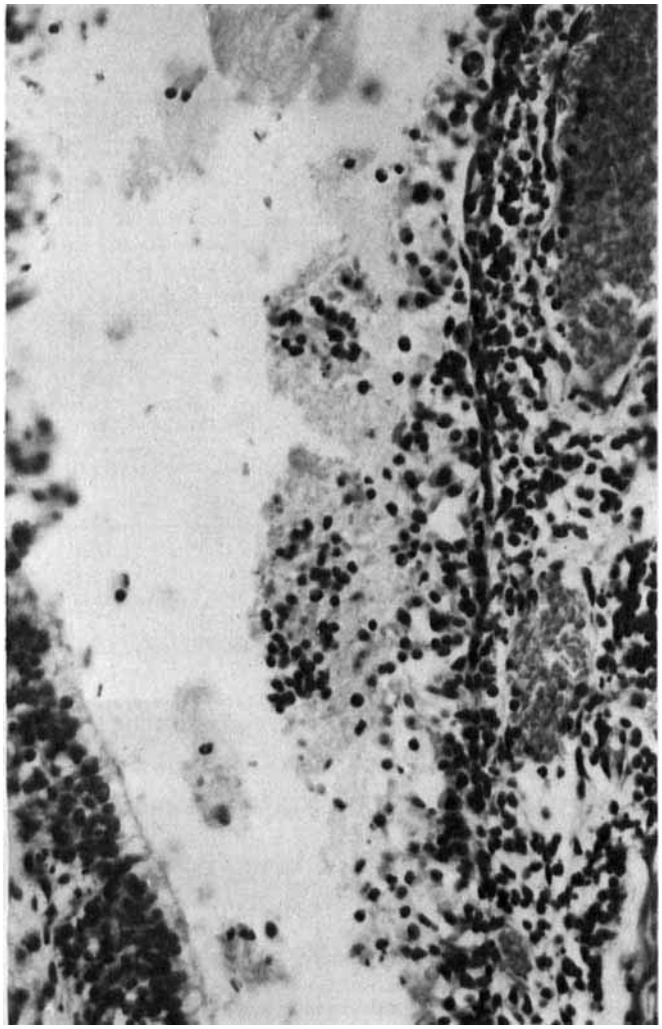

Figure 3—*Nasal mucosa of necropsy B; the rat was given a 1.2-mg/kg dose.*

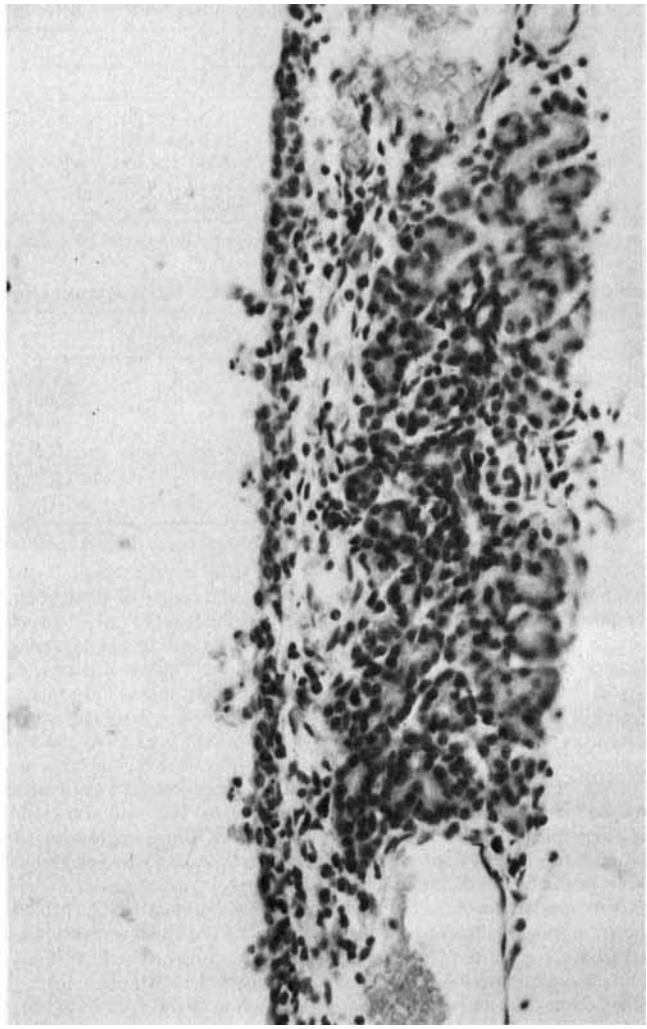

Figure 4—*Nasal mucosa of necropsy C; the rat was given a 0.6-mg/kg dose.*

under the AUC per unit dose remained constant (Table II). Thus, the amount of drug absorbed was directly proportional to the concentration in accordance with the law of diffusion. The observations are in agreement with those reported previously; that is, quaternary ammonium compounds are absorbed by a diffusion mechanism (6). Still, by administering a 0.3-mg/kg dose nasally, the nasal absorption was ~21-fold greater than the oral absorption. In these studies, it was indicated that clofilium tosylate was rapidly absorbed from the nasal mucosa. The peak blood level was attained ≤10 min after nasal instillation. A nasal drug delivery system for quaternary ammonium compounds appears to be feasible for this antiarrhythmic agent or for other applications.

Quaternary ammonium salts are often used as surface-active agents when dissolved in water for antimicrobial and/or antiseptic purposes (12, 13). The possibility that nasal absorption of clofilium tosylate could be attributable

Table IV—Summary of Histological Examination of Nasal Mucosa after Intranasal Administration of Clofilium Tosylate to Rats

Necropsy	Dose, mg/kg	Exposure, h	Microscopic Findings[a]
A	Control	0	No significant lesions.
B	1.2	6	About one-half of the mucosa was necrotic or missing. Occasional microabscesses were present in the mucosa. The lumens of affected turbinates contained debris formed of neutrophils and sloughed mucosa.
C	0.6	6	Mild necrosis was characterized by occasional eosinophilic, round, mucosal cells with pycnotic nuclei. Minimal amount of luminal debris.
D	0.3	6	Similar to that for the 0.6-mg/kg dose.

[a] Summarized from the observation from four cross sections of the nasal cavity of each rat and from a total of three rats in each study.

to damage to the mucosa was realized during the course of these studies. Therefore, histopathological studies were conducted. To avoid physical damage to any part of the nasal mucosa, the drug solution was delivered to the nasal cavity through the esophagus cannulation tubing with a syringe. Typical lesions of the exposed specimens of rat nasal mucosa are reported (Figs. 2-4). In general, large portions of mucosa that were in contact with the highest concentration of clofilium tosylate became necrotic. At the lower concentrations, only occasional epithelial cells were necrotic, and large areas of mucosa were unaffected. No histological differences between nasal mucosa exposed to the 0.3- or 0.6-mg/kg dose were detected. The results observed in the nasal mucosa of rats after administration of clofilium tosylate are summarized in Table IV. Control groups were also exposed to the vehicle.

The time course of the clofilium ion radioactivity in various tissues following nasal administration of clofilium tosylate in rats is summarized in Table III. The absorption kinetics of the radioactivity from the blood contrasted with that from some tissues. One hour after nasal administration, high levels of radioactivity relative to the blood were observed in the heart, lung, liver, and kidney tissues. There was a gradual accumulation of the drug in the heart, with a peak occurring between 4 and 6 h based on the experimental design. Radioactivity levels in the heart appeared to be very persistent. By 6 h after nasal administration, the total radioactivity in the heart was about 18-fold greater than that in the blood. The results are consistent with the previously reported gradual uptake by the myocardium after intravenous administration of the drug in rats and dogs (14). Distribution in blood and the relationship between tissue and blood concentrations appear to be similar, regardless of whether administration is intravenous or nasal. Other quaternary ammonium antiarrhythmic agents, such as bretylium and 1-(dimethylisopropylamino)-3-(1-naphthyloxy)-2-propanol methochloride (UM-272), are also known to have a high affinity for myocardial tissue relative to plasma (15, 16). The biological response of clofilium tosylate correlates with the levels of radioactivity in the heart (14). These data re-emphasize the fact that for the clofilium ion, and possibly other quaternary ammonium antiarrhythmic agents, blood levels are an insufficient indicator for estimating cardiac levels and thus pharmacological effect.

Methods for *In Vitro* Percutaneous Absorption Studies III: Hydrophobic Compounds

ROBERT L. BRONAUGH ˣ **and RAYMOND F. STEWART**

Received May 9, 1983, from the *Division of Toxicology, Food and Drug Administration, Washington, DC 20204.* Accepted for publication September 8, 1983.

Abstract □ The absorption of two hydrophobic compounds through rat skin was measured by *in vivo* and *in vitro* techniques. The permeation of the fragrance ingredients 3-phenyl-2-propenyl 2-aminobenzoate (I) and 1-(3-ethyl-5,6,7,8-tetrahydro-5,5,8,8-tetramethyl-2-naphthalenyl)ethanone (II) was measured from a petrolatum and an acetone vehicle. Increases in permeation of 8-fold (I) and 95-fold (II) were observed when the compounds were tested *in vivo* under conditions similar to *in vitro* procedures. The apparent inability of the compounds to freely enter the diffusion cell receptor fluid was partially reversed by replacing normal saline with other fluids: rabbit serum, 3% bovine serum albumin, organic solvents, and dilutions of four nonionic surfactants. The effect of the receptor fluids on the integrity of the skin barrier was assessed by measuring the permeability of control compounds (cortisone, urea, and water). A 6% solution of polyethylene glycol 20 oleyl ether was the receptor fluid of choice. Without apparent damage to the skin, 61% (petrolatum vehicle) or 73% (acetone vehicle) of the *in vivo* absorption of I was obtained. With II, only 32% of the *in vivo* absorption was achieved (petrolatum vehicle). Even when the surfactant solution is used, significant differences may still remain between *in vivo* and *in vitro* results.

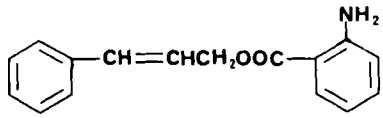
Keyphrases □ Absorption—percutaneous, *in vitro*, hydrophobic compounds □ Hydrophobic compounds—*in vitro* percutaneous absorption

For a number of compounds, good agreement is found between the results of *in vivo* and *in vitro* skin permeability studies (1-10). The *in vitro* values determined by Franz (1, 2) compared favorably with the *in vivo* permeability results of Feldmann and Maibach (3) for 12 organic compounds in human skin when considerations were made for experimental differences. Bronaugh *et al.* (4) have measured both the *in vivo* and *in vitro* absorption of three compounds through rat skin. Again, the diffusion cell studies were accurate in their prediction of *in vivo* absorption.

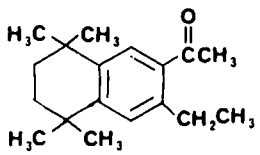
For a certain type of compound, however, erroneous results may be obtained when standard diffusion cell techniques are used. Compounds that are essentially insoluble in water may not partition freely from excised skin into an aqueous receptor fluid. When applied to skin *in vivo*, however, these compounds may readily leave the barrier layers of the skin because of their solubility in biological fluids. In the *in vivo* and *in vitro* absorption comparisons of Tsuruta (8, 9), values much lower than expected were obtained for *in vitro* permeability measurements of organic solvents with the lowest water solubility.

The problem was alluded to by Franz (1), who in selecting compounds for study, omitted highly water-insoluble compounds to avoid results that were "artificially limited due to insolubility in the dermal bathing solution." Brown and Ulsamer (11) have found that the skin permeation of the hydrophobic compound hexachlorophene increased twofold when normal saline was replaced with 3% bovine serum albumin (in a physiological buffer) in the diffusion cell receptor. This new receptor fluid had a 500-fold greater solubility for hexachlorophene. In a recent study (12), a nonionic surfactant (poloxamer 188[1]) was used to enhance the solubility of linoleic acid in the diffusion cell receptor medium. Although the potential problem inherent in the partitioning of a hydrophobic compound from skin is now recognized, no systematic studies to characterize and attempt to solve this problem have been carried out.

In determining the skin absorption of two fragrance materials, it seemed that their hydrophobic nature might cause difficulties in an *in vitro* analysis. The water solubilities of 3-phenyl-2-propenyl 2-aminobenzoate (cinnamyl anthranilate; I) and 1-(3-ethyl-5,6,7,8-tetrahydro-5,5,8,8-tetramethyl-2-naphthalenyl)ethanone (acetyl ethyl tetramethyl tetralin; II) were 0.23 and 0.012 mg/L, respectively. Therefore, percutaneous absorption of these compounds was initially determined *in vivo* in rats. Lipophilic receptor fluids were substituted for normal saline to try to enhance absorption and approximate the *in vivo* results without damage to the permeability barrier. Rabbit serum and aqueous dilutions of serum albumin, organic solvents, and four commonly used nonionic surfactants were utilized as the lipophilic receptor fluids.



I



II

EXPERIMENTAL SECTION

Materials—The following radiolabeled compounds were used to facilitate quantitation of skin absorption (specific activity): [^{14}C]II[2] (2.40 mCi/mmol); [^{14}C]I[2] (10.5 mCi/mmol); [^{3}H]cortisone[4] (43.0 Ci/mmol); [^{14}C]urea[4] (57.0 mCi/mmol); and tritiated water (55.5 mCi/mmol). All compounds were determined to have a radiochemical purity of 98%. Agents used in the receptor fluids, polyethylene glycol 20 oleyl ether (PEG-20 oleyl ether)[5], octoxynol 9[6], poloxamer 188, polysorbate 80[7], and bovine serum albumin[8], were prepared in distilled water at the indicated concentrations. All agents (except albumin) are commonly used nonionic surfactants.

***In Vitro* Studies**—Percutaneous absorption measurements were made in a one-chambered static diffusion cell as described previously (13). The receptor fluid was stirred with a magnetic stirring bar in a constant-temperature water bath maintained at 32°C.

The skin on the back was lightly shaved and then excised from 3- to 7-month-old female Osborne-Mendel rats. In some experiments, subcutaneous tissue was removed, and full-thickness skin was fixed in the diffusion cell. For most experiments, split-thickness skin (350 μm) was prepared with a dermatome[9]. Test compounds were applied to the epidermal surface of the skin

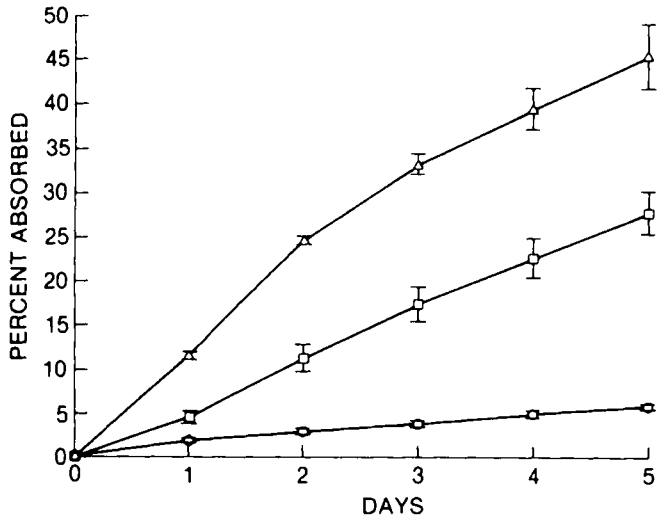

Figure 1—*Absorption of I from a petrolatum vehicle. Key: (Δ) in vivo results; (○) in vitro (saline in receptor); (□) in vitro (6% PEG-20 oleyl ether in receptor). At 5 d, 13% of the in vivo absorption was obtained by in vitro techniques, using saline in the diffusion cell receptor. Absorption was increased to 61% of the in vivo results by substituting 6% PEG-20 oleyl ether as the receptor fluid.*

dissolved in either a petrolatum or acetone vehicle. The 1.13-cm^2 area of skin was completely covered by the vehicle (30 mg of petrolatum, 20 μL of acetone). Aliquots of receptor fluid were removed from a side arm at various intervals, and the radioactivity was determined in a liquid scintillation counter[10].

Cortisone permeation was determined to monitor the effect of the receptor fluid on the integrity of the skin barrier. In most experiments, the permeability of the ^{14}C-labeled fragrance and the [^3H]cortisone was determined simultaneously by dual-label techniques. The absorption of the fragrances (I and II) was expressed as a percentage of the amount applied to the skin to facilitate comparison with the *in vivo* results. Cortisone permeation from the petrolatum vehicle was expressed as a permeability constant (steady-state absorption rate divided by the applied concentration). Other percutaneous absorption values were expressed as the percent dose absorbed and/or permeability constants.

***In Vivo* Studies**—The skin absorption of I and II was determined in rats by *in vivo* methods described previously (4). The back skin of the rats was lightly clipped and a nylon ring (inside area, 2 cm^2) was glued to the back with a cyanoacrylate adhesive. The rats were partially restrained with rubber tube collars, and the test compounds were applied inside the protective device on the back. Because of significant excretion in the feces expected with the lipophilic compounds, absorption was estimated by summing the amounts of compound excreted in the urine and feces (14). These samples were collected at 24-h intervals in metabolism cages for 5 d. Radioactivity in the samples was determined by liquid scintillation counting. Percutaneous absorption was expressed as the percentage of the applied dose excreted during the collection periods.

Statistical analysis was by the Student's *t* test. The significance of increased absorption of compounds resulting from changes in the receptor fluid was determined by using a one-tailed probability.

RESULTS

In vitro percutaneous absorption measurements, using a normal saline receptor solution, resulted in values that were much lower than the corresponding *in vivo* data for I and II. This difference is shown in the time course for the absorption of I (Fig. 1). In initial studies, the effect of different receptor fluids on the absorption of I was determined by comparing values obtained after 5 d (Table I). Only 12.7% of I absorbed *in vivo* during the 5-d period was obtained in a corresponding *in vitro* experiment, using normal saline receptor fluid and split-thickness rat skin. A 1.5% solution of the nonionic surfactant PEG-20 oleyl ether enhanced by threefold the skin permeability to I; the cortisone permeation determined simultaneously in the dual-label experiment was not altered. When full-thickness rat skin was used, no increase in the absorption of I was obtained with the PEG-20 oleyl ether. The optimal concentration of the surfactant was 6%. A fivefold increase in the absorption of I was obtained without altering the permeation of the cortisone control.

Rabbit serum and bovine serum albumin had no effect on the integrity of the barrier, but they were also less effective in increasing the absorption of I than PEG-20 oleyl ether. A methanol–water solution and 6% octoxynol 9 were equal or superior to 6% PEG-20 oleyl ether, but significant damage to the skin was indicated by the increased cortisone permeation since the absorption of cortisone is not limited by a lack of solubility in the normal saline receptor fluid. A 6% solution of poloxamer 188 in the receptor resulted in slight enhancement of both I and cortisone permeation.

An even greater difference was seen between the *in vivo* absorption of II and the diffusion cell data (Table I). Results similar to those determined with I were obtained by altering the receptor fluid. The enhanced absorption with 1.5% PEG-20 oleyl ether required the use of a dermatome skin section. Best results were obtained with 6% PEG-20 oleyl ether in the receptor, and no increase was observed in the permeation of the cortisone control. Use of a glycerol–water solution in the receptor resulted in permeability data similar to those obtained with normal saline. As was previously found when a methanol–water solution was used, the ethanol–water receptor fluid enhanced the penetration not only of II, but also of the cortisone control.

When I was applied to rat skin in an acetone vehicle, greater absorption was obtained than with a petrolatum vehicle (Table II). A 6% PEG-20 oleyl ether receptor fluid in the diffusion cells greatly increased the permeation of I without a significant effect on the permeation of cortisone.

The *in vitro* absorption of II and cortisone (acetone vehicle) was measured for 43 h to determine the effect on skin permeation of three nonionic surfactants (Table II). Use of 6% PEG-20 oleyl ether resulted in the greatest increase in the absorption of II without an increase in that of the cortisone control. At the same concentration (6%), both polysorbate 80 and octoxynol 9 resulted in increased cortisone permeation when compared with the value obtained with normal saline.

The effect of 6% PEG-20 oleyl ether on the absorption of water and urea

Table I—Effect of Diffusion Cell Conditions on the Absorption of I and II (Cortisone Control)[a]

Receptor Fluid	Percent Applied Dose Absorbed in 5 d	Cortisone Permeability Constant × 10^5

Table II—Effect of Nonionic Surfactants on I, II, and Cortisone Absorption[a]

Receptor Fluid	Percent Absorbed (5 d) I	Cortisone
Compound I[b]		
Normal Saline (9)	14.1 ± 1.3	21.5 ± 2.5
6% PEG-20 oleyl ether (8)	44.1 ± 4.3[c]	24.8 ± 3.2
Compound II		
Receptor Fluid	Percent Absorbed (43 h) II	Cortisone
Normal Saline (12)	0.7 ± 0.1	7.2 ± 0.9
6% PEG-20 oleyl ether (8)	7.5 ± 1.4[c]	6.0 ± 0.5
6% Polysorbate 80 (4)	4.1 ± 0.6[c]	10.6 ± 1.5[c]
6% Octoxynol 9 (4)	11.9 ± 1.8[c]	15.1 ± 1.0[c]

[a] Values are the mean ± *SE*; the number of determinations is in parentheses. Compounds were applied *in vitro* to rat skin (350-μm section) in an acetone vehicle. [b] *In vivo* absorption of I (acetone vehicle) was 60.7%. [c] Significant increase when compared with the appropriate saline control by one-tailed Student's *t* test, $p < 0.05$.

was examined with rat skin in diffusion cells (Table III). No significant increase was seen in the percutaneous absorption of these two additional control compounds.

DISCUSSION

A comparison of the *in vivo* and *in vitro* percutaneous absorption data for the fragrance ingredients I and II reveals the underestimation of absorption that can occur by using diffusion cell techniques with hydrophobic compounds. Increases of 8-fold (I) and 95-fold (II) in permeation were obtained when the compounds were tested *in vivo* under similar conditions.

In vitro absorption was therefore increased by substituting more lipophilic receptor fluids for normal saline. A physiological-based solution to the problem, it seemed, might result from the use of serum or serum proteins in the diffusion cell receptor. However, the use of rabbit serum as the receptor fluid did not substantially increase absorption of the fragrances. This failure may be the result of the absence of a continual replacement of the bathing medium, as occurs *in vivo* with blood flow through the skin. Use of 3% bovine serum albumin was more effective than serum, but only about a twofold increase in I absorption was obtained. Brown and Ulsamer (11) have observed a similar increase in hexachlorophene permeation through excised human stratum corneum when 3% bovine albumin was added to the receptor. The penetration rate of hexachlorophene correlated with the solubility of the compound in different buffer-albumin mixtures.

Nonionic surfactants have a relatively mild effect on skin, with a much lower irritation potential than ionic agents (15). Aqueous dilutions of a series of nonionic surfactants were evaluated in the diffusion cell system. The fact that split-thickness skin was required for an increase in I and II absorption with 1.5% PEG-20 oleyl ether indicates that a more physiological value may be obtained with this preparation of skin. A major portion of systemic uptake occurs in the highly vascular upper dermis; thus, use of full-thickness skin *in vitro* can introduce an artificial barrier, which is of importance particularly with hydrophobic compounds.

More than 60% of the absorption of I that occurred *in vivo* was obtained by using diffusion cells with a 6% solution of PEG-20 oleyl ether (Table I). The permeability constant for cortisone was unaffected. Attempts to increase the absorption of I with a 20% solution of the surfactant resulted in a slight increase in cortisone permeation and an unexpected decrease in absorption of I. The high viscosity of a 20% solution makes it difficult to use experimentally. Solutions of octoxynol 9, poloxamer 188, and polysorbate 80 resulted in enhanced permeation of the cortisone control in experiments with I and II, even at concentrations at which lower amounts of these hydrophobic compounds were absorbed than with the PEG-20 oleyl ether (Tables I and II). A 6% solution of PEG-20 oleyl ether was found to be the receptor fluid of choice.

Table III—Effect of PEG-20 Oleyl Ether on the Absorption of Water and Urea[a]

Receptor Fluid	Water Permeability Constant × 10^3	Percent Absorbed (43 h) Water	Urea
Normal Saline	2.5 ± 0.6	21.0 ± 5.4	9.3 ± 3.2
6% PEG-20 oleyl ether	2.7 ± 0.6[b]	23.5 ± 5.5[b]	10.3 ± 3.4[b]

[a] Values are the mean ± *SE* of eight determinations. Compounds were applied to rat skin (350-μm section) in 600 μL of water. [b] No significant increase when compared with saline controls by one-tailed Student's *t* test, $p < 0.05$.

Table IV—Comparison of Solubility Properties and the Effect of PEG-20 Oleyl Ether on Percutaneous Absorption

Compound	Water Solubility, mg/L	Octanol-Water, K	Skin Permeation Ratio[a]
Urea	1×10^6	0.002	1.1[b]
Cortisone	280	44	1.2[c]
Testosterone	11	2089	2.3[d]
I	0.23	652	3.1[c]
II	0.012	3589	30.0[e]

[a] 6% PEG-20 oleyl ether/saline. The skin permeation ratio was determined by comparing the amount of compound absorbed in experiments in which the two receptor fluids were used. [b] Water vehicle, 43 h. [c] Acetone vehicle, 5 d. [d] Acetone vehicle, 43 h. [e] Petrolatum vehicle, 5 d.

The use of cortisone as a control in many of the experiments was based on its good solubility in the petrolatum vehicle, reasonable water solubility, and ready availability in the tritiated form for dual-label experiments. It was considered important to establish additionally that the permeation of other molecules was also unaffected by the use of 6% PEG-20 oleyl ether as a receptor fluid. The percutaneous absorption of two small polar molecules (water and urea) was not significantly increased by the use of the surfactant solution (Table III).

The use of an acetone vehicle resulted in better agreement between the *in vitro* data for I and the diffusion cell results with PEG-20 oleyl ether as the receptor fluid (Table II). *In vitro* permeation of I after 5 d was 73% of that found in the corresponding *in vivo* experiment. This result may be due to higher levels of I absorbed into the skin in the absence of the lipophilic petrolatum layer.

The increase in absorption resulting from the use of 6% PEG-20 oleyl ether instead of saline in the receptor is presented in Table IV along with the octanol and water solubility properties of selected compounds. No significant effect of using PEG-20 oleyl ether was obtained with the more water-soluble compounds. The greatest increase in permeation was obtained with II, an extremely hydrophobic compound with a large octanol-water partition coefficient. Compounds that are essentially insoluble in water (solubility, ~10 mg/L or less) and more soluble in lipoidal media may partition only slightly from skin into a normal saline solution. For these types of compounds, caution must be exercised in interpreting *in vitro* absorption data.

In a system in which split-thickness rat skin is used as the membrane, the use of a surfactant in the receptor fluid was advantageous for absorption measurements of several hydrophobic compounds. Although results identical to *in vivo* values were not obtained, dramatic increases in absorption were achieved without apparent damage to the skin. Obviously, one receptor fluid is not beneficial to the same degree for all hydrophobic compounds. The permeation of compounds like II, which are extremely lipophilic and hydrophobic, will be increased to the greatest extent, but even so, <50% of the *in vivo* absorption may be obtained. For compounds with a lower lipid-water partition coefficient, values more closely in agreement with *in vivo* results should be achieved.

Kinetics of Aspirin Absorption Following Oral Administration of Six Aqueous Solutions with Different Buffer Capacities

WILLIAM D. MASON

Received October 29, 1982, from the *Pharmacokinetics Laboratory, Schools of Pharmacy and Medicine, University of Missouri-Kansas City, Kansas City, MO 64108.* Accepted for publication September 13, 1983.

Abstract □ Fifteen volunteers each received two of six aspirin solutions in a balanced incomplete block design. The solutions contained 0, 3, 6, 10, 16, and 34 mEq of sodium bicarbonate-citric acid buffer and 650 mg of aspirin. Plasma aspirin levels were measured in blood samples collected frequently during the first 2.5 h, and the accumulation of aspirin, salicylic acid, and salicyluric acid were measured over 2 and 24 h. The most rapid absorption rates occurred with solutions which contained small quantities of the antacid buffer. The 3- and 6-mEq antacid buffers had mean maximal aspirin concentrations of 17.3 and 17.8 μg/mL, respectively. In the absence of the buffering agent, the 650 mg of aspirin failed to dissolve completely and gave a mean maximal plasma concentration of 13.4 μg/mL. With 34 mEq of a buffering agent, a delay in the onset of absorption occurred and the presystemic hydrolysis increased. This was probably because more aspirin was emptied into and absorbed from the small intestine with higher concentrations of the buffering agent.

Keyphrases □ Aspirin—pharmacokinetics, oral administration, sodium bicarbonate-citric acid buffer, humans □ Pharmacokinetics—aspirin, sodium bicarbonate-citric acid buffer, oral administration, humans

Aspirin, the drug of choice when a mild analgesic-antipyretic is required, is also the primary agent in the chronic management of rheumatoid arthritis and osteoarthritis. After oral administration, rapid absorption beneficially provides rapid onset of effects and reduces the contact time with the gastric mucosa.

In an earlier report from this laboratory (1) the literature relating to the administration of aspirin in buffered solutions was reviewed, and data comparing an unbuffered tablet to two different buffered solutions was presented. The three dosage forms were an unbuffered tablet, an effervescent solution with 16 mEq of buffer, and an effervescent solution with 34 mEq of buffer. Significant differences in the aspirin absorption rate were observed: the solution of 16 mEq of buffer was fast, the solution of 34 mEq of buffer was intermediate, and the unbuffered tablet was slow. These differences were attributed primarily to gastric emptying and the rate of tablet dissolution.

It may be desirable to optimize the amount of buffer components to provide rapid absorption and to reduce gastric irritation through minimal alkalinization of urine and sodium intake. Thus, this study was undertaken to evaluate aspirin absorption kinetics over a range of buffer strengths.

EXPERIMENTAL SECTION

Dosage Forms—A series of soluble tablets were prepared that contained 650 mg of aspirin and sufficient sodium bicarbonate-citric acid buffer to provide 0, 3, 6, 10, 16, and 34 mEq of buffering. Just prior to administration, the tablets were placed in 140 mL of water and mechanically stirred to effect dissolution. The unbuffered tablet contained some undissolved particles in suspension, while all buffered tablets dissolved completely. Immediately following administration, the containers were rinsed with 100 mL of water which was also swallowed by the volunteers.

Subjects—Fifteen healthy volunteers, 21–33 years old and weighing 56.4–81.8 kg, were screened by a comprehensive physical examination, complete blood chemistry, complete blood count with differential, and urinalysis. All were free of any active disease such as influenza, and denied any use of medication for 14 d prior to the study. None of the subjects had a history of GI disease or surgery.

Method—The balanced incomplete block design, Table I, in which each of the 15 subjects received two of the six dosage forms with a 6-d washout between treatments, was employed. A 10-h fast preceeded dosing and continued 4 h postdose, except for water. Predose urine and blood samples were obtained, and a single dose of aspirin (650 mg) with 240 mL of water was administered as described. After dosing, 100 mL of water was administered at 1-, 2-, and 3-h intervals, and a uniform meal was served after 4 h. Subjects remained standing or sitting throughout the first 4 h, and exercise was limited to walking about the room.

Blood was drawn into chilled vacuum containers[1] *via* an indwelling catheter at 5, 10, 15, 20, 30, and 45 min and at 1, 1.5, 2, and 2.5 h. Plasma was separated by centrifugation at 1764×*g* within 20 min of collection. All urine was collected over a 0–2-h interval, the pH and volume were measured, and a 4-mL aliquot was taken for analysis. In addition, all urine was collected for 24 h. All plasma and urine samples were handled as described previously (2), which included storage at −20°C and HPLC analysis within 2 weeks. The HPLC method was updated by using a 5-μm octadecasilane column[2], measuring absorbance at 237 nm, and replacing the benzene with butyl chloride. These changes improved the sensitivity, safety, and reproducibility of the method over that reported previously (2); the statistics of the revised method will be the subject of a subsequent report.

Plasma aspirin concentration *versus* time plots for each dose to each subject were evaluated, and estimates for several kinetic parameters were obtained. The highest observed plasma concentration (C_{max}) and the time after dosing (t_{max}) to reach C_{max} were read directly from each plot. A terminal rate constant (k) and corresponding half-life ($t_{1/2}$) were computed by linear regression analysis of the natural logarithm of plasma concentration *versus* the time for all times greater than twice t_{max}. The trapezoid method was used to compute the area under the curve to the last measured concentration (C) and the value

Kinetics of Aspirin Absorption Following Oral Administration of Six Aqueous Solutions with Different Buffer Capacities

WILLIAM D. MASON

Received October 29, 1982, from the *Pharmacokinetics Laboratory, Schools of Pharmacy and Medicine, University of Missouri-Kansas City, Kansas City, MO 64108.* Accepted for publication September 13, 1983.

Abstract □ Fifteen volunteers each received two of six aspirin solutions in a balanced incomplete block design. The solutions contained 0, 3, 6, 10, 16, and 34 mEq of sodium bicarbonate-citric acid buffer and 650 mg of aspirin. Plasma aspirin levels were measured in blood samples collected frequently during the first 2.5 h, and the accumulation of aspirin, salicylic acid, and salicyluric acid were measured over 2 and 24 h. The most rapid absorption rates occurred with solutions which contained small quantities of the antacid buffer. The 3- and 6-mEq antacid buffers had mean maximal aspirin concentrations of 17.3 and 17.8 μg/mL, respectively. In the absence of the buffering agent, the 650 mg of aspirin failed to dissolve completely and gave a mean maximal plasma concentration of 13.4 μg/mL. With 34 mEq of a buffering agent, a delay in the onset of absorption occurred and the presystemic hydrolysis increased. This was probably because more aspirin was emptied into and absorbed from the small intestine with higher concentrations of the buffering agent.

Keyphrases □ Aspirin—pharmacokinetics, oral administration, sodium bicarbonate-citric acid buffer, humans □ Pharmacokinetics—aspirin, sodium bicarbonate-citric acid buffer, oral administration, humans

Aspirin, the drug of choice when a mild analgesic-antipyretic is required, is also the primary agent in the chronic management of rheumatoid arthritis and osteoarthritis. After oral administration, rapid absorption beneficially provides rapid onset of effects and reduces the contact time with the gastric mucosa.

In an earlier report from this laboratory (1) the literature relating to the administration of aspirin in buffered solutions was reviewed, and data comparing an unbuffered tablet to two different buffered solutions was presented. The three dosage forms were an unbuffered tablet, an effervescent solution with 16 mEq of buffer, and an effervescent solution with 34 mEq of buffer. Significant differences in the aspirin absorption rate were observed: the solution of 16 mEq of buffer was fast, the solution of 34 mEq of buffer was intermediate, and the unbuffered tablet was slow. These differences were attributed primarily to gastric emptying and the rate of tablet dissolution.

It may be desirable to optimize the amount of buffer components to provide rapid absorption and to reduce gastric irritation through minimal alkalinization of urine and sodium intake. Thus, this study was undertaken to evaluate aspirin absorption kinetics over a range of buffer strengths.

EXPERIMENTAL SECTION

Dosage Forms—A series of soluble tablets were prepared that contained 650 mg of aspirin and sufficient sodium bicarbonate-citric acid buffer to provide 0, 3, 6, 10, 16, and 34 mEq of buffering. Just prior to administration, the tablets were placed in 140 mL of water and mechanically stirred to effect dissolution. The unbuffered tablet contained some undissolved particles in suspension, while all buffered tablets dissolved completely. Immediately following administration, the containers were rinsed with 100 mL of water which was also swallowed by the volunteers.

Subjects—Fifteen healthy volunteers, 21–33 years old and weighing 56.4–81.8 kg, were screened by a comprehensive physical examination, complete blood chemistry, complete blood count with differential, and urinalysis. All were free of any active disease such as influenza, and denied any use of medication for 14 d prior to the study. None of the subjects had a history of GI disease or surgery.

Method—The balanced incomplete block design, Table I, in which each of the 15 subjects received two of the six dosage forms with a 6-d washout between treatments, was employed. A 10-h fast preceeded dosing and continued 4 h postdose, except for water. Predose urine and blood samples were obtained, and a single dose of aspirin (650 mg) with 240 mL of water was administered as described. After dosing, 100 mL of water was administered at 1-, 2-, and 3-h intervals, and a uniform meal was served after 4 h. Subjects remained standing or sitting throughout the first 4 h, and exercise was limited to walking about the room.

Blood was drawn into chilled vacuum containers[1] *via* an indwelling catheter at 5, 10, 15, 20, 30, and 45 min and at 1, 1.5, 2, and 2.5 h. Plasma was separated by centrifugation at 1764×*g* within 20 min of collection. All urine was collected over a 0–2-h interval, the pH and volume were measured, and a 4-mL aliquot was taken for analysis. In addition, all urine was collected for 24 h. All plasma and urine samples were handled as described previously (2), which included storage at −20°C and HPLC analysis within 2 weeks. The HPLC method was updated by using a 5-μm octadecasilane column[2], measuring absorbance at 237 nm, and replacing the benzene with butyl chloride. These changes improved the sensitivity, safety, and reproducibility of the method over that reported previously (2); the statistics of the revised method will be the subject of a subsequent report.

Plasma aspirin concentration *versus* time plots for each dose to each subject were evaluated, and estimates for several kinetic parameters were obtained. The highest observed plasma concentration (C_{max}) and the time after dosing (t_{max}) to reach C_{max} were read directly from each plot. A terminal rate constant (k) and corresponding half-life ($t_{1/2}$) were computed by linear regression analysis of the natural logarithm of plasma concentration *versus* the time for all times greater than twice t_{max}. The trapezoid method was used to compute the area under the curve to the last measured concentration (C) and the value

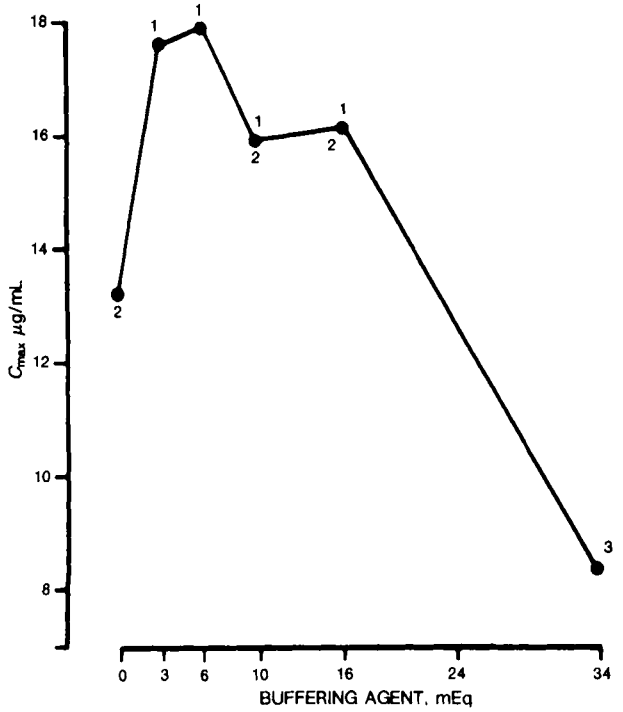

Figure 1—*A plot of C_{max} for aspirin as a function of buffer strength. A common number shared by two or more points indicates no significant difference ($p < 0.1$) for those points.*

C/k was added to estimate the area to infinity (AUC_∞). The renal clearance for aspirin (CL_r) was computed by dividing the amount of aspirin accumulated in the urine during the first 0–2-h interval by the area under the plasma curve for the corresponding time interval. Statistical moments (1, 3, 4) were used to compute the mean residence time for aspirin (MRT). An estimate of the residence time in the GI tract (MAT) for each dose was obtained by subtracting 16.2 min from each MRT value; 16.2 min approximates (4) the reported mean residence time for aspirin following intravenous administration and does not reflect experimental data from this report.

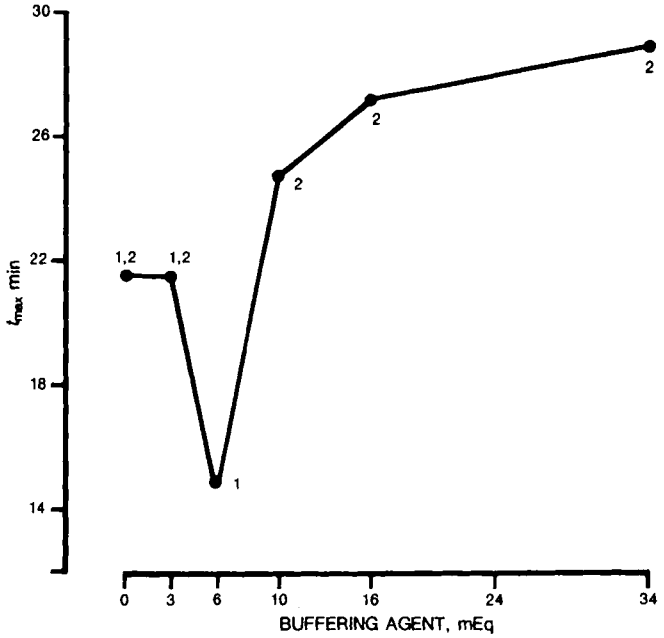

Figure 2—*A plot of t_{max} for aspirin as a function of buffer strength. A common number shared by two or more points indicates no significant difference ($p < 0.1$) for those points.*

RESULTS

In this study, the assay method had a lower limit of quantitation of 0.25 µg/mL and a relative coefficient of variation of 5%. Significant differences in the plasma aspirin concentration *versus* time curves, as presented in Table II, were observed for the various amounts of buffer in the dose. Although adjusted means (*i.e.*, least-square means) are employed in the balanced incomplete block design, these plots accurately reflect the plots for individual subjects. Unbuffered doses provided the highest aspirin concentration at the 5-min sample, while those with small amounts (*i.e.*, 3, 6, and 10 mEq) of buffer presented the most rapid rise between 5 and 10 min. With 34 mEq of the buffering agent there is a definite lag time preceding the appearance of aspirin in the plasma, followed by a rapid rise between the 10- and 20-min samples. All curves reached a maximum before 45 min with a subsequent monoexponential decay for which the mean half-lives ranged between 17.0 and 22.5 min across the six treatments.

Estimates of the comparative rate of aspirin absorption among the six different buffer strengths were obtained by referring to the mean C_{max}, t_{max}, MRT, and MAT values presented in Table III, and plotted in Figs. 1, 2, and 3. Although only some of the values are statistically significant ($p < 0.10$), the doses with 3 and 6 mEq of the buffer appear to provide higher C_{max} and lower t_{max} than unbuffered doses and for those doses with greater amounts of the buffering agent. This same trend is reflected in the statistical moment computations as expressed by the MAT and MRT values. The use of a 0.1 level of significance in computing the least significant differences is justified because the observations at each buffer level are not isolated; rather, they are

integral members of a sequence of buffer strengths. To require each to meet the 0.05 level of significance, independently, would be an excessively severe test.

Estimation of the extent to which aspirin reaches the circulatory system requires consideration of both the AUC_∞ and the CL_r for aspirin. The significantly lower AUC_∞ for aspirin with 34 mEq of the buffering agent, compared with aspirin with lesser amounts of the buffering agent, as presented in Table I, can partially be attributed to an increased renal clearance as the pH of the urine increased. While the observed increase in renal clearance from 0.84 L/h, with no buffering, to 1.96 L/h, with 34 mEq of the buffering, is significant ($p < 0.10$), the overall maximal increase in systemic aspirin clearance in urine is ~2–3%, if the systemic clearance is ~40 L/h as previously reported for similar subjects (1, 5). Based on these clearance changes one might expect a 2–3% lower AUC_∞ with 34 mEq of the buffering agent, rather than the 28% lower AUC_∞ shown in Table III. These data suggest that adding 34 mEq of the buffering agent to the aspirin dose results in about 25% less aspirin reaching the circulatory system.

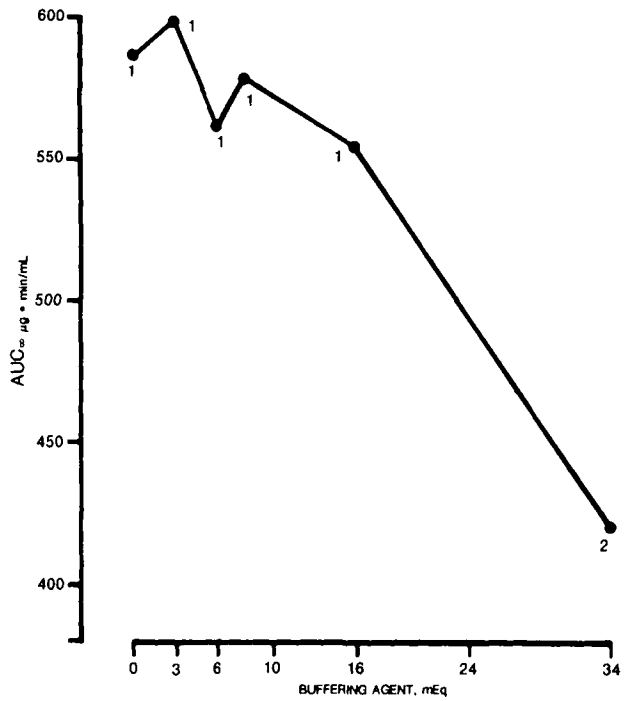

Figure 3—*A plot of AUC_∞ for aspirin as a function of buffer strength. A number shared by two or more points indicates no significant difference ($p < 0.1$) for those points.*

Although less aspirin reaches the circulatory system with the 34 mEq of the buffering agent, the total salicylate (*i.e.*, aspirin, salicylic acid, and salicyluric acid) which accumulates in the urine over 24 h is not decreased. Combining these observations suggests that the absorption of aspirin is not diminished by added buffering agents, but that the presystemic hydrolysis is increased. This is due to a greater portion of aspirin being emptied into and absorbed from the small intestine, where significant esterase activity has been reported to exist (6).

DISCUSSION

Aspirin was rapidly absorbed from all of the solutions, while the rate and extent of the bioavailability was dependent on buffer strength. Small quantities of the antacid buffering agent were associated with the most rapid rise in plasma aspirin, with mean maximal concentrations of 17.8 and 17.3 μg/mL for 6 and 3 mEq, respectively. This rapid rate of absorption was probably due to the increased solubility of the aspirin, with only a small increase in the pH of gastric contents and, thus, a minimal suppression of gastric absorption. In the absence of buffering the aspirin was only partly dissolved before reaching the stomach, which provided a rapid rate of absorption over the first few minutes only.

With 34 mEq of the antacid buffer, the gastric pH may rise above six and suppress absorption through the gastric mucosa (7, 8). Indeed, absorption would be predominately delayed until the aspirin was emptied into the small intestine, where the buffering effect of the antacid would be diminished and the surface area is much larger. The actual delay in absorption due to the increased gastric pH was only ~5 min, which was probably due to the acceleration of gastric emptying that is generally associated with administration of the sodium citrate-bicarbonate antacid (8).

The greater presystemic hydrolysis observed with the 34 mEq of buffering is consistent with the above hypothesis (*i.e.*, that the antacid can shift the absorption from the stomach to the intestine). Studies in dogs (9) and rats (10) support the supposition that a significant portion of the first-pass hydrolysis of aspirin occurs in the gut wall (6). With the gap between the 16- and 34-mEq strengths of the buffering agent used in the present study, one can only conclude that buffer quantities in excess of 16 mEq are required to significantly alter aspirin absorption kinetics.

Repeated contact with aspirin has been reported (11) to alter the gastric

membrane, allowing hydrogen-ion back-diffusion, which results in irritation, bleeding, and possible ulceration. If this mechanism is correct, then the rapid onset of absorption obtained with unbuffered solutions or solutions with less than 16 mEq of antacid buffering may not reduce the incidence of untoward effects as effectively as those containing a greater quantity of antacid buffering.

Determination of Ethoxzolamide in the Iris/Ciliary Body of the Rabbit Eye by High-Performance Liquid Chromatography: Comparison of Tissue Levels Following Intravenous and Topical Administrations

MARK G. ELLER and R. D. SCHOENWALD ˣ

Received March 3, 1983, from the *Pharmaceutics Division, College of Pharmacy, University of Iowa, Iowa City, IA 52242.* Accepted for publication September 22, 1983.

Abstract □ A specific high-performance liquid chromatographic method is described for ethoxzolamide following the extraction of the material from iris/ciliary body eye tissue in rabbits. The steps consist of base extraction and protein and enzyme deactivation, followed by acid treatment, extraction into ethyl acetate, evaporation, and solubilization with a 50% aqueous methanol solution. The samples were chromatographed on a reverse-phase phenyl column with a mobile phase consisting of 50% methanol in 1% acetic acid. The recovery was 74.3% over a 10-fold range of tissue concentrations. The sensitivity was 0.03 μg/mL, and the response was linear over the concentration range (0.03–0.5 μg/mL) used in the study. Intravenous (2.0- and 6.0-mg/kg) and topical (1% suspension) doses of ethoxzolamide were administered to rabbits. Iris/ciliary body tissues were excised 45 min after drug administration. The tissue levels after a dose of 6 mg/kg were statistically greater than the levels obtained after a dose of 2 mg/kg. The smaller intravenous dose represented the lowest dose for which a reduction in intraocular pressure could be measured. An initial transitory drop in intraocular pressure was detected for the topical dose. Iris/ciliary body levels in the treated eye could be detected for the 2-mg/kg iv and topical doses.

Keyphrases □ Ethoxzolamide—determination in the iris/ciliary body, rabbits, HPLC, GC □ Dosage forms—intravenous and topical administration of ethoxzolamide, iris/ciliary body of rabbit eyes, HPLC, GC

Ethoxzolamide, a carbonic anhydrase inhibitor used in glaucoma to lower intraocular pressure (IOP), is effective orally but not when administered topically to the eye, presumably due to inadequate drug levels at the active site. In recent studies, the anatomical location of carbonic anhydrase with the anatomical location of aqueous humor formation in the ciliary body have been identified (1, 2). Friedlander and Muther (3) have utilized the high binding affinity of [^{3}H]-acetazolamide for carbonic anhydrase to demonstrate the distribution of carbonic anhydrase in the epithelium of the ciliary body. The greater specificity of ethoxzolamide for the enzyme was shown by displacing [^{3}H]acetazolamide with a high concentration of unlabeled ethoxzolamide.

Although Maren (4) have devised a sensitive method for the determination of carbonic anhydrase and its inhibitors, the assay measures drug activity; therefore, specificity is always in doubt. It is also tedious and time consuming. It was the purpose of this study to develop a high-performance liquid chromatographic (HPLC) procedure for the determination of ethoxzolamide in the iris/ciliary body tissue of rabbit eyes. Data are also presented which compare tissue concentrations after administration by the topical and intravenous routes.

EXPERIMENTAL SECTION

Chemicals—Ethoxzolamide, a gift from a commercial source[1], was used as received. The substances used in the preparation of the various buffers and vehicles were of analytical or USP quality, and included monobasic sodium phosphate[2], dibasic sodium phosphate[3], sodium carbonate[2], hydrochloric acid[2], sodium chloride[4], polysorbate 80[5], and *N*,*N*-dimethylacetamide[2]. Ethyl acetate[6] was used as the organic phase in the extraction procedure. Acetic acid[7], methanol[8], and distilled deionized water were used to prepare the chromotographic mobile phase. The distilled deionized water was also used to make all aqueous dilutions.

Apparatus—The chemicals and tissues were weighed on an electronic[9] or analytical[10] balance. The pH values of the various solutions were measured[11] when necessary.

The HPLC system consisted of a solvent delivery pump[12], a syringe-loading sample injector[13] fitted with a 100-μL loop[14], a reverse-phase phenyl column[15], and a fixed-wavelength UV detector[16] operating at 313 nm. Chromatograms were recorded on a chart recorder[17] operating at 0.5 cm/min. The mobile phase consisting of methanol–1% aqueous acetic acid (50:50, v/v) was deaerated before use; the flow rate was 1.5 mL/min.

The tissue levels after a dose of 6 mg/kg were statistically greater than the levels obtained after a dose of 2 mg/kg. The smaller intravenous dose represented the lowest dose for which a reduction in intraocular pressure could be measured. An initial transitory drop in intraocular pressure was detected for the topical dose. Iris/ciliary body levels in the treated eye could be detected for the 2-mg/kg iv and topical doses.

Keyphrases □ Ethoxzolamide—determination in the iris/ciliary body, rabbits, HPLC, GC □ Dosage forms—intravenous and topical administration of ethoxzolamide, iris/ciliary body of rabbit eyes, HPLC, GC

Ethoxzolamide, a carbonic anhydrase inhibitor used in glaucoma to lower intraocular pressure (IOP), is effective orally but not when administered topically to the eye, presumably due to inadequate drug levels at the active site. In recent studies, the anatomical location of carbonic anhydrase with the anatomical location of aqueous humor formation in the ciliary body have been identified (1, 2). Friedlander and Muther (3) have utilized the high binding affinity of [^{3}H]-acetazolamide for carbonic anhydrase to demonstrate the distribution of carbonic anhydrase in the epithelium of the ciliary body. The greater specificity of ethoxzolamide for the enzyme was shown by displacing [^{3}H]acetazolamide with a high concentration of unlabeled ethoxzolamide.

Although Maren (4) have devised a sensitive method for the determination of carbonic anhydrase and its inhibitors, the assay measures drug activity; therefore, specificity is always in doubt. It is also tedious and time consuming. It was the purpose of this study to develop a high-performance liquid chromatographic (HPLC) procedure for the determination of ethoxzolamide in the iris/ciliary body tissue of rabbit eyes. Data are also presented which compare tissue concentrations after administration by the topical and intravenous routes.

EXPERIMENTAL SECTION

Chemicals—Ethoxzolamide, a gift from a commercial source[1], was used as received. The substances used in the preparation of the various buffers and vehicles were of analytical or USP quality, and included monobasic sodium phosphate[2], dibasic sodium phosphate[3], sodium carbonate[2], hydrochloric acid[2], sodium chloride[4], polysorbate 80[5], and *N*,*N*-dimethylacetamide[2]. Ethyl acetate[6] was used as the organic phase in the extraction procedure. Acetic acid[7], methanol[8], and distilled deionized water were used to prepare the chromotographic mobile phase. The distilled deionized water was also used to make all aqueous dilutions.

Apparatus—The chemicals and tissues were weighed on an electronic[9] or analytical[10] balance. The pH values of the various solutions were measured[11] when necessary.

The HPLC system consisted of a solvent delivery pump[12], a syringe-loading sample injector[13] fitted with a 100-μL loop[14], a reverse-phase phenyl column[15], and a fixed-wavelength UV detector[16] operating at 313 nm. Chromatograms were recorded on a chart recorder[17] operating at 0.5 cm/min. The mobile phase consisting of methanol–1% aqueous acetic acid (50:50, v/v) was deaerated before use; the flow rate was 1.5 mL/min.

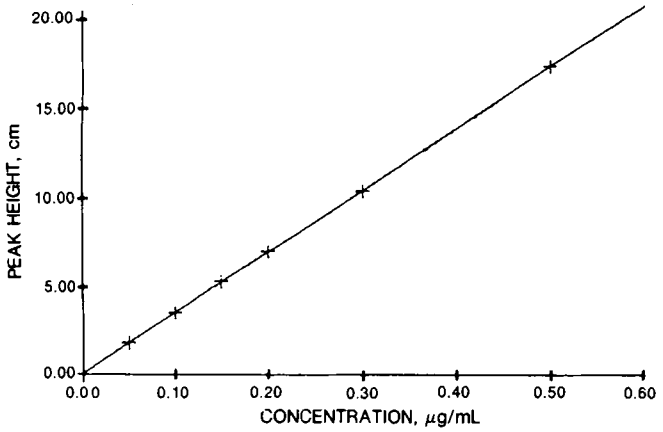

Figure 1—*Typical standard curve for ethoxzolamide over a concentration range of 0.03–0.5 μg/mL (single determinations).*

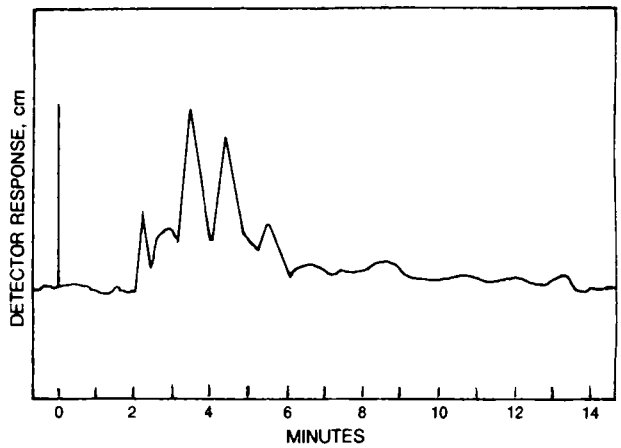

Figure 2—*Chromatograms of 100 μL of tissue extract devoid of drug (AUFS = 0.005).*

Drug Administration—New Zealand White rabbits[18] of either sex (age, 3–4 months; weight 2.0–3.5 kg) were administered ethoxzolamide by intravenous injection into the marginal ear vein or by topical application to the conjunctival sac of the eye. Because of the limited aqueous solubility of ethoxzolamide, a mixed solvent consisting of 60% *N,N*-dimethylacetamide–40% water was used for intravenous administration. With this vehicle, concentrations of up to 20 mg/mL could be injected. The intravenous dose of ethoxzolamide was either 2 or 6 mg/kg. The formulation was prepared immediately before use.

Ethoxzolamide was applied topically as a 1% suspension in Sörensen's modified phosphate buffer (5), to which 0.5% polysorbate 80 was added as a wetting agent. The pH of this vehicle was 7.2. The formulation was prepared ~8 h before use and was stirred continuously on a magnetic stir plate. A 50-μL volume of the suspension was applied every 2 min to one eye for a total of three doses; the blank vehicle was similarly applied to the other eye.

The rabbits were sacrificed 45 min after either intravenous or topical instillation by injecting a bolus of air into the marginal ear vein. The iris/ciliary tissue was immediately excised and weighed. This time interval was chosen to represent nearly the maximal IOP response. Preliminary studies in which ethoxzolamide was administered intravenously showed that a maximal pharmacological response (lowering of intraocular pressure) occurred at 45 min.

Tissue Extraction Procedure—Although the ciliary body has been identified as the active site (2, 3), it is difficult to excise precisely in the rabbit. The iris is easily removed, and the ciliary body remains attached to it when the iris is excised from the rabbit eye. Consequently, tissue levels, as reported here, represent an average level of the combined tissues. The wet tissue was cut into smaller segments and homogenized (30 rpm for 1.5 min) in centrifuge tubes[19] with dry ice; the latter disrupted cellular structure to facilitate extraction. A total of 5 mL of 0.025 M sodium carbonate solution was added to the tubes containing the homogenized tissue. The mixture was vigorously shaken[20] for 1 h at room temperature. The high pH and hypotonicity of the sodium carbonate solution promoted dissociation of the drug from carbonic anhydrase (6) and partitioning into the aqueous phase. The homogenate was then heated to 100°C for 5 min to denature and precipitate the tissue proteins. Identical treatment without iris/ciliary body tissue showed that the drug did not decompose. The mixture was cooled to room temperature, and 1 mL of 0.5 M HCl containing an additional 75 mg of NaCl/mL was added. The acid converted drug to the un-ionized form, and the salt aided in phase separation. Ethyl acetate (3 mL) was added to the mixture, which was shaken on a vortex mixer[21] and centrifuged[22] for 0.5 h. After centrifugation, the top layer, consisting of nearly 3 mL of ethyl acetate and containing drug, was transferred to a 5-mL vial[23]. The extraction was repeated twice with 3 mL of ethyl acetate each time; the ethyl acetate phases were then combined. The ethyl acetate solution was subsequently warmed[24] to 30°C and evaporated to dryness under a stream of nitrogen. To the residue was added 1 mL of 50% methanol to solubilize the drug. The 50% methanol solution containing drug was refrigerated until just before assay by HPLC. To assess the validity of the assay, iris/ciliary tissues were spiked with various known amounts of ethoxzolamide and treated by the extraction and assay procedure described above.

Chromatographic Assay Conditions—One hundred microliters of sample or standard was injected onto the column with the loop injector. Peak heights from five to seven known concentrations of ethoxzolamide, ranging from 0.03 to 0.75 μg/mL, were determined. A standard curve was constructed from these data, relating peak height to concentration. The standard curve was repeated whenever a set of unknowns was assayed. Also, standard concentrations were interspersed after approximately every third unknown sample to assess whether changes in column integrity, mobile phase, or detectors were occurring. The attenuation was 0.005 for all determinations.

Intraocular Pressure—A separate group of New Zealand White rabbits (n = 24) were maintained on 0.3% NaCl solution in place of drinking water for at least 3 weeks before the determination of IOP, because it has been shown that a diet deficient in sodium ion produces a variable IOP response to this class of drugs. Commercial rabbit chow does not provide a sufficient NaCl content compared with the diet available to rabbits in their natural habitat (7). Numerous measurements of IOP were made over 3 weeks to familiarize the rabbits with this procedure before drug administration. Baseline IOP measurements were determined by tonometry[25], followed by either intravenous or topical administration of ethoxzolamide (1% suspension). In each intravenous experiment, 25–50% of the rabbits received vehicle only; the observations were made on a "blind" basis. Whenever ethoxzolamide was administered topically, one eye was dosed as described above, and the opposite eye received vehicle only. Again, observations were made on a "blind" basis. IOP measurements were determined at 20-min intervals for 3 h.

RESULTS AND DISCUSSION

The standard curve (Fig. 1) was found to be linear over the concentration range (0.03–0.5 μg/mL) used in the study. The sensitivity of the assay was determined by analyzing progressively lower concentrations until the coefficient of variation for multiple determinations reached 10%. This occurred at a concentration of 0.03 μg/mL. This value also represented about five times the height of the baseline noise at 0.005 AUFS.

Figures 2 and 3 represent typical chromatograms for the analysis of ethoxzolamide in iris/ciliary body tissue. As shown in the chromatogram (Fig. 3), good separation was achieved from endogenous tissue components. When no drug was present, the baseline was observed (Fig. 2). A metabolite was not apparent in any of the observed chromatograms. The retention time for the drug was 7 min.

To determine the recovery and reproducibility of the assay procedure, iris/ciliary body tissue from the rabbits was spiked with known amounts of ethoxzolamide. The amount of drug was varied from 0.05 to 0.6 μg (Table I); the tissue weight also varied. The known amount of drug was first dissolved in 4 mL of distilled water, to which a freshly extracted tissue sample was added. A 12-mL test tube contained the mixture, which was incubated for ≥3 h at room temperature. Longer incubation periods (up to 72 h) did not increase the percent recovery. After incubation, 1 mL of 0.125 M sodium carbonate solution was added to the mixture to produce a final concentration of 0.025 M. The extraction procedure was continued from this step as described above. Identical extraction experiments were also conducted without the addition

of iris/ciliary body tissue but with varying amounts of drug (0.05–10 μg). Without added tissue, 85.8 ± 4.97% of the added drug could be extracted. When tissue was added, 74.3 ± 7.83% of the drug could be recovered. The presence of tissue was responsible for a significant increase in the extraction variability.

Without the presence of drug but including tissue, no ethoxzolamide peaks were observed in the chromatograms. A linear increase in the amount of drug recovered was detected by:

$$y = 0.099 + 0.706x \qquad (n = 31, r^2 = 0.995) \qquad \text{(Eq. 1)}$$

where x is the nanograms of drug added per milligram of tissue, and y is the nanograms of drug recovered per milligram of tissue. Although the mean percentage of drug extracted in the recovery experiments could be used to correct for the fraction of drug unavailable for extraction, its use would be somewhat less precise than the use of Eq. 1. This occurs because the calibration equation incorporates the weight of the tissue on a per-unit basis and because the variance can be expressed at every point on the regressed line.

Assay Application—The method described above was developed to compare iris/ciliary body concentrations of ethoxzolamide after intravenous and topical dosing to the eye.

Intraocular Pressure—Before tissue was extracted, a minimum dose was established which produced a significant reduction in IOP. This was accomplished by linear and quadratic regression analysis. If the IOP dropped below baseline values, a negative statistically significant slope from zero indicated a drug effect. Baseline measurements were made by measuring IOP repeatedly over 20 min just before dosing. Two intravenous doses were given. At 2 mg/kg, only 3 of 10 rabbits showed a response over 2 h, whereas at 6 mg/kg, 6 of 10 rabbits yielded a response, which at 45 min was 1.5 to 2 mm Hg lower than from 2 mg/kg. The maximum response occurred at 45 min after intravenous administration and at 40 min after topical administration (Table II).

When a 1% suspension of ethoxzolamide was administered topically to the eyes of 24 rabbits, a small but statistically significant drop in IOP was observed at 20–60 min. The criteria for observing a change in response was based on a statistical difference in IOP between the treated and untreated eyes at each time interval. Equation 2 expresses a change in IOP brought about by corneal penetration only. The responses measured for the two routes of administration are not directly comparable. For the topical route, a difference in response in treated and untreated eyes was measured over time, whereas by the intravenous route, both eyes responded so that changes were made relative to the baseline (*i.e.*, $t = 0$):

$$\text{IOP Changes} = (IOP_{DET} - IOP_{CET}) - (IOP_{DEO} - IOP_{CEO}) \qquad \text{(Eq. 2)}$$

where IOP_{DET} is the IOP measurement (mm Hg) of the dosed or treated eye at time t, IOP_{DEO} is the IOP measurement (mm Hg) of the treated eye at $t = 0$ but before receiving the dose, IOP_{CET} is the IOP measurement (mm Hg) of the control (nontreated) eye at time t, and IOP_{CEO} is the IOP measurement (mm Hg) of the control (nontreated) eye at time $t = 0$. By subtracting the IOP response from the nontreated eye at each time interval, the reduction in IOP occurring from systemic absorption is subtracted.

Interestingly, various manufacturers of carbonic anhydrase inhibitors have repeatedly been unable to detect a lowering of IOP from direct application to the eye[26]. These studies were often conducted with single doses in a small number of rabbits that had not been maintained on a diet sufficient in sodium chloride. This latter factor is most important in attempting to measure a small but detectable IOP response. These results, along with previously published reports (8, 9), have prompted researchers to conclude that intravenous doses of carbonic anhydrase inhibitors, including ethoxzolamide, were acting only centrally. More recently (1, 2, 10, 11), it has been shown that carbonic anhydrase inhibition occurs at the ciliary body. Nevertheless, studies (12, 13) have indicated that systemic acidosis, another effect of carbonic anhydrase inhibitors, contributes to a reduction in IOP. Maren *et al.* (12) have proposed that the acidotic effect of the lowering of the IOP and the direct effect on aqueous humor secretion are additive.

Tissue Levels—Tissue levels were determined in both eyes after either intravenous or topical administration (Tables III and IV, respectively). At each intravenous dose, the right and left eyes showed similar concentrations of ethoxzolamide. At 2 and 6 mg/kg (10 replications were conducted at each level), a statistically significant higher concentration was measured for 6 mg/kg.

120	0.085 (0.76)	0.59
140	0.625 (0.79)	0.94
160	0.045 (0.86)	0.54
180	0.085 (0.71)	0.59

[a] 50 μL q 2 min × 3 (n = 24). [b] $p < 0.02$. [c] See Eq. 2 in text; values in parentheses represent the 95% confidence interval. [d] Probability determined from paired t test.

Table III—Iris/Ciliary Body Levels of Ethoxzolamide after Intravenous Administration to Rabbits

Dose, mg/kg iv	n^b	Ethoxzolamide Level, ng/mg[a] Left Eye	Right Eye	Pooled[c]
2.0	10	2.67 ± 1.91	2.27 ± 1.00	2.48 ± 1.50
6.0	10	10.08 ± 1.84	10.43 ± 1.94	10.26 ± 1.83

[a] Nanograms of drug per milligram of iris/ciliary body tissue; mean ± *SD*. [b] Number of determinations for either the left or the right eye. [c] Pooled data for the left and right eyes (n = 20).

Table IV—Iris/Ciliary Body Levels of Ethoxzolamide after Topical Administration

Rabbit	Ethoxzolamide Level, ng/mg[a] Treated Eye	Untreated Eye
1	5.64	2.08
2	3.50	0
3	1.60	0.30
4	1.87	0.29
5	2.20	0
6	1.83	0
7	0.444	0
8	0.544	0
9	1.94	0
10	1.76	0
Mean ± *SD*	2.13 ± (1.50)	0.27 ± (0.65)

[a] Nanograms of drug per milligram of iris/ciliary body tissue.

The results for the topical dose (Tables II and IV) show that ethoxzolamide could be detected in the untreated eye in 3 of 10 rabbits and in the treated eye in all of the rabbits. An outlier value of 2.08 ng/mg was determined for rabbit 1 in the untreated eye (Table III). The measurement in the untreated eye likely represents systemic absorption. The pooled treated eyes yielded iris/ciliary body levels of 2.13 ± 1.5 ng/mg (n = 10). The mean level is statistically lower ($p < 0.05$) than the mean value obtained for dosing at 6 mg/kg iv but not statistically different from tissue levels obtained at 2 mg/kg iv.

For an average-sized rabbit (2.5 kg), the minimum intravenous dose to produce a response (2 mg/kg) represents a 3.3-fold higher dose than that administered by the topical route. Thus, the nearly equal tissue levels shown in Tables III and IV for the two routes of administration suggest that the tissue levels detected from the smaller topical dose are, at least in part, a consequence of corneal transport and not primarily systemic absorption. Although our results do not differentiate between the direct and systemic effects of the drug, they do add credence to the possibility of a contribution from the corneal pathway.

Factors Affecting Quinidine Protein Binding in Humans

DAVID J. EDWARDS *, JAMES E. AXELSON ¶, RICHARD L. SLAUGHTER, ‡§, ALFRED T. ELVIN *, and DAVID LALKA *§x

Received June 27, 1983, from the *Departments of *Pharmaceutics and ‡Pharmacy, School of Pharmacy, State University of New York at Buffalo, Amherst, NY 14260*, the *§Clinical Pharmacokinetics Laboratory, Buffalo General Hospital, Buffalo, NY 14260*, and the *¶Division of Pharmaceutics, Faculty of Pharmaceutical Sciences, University of British Columbia, British Columbia V6T 1W5, Canada.* Accepted for publication September 27, 1983.

Abstract □ The free (unbound) concentration of drug in plasma is often an important determinant of pharmacological and toxicological effects. Unfortunately, studies examining the factors influencing the free fraction of quinidine in plasma have yielded inconsistent results. It is probable that differences in the type of blood collection tubes utilized and the analytical procedure employed biased some of these estimates of quinidine binding. The present study was executed in a manner free of factors now known to introduce artifacts into estimates of the free fraction of quinidine. In healthy volunteers, the free fraction of quinidine (1.0 μg/mL) was 0.129 ± 0.019 (mean ± SD) and was constant throughout the therapeutic range. A high-affinity, low-capacity binding site ($K = 1.17 \times 10^5$ M^{-1}; $nP = 3.49 \times 10^{-5}$ M) and a low-affinity, high-capacity binding site ($K = 1.33 \times 10^3$ M^{-1}; $nP = 3.14 \times 10^{-3}$ M) were identified. The characteristics of quinidine binding in a 4.5-g/dL solution of human serum albumin ($K = 3.05 \times 10^3$ M^{-1}; $nP = 1.36 \times 10^{-3}$ M) suggested that the low-affinity, high-capacity binding site was on this protein. In the presence of tris(butoxyethyl) phosphate (75 μg/mL), the quinidine free fraction increased from 0.114 to 0.231. A lidocaine concentration of 250 μg/mL caused a similar increase. Patients suffering traumatic injury had a significant increase in α_1-acid glycoprotein concentration (197 mg/dL) and a decreased quinidine free fraction (0.075 ± 0.019). Patients with hyperlipidemia had free fractions similar to those observed in healthy individuals (0.118 ± 0.019). These data suggest that the high-affinity, low-capacity binding site is on α_1-acid glycoprotein and that lipoproteins are of little importance in the protein binding of quinidine.

Keyphrases □ Protein binding—quinidine, humans □ Quinidine—protein binding, humans

Despite the recent development of a number of new agents, quinidine continues to be a mainstay of oral antiarrhythmic therapy. Effective concentrations of quinidine in serum range between 1 and 5 μg/mL (1, 2). However, much interindividual variability in the concentration necessary for arrhythmia suppression has been noted (2). Studies with other antiarrhythmic drugs, such as disopyramide (3) and propranolol (4), have demonstrated that the free drug concentration in plasma correlates better with the pharmacological effect than does the total concentration. These observations support the principle that free drug in plasma is in equilibrium with drug at receptor sites (*i.e.*, that which is responsible for the pharmacological effect). Furthermore, alterations in the degree of protein binding can also affect the pharmacokinetic properties of a drug. Fremstad *et al.* (5) have demonstrated a significant positive correlation between the free fraction of quinidine and both volume of distribution and total body clearance. For these reasons, a thorough understanding of the determinants of the protein binding of quinidine is important.

Unfortunately, studies in which the factors influencing quinidine protein binding have been examined have yielded inconsistent results. The mean free fraction in studies with healthy volunteers has been reported to be 0.10 (6), 0.105 (7), 0.141 (8), 0.246 (9), and 0.288 (10). Albumin, α_1-acid glycoprotein, and lipoproteins have all been reported to be important for quinidine binding, but their relative roles have been disputed (10–12). Some of the discrepancies between studies may have been due to methodological differences, as several factors have been found to influence quinidine binding *in vitro*. Quinidine free fraction is two- to three-fold higher when blood is collected in evacuated blood collection tubes[1] rather than glass syringes (6). Other factors influencing estimates of

Factors Affecting Quinidine Protein Binding in Humans

DAVID J. EDWARDS *, JAMES E. AXELSON ¶, RICHARD L. SLAUGHTER, ‡§, ALFRED T. ELVIN *, and DAVID LALKA *§x

Received June 27, 1983, from the *Departments of *Pharmaceutics and ‡Pharmacy, School of Pharmacy, State University of New York at Buffalo, Amherst, NY 14260*, the *§Clinical Pharmacokinetics Laboratory, Buffalo General Hospital, Buffalo, NY 14260*, and the *¶Division of Pharmaceutics, Faculty of Pharmaceutical Sciences, University of British Columbia, British Columbia V6T 1W5, Canada.* Accepted for publication September 27, 1983.

Abstract □ The free (unbound) concentration of drug in plasma is often an important determinant of pharmacological and toxicological effects. Unfortunately, studies examining the factors influencing the free fraction of quinidine in plasma have yielded inconsistent results. It is probable that differences in the type of blood collection tubes utilized and the analytical procedure employed biased some of these estimates of quinidine binding. The present study was executed in a manner free of factors now known to introduce artifacts into estimates of the free fraction of quinidine. In healthy volunteers, the free fraction of quinidine (1.0 μg/mL) was 0.129 ± 0.019 (mean ± SD) and was constant throughout the therapeutic range. A high-affinity, low-capacity binding site ($K = 1.17 \times 10^5$ M^{-1}; $nP = 3.49 \times 10^{-5}$ M) and a low-affinity, high-capacity binding site ($K = 1.33 \times 10^3$ M^{-1}; $nP = 3.14 \times 10^{-3}$ M) were identified. The characteristics of quinidine binding in a 4.5-g/dL solution of human serum albumin ($K = 3.05 \times 10^3$ M^{-1}; $nP = 1.36 \times 10^{-3}$ M) suggested that the low-affinity, high-capacity binding site was on this protein. In the presence of tris(butoxyethyl) phosphate (75 μg/mL), the quinidine free fraction increased from 0.114 to 0.231. A lidocaine concentration of 250 μg/mL caused a similar increase. Patients suffering traumatic injury had a significant increase in α_1-acid glycoprotein concentration (197 mg/dL) and a decreased quinidine free fraction (0.075 ± 0.019). Patients with hyperlipidemia had free fractions similar to those observed in healthy individuals (0.118 ± 0.019). These data suggest that the high-affinity, low-capacity binding site is on α_1-acid glycoprotein and that lipoproteins are of little importance in the protein binding of quinidine.

Keyphrases □ Protein binding—quinidine, humans □ Quinidine—protein binding, humans

Despite the recent development of a number of new agents, quinidine continues to be a mainstay of oral antiarrhythmic therapy. Effective concentrations of quinidine in serum range between 1 and 5 μg/mL (1, 2). However, much interindividual variability in the concentration necessary for arrhythmia suppression has been noted (2). Studies with other antiarrhythmic drugs, such as disopyramide (3) and propranolol (4), have demonstrated that the free drug concentration in plasma correlates better with the pharmacological effect than does the total concentration. These observations support the principle that free drug in plasma is in equilibrium with drug at receptor sites (*i.e.*, that which is responsible for the pharmacological effect). Furthermore, alterations in the degree of protein binding can also affect the pharmacokinetic properties of a drug. Fremstad *et al.* (5) have demonstrated a significant positive correlation between the free fraction of quinidine and both volume of distribution and total body clearance. For these reasons, a thorough understanding of the determinants of the protein binding of quinidine is important.

Unfortunately, studies in which the factors influencing quinidine protein binding have been examined have yielded inconsistent results. The mean free fraction in studies with healthy volunteers has been reported to be 0.10 (6), 0.105 (7), 0.141 (8), 0.246 (9), and 0.288 (10). Albumin, α_1-acid glycoprotein, and lipoproteins have all been reported to be important for quinidine binding, but their relative roles have been disputed (10–12). Some of the discrepancies between studies may have been due to methodological differences, as several factors have been found to influence quinidine binding *in vitro*. Quinidine free fraction is two- to three-fold higher when blood is collected in evacuated blood collection tubes[1] rather than glass syringes (6). Other factors influencing estimates of

quinidine free fraction include the addition of heparin to blood *in vitro* (6), conditions under which equilibrium dialysis is performed (13), and the presence of dihydroquinidine, which is a common impurity in quinidine preparations (14). A principal purpose of the present investigation was to examine and clarify several aspects of quinidine protein binding in humans by using methods which do not bias estimates of the quinidine free fraction.

EXPERIMENTAL SECTION

Materials—Quinidine base was prepared from quinidine sulfate[2] by TLC (20% acetone in methanol) to separate quinidine from contaminants (primarily dihydroquinidine). [^{3}H]Quinidine[3] was also purified by this system, and a final purity of >98% was achieved.

Equilibrium Dialysis—Aliquots (400 μL) of phosphate buffer solution (pH 7.4, 0.134 M) containing quinidine (unlabeled, as well as a trace amount of radiolabeled drug) were dialyzed for 5 h at 37°C against an equal volume of serum in plexiglass cells. Postdialysis quinidine concentrations on each side of the dialysis membrane[4] were determined by liquid scintillation counting. All samples were assayed in triplicate, and the average coefficient of variation by this method was 2.97%. HPLC, coupled with liquid scintillation counting of the eluant, demonstrated that no degradation of quinidine occurred during the dialysis period.

Determination of Quinidine Binding Parameters: Rosenthal Analysis—Venous blood was obtained from three nonsmoking healthy male volunteers using glass syringes. The blood was transferred to glass tubes with polytef-lined screw caps and allowed to clot. The serum was removed after centrifugation and stored at 4°C. The serum was not frozen because of the possibility of structural alterations in lipoproteins (15). In all cases, binding studies were performed within 72 h of sample collection. The free fraction of quinidine was determined over a 2000-fold range of concentrations (initial quinidine concentrations, 0.5–1000 μg/mL), with the results plotted by the method of Rosenthal (16). The computer program PBNON[5] was used to estimate binding parameters. Quinidine binding in a solution of crystalline human serum albumin[6] (4.5 g/dL in phosphate buffer) was also determined over the same range of quinidine concentrations.

Effects of Potential Displacing Agents on Quinidine Binding—Serum obtained from a healthy volunteer was spiked with tris(butoxyethyl) phosphate[7] at a concentration of 75 μg/mL. Quinidine binding was studied over a range of concentrations from 0.5 to 1000 μg/mL, and the binding parameters obtained were compared with those from normal serum. Quinidine binding at a concentration of 1.0 μg/mL was also determined in serum containing lidocaine[8] at concentrations ranging from 1.0 to 500 μg/mL.

Effect of Hyperlipidemia and Trauma on the Serum Binding of Quinidine—Serum from six patients with elevated concentrations of lipoproteins and five healthy, nonsmoking male volunteers was obtained as described above and stored at 4°C for a maximum of 72 h before analysis. Quinidine binding was examined at an initial concentration of 1.0 μg/mL. In addition, quinidine binding was determined in two serum samples from each of four patients several days after traumatic injury (motor vehicle accidents). These samples were obtained as part of another investigation on the effect of trauma on α_1-acid glycoprotein concentration (17) and were handled in an identical manner to samples used in this investigation, with the exception that they were stored at −20°C. All samples were assayed for α_1-acid glycoprotein concentration by using a radial immunodiffusion procedure with commercially prepared kits[6]. Cholesterol and triglyceride concentrations were determined with an autoanalyzer by using the Liebermann–Burchard reagent and glycerol kinase method, respectively.

RESULTS

The quinidine serum protein binding data from three healthy volunteers are plotted (Fig. 1), by the method of Rosenthal (16). Two classes of binding sites are apparent over the concentration range studied. The affinity and capacity constants for each site are also shown (Fig. 1). At a concentration of 1.0 μg/mL, the free fraction of quinidine varied among individuals from 0.119 to 0.157 (mean, 0.138 ± 0.018). No evidence for clinically significant concentration-dependent changes in free fraction was observed within the usual therapeutic range (1–5 μg/mL). In isolated human serum albumin solution, quinidine binding was found to have characteristics consistent with those of the low-affinity, high-capacity class of sites in serum, with an observed value of 3.05×10^3 M^{-1} for the association constant (K) and 1.36×10^{-3} M for its binding capacity (nP; see Fig. 1).

Table I—Mean Values for Quinidine Free Fraction and Concentration of Relevant Substances in Serum from Healthy Volunteers and Patients with Hyperlipidemia

	Mean ± *SD* Quinidine Free Fraction		
	Healthy Volunteers[a]	Hyperlipidemic Patients[b]	Statistical Significance[c]
Quinidine free fraction	0.129 ± 0.019	0.118 ± 0.019	NS[d]
Albumin, g/dL	4.8 ± 0.4	4.7 ± 0.3	NS
α_1-Acid glycoprotein, mg/dL	70 ± 16	99 ● 34	NS
Cholesterol, mg/dL	178 ± 14	313 ± 71	$p < 0.01$
Triglycerides, mg/dL	125 ± 32	245 ± 107[e]	$p < 0.05$

[a] $n = 5$. [b] $n = 6$. [c] t Test for independent samples. [d] Not significant. [e] The triglyceride value for one patient with a concentration of 2330 mg/dL was not included, as this would result in a badly skewed distribution of data.

Figure 2 contains the Rosenthal plot for quinidine binding in serum from a normal healthy male with and without the addition of tris(butoxyethyl) phosphate. The addition of this compound appeared to eliminate the high-affinity class of binding sites, resulting in a single class of sites with $K = 2.26 \times 10^3\ M^{-1}$ and $nP = 1.22 \times 10^{-3}$ M. In the presence of lidocaine, the quinidine free fraction increased with increasing lidocaine concentration, with a maximal value of 0.229 at a lidocaine concentration of 500 μg/mL[9]. This value is consistent with that observed at therapeutic quinidine concentrations in the presence of tris(butoxyethyl) phosphate (0.231) and with the predicted value; assuming the complete absence of the high-affinity class of binding sites in serum (0.272).

In the serum from patients suffering trauma, the mean α_1-acid glycoprotein concentration was 197 mg/dL (corresponding value in healthy volunteers, 70 mg/dL). The quinidine free fraction ranged from 0.049 to 0.113, with a mean value of 0.075 ± 0.019. The relationship between the quinidine binding ratio and the α_1-acid glycoprotein concentration is shown in Fig. 3. A strong correlation was observed, and the relationship was found to be quite consistent with that predicted by using the mean binding parameters shown in Fig. 1 (assuming that the high-affinity, low-capacity class of binding sites is on α_1-acid glycoprotein). Patients with hyperlipidemia had a mean cholesterol concentration of 313 mg/dL and a mean triglycerides concentration of 245 mg/dL (Table I). The free fraction of quinidine in these patients was 0.118 ± 0.019 and was not significantly different from the free fraction observed in healthy individuals (0.129 ± 0.019). In one patient with a triglyceride concentration of 2330 mg/dL, the quinidine free fraction was 0.128.

DISCUSSION

The protein binding of quinidine has been the subject of a number of previous investigations, many of which have yielded conflicting results. The recent identification of a number of factors which may artificially alter estimates of the quinidine free fraction prompted the present investigation, with the goal of obtaining definitive and clinically useful data.

The mean free fraction of quinidine in healthy volunteers has varied widely among studies (range, 0.10–0.29). The value of 0.129 observed in this investigation is near the lower limit of previously reported values. Two main classes of binding sites were identified in the serum from healthy volunteers, with both sites contributing nearly equally to the fraction of drug bound at therapeutic concentrations of quinidine. Because of this, one would predict that the free fraction would only double in the complete absence of one or the other of these classes of sites.

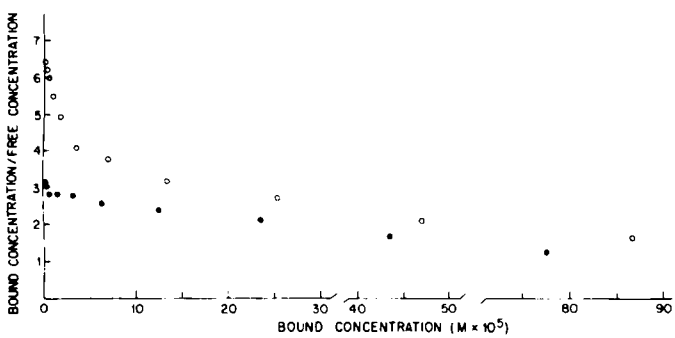

Figure 2—*Relationship between bound concentration/free concentration and bound concentration of quinidine in serum from a healthy male volunteer (○) and identical serum, to which tris(butoxyethyl) phosphate (●) at 75 μg/mL was added.*

Knowledge of the identity and characteristics of the binding proteins allows the prediction of the consequences of pathophysiological or pharmacological changes in the binding milieu. In this investigation, the binding of quinidine in an isolated albumin solution was found to have characteristics similar to the binding of quinidine to the low-affinity class of binding sites in serum. However, previous investigations have suggested that α_1-acid glycoprotein and lipoproteins, as well as albumin, contribute significantly to quinidine binding (11, 12). In attempting to establish the relative contributions of these proteins, quinidine binding was studied in the presence of tris(butoxyethyl) phosphate, a compound known to displace basic drugs from α_1-acid glycoprotein binding sites (18). The quinidine free fraction increased in a manner that was consistent with the absence of binding to the high-affinity class of sites. Because little is known about the specificity of tris(butoxyethyl) phosphate protein binding (*i.e.*, it could possibly also displace quinidine from lipoproteins), lidocaine was also studied as a potential displacer of quinidine. Lidocaine is known to be bound primarily to α_1-acid glycoprotein, with some binding to albumin and no demonstrable affinity for lipoproteins (17, 19). The ability of lidocaine to displace quinidine to the same extent as tris(butoxyethyl) phosphate suggests that interactions between quinidine and lipoproteins do not influence the free fraction of this drug.

The results of the quinidine binding studies in the trauma patients and hyperlipidemic patients support our conclusions concerning the identity of the binding sites. Trauma patients have been shown to have high concentrations of α_1-acid glycoprotein and increased binding of lidocaine (17). In this study, quinidine free fraction was reduced by >40% at a mean α_1-acid glycoprotein concentration of 197 mg/dL. Since concentrations of this magnitude are observed in several common conditions (acute myocardial infarction, rheumatoid arthritis, and cancer), similarly reduced quinidine free fractions are likely in many patients receiving the drug (20). A reduced free fraction has been reported in surgical patients (21) and in survivors of cardiac arrest (22). Using computer simulations, Kates *et al.* (10) have predicted that elevated concentrations of lipoproteins would have little effect on the quinidine binding ratio. Our results support this conclusion, as the small difference in

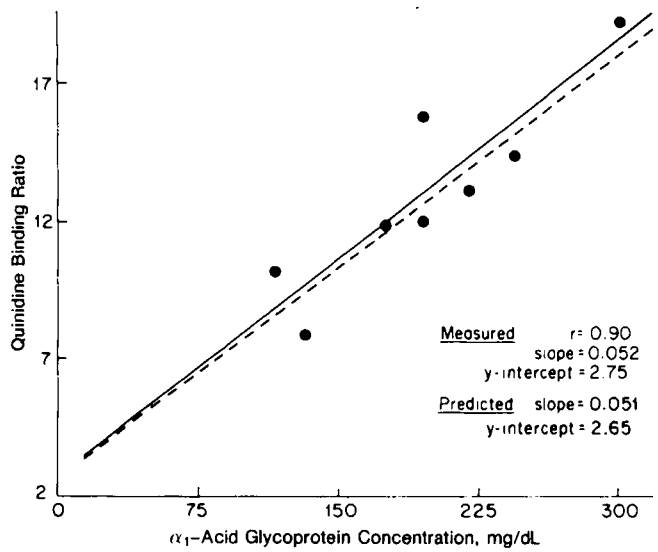

Figure 3—*Relationship between quinidine binding ratio (bound concentration/free concentration) and α_1-acid glycoprotein concentration in serum obtained from patients after traumatic injury. [9] Unpublished results.

free fraction between the hyperlipidemic patients and the healthy volunteers can be accounted for by slightly higher α_1-acid glycoprotein concentrations in the former group.

It appears, therefore, that the important binding proteins for quinidine are α_1-acid glycoprotein and albumin. Using the mean binding parameters for these proteins (Fig. 1), one can predict that at least a 50% decrease in albumin concentration would be necessary to obtain a 20% increase in quinidine free fraction. Clinically significant changes in quinidine binding are more likely to be due to changes in α_1-acid glycoprotein concentration, since serum levels of this protein may be increased in patients suffering from a number of common diseases.

Simple, Rapid Method for Comparing the Self-Emulsifiability of Hydrocarbon Oils

T. A. IRANLOYE *x and N. PILPEL ‡

Received October 25, 1982, from the **Department of Pharmaceutics, University of Ife, Ile-Ife, Nigeria* and the ‡*Department of Pharmacy, Chelsea College, University of London, Manresa Road, London SW3, U.K.* Accepted for publication May 12, 1983.

Abstract □ A simple and rapid method for comparing the degree of self-emulsifiability of different hydrocarbon oils is described. The method involved measurement of the intensity of light scattered at an angle of 31° to the incident radiation by the sample. The extent or degree of self-emulsification of selected hydrocarbon oils was observed to be affected by the nature of the oil as well as by the type and concentration of the surfactants employed. The method is useful when screening surfactant–hydrocarbon oil combinations as potential vehicles for drugs in the pharmaceutical industry or herbicides and pesticides for agricultural purposes.

Keyphrases □ Emulsions—surfactant-hydrocarbon oil, self-emulsifiability, measurement by laser nephelometry □ Laser nephelometry—self-emulsifiability, surfactant-hydrocarbon oil mixtures □ Hydrocarbon oils—self-emulsifiability, effect of added surfactants, measurement by laser nephelometry

Self-emulsifiable oils (also known as emulsifiable concentrates), widely used in the chemical and allied industries because they readily form emulsions without the need for powerful or sophisticated emulsification equipment, serve as vehicles for herbicides and pesticides and are used for cutting and rolling metals into thin sheets. They are also employed as lubricants in the textile industry and are currently being used for the recovery and processing of crude oils.

Self-emulsifiable oils have some potential applications in the drug industry. Solutions of drugs in oils have been administered to patients in soft gelatin capsules since the early part of the 19th century. In its modern form, this dosage is claimed to be advantageous since the accuracy, stability, and patient convenience is greater than that for the corresponding tableted form of a given drug. These oily solutions readily emulsify when released into the aqueous environment of the stomach. The generation of a large surface area means an optimum condition for extraction and absorption of the drug. The main requirement would be a suitable combination of nontoxic surfactants in bland oils.

It has been reported that the oil droplets in self-emulsifiable systems can be very small, ~1 μm (1). Measurement of droplet sizes in the submicrometer range has proved to be very tedious and/or time consuming (2). It is anticipated that the laser nephelometer[1], when used judiciously, can reduce the number of problems associated with particle size characterization in dispersed systems.

THEORETICAL SECTION

Several theories of light scattering by small particles (3–5) have appeared in the literature since the pioneering work of Rayleigh (6, 7) in this field. Recently, Bagchi and Vold (8) have commented on the limitations of some of these theories. In the present work, it is assumed that the basic equation

THEORETICAL SECTION

Several theories of light scattering by small particles (3–5) have appeared in the literature since the pioneering work of Rayleigh (6, 7) in this field. Recently, Bagchi and Vold (8) have commented on the limitations of some of these theories. In the present work, it is assumed that the basic equation

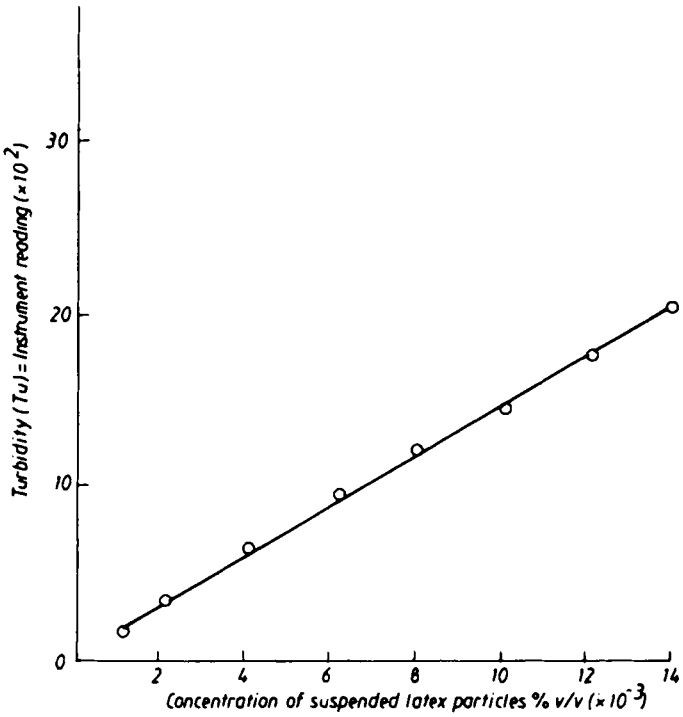

Figure 1—*Turbidity as a function on concentration of suspended latex particles. Nominal (manufacturer's) particle diamter = 0.24 μm.*

of Rayleigh (6) given by:

$$I_s(\theta) = \frac{9\pi NV^2}{2d^2\lambda^4} \cdot \frac{(n_i^2 - n_{ii}^2)}{(n_i^2 + 2n_{ii}^2)} \cdot (1 + \cos^2\theta) I_0 \qquad \text{(Eq. 1)}$$

is applicable. In this equation, $I_s(\theta)$ is the intensity of light scattered at angle θ, N is the number of particles in volume V, d is the distance between the measuring unit and the sample, n_i and n_{ii} are the refractive indices of the dispersed and continuous phases, respectively, and λ is the wavelength of the incident light of intensity I_0.

Lee and Groves (9) have shown that with the laser nephelometer, some factors (such as d and θ) may be regarded as constant, due to the design of the instrument, and they represented the measured intensity of scattered light by:

$$I_s(\theta) = fNV \cdot fn \cdot f(n_i - n_{ii}) \qquad \text{(Eq. 2)}$$

V is related to φ (*i.e.*, the volume fraction of the dispersed phase). The measured turbidity, Tu, is:

$$\text{Tu} = \frac{I_s(\theta)}{(n_i - n_{ii})\varphi} = f(\text{mean particle size}) \qquad \text{(Eq. 3)}$$

EXPERIMENTAL SECTION

Monosize latex[2] particles were used as received. High purity *n*-hydrocarbon[3] oils and a hydrocarbon mixture (I)[4] were purified further by repeated percolation through beds of fuller's earth[5] until their physical properties agreed closely with literature values. Surfactant mixture II[6] was used at a 1:1 ratio; surfactant mixture III[7] was used as 1:1 and 3:2 mixtures. Water was triple distilled from an all glass apparatus (surface tension, $\gamma a/w = 71.9$ mNm^{-1} at 25°C).

The laser nephelometer[1] utilizes a low-powered (0.5 mW) neon laser (λ = 632.8 nm) and an arbitrary scale of 0–200 to indicate increasing scattering intensity or turbidity, and was operated according to the manufacturer's manual (15).

Table I—Composition of Emulsifiable Oils

Total Conc. of Surfactants[a], % w/w	Conc. of Hydrocarbon Oil, % w/w
10	90
20	80
30	70
40	60
50	50

[a] Mixture II was used as a 1:1 ratio; mixture III was either a 1:1 or a 3:2 ratio.

Serial dilutions of suspensions of the latex particles in water were made. Emulsifiable oils were prepared by adding the hydrocarbon oils to the surfactant mixtures; all preparations were made on a weight basis, as indicated in Table I. Emulsions were prepared by adding 1 mL of the emulsifiable oil to 99 mL of water in a 100-mL graduated cylinder, which was then gently inverted until the dispersion was homogeneous. Serial dilutions of the emulsions were then made.

Sample tubes containing the dilute suspensions of the latex particles or the emulsions were placed, in turn, in the low-power laser beam, and the turbidity as indicated by the instrument reading was recorded after a scanning period

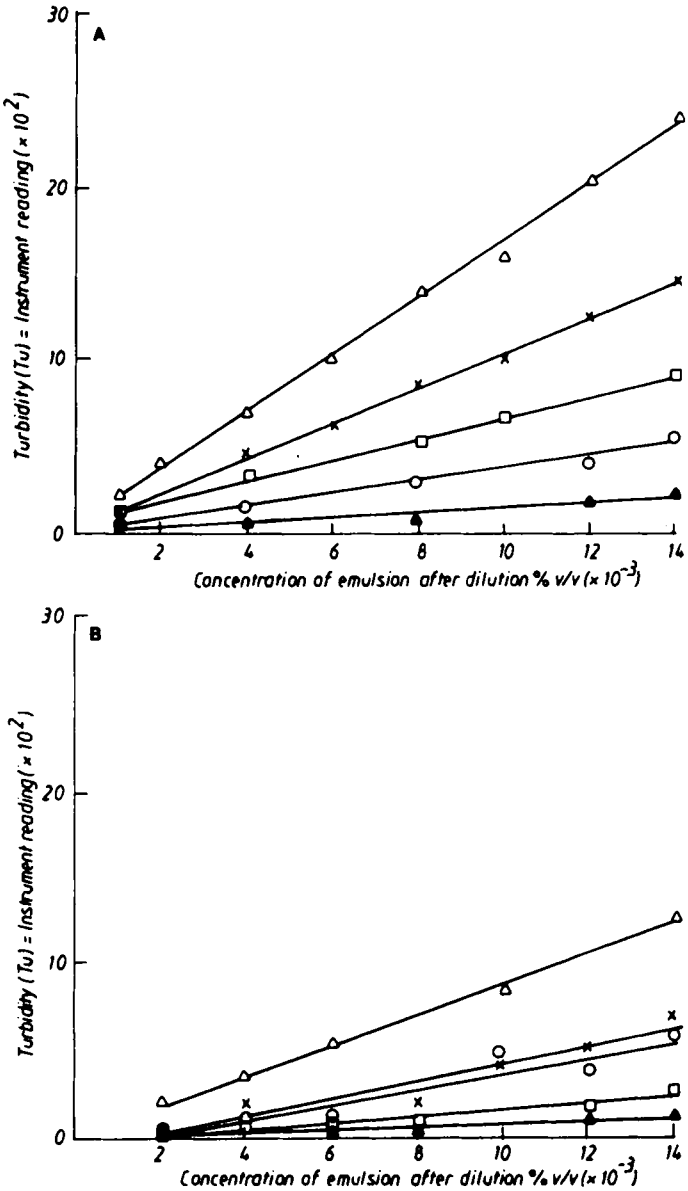

Figure 2—*Turbidity as a function of concentration of emulsions prepared from emulsifiable oils consisting of III (1:1) and I (A) and II (1:1) and n-hexane (B). Key: (□) 10% w/w; (△) 20% w/w; (×) 30% w/w; (○) 40% w/w; (▲) 50% w/w.*

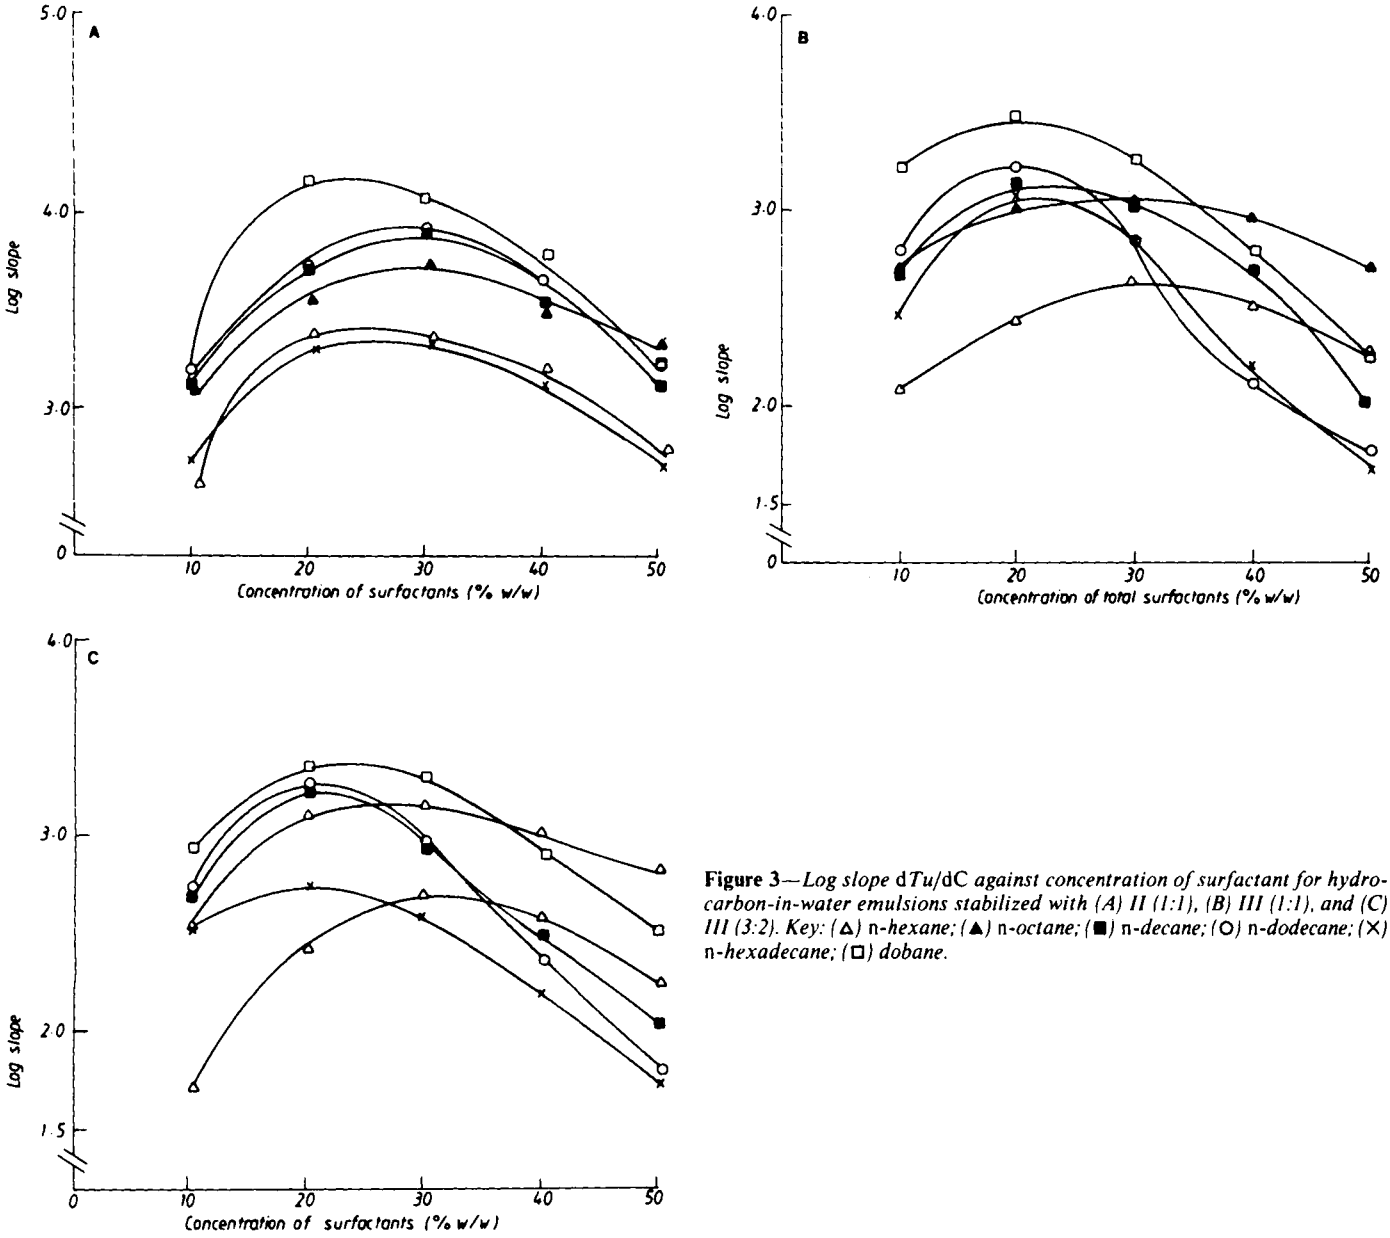

Figure 3—*Log slope* d*Tu*/d*C against concentration of surfactant for hydrocarbon-in-water emulsions stabilized with (A) II (1:1), (B) III (1:1), and (C) III (3:2). Key: (△) n-hexane; (▲) n-octane; (■) n-decane; (○) n-dodecane; (×) n-hexadecane; (□) dobane.*

of 5 s. At least 10 samples from each suspension or emulsion were analyzed and the results averaged.

RESULTS AND DISCUSSION

Graphs were plotted between turbidity (instrument reading) and concentration of latex particles or emulsions; representative results are shown in Figs. 1 and 2, respectively. The graphs were rectilinear within the range of concentrations examined. This observation conforms with Beer's law, which states that the decrease in intensity of radiation is related exponentially to the concentration of an absorbing substance in solution through which the radiation passes provided the light is monochromatic and the material homogenous.

To quantify the extent of emulsification of each hydrocarbon oil, slopes (*i.e.*, $d\mathrm{Tu}/dC$) were determined. The logarithms of the slopes (to accommodate the range) were then plotted against the concentration of surfactants in the emulsifiable oil (see Table I). Representative results[8] are shown in Fig. 3.

It can be seen that as the total concentration of the surfactants was increased, there was an increase in the value of the slope for each hydrocarbon oil until a maximum was reached, after which there was a decrease. The increase in slope (as a function of surfactant concentration) was probably the result of increased adsorption of surfactant molecules at the oil-water interface leading to an increase in the stabilization of the interfacial area until a maximum was reached. The fall in slope at higher concentrations of surfactants could be due to formation of associated structures with a corresponding decrease in translucency.

At any particular total concentration of surfactants, the numerical value of the slope (log $d\mathrm{Tu}/dC$) is a measure of the amount of light scattered by the system and, hence, a measure of its self-emulsifiability. Thus, from Fig. 3A it is seen that I is more readily emulsified by II (1:1) than *n*-hexane because at all concentrations of these emulsifiers, the curve for the former is above that of the latter. This observation is supported by recent work (16), which showed that droplets of *n*-hexane stabilized with equal weight ratios of these surfactants were larger and fewer than those of I.

When comparing the efficiency of II (1:1) with III (1:1) as an emulsifier for *n*-hexane, it can be said that the former is more efficient, since at each total concentration of surfactants the value of $d\mathrm{Tu}/dC$ with II (1:1) is higher than with III (1:1).

CONCLUSIONS

The objective in any formulation exercise should be to achieve a maximum value of $d\mathrm{Tu}/dC$ at the lowest convenient total concentration of surfactants. The present equipment and technique should prove suitable for comparing the relative self-emulsifiabilities of different oil-surfactant combinations.

Analytical Methods for the Determination of Sulindac and Metabolites in Plasma, Urine, Bile, and Gastric Fluid by Liquid Chromatography Using Ultraviolet Detection

D. G. MUSSON[x], W. C. VINCEK, M. L. CONSTANZER, and T. E. DETTY

Received March 15, 1983 from the *Merck Sharp & Dohme Research Laboratories, West Point, PA 19486.* Accepted for publication October 17, 1983.

Abstract □ A high-performance liquid chromatographic method using a linear elution gradient has been developed for the analysis of sulindac, sulindac sulfone, and sulindac sulfide in plasma, urine, bile, and gastric fluid. The methodology uses reverse-phase, radial compression chromatography with gradient elution, and UV detection. Sulindac and its metabolites in plasma can be quantitated at 0.25 μg/mL with a mean *CV* of 6.0 ● 2.9%; urine, bile, and gastric fluid (0.5 μg/mL) yield a mean *CV* of 5.5 ± 1.9%.

Keyphrases □ Sulindac—metabolites, liquid chromatography with UV detection, human plasma, urine, bile, and gastric fluid □ Liquid chromatography—sulindac and its metabolites, human plasma, urine, bile and gastric fluid

Sulindac (*cis*-5-fluoro-2-methyl-1-[*p*-(methylsulfinyl)-benzylidene]indene-3-acetic acid; I) is an anti-inflammatory drug with analgesic and antipyretic properties. Metabolites include sulindac sulfide (II) the active species (I), and sulindac sulfone (III). Sulindac and its metabolites are detected in plasma, while sulindac, sulindac sulfone, and their respective conjugates are the major constituents excreted in urine (2).

Previous methods of analysis include an isotope dilution radioimmunoassay (3), a computerized mass spectral assay (4), and a high-performance liquid chromatographic assay (HPLC) (5), and appear to be restricted to serum or plasma. A stepwise isocratic HPLC assay has been recently reported (6) for plasma and urine determination; however, it involves tedious extraction procedures and is not free of interfering substances.

Preliminary investigations using the Dusci and Hackett method (5) led to incomplete resolution of sulindac and its metabolites from endogenous substances. Modifying this method with gradient elution afforded an assay that is applicable for measuring total levels of sulindac and its metabolites in plasma, urine, bile, and gastric fluid, and one that appears to be free from interfering substances.

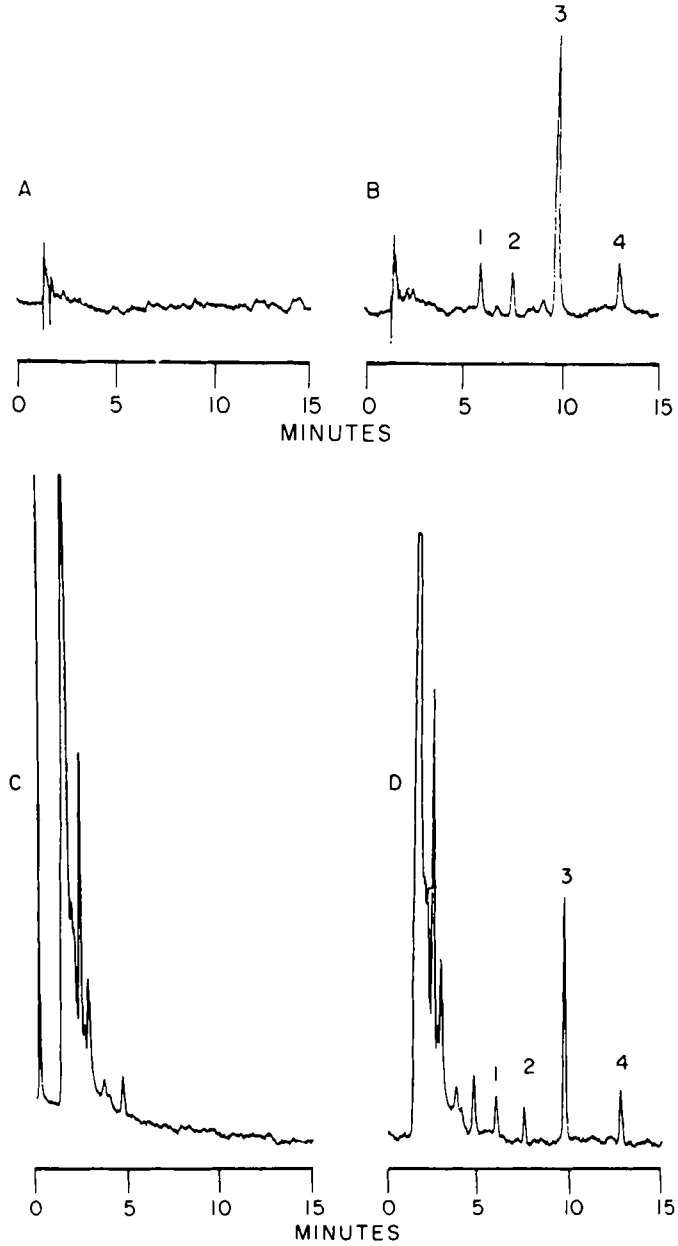

Figure 2—*Chromatograms from a radially compressed C_{18} column. Key: (A) is a control plasma blank; (B) is a plasma standard containing sulindac and its metabolites; (C) is a control urine; (D) is a urine standard. All concentrations of sulindac and its metabolites are at 0.5 μg/mL; the internal standard concentrations are 40.0 μg/mL for plasma and urine standards.*

HPLC grade[7], was filtered[8]; and water was purified[9]. Heparinized control plasma was collected and prepared in-house[6].

A C_{18} stainless steel column (30 cm × 3.9 mm i.d., 10 μm)[10], a C_{18} plastic cartridge (10 cm × 8 mm i.d., 10 μm) housed in a radial compression module[11], and a reverse-phase guard column[12] were used.

Prepared Solutions—Standard stock solutions of I, II, and III were prepared weekly by dissolving 2.0 mg of the appropriate compound in 2 mL of absolute ethanol and 8 mL of sodium borate buffer, pH 7.2 (12.4-g boric acid, 10.0-mL 1 M NaOH diluted to 1 L with purified[9] water). Working standards were mixed with appropriate dilutions from the stock solution with the boric acid buffer. Internal standard stock solutions were prepared weekly by dissolving indomethacin in the sodium borate buffer, pH 7.2 (300 μg/mL).

Chromatographic Conditions— The mobile phase gradients for the plasma, urine, bile, and gastric fluid assays were: a potassium phosphate buffer, pH 3.0 (6.8-g KH_2PO_4 in 1000 mL water with the pH adjusted to 3.0 with 85% phosphoric acid) and a mixture of acetonitrile and the phosphate buffer (70:30 v/v). Both solutions were filtered (cellulose, 0.5 μm) and kept under a helium atmosphere. During a gradient run the two solutions were mixed at 53:47, respectively, and changed to 7:93 over 10 min (linear gradient time) at 2 mL/min. The final solvent ratio continued to run for 5 min. The radial C_{18} column was reequilibrated for 5 min, with the initial mobile phase conditions, before the next sample run. Due to chromatographic interferences in the bile of certain patients in clinical studies, the gradient conditions for the bile assay required a 15-min gradient time and a 3-min hold.

Plasma Preparation—A 0.3-mL plasma sample was spiked with the internal standard, indomethacin (40.0 μL). One milliliter of acetonitrile was mixed with the plasma aliquot on a vortex mixer (30 s). The tube was then centrifuged (3500 rpm)[13], and the liquid sample was transferred to a tapered tube. The volume was reduced to 0.1 mL with a stream of nitrogen and a warm water bath (50°C) and then analyzed by HPLC (20-μL injection volume).

Urine, Bile, and Gastric Fluid Preparation—A 0.3-mL fluid sample of urine, bile, or gastric fluid was mixed with 0.1 mL of 5 M NaOH. The sample was

[13] International Centrifuge, Size 2, Model K.

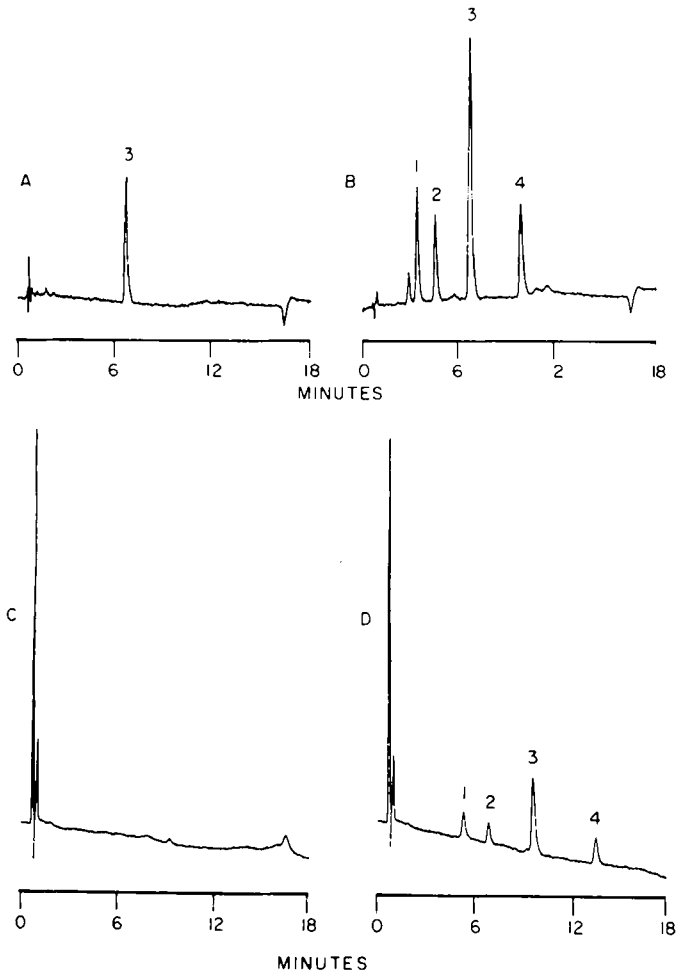

Figure 3—*Chromatograms from a radially compressed C_{18} column. Key: (A) is a control gastric fluid blank containing internal standard; (B) is a gastric fluid standard; (C) is a control bile blank; (D) is a bile standard. All concentrations of sulindac and its metabolites are at 0.5 μg/mL; the internal standard concentrations are 6.0 μg/mL for gastric and 25.0 μg/mL for bile standards.*

incubated at room temperature (25–27°C) for 15 min. The pH was then adjusted with the addition of 0.1 mL of phosphoric acid (28.3%). The internal standard (40 μL for urine, 6 μL for gastric fluid, and 25.0 μL for bile) and 1 mL of acetonitrile (1.5 mL for gastric and intestinal fluids) was mixed with the sample. In all cases, the samples were vortex-mixed (30 s) and centrifuged (3500 rpm)[13]. The organic layer was transferred to a tapered tube, the volume was reduced to 0.1 mL, and then it was analyzed by HPLC (20-μL injection volume for urine, 35-μL for bile, and 40-μL for gastric fluid).

Standard Curves—Plasma standards were prepared by mixing 1 mL of control plasma with the internal standard and appropriate volumes of I, II, and III to achieve concentrations from 0.25 to 10 μg/mL, *e.g.*, 0.25, 0.5, 1.0, 2.5, 5.0, and 10.0 μg/mL. From these standards, 0.3-mL aliquots were removed and processed as above.

Urine, bile, and gastric fluid standards (1 mL) were prepared similarly but without the internal standard, which is unstable under the basic conditions required for conjugate hydrolysis. The samples were hydrolyzed, pH adjusted, spiked with internal standard, and processed as above.

The standard curves were plotted with peak height ratios *versus* concentrations. A validation curve consisted of the above concentrations with six replicates per concentration (each replicate was prepared separately). A daily standard curve was assayed with the samples; unknown sample concentrations were interpolated from these daily curves.

Recovery Values—Recovery values were measured by comparing the amount of labeled material prepared in a standard sample with the amount detected in acetonitrile after deproteination and/or extraction. Standards of labeled sulindac ([2-^{14}C]acetic acid, 26 μCi/mg)[14], and sulindac sulfone ([^{3}H]methylene, vinyl, 50 μCi/mg), and sulindac sulfide ([^{3}H]methylene, 256 μCi/mg) were prepared in concentrations of 0.25, 1.0, and 10.0 μg/mL (3, 9) and processed. The acetonitrile extracts were measured for volume and counted for radioactivity. The radioactivity measured for the extracts was divided by the radioactivity of the standard solutions.

RESULTS AND DISCUSSION

This assay, a modification of an isocratic, reverse-phase HPLC method for the determination of sulindac in plasma (5), involves the use of a linear elution gradient to resolve sulindac and its metabolites from interfering peaks found in clinical plasma samples and other human fluids, *e.g.*, urine, bile, and gastric fluid. The mobile phase of acetonitrile and potassium phosphate buffer (pH 3.0) was adjusted so that separation from endogenous substances was achieved, the resolution of the sulfone metabolites and sulindac was enhanced, and the elution of the sulfide metabolite was hastened.

Chromatographic separation using a linear elution gradient was achieved, initially, for plasma and urine on a stainless steel C_{18} column[10] at 40:60 acetonitrile–potassium phosphate buffer (2 mL/min) changing to 65:35 over 10 min. Hold time and equilibration delay were set at 5 min. These HPLC conditions gave an assay applicable only to plasma and urine fluids (Fig. 1). Adaptation of the mobile phase conditions to a radially compressed C_{18} cartridge resulted in an assay applicable to plasma, urine, bile, and gastric fluid. This latter assay elutes and resolves sulindac and its metabolites in a chromatographic manner similar to the former assay with the stainless steel column. The chromatograms of plasma, urine, bile, and gastric fluid blanks did not show endogenous substances that would interfere with sulindac, its me-

[14] [^{14}C]Sulindac, (*Z*)-5-fluoro-2-methyl-1-[[4-(methyl-sulfinyl)phenyl] methylene]-1*H*-indene-3-[2-^{14}C]acetic acid, was prepared by Mr. Gregory, J. Gatto, and Miss Jane Chan in the Radiochemical Synthesis Laboratory of MSDRL, Rahway, N.J. under the direction of Dr. Holly E. Mertel. The procedure is unpublished. Labeled carbon was introduced by treating cyano[2-^{14}C]acetic acid (American Radiochemical Co., Sanford, Fla.) with 6-fluoro-2-methyl-1-indone, followed by hydrolysis and decarboxylation steps. The resulting 5-fluoro-2-methyl-1*H*-indene-3-[2-^{14}C]acetic acid was condensed with *p*-methyl-sulfinylbenzaldehyde to furnish the title tracer compound. A description of a related sequence is found in Canadian patent 1,027,967, March 14, 1978, (to John M. Chemerda and Seemon H. Pines).

Table III—Human Urine, Bile, and Gastric Fluid Levels of Sulindac and Metabolites (200 mg im of Sulindac)

Time[a]	Sulindac, μg/mL	Sulindac Sulfone, μg/mL	Sulindac Sulfide, μg/mL

[a] Time period: for urine in hours, for bile and gastric fluid in minutes. [b] 20-min period collections gave 0.0 conc. [c] Only sulindac was found in the 100–120-min interval (1.55 μg/mL). [d] The gastric fluid levels of sulindac and its metabolites are due to the reflux of bile into the stomach.

tabolites, or indomethacin. Sulindac, sulindac sulfone, sulindac sulfide, and indomethacin were completely resolved (Figs. 2 and 3).

Acetonitrile deproteination of plasma (4) provided a method with acceptable reproducibility and linearity. Organic extraction techniques (*e.g.*, diethyl ether) consistently gave coefficients of variation of intraday replicates exceeding 10%.

Standard curves for I, II, and III in plasma were linear over the concentration range of 0.25–10.0 μg/mL; urine and bile gave linear curves over the range of 0.5–10 μg/mL; gastric fluid gave a linear curve over the range of 0.5–5 μg/mL (Table I). Concentrations at 0.1 μg/mL in plasma and in urine could be detected, but poor reproducibility restricted the low concentrations to 0.5 μg/mL. Linearity is lost at the higher concentrations (tested at 20 and 40 μg/mL) due to lower absorbance responses.

The *CV* measured for the plasma assay of the three components gave an average of 4.7 ± 2.7% over the linear concentration range. The urinary, bile, and gastric fluid assays gave average *CV* values of 6.04 ± 1.6%, 7.80 ± 2.5%, and 4.87 ± 1.24%. Representative *CV* are listed in Table II.

Recoveries of I, II, and III from plasma *via* acetonitrile protein precipitation are 39.9 ± 4.2%, 49.8 ± 6.7%, and 86.3 ± 3.7%, respectively. Similarly, representative recovery values for acetonitrile extraction (urine) are 58.2 ± 7.4%, 65.1 ± 9.9%, and 96.7 ± 6.9%. These values are means over three concentrations.

The hydrolysis of urine conjugates for total sulindac and its two metabolites by base catalysis were studied over time. Peak height values for sulindac and its metabolites reached a maximum in the first 15 min and began to decline

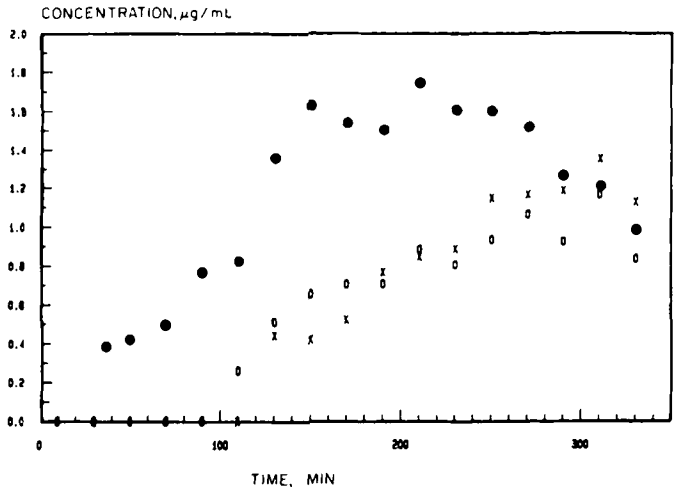

Figure 4—*Plasma levels of sulindac and its two metabolites in one subject administered a single 200-mg im injection of sulindac. Key: (●) sulindac; (○) sulindac sulfone; (X) sulindac sulfide.*

at 60 min. Reaction conditions were set with a 15-min incubation period at room temperature. Similar results were found for bile and gastric fluid.

Concentrations of sulindac and its metabolites in human plasma, urine, bile, and gastric fluid are represented in Fig. 4 and Table III. The data are of one subject who received a single intramuscular injection of sulindac (200 mg).

CONCLUSIONS

Gradient elution with acetonitrile and potassium phosphate buffer over a radially compressed, reverse stationary phase provides the necessary selectivity of the assay for quantitation of sulindac and its metabolites in plasma, urine, bile, and gastric fluid. The advantages of this gradient system over other available isocratic assays (5, 6) are: (*a*) a cleaner chromatogram for the plasma medium, (*b*) a shorter cleanup procedure for plasma and urine, and (*c*) a broader application of the assay to other biological fluids.

Abstract □ A two-tank perfect-mixing tank model was used to simulate GI absorption. The effect of drug parameters (pK_a, solubility, and intrinsic wall permeability) and system parameters (pH profile, volume of intestinal contents, and intestinal flow rate) on drug absorption were studied by numerical data simulation. When the dose did not exceed the solubility of the drug in the intestinal lumen, the fraction absorbed depended on the transit rate relative to the absorption rate and the pK_a relative to the pH profile, but was independent of drug dose. Saturation of one or both tanks led to dose-dependent absorption. The model was used to simulate absorption of chlorothiazide. Good agreement between simulated and experimental data led to the conclusion that the physical characteristics of chlorothiazide, rather than a saturable transport mechanism at the intestinal wall, may be responsible for the dose-dependent absorption observed for this drug. The model was also used to simulate hydrochlorothiazide absorption. By applying the same system parameters used for chlorothiazide, the model simulation correctly predicted the dose proportionality of hydrochlorothiazide absorption. The lack of dose dependency in this case may be attributed to the higher solubility and pK_a of hydrochlorothiazide compared with chlorothiazide.

Keyphrases □ Absorption—GI dose-dependent, physicochemical model □ Chlorothiazide—physicochemical model, dose-dependent GI absorption □ Hydrochlorothiazide—physicochemical model, dose-independent GI absorption

Dose-dependent drug absorption is often attributed to absorption *via* a saturable (carrier-mediated) mechanism or to the existence of a so-called absorption window for the drug. In many cases, however, an alternative approach, which takes into account the physical and chemical factors of the drug and GI tract, provides a more reasonable explanation of the observed behavior. Shore *et al.* (1) were the first to recognize the importance of physical parameters to drug absorption in their classical pH-partition hypothesis of GI absorption. They postulated that the rate of absorption is fastest when the drug is in its un-ionized form, with the degree of ionization being a function of pH and, hence, location in the GI tract. Solubility and dissolution rate effects on absorption were studied by Stricker (2, 3) using mechanical *in vitro* systems to simulate absorption. Among his conclusions was the finding that variability in absorption of some sulfonamides could be attributed to their limited and pH-dependent solubilities.

Physiological parameters such as gastric emptying rate may also influence absorption. Clements *et al.* (4) have shown that for drugs, such as acetaminophen, which are poorly absorbed in the stomach, gastric emptying can be the rate-limiting step in absorption. If, in such a case, gastric emptying does not follow a monoexponential relationship, the apparent absorption rate will not be first order, even though the drug is absorbed by passive diffusion. In this report, it is demonstrated that the physicochemical properties of a drug, *i.e.*, its solubility, pK_a, and intrinsic absorption rate, can play a significant role in the determination of the relationship between the dose administered and the oral bioavailability. The drugs chosen as examples are chlorothiazide and hydrochlorothiazide. For chlorothiazide, the fraction absorbed orally is known to decrease substantially with increasing dose. By contrast, hydrochlorothiazide exhibits dose-proportional absorption (5–7).

THEORETICAL SECTION

A two-tank mixing tank model (Fig. 1) provides a simple but useful picture of intestinal absorption. Tank 1 represents the duodenum and, hence, has a smaller volume and lower pH than tank 2, which represents the jejunum and ileum. The following assumptions are incorporated into the model:

1. Absorption from the stomach is minor compared with intestinal absorption. The model could be extended to a three mixing-tank model to accommodate cases in which this assumption is invalid.
2. The drug dose is delivered to the duodenum as a bolus. Dissolution is considered to be instantaneous compared with other processes such as absorption and transit rate. The dissolution rate may, in fact, play an important role in determining the percentage absorbed; its effects will be examined in a future study.
3. Uptake by the intestinal wall is a first-order process which does not involve a saturable carrier mechanism.
4. Absorption of the ionized form is negligible compared with that of the un-ionized form.
5. Transit is a first-order process.

Depending on the drug and the dose administered, three general cases apply:

1. Neither tank becomes saturated after drug is administered.
2. One tank becomes saturated after drug is administered.
3. Both tanks become saturated after drug is administered.

The three cases are illustrated in Figs. 2, 3, and 4, respectively. The basic set of parameters used in the simulations is listed in the *Appendix;* deviations from these values are noted where appropriate in the figure legends. The following symbols are used: X_{Ti}, the amount of drug in tank i; V_i, volume of tank i; f_{ui}, fraction un-ionized in tank i; Q, flow or transit rate; k_{ai}, intrinsic absorption rate in tank i; X_0, dose administered; C_{si}, saturation concentration in tank i; X_{si}, $X_{si} = C_{si} \cdot V_i$; $R_i = X_{si}$, apparent absorption rate under saturated conditions in tank i; τ_1, time at which $X_{T1} = X_{s1}$; τ_{2A}, time at which $X_{T2} = X_{s2}$ (X_{T2} increasing); and τ_{2B}, time at which $X_{T2} = X_{s2}$ (X_{T2} decreasing).

Case 1—In this case, X_{T1}/V_1 and X_{T2}/V_2 are always less than the saturation concentrations. Loss from tank 1 is given by:

$$-\frac{\partial X_{T1}}{\partial t} = (k_{a1}f_{u1} + Q_1/V_1)X_{T1} \qquad \text{(Eq. 1)}$$

whereas loss from tank 2 is given by:

$$-\frac{\partial X_{T2}}{\partial t} = (Q_2/V_2 + k_{a2}f_{u2})X_{T2} - Q_1X_{T1}/V_1 \qquad \text{(Eq. 2)}$$

Transit out of tank 2 represents drug which is not absorbed, *i.e.*:

$$\frac{\partial X_{t\text{-OUT}}}{\partial t} = Q_2X_{T2}/V_2 \qquad \text{(Eq. 3)}$$

These equations can be solved by using Laplace transforms to yield (for $X_{T1} = X_0$ at $t = 0$):

$$X_{T1} = X_0e^{-At} \qquad \text{(Eq. 4)}$$

$$X_{T2} = \frac{Q_1X_0}{V_1(B-A)}(e^{-At} - e^{-Bt}) \qquad \text{(Eq. 5)}$$

$$X_{t\text{-OUT}} = \frac{Q_2Q_1X_0}{V_2V_1B}\left(\frac{1}{A} + \frac{e^{-Bt}}{B-A} - \frac{Be^{-At}}{A(B-A)}\right) \qquad \text{(Eq. 6)}$$

where $A = k_{a1}f_{u1} + Q_1/V_1$ and $B = k_{a2}f_{u2} + Q_2/V_2$. The fraction of dose absorbed is then given by:

$$F = 1 - \frac{X^{\infty}_{t\text{-OUT}}}{X_0} = 1 - \frac{Q_2Q_1}{V_1V_2(k_{a1}f_{u1} + Q_1/V_1)(k_{a2}f_{u2} + Q_2/V_2)} \qquad \text{(Eq. 7)}$$

This result shows that the fraction absorbed depends on transit rate, intrinsic absorption rate of the un-ionized form, pK_a of the drug, and gastrointestinal pH profile. Variations in transit rate and gastrointestinal pH profile can affect the fraction absorbed in this case, but bioavailability is not dependent on the dose of the drug *per se*.

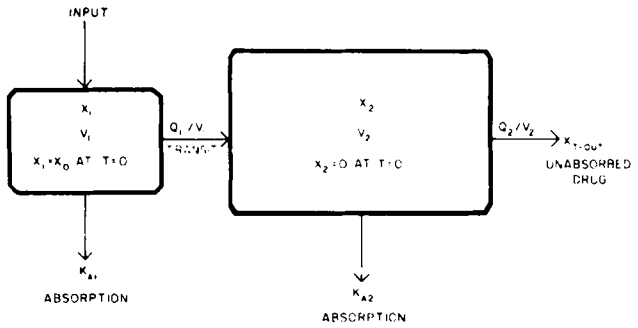

Figure 1—*Schematic of the two-tank perfect mixing tank model for oral drug absorption.*

Case 2—An example of the case in which one of the tanks becomes saturated occurs when the drug initially saturates tank 1 but levels in tank 2 never reach saturation, *e.g.*, absorption of a poorly soluble weak acid. In this case, it is convenient to split the derivation into two parts: (*a*) from $t = 0$ to $t = \tau_1$, the time at which concentration in tank 1 drops back below saturation, and (*b*) at times longer than τ_1. The second part is essentially described by the equations derived for case 1 by applying the appropriate boundary condition, *i.e.*, $X_{T1}/V_1 = C_s$ at $t = \tau_1$.

Equations for times shorter than τ_1 are:

$$-\frac{\partial X_{T1}}{\partial t} = R_1 + Q_1 X_{T1}/V_1 \qquad \text{(for tank 1)} \qquad \text{(Eq. 8)}$$

$$-\frac{\partial X_{T2}}{\partial t} = -Q_1 X_{T1}/V_1 + (k_{a2} f_{u2} + Q_2/V_2) X_{T2} \text{ (for tank 2)} \qquad \text{(Eq. 9)}$$

$$\frac{\partial X_{t\text{-OUT}}}{\partial t} = Q_2 X_{T2}/V_2 \qquad \text{(for unabsorbed drug)} \qquad \text{(Eq. 10)}$$

Solution of these equations by using Laplace transforms yields:

$$X_{T1} = -\frac{R_1 V_1}{Q_1} + e^{-Q_1 t/V_1}\left(X_0 + \frac{R_1 V_1}{Q_1}\right) \qquad \text{(Eq. 11)}$$

$$X_{T2} = -\frac{R_1}{B} - e^{-Q_1 t/V_1}\left(\frac{R_1 + Q_1 X_0/V_1}{Q_1/V_1 - B}\right) + e^{-Bt}\left(\frac{R_1 + BX_0}{B(Q_1/V_1 - B)}\right)\frac{Q_1}{V_1} \qquad \text{(Eq. 12)}$$

$$X_{t\text{-OUT}} = \frac{-Q_2 R_1 t}{BV_2} + (1 - e^{-Bt})\frac{Q_2}{V_2 B}\left[\frac{Q_1}{V_1 B}\frac{(R_1 + BX_0)}{(Q_1/V_1 - B)}\right] + (e^{-Q_1 t/V_1} - 1)\frac{Q_2 V_1}{V_2 Q_1}\left[\frac{R_1 + Q_1 X_0/V_1}{Q_1/V_1 - B}\right] \qquad \text{(Eq. 13)}$$

$$\tau_1 = \frac{-2.303 V_1}{Q_1}\log\left[\frac{Q_1 X_{s1}/V_1 + R_1}{Q_1 X_0/V_1 + R_1}\right] \qquad \text{(Eq. 14)}$$

The fraction of the dose absorbed can be determined by calculating τ_1 and then evaluating $X^{0\to\tau_1}_{t\text{-OUT}}$ by using Eq. 13 for $t = 0 \to \tau$ and Eq. 3 for $t = \tau_{1\to\infty}$ (solved with initial conditions $X_{T2} = X^{\tau_1}_{T2}$ and $X_{t\text{-OUT}} = X^{\tau_1}_{t\text{-OUT}}$ at $t = \tau_1$, the values of which are found from Eqs. 12 and 13, respectively); that is:

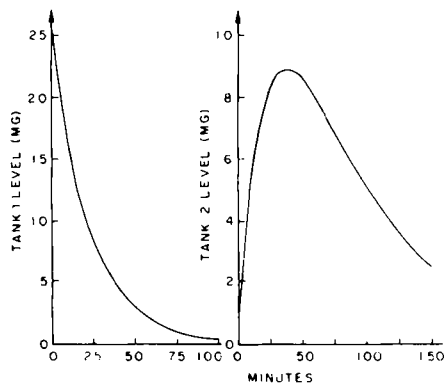

Figure 2—*Theoretical levels of drug in tanks 1 and 2 with time after administration of a dose lower than the saturation level in either tank. Case 1 equations apply throughout; the dosage is 25 mg.*

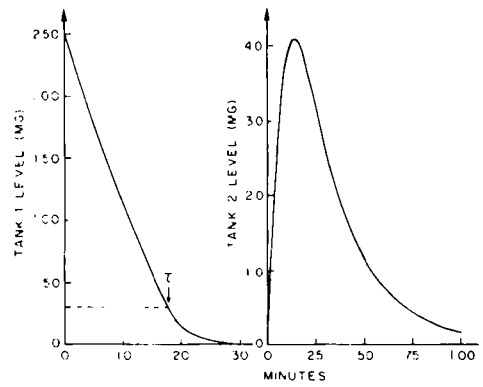

Figure 3—*Theoretical levels of drug in tanks 1 and 2 with time after administration of a dose which exceeds the saturation level in tank 1 only (τ_1 = 17.4 min). The intrinsic absorption rate constant is 0.3 min^{-1} for this simulation; the dosage is 250 mg. Case 2 equations apply from* t = 0 *to* t = τ_1.

$$X^{\tau_1\to\infty}_{t\text{-OUT}} = \frac{Q_2 X^{\tau_1}_{T2}}{V_2 B} + \frac{Q_1 X_0 Q_2}{V_1 V_2}\left(\frac{1}{AB}\right) \qquad \text{(Eq. 15)}$$

Then, the fraction absorbed is given by:

$$F_{abs} = 1 - \left(\frac{X^{0\to\tau_1}_{t\text{-OUT}} + X^{\tau_1\to\infty}_{t\text{-OUT}}}{X_0}\right) \qquad \text{(Eq. 16)}$$

Since the term for $X^{0\to\tau_1}_{t\text{-OUT}}$ is a function of the dose administered in addition to the factors listed under case 1, it appears that drugs which exceed their saturation solubilities in the GI tract will exhibit dose-dependent bioavailability. As expected, Eq. 13 indicates that as the dose increases, the fraction absorbed decreases.

Case 3—In this case, both tanks achieve levels greater than saturation. Assuming that tank 1 starts out above saturation, the times during which tank 2 becomes saturated ($\tau_{2A} \to \tau_{2B}$) may or may not overlap the time, τ_1, at which tank 1 falls below solubility, as this will depend on the flow rate relative to the absorption rate, solubility at the tank pH values, and the differences in tank volumes.

Differential equations governing drug levels when both tanks are saturated are:

$$-\frac{\partial X_{T1}}{\partial t} = R_1 + Q_1 X_{T1}/V_1 \qquad \text{(Eq. 17)}$$

$$-\frac{\partial X_{T2}}{\partial t} = R_2 + Q_2 X_{T2}/V_2 - Q_1 X_{T1}/V_1 \qquad \text{(Eq. 18)}$$

$$\frac{\partial X_{t\text{-OUT}}}{\partial t} = Q_2 X_{T2}/V_2 \qquad \text{(Eq. 19)}$$

By using the example in which $\tau_{2A} < \tau_{2B} < \tau_1$, the explicit solutions are as follows when $\tau_{2A} < t < \tau_{2B}$:

$$X_{T1} = [\mu(\tau_{2B}) - \mu(\tau_{2A})]\left\{-\frac{R_1 V_1}{Q_1} + e^{-Q_1(t-\tau_{2A})/V_1} \times \left[X_{T1}(\tau_{2A}) + \frac{R_1/V_1}{Q_1}\right]\right\} \qquad \text{(Eq. 20)}$$

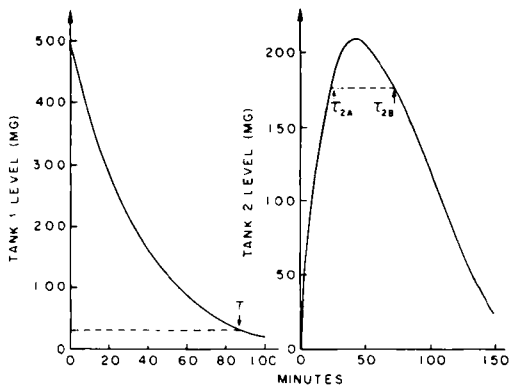

Figure 4—*Theoretical levels of drug in tanks 1 and 2 with time after administration of a dose which exceeds the saturation level in both tanks (τ_{2A} = 23, τ_{2B} = 71, τ_1 = 87 min). Case 3 equations apply from* t = τ_{2A} *to* t = τ_{2B}. *For this simulation, the dosage is 500 mg; pH_2 = 7.0.*

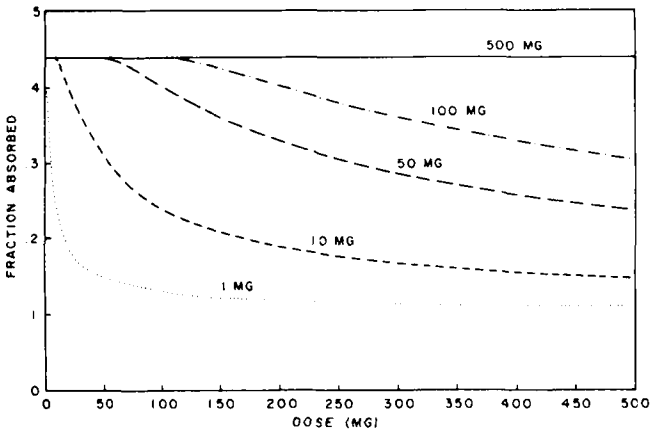

Figure 5—*Effect of solubility on the fraction of dose absorbed. Solubilities are expressed as the amount of drug required to saturate tank 1.*

$$X_{T2} = [\mu(\tau_{2B}) - \mu(\tau_{2A})]\left\{\frac{-(R_2 + R_1)V_2}{Q_2} + e^{-Q_1(t-\tau_{2A})/V_1} \times \left[\frac{Q_1 X_{T1}(\tau_{2A})/V_1 + R_1}{Q_2/V_2 - Q_1/V_1}\right] + e^{-Q_2(t-\tau_{2A})/V_2} \times \left[X_{s2} - \frac{Q_1 X_{T1}(\tau_{2A})/V_1}{Q_2/V_2 - Q_1/V_1} - \frac{Q_1 R_1/V_1}{Q_2/V_2(Q_2/V_2 - Q_1/V_1)} + \frac{R_2 V_2}{Q_2}\right]\right\} \quad \text{(Eq. 21)}$$

$$X_{t\text{-OUT}} = [\mu(\tau_{2B}) - \mu(\tau_{2A})]\left\{-(R_1 + R_2)(t - \tau_{2A}) - \frac{Q_2 V_1}{V_2 Q_1}\left[\frac{R_1 + Q_1 X_{T1}(\tau_{2A})/V_1}{Q_2/V_2 - Q_1/V_1}\right][e^{-Q_1(t-\tau_{2A})/V_1} - 1] + [1 - e^{-Q_2(t-\tau_{2A})/V_2}]\left[X_{s2} - \frac{Q_1 X_{T1}(\tau_{2A})/V_1}{Q_1/V_1 - Q_2/V_2} - \frac{Q_1 R_1/V_1}{Q_2/V_2(Q_2/V_2 - Q_1/V_1)} + \frac{R_2 V_2}{Q_2}\right]\right\} \quad \text{(Eq. 22)}$$

where $[\mu(\tau_{2B}) - \mu(\tau_{2A})] = 0$ at $t < \tau_{2A}$, $t > \tau_{2B}$ and 1 for $\tau_{2A} < t < \tau_{2B}$. In this instance, τ_{2A} is found by substituting X_{s2} for X_{T2} in Eq. 12 and solving for t. Similarly, τ_{2B} is found by substituting X_{s2} for X_{T2} in Eq. 21. At times $\tau_{2B} < t < \tau_1$, case 2 differential equations apply, and at $t > \tau_1$, the system reverts to case 1. A second possible order for τ_1, τ_{2A}, and τ_{2B} would be $\tau_{2A} < t_1 < \tau_{2B}$. The analogous set of equations for this order of τ values may be found by applying appropriate initial conditions.

A BASIC program incorporating initial value problem conditions for all possible orders of τ_1, τ_{2A}, and τ_{2B} and a zero-finding routine to determine the τ values was used to numerically evaluate the concentration–time profile and fraction absorbed for any given circumstance (see *Appendix*).

RESULTS AND DISCUSSION

Data were simulated under various conditions for the fraction absorbed *versus* dose plots. To cover the usual dosage range for most drugs, doses of 0–500 mg were studied. Parameters were initially chosen to simulate absorption for a poorly absorbed, weakly acidic drug. The effect of changing each drug and system parameter was then investigated. A discussion of initial parameter choices may be found in the *Appendix*.

Drug-Related Parameters—*Solubility*—Figure 5 depicts the influence of drug solubility on the fraction absorbed. For this simulation, solubility refers to the level required to saturate tank 1. For weak acids, tank 1 is saturated at lower levels than tank 2, in which the pH is higher and the volume is larger. Figure 5 shows that the solubility has a very pronounced effect on the relationship between the fraction absorbed and the dose administered. At very high solubility, the fraction absorbed is independent of dose since neither tank becomes saturated. In this case, the fraction absorbed depends on pK_a, pH profile, relative absorption, and transit rates but not on dose, since case 1 applies. When the dose exceeds the solubility, case 2 equations apply, and the fraction absorbed varies with dose. The form of the function varies with the drug solubility. The sharpest decrease in the fraction absorbed occurs at doses slightly above the solubility. At doses well above the solubility, the fraction absorbed is low and varies little with dose. Therefore, the dose dependency of absorption depends on the dosage range administered in relation to the solubility. If the doses given are near the solubility, marked dependency of the fraction absorbed on the dose may occur, but if the doses given exceed the solubility by a large amount, absorption will be poor and vary little with dose.

Drug pK_a—Variation in drug pK_a also causes a large effect on fraction absorbed as a function of dose (Fig. 6). Absorption of weakly acidic drugs with pK_a values ranging from 3.5 to 10.0 was simulated. Simulations indicate that drugs with low pK_a values (3.5 or 4.5) combined with poor intrinsic absorption rates would exhibit very poor absorption from the small intestine, with little dependency on dose. Even though the high pH relative to the drug pK_a ensures adequate solubility, the fraction un-ionized is very low, and so little absorption occurs during the drug residence time. The high solubility in both tanks results in case 1 conditions at all doses studied, which means that the percentage absorbed is independent of dose. Simulations for weaker acids indicate that absorption would be dose dependent in these cases. The fraction absorbed increases with increasing pK_a because the fraction of drug available for absorption, *i.e.*, in the un-ionized form, increases. When the pK_a of the drug is similar to or above the simulated intestinal pH, a high dose relative to the drug intrinsic solubility results in saturation in both tanks and, hence, case 3 equations apply. This occurs for $pK_a = 7.9$ at doses of >275 mg and for $pK_a = 10$ at doses of >225 mg under the conditions chosen (Fig. 6). When both tanks become saturated, the fraction absorbed decreases more rapidly with increasing dose than when only tank 1 is saturated. This is due to the further decrease in fraction available for absorption when both tanks are saturated. Overall, the drug pK_a affects both the form of the fraction absorbed *versus* dose function and the percentage of drug absorbed.

Intrinsic Absorption Rate Relative to Flow Rate—Figure 7 shows the impact of changing the ability of the drug to penetrate the membrane relative to the residence time of the drug in the system. The ratio of flow rate to intrinsic absorption rate was varied from 1:1 to 500:1. The absorption rates were chosen to represent a large spectrum of intestinal wall permeabilities. The flow rate was varied from 2 mL/min, which represents an approximate minimum flow in the human jejunum after a meal (8), up to 10 mL/min [maximum flow rate observed in dogs and sheep is ~6 mL/min (9)], thus covering the usual range of physiological values. When the absorption rate is on the same order as the flow rate, the fraction of dose absorbed is very high and virtually in-

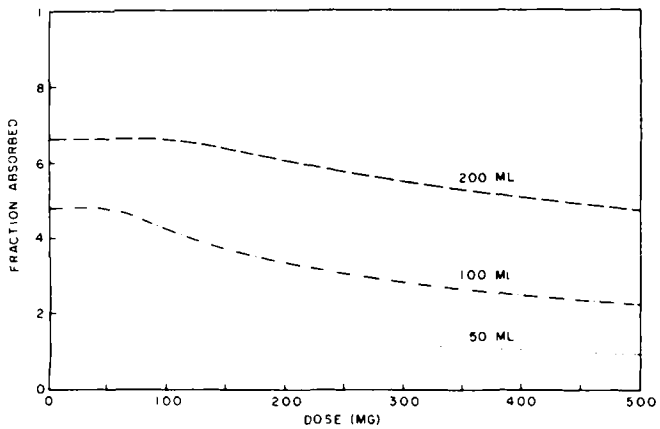

Figure 8— *Effect of tank volumes on fraction of dose absorbed. Equal volumes were used in the three simulations.*

dependent of dose. However, when the flow rate is large compared with the absorption rate, absorption is much poorer and more dose dependent. At very high flow rates, the residence time of the drug in the system is too short for extensive drug absorption. In this case, the percentage of dose absorbed is low at all doses and less dose dependency occurs. The major effect of changing the intrinsic absorption rate relative to the flow rate appears to be a shift in the fraction absorbed *versus* dose relationship. At extreme values, the form of the relationship is also affected.

System Parameters—*Tank Volumes*—Figure 8 shows the effect of increasing tank volumes on the fraction absorbed *versus* dose relationship. Equal tank volumes were used, ranging from 50 to 200 mL per tank. Increasing the tank volume has two effects. First, the level of drug required to saturate the tank increases. This changes to some degree the range of doses over which dose-dependent absorption occurs. Second, the drug residence time increases, so the drug is available for absorption for a longer period. This causes an upward shift in the fraction absorbed. The combined effect is that increasing the tank volume increases the fraction absorbed and decreases the dependency of absorption on dose. In the analogous *in vivo* situation, ingestion of a large volume of fluid with a poorly absorbed drug may improve the degree of absorption. However, the effect may be attenuated if there is a concomitant increase in flow rate in the intestine.

The effect of changing the relative tank volumes is shown in Fig. 9. Tank volume ratios were varied from 1:1 to 1:10. Although the jejunum is much longer than the duodenum, substantial water reabsorption occurs throughout the upper intestine. Therefore, the relative volume in the duodenum compared with the jejunum is not as low as would be suggested from a purely geometrical calculation. The volume ratios studied reflect these considerations. From the simulations, an increase in the tank volume ratio causes a small vertical shift in the fraction absorbed but has little effect on the shape of the curve. The shift is due to the increase in residence time with increasing total volume. The simulations shown in Fig. 9 all fell in the case 2 category, *i.e.*, only the first tank was saturated. Since the tank 1 volume was held constant, the lack of change in the degree of dose dependency with volume ratio change is reasonable. Overall, changing the relative tank volumes appears to have little

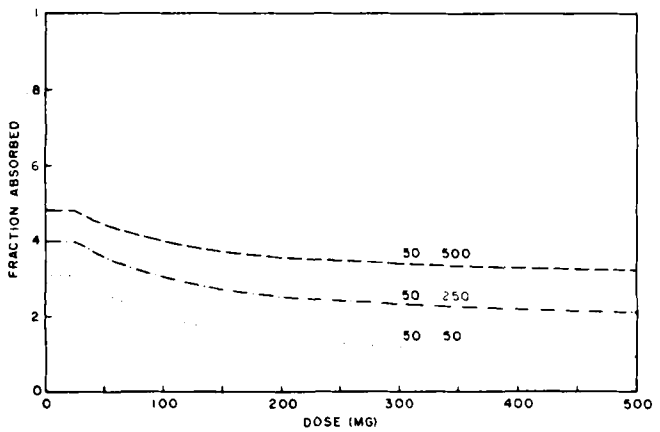

Figure 9— *Effect of relative tank volumes on the fraction of dose absorbed. The ratio is shown as tank 1:tank 2.*

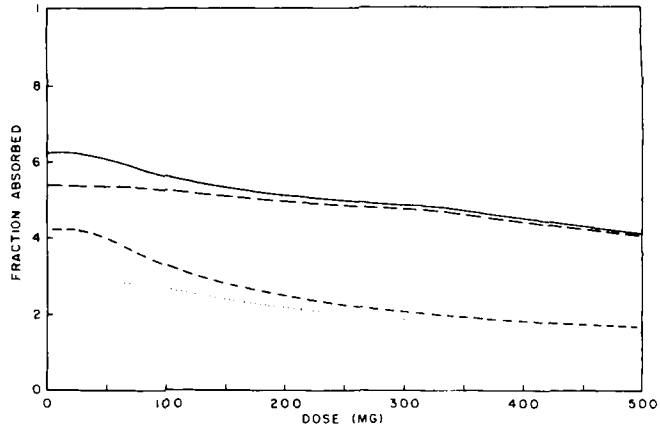

Figure 10—*Effect of pH profile on fraction of dose absorbed. Key: (—) pH_1 = 5.0, pH_2 = 6.7; (— —) pH_1 = 6.7, pH_2 = 6.7; (- - -) pH_1 = 5.0, pH_2 = 8.0; (· · ·) pH_1 = 6.7, pH_2 = 8.0.*

effect on the dose dependency of absorption over a reasonable range of volume ratios.

pH Profile—Simulations of drug absorption with several pH profiles are shown in Fig. 10. These represent the range of pH profiles one might reasonably expect to encounter in a normal patient population: low pH (5.0-6.7), high pH (6.7-8.0), flat pH profile (6.7), and sharp pH profile (5.0, 8.0) were simulated at a fixed drug pK_a of 6.7. The pH in tank 1 is the dominant factor in the determination of the shape of the fraction absorbed *versus* dose relationship. Within 2 units of the pK_a, the lower the tank 1 pH relative to the pK_a, the greater the fraction absorbed. This results from the higher fraction in the un-ionized, absorbable form when the pH is below the pK_a. The effect is only significant at doses in the vicinity of the solubility in tank 1 and below, since at high doses the solubility rather than the fraction un-ionized becomes the absorption-limiting factor. The pH in the second tank appears to determine the fraction absorbed. When the pH in tank 2 is similar to the pK_a, solubility may be low enough to cause case 3 behavior. When the pH in tank 2 is above the pK_a, solubility is higher due to ionization, and case 2 conditions will be operative.

From these simulations it appears that day-to-day and patient-to-patient variation in intestinal pH profile can play a significant role in the determination of the extent of absorption for incompletely absorbed drugs. This explains in part the observation that drugs which are poorly absorbed often exhibit variable absorption.

Model Assumptions—The assumptions made in the mixing tank model affect the simulations of the fraction absorbed *versus* dose. For instance, it is assumed that there is bolus delivery to the duodenum and that dissolution is instantaneous in both tanks while the concentration is below saturation. This provides a rather crude approximation of the input and dissolution functions which occur after oral drug administration. Passage of monolithic dosage forms out of the stomach intact would be an example of bolus input, but in most cases, the dosage form breaks up in the stomach so that delivery to the duodenum occurs over an interval of at least several minutes. The dissolution rate may be slow even for dosage forms designed for immediate drug release and particularly so for drugs with low solubility in intestinal fluids. If the dissolution rate is slow compared with the transit rate, absorption will be poorer than predicted by the mixing tank model analysis.

There are three assumptions which pertain to the absorption characteristics of the drug. First, absorption is negligible in the stomach as compared with the small intestine. It has been shown experimentally that for weak acids, such as sulfonamides and barbiturates which would be expected to be relatively well absorbed from the stomach (from pH-partition considerations), absorption occurs 5–10 times faster in the small intestine (10). Second, drug absorption occurs principally in the un-ionized rather than the ionized form. This is the basis of the pH-partition hypothesis (1). Both of these assumptions tend to underestimate the fraction absorbed, since absorption in the stomach or absorption of ionized drug would add to the overall extent of absorption. The third assumption with respect to drug absorption is that the drug is absorbed by a first-order process. First-order absorption applies to a broad range of drugs and is a reasonable assumption in the absence of specific data indicating that a saturable mechanism is in effect.

System assumptions pertain to the selection of values for the pH profile, the volume in the intestine, and the flow rate. The pH profile is constrained by the range of values which occurs physiologically. The volume and flow rate are interrelated. The flow rate in the intestine changes with ingestion of food and fluids, due to changes in gut motility and reabsorption of water. The as-

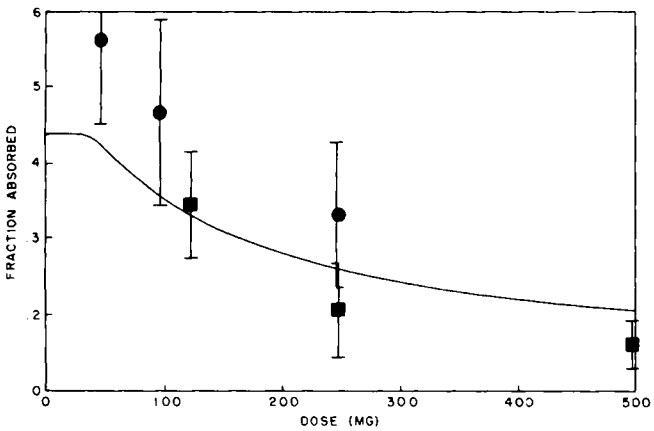

Figure 11—*Fraction absorbed* versus *dose simulated for chlorothiazide absorption. Data are taken from Refs. 5 (●) and 6 (■). Error bars indicate standard deviations. The solid line is the simulated data, using parameter values listed in the* Appendix.

sumption that the flow rate is constant throughout the small intestine therefore represents a simplified view of intestinal transit.

Simulation of Chlorothiazide Oral Absorption -Figure 11 shows a simulation for oral absorption of chlorothiazide. The selection of parameters used in this simulation is discussed in the *Appendix*. The experimental data were taken from two studies by Welling *et al.* (5, 6) in which solutions of chlorothiazide (prepared with the salt) were administered orally at different dosages. In the first study, doses of 50, 100, and 250 mg were administered. In the second study, the doses were 125, 250, and 500 mg. Although the relationship between the fraction absorbed and dose followed the same form in both studies, the actual extent of absorption seemed to be lower overall in the high-dose-range study, even when the same dosage was administered. The apparent displacement of the results of the second study from those of the first study may partly be explained by a difference in volume and transit rate in the two studies since the fluid intake protocol was not identical in both cases. Meyer and Straughn (11) and Welling and Barbhaiya (12) have shown that increasing the transit time of chlorothiazide in the GI tract, *via* concomitant administration of corn oil emulsion or a meal, resulted in substantial improvement in chlorothiazide bioavailability. A modest increase in fluid intake (12) had only a small effect, however, suggesting that volume/transit rate effects cannot explain all of the difference between the two studies. Comparison of both sets of data with the simulation curve indicates that the form of the fraction absorbed *versus* dose relationship is well described by the mixing tank model. Therefore, the dose-dependent absorption of chlorothiazide may be attributable to solubility ionization-permeability effects rather than a saturable transport mechanism in the intestinal wall. In particular, dose dependency of chlorothiazide may be attributable to limited solubility. Additionally, inspection of the pK_a simulation (Fig. 6) suggests that the low ionization constant is a major limitation to the extent of absorption.

Simulation of Hydrochlorothiazide Absorption—Figure 12 shows a simulation for oral absorption of hydrochlorothiazide. System parameters used

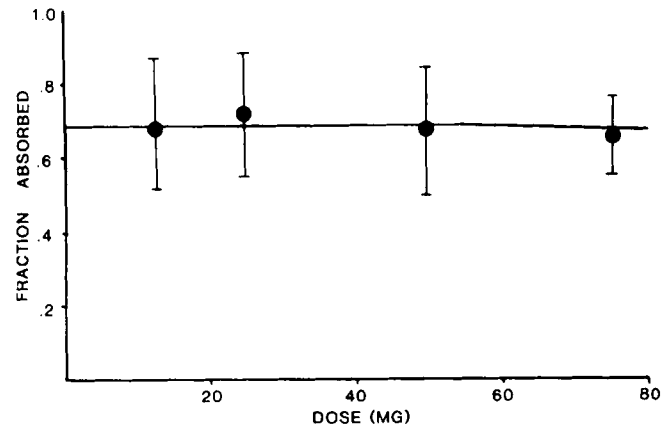

Figure 12—*Fraction absorbed* versus *dose simulated for hydrochlorothiazide absorption. Data are taken from Ref. 12. Error bars indicate standard deviations. The solid line is the simulated data, using parameter values listed in the* Discussion *and the* Appendix.

for chlorothiazide were kept the same for hydrochlorothiazide. The drug parameters were changed to literature values of intrinsic solubility (609 mg/L) (13) and pK_a (8.8) (13) and a lower estimate of the absorption rate constant (0.015 min^{-1}) to reflect the higher polarity of hydrochlorothiazide. The experimental data were taken from a study of eight subjects by Beerman and Groschinsky-Grind (14). Doses of 12.5, 25, 50, and 75 mg were administered orally. Urinary excretion data indicated that absorption was dose proportional, ~68% of the amount administered at each dose. Simulation of the dose-fraction absorbed relationship using the model correctly predicted the dose proportionality of hydrochlorothiazide absorption.

The difference in absorption behavior of hydrochlorothiazide from that of chlorothiazide is partly attributable to its higher solubility-dose ratio and partly due to the higher pK_a. Hydrochlorothiazide is in the un-ionized, absorbable form to at least a 90% extent in both the duodenum and the jejunum, whereas chlorothiazide is mainly in the ionized form at jejunal pH. These factors lead to the higher efficiency of absorption of hydrochlorothiazide that is observed clinically.

APPENDIX: Numerical Analysis and Parameter Value Selection

Although the initial value problems for cases 1 and 2 are analytically solvable with respect to their individual concentration-time profiles, the determination of τ_{2A} and τ_{2B} in case 3 is most conveniently achieved by using a zero-finding routine. In a given trial, the particular case followed depends on the values of the parameters such as solubility, dose, pK_a, flow rate, and intrinsic absorption rate of the drug. Also, case switching may occur with time as levels exceed or fall below saturation in the tanks. To accomodate all possibilities, a BASIC program was written that incorporated the three cases and allowed for case switching at τ_1, τ_{2A}, and τ_{2B}. Appropriate initial conditions were set for each case, depending on the order of τ_1, τ_{2A}, and τ_{2B}. It was thereby possible to examine the effects on the concentration-time profile and fraction absorbed for a wide variety of parameter values.

System parameters	V_i	volume of tank i
	pH_i	pH of tank i
	Q_i	flow rate from tank i
Derived system parameters	KT	Q_1/V_1
	KE	Q_2/V_2
Drug parameters	pK_a	
	solubility (intrinsic)	
Derived drug parameters	k_{ai}	intrinsic absorption rate constant in tank i

Drug variable	X_0	dose
Independent variable	t	time
Dependent variables	X_i	amount in tank i at time t
	$X_{t\text{-OUT}}$	amount existing unabsorbed at time t
Derived variables dictating initial value problem switching	τ_1	time when X_1/V_1 falls below C_{s1}
	τ_{2A}	time when X_2/V_2 first exceeds C_{s2}
	τ_{2B}	time when X_2/V_2 falls below C_{s2}
Derived system/drug parameters	$R_i = k_{ai}f_{ui}C_{si}$	

The HP BASIC programs written for an HP 87 system are available on request from the authors. For the simulation of the chlorothiazide dose-dependent absorption, pH, and volumes in the two mixing tanks were chosen to simulate duodenum and jejunum: $pH_1 = 5.5$, $V_1 = 75$ mL; $pH_2 = 7.7$, $V_2 = 150$ mL. This flow rate was 2 mL/min, which is representative of physiological conditions (8). The pK_a [6.7 (15)], solubility [0.4 g/L at pH 4, 0.65 g/L at pH 7 (16)], and the usual range of doses [50 500 mg (5, 6)] were taken from the literature. The intrinsic absorption rate constant (0.017 min^{-1}) was estimated on the basis of the effective permeability and the surface area to volume ratio, *i.e.*, $k_{ai} = (SA_i/V_i)\cdot P_{eff}$, where $1/P_{eff} = (1/P_{aq}) + (1/P_w)$. Effective permeability is considered to be a function of the drug and independent of the segment of small intestine under consideration. For chlorothiazide, P_{eff} was estimated to be 7×10^{-5} cm/min. The ratio of surface area available for absorption to volume was estimated to be 250, a value between the value calculated on a geometric basis using a filled cylinder model and the value calculated by dividing the estimated total intestinal surface area (including villi surface area) by the cylinder model volume.

These parameter values were also used as a basis for simulations of levels in tanks 1 and 2 in the *Theoretical Section* and for the fraction absorbed *versus*

dose curves in the *Results*. Where other values were used, they are noted in the appropriate figure legends. In the *Results*, values of important drug and system parameters were varied systematically to ascertain their effects on the dose dependency of absorption.

Microcalorimetric Investigation of the Binding of Some Chemotherapeutic Agents and Related Molecules to Calf Thymus DNA

WILLIAM R. VINCENT *, LEONARD S. ROSENBERG, and STEPHEN G. SCHULMAN ˣ

Received May 24, 1982, from the *College of Pharmacy, University of Florida, Gainesville, FL 32601.* Accepted for publication January 10, 1983.

*Present address: Arnold & Marie Schwartz College of Pharmacy and Health Science, Long Island University, Brooklyn, NY 11201.

Abstract □ Batch microcalorimetry was used to estimate directly the standard enthalpies of the binding of small molecules to DNA. These values were compared with those obtained from spectrophotometric binding constants and van't Hoff plots. The close agreement between the independently obtained enthalpies indicates that the appropriate (best) binding model has four phosphates per binding site. Thermodynamic binding constants were obtained from apparent binding constants measured at different ionic strengths. From these and the measured standard enthalpies, standard free energies and standard entropies of binding were calculated. The weak, presumably external, binding alleged to occur at high formal molar concentration ratios of ligand to DNA bases could not be detected by a measurable heat of binding.

The binding of certain aromatic cations to nucleic acids for some time has been implicated as a primary process in antibacterial, antiprotozoal, antiviral, mutagenic, and antineoplastic activity (1–7). The changes in the thermal stability and the hydrodynamic and spectroscopic properties of DNA to which aromatic cations are bound have been suggested to indicate that at high ratios of formal DNA base to cation concentrations, intercalation of the flat aromatic portion of the ligand between adjacent base pairs on DNA occurs (8). Intercalation (also called type I binding) entails insertion of the flat aromatic portion of the ligand between base pairs (8–10) or bases (11–12) on DNA, accompanied by a partial unwinding of the double helix. In crystalline samples, X-ray diffraction spectrometry has provided direct evidence for the intercalation of the fungal antibiotic, dactinomycin, between the adjacent base pairs of DNA (13, 14).

The intercalative mode of binding does not appear to extend to all ligand molecules bound to a DNA helix (4). Rather, it is believed that only one molecule of ligand can be accommodated in an intercalative fashion for every four or five phosphate groups of the DNA helix. When nearly all intercalative binding sites of a DNA double helix are occupied, further interaction of the DNA with excess ligand is still able to occur. However, this binding is weaker than the intercalative binding, is not accompanied by hydrodynamic changes in the DNA solutions, and is believed to entail the electrostatic association of the cationic ligands with the anionic phosphodiester linkages at the surface of the helix. This is referred to as external (or type II) binding and occurs in solutions of low DNA base to ligand formal concentration ratios. At high ligand concentrations, some of the larger polycyclic aromatic molecules appear to be bound to the surface of DNA as dimers, because complexes can be spectroscopically distinguished in which there are two ligand molecules bound for each DNA phosphate group (15). The apparent relationship of the reversible reactions of aromatic cations with nucleic acids to the antimicrobial, antineoplastic, and mutagenic activities of the former has resulted in considerable interest in the qualitative and quantitative investigation of these interactions. These studies have usually been concerned with the stoichiometries and formation constants of the complexes formed between the ligands and the nucleic acids (1–22), although more recent work has been centered about the kinetics of binding (16, 21). Techniques such as electronic absorption spectrophotometry, fluorometry, differential spectrophotometry, and circular dichroic spectrophotometry have been employed to determine the amounts of bound and free ligand at each point in the titration of a so-

lution of the free ligand with a concentrated solution of nucleic acid.

THEORETICAL SECTION

Methods for evaluating equilibrium association constants for the binding of small molecules to DNA are generally derived from the independent-site model, developed by Scatchard (23), to deal with the binding of small molecules to proteins and the extension of this model by McGhee and von Hippel (24) to include ligand cooperativity. Peacocke and Skerrett (25) redefined the parameters of the Scatchard equations to allow their application to nucleic acids. In this approach, the ligand is titrated with a solution of DNA of known phosphate concentration, and the concentration of free ligand [B] is determined at each point in the titration either by direct spectrophotometry or by spectrophotometry subsequent to separation of free and bound ligand by equilibrium dialysis or some other suitable method. From the formal ligand concentration C_B, the former DNA phosphate concentration C_P, and the equilibrium free ligand concentration, the average number of bound ligand molecules (occupied binding sites) per phosphate (r) is calculated at each point in the titration:

$$r = \frac{C_B - [B]}{C_P} \qquad \text{(Eq. 1)}$$

For two classes of independent, noninteracting binding sites I (intercalative) and II (external):

$$r = \frac{n_I K_I [B]}{1 + K_I [B]} + \frac{n_{II} K_{II} [B]}{1 + K_{II} [B]} \qquad \text{(Eq. 2)}$$

where n_I and n_{II} are the reciprocals of the numbers of phosphates in each type of binding site and K_I and K_{II} are the equilibrium association constants, belonging to class I and class II binding, respectively. The reactions characterized by K_I and K_{II} may be written:

$$B + S_I \rightleftarrows BS_I \qquad \text{(Eq. 3)}$$

and:

$$B + S_{II} \rightleftarrows BS_{II} \qquad \text{(Eq. 4)}$$

where S_I and S_{II} are the type I and type II binding sites on DNA. The equilibria may be written:

$$K_I = \frac{[BS_I]}{[B][S_I]} \qquad \text{(Eq. 5)}$$

and:

$$K_{II} = \frac{[BS_{II}]}{[B][S_{II}]} \qquad \text{(Eq. 6)}$$

A plot of $r/[B]$ *versus* r is then constructed. This plot is generally hyperbolic in appearance, and if the components of the system are sufficiently dilute so that no ligand aggregation occurs on the polymer, the plot is usually considered to represent a superposition of the type I and type II processes. If K_I and K_{II} differ by at least an order of magnitude, the type I and type II binding may be resolved into straight lines at the high and low $r/[B]$ extrema, respectively, of the $r/[B]$ *versus* r plot. In this case, the extrema of the hyperbola are linearly extrapolated to the $r/[B]$ and r axes. The line of steep slope (at low values of r) is associated with the type I (intercalative) binding and has a slope $-K_I$ and an intercept on the $r/[B]$ axis of $K_I n_I + K_{II} n_{II}$. The line of shallow slope (at high values of r) associated with the type II (external) binding has a slope of $-K_{II}$ and an intercept on the r-axis of $n_I + n_{II}$.

However, the extrapolation of the legs of the hyperbolic plot to obtain slopes and intercepts places an inordinately high degree of reliance on the data at the extrema of the titrations. It is at the extrema that the data, regardless of how they were obtained, are the least precise.

During the course of investigations in this laboratory (26) of the binding of the singly charged cation of 3-aminoacridine, at pH 5.9 ($pK_a = 8.04$) and ionic strength 5.0×10^{-3}, to double-stranded calf thymus DNA, it was found that at high values of $r/[B]$, there was sufficient curvature in the extremum of the plot of $r/[B]$ *versus* r that it was very difficult to make reasonable linear extrapolation to the $r/[B]$-axis. This led us to hypothesize that the reaction represented by Eqs. 3 and 5 might be inappropriate to represent, even qualitatively, the type I binding. An attempt was made to rewrite the type I binding reaction in a way that might fit the experimental data. A reaction of the form:

$$B + qS \rightleftarrows B(S)q \qquad \text{(Eq. 7)}$$

was chosen, in which an integral number of binding sites, q, would react with BH^+ to form the type I complex $B(S)q$. The equilibrium expression corresponding to Eq. 7 would then be:

$$K = \frac{[B(S)q]}{[B][S]^q} \qquad \text{(Eq. 8)}$$

Since n phosphates are associated with each type I complex:

$$m \cdot q = n \qquad \text{(Eq. 9)}$$

where m is the number of phosphates associated with one type I site, S. In most binding studies, it has been demonstrated that the type I binding is characterized by $n = 4$ or 5. However, in our empirical approach, values of $q = 1$-4 and of $m = 1$-6 were tried in Eqs. 8 and 9. It was found that the best straight lines could be obtained when $m = 2$ and $q = 2$ (*i.e.*, two sites per complex, each site having two phosphates). Hence, for the type I binding of the 3-aminoacridinium monocation:

$$K = \frac{[B(S)_2]}{[B][S]^2} \qquad \text{(Eq. 10)}$$

corresponding to the essentially termolecular overall reaction:

$$B + 2S \rightleftarrows B(S)_2 \qquad \text{(Eq. 11)}$$

The reaction shown in Eq. 11 is difficult to rationalize if both sites which react with B lie on the same DNA molecule, as indeed they must, unless intercalation involves the bridging of ligand between two distinct macromolecules. To test the thermodynamic feasibility of the variously proposed reaction models ($q = 1$, $m = 4$; $q = 1$, $m = 5$; and $q = 2$, $m = 2$) for the intercalative binding of small molecules to DNA, it was decided to attempt to determine the standard enthalpy of binding ($\Delta H°$) for the reactions of several cationic drugs and dyes with calf thymus DNA. These values of $\Delta H°$ could be determined from van't Hoff plots of the appropriately calculated apparent binding constants as a function of temperature. It should be mentioned that the occurrence of a reasonably linear van't Hoff plot alone might be an indication of the chemical significance of the way in which the equilibrium expression is written. The values of $\Delta H°$ taken from the van't Hoff plots could then be compared with enthalpies of reaction (ΔH) determined directly by microcalorimetry. Since the standard state for a solute in dilute solution is taken to be the infinitely dilute solution at standard conditions, the calorimetrically determined values of ΔH may be taken to approximate $\Delta H°$ very well in each case because the concentrations of the reactants will be kept very low ($\sim 10^{-4}$-10^{-3} M). Agreement between the graphically and calorimetrically determined values of $\Delta H°$ then should lend support to the validity of the model used in the calculation of the equilibrium constants giving the best values of $\Delta H°$. Additionally, once the appropriate intercalative binding model is known and the best values of $\Delta H°$ are in hand, it should be possible to determine thermodynamic binding constants by extrapolation to infinite dilution and then to determine the standard entropy of binding ($\Delta S°$). Assessments of the relative importance of DNA-ligand interactions and ligand-water interactions in the binding process could then be attempted. With these objectives in mind, the following study of the binding of four compounds to calf thymus DNA was undertaken.

EXPERIMENTAL SECTION

The pH was maintained throughout this study at 5.50 with an acetic acid-sodium acetate buffer to ensure that all ligands utilized were in only one state of protonation and thereby obviate the necessity to correct for competitive prototropic equilibria.

Ethidium bromide[1] and 9-aminoacridine hydrochloride[2] were recrystallized from 95% ethanol. Doxorubicin hydrochloride[3] was used without further purification. 3-Aminoacridine was prepared by the procedure of Martin and Tong (27). The sodium salt of calf thymus DNA[4] was used without further purification.

The molar absorptivity of each ligand was determined by accurately weighing and dissolving each compound in a 10-mL volumetric flask and then delivering successive 50-μL aliquots of this stock solution into 9.00 mL of pH 5.50 buffer and recording the long-wavelength absorption spectra. A Beer's law plot was constructed for each ligand, with the final concentration of ligand equal to or greater than the final concentration employed in the determination of the DNA-ligand binding constants. Linearity was observed in all cases, indicating that aggregation of the free ligand in solution was negligible within the concentration range employed.

The molar absorptivity of the intercalated form of each ligand was determined analogously by adding the stock solution to a concentrated solution of DNA and recording the absorption spectra after each addition. A Beer's law plot was then constructed and found to be linear. This indicates that successively bound ligands have identical molar absorptivities, irrespective of the degree of saturation of polymer. The final concentration of bound ligand was equal to or greater than the concentration used in the determination of the intrinsic association constant. Variation of temperature and/or ionic strength had no effect on the measured molar absorptivities. The exact molar absorptivity of native calf thymus DNA is disputed in the literature (28–30). Values range from 6300 $L \cdot mol^{-1} \cdot cm^{-1}$ (29) to 6600 $L \cdot mol^{-1} \cdot cm^{-1}$ (31), with the wavelength maximum at either 259 (31) or 260 nm (29). Throughout this study, the concentrations of DNA solutions were determined absorptiometrically at 259 nm with a corresponding molar absorptivity of 6500 $L \cdot mol^{-1} \cdot cm^{-1}$. All absorptiometric measurements were carried out on a recording UV-visible spectrophotometer[5], using cylindrical 5-cm quartz cells.

The intrinsic association constants of all ligands with native double-stranded DNA were determined as a function of temperature and ionic strength. A measured volume and concentration of ligand was added to a known volume and concentration of DNA prior to the titration. Absorption spectra of the preequilibrated DNA-ligand solution were then recorded at temperatures and ionic strengths corresponding to those from which intrinsic association constants were calculated. The titration was then carried out differentially by placing an identical volume of the preequilibrated DNA solution in both the sample and reference compartments. The preequilibration of the DNA solution with ligand ensures that the concentration of unbound ligand is measurable from the outset and allows the differential spectral technique to be optimized for that region of the titration. Aliquots of the known concentration of ligand solution were then added with a micropipet[6] to the sample cell, and the resulting rise in the absorption spectra was recorded. The transfer of ligand solutions was found to be more reproducible than the more commonly used method of transferring the DNA solution, owing to the relatively high viscosity of the latter. Absorption spectra of all ligands during the titration were recorded starting at wavelengths at least 20 nm greater than the first observable absorbance and ending ~20 nm below the analytical wavelength of choice. Analytical wavelengths were chosen according to the ligand and were at the long-wavelength maxima of the free drug. The titrations were performed in duplicate for at least three temperatures between 15°C and 40°C for each ligand and at ionic strengths of 0.1, 0.05, and 0.01. The temperature in the absorbance cell was monitored by a submersible temperature probe and maintained with a constant-temperature bath[7] and a jacketed cell compartment. At least 10 points, and usually 20 points, were acquired in each titration.

The conservation of mass of the ligand requires that:

$$C_B = [B] + [BS] \qquad \text{(Eq. 12)}$$

where B and BS are the free and bound ligand, respectively, and C_B is the total concentration of ligand. At any point in the titration, assuming no aggregative binding, the absorbance is:

$$A_T = \epsilon_B[B]l + \epsilon_{BS}[BS]l \qquad \text{(Eq. 13)}$$

where A_T is the total absorbance at the analytical wavelength of choice, and l is the optical path length of the sample cell. Combination of Eqs. 12 and 13 gives:

$$[B] = \frac{A_T - \epsilon_{BS}C_B l}{(\epsilon_B - \epsilon_{BS})l} \qquad \text{(Eq. 14)}$$

and:

$$[BS] = \frac{\epsilon_B C_B l - A_T}{(\epsilon_B - \epsilon_{BS})l} \qquad \text{(Eq. 15)}$$

for the concentration of free and bound ligand at any point in the titration.

The heat generated by the binding of the ligands by DNA was measured with a batch microcalorimeter[8]. The reaction cells employed in the batch microcalorimeter are of the mixing type, each having two compartments into which liquid reactant can be introduced. The maximum volume that can be contained within each divided cell is 4.5 and 2.5 mL to minimize the heat of dilution and maximize concentration. DNA was introduced into the 4.5-mL compartment, and the ligand was introduced into the 2.5-mL chamber. The temperature within the microcalorimeter was maintained at 25.00 ± 0.01°C with a thermostatically controlled air bath[9] with an external adjunct water bath[10]. The temperature inside the sealed microcalorimeter was checked with a calibrated thermostat embedded in a heat sink. The microcalorimeter at thermal equilibrium was rotated, allowing the reactants to mix, and the heat of reaction was recorded. The output from the microcalorimeter was recorded on a linear strip chart recorder with a disk-driven integrator[11]. The microcalorimeter was calibrated with an electrical calibration current which passed through the reactant cell for a measured period of time[12]. A comparison of the signal from the calibration run with that measured for the heat of reaction of ligand with DNA yields an exact molar enthalpy of reaction. The heat of dilution of both reactants was measured and subtracted from the measured heat of reaction. The apparent enthalpy of binding can be calculated from:

$$\Delta H = \frac{Q}{C_B V_i f_{BS}} \qquad \text{(Eq. 16)}$$

where Q is the measured heat, V_i is the initial volume of ligand, C_B is the initial concentration of ligand, and f_{BS} is the fraction of the total ligand bound by the DNA at the end of the reaction. An *a priori* knowledge of the intrinsic association constant at the same temperature and ionic strength is necessary to calculate f_{BS}. However, to a first approximation, the value of the binding is not necessary since an excess of DNA was used, such that f_{BS} was >0.95. The error incurred in this assumption is <5% of the final value. The heat of binding for each compound was measured at ionic strengths of 0.1, 0.05, and 0.01. Data were analyzed using the facilities of the Northeast Regional Data Center[13].

RESULTS AND DISCUSSION

Intercalative binding of a cationic ligand with native DNA entails the slipping of the aromatic drug in between adjacent base pairs on the double helix. Concomitantly, the molar absorptivity of the ligand decreases dramatically. The concentration of free and bound ligand can be evaluated at each point in the titrations by Eqs. 14 and 15. These values were subsequently used for the evaluation of apparent binding constants from Eqs. 8 and 9 with values of $m = 1$–6 and $q = 1$–4, as described previously (26). Particular attention was paid to the values of $m = 4$, $q = 1$ and $m = 5$, $q = 1$ (corresponding to the modified Scatchard treatment of type I binding), $m = 3$, $q = 1$ (corresponding to the suggested stoichiometry for type II binding), and $m = 2$, $q = 2$ [for the termolecular treatment of type I binding (26)]. Of these, only values of $m = 4$, $q = 1$ and $m = 2$, $q = 2$ yielded binding constants which did not exhibit systematic variance and were positive over the entire titration interval. In addition, the values of $m = 4$, $q = 1$ gave estimated errors in the binding constants which were consistently less than those calculated by using values of $m = 2$, $q = 1$. However, both models gave feasible results, and each must be considered further.

Binding data for each compound at a different absolute temperature (T) were treated in the manner described above, with values of $m = 4$, $q = 1$ (bimolecular overall reaction) and $m = 2$, $q = 2$ (termolecular overall reaction). The logarithms of the apparent binding constants calculated therefrom are plotted against reciprocal absolute temperature (van't Hoff plots) in Figs. 1 and 2, respectively. The best first-order least-squares lines for these data are also shown, the slopes of which should be $-\Delta H°/2.303R$, where R is the universal gas constant. The calculated values of $\Delta H°$ are listed in Table I. The van't Hoff plots are apparently linear, with the deviations from linearity being very similar for both models. If the linearity of the plots is taken as a criterion for the validity of a binding model, then both models appear to be equally correct. However, a major difference between them is the magnitudes of the resultant values of $\Delta H°$ which are significantly larger for the termolecular model than those from the bimolecular model. Thus, to establish the appropriate model, the standard enthalpies of binding of each compound to DNA must be measured by an independent experimental procedure.

The calorimetric measurement of the binding enthalpies was therefore performed by batch microcalorimetry. The major advantage of batch microcalorimetry over the more commonly used flow calorimetry is the relatively small amounts of reagents required for the analysis. The heats of binding were found to be virtually identical at three ionic strengths and were subsequently averaged, and the resulting standard enthalpies for each compound were calculated (Table I). The calorimetrically determined enthalpies are in agreement with the values described above for the bimolecular model and significantly different from the termolecular values. This agreement of the standard enthalpies of binding, which were determined independently by

spectrophotometry and calorimetry, is strong evidence for the bimolecular model with four bases per binding site ($m = 4, q = 1$).

The determination of enthalpic contributions to the binding process inevitably leads to questions about the corresponding entropic contributions and to the standard free energy of the system. To calculate the standard free energy of binding from the association constant for the DNA-ligand interaction, the thermodynamic association constant must be known. Only from the thermodynamic constant can the standard free energy of binding ($\Delta G°$) be calculated. The standard entropy of binding ($\Delta S°$) can then be calculated from $\Delta G°$ and the standard enthalpy of binding, $\Delta H°$, using:

$$\Delta S° = \frac{\Delta G° - \Delta H°}{T} \qquad \text{(Eq. 17)}$$

The majority of reported association constants in the literature for DNA-ligand interactions are apparent equilibrium association constants. The use of an apparent association constant in the calculation of the free energy of binding does not yield $\Delta G°$ but rather an entity which varies with the ionic strength. The calculated entropy of binding will then also appear to fluctuate with ionic strength. However, the determination of a thermodynamic affinity constant extrapolated to zero ionic strength allows the direct and unambiguous determination of $\Delta G°$ and, subsequently, $\Delta S°$, which are thermodynamic constants of the reaction.

The Debye-Hückel relationship (Eq. 18) can serve as a starting point from which to correct the apparent association constants for ionic screening of the various reactants. The activity coefficient of the ith species can be calculated from:

$$-\log \gamma_i = \frac{AZ_i^2\mu^{1/2}}{1 + \mu^{1/2}} \qquad \text{(Eq. 18)}$$

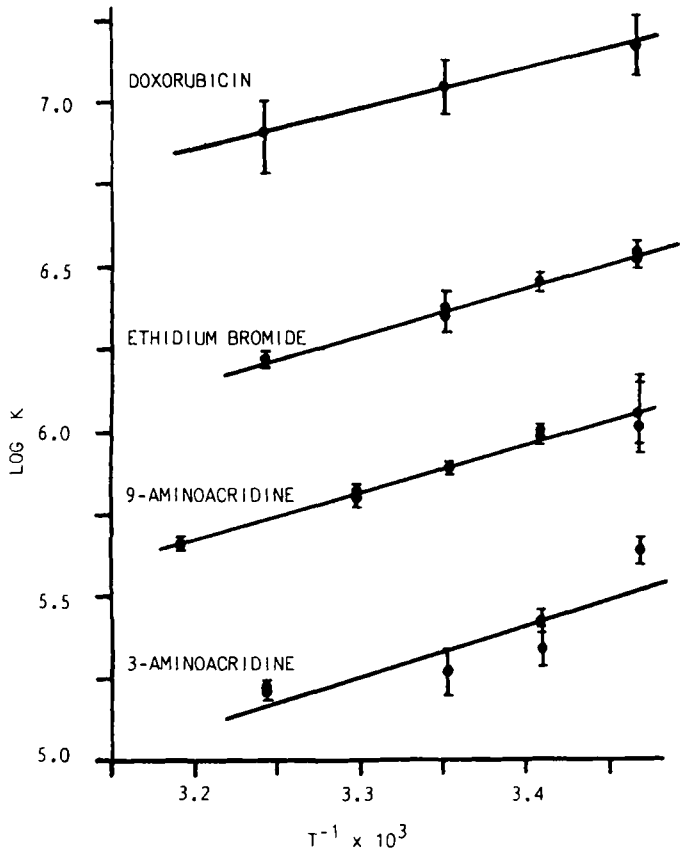

Figure 1—*Van't Hoff plots for the indicated compounds, assuming a bimolecular model* (m = 4, q = 1).

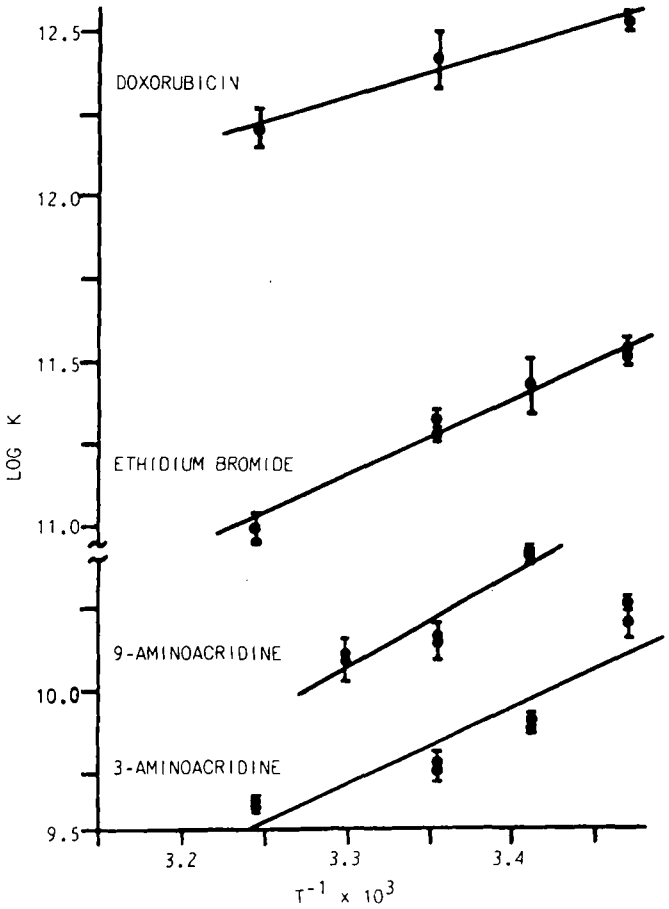

Figure 2—*Van't Hoff plots for the indicated compounds, assuming a termolecular model* (m = 2, q = 2).

where A is a constant dependent on the temperature and dielectric constant of the solute, Z_i is the charge on the ith species in solution, and μ is the ionic strength of the solution.

The thermodynamic equilibrium constant $K°$ can be related to the apparent constant K by:

$$K° = K\frac{\gamma_{BS}}{\gamma_B\gamma_S} \qquad \text{(Eq. 19)}$$

where the subscripts of the activity coefficients refer to the reactant species. Combination of Eqs. 18 and 19 yields, in logarithmic form:

$$\log K = \log K° + C\frac{\mu^{1/2}}{1 + \mu^{1/2}} \qquad \text{(Eq. 20)}$$

It is then possible to extract a thermodynamic association constant. Even if the Debye-Hückel equation is not quite correct for DNA solutions, the fact that log $K°$ is an intercept and not a slope minimizes the dependence on how γ_i is calculated. The apparent association constants at three ionic strengths and the thermodynamic association constant taken from the corresponding least-squares intercept are given for each ligand in Table II. The association constants agree well with the results of other workers (32–36). Values for all thermodynamic parameters are given in Table I. Note that the precision of the calorimetrically obtained enthalpies is better than that which could be obtained from spectrophotometric data.

Examination of the thermodynamic parameters gives some insight into the molecular forces which control the binding process. A favorable enthalpy of binding should be evident with large, planar, aromatic molecules. Their pla-

narity allows their insertion into the DNA helix with minimal disturbance of the DNA structure. Larger compounds enhance the opportunity for the van der Waals binding interaction between the ligand and the DNA bases. The largest binding enthalpy for ligands studied herein is that of ethidium bromide. In contrast to 9-aminoacridine and 3-aminoacridine, which also contain tricyclic aromatic ring systems, ethidium bromide has an exocyclic phenyl substituent which might at first be expected to sterically inhibit its intercalation. However, the observed large enthalpy of binding relative to those of the aminoacridines suggests that the phenyl ring of ethidium bromide reinforces binding. This would seem to indicate that the phenyl substituent serves to extend the area of the ligand which is bound to the DNA base pairs, perhaps by becoming coplanar with the aromatic nucleus of the ligand. In contrast, doxorubicin, which exhibits the least-favorable binding enthalpy, has a nonplanar ring linearly annulated with the aromatic system and an exocyclic amino sugar group. The weakness of the enthalpic binding contribution may be attributed to either the steric inhibition of the insertion of the planar portion of the molecule into the DNA helix or to the disruption of the DNA structure by the intercalation of the buckled ring segment or the amino sugar side chain.

The entropy of binding is probably influenced mainly by changes in the translational freedom due to the binding or release of solvent molecules by the ligands and/or the DNA. This is evidenced by the entropy of binding for doxorubicin which is much larger than that observed for the other ligands. The binding of the doxorubicin can be expected to displace water from its amino sugar side chain. In addition, the structure of the DNA helix and its accompanying waters of hydration may be disrupted significantly if the buckled ring or the amino sugar group makes contact with the double helix. Because of the limited number of compounds investigated in this study and the substantial structural differences between them, it would probably be premature and excessively speculative to attempt to account for the differences between their enthalpies and entropies of binding to DNA in any but those most obvious examples just cited.

Batch microcalorimetry can be used to investigate type II binding as well. The only condition necessary for the separation of type I and type II binding is that their heats of complexation be different and measurable. In that type II binding becomes prevalent in the presence of an excess concentration of free ligand, type II binding should demonstrate a heat of interaction in this region of titration, and an enthalpy of binding should be measurable by microcalorimetry. By using excess DNA, the heat for intercalative binding can be accurately calculated at any known concentration of DNA and ligand. By using these calculated values as a reference and by repeating the measurement with excess free ligand, any deviation from the reference value will be taken as being due to external binding. Table III shows the results of this experiment. Even in the presence of an excess free ligand concentration, which is equal to the total concentration of bound ligand, the measured enthalpy of binding is invariant from the reference value for intercalative binding. The heats of binding were checked at a number of bound ligand–free ligand concentrations, and in all cases the resulting enthalpy was equal to the reference value within experimental error.

The lack of a measurable heat of binding for type II interactions can be explained in two ways. First, type II binding may have a small, unmeasurable heat of complexation, such that the batch microcalorimeter cannot detect this heat above the reference value. Second, type II binding may be an artifact of the Scatchard plot. As such, external binding may not occur for nonaggregating ligands. For ligands which aggregate, if the concentration is maintained at a low value, external binding again may not occur.

The inaccuracy in measuring the exact concentration of free and bound ligand, when either is in a large excess, is great. Such is the case for external binding, in which it is an excess of free ligand that creates the difficulties. The curvature in the modified Scatchard plots is probably due to this inability to accurately measure free and bound ligand concentrations.

Antiradiation Compounds XIX: Metal-Binding Abilities of Thioureas

WILLIAM O. FOYE ˣ and CHING-CHIU CHAO

Received July 13, 1983, from the *Samuel M. Best Research Laboratory, Massachusetts College of Pharmacy and Allied Health Sciences, Boston, MA 02115.* Accepted for publication August 5, 1983.

Abstract □ Metal-binding stability constants for a series of *N*- and *N,N'*-substituted thioureas with Cu(II), Ni(II), Al(III), and Fe(III) ions were determined by potentiometric titration. The sequence of constants for thiourea, *N*-methylthiourea, and *N,N'*-dimethylthiourea indicated steric effects of the methyl groups and that both nitrogen and sulfur were involved in the complexation. The magnitude of the constants was somewhat lower than those of the simple peptides. The mechanism of protection against ionizing radiation by thioureas is probably due to hydrogen-atom transfer rather than binding of metal ions that catalyze cellular oxidations.

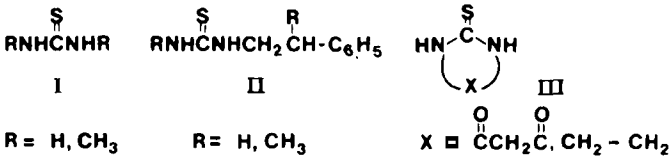
Keyphrases □ Thioureas—metal-ion complexes, stability constants, antiradiation protection □ Antiradiation protection—thioureas, metal-ion complexes, stability constants □ Stability constants—thioureas, metal-ion complexes, antiradiation protection

Metal-ion complexation has been shown or postulated to be involved in a number of biological activities. The effect of complexing agents such as dithiocarbamates (1) and some thioureas (2) on the inhibition of dopamine-β-oxidase, a copper-containing enzyme, is well known. Metal-ion complexation has also been postulated for the antithyroid activity of thiouracil (3), the inhibitory effects of dithiocarbamates against *Mycobacterium tuberculosis* (4), and the fungistatic effects of dithiocarbamates and other complexing agents (5). The nitrate reductase complex of *Neurospora crassa* is also sensitive to inhibition by metal-binding agents, including thiourea (6), and polyphenol oxidase is also inhibited by thiosinamine (allylthiourea) (7).

Several postulations (8–10) regarding the protective effects of a number of metal-binding radiation-protective agents have also been made. Although thiourea and its simple derivatives have some protective ability for whole-body irradiation of animals, these effects have not been appreciable. Thioureas have, however, shown substantial radiation-protective effects in other systems, such as mouse lung (11), human erythrocytes (12), T_2 phage (13), Ehrlich ascites cells (14), and macromolecules (15) (Table I). The radiation-protective effects of thiourea have been attributed to metal binding (11).

With such a significant number of postulations involving the metal-binding aspects of thioureas, it is surprising to find that, other than for thiourea itself (16), metal-binding abilities of substituted thioureas have not been determined. Stability constants for a series of cyclic thioureas, including mercaptoimidazoles and mercaptouracils, were determined with copper, iron, and aluminum ions (17), and the constants were surprisingly high. It was considered important, therefore, to measure the metal-binding stability constants for a series of alkyl, aralkyl, and cyclic thioureas. Knowledge of the magnitude of the constants would indicate whether thiourea complexes were capable of existence in the presence of cellular complexing agents, such as peptides, or whether thiourea might function as a transient metal complexer.

Compounds of the general structures I–III were measured for binding abilities to Cu(II), Ni(II), Al(III) and Fe(III) ions using the method of potentiometric titration.



EXPERIMENTAL SECTION

Materials—Analytical reagent-grade[1] aluminum chloride hexahydrate, cupric chloride dihydrate, ferric nitrate nonahydrate, and nickel(II) chloride hexahydrate were used for the metal complexation determination. Carbonate-free 0.01 M KOH was prepared according to the method of Armstrong (18). Solutions of the metal salts were prepared in boiled distilled water and stored in polyethylene bottles under nitrogen; they were diluted quantitatively with carbon dioxide-free water just prior to use. Normalities were checked against potassium biphthalate.

The organic ligands were obtained commercially[2]. *N*-Methyl-*N'*-phenethylthiourea was reported previously (19), and *N*-methyl-*N'*-phenyl-2-propylthiourea was described earlier (20). Purity was ascertained by TLC using chromagram sheets[3]. Solutions (0.1%) of the compounds in ethanol were spotted, and the sheets were developed with benzene–methanol (8:2); spots were detected with iodine vapor.

Ionization Constants—The method of Albert and Serjeant (21) was used, which consisted of titrations of 0.001 M solutions of the compounds in 95% ethanol with 0.01 M KOH in 0.5-mL portions. The pH was recorded with a pH meter[4] with glass and calomel electrodes after each addition. Each titration thus yielded 10 pH values, giving 10 values for the pK_a, which were averaged (Table II). Since most of the pH values fell outside the 5–9 range, corrections were made for hydrogen-ion concentrations.

Stability Constants—Potentiometric titrations were carried out under nitrogen in 95% ethanol at 25°C with the described pH meter. Volumes of 50 mL of the 0.001 M solutions of the organic ligands were titrated with 0.01 M KOH in 0.5-mL portions, first in the absence of metal ions, and then in the

Table I—Radiation Protection by Thioureas

Compound	Test System	Radiation Dose	Protection	Ref.
Thiourea	Mice	875 rad	Increased lifespan	31
Methylthiourea	Mice	650–700 rad	No effect on lifespan	32
Allylthiourea	Mice	700 rad	No effect on lifespan	8
Phenylthiourea	Mice	650–700 rad	No effect on lifespan	32
α-Naphthylthiourea	Mice	200 rad	No effect on lifespan	33
Ethyl isothiourea	Mice	800 rad	Increased lifespan	34
Sulfanilylthiourea	Mice	900 rad	Increased lifespan	35
Guanylthiourea	Mice	900 rad	Increased lifespan	35
Thiourea	Human erythrocytes	84 krad	Protection	12
Thiourea	T_2 phage	1000 rad/s	Protection	13
Thiourea	Ehrlich ascites cells	4000 rad	Protection	14
Allylthiourea	Human erythrocytes	84 krad	Protection	12

Table II—Ionization Constants [a]

Compound	pK_a
Thiourea	2.54[b]
N-Methylthiourea	3.06
N,*N*′-Dimethylthiourea	2.98
N-Methyl-*N*′-phenethylthiourea	3.12
N-Methyl-*N*′-phenyl-2-propylthiourea	3.04
2-Imidazolidinethione	3.08
2-Thiobarbituric acid	4.15
Thioacetamide	3.34

[a] Determined in 95% ethanol at 25°C. [b] Literature value (H_2O) is 2.03: T. J. Lane, J. A. Ryan, and J. L. Walter, *J. Am. Chem. Soc.*, **78**, 5560 (1956).

presence of 0.0005 mol of divalent metal salt or 0.00033 mol of trivalent metal salt.

Volumes of 50 mL of the same quantities of the metal salts were also titrated with 0.01 M KOH. The pH readings were recorded 2 min after each addition of titrant to allow equilibrium to be reached. Solvent concentration at the end of the titrations (if all 10 additions were made) was ~72% ethanol.

Calculations were performed as previously described (17) with a computer. The log K values obtained for the divalent metal complexes are recorded in Table III; values for the trivalent metal complexes are recorded in Table IV. Values for K_1, K_2, and K_3 were obtained from Eqs. 1–3, according to Flood and Loras (22) and Albert (23):

$$K_1 = \frac{\bar{n}}{(1-\bar{n})[L^-]} \quad \text{(Eq. 1)}$$

$$K_2 = \frac{(\bar{n}-1)}{(2-\bar{n})[L^-]} \quad \text{(Eq. 2)}$$

$$K_3 = \frac{(\bar{n}-2)}{(3-\bar{n})[L^-]} \quad \text{(Eq. 3)}$$

where $\bar{n}$ is the average number of ligand molecules bound by a metal ion at any stage in complex formation and $[L^-]$ is the concentration of the free chelating species.

Formation curves were plotted ($\bar{n}$ *versus* $-\log L^-$) to show whether stepwise complexation may have taken place. No steps were shown in the plots, probably because of the closeness of the log K values.

RESULTS AND DISCUSSION

The K_1 values for the Al(III) and Fe(III) complexes were not uncovered, with the exception of the ferric complex of thioacetamide, possibly because of lack of stepwise complexation (no values for $\bar{n}$ below 1 were obtained). No values for the ferric complex of 2-thiobarbituric acid were obtained because of precipitate formation at the beginning of the titration. Values for K_2 for the Cu(II) and Ni(II) complexes were not obtained because of the formation of precipitates, with the exception of the complexes of 2-thiobarbituric acid. Although log β values could not be obtained in most cases, for the purposes of comparison and for determining whether thiourea complexes are capable of existence in the presence of cellular complexing agents, the constants found should suffice.

The sequence of stability constants of thiourea, *N*-methylthiourea, and *N*,*N*′-dimethylthiourea allow some conclusions regarding structure of the complexes. The complexes of *N*-methylthiourea showed decreased stability constants, compared with those of thiourea, for the aluminum and ferric systems, but increased constants for the cupric and nickel systems. For the latter systems, where only K_1 values were observed, steric effects of the methyl group would be minimal. For the aluminum and ferric systems, the decrease in stability constants may be attributed to steric effects, since 2:1 and 3:1 complexes are involved. These sequences suggest that both the sulfur and a nitrogen atom are involved in bond formation of the complexes.

With the complexes of *N*,*N*′-dimethylthiourea, the additional methyl group caused a decrease in constants for all four metal ions observed. Two methyl groups apparently cause steric hindrance of the 1:1 complexes as well. The longer-chain substituents gave somewhat higher constants than the methyl groups, so the α-methylene groups were less interfering than the methyl groups. For the cyclic thioureas, particularly 2-thiobarbituric acid, where steric hindrance would be less than for the open-chain complexes, the stability constants were the largest of the series. It is also possible that some degree of aromaticity is possible with 2-thiobarbituric acid.

Table III—Stability Constants for Cu(II) and Ni(II) Complexes (25°C)

Compound	Cu(II) Complexes[a]			Ni(II) Complexes		
	log K_1	log K_2	log β_2	log K_1	log K_2	log β_2
Thiourea	1.38[b]			1.00		
N-Methylthiourea	1.67			1.39		
N,*N*′-Dimethylthiourea	1.35			1.33		
N-Methyl-*N*′-phenethylthiourea	1.51			1.47		
N-Methyl-*N*′-phenyl-2-propylthiourea	1.44			1.45		
2-Imidazolidinethione	1.66			1.40		
2-Thiobarbituric acid	4.35	3.79	8.14	3.76	3.18	6.94
Thioacetamide	2.30			1.69		

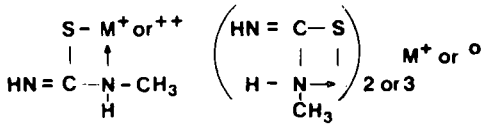
[a] The product of Cu(II) and thiourea is claimed to be a Cu(I) complex: E. I. Onstott and H. A. Laitinen, *J. Am. Chem. Soc.*, **72**, 4724 (1950). [b] The log β_2 for Cu(II) and thiourea was estimated by Bjerrum to be ~2: L. G. Sillén and A. E. Martell, "Stability Constants of Metal-Ion Complexes," The Chemical Society, London, 1964, p. 359.

Table IV—Stability Constants for Al(III) and Fe(III) Complexes (25°C)

Compound	Al(III) Complexes		Fe(III) Complexes			
	$\log K_2$	$\log K_3$	$\log K_1$	$\log K_2$	$\log K_3$	$\log \beta_3$
Thiourea	3.01	1.69		3.55	2.16	
N-Methylthiourea	2.73	1.90		3.00	2.16	
N,N'-Dimethylthiourea	2.61	1.81		2.87	2.28	
N-Methyl-*N'*-phenethylthiourea	3.79	2.21		3.59	2.41	
N-Methyl-*N'*-phenyl-2-propylthiourea	3.59	2.21			2.84	
2-Imidazolidinethione	3.61	2.12		3.92	2.40	
2-Thiobarbituric acid	5.15	3.29				
Thioacetamide	3.06	2.23	4.12	3.40	2.25	9.77

It has been shown previously (17) that stability constants for metal complexes of 2-mercaptoimidazoles and mercaptopyrimidines were relatively high, and that both sulfur and nitrogen were involved in bond formation to give four-membered rings. Four-membered metal chelate rings have also been reported for dithiocarbamates and xanthates (24), and for dithiocarboxylates (25). Ruthenium complexes of thioureas have also been postulated to involve the sulfur and nitrogen in four-membered rings (26).

If complexation to sulfur alone were involved, the presence of *N*-methyl substituents would be expected to increase stability constants by electron release. But the probable effect of steric hindrance by the methyl groups, as indicated for the decreased stability of 2:1 and 3:1 Al(III) and Fe(III) complexes, allow the postulation of four-membered chelate rings involving bonding to both sulfur and nitrogen (IV and V).



IV V

The magnitude of the metal-binding stability constants observed is somewhat lower than that for simple peptides. Log K_1 values reported for the Cu(II) and Ni(II) complexes of glycyl-DL-alanine, for instance, are 5.92 and 4.08, respectively (27). Although metal complexes of thioureas, with the possible exception of cyclic thioureas, should not be expected to exist in the presence of cellular peptides for any appreciable period, they should be capable of binding to the metal constituents of metalloenzymes.

Wheeler and Ribot (28) observed the protective effect of thiourea and methylthioureas for radiation damage to a synthetic polymer. Presence of the methyl groups distinctly lowered the protective ability of thiourea. It would not appear in this system that metal ions are involved in the radiation damage, which must be due largely to the radicals resulting from radiolysis of water. In this case, the ability of the thioureas to act similarly to the thiol radiation-protectors, in transferring hydrogen atoms to the radiation-produced radicals (29), would appear to offer a more probable mechanism of protection. The ability of thioureas to enter a thione–thiol equilibrium would make hydrogen atom transfer a realistic possibility, and in view of the rather low metal-binding stability constants for thioureas, a more likely mechanism than the ability to bind copper or iron ions, which catalyze cellular oxidations. A previous attempt to relate metal-binding ability to radiation protection of a series of aminoalkyl disulfides and thiosulfates did not give a positive correlation (30).

Involvement of thioureas with metalloenzymes, such as dopamine-β-oxidase, nitrate reductase, or polyphenol oxidase, is still a likely possibility by complexation of the metal constituent, however. A correlation between metal-binding ability and the antimicrobial effects of cyclic thioureas has already been observed (17), possibly through the inhibition of metalloenzyme activity.

Percutaneous Absorption of Corticosteroids: Age, Site, and Skin-Sectioning Influences on Rates of Permeation of Hairless Mouse Skin by Hydrocortisone

CHARANGIT R. BEHL *, GORDON L. FLYNN ˣ, EDWARDS E. LINN, and WARD M. SMITH

Received July 25, 1983, from the *College of Pharmacy, The University of Michigan, Ann Arbor, MI 48109.* Accepted for publication October 5, 1983. *Present address: Pharmacy Research, Hoffmann-LaRoche, Inc., Nutley, NJ 07110.

Abstract □ As part of a long-range plan to decipher the mechanism of mass transfer of corticosteroids across skin, the permeation of [^{3}H]hydrocortisone through hairless mouse skin was characterized by *in vitro* diffusion cell techniques. Age and anatomical site-related behaviors were explored mainly with whole skin but also with skin stripped of its horny layer. Permeability of the mouse skin was low shortly after birth and increased during the singular normal hair cycle exhibited by the SKH-hr^{-1} mouse strain. The return to a hairless state over a period of 20–35 d was accompanied by decreased permeability of hydrocortisone. A permeability coefficient of $\sim 2 \times 10^{-4}$ cm/h was found for the mature mouse. For whole skin, there was no difference in the permeabilities of dorsal and abdominal skin sections, but for stratum corneum-free membranes and dermal membranes, the abdominal site appeared to be more permeable, which is consistent with its thinner dimensions. Totally stripped skin and isolated dermis are ~500 and ~1000 times more permeable than intact skin, respectively; the unaltered stratum corneum of the hairless mouse is thus shown to be the major barrier to the mass transfer of hydrocortisone.

Keyphrases □ Absorption, percutaneous—hydrocortisone, influence of age, site, and skin sectioning on permeation rates, hairless mouse skin □ Hydrocortisone—percutaneous absorption, influences of age, site, and skin sectioning on permeation rates, hairless mouse skin

In previously published studies on the absorption through skin of hydrocortisone (the prototype of the corticosteroids), it was noted that the process is highly sensitive to the manner of treatment of the skin sample. The first evidence of its absorption was skin atrophy on repetitive applications to rat skin (1). When ^{14}C-labeled hydrocortisone became available, direct proof of its passage through skin in the form of radioisotope collected in urine after topical applications to human volunteers was gathered (2). By such methods, it was possible to show that only tiny fractions of the applied steroid passed through intact skin (2, 3), but that absorption through diseased and inflamed skin was far more facile (4). Occlusion was demonstrated to improve absorption by several times that without occlusion (3), and stripping of skin had exaggerated effects of enhancement (3, 5). By using a similar technique in monkeys, the influences of the amount of hydrocortisone applied to a specified area and the frequency of application have been described (6), and the important conclusion that absorption of hydrocortisone through skin is increased on long, continuous application has been reached (7). Along these lines, hairless mouse epidermal sections excised from animals treated with UV light and acetic acid–retinoic acid (vitamin A), all of which were under circumstances that induced epidermal hyperplasia, were measurably more permeable to hydrocortisone than were the skin samples used as controls (8). Excised skin (human) has also been used to study vehicle effects (9, 10). Hydrocortisone has also been shown in human volunteers to be a relatively feeble inhibitor of induced inflammation when directly compared with its intermediate-chain-length 21-alkyl esters (11).

All of the mentioned absorption-related phenomena and influences can be put to stringent, quantitative testing by *in vitro* diffusion cell methods. Yet, to date, only Scheuplein *et al.* (12) have characterized the permeabilities of such compounds, finding human epidermal permeability coefficients of 3×10^{-6} cm/h for hydrocortisone and 1×10^{-5} cm/h for cortisone. It is the specific purpose of this study to obtain, by using the hairless mouse model system, baselines on the absorption of hydrocortisone as a prelude to factoring the degree of permeation dependency of corticosteroid pharmacological responses.

EXPERIMENTAL SECTION

Chemicals—The tritiated hydrocortisone[1] used in these studies had a stated radiochemical purity of >99% and a specific radioactivity of 95.2 Ci/mmol. Sodium chloride irrigation[2] was used as an isotonic medium in which to prepare the hydrocortisone solutions and as the medium of the receptor compartment of the diffusion cell. [^{3}H]Hydrocortisone stock solutions, with a radiochemical activity of ~100 μCi/mL, were prepared. These solutions were diluted roughly 15-fold during the course of charging the donor compartment of the cell. Final concentrations of hydrocortisone in the chamber of the diffusion cell were $<10^{-5}$ M.

Membrane Preparation—The basic techniques for prepartion of the membranes and for running of the permeation experiments have been previously reported (13–16) and, therefore, are only briefly described herein. In most studies, the membranes were full-thickness skin sections from the abdominal and dorsal surfaces of hairless mice, SKH-hr^{-1} strain[3]. Male hairless mice of known ages were sacrificed by spinal cord dislocation. Rectangular sections of skin, several centimeters in each dimension, were excised from the animal, and the adhering fat and other visceral debris were removed. After trimming each excised skin section into an oversized, rough circle, the tissue was placed in a diffusion cell. Stretching of the skin, as evidenced by distortion or expansion of the circular marking, was corrected, and the cell halves were made fast with a spring clamp. The area available for diffusion between compartments was ~0.6 cm^2.

For some experiments, the skin surface, while still on the animal carcass, was stripped repeatedly of its stratum corneum cells by fastening adhesive tape[4] smoothly and securely to the surface with light pressure from the fingers. Attempts were made to obtain adhesion over the entire covered surface before the tape was abruptly removed. This procedure was repeated many times on each site with fresh pieces of adhesive tape used for each stripping.

Dermal sheets were prepared for the permeation studies by soaking excised skin sections for ~24 h, at which time the epidermis could be separated from the dermis by peeling carefully with the blade of a spatula. The isolated dermis layer was mounted in the diffusion chamber.

Diffusion Cells—Small glass diffusion cells, the dimensions of which have been reported previously, were employed (13–16). The cells were assembled with the freshly excised mouse skin between the half-cells. The assembled cells were then immersed in constant-temperature baths. The cell contents were stirred at 150 rpm.

Permeation Procedure—Each half-cell was partially filled (~1 mL) with saline, evacuated with a syringe, and filled with 1.4 mL of saline. The contents were mixed for 5 min to ensure temperature equilibration. Samples (100 μL) were withdrawn from each side; the samples were assayed to ensure that no residual radioactivity remained from previous runs. At this point, the donor

compartment was charged with 100 μL of the stock solution. Saline (100 μL) was added to the receiver. At predetermined intervals, samples were withdrawn from the respective compartments, transferred to vials containing scintillation cocktail[5] (10 mL), and assayed on a liquid scintillation counter[6].

The moment of charging the donor half-cell marked the zero time point for the diffusional run. Two minutes elapsed before the initial donor sample was withdrawn to allow for uniform mixing, and the concentration of this sample was used as the initial donor cell concentration. The overall procedure was designed to maintain an essentially fixed concentration across the membrane during the course of a run. The permeation entered pseudo steady state, and the permeability coefficients of the steroids were readily ascertained.

Analysis of Data—The data were plotted as counts collected in the receptor compartment as a function of time. Correction was made for sampling, which in all cases was done by replacing with saline. The permeability coefficient for a given run was calculated from:

$$J_T = P \cdot A \cdot \Delta C = V\frac{dC}{dt}$$

where J_T is the total pseudo-steady-state flux (in cpm/s) across the skin, P is the permeability coefficient (in cm/s); A is the diffusional area (in cm^2); ΔC is the concentration differential across the membrane, which was taken to be equal to the donor phase concentration, (in cpm/mL); V is the half-cell volume and volume of the receptor compartment (in mL); and dC/dt is the steady-state slope in terms of cpm/mL/s.

RESULTS

Some representative permeation plots obtained from runs with full-thickness skin sections taken from mice at 5, 20, 35, and 516 d of age are shown in Fig. 1. All runs were carried out for ~40 h. At 5 and 35 d, such plots were of a biphasic nature. Two lag times and two permeability coefficients were recorded in such instances. Data from runs such as these are summarized in Table I.

Table II is a compilation of data obtained on processed skins, *i.e.*, skins stripped of stratum corneum and dermis isolated by soaking overnight in saline. All data in Tables I and II were collected at 37°C.

DISCUSSION

Effect of Age—The permeabilities of the SKH-hr^{-1} hairless mouse skin to alkanols have previously been shown to pass through a cycle over the first 3 weeks of life (17), which is coincident with the development of a coat of fur. Similar behavior is evident for hydrocortisone, even within the limited number of age points available (Fig. 2). At 5 d (before the first appearance of hair), the permeability was low. By 15 d (slightly past midcycle and about the point in time of the first shedding of the coat), the permeability coefficient was ~3.7 times larger than the value at 5 d, and it remained high to near the end of the hair cycle (20 d). The overall averages at the latter two time points are statistically larger than the greater 5-d average (Student t test; $p < 0.01$). Based on permeability coefficients measured in the early phase of permeability of skins from 35-d-old mice and older, the permeability of hydrocortisone through the intact skin declined slightly after shedding of the furry coat, which was more or less complete at 25 d of age. The permeability coefficients of hydrocortisone through unbroken, mature mouse skin of the specified strain is on the order of 2×10^{-4} cm/h.

Permeability of Processed Skin Sections—In these studies, some skin samples were stripped 25, 50, and 100 times with adhesive tape and others were soaked overnight to remove the entire epidermal layer from the skin, leaving sheets comprised strictly of dermis and a thin film of protective tissue covering the undersurface of the dermis. The overall averages for the permeability coefficients of these processed tissues (Table II) are plotted against the number of strippings (Fig. 3). The isolated dermis represents infinite stripping. This plot indicates a systematic increase in permeability as the

strippings become more numerous, but even at 100 strippings, the skin appears to be less permeabile than the dermis alone. The bulk of the barrier impairment is accomplished with 25 strippings, however, and the permeability coefficient is increased by roughly 300 times relative to the intact skin at this point. Seventy-five more tape strippings only doubled the coefficient again, whereas removal of the entire epidermis produced only a 2.5-fold additional increase. Past work with alkanols has indicated that 25 strippings effectively removed the entire stratum corneum. At first impression, the data obtained with hydrocortisone suggest that this may not be so. However, the stripping procedure is laborious and it is suspected that wear and tear of the resident living epidermal matrix, and possibly the dermis, may be responsible for increased permeability after exaggerated stripping rather than further removal of horny cells. As with all previous permeating species, the isolated dermal membrane is from 1.5 to 2 times more permeable than stripped skin, which is consistent with a resistance in the viable epidermis of the same order of magnitude as that of the dermis, which is much thicker. Finally, the absolute permeability coefficients of skin stripped 25 times (~0.085 cm/h) and isolated dermis (~0.17 cm/h) are roughly one-half the values found for the alkanols (14, 18) and for phenol (19) with tissue prepared in a comparable manner from mice of comparable age. On the other hand, neomycin, a larger molecule than hydrocortisone, is less permeable than the corticosteroid (20). There is a readily evident molecular size dependency to diffusion across these processed skin sections.

Anatomical Site as a Permeability Variable—Among all the studies, dorsal and abdominal skin sections from the same animals were studied in tandem. As far as we could determine, the permeabilities of full-thickness skin sections taken from these locations were the same. In contrast, stripped skin sections and isolated dermal sections from the abdomen appear to be one-third more permeable than comparably prepared sections from the back of the animals. Given that the intact skin section is several hundred times less permeable than the least-permeable sample of processed tissue, the implication is clear that the horny layers on the two sites have essentially the same barrier property. When the stratum corneum is removed, back sections evidence slightly greater diffusional resistance because they are, based on previous measurement (17), 40–50% thicker at 65 d of age.

Hairless Mouse–Human Comparison—Scheuplein *et al.* (12) have reported 3×10^{-6} cm/h as the 25°C value for the permeability coefficient of hydrocortisone through human epidermal membranes under similar experimental conditions. Considering that the 37°C permeability coefficient for hairless mouse skin lies somewhere between 1.1×10^{-4} and 4.1×10^{-4} cm/h (Table I, early phase or P_1 values), it appears as if this tissue in its normal state is many

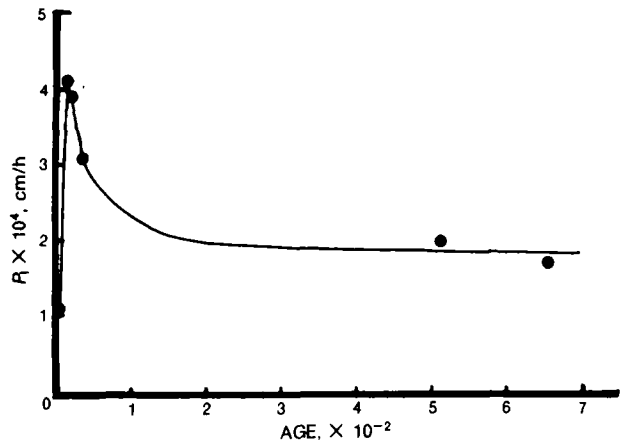

Figure 2—*Permeability coefficients (P_1 values) of hydrocortisone through hairless mouse skin as a function of mouse age.*

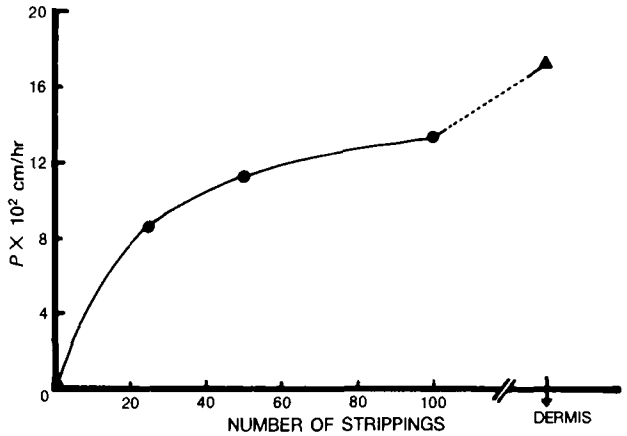

Figure 3—*Permeability coefficients of hydrocortisone through hairless mouse skin as a function of number of strippings. Data are also presented for the dermis. All data points represent average values of the abdominal and dorsal permeability coefficients.*

times more permeable to hydrocortisone than human skin. Assignment of an exact factor to this difference is made difficult, as the representativeness of the human epidermal value is uncertain, with there being no statistical data provided, nor are the temperature sensitivities of the permeation of hydrocortisone through the tissues known (but they can be assumed to be large). Nevertheless, this appears to be the first clear demonstration that to some permeating species, intact human and hairless integuments offer quantitatively different mass transfer resistances, with human skin being at least one logarithmic order less permeable. Previous diffusion cell-generated data for the alkanols (13, 14, 16) and phenol (19) have left the impression that the two skin types were, for practical purposes, identical in permeability.

Biphasic Character in Some Permeability Plots—A most unusual feature of some of these data is the biphasic quality of the permeability plots obtained with mice 5 and 35 d old. At 35 d of age, this aspect of the data was unequivocal. Like other researchers (8), we at first assumed that the skin membranes were deteriorating. However, when the permeability coefficient of a single section of skin was repetitively assessed approximately every 12 h over a 100-h period, using a previously outlined "hydration" protocol (16), the permeability coefficient remained constant at 2.5×10^{-4} cm/h. Subsequently, additional evidence has been gathered on skin of older animals which shows these same qualities (21), and it now appears that if a run is long and continuous, two distinct phases of permeation will be evident, with the second, more permeable, phase being as reproducible in its time of onset and permeability rate as the first. However, the onset of the second phase is at >40 h with the older skin sections, which is, by chance, the arbitrarily selected duration for the experiments reported here and which explains why the second phase was not apparent with the older skin sections. Also, the permeability coefficient of the second phase seems to increase dramatically with mouse age (consider the data for 5- and 35-d-old mice presented here). We suspect it was not evident after 5 d but not until 35 d because permeability in the early phase dominated events at 15 and 20 d. The physicochemical implication that this represents two separate and parallel permeability pathways through the stratum corneum with different dependencies on animal age is clear. This concept is mechanistically important and is thus being put to rigorous experimental testing.

Determination of Minoxidil in Bulk Drug and Pharmaceutical Formulations by Ion-Pairing High-Performance Liquid Chromatography

P. A. ASMUS ˣ, J. B. LANDIS, M. E. GRANT, and H. A. HAVEL

Received June 8, 1983, from *Control Analytical Research and Development, The Upjohn Company, Kalamazoo, MI 49001.* Accepted for publication September 23, 1983.

Abstract □ An ion-pairing liquid chromatographic method with UV detection is described for the determination of minoxidil in bulk drug, compressed tablet, and topical solution formulations. The chromatographic system consists of a microparticulate octadecylsilica column and a mobile phase composed of sodium dioctylsulfosuccinate in aqueous methanol (pH 3). The bulk drug and the topical solution samples are prepared by the dissolution of the drug in internal standard solution. Sample preparation for the compressed tablet formulation involves dissolving the drug from an aliquot of pulverized sample and centrifuging to remove insoluble excipients. Quantitative recovery of minoxidil from formulation excipients was demonstrated; assay precision was <1% *CV*.

Keyphrases □ Minoxidil—compressed tablets, topical solution and bulk drug, HPLC □ HPLC—minoxidil, compressed tablets, topical solution, and bulk drug

Minoxidil (I), 2,4-diamino-6-piperidinopyrimidine 3-oxide, a potent, orally active antihypertensive agent, is commercially available as a compressed tablet formulation[1]. There are, as yet, no published methods for the determination of minoxidil in bulk drug or dosage forms. A simple, precise, and specific assay method for minoxidil in these matrices was needed for quality control activities. For use in accelerated stability studies, potential decomposition products of minoxidil must be separated from the drug peak. Minoxidil is quite stable, decomposing only at high temperatures to form 2,4-di-

times more permeable to hydrocortisone than human skin. Assignment of an exact factor to this difference is made difficult, as the representativeness of the human epidermal value is uncertain, with there being no statistical data provided, nor are the temperature sensitivities of the permeation of hydrocortisone through the tissues known (but they can be assumed to be large). Nevertheless, this appears to be the first clear demonstration that to some permeating species, intact human and hairless integuments offer quantitatively different mass transfer resistances, with human skin being at least one logarithmic order less permeable. Previous diffusion cell-generated data for the alkanols (13, 14, 16) and phenol (19) have left the impression that the two skin types were, for practical purposes, identical in permeability.

Biphasic Character in Some Permeability Plots—A most unusual feature of some of these data is the biphasic quality of the permeability plots obtained with mice 5 and 35 d old. At 35 d of age, this aspect of the data was unequivocal. Like other researchers (8), we at first assumed that the skin membranes were deteriorating. However, when the permeability coefficient of a single section of skin was repetitively assessed approximately every 12 h over a 100-h period, using a previously outlined "hydration" protocol (16), the permeability coefficient remained constant at 2.5×10^{-4} cm/h. Subsequently, additional evidence has been gathered on skin of older animals which shows these same qualities (21), and it now appears that if a run is long and continuous, two distinct phases of permeation will be evident, with the second, more permeable, phase being as reproducible in its time of onset and permeability rate as the first. However, the onset of the second phase is at >40 h with the older skin sections, which is, by chance, the arbitrarily selected duration for the experiments reported here and which explains why the second phase was not apparent with the older skin sections. Also, the permeability coefficient of the second phase seems to increase dramatically with mouse age (consider the data for 5- and 35-d-old mice presented here). We suspect it was not evident after 5 d but not until 35 d because permeability in the early phase dominated events at 15 and 20 d. The physicochemical implication that this represents two separate and parallel permeability pathways through the stratum corneum with different dependencies on animal age is clear. This concept is mechanistically important and is thus being put to rigorous experimental testing.

Determination of Minoxidil in Bulk Drug and Pharmaceutical Formulations by Ion-Pairing High-Performance Liquid Chromatography

P. A. ASMUS ˣ, J. B. LANDIS, M. E. GRANT, and H. A. HAVEL

Received June 8, 1983, from *Control Analytical Research and Development, The Upjohn Company, Kalamazoo, MI 49001.* Accepted for publication September 23, 1983.

Abstract □ An ion-pairing liquid chromatographic method with UV detection is described for the determination of minoxidil in bulk drug, compressed tablet, and topical solution formulations. The chromatographic system consists of a microparticulate octadecylsilica column and a mobile phase composed of sodium dioctylsulfosuccinate in aqueous methanol (pH 3). The bulk drug and the topical solution samples are prepared by the dissolution of the drug in internal standard solution. Sample preparation for the compressed tablet formulation involves dissolving the drug from an aliquot of pulverized sample and centrifuging to remove insoluble excipients. Quantitative recovery of minoxidil from formulation excipients was demonstrated; assay precision was <1% *CV*.

Keyphrases □ Minoxidil—compressed tablets, topical solution and bulk drug, HPLC □ HPLC—minoxidil, compressed tablets, topical solution, and bulk drug

Minoxidil (I), 2,4-diamino-6-piperidinopyrimidine 3-oxide, a potent, orally active antihypertensive agent, is commercially available as a compressed tablet formulation[1]. There are, as yet, no published methods for the determination of minoxidil in bulk drug or dosage forms. A simple, precise, and specific assay method for minoxidil in these matrices was needed for quality control activities. For use in accelerated stability studies, potential decomposition products of minoxidil must be separated from the drug peak. Minoxidil is quite stable, decomposing only at high temperatures to form 2,4-di-

I

amino-6-piperidinopyrimidine (the deoxy product).

This paper reports the development of a reversed-phase ion-pairing high-performance liquid chromatographic (HPLC) assay method for minoxidil in several formulations and bulk drug. Since the work of Schill and co-workers (1, 2), Haney *et al.* (3, 4), and Knox *et al.* (5, 6), many workers have found that reversed-phase ion-pairing with alkylsulfates of alkylsulfonates is effective in reducing tailing and also for adjusting retention and selectivity (7-14). The method is simple, precise, and specific for minoxidil in the presence of possible decomposition products and several synthetic intermediates.

EXPERIMENTAL SECTION

Materials—Minoxidil[2], 2-*N*-dicyano-*N'*,*N'*-pentamethylene acetoamidine[2], 2,4-diamino-6-chloropyrimidine 3-oxide[2], 2,4-diamino-6-chloropyrimidine[2], 2,4-diamino-6-piperidinopyrimidine[2], and sodium dioctylsulfosuccinate[3] were >95% pure by HPLC and used as received. The internal standard, medroxyprogesterone acetate, was USP-NF quality. The methanol[4] and water used in the mobile phases were distilled. All other chemicals were reagent grade.

Apparatus—Experiments were conducted on a modular HPLC consisting of a reciprocating piston pump[5], a loop injection valve[6], a UV detector[7] (254 nm), and a recorder[8]. For quantitation, data were collected and processed by a digital computer[9].

Mobile Phase—The mobile phase was prepared as follows. Sodium dioctylsulfosuccinate (3.0 g) and 10 mL of glacial acetic acid were dissolved in 700 mL of methanol. Stirring was continued and 300 mL of water was added. The apparent pH was adjusted to 3.0 with concentrated perchloric acid. The solution was filtered through a 0.45 μm filter[10] before use.

The separation between minoxidil and the internal standard, medroxyprogesterone acetate, could be increased without affecting selectivity by decreasing the methanol concentration of the mobile phase.

The volume of the mobile phase in the column, V_m, which is equal to the retention volume of an unretained compound, was estimated by the retention volume of sodium nitrate (20 mg/mL in the mobile phase). The retention times of the compounds studied were measured using 1 mg/mL solutions of authentic standards. Capacity factors, k', were determined using the equation: $k' = V_R - V_m/V_m$, where V_R is the retention volume of the compound being measured. The separation factors were calculated by taking the ratio of the capacity factor of the compound to the capacity factor of minoxidil.

Column—The microparticulate octadecylsilane column[11] (10-μm particles, 300 × 3.9 mm) used was washed with methanol–water (80:20, v/v) and stored in the same solvent when not in use. The column temperature was ambient, the column pressure was ~1500 psi, the injection volume was ~10 μL, and the flow rate was 1.0 mL/min.

Sample Preparation—Standards and bulk drug samples were prepared by accurately weighing ~5 mg of the sample and dissolving it in 20 mL of internal standard solution (~0.2 mg/mL medroxyprogesterone acetate in mobile phase). For compressed tablet samples, 10 tablets were weighed and then pulverized to a fine powder. An accurately weighed aliquot of the powder containing ~5 mg of minoxidil was dissolved in 20 ml of internal standard solution, and insoluble excipients were separated by centrifugation. The clear supernatant was separated for analysis. Topical solution samples were prepared by accurately measuring an amount of solution containing ~50 mg minoxidil and diluting to 50 mL with mobile phase. Five milliliters of this solution was dissolved in 20 mL of the internal standard solution.

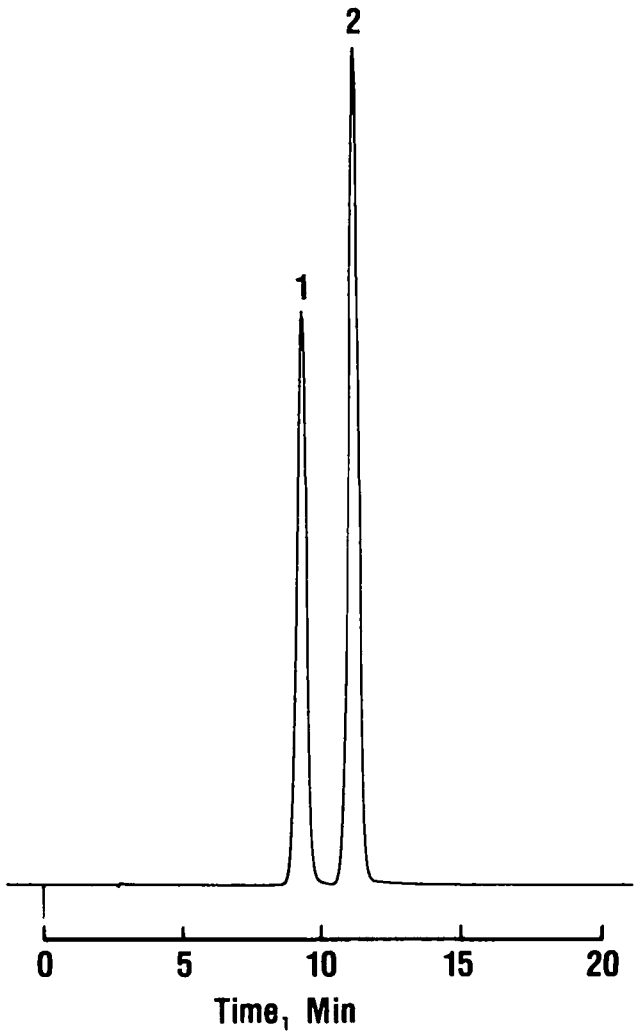

Figure 1—*Chromatogram of a compressed tablet preparation of minoxidil. The mobile phase was 6.7 mM sodium dioctylsulfosuccinate and 175 mM acetic acid in 70% methanol, pH 3.0; the flow rate was 1.0 mL/min; the temperature was ambient; the attenuation was 0.512 AUFS. Key: (1) medroxyprogesterone acetate (internal standard); (2) minoxidil.*

RESULTS AND DISCUSSION

A typical chromatogram of a minoxidil compressed tablet sample preparation is shown in Fig. 1. No excipient peaks are observed even though no sample clean-up steps were employed. The minoxidil peak was symmetrical and an adequate number of theoretical plates (3500) were generated. Retention and selectivity data for minoxidil and related compounds are shown

Table I—Retention and Selectivity Data for Minoxidil and Related Compounds

Compound	Retention Time, min	Capacity Factor	Separation Factor
2-*N*-Dicyano-*N'*,*N'*-pentamethylene acetoamidine	3.41	0.34	0.12
2,4-Diamino-6-chloropyrimidine 3-oxide	4.13	0.63	0.22
2,4-Diamino-6-chloropyrimidine	6.25	1.46	0.51

in Table I. The sample preparation involved dissolution of the drug from a powdered tablet using the mobile phase which contained the internal standard. Insoluble excipients were separated by centrifugation and the supernatant was chromatographed.

The specificity of the chromatographic system was evaluated by chromatographing a mixture of minoxidil and its possible impurities. Figure 2 shows the very good resolution obtained between all components. This degree of specificity was achieved by manipulation of the mobile phase constituents, *i.e.*, the ion-pairing reagent concentration, the organic modifier concentration, and the pH.

Sodium dioctylsulfosuccinate was chosen as the ion-pairing reagent after several alkylsulfates and alkylsulfonates were tried. The dioctylsulfosuccinate anion is a large hydrophobic sulfonic acid containing 20 carbon atoms, of which 18 can be considered alkyl chain carbons. It has, therefore, a very large affinity for the alkyl groups on the packing material surface. Ion-pairing reagents with smaller carbon chain lengths allowed the minoxidil peak to tail. Sodium dioctylsulfosuccinate has been successfully used as an ion-pairing reagent in several other HPLC assay methods (10–14).

The relationship between retention and the dioctylsulfosuccinate concentration in the mobile phase was studied for minoxidil and related compounds (Fig. 3). In accordance with well known reversed-phase ion-pairing behavior, retention of all the basic compounds was proportional to the dioctylsulfosuccinate concentration. The concentration of dioctylsulfosuccinate was 6.7 mM, since adequate retention and resolution was observed at that level. Selectivity was not affected enough to cause peak reversal over a 1–25 mM dioctylsulfosuccinate concentration range.

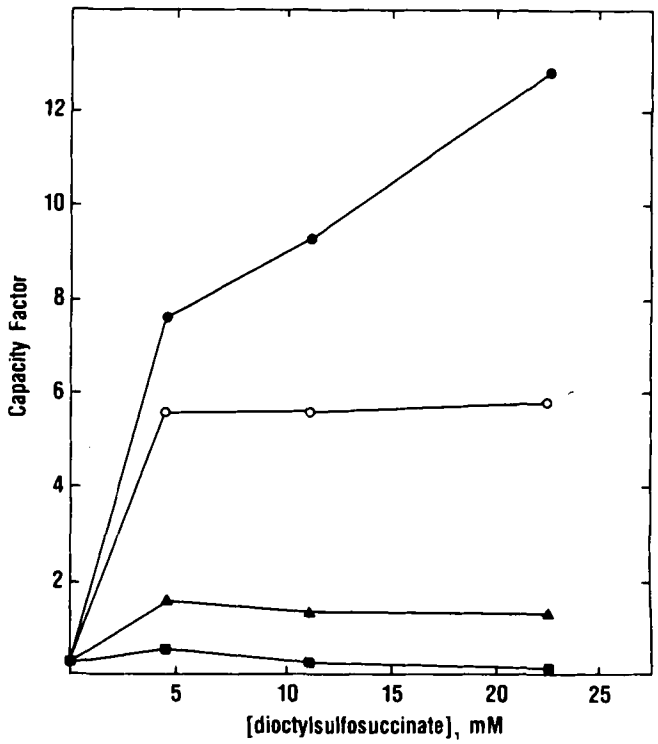

Figure 3—*Effect of mobile phase dioctylsulfosuccinate concentration on retention. Key: (■) 2-N-dicyano-N′,N′-pentamethylene acetoamidine and 2,4-diamino-6-chloropyrimidine 3-oxide; (▲) 2,4-diamino-6-chloropyrimidine; (○) minoxidil; (●) 2,4-diamino-6-piperidinopyrimidine. The mobile phase was 175 mM acetic acid in 70% methanol, pH 3.0.*

The mobile phase contained methanol as the organic modifier. The dependence of retention on its concentration was studied, and the results are

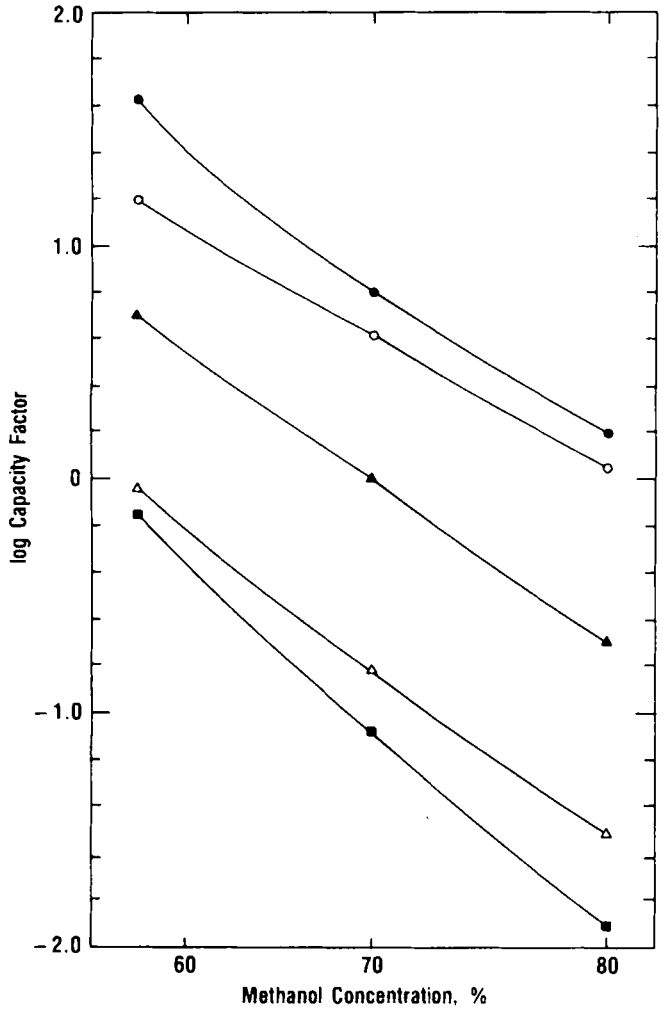

Figure 4—*Effect of mobile phase methanol concentration on retention. Key: (■) 2-N-dicyano-N′,N′-pentamethylene acetoamidine; (△) 2,4-diamino-6-chloropyrimidine 3-oxide; (▲) 2,4-diamino-6-chloropyrimidine, (○) minoxidil, (●) 2,4-diamino-6-piperidinopyrimidine. The mobile phase was 6.7 mM sodium dioctylsulfosuccinate and 175 mM acetic acid, pH 3.0.*

shown in Fig. 4. As expected, retention varies linearly with the log of the methanol concentration. It can be seen that selectivity does not change as the methanol concentration varies. The mobile phase methanol concentration can, therefore, be reduced to compensate for reduced retention as the column ages.

In reversed-phase ion-pairing liquid chromatography, the mobile phase pH is an important variable. The retention behavior of the compounds was studied as a function of the apparent pH of the mobile phase (Fig. 5). From this experiment, an apparent pH of 3.0 was chosen for the best separation of all compounds. At that pH, the ion-pairing reagent was ionized and the solutes were fully protonated. In the pH region of 4–7, the retention of minoxidil decreased due to deprotonation of the molecule, which decreased the magnitude of the interaction between minoxidil and dioctylsulfosuccinate. Glacial acetic acid and perchloric acid were added to the mobile phase to obtain an apparent pH of 3. The effect of the acetic acid concentration on retention is minimal.

Linearity of the assay for bulk drug was determined over a range of 75–125% of the amount called for in this procedure. The regression equation for the line was: minoxidil found = (1.014 ± 0.038) (minoxidil added) + (−0.102 ± 0.196). Tablet placebo samples were spiked with minoxidil, mixed in the

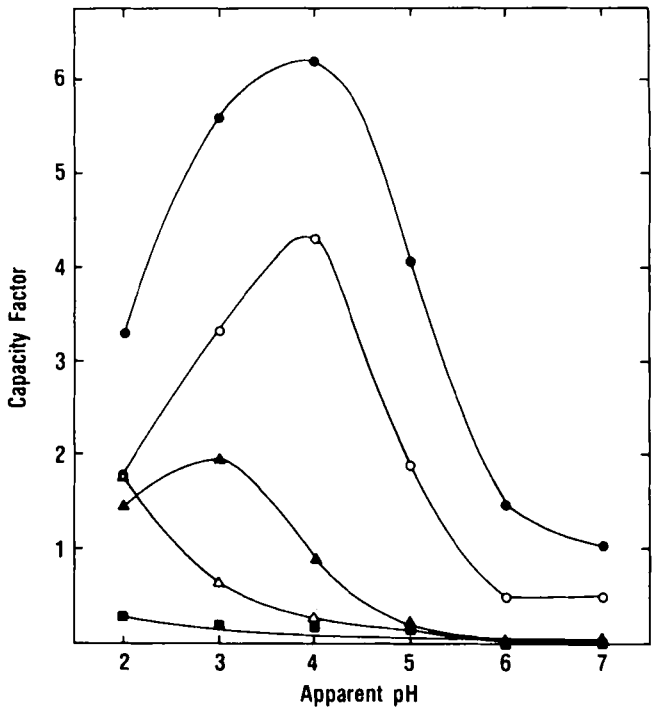

Figure 5—*Effect of mobile phase apparent pH on retention. See Fig. 3 for the key. The mobile phase was 6.7 mM sodium dioctylsulfosuccinate and 175 mM acetic acid in 70% methanol; pH from 2.0 to 3.5 adjusted with perchloric acid and from 3.5 to 7.0 adjusted with ammonium hydroxide.*

solid state, and analyzed by this method to measure recovery. Quantitative recovery of minoxidil was observed over the range of ~1.4–9.9 mg/0.13 g of compressed tablet placebo (Table II). This range corresponds roughly to 30–200% of the label claim for a 10 mg compressed tablet formulation. Replicate analyses of a single lot of 5-mg compressed tablets gave a method precision of 0.6% *RSD*. Results from the analyses of several lots of compressed tablets and topical solution formulations of various strengths are shown in Table III. Good agreement between assay results and the label claim amount was observed in all cases.

Controlled Release of a Luteinizing Hormone-Releasing Hormone Analogue from Poly(*d*,*l*-lactide-co-glycolide) Microspheres

L. M. SANDERS *x, J. S. KENT *, G. I. McRAE *,
B. H. VICKERY *, T. R. TICE ‡, and D. H. LEWIS ‡

Received July 18, 1983, from the *Institutes of Pharmaceutical and Biological Sciences, Syntex Research, Palo Alto, CA 94304 and ‡Southern Research Institute, Birmingham, AL 35255. Accepted for publication October 3, 1983.

Abstract □ The performance *in vivo* of nafarelin acetate, a potent analogue of luteinizing hormone-releasing hormone, microencapsulated in poly(*d*,*l*-lactide-co-glycolide), was evaluated. The influence of polymer composition and molecular weight on the estrus-suppressing activity of the microspheres in female rats was determined. Compound release was shown to be effected by polymer erosion rather than by diffusion. A triphasic release of compound was observed, which was adjusted by altering the critical parameters of the polymer. A mechanism for the release of the compound was proposed. The primary release phase was compound loss by diffusion from the surface of the microspheres. The secondary phase of subeffective rates of release occurred concomitantly with polymer hydrolysis and a decrease in its molecular weight, although it remained insoluble. Dissolution of low-molecular weight fragments and erosion of the bulk of the polymer then initiated the tertiary phase of release of compound.

Keyphrases □ Microencapsulation—nafarelin acetate in poly(*d*,*l*-lactide-co-glycolide) □ Nafarelin acetate—microencapsulation in poly(*d*,*l*-lactide-co-glycolide) □ Controlled-release formulations—microencapsulation of nafarelin acetate in poly(*d*,*l*-lactide-co-glycolide)

Poly(*d*,*l*-lactide-co-glycolide) and its homopolymers have a long history of use in such products as biodegradable sutures (1) and bone plates (2, 3) and have more recently been used to achieve controlled release of pharmaceuticals. A great deal has been done with narcotic antagonists such as naltrexone (4–7), local anesthetics (8), and steroids (9). A system consisting of norethisterone microencapsulated in poly(*d*,*l*-lactide-co-glycolide) has recently been shown to provide controlled release in clinical studies over 6 months (10). These systems all share a common feature in that the kinetics of compound release are diffusion controlled, through the polymer continuum and/or through channels formed within the device which are achieved by a high loading level of active material.

In this report, the controlled release of nafarelin acetate (I), an analogue of luteinizing hormone-releasing hormone (II) is described. Compound I has high biological potency, ~200 times that of II (11).

(Pyro)Glu-His-Trp-Ser-Tyr-3-(2-naphthyl)D-alanine-Leu-Arg-Pro-Gly-NH_2
I

(Pyro)Glu-His-Trp-Ser-Tyr-Gly-Leu-Arg-Pro-Gly-NH_2
II

The system described is controlled by erosion, with the kinetics of compound release determined by parameters of the copolymer.

EXPERIMENTAL SECTION

Materials—Poly(*d*,*l*-lactide-co-glycolide) and microspheres were prepared in-house[1] and used as supplied. Intrinsic viscosity (η_i) which is a measure of relative molecular weight, was determined by measuring the flow times of solutions of the copolymer with concentrations of 1.0–10.0 mg/mL in chloroform through a viscometer[2] at 30°C. Specific viscosities were calculated by:

$$\eta_{sp} = \frac{t_s - t_0}{t_0} \qquad \text{(Eq. 1)}$$

where t_s is the time required for a solution to pass through the viscometer, and t_0 is the time required for the pure solvent to pass through the viscometer. The plot of η_{sp}/C *versus* C was extrapolated back to the ordinate, where the intercept represents the intrinsic viscosity and C is the concentration.

The microsphere-suspending vehicle consisted of 0.5% carboxymethylcellulose[3]–0.8% sodium chloride USP 0.1% polysorbate 80 USP[4], in aqueous solution.

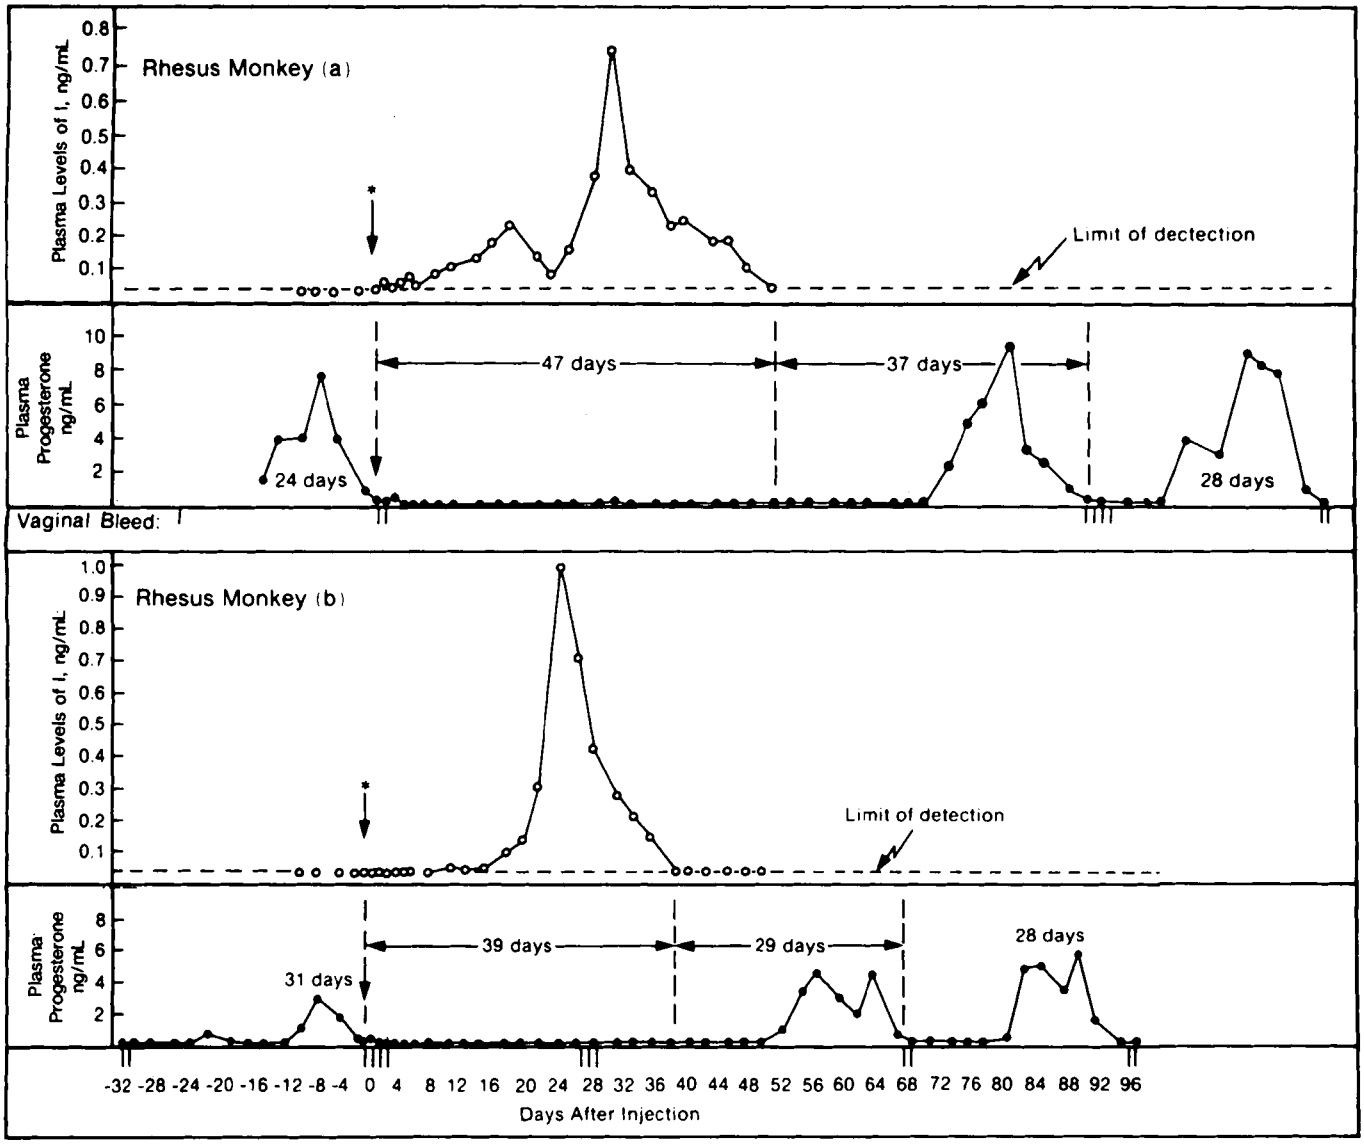

Figure 3—*Plasma levels of nafarelin acetate and progesterone in rhesus monkeys after a single subcutaneous injection of 1.0 mg of nafarelin acetate microencapsulated in 50:50 copolymer. The asterisks represent injection times.*

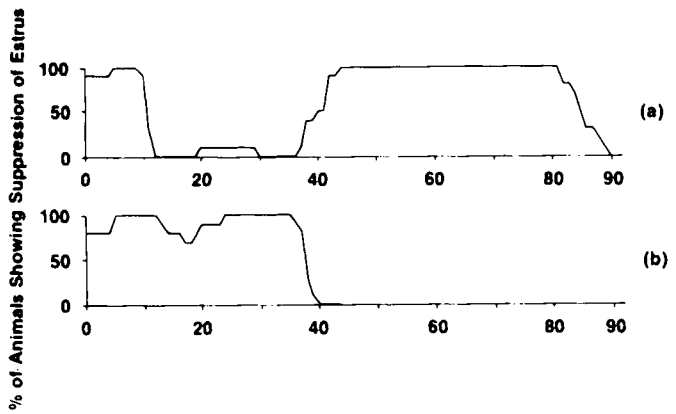

Figure 4—*Estrus suppression profiles provided by (a) 69:31 (η_i = 0.97 dL/g) and by (b) 50:50 (η_i = 1.52 dL/g) copolymer mixtures.*

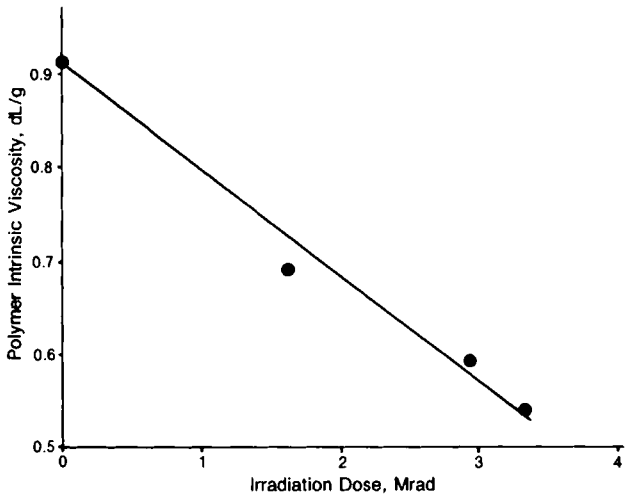

Figure 5—*Effect of gamma-irradiation on intrinsic viscosity of 69:31 copolymer.*

Animals—The rats used were mature females derived from the Sprague–Dawley line (weight, 155–165 g). Adult female rhesus monkeys (*Macaca mulatta*) that had menstrual cycles of predictable length based on prior history were also used.

Microencapsulation of I in Poly(*d,l*-lactide-co-glycolide)—Preparation of microspheres was by phase separation. An aqeous solution of I and a solution of the copolymer in dichloromethane were coemulsified to form a water-in-oil emulsion. A nonsolvent for the copolymer was then added to precipitate out the polymer around the aqueous droplets. The suspension of semi-formed

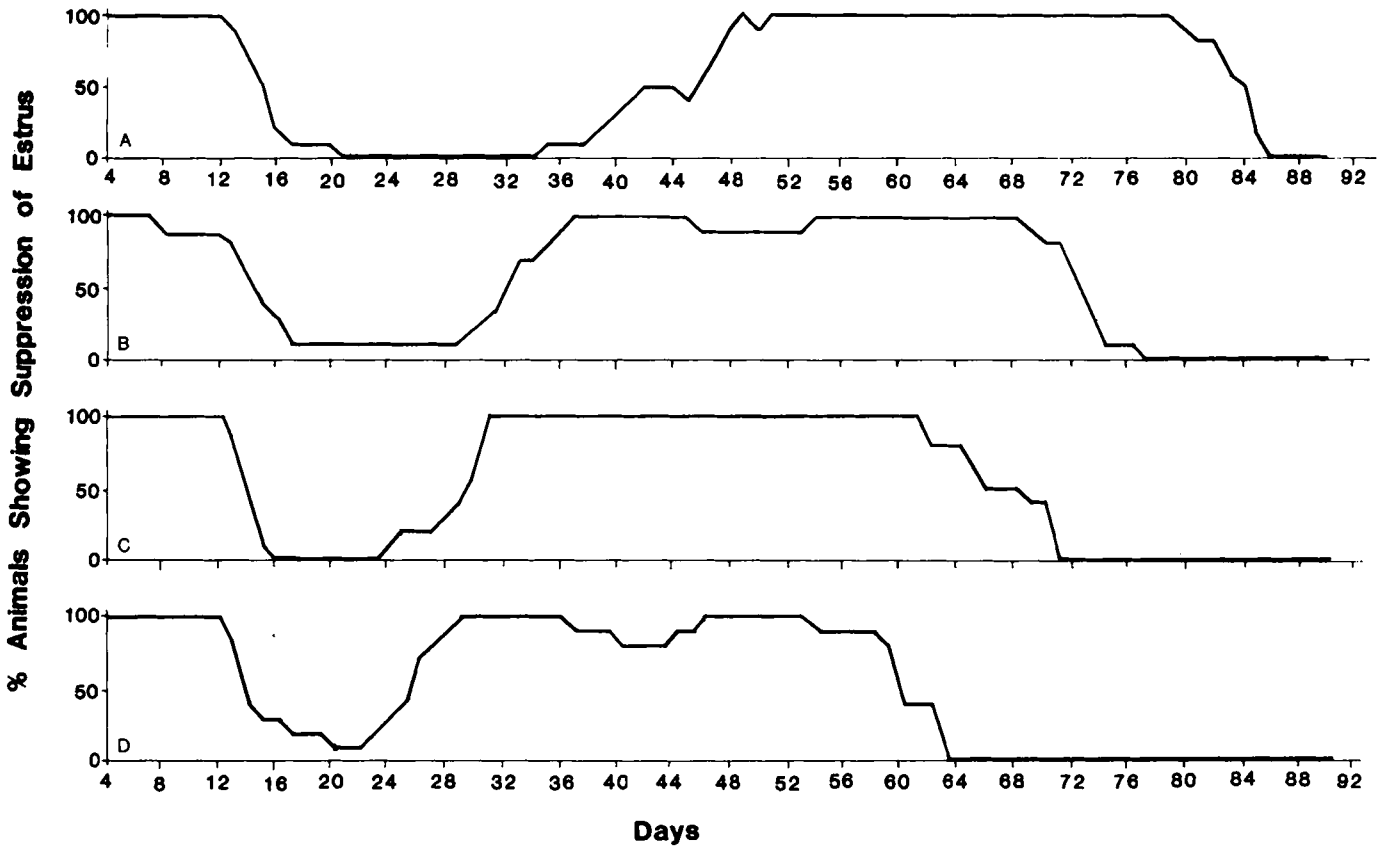

Figure 6—*Effect of irradiation on the biological activity of 69:31 copolymer microspheres (10–40 μm) containing I; n = 10. Key to irradiation: (A) none; (B) 1.6 Mrad; (C) 2.9 Mrad; (D) 3.3 Mrad.*

microspheres was added to a large volume of nonsolvent to cause them to harden and to complete the extraction of dichloromethane. The microspheres were then sieved, washed, and dried. Microspheres were thus prepared to contain ~1% (w/w) I.

Assay of I in Microspheres—A quantity of microspheres containing ~500 μg of I was dissolved in 3.3 mL of acetonitrile–water (9:1), in which both the copolymer and I are sufficiently soluble. Aqueous potassium dihydrogen phosphate (0.184 M) was added to 10.0 mL to precipitate the copolymer, and the suspension was stirred until the precipitate coalesced into a single mass. The supernatant was then assayed by reverse-phase HPLC by using a C_{18} 10-μm column[5], with a mobile phase[6] flow rate of 1.2 mL/min, an injection volume of 100 μL, and a detector wavelength of 225 nm. Compound recovery was 100 ± 1.5%.

Biological Assay—The microspheres were evaluated *in vivo* by using a rat estrus suppression model. It was shown that twice daily injection or continuous subcutaneous administration of ~0.4 μg/d is sufficient to maintain suppression of estrus in this model (Table I). Microspheres containing 300 μg of I were suspended in 0.5 mL of suspension vehicle and administered by a single subcutaneous injection. The animals were monitored for suppression of estrus by daily examination of vaginal smears. This model provides a reliable indication of the duration of compound release, although not of the release rate.

It was not possible to measure plasma levels of I in the rat since the compound is not sufficiently stable in rat plasma *in vitro*. Release kinetics in the rat were, therefore, determined by sequential sacrifice of treated animals, followed by excision of the injection sites and assay of the level of I remaining.

Biological efficacy of I in the female rhesus monkey was evaluated by monitoring menstrual bleeding and by measuring plasma levels of progesterone by RIA (12) after a single subcutaneous injection of microspheres containing 1.0 mg of I on day 1 of the menstrual cycle of the animal. The release profile of the compound was determined by the measurement of plasma levels of I by RIA (13).

Assay of I in Tissue Samples—The tissue samples, *i.e.*, excised injection sites, were frozen for ease of handling and sectioned into thin slices. They were vortexed with 5 mL of acetonitrile–water (9:1) periodically over 4 h. Potassium dihydrogen phosphate (0.184 M; 10 mL) was added, and the suspensions were vortexed over ~4 h. The samples were centrifuged at 1000 × *g* for 20 min and assayed by HPLC as described above. Compound recovery was 83 ± 5%.

[6]Acetonitrile–0.175 M aqueous potassium dihydrogen phosphate (30:70).

RESULTS AND DISCUSSION

Injection of rats with microspheres of a low intrinsic viscosity (0.38 dL/g), 50:50 mol% copolymer produced continuous suppression of estrous cyclicity for 24 d, followed by an abrupt resumption of normal estrous cycling (Fig. 1). In this experiment, 30 animals were injected at time zero, and 5 animals were sacrificed at each of the six indicated times. Assay of the excised injection sites indicated a compound release profile (Fig. 2) that exhibited complex kinetic behavior, possibly reflecting a triphasic release mechanism. Overall, release kinetics were quite satisfactory, as indicated by comparison with zero-order kinetics, with exhaustion of the compound from the injection sites at ~22 d. Plasma levels of I in female rhesus monkeys a and b, which received 1 mg of compound in the same 50:50 copolymer, were detectable (*i.e.*, >0.05 ng/mL) for 47 and 39 d, respectively, during which time ovulation was completely inhibited (Fig. 3). Ovulation in these monkeys, as indicated by a rise in plasma progesterone levels, occurred at 19 and 14 d, respectively, after the disappearance of I in the plasma; normal menstrual cycling resumed thereafter.

A high molecular weight 50:50 copolymer (η_i = 1.52 dL/g) and a 69:31 copolymer (η_i = 0.97 dL/g) were screened in the rat estrus suppression model and gave efficacy profiles with degrees of partial or complete discontinuity at an intermediate point of the release cycle (Fig. 4). The data are consistent with the release of compound by homogeneous polymer erosion. A 69:31 copolymer of relatively high intrinsic viscosity gives a clearly triphasic compound release over 90 d (Fig. 4a). It is postulated that the primary phase of compound release is by dissolution from the superficial regions of the microspheres. A secondary, latent period of some 25 d then follows, during which time <0.4 μg/d is released. The copolymer hydrates and hydrolyzes *in situ* and decreases in molecular weight, although it remains water insoluble. There are no grossly observable changes and no release of the compound. The duration of this latent phase is controlled by both the initial molecular weight and by the composition of the polymer, which determines hydrophilicity and the inherent hydrolysis rate of the polymer *in vivo*. When the molecular weight decreases to a point at which there is significant water solubility, the polymer begins to erode homogeneously, and both the compound and polymer degradation products

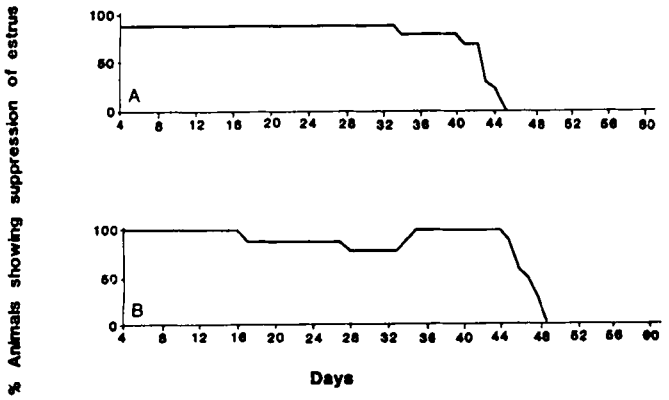

Figure 7—*Effect of size of 55:45 copolymer microspheres on duration of efficacy in female rats; n = 10. Key (A) large, 80–150 μg and (B) small, 30–50 μg.*

diffuse away from the loosening polymer matrix. This phase is diffusion controlled, although an increase in the permeability of the polymer as it erodes tends to compensate for an anticipated decrease in compound release with time. The system providing the plasma profile (Fig. 4a) demonstrates a clear definition of these three phases. When the composition is adjusted to 50:50 mol% *d,l*-lactide-co-glycolide (Fig. 4b) there is partial overlap of the primary and tertiary phases, and when the intrinsic viscosity is then decreased (Fig. 1), there is complete overlap. However, even in the system providing continuous efficacy in the rat (Fig. 1), the data clearly indicate a triphasic compound release, as shown by the release profile (Fig. 2) and by nonlinearity in the plasma profiles (Fig. 3a).

This postulated release mechanism was further supported by a study of the effects of gamma-irradiation on the intrinsic viscosity of a 69:31 copolymer (Fig. 5) and of the performance *in vivo* of the microspheres made from that polymer (Fig. 6). There was a decrease in the intrinsic viscosity of the polymer with an increase in radiation dose and, as would be predicted, a concomitant shortening of the secondary phase and a decrease in the time of onset of the tertiary phase.

The size of the microspheres was shown to have an insignificant influence on the duration of action *in vivo* (Fig. 7). This confirms the homogeneous or bulk nature of hydrolysis of this polymer and indicates that hydration is not a rate-limiting step in polymer degradation.

Improved Bioassay for Glucagon by Continuous Glucose Monitoring

CHANA R. KOWARSKI *, MING YU LIAOU *, DAVID KOWARSKI ‡, JEFFREY WEIZER *, DUTTON BOYNES *, and A. AVINOAM KOWARSKI §x

Received July 15, 1983 from the *Temple University School of Pharmacy, Philadelphia, PA 19140, ‡The University of Pennsylvania School of Medicine, Philadelphia, PA, and §The University of Maryland School of Medicine, Baltimore, MD 21201. Accepted for publication September 22, 1983.

Abstract □ A simplified and rapid *in vivo* bioassay for glucagon is described. The test involves continuous monitoring of blood glucose which makes possible an exact rendering of the glucose peaks induced by intravenous injection of glucagon. Two injections of known amounts of glucagon (0.002 and 0.004 U) are followed by an intravenous injection of a solution containing an unknown amount of glucagon for testing. The whole procedure can be completed in 8 h. The interassay variability of 6 bioassay procedures was ±12.4%. The intra-assay variability was ±3%.

Keyphrases □ Glucagon—*in vivo* bioassay, continuous glucose monitoring, dogs □ Glucose monitoring—glucagon, *in vivo* bioassay, dogs □ *In vivo* bioassay—glucagon, continuous glucose monitoring, dogs

Measurement of glucagon and its synthetic analogues by radioimmunoassay (1–3) does not necessarily reflect their biological activity, since there is no relationship between the binding affinity of glucagons to antibodies and their biological activity. There are several established *in vitro* bioassays for glucagon that are based on: (*a*) the *in vitro* release of glucose by liver slices; (*b*) the stimulation of adenyl cyclase in subcellular particles of the dog liver (4); and (*c*) the relaxing action on strips of rabbit renal artery (5).

Although these *in vitro* bioassays are more specific than the immunoassays, they do not necessarily reflect biological activity *in vivo*. Consequently, the USP bioassay of glucagon requires measurements of the *in vivo* hyperglycemic effect of glucagon (6). The USP bioassay also calls for multiple assays of the glucose levels in eight fasting adult cats and requires four intravenous injections of glucagon to each cat (two injections of a standard solution and two injections of assay samples). Two blood samples are taken after each injection.

The purpose of this study is to describe a simplified and rapid *in vivo* bioassay for glucagon, which can be completed in 8 h and requires only one dog.

EXPERIMENTAL SECTION

Animals—Six female hound dogs, weighing 17 kg, were used. The test was repeated six times on each dog at 2-week intervals. The dogs were anesthetized with intravenous sodium pentobarbital[1] (150-mg initial dose, 25 mg every 30 min for maintenance). Continuous glucose monitoring was then initiated, using a nonthrombogenic catheterization of the front paw.

Instruments—The glucose monitoring instrument consisted of systems for blood withdrawal and glucose measurement. The blood withdrawal system included a disposable sterile intravenous catheter connected to a peristaltic pump. Coating the inside of the catheter with triiododecylmethylammonium chloride complexed with heparin created a nonthrombogenic surface. The blood that was withdrawn continuously (at a rate of 8 mL/h) from a vein through the nonthrombogenic catheter was diluted in the plexiglass mixing chamber with 6 volumes of simultaneously withdrawn phosphate buffer solution (0.15 M, pH 7.4) and moved into the sensory chamber.

2	125	148	133	0.00 26
3	109	121	115	0.00 28
4	95	105	97	0.00 23
5	108	128	120	0.00 30
6	108	135	124	0.00 30
Mean	112.3	132	122.7	0.00 28
±*SD*	12.5	18.2	16.8	0.00 035
CV, %	11.12	13.70	13.60	12.4

The glucose measuring system included a plexiglass mixing chamber, a glucose-sensing probe, a digital display and a microprocessor-controlled digital graphic recorder. The glucose probe was a Clark electrode (7). A membrane impregnated with glucose oxidase covered the tip of the probe. Enzymatic oxidation of glucose diffusing through the glucose oxidase membrane generated hydrogen peroxide at a rate proportional to the concentration of glucose. Thus, current flow through the electrode was linearly related to the concentration of blood glucose. The level of blood glucose was exhibited by a digital display and by the digital graphic recorder.

Reagents—A glucagon standard solution for intravenous injection was prepared in accordance with the USP (6).

Bioassay Method—The hyperglycemic peak induced by intravenous injection of glucagon was accurately depicted in real time, using the nonthrombogenic glucose monitor. The assay consisted of comparing the hyperglycemic peak, induced by an unknown amount of glucagon, to the peaks induced by two intravenous injections of a known amount of glucagon.

The blood level of glucose was first monitored for at least 0.5 h in order to establish a baseline level of glucose. After establishing a steady baseline, the dog was given the first standard amount of glucagon. The glucagon was administered as an intravenous injection in a rapid bolus which was immediately flushed with 10 mL of saline. The first peak of glucose was recorded by the glucose monitor within 14 min after the injection of glucagon. A period of 41 min following a peak was allowed for restabilization of the glucose baseline. This procedure was then repeated using a second standard amount of glucagon. The second standard was usually higher than the first standard. After recording the second peak of glucose, a third injection of an unknown amount of glucagon was administered. The level of "unknown" glucagon was then calculated by linear regression of semilogarithmic paper of the three peak levels P_1, P_2, and P_3.

RESULTS

Interassay Variability—The bioassay was repeated six times using standards of 0.002 and 0.004 U of glucagon and an injection of 0.003 U to represent the unknown. The results are given in Table I. The interassay variability of the six consecutive assays was 12.4%.

Intra-assay Variability—The intra-assay variability of the bioassay was measured by comparing the variability of five consecutive peaks by a constant amount of glucagon. Two assays of intra-assay variabilities were carried out: one with 0.002 U, the other with 0.004 U. The results are recorded in Tables

±*SD*	13.20	17.70	19.08	14.90	13.60			
CV, %	11.07	15.08	16.12	12.60	11.35			

II and III. The intra-assay variability of the assay using 0.002 U of glucagon was 3.2%. The intra-assay variability of the assay using 0.004 U was 3.5%.

The time interval from the intravenous injection of 0.002 U of glucagon to the peak level of glucose was 10.0 ± 1.2 min (mean ±1 *SD*), while the time to peak of 0.004 U glucagon was 11.9 ± 2.5 min. The peak level of glucose was maintained for 100 ± 69 s after 0.002 U of glucagon and 92 ± 49 s after 0.004 U of glucagon.

DISCUSSION

This new bioassay of glucagon is very similar to a previously published improved bioassay for insulin (8). Similar to the insulin bioassay, the improved accuracy of the bioassay for glucagon is based on the ability to obtain a continuous and almost instantaneous record of the changing levels of blood glucose. The continuous glucose monitor made possible an accurate determination of the glucagon-induced peaks of blood glucose, even though it lasted only for a few minutes and occurred at unpredictable times.

The USP bioassay depends on sampling of blood for glucose at predetermined times (6) which almost never occurred at the precise moment of the glucose peak. We have found the actual peaks of blood glucose, which were induced by a repeated but constant dose of glucagon, to be markedly consistent. The time to peak, on the other hand, was highly variable in relation to its duration. Thus, it is obvious that the USP bioassay, which depends on blood sampling for glucose levels at predetermined times, is inherently less accurate. This new bioassay procedure would be more practical, less expensive, and more accurate than the USP bioassay for the standardization of USP preparations of glucagon, provided the actual dose used for injection is adjusted to range from 0.002 to 0.004 U.

Nasal Absorption of Testosterone in Rats

ANWAR A. HUSSAIN, RYOHEI KIMURA, and CHONG HENG HUANG

Received July 22, 1983 from the *College of Pharmacy, University of Kentucky, Lexington, KY 40536-0053.* Accepted for publication September 19, 1983.

Abstract □ Testosterone levels in the blood were determined in rats following nasal, intravenous, and intraduodenal administration of 25-μg and 50-μg doses. The results indicated that the drug levels after nasal and intravenous administration were similar, whereas intraduodenal administration resulted in considerably lower levels. The bioavailability of the nasally administered drug was calculated to be 99% and 90% at the 25-μg and 50-μg doses, respectively. The intraduodenal bioavailability was only 1% at the dose studied.

Keyphrases □ Testosterone—nasal absorption, rats □ Nasal absorption—testosterone, rats

Testosterone is considered to be the most potent of the natural male sex hormones. This androgen is readily absorbed orally, but it is ineffective when so administered because of extensive metabolism in the GI tract and the liver before reaching systemic circulation (1). The esters of testosterone are similarly metabolized (1). Consequently, testosterone and its esters are generally administered by intramuscular injection. Other routes of administration, for example, buccal, transdermal, and subcutaneous implantation, have been attempted, but success has been limited (1).

Previous studies by Hussain and co-workers have shown that selected drugs, for example, propranolol and progesterone, are efficiently and completely absorbed following nasal absorption in animals and man (2–5). To enhance testosterone bioavailability from non-parenteral routes, the nasal route was examined. This report presents results on the nasal administration of testosterone in rats as compared to intravenous and intraduodenal administration of the drug.

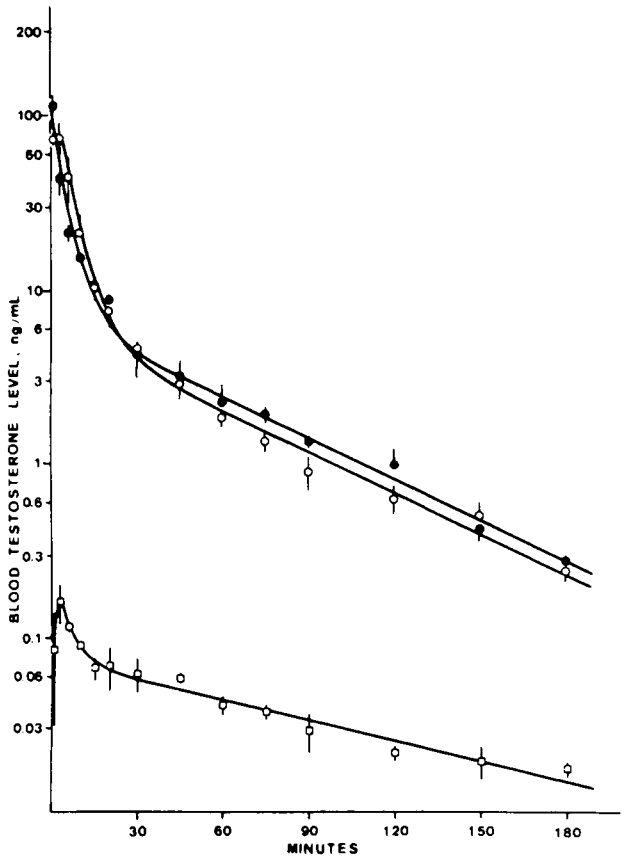

Figure 1—*Mean blood levels of testosterone in rats following nasal (○), intravenous (●), and intraduodenal (□) administration of 25-μg testosterone per rat. Points represent mean values of 3 animals ±SEM.*

	Intraduodenal	8.9 ± 0.19	0.01
50	Intravenous	1716.3 ± 47.2	—
	Nasal	1545.7 ± 168.6	0.90

[a] Mean ± *SEM* (n = 3).

EXPERIMENTAL SECTION

Animal Studies—Male Sprague-Dawley rats, each weighing approximately 300 g, were anesthetized with pentobarbital (50 mg/kg). The surgical operation carried out on the rats was that described by Hussain *et al.* (2). For nasal administration of [^{3}H]testosterone[1], an incision was made in the neck of the animals, and the trachea was cannulated with a polyethylene tube. A closed tube was inserted through the esophagus to the posterior part of the nasal cavity. The nasopalatine passage was closed with an adhesive agent to prevent drainage of the drug from the nasal cavity to the mouth. Two doses of 25 and 50 μg of [^{3}H]testosterone, each containing 20 μCi of [^{3}H]testosterone in 0.1 mL of 1% polysorbate 80-saline solution, were administered to the nasal cavity by means of micropipet, and the nostrils were then closed with an adhesive agent. For intravenous administration, the same doses were injected through the femoral vein. For intraduodenal administration, the abdomen was opened by a midline incision, and the 25-μg dose in 0.1 mL of 1% polysorbate 80-saline solution was injected directly through the duodenum.

Analytical Method—The blood samples were placed in polyethylene tubes, to which 0.2 g of NaCl, 200 μL of nonradioactive testosterone solution (1.25 mg/mL) in ethyl acetate, and 5 mL of ether were added. After shaking and centrifugation, the tube was frozen in a dry ice–acetone mixture. The ether layer was decanted into another tube and evaporated to dryness. The residue was then dissolved in 60 μL of methanol and 40 μL was spotted on TLC plates and developed using chloroform–acetone (9:1, v/v). The spot that corresponded to unchanged testosterone was then scraped off the plate, and the powder was suspended in 10 mL of scintillation cocktail for a radioactivity count. The developing solvent system was shown to separate unchanged testosterone from its metabolites.

RESULTS AND DISCUSSION

The levels of testosterone in the blood after nasal administration increased rapidly and attained the peak level within 2 min, whereas the intraduodenal administration resulted in considerably lower blood levels. The blood levels following nasal administration were similar to those following intravenous administration, and the half-life of elimination for the two routes was ~40 min.

The nasal bioavailability, calculated from the ratio of the area under the blood level–time curve [(nasal/intravenous) × 100], was 99% at the 25-μg dose and 90% at the 50-μg dose; the intraduodenal bioavailability was only 1% of that of the intravenous bioavailability at the dose studied (Table I; Fig. 1).

The results of this study strongly suggest that the natural male sex hormone, testosterone, is rapidly absorbed from the nasal mucosa into systemic blood

Colorimetric Determination of Gentamicin, Kanamycin, Tobramycin, and Amikacin Aminoglycosides with 2,4-Dinitrofluorobenzene

JAMES A. RYAN

Received March 29, 1983, from the *Department of Pharmaceutical Research and Development, Merck Sharp and Dohme Research Laboratories, Division of Merck and Company, Inc. West Point, PA 19486.* Accepted for publication August 3, 1983.

Abstract □ The reaction of 2,4-dinitrofluorobenzene (Sanger's reagent) is used to form colored products with aminoglycoside antibiotics. Stopping the progress of the reaction with acid after a fixed time allows aqueous solubility to be maintained while discharging any color due to excess reactant. The choice of an appropriate analytical wavelength results in adherence to Beer's law. Although this colorimetric method is not expected to be stability-indicating, it is convenient and should be useful in content uniformity determinations for pharmaceutical dosage forms (*e.g.*, ointments).

Keyphrases □ Colorimetry—aminoglycosides, 2,4-dinitrofluorobenzene □ Aminoglycosides—2,4-dinitrofluorobenzene, colorimetric determination

Most assays for monitoring aminoglycoside antibiotics which are mentioned in the Federal Register (1) are plate-cup bioassays. A number of chemical assays (2) have been developed for use with pharmaceutical dosage forms and content determinations. These assays are useful, in some cases, as rapid control procedures featuring high precision, but do not actually measure bioactivity; most are amine reagents (3). We found in our preliminary work that certain pharmaceutical formulation excipients do not react with 2,4-dinitrofluorobenzene (Sanger's reagent) (4–6); therefore, this reagent could be useful when determining aminoglycosides. Sanger's reagent was originally used to detect terminal amino groups in insulin, and was utilized recently (7) for postcolumn HPLC-derivatization and detection of neomycin sulfate.

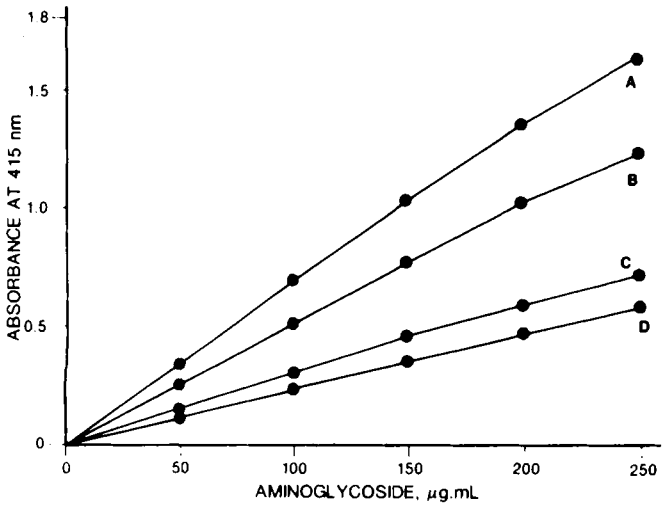

Figure 1—*Absorbance of aminoglycosides at 415 nm with 20-min reaction time. Key: (A) amikacin, (B) tobramycin, (C) kanamycin, (D) gentamicin.*

This paper reports the direct one-phase determination of gentamicin sulfate, kanamycin sulfate, tobramycin, and amikacin. The reaction was allowed to proceed under ambient conditions and then it was stopped, after an appropriate time, by acidification. The analytical wavelength chosen was not the absorption maximum, but one which permitted measurement in the aqueous-alcoholic medium without problem precipitation and with adherence to Beer's law over the range of 0–1000 μg/mL (Fig. 1). A typical reaction profile of gentamicin sulfate is outlined in Fig. 2.

EXPERIMENTAL SECTION[1]

Colorimetric Measurement—Exactly 5.0 mL of an aqueous solution containing ~500 μg of the aminoglycoside being tested was transferred to a 10-mL glass-stoppered flask or tube. Similarly, a series of flasks or tubes containing

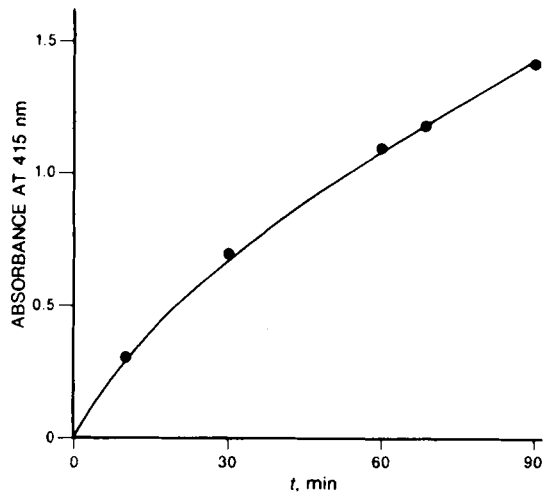

Figure 2—*Gentamicin sulfate reaction profile.*

[1] Gentamicin sulfate (lot GMC-6M-6024, potency 581 μg/mg) was obtained from the Schering Corp., Kenilworth, N.J. Kanamycin sulfate (lot 76F-140, potency 780 mg/mL) and amikacin (lot 74F-1805, potency 934 mg/mL) were both obtained from Bristol Labs., Syracuse, N.Y. The tobramycin (lot OCU55, potency 960 μg/mg) was made available through the courtesy of Eli Lilly and Co., Indianapolis, Ind. Sanger's reagent, 2,4-dinitrofluorobenzene (lot 101547, purity 98%), was obtained from the Aldrich Chemical Co., Milwaukee, Wis. Measurements were made on a Cary Model 15 UV-visible spectrophotometer.

Colorimetric Determination of Gentamicin, Kanamycin, Tobramycin, and Amikacin Aminoglycosides with 2,4-Dinitrofluorobenzene

JAMES A. RYAN

Received March 29, 1983, from the *Department of Pharmaceutical Research and Development, Merck Sharp and Dohme Research Laboratories, Division of Merck and Company, Inc. West Point, PA 19486.* Accepted for publication August 3, 1983.

Abstract □ The reaction of 2,4-dinitrofluorobenzene (Sanger's reagent) is used to form colored products with aminoglycoside antibiotics. Stopping the progress of the reaction with acid after a fixed time allows aqueous solubility to be maintained while discharging any color due to excess reactant. The choice of an appropriate analytical wavelength results in adherence to Beer's law. Although this colorimetric method is not expected to be stability-indicating, it is convenient and should be useful in content uniformity determinations for pharmaceutical dosage forms (*e.g.*, ointments).

Keyphrases □ Colorimetry—aminoglycosides, 2,4-dinitrofluorobenzene □ Aminoglycosides—2,4-dinitrofluorobenzene, colorimetric determination

Most assays for monitoring aminoglycoside antibiotics which are mentioned in the Federal Register (1) are plate-cup bioassays. A number of chemical assays (2) have been developed for use with pharmaceutical dosage forms and content determinations. These assays are useful, in some cases, as rapid control procedures featuring high precision, but do not actually measure bioactivity; most are amine reagents (3). We found in our preliminary work that certain pharmaceutical formulation excipients do not react with 2,4-dinitrofluorobenzene (Sanger's reagent) (4–6); therefore, this reagent could be useful when determining aminoglycosides. Sanger's reagent was originally used to detect terminal amino groups in insulin, and was utilized recently (7) for postcolumn HPLC-derivatization and detection of neomycin sulfate.

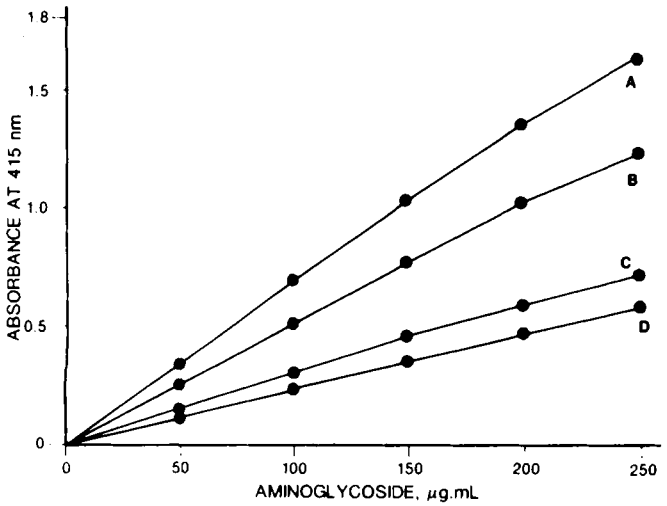

Figure 1—*Absorbance of aminoglycosides at 415 nm with 20-min reaction time. Key: (A) amikacin, (B) tobramycin, (C) kanamycin, (D) gentamicin.*

This paper reports the direct one-phase determination of gentamicin sulfate, kanamycin sulfate, tobramycin, and amikacin. The reaction was allowed to proceed under ambient conditions and then it was stopped, after an appropriate time, by acidification. The analytical wavelength chosen was not the absorption maximum, but one which permitted measurement in the aqueous-alcoholic medium without problem precipitation and with adherence to Beer's law over the range of 0–1000 μg/mL (Fig. 1). A typical reaction profile of gentamicin sulfate is outlined in Fig. 2.

EXPERIMENTAL SECTION[1]

Colorimetric Measurement—Exactly 5.0 mL of an aqueous solution containing ~500 μg of the aminoglycoside being tested was transferred to a 10-mL glass-stoppered flask or tube. Similarly, a series of flasks or tubes containing

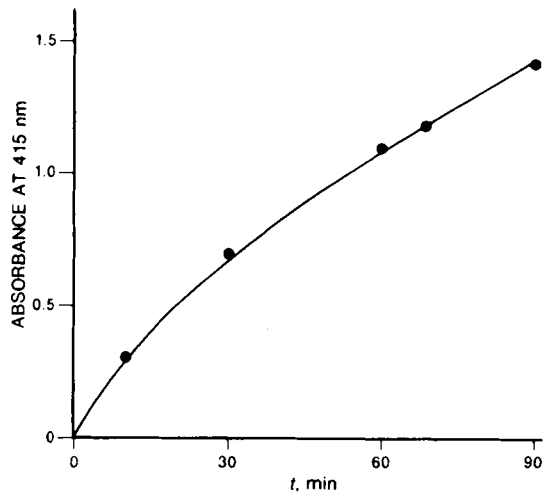

Figure 2—*Gentamicin sulfate reaction profile.*

[1] Gentamicin sulfate (lot GMC-6M-6024, potency 581 μg/mg) was obtained from the Schering Corp., Kenilworth, N.J. Kanamycin sulfate (lot 76F-140, potency 780 mg/mL) and amikacin (lot 74F-1805, potency 934 mg/mL) were both obtained from Bristol Labs., Syracuse, N.Y. The tobramycin (lot OCU55, potency 960 μg/mg) was made available through the courtesy of Eli Lilly and Co., Indianapolis, Ind. Sanger's reagent, 2,4-dinitrofluorobenzene (lot 101547, purity 98%), was obtained from the Aldrich Chemical Co., Milwaukee, Wis. Measurements were made on a Cary Model 15 UV-visible spectrophotometer.

Table I—Stability of Developed Color after Acidification

	Absorbance Values	
	Initial	$T + 17$ h at Room Temperature
Blank	0.066	0.069
Gentamicin sulfate	0.321	0.318
Kanamycin sulfate	0.419	0.419
Amikacin	0.747	0.747
Tobramycin	0.586	0.586

5-mL aliquots of standard solutions containing 250, 500, 750, 1000, 1250 μg per 5.00 mL of the aminoglycoside were prepared. Using a definite sequence and a convenient but reproducible time interval between reagent additions, the following operations were performed on each sample and standard solution.

One milliliter of a 2% aqueous $NaHCO_3$ solution was added to each tube. The tubes were stoppered and mixed. Exactly 2.0 mL of a freshly prepared ethanolic (95%) solution of 2,4-dinitrofluorobenzene[2] (5, 6) containing 0.25 mL/100 mL was added to each tube. The contents of the tube were mixed thoroughly. After 20 min for tobramycin, amikacin, and kanamycin sulfate, or 30 min for gentamicin sulfate, the solution was neutralized by the addition of 0.5 mL 1 M HCl. After tapping the cell gently to remove any CO_2 bubbles, the absorbance was determined at 415 nm in the spectrophotometer using 1 cm cells and distilled water as a reference liquid.

RESULTS AND DISCUSSION

Inasmuch as adherence to Beer's law was obtained, the concentration of each aminoglycoside was determined by direct ratio to the diluted reference standard. Since the yellow color, due to excess reagent, is discharged by the acid solutions, no reagent blank was required when assaying colorless solutions. The *RSD* of each of the aminoglycosides tested was: gentamicin sulfate ±1.4%, kanamycin sulfate ±0.86%, tobramycin ±1.6%, and amikacin ±1.1%. The color that developed after acidification was found to be stable for at least 17 h (Table I). Use of filter photometers or other instruments with wide spectral band-pass may possibly result in deviations from Beer's law at 415 nm.

A probe experiment was also conducted to check the stability of the response of aqueous solutions of these antibiotics to the assay. Dilutions of the individual antibiotics in unbuffered aqueous solutions were prepared at levels of ~10 mg/100 mL. The solutions were sampled for their color response and then rechecked after 35 d under ambient conditions (~21.5°C in laboratory light) (Table II).

Compatibility of the Method with Various Pharmaceutical Excipients used for Topical Administration of the Antibiotics—Five grams of an ointment base[3] was mixed for 5 min with 20 mL of water and filtered[4]. The clear filtrate was used as a gentamicin sulfate diluent instead of water in the assay method and compared to a standard in distilled water. The average of three consecutive comparisons of these gentamicin solutions showed water extract absorbance values only 100.5% of those obtained with distilled water diluent solutions which demonstrates the lack of significant interference from the excipients.

Phosphate buffers are often used in connection with the bioassays of aminoglycosides such as gentamicin sulfate, however, they were found to interfere with the color development reaction. Those studied were 0.1–1.0 M buffers adjusted to pH 7.0. An average of eight measurements of four buffer strengths at pH 7 produced only 31.2% of the color development of a sample in distilled water.

Potential Automated Modifications—The requirement for precise timing during the initial reaction step and the need for caution to prevent exposure of Sanger's reagent to the skin indicates that, if automated, this method might reasonably be expected to have wide application.

Table II—Color Responses of Amino Functions after 35 d at 21.5°C in Unbuffered Aqueous Solutions

	Initial mg/mL	Final mg/mL	% Initial
Gentamicin sulfate	10.1	10.1	100
Kanamycin sulfate	9.74	10.5	107
Amikacin	10.3	10.2	99.0
Tobramycin	10.7	11.1	104

High-Performance Liquid Chromatographic Determination of The Nitrate Esters Isosorbide Dinitrate, Pentaerythritol Tetranitrate, and Erythrityl Tetranitrate in Various Tablet Forms

CAROLYN S. OLSEN ˣ **and HENRY S. SCROGGINS**

Received April 11, 1983, from the *Food and Drug Administration, 4298 Elysian Fields Avenue, New Orleans, LA 70122.* Accepted for publication June 22, 1983.

Abstract □ A reliable, sensitive, and specific assay for isosorbide dinitrate, pentaerythritol tetranitrate, and erythrityl tetranitrate in sublingual, uncoated, sustained-release, and chewable dosage forms, using high-performance liquid chromatography, is described. The nitrate ester dosage forms were dissolved in methanol, filtered, and injected directly into the liquid chromatograph. A variable-wavelength UV detector, operated at 220 nm, and a reverse-phase C_{18} microporous silica column were employed. The mobile phase was methanol–water (40:60). The proposed method is quantitative and reproducible.

Keyphrases □ Isosorbide dinitrate—HPLC, tablet forms □ Pentaerythritol tetranitrate—HPLC, tablet forms □ Erythrityl tetranitrate—HPLC, tablet forms

Isosorbide dinitrate (I), pentaerythritol tetranitrate (II), and erythrityl tetranitrate (III) are members of a group of vasodilator drugs that are useful in the treatment of angina pectoris and ischemia of skeletal muscles. Since these nitrate esters have a slower onset of action and their duration is longer than nitroglycerin (IV), they are beneficial in the prevention of attacks, but not in the management of the acute attack (1).

Nitrate esters have been determined by polarographic (2–4), IR, spectrophotometric (5–8), and colorimetric (9–11) procedures. The basis for several procedures (12, 13) is nitration of phenoldisulfonic acid with the nitrate moiety of the ester and subsequent formation of a colored ion in a basic solution. These standard methods are time consuming and complex, and the colorimetric method is nonspecific for the active ingredient.

The objective of this investigation was to devise a simple, rapid, and specific procedure that would be applicable to the three nitrate esters cited above and to the majority of other nitrate esters. High-performance liquid chromatography (HPLC) as a determinative technique offered the best approach (14, 15). This straightforward procedure has already been successfully used to quantitatively determine IV (16, 17). This paper presents a method for the analysis of I, II, and III in various dosage forms by reverse-phase HPLC with IV as the internal standard. This method is simple, rapid, and reproducible.

EXPERIMENTAL SECTION

Reagents and Materials—HPLC-grade methanol[1] and water[1] were used. All other chemicals and solvents were reagent grade and were used without further purification. Ten percent of II[2], 10% of III[3], and 25% of I[4], all as lactose triturates, were used as reference standards; II and III were assayed by the USP phenoldisulfonic acid method (18). A 10% IV[5] triturate was used as an internal standard.

Instrumentation—The liquid chromatographic system consisted of a dual-head reciprocating piston positive-displacement pump[6], a septumless syringe-loaded loop injector with a 20-μL loop[7], a variable-wavelength UV detector[8], operated at 220 nm, and a 10-mV recorder[9]. A 30 cm × 3.9-mm i.d. 10-μm C_{18} microparticulate column[10] with a 4 cm × 4.6-mm guard column packed with pellicular octadecyl reverse-phase material[11] was used at ambient temperature. The mobile phase was methanol–water (40:60). The flow rate was 1 mL/min with a pressure of 1600 psi.

Solution Preparation—The internal standard, IV, was prepared as a 75-μg/mL solution in methanol and filtered through 0.7-μm filter paper[12]. To prepare a standard solution, 1 mg of I, 2 mg of II, or 3 mg of III was accurately weighed into a 50-mL glass-stoppered Erlenmeyer flask and diluted with 10.0 mL of internal standard solution. The desired solution was sonicated for 2 min, mechanically shaken for 30 min, and then filtered through 0.7-μm filter paper[12]. Samples of each drug were prepared by weighing and finely powdering 20 tablets. An accurately weighed portion of the powder, equivalent to 1 mg of I, 2 mg of II, or 3 mg of III, was transfered to a 50-mL glass-stoppered Erlenmeyer flask and diluted with 10.0 mL of internal standard solution,

Table I—Assay Results for Tablet Forms

Dosage Form	Tablet Conc., mg	Found, mg	Found, %
	Isosorbide Dinitrate		
Sublingual	2.5	2.34	93.6
Sublingual	2.5	2.40	96.0
Sustained-release	40	40.57	101.4
Sustained-release	40	38.53	96.3
	Pentaerythritol Tetranitrate		
Uncoated	10	9.04	90.4
Uncoated	10	10.05	100.5
Uncoated	10	9.17	91.7
Sustained-release	80	84.00	105.0
	Erythrityl Tetranitrate		
Chewable	10	10.80	108.0
Sublingual	10	10.13	101.3
Sublingual	10	10.36	103.6

sonicated for 2 min, mechanically shaken for 30 min, and filtered through 0.7-μm filter paper[12].

Assay of Standard and Sample—Using the HPLC parameters described, three 20-μL portions of the standard and sample filtrates were chromatographed. The calculation of the peak area ratio, R, was determined from the area of I/the area of internal standard peak. The concentration of I (C) was then determined from:

$$C_{sample} = C_{standard} \times (R_{sample}/R_{standard})$$

The percent of I was determined from the percent of label = (sample concentration/theoretical sample concentration) × 100.

Precision and Accuracy Studies—Twenty tablets were weighed and triturated to a fine powder. From this powder, seven samples were weighed and treated as described above. Triplicate injections were made of each sample. The spiked samples of each dosage form were prepared using standard addition procedures. Weighed amounts of the triturate were added to previously assayed dosages containing the active ingredient. These preparations were then analyzed as described (19).

RESULTS AND DISCUSSION

Figure 1 shows a typical chromatogram of a mixture of 2 μg of I, 4 μg of II, and 6 μg of III, using 1.5 μg of IV as the internal standard. The retention time with 40% methanol in water was ~10 min for I, 14 min for IV, 25 min for II, and 30 min for III.

During the development of this method, a number of variations were tried. Methanol was chosen as the extracting solvent because of its ability to solubilize the nitrate ester from its excipients in the various dosage forms. Methanol and acetonitrile performed equally well as the mobile phase; however, methanol was chosen because it is less costly. Compound IV was chosen as the internal standard because it does not interfere with the nitrate esters or any of the excipients present in the various dosage forms.

The various nitrate esters were separated by the HPLC method described. Detection with 220 nm gave twice the sensitivity with quantitative results compared with those obtained at 254 nm. Commercial preparations were analyzed by the proposed HPLC method. Results are given in Table I.

Quantitation was based on the nitrate ester-to-internal standard peak area ratio. Linearity was obtained between 0.2–40 μg of I, 0.4–50 μg of II, and 0.6–50 μg of III. The correlation coefficients were 0.9980, 0.9999, and 0.9999 for I, II, and III, respectively. The precision of the method showed an *RSD* of 1.56% ($n = 7$) (Table II). The overall percent recoveries (±*SD*) from the spiked sample mixtures were 100.8 (±1.4) for I, 101.1 (±0.5) for II, and 101.5 (±0.6) for III.

Table II—Precision of HPLC Assay of Isosorbide Dinitrate

Tablet	Absorbance[a]	Found, mg	Percent of Label Found
1	0.5500	2.43	97.2
2	0.5618	2.48	99.2
3	0.5694	2.51	100.4
4	0.5793	2.56	102.4
5	0.5657	2.50	100.4
6	0.5616	2.48	99.2
7	0.5656	2.50	100.0
Mean			99.8
SD (σ) =			1.56
RSD[b]			1.57%

[a] Factor = 4.4145. [b] *RSD* derived from 100 ($\sigma/\bar{x}$).

The HPLC assay provides a rapid, sensitive, and specific method for the determination of the nitrate esters in the various dosage forms. This method is faster and more specific than the present official methods.

Determination of Ethylene Oxide, Ethylene Chlorohydrin, and Ethylene Glycol in Aqueous Solutions and Ethylene Oxide Residues in Associated Plastics

N. A. BALL

Received May 31, 1983 from *Fisons plc, London Road, Holmes Chapel, Crewe, Cheshire, England.* Accepted for publication September 8, 1983.

Abstract □ A gas chromatographic (GC) method was developed for the determination of ethylene oxide and its two reaction products, ethylene chlorohydrin and ethylene glycol, in aqueous ophthalmic solutions. Propylene oxide was used as an internal standard. All three components were determined in one isothermal chromatographic analysis in <15 min. An extraction method for the determination of ethylene oxide residues in plastic components was also developed, and certain plastics with different ethylene oxide retention characteristics were identified.

Keyphrases □ Gas chromatography—determination of three components in one analysis, ethylene oxide residues □ Ethylene oxide residues—GC, determination of three components in one analysis

The Food and Drug Administration published guidelines in 1978 for the levels of ethylene oxide and its hydrolysis products in ophthalmic solutions; ethylene oxide was used to sterilize plastic components. Manufacturers are now required to control the levels of ethylene oxide (I), ethylene chlorohydrin (II), and ethylene glycol (III) in their ophthalmic products for sale in the United States.

Many papers have been published on the analysis of ethylene oxide (1–7), ethylene chlorohydrin, and/or ethylene glycol (8–13). Very few papers deal with the analysis of all three compounds (14–16), and, of these, the analyses either involve two different gas chromatography (GC) columns (14, 15) or two analyses on one column (16).

EXPERIMENTAL SECTION

Apparatus—The gas chromatograph[1] was equipped with a flame-ionization detector and a glass column, 3% Carbowax 20M on Chromosorb 101 (80–100 mesh), 200 cm × 3 mm i.d. The gas chromatograph was linked to a data station[2] which controlled the temperatures and flow rates and processed the peak area data. The column was conditioned at 170°C under a nitrogen flow of 30 mL · min^{-1} for 14–16 h, at which time the temperature was reduced to 150°C, and several 1-μL injections of water were made before analysis commenced. This temperature and flow rate was maintained throughout the analysis. The injector temperature was 300°C and the detector temperature was 250°C.

Compounds I[3], II[3], III[4], and propylene oxide (IV)[3] were used as received.

Extraction Procedure—Approximately 15 g of cut-up plastic was weighed into a 500-mL conical flask; 100 mL of 1 M HCl was added and the flask was stoppered and sealed[5]. The flask was then placed in a water bath for 14–16 h at 80°C. The resultant solution was transferred to a 200-mL flask, neutralized to pH 7.0 ± 1.0 (using 1 M NaOH) and made to volume with water.

Approximately 15 g of plastic was exposed to an atmosphere of ethylene oxide under a pressure of 15 psi for 6 h and then sampled immediately for extraction.

Solution Preparation—Standards I and IV were prepared by accurately weighing ~50 μL of cold liquid (0–5°C) into a 10-mL flask, containing 3 mL of water, using a previously cooled (0–5°C) 100-μL syringe. The solution was then transferred quantitatively to a 100-mL flask and made to volume with water. Standards II and III were prepared in a similar way; however, the cooling stage was not necessary. A working standard was prepared by adding 1 mL of each solution to a 10-mL flask and diluting to volume with water. Standard IV was the internal standard.

The sample was prepared with 1 mL of IV which was added to a 10-mL flask and made to volume with sample solution.

RESULTS AND DISCUSSION

Column conditioning was found to be very important in achieving reproducible retention times. A high injection temperature of 300°C was used to achieve a sharper ethylene glycol peak. The peak shape was improved further by using a "hot needle" injection technique. Using a 5-μL syringe, a small volume of air was drawn into the barrel both before and after the uptake of 1 μL of sample solution. The needle was then placed in the injection port (300°C) for 5 s, the sample injected, left for a further 5 s in the port, and, finally, withdrawn. The ghosting phenomenon encountered by some authors (16) was not manifested in this analysis.

From the standard chromatogram, it can be seen that the I and IV peaks are very close to the solvent, *i.e.*, water peak. By using a peak skimming technique it was possible to achieve accurate and precise values for I content to 1 ppm.

Water flow peaks in GC are more intense with ophthalmic products. None of the ophthalmic products tested using this method gave rise to a sufficiently intense water flow peak as to overwhelm the ethylene oxide peak. The ophthalmic products[6] were tested with and without 2-phenylethanol.

The ethylene glycol peak was broad and, by altering the integration period during the analysis, accurate and precise figures for III content of samples down to 6 ppm were achieved. Below this level, III values become nonlinear. Without the advanced peak processing techniques inherent in the micro-

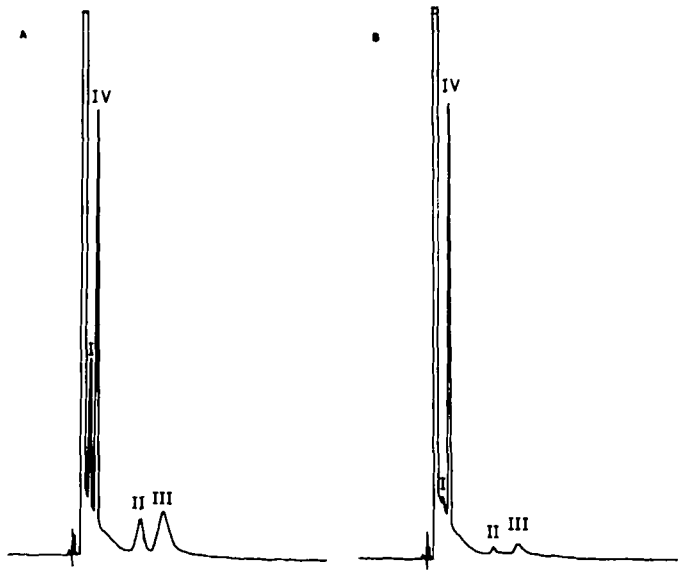

Figure 1—*Typical chromatograms of I–IV. Key: (A) 10 ppm of I, 20 ppm of II, 60 ppm of III, and 15 ppm of IV; (B) 1 ppm of I, 2 ppm of II, 6 ppm of III, and 15 ppm of IV.*

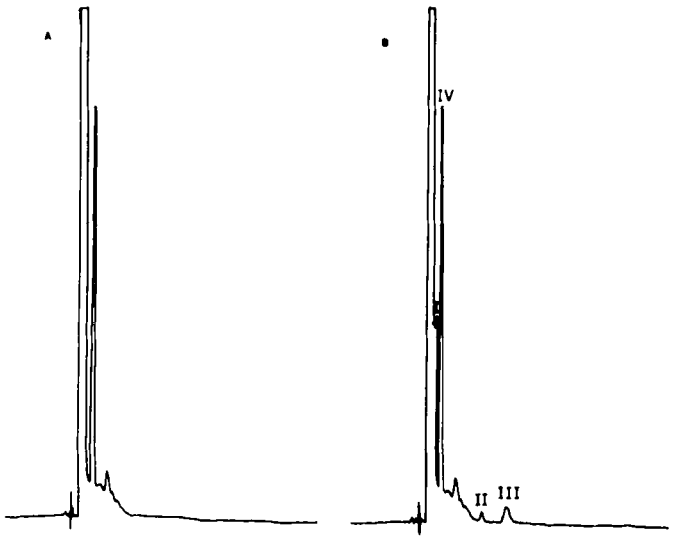

Figure 2—*Chromatograms of an ophthalmic solution (A) and an ophthalmic solution spiked with 2 ppm of I, 4 ppm of II, and 10 ppm of III (B).*

computer software, it would have been impossible to achieve the analysis in one isothermal run.

Coefficients of variation of 3.7, 2.1, and 5.7% for I, II, and III, respectively, were determined at concentrations of 18, 21, and 70 ppm, and coefficients of variation of 1.2, 1.3, and 6.2% were determined at concentrations of 90, 105, and 127 ppm, respectively. The limits of detection were 1, 2, and 6 ppm for I, II, and III, respectively (Fig. 1). Figure 2 shows a chromatogram of an ophthalmic solution and a chromatogram of an ophthalmic solution "spiked" with 2 ppm of I, 4 ppm of II, and 10 ppm of III.

Table I shows recovery data for I–III. For I and III, the recovery was worse at lower levels due to a shouldering of peaks and nonlinearity of response. Recovery values for II are very satisfactory at all levels. The system was calibrated at 10 ppm for I, 20 ppm for II, and 60 ppm for III.

This method was also employed to produce ethylene oxide hydrolysis curves in aqueous solution at 25°C (Fig. 3). It can be seen that ethylene oxide hydrolyzes steadily to ethylene glycol in solution, the reaction going to completion in <40 d at 30 ppm. At 80°C ethylene oxide fully hydrolyzes in <16 h.

An acidic medium was chosen for the extraction of ethylene oxide from plastics for two reasons. First, acid extracts I faster from plastic than does an entirely aqueous medium. Using an acid medium at 80°C, consistent ethylene oxide contents for plastics were achieved after 16 h, whereas an aqueous medium at 80°C required 7 d. At 25°C, recoveries of 18% after 16 h and 37% after 7 d were achieved for both media. Second, by choosing hydrochloric acid, the ethylene oxide thus extracted will be converted to II rather than III. Compound II is both easier to quantify and has a lower detection limit. Thus, by combining 1 M HCl with an elevated temperature (80°C), an efficient extraction procedure was developed. The retention characteristics of different plastics were studied in this way.

Solutions equivalent to 10, 20, and 30 ppm of ethylene oxide in 1 M HCl were prepared. After only 12 h at 80°C, ethylene oxide was fully converted to ethylene chlorohydrin. The recoveries ranged from 94 to 98% (Fig. 4).

The retention characteristics of polystyrene, high-density polyethylene, and low-density polyethylene were tested. The plastics had ethylene oxide contents of 430, 280, and 53 μg/g, respectively, after fumigation with ethylene oxide for 6 h at 15 psi. It was found that polystyrene retains a greater amount of I than does high-density polyethylene, which retains more I than does

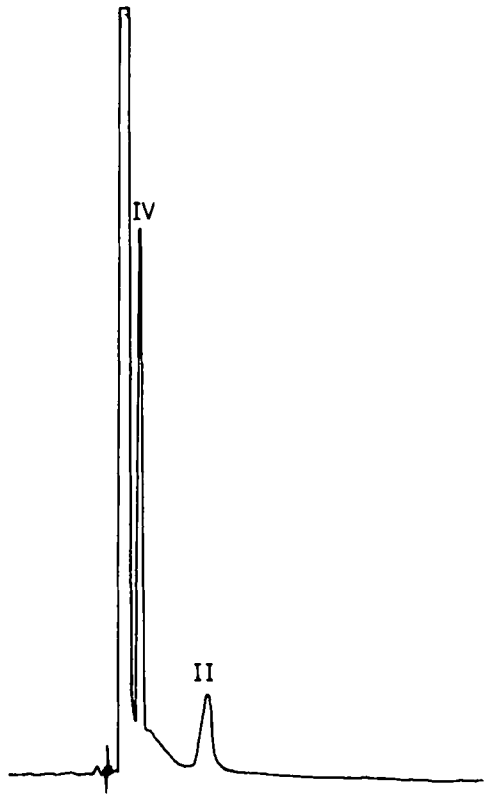

Figure 4—*Chromatogram showing complete conversion of I to II in 1 M HCl.*

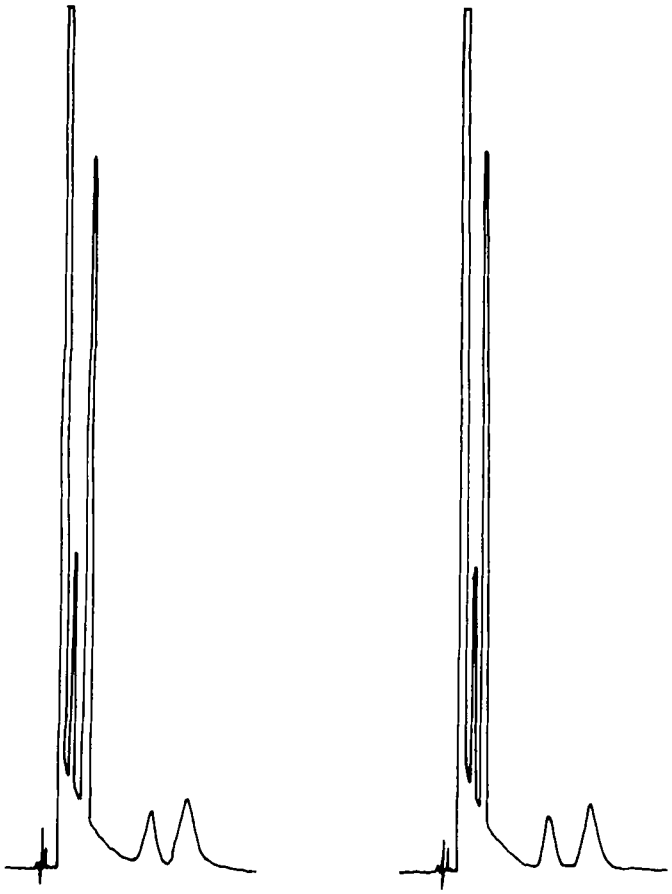

Figure 5 —*Duplication of the chromatographic column.*

low-density polyethylene. The average thickness for the materials were 1.26 mm for polystyrene and high-density polyethylene and 1.00 mm for low-density polyethylene.

When using polystyrene for manufacturing plastic components which are to be sterilized with ethylene oxide, there is the possibility of a "mesh" effect due to the composite nature of the plastic; the presence of bulky phenyl groups gives the plastic many interstitial spaces. Ethylene oxide may enter these spaces within the plastic and remain there, dissipating slowly over a long time period. Obviously, elevated temperature and reduced pressure will increase the rate of dissipation. Likewise, high-density polyethylene plastic components retain more ethylene oxide than low-density polyethylene plastics due to their higher density, where it is less likely that the fumigant will penetrate the plastic.

A most satisfying feature of this method has been the extraordinary longevity of the column. This method of analysis has been used routinely for 18 months with only two replacement columns, giving ~1000 injections per column life. The end of the useful life of a column manifests itself in the broadening of the ethylene glycol peak and a drift in retention times. Duplication of the chromatographic column has been achieved several times with no adverse effects on the separation of the components (Fig. 5). Since this method uses only one isothermal column run for the analysis of all three components and no elaborate sample preparation is necessary, it would appear that this method is ideal for use in quality control laboratories of companies which need to comply with the Food and Drug Administration proposals.

Anti-Influenza A Activity of Some *N*-Substituted Bicyclo[3.2.1]octane-3-spiro-3′-pyrrolidine Hydrochlorides: Synthesis and Structure

ELENA DE LA CUESTA, PALOMA BALLESTEROS, and GREGORIO G. TRIGO[x]

Received March 9, 1983, from the *Departamento de Quimica Organica y Farmaceutica, Facultad de Farmacia, Universidad Complutense, Madrid-3, Spain.* Accepted for publication July 19, 1983.

Abstract □ Some *N*-substituted bicyclo[3.2.1]octane-3-spiro-3′-pyrrolidine hydrochlorides (IX–XII) prepared from bicyclo[3.2.1]octan-3-one (I), were assayed *in vitro* against influenza A viruses. All materials showed activity similar to 1-adamantanamine hydrochloride. A ^{1}H-NMR study revealed only one isomer at the spiro carbon atom.

Keyphrases □ *N*-Substituted bicyclo[3.2.1]octane-3-spiro-3′-pyrrolidine hydrochlorides — synthesis, structure, antiviral activity against influenza A □ Antiviral agents—potential, *N*-substituted bicyclo[3.2.1]octane-3-spiro-3′-pyrrolidine hydrochlorides, influenza A

Since Davis *et al.* (1) described the antiviral activity of 1-adamantanamine (amantadine) against influenza A viruses, a wide variety of derivatives have been prepared (for review; 2). Among them, some spiropyrrolidine derivatives of adamantane and other cyclic systems (3, 4) have been reported to show amantadine-like antiviral activity.

In this report we describe the synthesis of the *N*-substituted bicyclo[3.2.1]octane-3-spiro-3′-pyrrolidine hydrochlorides

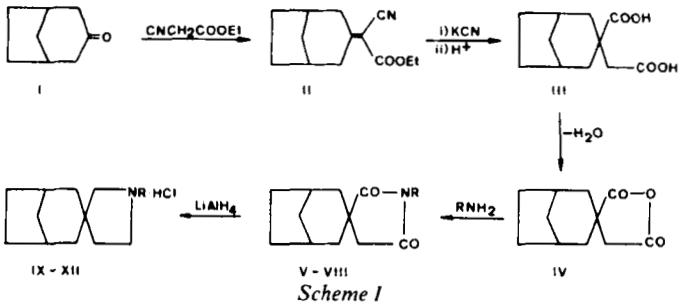


Scheme I

(IX-XII) (Scheme I) and their evaluation as potential antiviral agents.

EXPERIMENTAL SECTION[1]

Chemistry—Bicyclo[3.2.1]octan-3-one (I) was obtained according to a general literature method (5), using phase-transfer catalysis for the dichlorocarbene addition (6). Spiropyrrolidine hydrochlorides (IX-XII) were synthesized from I according to Scheme I.

Ethyl Bicyclo[3.2.1]octan-3′-yliden Cyanoacetate (II)—A solution of I (16.6 g, 0.133 mol), ethyl cyanoacetate (15.12 g, 0.133 mol), ammonium acetate (2.10 g, 0.026 mol), and glacial acetic acid (6.8 mL) in benzene (50 mL) was refluxed for 24 h using a Dean-Stark water separator. The mixture was cooled, washed with water, and dried over anhydrous Na_2SO_4. The benzene was removed under reduced pressure, and the residue was distilled *in vacuo* to yield 29.2 g (89%) of a colorless liquid, bp 103°C (0.5 mm Hg). IR (neat film): ν 2220 (C≡N) and 1725 cm^{-1} (C=O); ^{1}H-NMR (C_6D_6): δ 4.00 (q, 2, CH_2), 2.10 and 1.20 (two m, 12, cyclic H), and 1.00 ppm (t, 3, CH_3).

Anal.—Calc. for $C_{13}H_{17}NO_2$: C, 71.2; H, 7.8; N, 6.4. Found: C, 70.9; H, 7.8; N, 6.3.

3-Carboxybicyclo[3.2.1]octane-3-acetic Acid (III)—To a solution of ester II (17.25 g, 0.078 mol) in ethanol (170 mL), a solution of KCN (13.36 g, 0.2 mol) in water (34 mL) was added. After stirring for 5 d, the solvent was removed at reduced pressure. The residue was heated at reflux for 48 h with concentrated HCl (134 mL). The mixture was diluted with an equal volume of water and cooled overnight. The precipitate was removed by filtration and washed with water. The crude product was dissolved in a boiling saturated solution of $KHCO_3$, decolorized with charcoal, filtered, and the product was precipitated by the addition of concentrated HCl to yield 11.8 g (71%) of III as a white solid, mp 156-157°C. IR (KBr): ν 3100-2500 (COOH) and 1725 and 1700 cm^{-1} (COOH); ^{1}H-NMR (Me_2SO-d_6): δ 12.00 (br s, 2, COOH), 2.40 (s, 2, CH_2—COOH), and 2.15 and 1.50-1.15 ppm (two m, 12, cyclic H).

Anal.—Calc. for $C_{11}H_{16}O_4$: C, 62.6; H, 7.5. Found: C, 62.3; H, 7.8.

Bicyclo[3.2.1]octane-3-spiro-3′-succinic Anhydride (IV)—Carboxylic acid III (7.0 g, 0.033 mol) and acetic anhydride (20 mL) were refluxed for 2 h. The mixture was concentrated to dryness and crystallized from petroleum ether to give 6.02 g (94%) of the anhydride IV as a white solid, mp 57°C. IR (KBr): ν 1860 and 1790 cm^{-1} (C=O); ^{1}H-NMR ($CDCl_3$, 250 MHz): δ 2.80 (s, 2, CH_2—CO), 2.34 (br s, 2, $C_{1(5)}H_X$), 2.18 (dd, 2, J_{BA} = −14.34 Hz, $C_{2(4)}H_B$), 1.96 (dd, 2, $J_{B'A'}$ = −8.09 Hz, $C_{6(7)}H_{B'}$), 1.80 (dd, 2, J_{AB} = −14.34 Hz, $C_{2(4)}H_A$), and 1.70 ppm (dd, 2, $J_{A'B'}$ = −8.09 Hz, $C_{6(7)}H_{A'}$).

Anal.—Calc. for $C_{11}H_{14}O_3$: C, 68.04; H, 7.21. Found: C, 68.31; H, 7.55.

***N*-Substituted Bicyclo[3.2.1]octane-3-spiro-3′-succinimides**—*General Procedure*—To a solution of anhydride IV (0.15 mol) in hot benzene (50 mL), the corresponding amine (0.15 mol) in benzene (30 mL) was added with vigorous stirring at 60-65°C. After standing for 0.5 h at 60-65°C, the mixture was cooled, and the precipitate was removed by filtration and washed with benzene. The carboxyamide was heated for 1 h at 220-225°C. After cooling, the residue was crystallized giving the corresponding succinimides.

N-Benzyl Bicyclo[3.2.1]octane-3-spiro-3′-succinimide (*V*)—Yield: 78%; mp 68-69°C (white prisms, absolute ethanol). IR ($CHBr_3$): ν 1740 and 1714 cm^{-1} (C=O); ^{1}H-NMR (CCl_4): δ 7.15 (s, 5, ArH), 4.40 (s, 2, $CH_2C_2H_5$), 2.40 (s, 2, $C_{4'}H_2$), and 2.20, 1.80, and 1.40 ppm (m, 12, cyclic H).

Anal.—Calc. for $C_{18}H_{21}NO_2$: C, 76.3; H, 7.4; N, 4.9. Found: C, 76.3; H, 7.7; N, 5.0.

N-Cyclohexyl Bicyclo[3.2.1]octane-3-spiro-3′-succinimide (*VI*)—Yield: 58%; mp 78-79°C (white prisms, absolute ethanol). IR ($CHBr_3$): ν 1775 and 1700 cm^{-1} (C=O); ^{1}H-NMR ($CDCl_3$): δ 3.90 (m, 1, CH—N), 2.50 (s, 2, $C_{4'}H_2$), and 2.20, 1.80 and 1.40 ppm (m, 22, cyclic H).

Anal.—Calc. for $C_{17}H_{25}NO_2$: C, 74.2; H, 9.1; N, 5.1. Found: C, 73.9; H, 9.3; N, 5.0.

N-n-Butyl Bicyclo[3.2.1]octane-3-spiro-3′-succinimide (*VII*)—Yield: 66%; mp 86-87°C (white prisms, absolute ethanol). IR ($CHBr_3$): ν 1770 and 1700 cm^{-1} (C=O); ^{1}H-NMR (CCl_4): δ 3.35 (t, 2, CH_2—N), 2.50 (s, 2, $C_{4'}H_2$), 2.25, 1.80, and 1.35 (m, 18, cyclic H), and 1.00 ppm (t, 3, CH_3).

Anal.—Calc. for $C_{15}H_{23}NO_2$: C, 72.3, H, 9.3; N, 5.6. Found: C, 72.6; H, 9.5; N, 5.6.

N-β-Hydroxyethyl Bicyclo[3.2.1]octane-3-spiro-3′-succinimide (*VIII*)—Yield: 39%; mp 98-99°C (white plates, absolute ethanol). IR ($CHBr_3$): ν 3450 (OH), and 1775 and 1700 cm^{-1} (C=O); ^{1}H-NMR ($CDCl_3$-CCl_4): δ 3.55 (s, 4, CH_2—OH and CH_2—N), 3.00 (s, 1, OH), 2.60 (s, 2, $C_{4'}H_2$), and 2.25, 1.80, and 1.40 ppm (m, 12, cyclic H).

Anal.—Calc. for $C_{13}H_{19}NO_3$: C, 65.8; H, 8.2; N, 5.9. Found: C, 65.6; H, 8.3; N, 5.7.

***N*-Substituted Bicyclo[3.2.1]octane-3-spiro-3′-pyrrolidine Hydrochlorides**—*General Procedure*—A solution of the corresponding succinimide (0.08 mol) in ether was slowly added with stirring to a suspension of lithium aluminum hydride (0.32 mol) in ether. The mixture was stirred overnight, decomposed, filtered, and dried over anhydrous Na_2SO_4. The solvent was removed at reduced pressure, and the pyrrolidine was distilled. Pyrrolidine hydrochlorides were formed by treatment of the bases with 3 M HCl. After concentration under reduced pressure, the hydrochloride was crystallized.

N-Benzyl Bicyclo[3.2.1]octane-3-spiro-3′-pyrrolidine Hydrochloride (*IX*)—Yield: 83%; mp 265-266°C (white prisms, isopropyl alcohol). IR ($CHBr_3$): ν 2500 (N—H), and 1450, 1435, and 1410 cm^{-1} (aromatic); ^{1}H-NMR ($CDCl_3$): δ 7.65-7.35 (m, 5, ArH), 4.30 (s, 2, $CH_2C_6H_5$), 3.65-3.00 (m, 4, $C_{2'}H_2$ and $C_{5'}H_2$), and 2.25, 1.65, and 1.50 ppm (m, 14, $C_{4'}H_2$ and cyclic H).

Anal.—Calc. for $C_{18}H_{26}ClN$: C, 74.1; H, 8.9; N, 4.8. Found: C, 73.8; H, 9.0; N, 5.0.

N-Cyclohexyl Bicyclo[3.2.1]octane-3-spiro-3′-pyrrolidine Hydrochloride (*X*)—Yield: 57%; mp 178-179°C (white prisms, acetone). IR ($CHBr_3$): ν 2500 cm^{-1} (N—H); ^{1}H-NMR ($CDCl_3$): δ 3.65-2.95 (m, 5, $C_{2'}H_2$, $C_{5'}H_2$, and CH—N), and 2.00, 1.70, and 1.40 ppm (m, 24, cyclic H).

Anal.—Calc. for $C_{17}H_{30}ClN$: C, 71.9; H, 10.6; N, 4.9. Found: C, 71.6; H, 10.3; N, 4.8.

N-n-Butyl Bicyclo[3.2.1]octane-3-spiro-3′-pyrrolidine Hydrochloride (*XI*)—Yield: 39%; mp 186-187°C (white prisms, acetone). IR ($CHBr_3$): ν 2500 cm^{-1} (N—H); ^{1}H-NMR ($CDCl_3$): δ 3.76-2.90 (m, 6, $C_{2'}H_2$, $C_{5'}H_2$, and CH_2—N), 2.25, 1.90, 1.70, and 1.40 [m, 18, $(CH_2)_2$ and cyclic H], and 1.00 ppm (t, 3, CH_3).

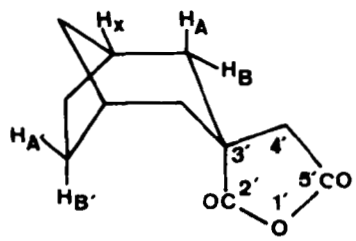
Anal.—Calc. for $C_{15}H_{28}ClN$: C, 69.9; H, 10.9; N, 5.4. Found: C, 69.6; H, 10.6; N, 5.1.

N-β-Hydroxyethyl Bicyclo[3.2.1]octane-3-spiro-3′-pyrrolidine Hydrochloride (*XII*)—Yield: 74%; mp 160-161°C (white prisms, absolute ethanol). IR ($CHBr_3$): ν 3280 (OH) and 2500 cm^{-1} (N—H); ^{1}H-NMR (D_2O): δ 3.60 (t, 2, CH_2—OH), 3.20 (m, 6, CH_2—N, $C_{2'}H_2$, and $C_{5'}H_2$), 2.00, 1.50, and 1.15 ppm (m, 14, $C_{4'}H_2$ and cyclic H).

Anal.—Calc. for $C_{13}H_{24}ClNO$: C, 63.5; H, 9.4; N, 5.7. Found: C, 63.8; H, 9.7; N, 5.4.

RESULTS AND DISCUSSION

Structural Assignment—Due to the rigid structure of the bicyclo[3.2.1]-octane system, two different isomers (XIII and XIV) are possible. On the basis of the ^{1}H-NMR spectrum of the anhydride IV, only the configuration shown (XIII) appears to be present.



From the 250-MHz ^{1}H-NMR spectrum of anhydride IV, only one isomer is observed from the presence of only one singlet at δ 2.80 ppm for the $C_{4'}$-methylene group. The presence of two isomers should be evidenced by the

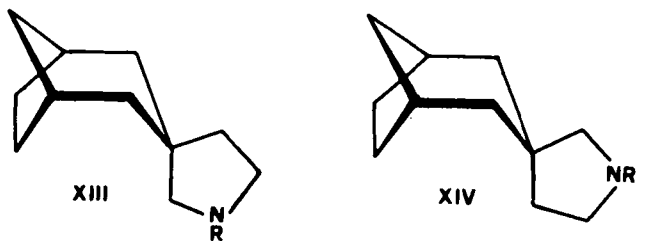
[1] All melting points were taken in open capillary tubes. Melting and boiling points are uncorrected. IR spectra were carried out on a Perkin-Elmer 577 spectrophotometer. ^{1}H-NMR spectra were recorded in $CDCl_3$ solution at room temperature using Bruker WM-250 (250 MHz) and Varian EM 360-A (60 MHz) spectrometers (Me_4Si as internal reference): (s) singlet; (d) doublet; (t) triplet; (m) multiplet; (br s) broad signal; (dd) doublet-doublet.

Table I—Inhibition of Growth of Influenza A Viruses by IX-XII and 1-Adamantanamine Hydrochloride

Inhibitor[a]	Titration of Infection[b], Plaque-Forming Units/mL	Inhibition[c]
None	2×10^7	—
IX	1×10^6	−1.30
X	7×10^5	−1.45
XI	1×10^7	−0.30
XII	7×10^6	−0.45
1-Adamantanamine hydrochloride	2×10^6	−1.00

[a] Inhibitors were administered at a concentration of 100 μM in an alcohol-water solution. [b] Plaque assay and primary isolation of influenza A viruses were carried out in an established line of canine kidney cells (MDCK), in the presence of trypsin (7). [c] Inhibition is expressed as the decimal logarithm of the quotient of plaque-forming units in the presence of inhibitor to that found in the absence of inhibitor: $\log_{10}$ [(pfu/mL of inhibitor)/(pfu/mL of control)].

appearance of two singlets, one each for the *endo* and *exo* $C_{4'}$-methylene groups. The same feature was observed in the NMR spectra of succinimides V-VIII.



Protons $H_AH_BH_{A'}H_{B'}H_X$ behave as two different ABX and A'B'X systems. The influence of the deshielding effect of the *endo* $C_{2'}$-carbonyl group on protons H_B and $H_{B'}$ is shown by the downfield chemical shift of these protons at $\delta H_B = 2.18$ ppm and $\delta H_{B'} = 1.96$ ppm relative to those of the less-affected protons H_A and $H_{A'}$, which appear upfield at δ 1.80 and 1.70 ppm, respectively. Assignation of H_B and $H_{B'}$ has been done on the basis of the observable geminal coupling constants $J_{BA} = -14.34$ Hz and $J_{B'A'} = -8.09$ Hz, which are in agreement with reported values for cyclohexane and cyclopentane, respectively (8).

X-ray diffraction data of succinimide VI (9) conclusively confirm that the $C_{2'}$-carbonyl group is attached on the *endo*-position. In this case the spirocyclohexane ring appears to adopt a boat conformation to avoid the steric interaction between the $C_{2'}$-carbonyl group and the $C_{6(7)}$-methylene groups.

Biology—According to results shown in Table I, IX-XII, especially the *N*-benzyl and *N*-cyclohexyl derivatives (IX and X), show antiviral activity against influenza A viruses similar to or greater than that shown by 1-adamantanamine hydrochloride.

Distribution and Elimination of Polymethyl Methacrylate Nanoparticles After Peroral Administration to Rats

MARIJKE NEFZGER *, JÖRG KREUTER ‡x, ROLF VOGES §, EKKE LIEHL *, and RUDOLF CZOK *

Received March 7, 1983 from the **Sandoz Forschungsinstitut GmbH, Brunner Strasse 59, A 1235 Vienna, Austria*, the ‡*Department of Pharmaceutics, Swiss Federal Institute of Technology, Clausiusstrasse 25, CH 8092 Zurich, Switzerland*, and the §*Pharmaceutical Division, Sandoz Ltd., CH 4002 Basle, Switzerland.* Accepted for publication September 13, 1983.

Abstract □ Polymethyl [1-^{14}C]methacrylate nanoparticles were administered orally to bile cannulated rats. Ten to fifteen percent of the administered radioactivity was absorbed and found in the bile and urine. Within 48 h, 94 97% of the absorbed radioactivity had been eliminated from the body. After 8 d, the highest residual radioactivity was found in the bone marrow, fatty renal tissue, stomach, liver, and lymph nodes.

Keyphrases □ Polymethyl methacrylate—peroral administration, distribution, elimination, rats □ Peroral administration—polymethyl methacrylate, elimination and distribution, rats

A possible pathway of absorption is the uptake of colloidal particulate materials by the GI tract in liquid (pinocytosis) or solid (endocytosis) form. This uptake pathway was suggested for fat absorption by Frazer (1, 2). The uptake of corn starch and some other particulate materials by endocytosis was extensively studied by Volkheimer (3). No uptake of polymethyl methacrylate particles (labeled with a fluorescent dye and ranging in size from 10 nm–1.2 μm) was observed by Juhlin (4). This may, however, be due to leakage of the label or to the small size of the particles, which prevented optical observation. For this reason, ^{14}C-labeled polymethyl methacrylate nanoparticles of a mean size of 130 nm were employed in this study. These particles were shown to be taken up by the reticuloendothelial system after intravenous administration (5). After subcutaneous administration, the particles stayed at the injection site for about 200 d. After this time, the beginning of redistribution and elimination was observed (6).

Oral administration of these nanoparticles seems to be of

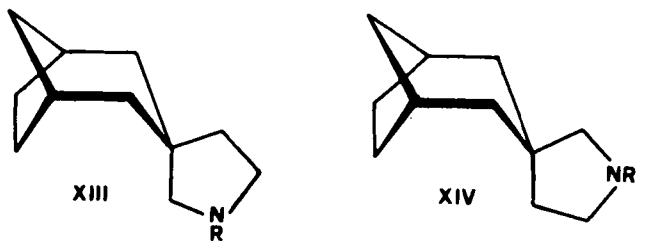
Table I—Inhibition of Growth of Influenza A Viruses by IX-XII and 1-Adamantanamine Hydrochloride

Inhibitor[a]	Titration of Infection[b], Plaque-Forming Units/mL	Inhibition[c]
None	2×10^7	—
IX	1×10^6	−1.30
X	7×10^5	−1.45
XI	1×10^7	−0.30
XII	7×10^6	−0.45
1-Adamantanamine hydrochloride	2×10^6	−1.00

[a] Inhibitors were administered at a concentration of 100 μM in an alcohol-water solution. [b] Plaque assay and primary isolation of influenza A viruses were carried out in an established line of canine kidney cells (MDCK), in the presence of trypsin (7). [c] Inhibition is expressed as the decimal logarithm of the quotient of plaque-forming units in the presence of inhibitor to that found in the absence of inhibitor: $\log_{10}$ [(pfu/mL of inhibitor)/(pfu/mL of control)].

appearance of two singlets, one each for the *endo* and *exo* $C_{4'}$-methylene groups. The same feature was observed in the NMR spectra of succinimides V-VIII.



Protons $H_AH_BH_{A'}H_{B'}H_X$ behave as two different ABX and A'B'X systems. The influence of the deshielding effect of the *endo* $C_{2'}$-carbonyl group on protons H_B and $H_{B'}$ is shown by the downfield chemical shift of these protons at $\delta H_B = 2.18$ ppm and $\delta H_{B'} = 1.96$ ppm relative to those of the less-affected protons H_A and $H_{A'}$, which appear upfield at δ 1.80 and 1.70 ppm, respectively. Assignation of H_B and $H_{B'}$ has been done on the basis of the observable geminal coupling constants $J_{BA} = -14.34$ Hz and $J_{B'A'} = -8.09$ Hz, which are in agreement with reported values for cyclohexane and cyclopentane, respectively (8).

X-ray diffraction data of succinimide VI (9) conclusively confirm that the $C_{2'}$-carbonyl group is attached on the *endo*-position. In this case the spirocyclohexane ring appears to adopt a boat conformation to avoid the steric interaction between the $C_{2'}$-carbonyl group and the $C_{6(7)}$-methylene groups.

Biology—According to results shown in Table I, IX-XII, especially the *N*-benzyl and *N*-cyclohexyl derivatives (IX and X), show antiviral activity against influenza A viruses similar to or greater than that shown by 1-adamantanamine hydrochloride.

interest for the administration of certain vaccines. For example, good protection was observed with an inactivated rabies vaccine adsorbed to polymethyl methacrylate nanoparticles, whereas no protection was obtained with different control vaccines[1]. These particles might also be useful as cytostatic carriers against tumors of the GI tract.

EXPERIMENTAL SECTION

Preparation of Polymethyl [1-^{14}C]methylacrylate nanoparticles—Polymethyl [1-^{14}C]methacrylate was produced as described by Kreuter *et al.* (6). The monomer was dissolved in phosphate buffered saline, with or without influenza virions, to yield 0.5% polymethyl [1-^{14}C]methacrylate solutions. Nanoparticles were produced by polymerization of these monomer solutions using γ-irradiation with 500 krad (2.2 krad/min) in a cobalt-60 source. The resulting suspension had an activity of (5.22 ± 0.46) × 10^8 dpm/mL. The physicochemical characteristics of similar nonradioactive nanoparticles were described by Bentele *et al.* (7) and Kreuter (8).

Excretion and Tissue Distribution after Peroral Administration—Two female and three male bile-cannulated Sprague–Dawley rats weighing 181–370 g were administered 0.5 mL of the well-stirred virus containing nanoparticle suspension with a stomach tube. The animals were kept in metabolism cages with free access to food and a salt solution containing 0.9% sodium chloride, 0.04% potassium chloride, 0.017% calcium dichloride dihydrate, and 0.02% sodium hydrogen carbonate.

Urine was collected in dry ice. The storage container contained 100 μL of diethylamine in order to keep the urine at a pH ≥ 9, thus assuring the binding of the carbon-14 activity excreted as carbonate. After each collection period, the cage was rinsed with water (30–40 mL) to wash out dried urine residues. Samples of 400–500 μL were assayed for radioactivity. The collected feces was homogenized with about the same amount of water. Three samples (200–400 mg) of each homogenate were analyzed. The bile was collected in ice-cooled containers. Samples of 40 (0–8 h) and 100 μL (24–192 h) were assayed for radioactivity.

Eight days after administration, the activity in the organs was measured after sacrificing the animals with an intraperitoneal injection of ~0.5 mL of a euthanasia solution[2]. From the adrenal glands, epididymis, ovary, thyroid gland, lymph nodes, and bone marrow, one 7–130 mg sample was taken; from the other organs, two 50–400 mg samples were taken.

The radioactivity of the excreta, blood, plasma, and organs was determined after combustion in a sample oxidizer[3] (recovery of standard radioactivity: 92–100%). The resulting carbon dioxide was absorbed in a mixture of absorber solution and scintillation liquid[4]. The samples were then counted in a liquid scintillation counter for 20 min. The counting efficiency was determined by an automatic external standardization and previously prepared quench curves. The detection limit was 4 ng/g for the bone marrow, lymph nodes, and thyroid gland and 2 ng/g for all other organs and tissues.

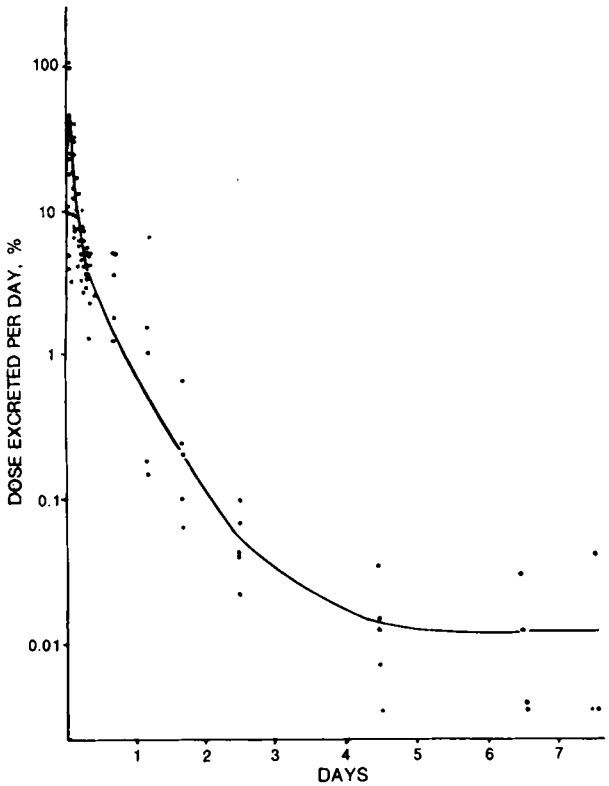

Figure 1—*Rate of biliary excretion of carbon-14 after peroral administration of ^{14}C-labeled polymethyl methacrylate nanoparticles to rats (n = 5).*

RESULTS AND DISCUSSION

Bile-cannulated rats were used so that the amount of radioactivity excreted *via* the bile could be determined. Within 8 d, between 5 and 8% of the administered dose was excreted *via* the bile and 4–6% *via* the urine (Table I).

Small intestine content	4.3 ± 1.6
Colon content	4.6 ± 2.7

[a] $n = 3$; mean, ±*SD*. [b] $n = 1$. [c] $n = 2$.

Since little radioactivity remained in the body after 8 d (Table II), the total absorption amounted to ~10–15% of the administered dose.

The absorption and excretion occurred rather rapidly. The biliary excretion rate reached a maximum after 1 h (Fig. 1) and then declined in a hyperbolic fashion. The maximal urinary excretion rate probably was reached within 2 h (Fig. 2) followed by a hyperbolic decline. Within 1 d ~83% and within 2 d ~95% of the total amount absorbed were eliminated from the body.

After 8 d, <0.5% of the administered dose remained in the body. The highest radioactivity (10 times more than in blood) was found in bone marrow. Higher levels of radioactivity were observed in renal fatty tissue, liver, pancreas, skin, adrenals, and the lymph nodes than in the blood. The values from the lymph nodes, however, give only an estimate of the actual value, due to the very small amounts of material available for the determination of the radioactivity in these organs.

The small amount of radioactivity absorbed from the GI tract probably consisted of low molecular weight components in the polymer. The figure of 10–15% is very similar to the 13% that was rapidly excreted after subcutaneous injection (6) and was, as mentioned above, attributed to low molecular weight components of the nanoparticle material. Whether these components can be used as carriers for nonabsorbable drugs is still an open question. The main part of the nanoparticle material, though capable of a carrier function, is not absorbable by rats. Because of the enhanced endocytotic activity of tumor cells (9), nanoparticles loaded with cytostatic carriers may be useful for the treatment of carcinomas of the GI tract.

High-Performance Liquid Chromatographic Determination of Acetylcholine in a Pharmaceutical Preparation

FRANK T. TAO ˣ, JOAN S. THURBER, and DANIEL M. DYE

Received September 7, 1982, from the *Analytical Development Department, CooperVision Pharmaceutical, Inc., Mountain View, CA 94043.* Accepted for publication September 22, 1983.

Abstract □ A simple and rapid method for quantitating acetylcholine in a lyophilized preparation by high-performance liquid chromatography (HPLC) is described. A reverse-phase column with a refractive index detector was utilized for the assay. The HPLC system was able to separate acetylcholine from choline, a major degradation product, which was verified by running a degraded sample of a commercial preparation. The HPLC results were compared with the results obtained by a spectrophotometric procedure.

Keyphrases □ Acetylcholine—high-performance liquid chromatographic determination, lyophilized preparation □ High-performance liquid chromatography—determination of acetylcholine □ Lyophilized preparation—acetylcholine, high-performance liquid chromatographic determination

Acetylcholine is an endogenous parasympathomimetic agent thought to play an important role in the transmission of nerve impulses at synapses and myoneural junctions. Because the action of this parasympathetic stimulation is abrupt and fleeting, acetylcholine has limited therapeutic use. However, this unique property is presently being used to advantage in an intraocular irrigating fluid to obtain complete miosis instantaneously after delivery of the lens in cataract surgery. The product[1] is in a vial of two compartments: the lower chamber contains a lyophilized preparation of acetylcholine chloride with mannitol as a tonicity adjusting agent. The upper chamber contains sterile water for injection, and the two chambers are separated by a rubber plug. Since aqueous solutions of acetylcholine are unstable, the drug is reconstituted in sterile water just prior to use.

There have been several reports on chemical assays for acetylcholine. An excellent review of the current chemical methods has been published (1). The classical colorimetric method (2) suffers from lack of specificity.

Several gas chromatographic procedures have been reported. Primary means of detection have been either flame ionization (3) or mass spectrometry (4). In all cases, they involve volatilizing acetylcholine either by demethylation (5)

or by pyrolysis in order to transform the molecule to the gas phase (6, 7).

A high-performance liquid chromatographic (HPLC) procedure (8) has been reported using a normal-phase column with phosphate buffered picrate ion as the stationary phase and with chloroform–butanol as the mobile phase. Separation of choline and acetylcholine has been achieved by cation-exchange chromatography (9).

This paper describes the application of a reverse-phase, paired-ion HPLC analysis of acetylcholine in the pharmaceutical preparation described above. The procedure is quick, specific, and stability indicating since it separates the drug from the principle degradation products, choline and acetic acid. A comparison of the results of HPLC and colorimetric methods was made.

EXPERIMENTAL SECTION

Chemicals and Reagents—Acetylcholine chloride[2], choline chloride[3], and mannitol[4] were used as received from the suppliers without further purification. Acetonitrile[5] was HPLC grade. Ammonium hydroxide[6] and acetic acid[6] were ACS grade or equivalent. The water used was glass distilled.

Sample	Acetylcholine Chloride, mg/vial
1	21.62
2	21.22
3	22.04
4	21.23
5	21.70
6	20.96
Mean	21.46
SD	0.40
RSD, %	1.86

Instrumentation—The HPLC system consisted of a pump[7] capable of producing pressures of 6000 psi, a universal loop injector[8], a microparticulate reverse-phase column[9], a refractive index detector[10], and a microprocessor-controlled data system[11].

Mobile Phase—The mobile phase was prepared by adding sodium 1-heptanesulfonate[12] to 900 mL of water. After thorough mixing, 6 M ammonium hydroxide was added to adjust the pH to 4.0. After addition of 50 mL of acetonitrile, the solution was made up to 1 L with water.

Standard Stock Solution—Acetylcholine chloride, previously dried at 105°C for 4 h, was weighed (100 mg) into a 10.0-mL volumetric flask and dissolved in 5 mL of water. After mixing, the solution was brought to mark with water to make the stock standard solution.

Standard Solution—The standard solutions were prepared by pipetting 1.0, 2.0, and 3.0 mL of the stock standard solution to individual 10.0-mL volumetric flasks and bringing to mark with the mobile phase.

Decomposition of Acetylcholine—To prepare samples for heat stressing, the lyophilized solid in the commercial package was reconstituted in the sterile water. The solution was transferred quantitatively to a 10-mL clear glass ampule and the vial was washed with 1 mL of water; the wash solution was transferred to the ampule. After flame sealing, the ampule was placed in an oven at 130°C for 19 h. After cooling the ampule, the solution was transferred quantitatively to a 10.0-mL volumetric flask and was brought to the mark with the mobile phase.

Chromatographic Conditions—The volumetric flow rate was 2.0 mL/min, and the column temperature was ambient.

Standard Curve and Sample Analysis—Fifty-microliter volumes of each

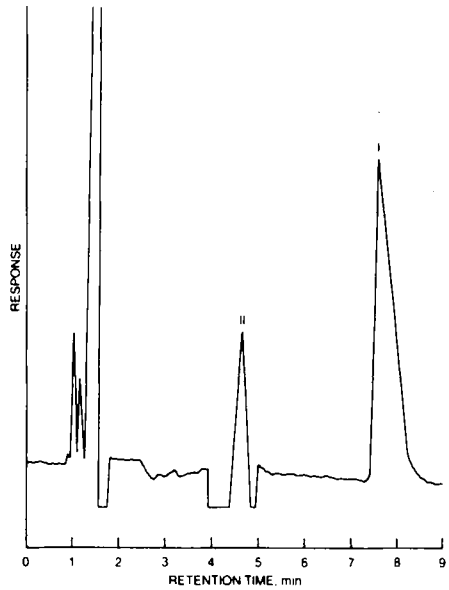

Figure 2—*Chromatogram of a heat-stressed sample of lyophilized preparation of acetylcholine chloride. The sample was heated at 130°C for 19 h. The final concentration of acetylcholine chloride was determined to be 11.13 mg/vial (55.65% of label claim). Key: (I) acetylcholine; (II) choline.*

of the three standard solutions were injected consecutively into the HPLC. With the aid of the data system, a three point linear calibration curve was constructed which plotted the weight (μg) of acetylcholine chloride injected as a function of area under the peak. The sample was quantitated by injecting 50 μL of the test solution and the weight (μg) of acetylcholine chloride obtained from the calibration curve. The test solution was prepared by transferring quantitatively the reconstituted solution into a 10.0-mL volumetric flask. The flask was brought to the mark with the mobile phase.

RESULTS AND DISCUSSION

Reverse-phase paired-ion HPLC was useful in separating intact acetylcholine from its decomposition products and its excipient, mannitol. Use of the mobile phase described gave a sharp, well resolved peak. The refractive index detector was the detector of choice since the drug lacks a chromophore; the sensitivity of the detector was more than adequate in quantitating acetylcholine chloride in the preparation.

Figure 1 illustrates the elution profile of acetylcholine. The retention time varied with the amount injected. The retention time increased with decreasing amounts of acetylcholine and ranged from 8.2 to 7.9 min for 50–150 μg of the acetylcholine standard. The variation in retention time is probably a manifestation of nonlinearity in the interaction of acetylcholine in the mobile phase with the stationary phase (reduction in interaction with increasing amounts of the drug). However, the variation of the retention time with the amount of acetylcholine injected did not negate the usefulness of the assay, since excellent linear curves were obtained. A standard curve constructed from 50, 100, and 150 g of the drug injected had a correlation coefficient of 0.9996.

Choline, acetic acid, and mannitol were shown not to interfere with the determination of acetylcholine (Fig. 2). One the the peaks in the sample displayed the same retention time, 5 min, as that of the authentic choline chloride solution. Acetic acid eluted with the solvent front and mannitol was retained on the column.

Three lots of the pharmaceutical preparation were analyzed by HPLC in duplicate and the results were compared with those from the hydroxylamine colorimetric method (2) (Table I). Precision data for the HPLC assay is presented in Table II. These results demonstrate the utility of the HPLC procedure; the method is simple, fast, specific, and stability indicating.

Electron-Capture Capillary Gas Chromatographic Determination of Phenylpropanolamine in Human Plasma Following Derivatization with Trifluoroacetic Anhydride

N. CRISOLOGO, D. DYE ˣ, and W. F. BAYNE ‡

Received July 25, 1983 from the *ALZA Corporation, Palo Alto, CA 94303.* Accepted for publication September 26, 1983. ‡ Present address: Merck Sharp & Dohme Research Laboratories, West Point, PA 19486.

Abstract □ A capillary gas chromatographic analysis of phenylpropanolamine in human plasma, following extraction and derivatization with trifluoroacetic anhydride, is presented. Using an electron-capture detector, the method was sensitive enough to quantitate as little as 1 ng of drug/mL of plasma. The coefficient of variation from 5–262 ng/mL varied between 5.6 and 1.6%, respectively. Plasma concentration data following one 25-mg dose of phenylpropanolamine hydrochloride in four healthy volunteers illustrates the suitability of this analytical method for monitoring plasma levels after oral administration of a typical dosage form.

Keyphrases □ Capillary gas chromatography—phenylpropanolamine, human plasma, trifluoroacetic anhydride derivatization □ Phenylpropanolamine—capillary gas chromatography, human plasma, trifluoroacetic anhydride derivatization □ Derivatization—trifluoroacetic anhydride, capillary gas chromatography, human plasma

Previously reported methods for the determination of phenylalkanolamines and related compounds in biological fluids include gas chromatography (GC) after extraction and formation of perfluoroacyl or pentafluorobenzylimine-trimethylsilyl derivatives (1–10), GC after formation of a pentafluorophenyloxazolidine derivative (11), GC after extraction and detection with a nitrogen-selective detector (12), and HPLC following extraction and precolumn derivatization with *o*-phthalaldehyde (13), 4-chloro-7-nitrobenz-2,1,3-oxadiazole and sodium naphthaquinone-4-sulfonate (14), and phenyl isothiocyanate (15).

A procedure for extraction of phenylpropanolamine and an internal standard from plasma, derivatization with trifluoroacetic anhydride, separation by capillary GC, and detection by electron capture is presented in this report. The achievable detection limit of the method is 1 ng/mL. Plasma concentrations >5 ng/mL can be determined with accuracy and precision suitable for pharmacokinetic studies.

EXPERIMENTAL SECTION

Instrumentation—The gas chromatograph[1] was equipped with a capillary inlet system and an 8-mCi Ni^{63} electron-capture detector connected to an integrator-calculator[2]. The fused silica capillary column (0.25 mm i.d. × 30 m) was coated with polymethyl (5% phenyl) siloxane[3] to a final thickness of 0.25 μm.

The chromatographic conditions were as follows: injection volume of the

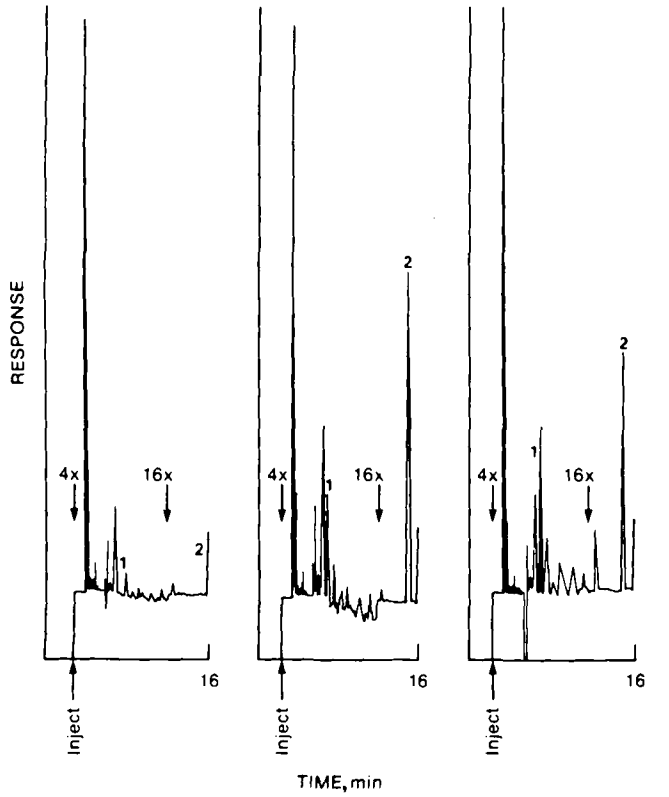

Figure 1 —*Chromatogram of an analysis of a plasma blank (A), a plasma sample with added phenylpropanolamine and internal standard (5.2 and 200 ng/mL, respectively) (B), and a plasma sample from a subject dosed with 25 mg of phenylpropanolamine hydrochloride with added internal standard (18 and 200 ng/ml, respectively) (C). Key: (1) phenylpropanolamine (retention time = 10.8 min); (2) internal standard, 2-amino-3-phenyl-1-propanol, (retention time = 15.3 min). (Note: Chart speed was 0.1 cm/min until 9 min into each run, and 0.5 cm/min thereafter.)*

sample, 1-2 μL; injector temperature, 220°C; detector temperature, 250°C; column temperature, initially at 117°C for 10 min, programmed at 3°C/min to 125°C, followed by a 6-min hold at 125°C; helium (high purity) carrier gas flow, 0.3 mL/min; nitrogen (high purity) make-up gas flow, 30 mL/min. Injections were made in the split mode; the split ratio was 1:50.

Reagents—Phenylpropanolamine hydrochloride[4] and internal standard 2-amino-3-phenyl-1-propanol hydrochloride[5] were used to prepare standard solutions. 4-Dimethylaminopyridine[5], trifluoroacetic anhydride[6], and toluene[7] (UV grade, distilled in glass) were used as received. All other reagents were reagent grade.

Standard Solutions—The stock standard solutions (1 mg/mL) of phenylpropanolamine hydrochloride and 2-amino-3-phenyl-1-propanol hydrochloride were prepared in water and stored at 4°C.

Preparation and Extraction of Plasma Standards and Samples—Varying microliter volumes of a 0.001 dilution of phenylpropanolamine hydrochloride stock standard solution in water were added to 1-mL plasma aliquots to obtain concentrations of 5.2, 20.9, 104.7, 157.1, and 261.8 ng/mL of plasma. An aliquot (200 μL) of a 0.001 dilution of 2-amino-3-phenyl-1-propanol hydrochloride stock standard solution in water was added to each plasma standard and the sample (1 mL) for a final concentration of 200 ng/mL.

To the plasma standards and samples contained in 12-mL polytef-stoppered conical centrifuge tubes (silanized with 5% dimethyldichlorosilane[8] in toluene) were added 0.2 mL of 0.5 M KH_2PO_4 buffer (adjusted to pH 11.0 with NaOH) and 3 mL of toluene. The tubes were sealed and shaken gently for 30 min at room temperature on a horizontal shaker[9]. After centrifugation at 2000 rpm for 5 min, the organic layers were transferred to another set of 12-mL centrifuge tubes and concentrated to ~0.5 mL under nitrogen in a 40°C water bath. 4-Dimethylaminopyridine (0.2 mg dissolved in 50 μL of toluene, added as a catalyst) and trifluoroacetic anhydride (70 μL) were then added; the tubes were then stoppered and heated for 30 min in a 60°C water bath. Two milliliters of 0.5 M Na_2HPO_4 buffer (pH 6.0) was then added, followed by vortex-mixing for 15 s. Aliquots (1-2 μL) of the toluene layer were injected into the gas chromatograph.

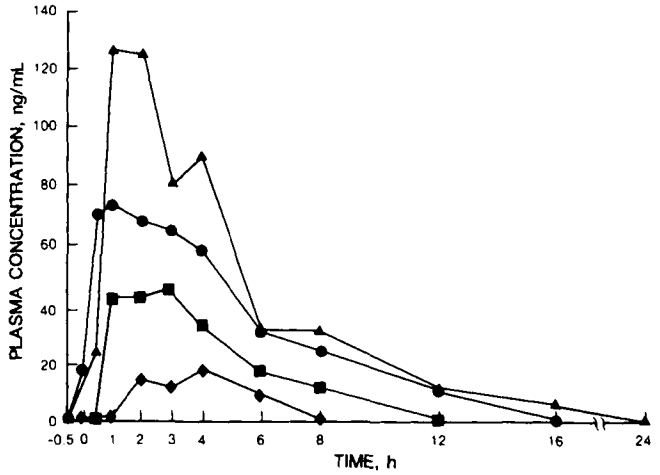

Figure 2—*Plasma levels of phenylpropanolamine base in four subjects following ingestion of 25 mg of phenylpropanolamine hydrochloride in water. Key: (●) subject 1; (▲) subject 2; (■) subject 3; (◆) subject 4.*

Standard Curve—The retention times of the di-trifluoroacetyl derivatives of phenylpropanolamine and 2-amino-3-phenyl-1-propanol were 10.8 and 15.3 min, respectively. The area responses for these chromatographic peaks were used to construct standard curves by plotting area ratio of phenylpropanolamine-internal standard against the respective phenylpropanolamine plasma concentration.

Clinical Study—As part of a clinical study, normal healthy subjects received a single 25-mg dose of phenylpropanolamine hydrochloride in water. Blood samples were collected at −0.5, 0, 0.5, 1, 2, 3, 4, 6, 8, 16, and 24 h in heparin-containing vacuum containers[10]. The plasma was separated immediately by centrifugation and frozen within 30 min. All samples were stored at −20°C until assayed.

RESULTS AND DISCUSSION

Figure 1 shows a typical chromatogram for phenylpropanolamine in spiked human plasma and in plasma obtained from a human subject after oral ingestion of 25 mg of phenylpropanolamine hydrochloride. Analysis of predose plasma samples from 24 human subjects presented no chromatographic peaks that interfered with either phenylpropanolamine or the internal standard. Plots of peak area ratios (phenylpropanolamine to internal standard) against phenylpropanolamine concentrations were linear. Typical standard curves for phenylpropanolamine in plasma had correlation coefficients of 0.9997.

The derivatization reaction was quantitative under the conditions described. This was determined in recovery experiments by monitoring the disappearance of underivatized drug in the reaction mixture. The reaction rate was increased several fold when 4-dimethylaminopyridine was present as a catalyst. The efficiency of extraction of drug from plasma was 60% due to the high water solubility of the phenylpropanolamine.

The coefficients of variation for five replicate assays at 5.2, 20.9, 104.7, 157.1, and 261.8 ng/mL of plasma were ±5.6, ±1.8, ±6.5, ±1.6, and ±1.6%, respectively. The lowest standard routinely used was 5 ng/mL, although the achievable detection limit of the assay was 1 ng/mL.

Figure 2, which shows typical plasma phenylpropanolamine levels following a single oral dose of 25 mg of phenylpropanolamine hydrochloride in water, demonstrates that the method is adequate for use in bioavailability studies.

Determination of Sodium Levothyroxine in Bulk, Tablet, and Injection Formulations by High-Performance Liquid Chromatography

JAMES F. BROWER ˣ, DUCKHEE Y. TOLER, and JOHN C. REEPMEYER

Received July 15, 1983, from the *National Center for Drug Analysis, Food and Drug Administration, St. Louis, MO 63101.* Accepted for publication September 28, 1983.

Abstract □ Sodium levothyroxine was determined in bulk drugs, tablets, and injections by high-performance liquid chromatography (HPLC). Levothyroxine was separated from excipients and impurities on a 10-μm cyanoalkyl column using an acetonitrile–water–phosphoric acid mobile phase. The HPLC method is shown to be linear, accurate, and precise, and the results obtained by the HPLC and USP XX methods are compared.

Keyphrases □ Sodium levothyroxine—HPLC, determination of bulk, tablet, and injection formulations □ HPLC—sodium levothyroxine, determination of bulk, tablet, and injection formulations

In a survey[1] of sodium levothyroxine products and formulations, 63 samples of tablets, representing 20 formulations from 5 manufacturers, 9 samples of injections from 2 manufacturers, and 6 samples of bulk sodium levothyroxine from 5 manufacturers, were analyzed in this labroatory. The purpose of the survey was to evaluate the quality of sodium levothyroxine products on the market and the adequacy of present compendial standards and methods. Methodology was developed for content uniformity analysis of sodium levothyroxine by high-performance liquid chromatography (HPLC). This method, unlike the official compendial method (1), differentiates levothyroxine from iodinated impurities and degradation products.

Previously developed methods for the determination of sodium levothyroxine (2–13) were evaluated and tested. A modification of the HPLC procedure described by Garnick *et al.* (13), using a cyanoalkyl bonded phase column, was selected. This method offers advantages over those already in the literature by avoiding buffers in the mobile phase, no sample derivatization, faster analysis times, greater sensitivity due to shorter retention times, lower flow rates, and 229 nm detection. A sample solvent was selected that readily dissolved sodium levothyroxine without degradation from tablet formulations. This method and the results obtained on the survey sample are reported here.

[1] This study was a national survey for the Food and Drug Administration.

EXPERIMENTAL SECTION

Apparatus A modular high-performance liquid chromatograph[2] (HPLC) was equipped with a fixed-wavelength (229 nm) cadmium lamp UV detector[3], an automated injector[4], a microprocessor controller[5], and a recorder-integrator[6]. A stainless steel column (3.9 mm × 30 cm) was packed with irregular 10-μm silica particles to which a layer of cyanoalkyl silane was chemically bonded[7].

The mobile phase consisted of acetonitrile–water–phosphoric acid (350:650:1). This solution was passed through a 0.45-μm filter[8], deaerated, and then pumped through the HPLC system at a rate of 1 mL/min.

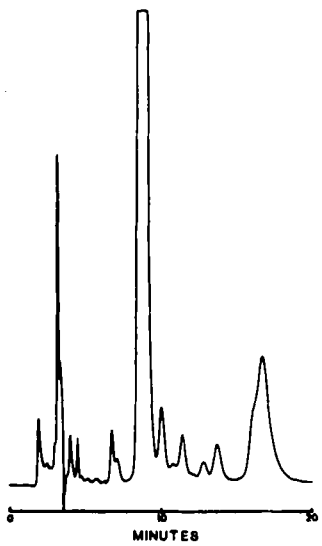

Figure 1—*Chromatogram of sodium levothyroxine bulk drug decomposed by heating in air; detector at 229 nm and 0.02 AUFS. Key: (1) sodium levothyroxine at a level of ~100 μg/mL.*

Abstract □ Sodium levothyroxine was determined in bulk drugs, tablets, and injections by high-performance liquid chromatography (HPLC). Levothyroxine was separated from excipients and impurities on a 10-μm cyanoalkyl column using an acetonitrile–water–phosphoric acid mobile phase. The HPLC method is shown to be linear, accurate, and precise, and the results obtained by the HPLC and USP XX methods are compared.

Keyphrases □ Sodium levothyroxine—HPLC, determination of bulk, tablet, and injection formulations □ HPLC—sodium levothyroxine, determination of bulk, tablet, and injection formulations

In a survey[1] of sodium levothyroxine products and formulations, 63 samples of tablets, representing 20 formulations from 5 manufacturers, 9 samples of injections from 2 manufacturers, and 6 samples of bulk sodium levothyroxine from 5 manufacturers, were analyzed in this labroatory. The purpose of the survey was to evaluate the quality of sodium levothyroxine products on the market and the adequacy of present compendial standards and methods. Methodology was developed for content uniformity analysis of sodium levothyroxine by high-performance liquid chromatography (HPLC). This method, unlike the official compendial method (1), differentiates levothyroxine from iodinated impurities and degradation products.

Previously developed methods for the determination of sodium levothyroxine (2–13) were evaluated and tested. A modification of the HPLC procedure described by Garnick *et al.* (13), using a cyanoalkyl bonded phase column, was selected. This method offers advantages over those already in the literature by avoiding buffers in the mobile phase, no sample derivatization, faster analysis times, greater sensitivity due to shorter retention times, lower flow rates, and 229 nm detection. A sample solvent was selected that readily dissolved sodium levothyroxine without degradation from tablet formulations. This method and the results obtained on the survey sample are reported here.

[1] This study was a national survey for the Food and Drug Administration.

EXPERIMENTAL SECTION

Apparatus A modular high-performance liquid chromatograph[2] (HPLC) was equipped with a fixed-wavelength (229 nm) cadmium lamp UV detector[3], an automated injector[4], a microprocessor controller[5], and a recorder-integrator[6]. A stainless steel column (3.9 mm × 30 cm) was packed with irregular 10-μm silica particles to which a layer of cyanoalkyl silane was chemically bonded[7].

The mobile phase consisted of acetonitrile–water–phosphoric acid (350:650:1). This solution was passed through a 0.45-μm filter[8], deaerated, and then pumped through the HPLC system at a rate of 1 mL/min.

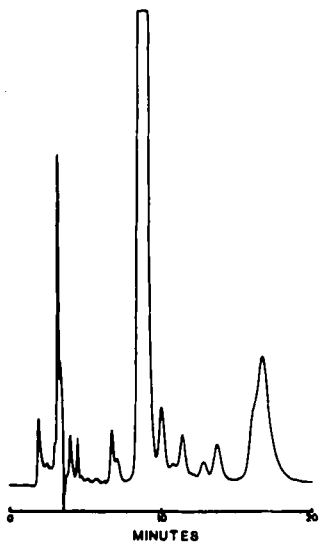

Figure 1—*Chromatogram of sodium levothyroxine bulk drug decomposed by heating in air; detector at 229 nm and 0.02 AUFS. Key: (1) sodium levothyroxine at a level of ~100 μg/mL.*

[a] (A) Armour Pharmaceutical Co., Scottsdale, Ariz.; (B) Chelsea Laboratories Inc., Inwood, N.Y.; (C) Generic Pharmaceutical, Palisades Park, N.J.; (D) Western Research Laboratories, Denver, Colo.; (E) Travenol Laboratories, Deerfield, Ill.; (F) Carter-Glogau Laboratories, Glendale, Ariz. [b] Content uniformity by HPLC, mean; *RSD* in parentheses; number of units tested.

Reagents—Methanol[9], acetonitrile[9], phosphoric acid[10], and sodium hydroxide[11] were used as received. Deionized water was supplied by a commercial[12] water system. Samples and standards were prepared in 0.01 M sodium hydroxide in 50% methanol.

Standard Preparation—About 10 mg of USP levothyroxine reference standard was accurately weighed into a 50-mL volumetric flask, dissolved, and diluted to volume with 0.01 M methanolic sodium hydroxide. (This stock solution is stable for several weeks when refrigerated.) Two milliliters of this solution was pipetted into a 100-mL volumetric flask and diluted to volume with 0.01 M methanolic sodium hydroxide.

Sample Preparation—*Tablets*—One tablet was placed in a glass-stoppered flask and accurately diluted with 0.01 M methanolic sodium hydroxide to ~4 μg/mL. The flask was placed in an ultrasonic bath[13] until the tablet disintegrated; the tablet was then mechanically shaken[14] for 30 min. The solution was then filtered[15] into a vial for injection.

Powdered Composites and Lyophilized Injections—An accurately weighed portion of the powdered sample, equivalent to ~400 μg of sodium levothyroxine, was placed in a 100-mL volumetric flask. Fifty milliliters of 0.01 M methanolic sodium hydroxide was added, and the flask was placed in an ultrasonic bath for 1 min. The flask was shaken for 5 min; the contents were diluted to volume with 0.01 M methanolic sodium hydroxide and mixed well. The solution was then filtered[15] into a vial for injection.

Bulk Drug Substances—A sample of bulk drug substance was prepared in the same manner as the standard.

Determination—Fifty microliters each of the standard and sample solutions were injected into the liquid chromatograph, and the chromatograms were recorded. Sodium levothyroxine was calculated on the basis of peak areas.

RESULTS AND DISCUSSION

Linearity, Reproducibility, and Recovery—A series of validation tests were performed on the HPLC method. A linear response was obtained when four standard solutions containing from 1 to 8 μg/mL were tested. Placebo samples, based on the batch formulation of the manufacturers, were spiked with various levels of the standard. The recoveries ranged from 99.5 to 100.6%. The reproducibility of the method was determined by consecutively injecting 10 aliquots of standard solution. The *RSD* was 0.2%.

Decomposition and Stability Studies—In the course of the survey, it was found that the bulk drug substances were sensitive to the conditions of the USP drying procedure (60°C in a vacuum over P_2O_5). If the vacuum was not maintained below 10 mm Hg, sodium levothyroxine decomposed rapidly (10–15% in 4 h). Undried bulk drug samples were used in the analyses because of this problem, and corrections were made for moisture content. Figure 1 shows a chromatogram of sodium levothyroxine bulk drug dried in the presence of air. Some decomposition products can be seen in the chromatogram; these were not observed in the chromatograms of an unheated sample of sodium levothyroxine measured at the same sensitivity. In addition, there are probably other decomposition products in the heated sample which are not eluted from the column. The identity of these decomposition products will be investigated at a later time.

To test the stability of sodium levothyroxine in the sample solvent (0.01 M methanolic sodium hydroxide), solutions of the bulk drug samples were stored at 5°C and assayed periodically (*versus* freshly prepared reference standards) over a six month period. The assay values remained constant over the entire testing period, indicating little or no decomposition.

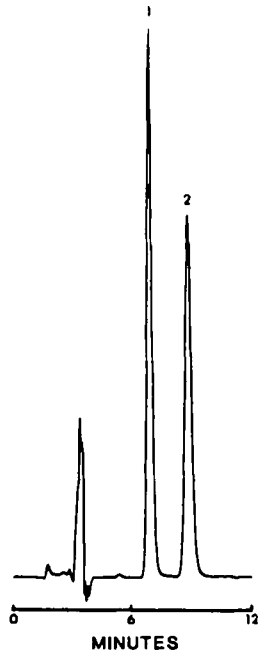

Figure 2—*Chromatogram of sodium levothyroxine and sodium liothyronine; detector at 229 nm and 0.02 AUFS. Key: (1) sodium liothyronine; (2) sodium levothyroxine, each at a level of ~4 μg/mL.*

The chromatographic system parameters were adequate to separate sodium levothyroxine from sodium liothyronine for testing the bulk drug substances for impurities; Fig. 2 shows a chromatogram of this separation. Liothyronine was found at levels of 0.04–0.96% in five sodium levothyroxine bulk drug samples analyzed by HPLC.

Sample Analysis—Table I lists the results obtained from survey by the HPLC procedure. A comparison of results for composite samples, obtained with the HPLC and the USP XX methods, shows that the latter gave a higher result in practically every case. This is not surprising since the USP XX assay is nonspecific for levothyroxine and measures total iodine content. However, the difference in assay values could not be totally accounted for by a total area summation of HPLC peaks. The major impurities and degradation products probably are not eluted from the column with this mobile phase.

Low assay values were a problem experienced by most manufacturers; this problem would not be recognized if the assays were based only on the results from the USP method. Some tablet composite samples gave suitable assay values for total iodine by the USP method, but gave extremely low assays for sodium levothyroxine by HPLC. All samples which gave low assay values by HPLC gave suitable assays by the USP method. This fact indicates that the problems of low assays of marketed sodium levothyroxine are, in all probability, attributable to sodium levothyroxine instability.

Determination of Isosorbide 5-Mononitrate in Human Plasma by Capillary Column Gas Chromatography

P. STRAEHL and R. L. GALEAZZI ˣ

Received February 22, 1983, from the *University of Bern, Department of Medicine, Inselspital, CH-3010 Bern, Switzerland.* Accepted for publication August 25, 1983.

Abstract □ An electron-capture gas chromatographic method for the determination of isosorbide 5-mononitrate in human plasma using a capillary column is described. Isosorbide 5-mononitrate and the internal standard (isosorbide dinitrate) are extracted from the alkalinized plasma with ether. The lower limit of detection for isosorbide 5-mononitrate is 1 ng/mL of plasma.

Keyphrases □ Gas chromatography—isosorbide 5-mononitrate, human plasma □ Isosorbide 5-mononitrate—GC, human plasma

Isosorbide 5-mononitrate [1,4:3,6-dianhydro-D-glucitol 5-nitrate (I)] is the primary metabolite of isosorbide dinitrate [1,4:3,6-dianhydro-D-glucitol dinitrate (II)] which has been used for many years in the treatment of angina pectoris and congestive heart failure. Recent studies of the hemodynamic effect of the mononitrate (1) indicate that, after acute administration, cardiac work load decreases at rest and during exercise. Pharmacokinetic studies (2–4) showed that the mononitrate is rapidly and completely absorbed from the GI tract without undergoing first-pass elimination. The maximum concentrations were reached within 1 h after oral administration, and the substance was eliminated with a half-life of ~4 h. Thus, the mononitrate has a half-life which is at least four times as long as the half-life of the dinitrate (5). Published gas chromatography (GC) assays (2, 6, 7), using older column

Determination of Isosorbide 5-Mononitrate in Human Plasma by Capillary Column Gas Chromatography

P. STRAEHL and R. L. GALEAZZI ˣ

Received February 22, 1983, from the *University of Bern, Department of Medicine, Inselspital, CH-3010 Bern, Switzerland.* Accepted for publication August 25, 1983.

Abstract □ An electron-capture gas chromatographic method for the determination of isosorbide 5-mononitrate in human plasma using a capillary column is described. Isosorbide 5-mononitrate and the internal standard (isosorbide dinitrate) are extracted from the alkalinized plasma with ether. The lower limit of detection for isosorbide 5-mononitrate is 1 ng/mL of plasma.

Keyphrases □ Gas chromatography—isosorbide 5-mononitrate, human plasma □ Isosorbide 5-mononitrate—GC, human plasma

Isosorbide 5-mononitrate [1,4:3,6-dianhydro-D-glucitol 5-nitrate (I)] is the primary metabolite of isosorbide dinitrate [1,4:3,6-dianhydro-D-glucitol dinitrate (II)] which has been used for many years in the treatment of angina pectoris and congestive heart failure. Recent studies of the hemodynamic effect of the mononitrate (1) indicate that, after acute administration, cardiac work load decreases at rest and during exercise. Pharmacokinetic studies (2–4) showed that the mononitrate is rapidly and completely absorbed from the GI tract without undergoing first-pass elimination. The maximum concentrations were reached within 1 h after oral administration, and the substance was eliminated with a half-life of ~4 h. Thus, the mononitrate has a half-life which is at least four times as long as the half-life of the dinitrate (5). Published gas chromatography (GC) assays (2, 6, 7), using older column

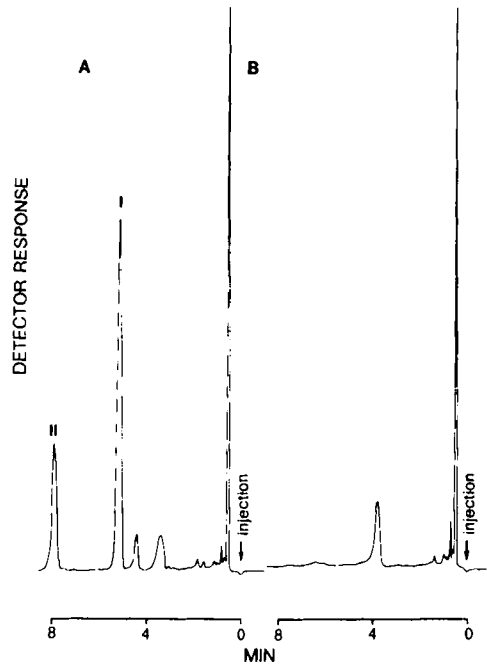

Figure 2—*Chromatograms of 1-mL plasma sample extracts obtained from a subject before (B) and 40 min after (A) an infusion of 5 mg of isosorbide 5-mononitrate; 20 ng of isosorbide dinitrate was added as the internal standard (A).*

coating or packing (OV-17, QF_1) and complicated extraction procedures, lack sufficient sensitivity and fail to give reproducible results.

EXPERIMENTAL SECTION

Apparatus—The analysis was performed on a GC[1] with a Grob-type, nonvaporizing, specially cooled on-column injector and equipped with a nickel-63 electron-capture detector.

Column—A wall-coated open tubular (WCOT) capillary column (16 m × 0.33 mm i.d.), with immobilized stationary phase SE-54[2], was used. Acidic leaching, silylation, and static coating, including immobilization, was carried out according to the method of Grob and Grob (8, 9). The film thickness was ~0.8 μm.

Reagents—The ethyl acetate[3] was pesticide grade, while the ether[3] and potassium carbonate[4] were analytical grade. Compounds I and II were used as received[5].

Instrumental Conditions—The carrier gas was helium with a flow rate of ~4 mL/min. The detector was operated with argon gas and 5% methane (v/v) at a flow rate of ~20 mL/min. The column was 160°C, the injector port was 200°C, and the electron-capture detector was 225°C. Direct on-column injection was used.

Procedure—Isosorbide dinitrate [the internal standard (20 ng in 50 μL of 0.9% NaCl)], 1 mL of patient plasma, 2 mL of saturated solution of potassium carbonate (pH 12.2), and 2 mL of ether were shaken in a 10-mL glass tube, with a polytef-lined screw cap, for 40 min at low speed (~25 rpm). After centrifugation (10 min at 4000 rpm) the organic phase was removed by aspiration in a conical tube. The solvent was evaporated to dryness under a gentle stream of nitrogen at room temperature. The residue was redissolved in 10–50 μL of ethyl acetate to give the desired concentration, and 0.4 μL of the solution was injected. All glassware was cleaned in an ultrasonic bath but not silanized; no plastic material was used.

Calibration—For calibration, human plasma (1 mL) was spiked with increasing concentrations of I (5–400 ng in 50 μL of 0.9% NaCl) and the internal standard, II (20 ng in 50 μL of 0.9% NaCl). Two milliliters of a saturated solution of potassium carbonate and 2 mL of ether were added to each solution. Extraction was performed as described above. The ratios of the peak heights of the mononitrate to the internal standard were plotted *versus* the concentrations of the mononitrate. Values of unknown plasma drug concentrations were determined from this calibration curve. Calibration chromatograms are shown in Fig. 1.

RESULTS AND DISCUSSION

This GC assay provides a method for determining I in plasma following a single extraction. A linear calibration curve, determined daily, was obtained for concentrations between 5 and 200 ng/mL of plasma. The mean slope was 0.058 ± 0.001 (peak height ratio/ng·mL^{-1} ± *SD*) and the mean intercept was 0.077 ± 0.09 (peak height ratio ± *SD*). The reproducibility from day-to-day analyses gave a coefficient of variation of 3.03% for 10 control plasma samples of 78 ng/mL of the mononitrate (78.71 ± 3.9), which were assayed on different days over 2 months. Within-day precision was assessed by analyses of five replicate plasma samples to which 10 and 50 ng/mL of I were added. The coefficients of variation were 1.6% for 10 ng (10.30 ± 0.165) and 1.49% for 50 ng (49.61 ± 0.793).

The use of a chemically similar drug as the internal standard, the quality of our column, and the on-column injection technique are probably the main reasons for the good reproducibility of the results. The attempted use of glyceryl trinitrate as internal standard was a failure because of its instability.

The recoveries for I and II were similar, varying between 70 and 75%. The retention times were 5.2 min for the mononitrate (mp 89°C) and 7.8 min for the dinitrate (mp 71°C). The lower limit of detection was ~1 ng/mL of plasma for the mononitrate and 0.5 ng/mL for the dinitrate. In some cases, small amounts of the mononitrate (<5 ng) were difficult to determine due to an unknown interfering peak. The use of peak height ratios was sufficient because the calibration curve passed through the origin and was linear up to 200 ng/mL. The column was washed every month with dichloromethane[3] and pentane[3], analytical grade.

Two chromatograms of human plasma extracts are shown in Fig. 2: a blank plasma extract and a plasma extract from the same subject 40 min after an infusion of 5 mg of the mononitrate. The dinitrate was added as an internal standard before analysis. Apart from an unknown peak with the retention time of 4.3 min (which always occurred), there is a second peak with about the same retention time as isosorbide 2-mononitrate (3.2 min). This peak, due to a contaminant in the internal standard, was eliminated later by recrystallization of isosorbide dinitrate.

Further investigations showed that this method could easily be adapted to determine the concentrations of the dinitrate and isosorbide 2-mononitrate by using the chemically similar substances isomannide dinitrate and isoidide dinitrate as internal standards, respectively. The use of pure solvents for ex-

Binding of Sulfadimethoxine to Isolated Human Blood Protein Fractions

J. W. HUBBARD *x, C. J. BRIGGS ‡, C. SAVAGE ‡, and D. SMITH ‡

Received January 24, 1983, from the **College of Pharmacy, University of Saskatchewan, Saskatoon, Saskatchewan, S7N 0W0, Canada* and the ‡*Faculty of Pharmacy, University of Manitoba, Winnipeg, Manitoba, R3T 2N2, Canada.* Accepted for publication September 8, 1983.

Abstract □ The binding of sulfadimethoxine to selected human blood protein fractions and to fresh serum has been examined by means of a new equilibrium dialysis technique which minimizes experimental error and permits the evaluation of low-level binding. Certain α-globulin fractions, containing mixtures of proteins, were found to bind the drug. Scatchard analysis of the binding of sulfadimethoxine to fresh serum, calculated as though all of the binding is due to albumin, gives a different result from that obtained with isolated albumin. This may be a reflection of the contribution of the α-globulins to the overall binding of sulfadimethoxine in fresh serum. Although sulfadimethoxine is amphoteric, it did not bind to the α_1-acid glycoprotein. The drug behaves as an acidic compound when binding to the blood proteins.

Keyphrases □ Sulfadimethoxine—blood fraction binding, equilibrium dialysis, humans □ Blood fraction binding—humans, sulfadimethoxine, equilibrium dialysis

Sulfadimethoxine is a long-acting sulfanilamide antibacterial drug which is extensively bound to the proteins of the blood (1, 2). It has been shown that the antibacterial activity and rate of metabolic *N*-acetylation of sulfanilamide drugs depend on the concentration of free, unbound drug in the plasma (3, 4). Nonlinearity in the pharmacokinetics of sulfadimethoxine has been associated with dose-dependent changes in the percentage of the drug bound to plasma proteins (5). Furthermore, the volume of distribution of sulfadimethoxine is altered significantly by small changes in the concentration of plasma albumin (6).

Albumin is the most important of the blood proteins in the binding of sulfanilamide drugs (2, 6–11), although the involvement of other plasma proteins has been implied (12). Sulfadimethoxine is an amphoteric compound (13) with an acidic center at the sulfonamide (pK_a 6.7) and a basic center at the aniline-like primary amino group (pK_b 11.98). The isoelectric point is at pH 4.36. Albumin is effective in binding acidic drugs such as warfarin (14–16), fenoprofen (17, 18) and phenylbutazone (19). Unlike these compounds, basic drugs such as imipramine (20), alprenolol (21), propranolol, (22) and lidocaine (23) bind significantly to α_1-acid glycoprotein and lipoproteins in addition to albumin. The individual contributions of different proteins to the binding of drugs becomes significant in disease states which lead to changes in the concentration of one or more of the blood proteins (24–27). The present study was undertaken to determine whether proteins other than albumin are involved in the overall binding of the amphoteric drug sulfadimethoxine.

The binding of sulfadimethoxine to isolated human plasma protein fractions was measured by a newly developed equilibrium dialysis technique (28). This method employs calibration and control procedures that minimize artifactual errors and permit statistical evaluation of control and test data. This stringent control technique also permits correction to be made for concentration-dependent binding to the dialysis membrane or other equipment; thus, it is possible to demonstrate statistically significant binding at low levels (<10%).

EXPERIMENTAL SECTION

Equilibrium dialysis was performed using 20-cm strips of dialysis tubing[1], 1-cm diameter, 4.8-nm pore diameter, with a molecular weight cut-off of 12,000. These membranes were immersed in boiling water and then stirred for 2 h as they cooled. The tubing was then stirred with 70% methanol for 30 min, stored in 50% methanol overnight, rinsed with distilled water, and soaked in phosphate buffer (pH 7.4) for 2–3 h prior to use. The membranes were used immediately after preparation. The tubing was tied with a double knot at one end, and then filled with 2 mL of protein solution in phosphate buffer (pH 7.4) containing sulfadimethoxine. The protein solutions were as follows: Cohn Fraction I (fibrinogen)[2] 0.34% (w/v); Cohn Fraction II (α-globulin)[3], 0.74% (w/v); Cohn Fraction IV-1 (α-globulin)[3], 0.81% (w/v); Cohn Fraction IV-4 (α-globulin)[3], 0.81% (w/v); Cohn Fraction V (albumin)[3], 4% (w/v); Cohn Fraction VI (α_1-acid glycoprotein)[3], 0.1% (w/v); lyophilized serum[3], 7.3%; and fresh serum[4], reduced to half volume by ultrafiltration. Except for the fresh serum, the protein solutions were prepared initially at double strength in buffer and then diluted with an equal volume of buffer containing sulfadimethoxine. The fresh serum, concentrated to half volume, was diluted with

[a] Unless otherwise noted each value is the mean of five replicates, ±*SE*; all values are significantly different from control values; $p < 0.001$. [b] $n = 3$. [c] $n = 4$. [d] $p < 0.01$.

an equal volume of buffer containing sulfadimethoxine. Albumin concentrations in fresh serum and lyophilized serum were measured by the method of Mancini *et al.* (29). The drug concentrations were 100, 140, 180, 250, and 340 μg/mL.

The following procedure was adopted for each of the solutions described above. The tubing was sealed and placed in a glass culture tube (16 × 125 mm) with a polytetrafluorethylene cap. Four milliliters of phosphate buffer (pH 7.4) were placed in each culture tube, and the solutions were dialyzed for 24 h at 37°C[5]. The tubes were rotated vertically through 360°, 12 times per minute using a rotary mixer[6]. The protein solution and dialysate were assayed for sulfadimethoxine using the Bratton-Marshall method (30), and absorbance was measured at 420 nm. Five replicates of each test concentration were dialyzed. A set of five controls was prepared for each sulfadimethoxine concentration studied and placed in the rotary mixer next to the test samples. Controls were identical to the test samples, except that the solution inside the dialysis membrane contained no protein. Glassware and buffer were autoclaved[7] prior to use. Preparation and transfer of solutions was carried out under aseptic conditions in a laminar airflow hood[8]. The dialysate was tested for the absence of protein visually (absence of frothing) and by means of a semiquantitative colorimetric indicator[9].

RESULTS AND DISCUSSION

For each of the protein-sulfadimethoxine systems described above, mean optical density values ($n = 5$) were calculated for tests and controls after dialysis. The percentage of binding was calculated for subtracting the mean test optical density from that of the control and expressing the result as a percentage of control, as previously described (28).

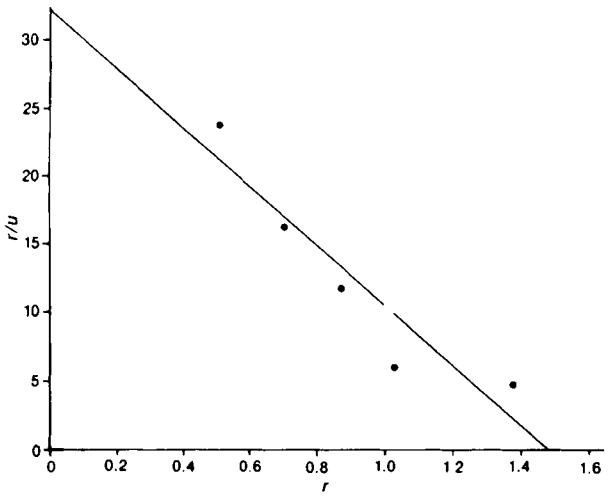

Figure 1—*A Scatchard plot of the binding of sulfadimethoxine to Cohn Fraction V albumin.*

There was a negative linear correlation between the concentration of sulfadimethoxine and the percentage binding to fresh serum (Table I; $y = -0.01316x + 102.0$; $r = -0.9475$, $p < 0.02$) and to isolated albumin (Table I; $y = -0.02807x + 102.5$; $r = 0.9863$, $p < 0.01$). This give the impression that the "degree of protein binding decreases with increasing concentration of sulfonamide" (3). However, the number of moles of sulfadimethoxine bound to fresh serum or to isolated albumin actually increased in a linear manner with increasing concentrations of drug (Table I; fresh serum: $y = 0.8223x + 62.97$; $r = 0.9978$, $p < 0.001$: albumin: $y = 0.6281x + 118.6$; $r = 0.9964$, $p < 0.001$). It is also important to realize that the concentration of free, unbound drug increased with total concentration of drug (fresh serum: $y = 0.1778x - 62.96$; $r = 0.9556$, $p < 0.02$; albumin: $y = 0.3719x - 118.6$; $r = 0.9899$, $p < 0.01$).

The results of the study of the binding of sulfadimethoxine to fresh serum (Table 1) are comparable to those published by Walker (1). Scatchard analysis (31) of the data was carried out in the same manner used by Walker who assumed that all of the binding was due to albumin (mol. wt. 69,000). In the present study, the concentration of albumin in the serum (44.25 mg/mL) was measured by radial immune diffusion (29). The five point linear regression equation ($y = -34361x + 61411$; $r = -0.8900$, $p < 0.05$) gave an x-axis intercept value of 1.8. A double reciprocal plot (32) derived from the same data ($y = 0.00002688x + 0.7377$; $r = 0.9893$, $p < 0.001$) gave a value of $n = 2.1$. This corresponds to the much quoted value of 2.0 binding sites for sulfadimethoxide per mole of albumin (1). In the study by Walker, the concentration of albumin in the serum was estimated to be 0.63 mM (43.47 mg/mL). Working from the published data (1), however, we obtained a value of 2.0 binding sites per mole only if we assumed the albumin concentration to be 40.00 mg/mL ($n = 2.1$ by Scatchard analysis; $n = 2.0$ by double reciprocal plot analysis).

In our studies on the binding of sulfadimethoxine to isolated albumin, the concentration of the protein was held constant at 40.00 mg/mL, an albumin concentration which is commonly employed in binding studies. The binding data cannot be compared directly because the isolated albumin was at a slightly different concentration from that in the fresh serum. The intercept values of Scatchard or reciprocal plot analysis can be compared, however, because these techniques are concerned with the number of moles of ligand bound per mole of protein. Therefore, if all the binding in serum was attributable to albumin, Scatchard plots of the respective data should give the same x-axis intercept value for serum as for isolated albumin. However, Scatchard analysis of the data (Table I), for the binding of sulfadimethoxine to isolated human albumin ($y = -22357x + 32829$; $r = 0.9511$, $p < 0.01$), gave an x-axis intercept value of 1.5. A double reciprocal plot derived from the same data ($y = 00002688x + 0.7377$; $r = 0.9893$, $p < 0.001$) gave a value of $n = 1.4$. There is a discrepancy between the corresponding values obtained with fresh serum, in the present study, and in the study by Walker (1). This suggests that (*a*) isolation of albumin from other serum constituents may alter the binding characteristics from those which prevail *in situ*, and/or (*b*) proteins other than albumin may be involved in the binding of the drug in serum.

The Scatchard plot (Fig. 1) of the binding of sulfadimethoxine to isolated albumin shows that the first four data points appear to fall on a straight line ($y = -31258x + 39244$; $r = -0.9958$, $p < 0.001$; x-axis intercept value 1.26), while the fifth point deviates considerably from this line. The study was not designed to investigate the binding of sulfisoxazole to albumin at high saturation, but the Scatchard plot does suggest that more than one binding site

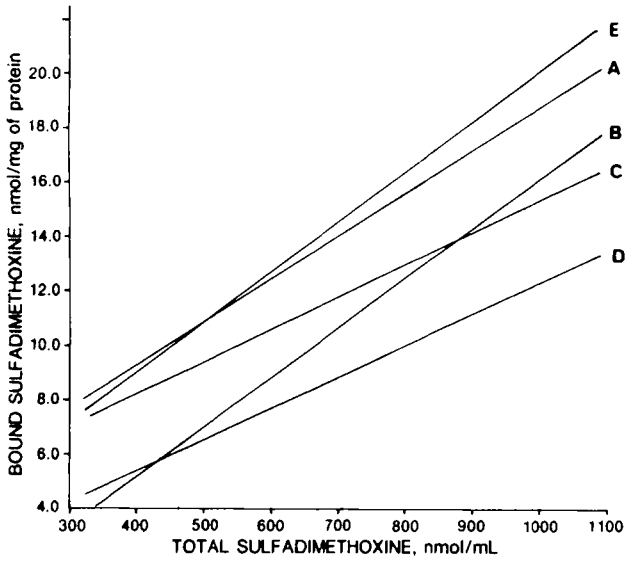

Figure 2—*The binding of sulfadimethoxine expressed in nmol/mg. Key: (A) Cohn Fraction V albumin,* $y = 0.01570x + 2.972$; $r = 0.9964$, $p < 0.001$. *(B) Cohn Fraction IV-1 α-globulin,* $y = 0.01817x - 2.1102$; $r = 0.9911$, $p < 0.01$, *(C) Cohn Fraction IV-4 α-globulin,* $y = 0.09612x + 27.69$; $r = 0.9883$, $p < 0.01$. *(D) Fresh serum, with calculations based on a total protein concentration of 72.5 mg/mL,* $y = 0.01133x + 0.8679$; $r = 0.9978$, $p < 0.001$. *(E) Fresh serum, calculated as if all the binding were due to albumin at a concentration of 44.25 mg/mL,* $y = 0.0186x + 1.422$; $r = 0.9978$, $p < 0.001$.

is involved. It is possible that at low saturation ($r < 1$), the drug binds primarily to a high affinity site, while at a higher saturation ($r > 1$), a lower affinity site will also bind sulfadimethoxine. At high saturation, however, the binding of the drug *in vivo* would be further complicated by the presence of other binding proteins.

Sulfadimethoxine showed low-level, but statistically significant, binding to two Cohn Fractions (33) of human plasma-serum, as shown in Table I. There were positive linear correlations between the concentration of sulfadimethoxine and the number of moles of the drug bound to Cohn Fraction IV-1 (α-globulin) ($y = 0.1472x - 17.0846$; $r = 0.9912$, $p < 0.001$) and to Cohn Fraction IV-4 (α-globulin) ($y = 0.09612x + 27.69$; $r = 0.9883$, $p < 0.01$). Unfortunately, it was not possible to carry out Scatchard analysis on these data because both α-globulin fractions are complicated mixtures of proteins (33), and there is no way of selecting a molecular weight with which to work.

Figure 2 suggests, however, that when the binding of sulfadimethoxine is expressed in terms of nanomoles bound per milligram of protein, the α-globulins have a significant capacity to bind the drug. Consequently, their contribution to the overall binding of the drug may be augmented in disease states, where plasma concentrations are elevated relative to albumin. Similar conclusions have been drawn about the role of lipoproteins in the overall binding of quinidine (34).

In Fig. 2, line E represents the binding of sulfadimethoxine to fresh serum, calculated as if all the binding were due to albumin alone. Line A represents the binding of the drug to isolated albumin. Note that the slopes of lines A and E are different and that there are larger discrepancies between binding values as the concentration of the drug increases. This may be an indication of increasing contributions by the α-globulin fractions (lines B and C) to the overall binding of the drug in serum as the concentration of sulfadimethoxine increases. Line D represents the binding of sulfadimethoxine to fresh serum based on the total concentration of protein in the serum (72.5 mg/mL). In this case, the values obtained are low because the binding proteins are diluted with protein materials which do not bind the drug.

There was no significant difference between tests and controls for the binding of sulfadimethoxine to Cohn Fractions I (fibrinogen), II (α-globulin), or VI (α_1-acid glycoprotein). These, and all of the other isolated protein fractions were comparable to their natural concentration ranges in the blood (35). Unfortunately, Cohn Fractions III^3 (β-globulin), and III-0^3 (β-lipoprotein) could not be reconstituted at or near physiological concentration and were, therefore, not examined.

Anomalous results were obtained when the binding of sulfadimethoxine to reconstituted lyophilized serum was examined. It was expected that the binding profile would be similar to that of fresh serum (Table 1), but the values obtained experimentally were ~20% of those of fresh serum. This discrepancy was undoubtedly due to low albumin concentration (15.50 mg/mL) in the reconstituted lyophilized serum. Total protein concentration was only 42 mg/mL (Biuret method), whereas normal fresh serum contains ~70 mg/mL of total protein (35).

In the experiment, care was taken to standardize the manipulative procedures in order to minimize experimental error. The use of tubes with polytetrafluoroethylene caps avoided the problem of plasticizers which can leach molecules from rubber or polyvinyl chloride-lined caps and cause displacement of drugs from protein binding sites (21, 36, 37). All solutions and glassware were sterilized before use, and solution transfers were made under aseptic conditions in a laminar airflow hood. This eliminated the possibility of microbial growth during dialysis and permitted the experiment to be conducted for 24 h without the use of preservatives, which could have influenced binding characteristics. All dialysates were checked for the absence of protein, both visually (absence of frothing) and by the use of a semiquantitative colorimetric indicator.

The concentration range of sulfadimethoxide was selected to include the reported plasma concentration obtained 4 h after an oral dose (38). Protein concentrations were held constant within normal physiological concentrations because binding parameters obtained with dilute albumin solutions have been shown to predict a higher degree of binding than those obtained by direct measurement (6–8). This phenomenon may be significant in disease states which cause hypoalbuminaemia (6), as may the role of minor binding proteins such as the α-globulins.

The plasma protein binding profile of sulfadimethoxine resembles that of an acidic drug although it is amphoteric. It did not bind to α_1-acid glycoprotein, which binds many basic drugs. This is presumably brought about by the predominance of the acidic center of sulfadimethoxine (pK_a 6.7) over the much weaker basic center (pK_b 11.98). Basic drugs, such as imipramine and propranolol, which binds strongly to α_1-acid glycoprotein, appear to have pK_b values which fall roughly within the range of 4–6. Presumably, the basic center of sulfadimethoxine is too weak to permit interaction with α_1-acid glycoprotein.

CONCLUSIONS

Sulfadimethoxine is an amphoteric drug which behaves like an acidic compound in its serum protein binding profile. Albumin is the protein largely responsible for the binding of the drug in blood, although there is also a significant amount of α-globulin binding of sulfadimethoxine in fresh serum.

Degradation of Crystalline Ergocalciferol [Vitamin D_2, (3β,5*Z*,22*E*)-9,10-Secoergosta-5,7,10(19),22-tetraen-3-ol]

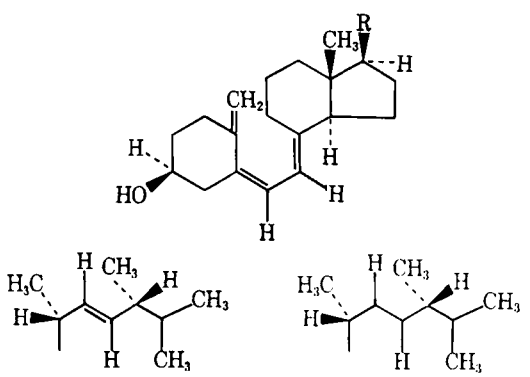
B. A. STEWART, S. L. MIDLAND, and S. R. BYRN ˣ

Received June 15, 1981, from the *Department of Medicinal Chemistry and Pharmacognosy, School of Pharmacy and Pharmacal Sciences, Purdue University, West Lafayette, IN 47907.* Accepted for publication October 17, 1983.

Abstract □ The products of the degradation of crystalline ergocalciferol were investigated. These studies showed that numerous acidic and neutral oxidation products were formed resulting in the complete destruction of the triene functionality. Separation of the neutral products by preparative TLC led to material identified as the Windaus ketone IIa, 2,3,3a,4,5,6,7,7aβ-octahydro-7aα-methyl-1*R*-(1α,1*R*,4*R*,5-trimethyl-2*E*-hexenyl)-4*H*-inden-4-one.

Keyphrases □ Ergocalciferol—crystal degradation products, liquid chromatography, identification of a Windaus ketone □ Liquid chromatography—determination of the crystal degradation products of ergocalciferol

Solid-gas reactions are often catalyzed by heat and/or light; thus, these reactions are of importance when studying the mechanism of drug degradation (1-6). This paper reports studies on a specific class of solid-gas reactions: solid-oxygen reactions. A review (1) reports our preliminary studies on the complex heat- and light-catalyzed solid-oxygen reactions of vitamin D_2, ergocalciferol (Ia). This paper presents these studies in greater detail.



Ia, R = Ib, R =

The oxidative degradation of ergocalciferol has been known for over 40 years (7-11); however, the structures of the solid-state degradation products have not been elucidated. Thus, it is the aim of this study to isolate and unequivocally identify these products. Initially, the decomposition of ergocalciferol in room fluorescent light and air was investigated, resulting in the identification of the Windaus ketone (IIa).

EXPERIMENTAL SECTION

Reagents—Ergocalciferol[1] purchased in sealed ampules was used in all experiments. All reagents employed were of either reagent, spectral, or ACS grade. Methanol used in recrystallization of compounds was purified by reflux with magnesium and iodine followed by distillation over molecular sieves.

Apparatus—All melting points were obtained on a hot stage[2] and are uncorrected. IR spectra[3] were determined neat or as KBr pellets. NMR spectra were obtained using a 60-MHz instrument[4] with either $CDCl_3$ or acetone-d_6 as the solvent and 1% tetramethylsilane as the internal standard. Low-[5] and

high-resolution[6] mass spectra were determined using mass spectrometers operated in both the electron-impact and chemical-ionization modes.

Chromatography—Thin-layer silica gel chromatography plates containing fluorescent indicator[7] were used. Mixtures were applied to the preparative layer silica gel chromatography plates[8] with an applicator[9].

Synthesis of 2,3,3a,4,5,6,7,7aβ-octahydro-7aα-methyl-1*R*-(1α,1*R*,4*R*,5-trimethyl-2*E*-hexenyl)-4*H*-inden-4-one (IIa) and Its Semicarbazone (IIb)—Compounds IIa and IIb were synthesized according to the procedure of Windaus and Grundman (12). Compound IIb was crystallized as a white solid, mp 222°C [lit. (12) mp 222°C]; IR (KBr): 3440, 3240, 3170 (NHC=O amide), 1680 (primary amide), 1570 (secondary amide), and 960 cm^{-1} (*trans* RHC=CHR); ^{1}H-NMR (acetone-d_6): δ 0.57 (s, 3, C-18 CH_3), 0.80 (d, 6, C-26,27 CH_3), 0.90 (d, 3, C-28 CH_3), 1.1 (d, 3, C-21 CH_3), 1.1–2.9 (m, 15), 5.2 (m, 2, 22-H, 23-H), 5.6 (d, 2, H_2N—C=O), and 8.2 ppm (s, 1, HNC=O); MS: *m/z* 333 (M^+, 58%).

Anal.—Calc. for $C_{20}H_{35}N_3O$: C, 72.03; H, 10.57; N, 12.60; O, 4.80. Found: C, 71.91; H, 10.68; N, 12.80[10].

Degradation of Ergocalciferol in the Solid State—The experiments, performed in triplicate by different investigators at different times of the year, led to similar results. Crystalline ergocalciferol from a newly opened refrigerated ampule was spread in a petri dish and left exposed to artificial light and room air (with average humidity, room temperature, and atmospheric pressure). The colorless needles gradually changed to an orange powder. The IR and NMR spectra of the degrading compound gradually changed for the first 6 months and then remained unchanged after 6 months.

A sample of ergocalciferol (0.81 g), which had been stored for 6 months at room temperature, chloroform (150 mL), and a 10% $NaHCO_3$ solution (150 mL) were stirred for 5 min at room temperature. The organic phase was removed at reduced pressure. Thin-layer chromatography of the residue [cyclohexane–ethyl acetate–chloroform–acetic acid (5:2:1:1)] indicated three fractions ($R_f \times 100$: 0, 31, 53):

1. Material *A* R_f (× 100) 0; 0.038 g; 46% of the recovered material was an amber oil that could not be crystallized. IR (neat): 3400 (broad), 1700 (C=O, broad), and 1620 cm^{-1} (C=C); MS (C.I.): *m/z* 309 (5.7%), 279 (11.0), 153 (11.0), 143 (28.0), and 91 (100.0).
2. Material *B* R_f (× 100) 31; 0.023 g; 28% of the recovered material was an amber oil that could not be crystallized. IR (neat): 3400 (ROH), 1710 (C=O, broad), and 1620 cm^{-1} (C=C); MS (C.I.): *m/z* 309 (40.5%), 307 (33.8), 294 (22.3), 293 (100.0), 292 (24.3), 291 (86.5), 279 (27.0), 275 (72.3), and 125 (21.6).
3. Material *C* R_f (× 100) 53; 0.021 g; 26% of the recovered material was an amber oil that could not be crystallized. IR (neat): 2490 (C—H), 1700 (C=O), and 1630 cm^{-1} (C=C); MS (C.I.): *m/z* 209 (11.3%), 278 (22.6), and 277 (100). The exact mass of the 276 peak was determined to be 276.247.

Material *C* and IIa co-chromatographed on silica gel plates using a three solvent system: cyclohexane–ethyl acetate chloroform–glacial acetic acid (5:2:1:1); chloroform–methanol (9:1); and ethanol.

Preparation of the Semicarbazone Derivative of Material *C*—A mixture of material *C* (0.04 g), semicarbazide hydrochloride (0.26 g, 0.002 mol), sodium acetate (0.41 g, 0.01 mol), and methanol (10 mL) was heated to a reflux temperature in an 80°C oil bath. Water (0.5 mL) was added dropwise over a 5 min period. The mixture was refluxed for 0.5 h, then cooled. Recrystallization of the material from methanol gave a white crystalline solid (0.005 g), mp 220°C, the IR spectrum (KBr) of which was identical to that of the aforementioned semicarbazone, IIb.

RESULTS AND DISCUSSION

Degradation of ergocalciferol in ordinary fluorescent light at average room temperature and humidity results in the oxidation and fragmentation of the triene functionality. The ^{1}H-NMR spectrum of degraded ergocalciferol showed that the peaks assigned to the vinyl protons of the triene system at δ 4.7, 5.0, 5.94, and 6.14 ppm had disappeared while the peaks assigned to the vinyl protons of the C-22 to C-23 olefinic bond remained unchanged (13). In addition, carbonyl absorption appeared in the IR spectrum of the degraded material. In the NMR spectrum the peak attributed to the C-18 CH_3 absorption had decreased in intensity and shifted downfield. A broad, D_2O exchangeable peak, appeared between δ 3.3 and 5.38 ppm.

The degraded material *C* can be identified as IIa based on co-chromatography and the preparation of the semicarbazone derivative which had the same melting point and IR spectrum as the semicarbazone derivative of authentic IIa. Material *B* appeared to contain two components with structures similar to IIa. The high-resolution MS indicate that these components correspond to IIa with one or two hydrogen atoms replaced by hydroxyl groups. These two components have so far resisted complete characterization.

These results are consistent with literature reports which indicate that in air and light crystalline ergocalciferol decomposes, while storage under vacuum results in increased stability (7–9, 11). The extensive oxidation observed in our studies does not rule out other nonoxidative pathways of degradation, but it does indicate that oxidation is the major pathway of ergocalciferol degradation.

The nucleus of the ergocalciferol molecule undergoes extensive oxidation; however, the side chain appears to remain intact. This may be due to the lesser reactivity of the side-chain olefin and to the crystal packing which promotes oxidation of the ergocalciferol nucleus. Preliminary studies of cholecalciferol (Ib) degradation indicate this compound to be much more stable, confirming earlier reports (14). The greater stability exhibited by cholecalciferol may be due to different crystal packing. Recently, studies of hydrocortisone *tert*-butyl acetate have shown that different crystal forms have different reactivity towards oxygen, presumably because of different crystal packing (15). Crystals of cholecalciferol may also contain fewer defects or sites for potential nucleation, therefore being more stable.

Instrumentation of a Tablet Breaking-Strength Tester

RALPH E. BERTERMANN ˣ, MARK E. ADAMS, JOHN WARNER, and MERRIL SINGLETERRY

Received May 16, 1983, from the *Searle Research and Development Division, G. D. Searle & Co., 4901 Searle Parkway, Skokie, IL 60077.* Accepted for publication August 18, 1983.

Abstract □ The instrumentation of a tablet breaking-strength tester, for the automatic recording of hardness values, is described. A comparison is made between a computerized hardness tester and another identical model hardness tester from the same manufacturer ("standard"). Three lots of placebo tablets at different hardness values were compared. No significant difference was observed between the computerized unit compared with the "standard" unit.

Keyphrases □ Tablet-hardness tester—computerized *versus* unaltered models □ Breaking strength—tablets, computerized *versus* unaltered hardness values

The measurement and recording of tablet-hardness values is an important and necessary measurement during the processing of tablets. This project was initiated with the purpose of automating the measurement process in order to allow more measurements to be taken in a given period of time, to eliminate the chances of operator error and bias, and to incorporate the data automatically in a data base for long term storage and statistical treatment.

EXPERIMENTAL SECTION

The hardness tester[1] (Fig. 1), consists of the following: a rotary shaft encoder[2], a tablet-break signal, filters and a gate, and a microcomputer[3]. A table of values was programmed into the computer relating input counts to hardness values. The test button on the hardness tester was pushed to start the hardness measurement cycle. This opened a gate which allowed pulses from the rotary shaft encoder attached to the counterweight shaft, to enter the microcomputer. When the tablet broke, the signal generated by the hardness tester was to turn off the shaft encoder gate. The hardness value of the tablet was then locally displayed and sent to a terminal or computer.

Placebo tablet hardness values obtained over the working range of the instrument were: 5 kiloponds (kp) for round tablets, 10 kp for oval tablets, and 15 kp for capsule-shaped tablets. These tablets were used to validate the computerized tablet-hardness tester. Prior to these tests, each hardness tester had been modified and calibrated according to procedures previously described (1).

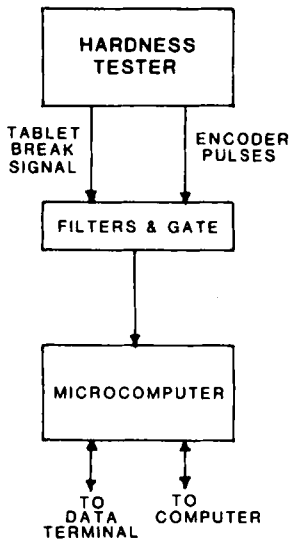

Figure 1—*Computerized hardness-tester block diagram.*

Twenty-five tablets of each hardness value were tested on both the computerized tablet-hardness tester and another identical model tablet-hardness tester, from the same manufacturer ("standard"). The scale reading and digital reading were taken from the computerized instrument after each of the 25 tablets were tested. Also, the scale reading was recorded from the "standard" tablet-hardness tester after another 25 tablets were tested. Tablets

tested on both tablet-hardness instruments, for each hardness group, were from the same lot of tablets. One operator ran the tablets on the computerized tablet-hardness tester and recorded the scale readings; the digital results were recorded on a digital printer. Tablets for the "standard" unit were tested, and scale readings were recorded by a second operator.

RESULTS AND DISCUSSION

Tables I, II, and III show the results of the approximate 5, 10, and 15 kp placebo tablets tested on both the computerized and the "standard" tablet-hardness testers. Column C1 contains the analog data from the "standard" tester, while columns C2 and C3 contain data from the computerized unit. Column C2 data are the analog readings and column C3 data are the readings from the printer. The data were analyzed by the AOVONEWAY, program for the one-way analysis of variance. To compare the means of these populations, a random sample with a normal and independent distribution and equal variance was assumed for each population. The analyses of data from Tables I, II, and III, by the MINITAB B program (2) are listed in the *Appendix*.

Therefore, we questioned whether all of the populations had the same mean. To answer this question, a null hypothesis, that the variation between the tablet-hardness testers is not greater than the variation due to random error, was established.

The F ratio is a useful statistic when determining whether the variation between the computerized tablet-hardness tester and the "standard" tablet-hardness tester is greater than the variation due to random error (3). The corresponding value from an F table for all sets of data for the F ratio to be checked against is 3.1. The F ratios were 0.74, 0.66, and 1.25 for placebo tablets of 5, 10, and 15 kp, respectively. Since all of the F ratio values are <3.1, we accept the null hypothesis and conclude that there is no significant difference between the tablet-hardness testers.

The Effects of Salicylate on the Rectal Absorption of Phenylalanine and Some Peptides, and the Effects of These Peptides on the Rectal Absorption of Cefoxitin and Cefmetazole

TOSHIAKI NISHIHATA, CHIA-SHUN LEE, MIDORI YAMAMOTO, J. HOWARD RYTTING ˣ, and TAKERU HIGUCHI *

Received June 8, 1983 from the *Department of Pharmaceutical Chemistry, The University of Kansas, Lawrence, KS 66045.* Accepted for publication October 13, 1983. *Also affiliated with: INTER$_x$, Merck Sharp and Dohme Research Laboratories, Lawrence, KS 66044.

Abstract □ The disappearance of phenylalanine and phenylalanylglycine from a perfusate circulated across rat rectal tissue was enhanced significantly in the presence of salicylate or 5-methoxysalicylate at pH 4.5, 7.4, and 8.5. The disappearance of di-, tri-, and tetraphenylalanine from a perfusate at pH 7.4, although facilitated by the presence of salicylate and 5-methoxysalicylate, was also fairly substantial when no adjuvant was present. These peptide analogues of phenylalanine also enhanced the rectal absorption of cefoxitin and cefmetazole, two highly water soluble antibiotics. Phenylalanine and phenylalanylglycine, both poorly absorbed across the rectal membrane when administered alone, did not enhance the rectal absorption of either antibiotic.

Keyphrases □ Rectal absorption—phenylalanine and peptide analogues □ Adjuvant action—salicylate, 5-methoxysalicylate, and peptides □ Absorption study—*in situ* perfusion method, *in vivo* experiments using a microenema technique

Many peptide drugs have been developed for clinical therapy. However, their administration is generally limited to intramuscular, subcutaneous, or intravenous injection. Parenteral administration has inherent disadvantages for some patients such as small children, elderly persons, or those receiving frequent drug administration (*e.g.*, insulin).

Recently, there have been reports of attempts to develop new dosage forms which do not involve parenteral administration, *e.g.*, insulin suppositories (1-3). Our laboratory has been studying several novel nonsurfactant adjuvants that enhance rectal or small intestinal absorption of water-soluble drugs (4, 5) as well as high molecular weight drugs such as insulin, heparin (6, 7), and gastrin (8).

The rectal absorption of phenylalanine and di-, tri-, and tetraphenylalanine has been studied and the effects of adjuvants on their absorption have been examined and are reported here. In addition, these peptides were found to exert an enhancing effect of their own.

EXPERIMENTAL SECTION

Materials—Cefmetazole[1], cefoxitin[2], phenylalanine[3], and di-, tri-, and tetraphenylalanine[3] were used as obtained from the manufacturer. All other chemicals used were at least reagent grade.

Animals—Sprague-Dawley male rats, 224–250 g, were fasted for 16 h prior to the experiments. During the experiments, rats were anesthetized with sodium pentobarbital (60 mg/kg) and kept on a 38°C surface.

***In Situ* Perfusion of Rat Rectum**—The perfusion experiments were carried out by a method similar to one described previously (4). The rectum was exposed by an abdominal incision and a glass cannula was inserted in the distal direction and tied firmly to keep it in position. A second cannula was inserted through the anus and secured by ligation, thus exposing ~5 cm of the rectal compartment (rectum and lower colon) to the perfusate. The perfusate (5 mL) consisting of a phosphate buffer (0.067 M) was circulated at a rate of 1 mL/min at 38°C; 0.1 M HCl was employed to maintain the perfusate pH at 5.0. The ionic strength was maintained at 0.45 with sodium chloride.

***In Situ* Loop Technique of Rectal and Jejunal Compartments**—For this study, a 5-cm section of the rectal compartment, described above, or the upper jejunum were used by ligating at both ends. A 3.0-mL microenema prepared with a 0.067 M phosphate buffer solution was administered. At a designated time following administration, the rectal and jejunal loops were removed from the body and the amount of compound remaining was measured.

***In Vitro* Rectal Everted Sac Studies**—In these studies about 4 cm of the rectum, including the lower colon, were removed from the body and everted. Following the addition of 0.5 mL of buffer solution into the everted sac, the sac was ligated at both ends. The sac was then immersed in 5 mL of a buffer solution containing the test compounds and maintained for 1 h at 37°C while bubbling a mixture of 95% O_2 and 5% CO_2 through the solution. The concentration of the test compound inside the everted sac was measured, and the permeation percent was calculated from the ratio of the test compound in the inside solution to the initial concentration in the outside solution, *i.e.*:

$$\frac{\text{(concentration inside after 1 h)} \times 100}{\text{initial concentration outside}} = \%\ \text{permeation}$$

***In Vivo* Absorption Studies**—A microenema (1.0 mL/kg) was administered into the anus through a polyethylene tube inserted at a depth of 1 cm. The anus was ligated with thread to prevent leakage of the drug solution. After administration, blood samples were collected from the jugular vein as a function of time.

Assay Method—Cefoxitin and cefmetazole concentrations in the plasma or in the perfusate were measured by HPLC (9). Phenylalanine and its peptides were assayed by HPLC under the following conditions: RP-18 column material with a column length of 15 cm (4.6 mm i.d.); the mobile phase for phenylalanine (I) consisted of methanol and 0.05 M citrate phosphate buffer at pH 3.4 (15:85); the mobile phase for diphenylalanine (II) consisted of methanol-acetonitrile-0.05 M ammonium acetate (28:12:60); the mobile phase for triphenylalanine (III) consisted of methanol-acetonitrile-0.05 M ammonium acetate (25:20:55); and the mobile phase for tetraphenylalanine (IV) consisted of methanol-acetonitrile-0.05 M ammonium acetate (25:25:50). The flow rate was 1.0 mL/min, and a spectrophotometric detector at 254 nm was used.

RESULTS AND DISCUSSION

The absorption of amino acids from the upper digestive tract usually occurs by active transport. In fact, absorption of L-phenylalanine (I) from the jejunum using the *in situ* loop technique was significantly greater than that from the rectal compartment. In the absence of sodium salicylate, 10 ± 1% of a 15-mg/mL dose of phenylalanine disappeared from a rectal loop compared with 79 ± 6% from a jejunal loop after 60 min. In the presence of 60 mg/mL of sodium salicylate, 62 ± 9% of the phenylalanine was lost from the rectal loop while 84 ± 5% was lost from the jejunal loop. As shown in Table I, there was no absorption of phenylalanine from the rectal perfusate at pH 4.8 and only slight absorption at pH 7.4 and 8.5 in the absence of salicylate.

In previous papers (4-6), it has been reported that salicylate and 5-methoxysalicylate enhanced the absorption of many kinds of water-soluble drugs from the rat rectum. The present study indicates that the rectal absorption of amino acids is also facilitated by the presence of salicylate and 5-methoxysalicylate. The presence of 1.0% sodium salicylate or sodium 5-methoxysalicylate in the rat rectal perfusate caused a significant disappearance of I from the perfusate (Table I).

As described above, studies using the *in situ* loop technique also showed that coadministration of 60-mg sodium salicylate/kg significantly enhanced the absorption of I from the rectal compartment and slightly facilitated the

Tetraphenylalanine	7.4	20.4 ± 3.2 (n = 4)	44.6 ± 3.2[b] (n = 4)	39.7 ± 4.4[b] (n = 4)

[a] Uncertainties are expressed as *SEM*. [b] $p < 0.001$ compared with the control not containing adjuvant (using a Student's t test).

absorption of I from the jejunum. The significant enhancement of the rectal absorption of peptides with nonsurfactant adjuvants has had limited examination, except for reports by Nishihata *et al.* (4-7, 10-14) on facilitated rectal and intestinal absorption of insulin in the presence of adjuvants.

To further study facilitated peptide absorption, II, III, and IV were examined. As seen in Table I, the disappearance of these peptides from rat rectal perfusate at pH 7.4 was significantly facilitated by the presence of salicylate and 5-methoxysalicylate. This result indicates that rectal administration can offer an effective alternative route for peptide drug delivery.

Matthews (15) has reported that uptake of dipeptides from the small intestine is more rapid than that of comparable equimolar concentrations of the constituent amino acids. The present study shows that absorption of II is faster than that of I even from the rectum. Shoof *et al.* (16) have reported that the uptake of II into the brush-border membrane prepared from the small intestine occurred significantly, and hydrolysis of II occurs at a point on the cytosol side of a diffusion barrier located in the membrane. It has been demonstrated (17) that salicylate at pH 7.4 was taken up into the brush-border membrane vesicles prepared from the rat rectal compartment, including the rectum and lower colon. These findings may explain why II is substantially absorbed from the perfusate even when no adjuvant is present. That is, rectal absorption of II by itself occurs *via* the microvillus membrane in the rectal compartment as well as in the small intestine.

In the study using the *in vitro* rat rectal everted sac technique described above, the percents of the compounds permeating the everted sac membrane after 1 h were 12.4 ± 3.5, 29.6 ± 4.3, 18.3 ± 4.6, and 16.7 ± 3.1% for L-phenylalanine, II, III, and IV, respectively. When the outside solution initially contained 1% sodium salicylate along with 500 μg/mL of the test compound (I, II, III, or IV), the percents of drug permeating the sac increased to 34.6 ± 6.2 ($p < 0.001$ compared with the solution of the drug without salicylate, n = 4), 41.7 ± 6.4 ($p < 0.01$, n = 3), 36.7 ± 5.8 ($p < 0.001$, n = 4), and 30.6 ± 5.4% ($p < 0.001$, n = 3), for I, II, III, and IV, respectively. These results are an additional indication that the losses of phenylalanine, II, III, and IV from the perfusion studies described earlier involved permeation through the rectal membrane.

Nishihata and Higuchi (17) reported that the enhancing action of salicylate on the absorption of cefoxitin and I into the brush-border membrane vesicles appeared to involve the simultaneous uptake of salicylate into the vesicles. This observation raised the question as to whether II, also significantly absorbed by itself, may act as an adjuvant. Subsequent experiments indicated that the presence of 500 μg of II/mL, in a perfusate containing 500 μg of cefoxitin at pH 7.4, did in fact facilitate the disappearance of cefoxitin, raising the drug bioavailability to 27 ± 2% ($p < 0.001$, Student's t test, n = 6), compared with 4 ± 1% (n = 6) in the absence of II.

The adjuvant effects of III and IV were also studied. The disappearance of cefoxitin from rat rectal perfusate was slightly facilitated by the presence of III (16 ± 3% at a dose of 500 μg of III/mL) or IV (15 ± 2%, n = 6 at a dose of 200 μg of IV/mL). This result appears to indicate that the adjuvant effect of the peptides II, III, or IV on rectal drug absorption is contingent upon the simultaneous absorption of the peptides themselves. Their uptake into the microvillus membrane may alter the nature of the membrane barrier. The

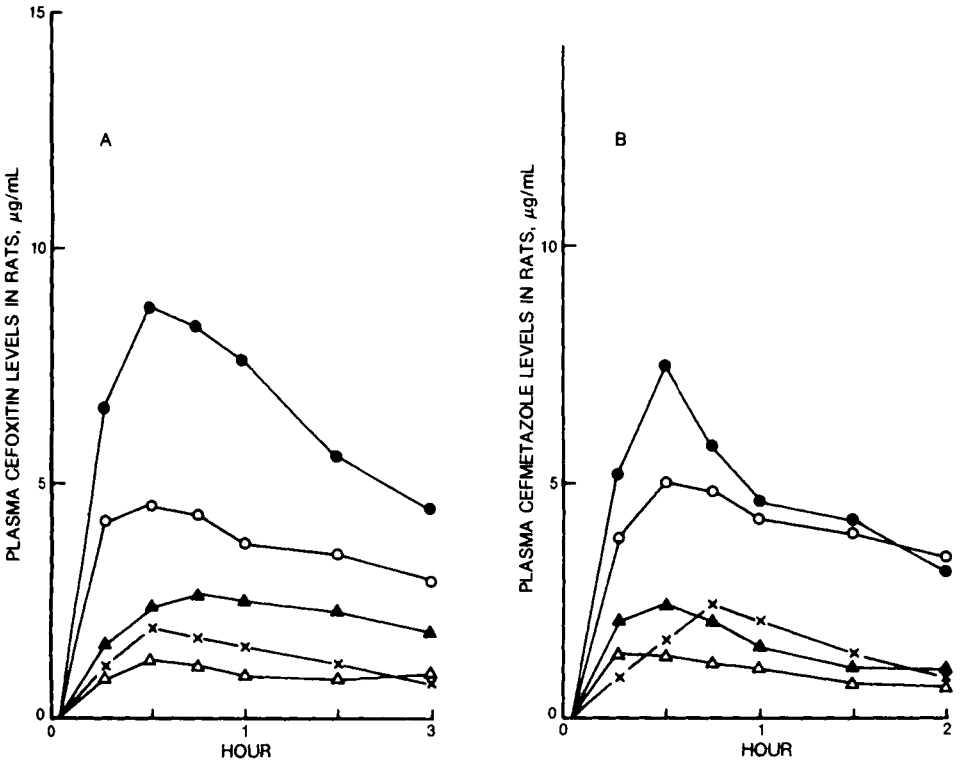

Figure 1 - *(A) Plasma cefoxitin and (B) plasma cefmetazole levels after rectal administration of a microenema containing either 20 mg of cefoxitin/kg or 30 mg of cefmetazole/kg and one of the following: 1 mg of II/mL/kg (△); 27 mg of NaCl/mL/kg (×); 5 mg of II and 27 mg of NaCl/mL/kg (●); 5 mg of II/mL/kg (▲); 1 mg of II and 27 mg of NaCl/mL/kg (○). Rectal administration of cefoxitin or cefmetazole in a microenema without II and/or NaCl produced a plasma cefoxitin level of <0.4 μg/mL and a plasma cefmetazole level of <0.2 μg/mL at peak heights.*

enhancing effect of II was further studied in *in vivo* experiments using a microenema technique. Plasma cefoxitin levels in the rat after rectal administration of a microenema containing 20 mg of cefoxitin and 1–5 mg of II increased significantly over drug levels obtained in the absence of II (Fig. 1). The higher the concentration of II in the microenema, the higher the plasma cefoxitin level. Increasing the ionic strength with NaCl resulted in an even greater increase in the plasma drug levels. These results seem to indicate that rectal absorption of cefoxitin by itself, and enhanced by II, shows some Na^+ dependency. As shown in Fig. 1, rectal absorption of cefmetazole was also enhanced by the presence of II in the microenema.

As shown above and in earlier reports (5, 8), the promotion of the absorption of these antibiotics appears to require the simultaneous absorption of the adjuvant, which alters the nature of the membrane barrier, increasing its permeability.

High-Performance Liquid Chromatographic–Ultraviolet Determination of Primaquine and Its Metabolites in Human Plasma and Urine

GEORGE W. PARKHURST ˣ, MARIS V. NORA, RUSSEL W. THOMAS, and PAUL E. CARSON

Received August 1, 1983, from the *Department of Pharmacology, Rush Medical College, Chicago, IL 60612.* Accepted for publication October 20, 1983.

Abstract □ A high-performance liquid chromatographic method was developed for the simultaneous determination of primaquine and its metabolites from plasma and urine samples obtained after oral administration of primaquine diphosphate. Following partial deproteinization with acetonitrile, samples were chromatographed by direct injection onto a cyano column with UV detection at 254 nm. Levels as low as 100 ng/mL per 20-μL injection were quantitated. Preliminary pharmacokinetic analysis is reported for two human volunteers after oral doses of 60 mg and 90 mg. Two apparent plasma metabolites and two possible urinary metabolites of primaquine are also reported.

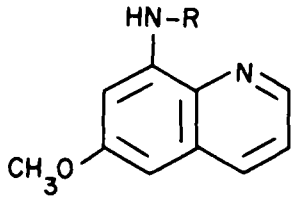
Keyphrases □ Primaquine—liquid chromatographic analysis, human plasma and urine, pharmacokinetics □ Liquid chromatography—primaquine, human plasma and urine, pharmacokinetics

Primaquine, 8-[(4-amino-1-methylbutyl)amino]-6-methoxyquinoline (I), is well tolerated in the therapeutic range except in individuals with glucose-6-phosphate dehydrogenase deficiency in whom it causes hemolytic anemia (1). The severity of hemolysis is thought to be related to either the concentration of primaquine or primaquine metabolite(s) and the duration of exposure (2). Nevertheless, primaquine is a true tissue schizonticide and is not only the drug of choice for radical cure of vivax malaria but also is a causal prophylactic agent against falciparum and vivax malaria. Early attempts to correlate primaquine blood levels with either antimalarial effects or toxicity, using a diazotization procedure, were unsuccessful (3).

Recently, several different techniques have been developed which are potentially selective and sensitive enough to measure human primaquine blood concentrations and to quantitate blood concentrations of human metabolites (4–6). The primary objective of this report is to describe the development of a high-performance liquid chromatographic (HPLC) method sensitive enough to measure primaquine concentrations in plasma from human subjects after a single oral dose of primaquine diphosphate. In addition, we report a preliminary pharmacokinetic analysis of human blood level curves, the probable identification of one of the two plasma metabolites, and two unidentified urinary metabolites.

EXPERIMENTAL SECTION

Reagents and Materials—The standards used in this assay were primaquine diphosphate (>99% pure)[1], 6-methoxy-8-aminoquinoline (II)[2], and 8-(3-carboxy-1-methyl propylamino)-6-methoxyquinoline (III)[3]. The chemicals used in the preparation of the mobile phase buffer were reagent-grade ammonium formate and formic acid (88% pure)[4]. Acetonitrile and methanol were UV grade[5]. All solutions containing I, II, and III were placed in amber glassware and refrigerated.



I, R = $-CH(CH_3)CH_2CH_2CH_2NH_2$
II, R = $-H$
III, R = $-CH(CH_3)CH_2CH_2COOH$

HPLC Conditions—The HPLC system consisted of a pump and a fixed-absorbance detector equipped with a 254-nm filter[6]. Samples were either injected manually using an injector with a manual signal recorder[7] or an automated injector[8] and integrator[9,10]. The separations were accomplished using a reverse-phase cyano column (30 × 0.39 cm i.d.; particle size 10 μm)[11]. The mobile phase consisted of a mixture of 0.1 M ammonium formate adjusted to pH 3.85 with formic acid and acetonitrile (89:11). It was filtered through a 0.45-μm filter[12] and deaerated under a house vacuum for 10 min. The flow rate of the mobile phase was 2 mL/min at ambient temperature. Deionized water was used in the final rinsing of glassware and in the preparation of the buffer and the standards[13].

Analytical Procedure—Blood samples were collected in EDTA containers[14] and centrifuged at 1900×*g* for 10 min to separate the plasma. The plasma was kept in aluminum foil covered glass tubes at 4°C until analysis.

The plasma (0.2 mL) was diluted 1:1 with acetonitrile and mixed well. The solution was incubated in the dark for 1 h and centrifuged at 1900×*g* for 10 min. Analyses by HPLC were carried out on 20-μL samples of the resulting supernatant.

Urine was collected in plastic urine specimen jars. The jars were capped and kept at 4°C in the dark until preparation for analysis. Urine was extracted by a modification of the method published by Baty *et al.* (4). Ten grams of resin[15] was suspended in methanol and put in a 1.8 × 25-cm column and washed with 100 mL of methanol followed by 200 mL of deionized water. Up to 100 mL of the urine was passed through the column at a rate of ~5 mL/min. The column was then washed with 100 mL of water. Primaquine and its metabolites were eluted from the column by 75–100 mL of methanol and then quantified by HPLC assay using 10-μL injections. The column was regenerated by washing with 100 mL of water, and then a new sample of urine was passed through the column and the process repeated.

Recovery Studies—Plasma standards containing known amounts of each of the three compounds were compared with standards in distilled water. The plasma standards were treated as in the analytical procedure and the water standards were injected directly. Other deproteinizing agents, *i.e.*, 15% trichloroacetic acid, 5% metaphosphoric acid, 6% perchloric acid, and copper sulfate–sodium tungstate, were also tested for recovery. Additionally, solutions of I and II in plasma and water were placed in membrane cones[16] and centrifuged at 12,000×*g* for 1 h. The concentrations of each compound were then determined for the plasma and water filtrates.

The recoveries were determined for urinary primaquine samples by passing a standard solution of primaquine through the column and analyzing the

Table I—Recovery Values from Plasma Using Several Precipitating Agents

	Aceto-nitrile	15% Trichloro-acetic Acid	5% Meta-phospho-ric Acid	6% Perchlo-ric Acid	Copper Sulfate Sodium Tungstate
I (0.78 μg/mL)	98%	38%	38%	46%	0
II (0.34 μg/mL)	97%	30%	33%	53%	0
III (0.6 μg/mL)	98%	—		—	—

eluant for primaquine content. Recoveries of urine metabolites were determined by dividing urine samples into two parts. One part was passed through the column, eluted with methanol, and quantitated by HPLC. Four hundred microliters of the other part was added to an equal volume of acetonitrile, vortex mixed, and left for ≥30 min before being centrifuged. An aliquot of the supernatant was chromatographed, and the two chromatograms were then compared.

Calibration Curves—Calibration standards were prepared by adding known amounts of I and III (0.1 μg/mL–20 μg/mL and 0.23 μg/mL–0.96 μg/mL, respectively) to control plasma and urine samples. Solutions were then assayed by following the analytical procedure. The calibration curves for the quantitation of I and III were obtained by plotting peak height against concentration for each of the standard solutions. (Note: Aqueous solutions of primaquine are light sensitive and will begin to degrade within 30 min. Light protected, aqueous solutions showed no detectable changes after 1 week at −20°C and only slight changes after 1 month.)

Dosing and Sampling Procedure—After Institutional Review Board approval, 60 mg and 90 mg of primaquine diphosphate (calculated as the base) were administered with 118 mL of water to two healthy male volunteers. Three hours after the dose, volunteers were allowed to eat and drink *ad libitum*.

Venous blood was collected at 0, 0.5, 1, 2, 2.5, 3, 4, 5, 6, 7, 8, and 10 h for each subject. Urine was collected at time zero and at each void for up to 72 h.

RESULTS AND DISCUSSION

Assay—To obtain suitable sample preparation from plasma samples for HPLC analysis with UV detection in the nanogram range, various deproteinization techniques were examined on the basis of a previous report (7). The inorganic agents and trichloroacetic acid resulted in nonquantitative and variable recoveries of I and II, Table I. Treatment with acetonitrile (1:1) yielded 98 + 2% recovery of I, II, and III from spiked plasma. Extensive protein binding of primaquine probably accounts for poor recovery with many agents. When solutions containing I and III in plasma and water were filtered through membrane cones, 99% of the compounds were recovered in the water filtrate, while neither compound was detectable in the plasma filtrate[17].

The mobile phase was chosen to achieve separation between I and III and still maintain desirable retention times. Under the HPLC conditions given, I, II, and III had retention times of 6.3 min (K', −4.2), 4.4 min (K', −2.8), and 10.9 min (K', −7.8), respectively.

Calibration curves were constructed for each compound in time zero plasma and urine specimens. In the range of concentrations tested, responses were linear and had coefficients of determination (r^2) >0.99. The detection limit using 20-μL injections was 100 ng/mL of primaquine, 500 ng/mL of III, and 50 ng/mL of II using a signal to noise ratio >3 in plasma and 100 ng/mL of primaquine in urine. Reproducibility of this method at the above detection limits was 98 ± 3.8% for primaquine (n = 10), 98 ± 4.2% for III (n = 10), and 97 ± 1.4% for II (n = 10), using separate determinations. Figure 1 shows

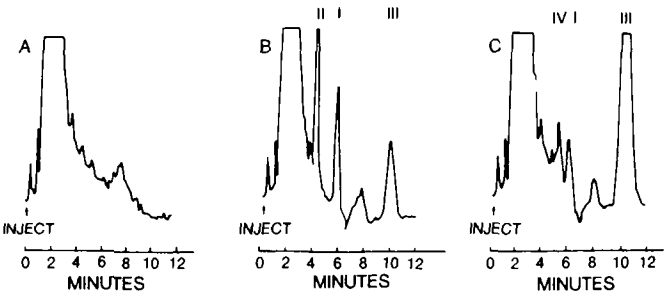

Figure 1—*Chromatograms of (A) time zero plasma; (B) time zero spiked plasma containing 200 ng/mL of 6-methoxy-8-aminoquinoline (II), 450 ng/mL of primaquine (I), and 1.2 μg/mL of primaquine metabolite (III); (C) plasma 2.5 h after a 90-mg oral dose of primaquine diphosphate (I) where IV is the more polar metabolite.*

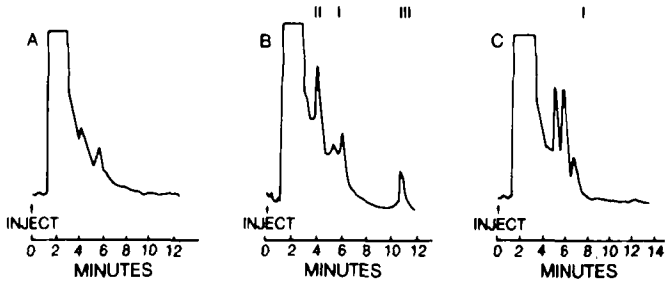

Figure 2—*Chromatograms of (A) time zero urine; (B) time zero spiked urine containing 1.0 μg/mL of 6-methoxy-8-aminoquinoline (II), 1.0 μg/mL of primaquine (I), and 2.0 μg/mL of primaquine metabolite (III); (C) urine 4 h after a 90-mg oral dose of primaquine diphosphate.*

chromatograms of plasma before and 2.5 h after primaquine administration. In addition, a time zero plasma sample spiked with primaquine, II, and III is shown in Fig. 1B. Chromatograms of urine samples taken at time zero, 4 h post primaquine administration, and time zero spiked with I, II, and III are shown in Fig. 2.

Metabolism and Pharmacokinetics—To demonstrate the utility of the present method, it was applied to plasma and urine samples obtained from the two volunteers who were part of an ongoing study (8). These data were fitted to an open one-compartment pharmacokinetic model (9) using a nonlinear least-squares regression program (NONLIN) (10). Oral absorption lag time was incorporated into the model. The unavailability of intravenous data precluded the individual estimation of volume of distribution and bioavailability; therefore, the ratio F/V was inserted in the model:

$$C = \frac{k_a \frac{F}{V} X_o}{(k_a - K)} (e^{-K(t-t_L)} - e^{-k_a(t-t_L)})$$

where t_L is the lag time.

Figure 3 shows the results of the analysis of 11 plasma samples from each volunteer and the fitted curves obtained from these results. As would be expected, there appeared to be a considerable difference in absorption rates between the two subjects; however, the elimination rates were similar for both. Estimated pharmacokinetic parameters are summarized in Table II. Visual analysis of the chromatograms of plasma at the several sampling times after the ingestion of primaquine suggested the presence of primaquine metabolites. However, II, a human metabolite of primaquine metabolism reported by Baty *et al.* (4), was not observed to be present either by comparison of retention times or by addition of II to volunteer samples containing the presumed metabolites. Using our HPLC system, the presumed plasma metabolites were labeled as either more polar than primaquine or less polar than primaquine. They can be detected very shortly after primaquine ingestion and are detectable long after the primaquine concentration falls below detectable levels, Fig. 4. Authentic samples of III[18] (5) have the same retention time as the less polar metabolite in our HPLC system. In addition, in the samples from the two volunteers, the less polar metabolite was subsequently identified as III by mass spectrometry[19]. We conclude that the major primaquine plasma metabolite in humans is the same as that found in rats.

Analysis of the urinary data from the two volunteers indicated that only a small percent of primaquine was excreted unchanged. Values were 4.2% (subject 1) and 2.2% (subject 2) of the oral primaquine dose in 24 h. Chromatograms indicated the presence of two possible primaquine urinary me-

[a] Ratio of bioavailability/Vd. [b] After oral administration of 90 mg of primaquine diphosphate. [c] After oral administration of 60 mg of primaquine diphosphate.

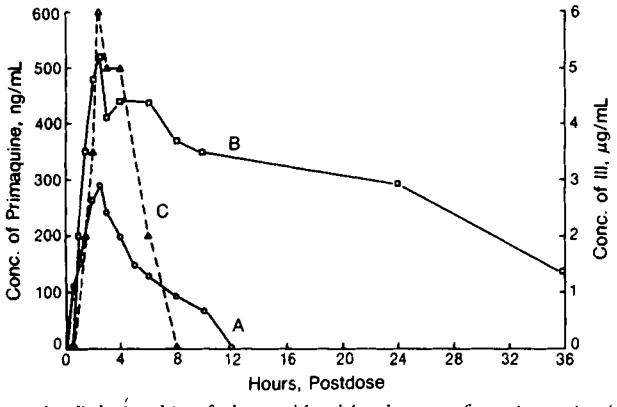

Figure 4—*Relationship of plasma blood level curves for primaquine (A), primaquine metabolite (B), and the more polar metabolite (C), reported as peak height in centimeters.*

tabolites, Fig. 2C. Both of these presumed urinary metabolite compounds are more polar than primaquine in our HPLC system. Neither urinary metabolite appeared to be II or III, but one appears to have a retention time which was the same as that of the more polar plasma metabolite.

The present method utilizing HPLC with UV detection for the simultaneous determination of primaquine and its carboxy metabolite (III), is rapid and precise. The use of this method for plasma and urine samples of volunteers after oral administration of primaquine diphosphate indicates that absorption and metabolism is rapid, that there appear to be at least two plasma metabolites (one identified as an oxidative-deamination product of primaquine, III), and that there appear to be two as yet unidentified urinary metabolites of primaquine.

Quantitation of Metronidazole in Pharmaceutical Dosage Forms Using High-Performance Liquid Chromatography

V. DAS GUPTA

Received June 6, 1983, from the *Department of Pharmaceutics, University of Houston, Houston, TX 77030.* Accepted for publication September 26, 1983.

Abstract □ A high-performance liquid chromatographic (HPLC) method for the quantitation of metronidazole in pharmaceutical dosage forms has been developed. The method is accurate and precise with an *RSD* of 0.68%, based on six readings. The excipients present in various dosage forms did not interfere with the assay procedure. A solution of metronidazole decomposed using heat showed 0% potency.

Keyphrases □ Metronidazole—HPLC, pharmaceutical dosage forms □ HPLC—pharmaceutical dosage forms of metronidazole

Metronidazole is extensively used in medicine as an antiprotozoal agent. The USP-NF method (1) for the quantitation of metronidazole in tablets is based on titration with perchloric acid, which requires a tedious extraction-purification procedure; moreover, other weak bases, impurities, and products of decomposition usually interfere with this type of volumetric titration. The quantitation of metronidazole in biological fluids was reviewed by Wood (2). The purpose of these investigations was to develop a stability-indicating assay procedure for the quantitation of metronidazole in pharmaceutical dosage forms based on HPLC.

EXPERIMENTAL SECTION

Chemicals and Reagents—All the chemicals and reagents were USP, NF, or ACS quality and were used without further purification. The USP quality powder of metronidazole[1] (2-methyl-5-nitroimidazole-1-ethanol; I) was used as received.

Apparatus—The high-performance liquid chromatograph[2] (HPLC) was equipped with a multiple-wavelength detector[3] and a recorder[4]. A semipolar column[5] (30 cm × 4 mm i.d.) was used. The average size of the particles was 10 μm.

Synthetic solution 3	2.5	Mannitol 2.5	—[a]	100.2 (0.67)

[a] USP-NF method not specified for solutions and not applicable to metronidazole hydrochloride powder. [b] These single tablets were not assayed using the USP-NF method. [c] Not determined for single-tablet assay. [d] All commercial solutions were obtained from G. D. Searle & Co.; solution no. 1 from lot 52V054N4. [e] Lot ZH 104. [f] Lot 3L 011. [g] Lot 1181-166. [h] Lot 483-174. [i] Lot 782-008; average of 10 tablets, one determination. [j] Lot 683-048; average of four tablets, one determination. [k] Lot 782-008.

Chromatographic Conditions—The mobile phase was an aqueous solution of 0.02 M KH_2PO_4 (pH ~4.2). The flow rate was 2.5 mL/min, and the temperature was ambient. The sensitivity was set at 0.04 (254 nm) and the chart speed was 30.5 cm/h.

Solution Preparation—The stock solutions of metronidazole (1.60 mg/mL) and phenylpropanolamine hydrochloride (10.0 mg/mL) in water were prepared fresh daily. Metronidazole was dissolved in water with the aid of gentle heat (≤60°C) to hasten dissolution. Preliminary investigations indicated that there was no decomposition with gentle heat. A stock solution of acetaminophen (0.40 mg/mL) was prepared by dissolving 40.0 mg of acetaminophen in 1 mL of methanol and then bringing it to volume (100.0 mL) with water. The standard solutions were prepared as needed by diluting the stock solutions with water. For assays, the concentrations (in μg/mL) of metronidazole, phenylpropanolamine hydrochloride, and acetaminophen were 200, 1400 and 40, respectively.

The assay solutions were prepared by mixing a solution (from ready-to-use bags or vials) representing 20.0 mg of metronidazole with 14.0 mL of the stock solution of phenylpropanolamine hydrochloride (the internal standard) and then bringing it to volume (100.0 mL) with water. To assay the contents of the vials containing powder (metronidazole hydrochloride ≅500 mg of metronidazole), the contents were dissolved in water and brought to volume (100.0 mL) with water. Four milliliters of the mixture were combined with 14.0 mL of the stock solution of phenylpropanolamine hydrochloride and brought to volume (100.0 mL) with water.

Extraction Procedure for Tablets—Ten tablets were accurately weighed and ground to a fine powder. (When content uniformity was to be determined, a single tablet was ground to a fine powder.) Powder representing 80.0 mg of metronidazole was added to ~90 mL of water in a 150-mL beaker. The solution was gently heated (with stirring) to 60°C on a hot plate and then allowed to cool to room temperature. The solution was transferred to a 100-mL volumetric flask, brought to volume with water, and filtered[6]. The first 20 mL of the filtrate was rejected; the rest was further diluted. Then, 12.5 mL of the solution was mixed with 7.0 mL of the stock solution of phenylpropanolamine hydrochloride and brought to volume (50.0 mL) with water.

Assay Sample of Decomposed Ready-to-Use Solution (5.0 mg/mL)—Ten milliliters of the solution was mixed with ~4 mL of ~1 M NaOH solution in a 150-mL beaker and then heated to boiling on a hot plate for ~25 min (water was replaced as necessary). The mixture was cooled, the pH adjusted to ~6 using ~0.5 M HCl, and brought to volume (250.0 mL) with water.

Chromatographic Procedure—A 20-μL aliquot of the assay solution was injected into the chromatograph under the conditions described above. For comparison, a 20-μL aliquot of the standard solution containing identical concentrations of metronidazole and phenylpropanolamine hydrochloride was injected after the assay was eluted.

Calculations—Since preliminary investigations indicated that the ratio of the peak heights of metronidazole and phenylpropanolamine hydrochloride were directly related to the concentration of metronidazole (range tested 2–6 μg), the results were calculated using the equation:

$$\frac{R_{pha}}{R_{phs}} \times 100 = \text{percent of label claim found}$$

where R_{pha} is the ratio of the peak heights of drug–internal standard of the

[6] Whatman # 1 filter paper.

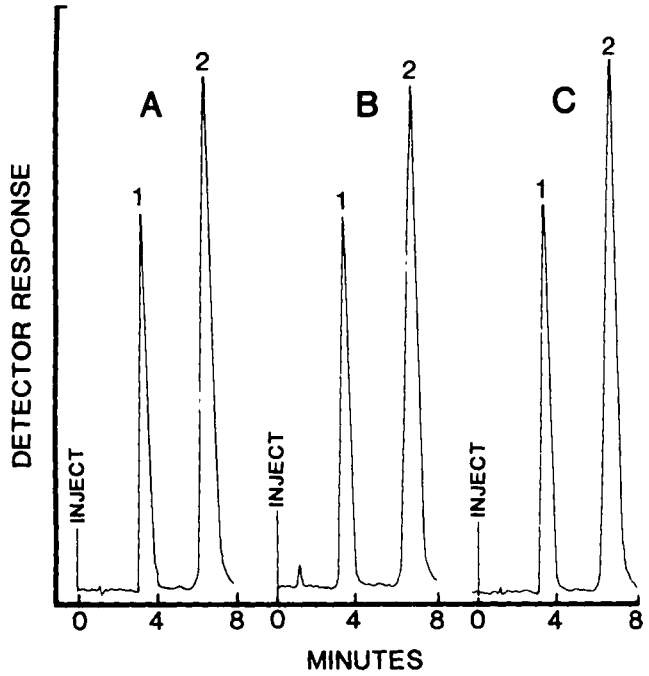

Figure 1—*Typical chromatograms; peaks 1 and 2 are from phenylpropanolamine and metronidazole, respectively. Chromatograms A–C are from a standard solution, a ready-to-use solution (No. 1, Table I), and from tablets, respectively.*

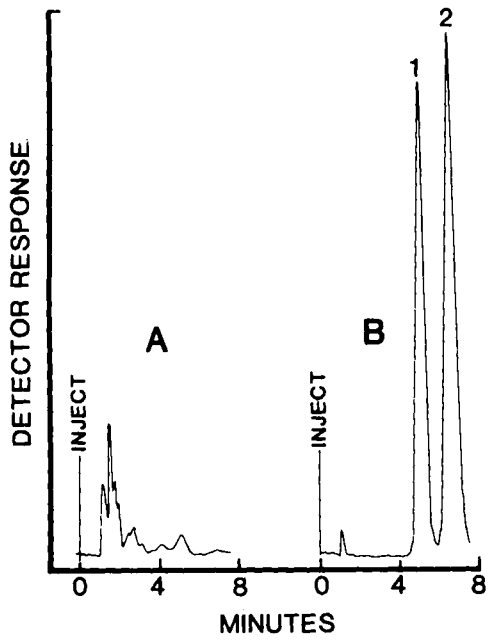

Figure 2—*Typical chromatograms; chromatogram A is from a decomposed solution (see text). All the peaks are from the decomposition products; no internal standard was added to this solution. Chromatogram B is from a standard solution with acetominophen (peak 1) as the internal standard and metronidazole (peak 2).*

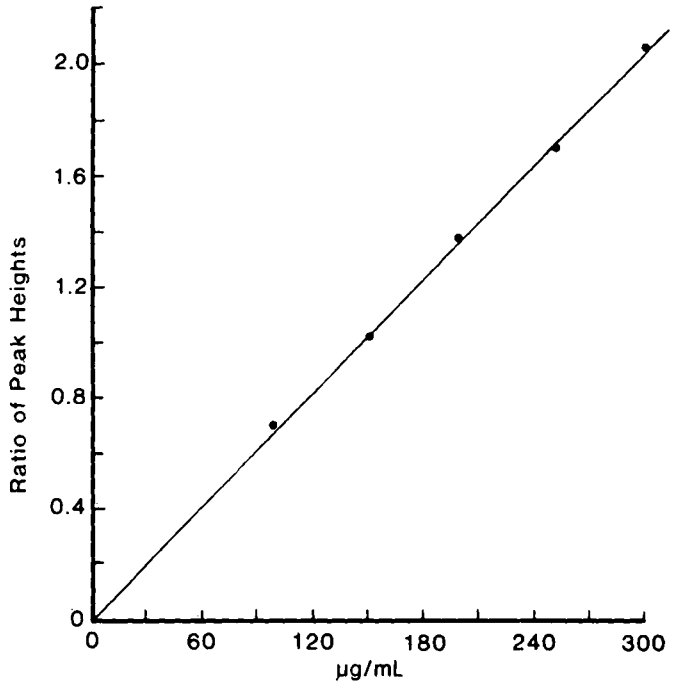

Figure 3—*A calibration curve of the ratio of the peak heights (metronidazole–phenylpropanolamine) and concentration of metronidazole. An average* RSD *based on six injections, was 0.68%.*

assay solution, and R_{phs} is the ratio of the peak heights of drug–standard solution. Alternatively, the results may be calculated using the standard curve.

RESULTS AND DISCUSSION

The assay results (Table I) indicate that the developed HPLC method for the quantitation of metronidazole in pharmaceutical dosage forms can be adopted. It is accurate and precise with an *RSD* of 0.68%, based on six injections. Before developing phenylpropanolamine hydrochloride as the internal standard (Fig. 1), acetaminophen was tried (Fig. 2). Acetaminophen can be used as an internal standard if some active or inactive products of decomposition interfere with the phenylpropanolamine peak. The concentrations were directly related to the ratio of peak heights between a range of 2–6 μg (Fig. 3). No preliminary extraction procedure was required to assay the ready-to-use solutions or the powders, which contained 415 mg of mannitol for each 500 mg of metronidazole. The presence of sodium phosphate, citric acid, and sodium chloride in the ready-to-use solutions, and mannitol in the powders, did not interfere with the assay procedure.

A very simple preliminary extraction procedure was required to assay the tablets. The coloring matter and the excipients present in the tablets did not interfere with the assay procedure. The method is stability indicating since a sample decomposed by using heat (see *Experimental Section*) showed almost 0% potency and a number of new peaks in the chromatogram (Fig. 2A). The developed method can be used to assay metronidazole in various dosage forms and also can be used to test content uniformity of the tablet formulations.

A Reply to "Problems Involved with Developing a Suitable Model for Evaluating Exposure to Bis(2-ethylhexyl) Phthalate from Medical Devices"

In February of this year, we reported a study in rats which indicated that chronic oral administration of the phthalate plasticizer, bis(2-ethylhexyl) phthalate (I), can result in induction of antipyrine metabolism[1]. Based on this observation, we hypothesized that the apparent stimulation of antipyrine clearance reported in earlier clinical studies in chronic renal failure patients could be the result of inadvertent exposure to I during hemodialysis treatment. In a subsequent commentary[2], which appeared in the June issue of this journal, Lawrence and Autian questioned the validity of our hypothesis on the grounds that the metabolism of I may differ between parenteral and peroral routes of administration. They cited various literature reports[3-5] which showed that I can be readily hydrolyzed to form mono(2-ethylhexyl) phthalate (II) in various tissues and biological fluids. The rates of hydrolysis were notably rapid in intestinal tissues and the gut contents[5]. Authors of several of these cited articles had stated that orally administered I *would probably* be absorbed from the GI tract primarily as the monoester. Apparently based on these statements, Lawrence and Autian drew the conclusion that II is formed much more extensively (or even exclusively) after oral administration as compared with after parenteral administration. Since there are data indicating differences in biological activities between I and II[6-9], Lawrence and Autian suggested that parenteral studies with I (which presumably better mimic the introduction of I into patients during hemodialysis) should be performed before our results on antipyrine disposition can be accepted as being valid.

There is no disagreement that hydrolysis of I to II can occur in the gut and/or liver after oral administration. However, we would caution that all of the literature articles cited by Lawrence and Autian were reports of *in vitro* studies on the hydrolysis of I by blood and tissue lipases. It is not possible to draw definite conclusions in regards to the *extent* of oral "first-pass" mono-deesterification of I in the various animal species studied. In fact at the time of our study (*ca.* 1981), detailed *in vivo* pharmacokinetic studies of I and its derived monoester were not available. Furthermore, it was not possible to rule out the existence of a significant degree of mono-deesterification following systemic introduction of I (such that the *overall* extent of formation of II would be comparable between enteral and parenteral administration). For example, it is conceivable that the diester can be excreted in the bile and be subjected to hydrolysis during transit through the intestinal tract. Also, extensive systemic hydrolysis of I certainly can occur.

We were aware of the literature on *in vitro* enzymatic hydrolysis of I (and the lack of quantitative information) at the outset of our study. More importantly, it was recognized that further *in vivo* studies were needed to address the unanswered metabolic and pharmacokinetic questions. We have, over the last 2 years, undertaken a series of studies in rats and in hemodialysis patients which provided much greater insights into the relative pharmacokinetic and pharmacological importance of I and its derived monoester. The results of these studies are currently under review for publication. We believe a brief summary of the relevant data will clarify the question concerning the factor of route of administration in the effect of I on antipyrine metabolism and will illustrate the complexities of the issue.

Our first follow-up study was aimed at elucidating the pharmacokinetics of I and derived II following a single intra-arterial (100 mg/kg), intraperitoneal (4 g/kg), or peroral dose (2 g/kg) of the diester. The key finding from this acute dosing study was a striking difference in the relative concentrations of the monoester metabolite to the parent diester between the parenteral and peroral routes of administration. The area under the plasma concentration–time curve (AUC) ratios of II to I were 0.050 ± 0.024, 0.35 ± 0.27, and 6.90 ± 1.75, respectively. A similar difference in AUC ratios between intraperitoneal and oral routes was found during repetitive administration of I. Using the pharmacokinetic methodologies proposed by Pang and Kwan[10] together with AUC data obtained after direct administration of II, we estimated that ~80% of an oral dose of I was hydrolyzed to II during first passage through the GI tract whereas <2% of the intra-arterial or intraperitoneal dose was mono-deesterified in the liver and other systemic tissues.

Our next step was to compare the effect of I on antipyrine clearance following repetitive intraperitoneal and oral administrations of I in the rat. The observed route dependency in the deesterification of I did indeed result in a difference in the effect of the phthalate plasticizer on antipyrine metabolism, although the results were much more complex than were anticipated. The complicating factor (which was alluded to in our earlier publication) was the elapsed time between the last dose of I and the administration of the antipyrine test. Consistent with our earlier study, a marked degree of induction in antipyrine clearance (an approximately twofold increase) was observed at both 4 and 48 h after the last oral dose of the phthalate ester. On the other hand, the effect after intraperitoneal treatment with I was variable depending on the time at which the antipyrine test was performed. At 48 h postadministration of I, a small degree of *inductive* effect (an ~25% increase in antipyrine clearance) was observed. At the earlier time point (*i.e.*, 4 h), either *no effect* or an apparently *inhibitory* effect was observed. The most likely explanation, which would take into account both the route- and time-dependency in the metabolic effects, is that induction is largely associated with the monoester and that the diester exerts an opposing effect, *i.e.*, inhibition of antipyrine metabolism. Indeed, we were able to demonstrate pronounced inhibition of antipyrine clearance after an acute dose of the diester given either intraperitoneally or orally.

Although our new findings in the rat seem to support the contention of Lawrence and Autian that the study on antipyrine metabolism should have been conducted after parenteral pretreatment of I, we have further data in hemodialysis patients which suggest that neither oral nor intraperitoneal administration of I in the rat exactly mimic the situation during clinical exposure. Studies in a group of renal failure patients on maintenance hemodialysis showed that the circulating concentrations of derived II were comparable to the parent diester during a 4-h dialysis session (AUC ratio of 2.42 ± 0.66). This suggests that mono-deesterification of I in the systemic circulation occurs much more readily in humans than in rats. Alternatively, II may be eliminated much more slowly (relative to the parent compound) in humans than in rats.

In summary, we believe the oral bis(2-ethylhexyl) phthalate study in the rat was a reasonable first step in elucidating the potential *in vivo* effects of I on hepatic drug metabolism during human exposure. The results generated from that study are still indicative, albeit in a qualitative fashion, of the probable influence of I on antipyrine disposition in renal failure patients. However, given the differences in the pharmacokinetic and metabolic characteristics of I between the rat and human, we now conclude that further investigations in other animal species are needed to establish a valid experimental model for assessing the biological effects of I.

The Need for Information on Product Formulations

I thoroughly enjoyed your editorial "Putting An End to Secret Formulations." [1] Over the years I've had numerous debates with manufacturers over the issue of "trade secrets" (Boloney!) *versus* the health professionals' need for information on product formulations.

As you pointed out, any competitors' laboratory worth their salt will rapidly crack such "secret formulations." Therefore, the only ones kept in the dark are the physician prescribers and pharmacist dispensers of these pharmaceuticals.

Although you state that "manufacturers are required by law and regulation to make known the identity and quantity of the medicinally active ingredients in their products," even this is not always the case. For example, in many artificial tear solutions and contact lens solutions, the functionally active components may only be identified as "a water-soluble polymeric system" or "an anionic surface-active agent."

If health care professionals are to make informed product selection decisions, the industry must provide this needed information. Although regulatory remedies may be necessary, industry leaders with vision might see that voluntary cooperation would result in benefits to all concerned.

Must we have mandatory CE before pharmacists accept their obligation to maintain their competence? Must we have mandatory relabeling requirements before the industry responds to the information needs of the public? Must we always have an expensive, legislative, regulated, bureaucratized solution to every problem?

The PMA has taken a significant first step in stating "the medical justification for disclosure . . . warrants release of that information . . ." Let's hope that individual manufacturers respond to your call for "putting an end to secret formulations."

BOOKS

Instrumental Data for Drug Analysis. Vol. 2. (Elsevier Series in Forensic and Police Science.) By TERRY MILLS III, WILLIAM N. PRICE, and J. CONRAD ROBERTSON. Elsevier Science Publishing Co., Inc. 52 Vanderbilt Ave., New York, NY 10017. 1983. pp. 662-1358. 22 × 28.5 cm. Price $95.00.

This second volume contains data on an additional 300 drug substances bringing the total compounds covered in both volumes to 600.

Each drug substance is allotted two pages on which ultraviolet, electron impact mass, proton nuclear magnetic resonance, and Fourier transform infrared spectra are presented. All spectra are of exceptional quality. Also given are molecular formulas and weights, synonyms, trade names, therapeutic categories and, in shorthand style, HPLC and GC data where applicable. There are also four appendices containing standard KBr infrared spectra and, in tabular form, Kovats retention indices for gas chromatography, the ultraviolet absorption maxima in acid, basic and ethanol solution, and mass spectral indices for base peaks and prominent ions.

The atlas has been compiled by forensic scientists of the Georgia State Crime Laboratory and should be useful for the identification of drugs. Thus, the compilation serves as a supplement to the *Merck Index* which does not present spectra. The two volumes compete with two *CRC Handbooks of Mass Spectra and Spectrophotometric Data of Drugs* which together sell for about the same price. I prefer the volumes under review for better organization, clearer spectra and coverage of more drugs. One can quibble that the shorthand data on HPLC and GC are of questionable value. It also would have been useful to identify for each drug the source of the sample, particularly whether the drug was a USP reference standard.

All efforts to provide comprehensive information on drugs are welcome. Therefore, the authors should be congratulated and encouraged to continue the series.

Applied Therapeutics: The Clinical Use of Drugs, 3rd Ed. Edited by BRIAN S. KATCHER, LLOYD YEE YOUNG, and MARY ANNE KODA-KIMBLE. Applied Therapeutics, Inc., P.O. Box 1903, Spokane, WA 99210-1903. 1983. 1,619 pp. 19.5 × 24 cm. Price $54.00.

The editors and authors of *Applied Therapeutics: The Clinical Use of Drugs*, 3rd edition, have refined and expanded the book previously titled, *Applied Therapeutics for Clinical Pharmacists*. It is appropriate that the title has been changed because the book can be of great value to any health professional involved in treating and monitoring patients receiving drug therapy.

Applied Therapeutics: The Clinical Use of Drugs is relatively comprehensive. The book consists of 61 chapters, 1619 pages with numerous tables and figures. The more commonly occurring chronic and acute diseases are presented with heavy emphasis being placed on drug therapy management. This book is not a substitute for a standard textbook of medicine in terms of understanding pathophysiology and diagnosis of various disease entities. It is an essential companion textbook to a medical textbook, however, and is evolving as the premier book in the field of drug therapy management of disease processes.

The book is well written and referenced. The question and answer format and utilization of case studies is particularly effective in demonstrating appropriate application of pharmacotherapeutic information in specific clinical situations. The book fosters the development of a rational approach to drug therapy management.

There is nothing esoteric about this book. It is a practical guide to optimal drug therapy. It is an excellent manual for the clinician. All health care professionals involved in primary medical care, particularly pharmacists, physicians, and nurse practitioners, would be well served by this book.

Advances in Chromatography, Vol. 22. Edited by J. CALVIN GIDDINGS, ELI GRUSHKA, JACK CAZES, and PHYLLIS R. BROWN. Marcel Dekker, 270 Madison Avenue, New York, NY 10016. 1983. 344 pp. 15.5 × 23.4 cm. Price $49.75.

The latest volume maintains the high quality that chromatographers have come to expect from this invaluable series. Eleven authors present reviews of seven contemporary topical areas in liquid chromatography.

This volume is comprised of chapters dealing with HPLC and mass spectrometry of neuropeptides, HPLC of amino acids, chromatographic resolution of racemates, HPLC of metal complexes, chromatography of carotenoids and retinoids, HPLC of porphyrins, and small bore columns in liquid chromatography. Without exception, these reviews are authored by individuals actively working and publishing in their respective fields and all are authoritative and well written. There is also reasonable uniformity of organization of the first six chapters, indicative of active editorial involvement in the final publication. The final chapter focuses on the theoretical and practical application of a technology (small bore columns) rather than on a specific class of compounds, and is also well written, albeit organized along different lines.

Following a brief introduction, each chapter presents a critical review of the specific analytical problem using detailed examples. The summary sections, in which the authors' views toward the direction that important developments will likely take, separates this treatment from a bland, noncritical review of a multitude of published articles. The chapters are well referenced and generally encompass the literature well into 1982, making this a reasonably up-to-date volume in this rapidly changing field.

Like previous volumes in this series, this book is more useful as a reference for scientists from many disciplines involved with separation problems than as a textbook in a specific graduate course. Because of its obvious emphasis on biologically important molecules (neuropeptides, amino acids, retinoids, and porphyrins), it is particularly recommended to biochemists and clinical/analytical chemists involved with these separation problems. Its treatment, however, is sufficiently broad so that many other researchers who utilize HPLC should consider adding this to their personal libraries.

Information Theoretic Indices for Characterization of Chemical Structures. By DANAIL BONCHEV. Research Studies Press. John Wiley & Sons, Inc. One Wiley Dr., Somerset, NJ 08873. 1983. 249 pp. 15.5 × 23.5 cm. Price $54.95

This book is a presentation of information theory as it is applied to chemical structures. Regretably, the author devotes only eight pages to the basic Shannon equation—its meaning and broad implications in science. Much of the work presented in this book is based on Bonchev's studies. Chapters 3 and 4 deal with atomic and molecular information, respectively. Under the discussion of molecules, the author briefly reviews graph theory and some of the topological indices such as molecular connectivity. These are not based upon probabilities, as is the Shannon equation, and so should not be classed with indices based upon information theory. A large number of indices are reviewed in Chapter 4 based upon various attributes of molecular structure or their graphic representations. It is apparent that there is a rich potential here for structure quantitation; however, practically no examples are presented where correlations with real physical properties are achieved. Only 30 pages at the end of the book are devoted to applications of any of the indices to chemical or biological problems.

Much of the work presented in this book has yet to bear real fruit in terms of structure quantitation influencing physical or biological properties. Perhaps within a decade much will have been published using this approach in QSAR studies and then this book may be regarded as a classic work. On that basis it is valuable to the scientist with a creative and pioneering spirit. I'm glad I've got a copy.

The Clinical Research Process in the Pharmaceutical Industry. (Drugs and the Pharmaceutical Sciences, Vol. 19). Edited by GARY M. MATOREN. Marcel Dekker, Inc., 270 Madison Ave., New York NY 10016. 1984. 549 pp. 16 × 23.5 cm. Price $59.75.

The first edition of this comprehensive reference covers all of the pertinent aspects of industrial pharmaceutical research and development. It represents a major step forward in the identification and description of the critical aspects of new drug development, which the book terms "pharmogenology."

The 27 chapters in this book have been written by a truly distinguished group of academicians, industrial scientists, and regulatory experts. Each chapter represents a step in the critical path through which each new drug must pass on its way towards an N.D.A. submission. In addition, there are a number of specialized chapters in this book dealing with critical aspects that form the background for the drug development process. In these chapters, the following topics are covered: Legal and Ethical Problems in Clinical Research; The Monitoring Process; Research Quality Assurance; The Role of Contract Research Organizations; The Impact of the Pharmaceutical Industry on Health Care; and Career Opportunities in Industrial Clinical Research.

The Clinical Research Process in the Pharmaceutical Industry is an indispensable reference for R&D managers in the pharmaceutical industry, for clinical pharmacists in medical center hospitals, and for academicians and students in clinical research and drug regulatory affairs.

Drug Dosage and Administration—Modern Theory and Practice. By JOSEPH WARTAK. University Park Press, 300 North Charles Street, Baltimore, MD 21201. 1983. 173 pp. 18 × 26 cm. Price $32.50.

This volume is authored by a research cardiologist from Canada who claims it is "intended for medical students and physicians." The book is divided into five parts dealing with "Dosage of Drugs," "Drug Concentrations in Blood," "Presentation of Drugs," "Administration of Drugs," and "Rational Use of Drugs." Each part is further divided into five or more chapters. In addition, a slide rule is provided for dosage adjustment and calculations. The current volume appears to be closely related to another book, by the same author, entitled "Clinical Pharmacokinetics: A Modern Approach to Individualized Drug Therapy," published by Praeger Scientific.

Part I presents very basic information on drug dosage scales; concepts of minimal, maximal, and average doses; and individualization of drug dosage and dosage adjustment in children and in patients with renal impairment. Use of the slide rule is included in the illustrations.

Part II deals with elementary pharmacokinetic principles presented in a manner that assumes that the reader is completely unfamiliar with any of these concepts. A few comments on the dose-response relationship are also included. Drug dosage forms including basic information on solid, semi-solid, liquid, long-acting, and sustained release dosage forms are presented in Part III.

Part IV contains information on different modes of drug administration including enteral administration, intravenous injection and infusion, pulmonary and local administration, and a few sentences on transdermal drug delivery systems. Planning a treatment program, choice of drugs and the outcome of drug treatment are discussed in Part V. A bibliography of 52 references is presented at the end of the book.

This book is a very superficial presentation of the many concepts embodied in the disciplines of pharmacokinetics and biopharmacokinetics and their application to drug therapy. These concepts are presented in such a simplistic fashion that the text can easily be read by a lay person. The book cannot be recommended for anyone other than the junior medical student, nursing staff, or other paramedical personnel. It is of very limited value for the pharmacist, pharmacy student, academic physician, or pharmaceutical scientist. Its purchase, therefore, cannot be recommended.

Advances in Chromatography, Vol. 22. Edited by J. CALVIN GIDDINGS, ELI GRUSHKA, JACK CAZES, and PHYLLIS R. BROWN. Marcel Dekker, 270 Madison Avenue, New York, NY 10016. 1983. 344 pp. 15.5 × 23.4 cm. Price $49.75.

The latest volume maintains the high quality that chromatographers have come to expect from this invaluable series. Eleven authors present reviews of seven contemporary topical areas in liquid chromatography.

This volume is comprised of chapters dealing with HPLC and mass spectrometry of neuropeptides, HPLC of amino acids, chromatographic resolution of racemates, HPLC of metal complexes, chromatography of carotenoids and retinoids, HPLC of porphyrins, and small bore columns in liquid chromatography. Without exception, these reviews are authored by individuals actively working and publishing in their respective fields and all are authoritative and well written. There is also reasonable uniformity of organization of the first six chapters, indicative of active editorial involvement in the final publication. "Scientific Proof"—An Elusive Goal

Every two to three years since 1965, we have witnessed the appointment and installation of a new Commissioner to head the U.S. Food and Drug Administration. And, although their respective interests, expertise, and styles of operation have varied, we can honestly say that each performed capably and with distinction. Each of them was a credit to the Agency, to the health care professions, and to the nation.

We have often used the occasion of a new Commissioner's appointment to devote our editorial to welcoming him to Washington and to his new position. But the "welcome" was only an incidental message packaged in with some other key point that appeared to us to be pertinent and timely.

For example, when Commissioner Arthur Hull Hayes assumed office we noted the prevailing change in the national regulatory climate ("FDA Takes a Turn in the Road"). With Commissioner Jere Goyan we addressed his philosophic approach to education *versus* regulation ("FDA: Policeman or Teacher?"). The Alexander M. Schmidt to Donald Kennedy transition prompted us to comment on how each Commissioner has left his own individual imprint on the Agency ("Passing the Baton at FDA"). And, in addition to welcoming the new Commissioner, we have also expressed concern that the frequent rate of turn-over in that office has had a damaging effect on the FDA and the morale of its staff ("A Plea for FDA Stability").

The opening two paragraphs from that latter editorial, in July 1979, are again all too relevant and seem to merit repeating:

"Kings, popes, and presidents come and go with the passing of time. It should not be strange, therefore, that the same is true of Food and Drug Commissioners.

"Nevertheless, the departure of the last several FDA Commissioners has seemed to have come too soon, too abruptly, and all too unexpectedly. Indeed, each of them seems to have little more than arrived, got settled in office, established an operating style, developed a rapport with the health professions and the regulated industry, when 'poof!'—they were gone from office!"

With that lamentation regarding all-too-brief tenure now aside, it is our pleasure to welcome the latest resident to the "hot seat" of the Parklawn Building where FDA is headquartered.

Frank E. Young, M.D., Ph.D., comes to the Agency with little previous FDA or regulatory background, but with a solid reputation as a microbiological scientist. He is noted for his work in genetics and recombinant DNA—an area that is soon going to require some landmark FDA attention and regulation. Consequently, we may again see a fortuitous situation at FDA in that the right person was in the job at just the right time to handle the chief problem or problems of the period.

But the key observation that we would like to bring out in this editorial relates to the increasing complexity of the decisions that the FDA Commissioner is required to make as technology advances and life in general becomes more and more complicated.

Consider, for example, one of the items that Commissioner Young found near the top of his "in box" when he assumed office: namely, the Pandora's Box of artificial sweeteners.

At various times, FDA has approved three artificial sweetening agents: saccharin, cyclamate, and aspartame. Subsequently, it rescinded its approval of cyclamate and that agent is currently off the market in the U.S. (but continues to be available in Canada and some other countries). Later, it acted to rescind its approval of saccharin, but Congress stepped in and, *via* legislation, applied a year-by-year staying action on that ban. And, although it has yet to respond officially (as of this writing), FDA is now the object of a request to Congress by the consumer-oriented lobbying group Common Cause to investigate the merit and justification for FDA's approval of aspartame. Common Cause has been joined by a second organization, the Community Nutrition Institute, which has also mounted a legal challenge to the approval of aspartame.

The basic problem common to all three of these regulatory actions dealing with the artificial sweeteners is the Delany Amendment to the Federal Food, Drug, and Cosmetic Act. That clause prohibits the marketing of any food additive that, under virtually any conditions of use or testing, has been shown to cause cancer. The specific wording reads: "no (food) additive shall be deemed to be safe if it is found to induce cancer when ingested by man or animal."

Deceptively simple sounding, this provision leads to incredible complications. In animal studies, for example, animals have been tested for their full life-time with daily dose-levels at thousands of times what would normally be ingested; then perhaps only a few animals developed tumors—but at just slightly higher levels than the control group. Under these circumstances, how does a scientist make a judgment that the agent induced cancer or not?

Dr. Young will soon find that even the legendary wisdom of Solomon would be sorely tested in deciding upon the artificial sweetner question. Specifically, in addition to the above mentioned brouhaha over aspartame, the Congressional stay on the saccharin ban will expire in April 1985 and, if the stay is not extended, FDA will need to take some action. But perhaps even more significant is the reconsideration now being given to cyclamate.

The FDA's cancer assessment committee concluded in April that cyclamate is not a carcinogen after all, and the National Research Council (NRC) has been commissioned to issue an independent judgment.

The NRC's Commission on Life Sciences reported on its acceptance of this study assignment in that organization's Summer 1984 *newsletter*. In the lead article, entitled "Cyclamates Revisited," the NRC reporter begins with a quote from the September 16, 1980, issue of the *Federal Register:* "Cyclamate has not been shown not to cause cancer; and . . . cyclamate has not been shown not to cause heritable genetic damage." The reader is literally tied in knots by the double negatives!

The difficult position of the FDA Commissioner was further emphasized to us recently in a private conversation with a past Commissioner in which he told us that he saw no proof that saccharin was carcinogenic; but he also saw no absolute proof that it wasn't carcinogenic either. Hence, he felt that the law obligated him to recommend it be banned—demonstration of safety being a prerequisite of marketing approval.

But how can safety be proven? Especially absolute safety, and proven in terms that satisfy scientists, the public, and the Congress?

Commissioner Young will probably be forced "to bite the bullet" in this issue, to a far greater degree than any of his predecessors. It will be a most difficult decision. For his own sake, as well as that of science, the FDA, and the public at large, we hope that he has the scientific wisdom—as well as the scientific knowledge—to make the right choice.

Triprolidine Radioimmunoassay: Disposition in Animals and Humans

JOHN W. A. FINDLAY *x, ROBERT F. BUTZ *, GEOFFREY G. COKER ‡, RICHARD L. DEANGELIS *, and RICHARD M. WELCH *

Received August 11, 1983, from the *Department of Medicinal Biochemistry, The Wellcome Research Laboratories, Research Triangle Park, NC 27709, and the ‡ Department of Therapeutic Chemistry, The Wellcome Research Laboratories, Beckenham, Kent, United Kingdom. Accepted for publication December 6, 1983.

Abstract □ A hapten derivative of triprolidine, bearing an acrylic acid side chain *ortho* to the pyridine ring nitrogen atom, was synthesized and coupled to bovine serum albumin. Immunization of New Zealand White rabbits with the resulting drug-protein conjugate resulted in the production of antisera capable of binding a radioiodinated tyramine conjugate of the triprolidine hapten derivative at high antiserum dilutions (1:70,000–1:150,000). These antisera were used to develop a radioimmunoassay (RIA) for triprolidine in human plasma with a sensitivity limit of 0.1 ng/mL (0.01 ng of actual mass). The known hydroxymethyl and carboxyl metabolites of triprolidine cross-reacted weakly (<2 and <0.05%, respectively) with this antiserum. The RIA could be used for the direct analysis of triprolidine in human and rabbit plasma, but not for rat or dog plasma, presumably due to the presence of other interfering substances (possibly metabolites). The validity of the RIA procedure in human plasma was demonstrated by comparative analysis of a number of samples by quantitative TLC (r = 0.985, slope = 1.076). The assay was employed to describe the pharmacokinetics of triprolidine in the rabbit ($t_{1/2,\beta}$ = 1.7 h). The assay had adequate sensitivity to detect low circulating drug concentrations in humans after therapeutic oral doses and also substantiated previous disposition experiments with triprolidine in humans ($t_{1/2,\beta}$ = 2.27 h). TLC analysis demonstrated that the absolute oral bioavailability of triprolidine (1-mg/kg dose) in the dog was low (4%). A comparison of triprolidine pharmacokinetic parameters in dogs, rabbits, rats, and humans revealed considerable similarity in elimination characteristics in these species.

Keyphrases □ Triprolidine—bovine serum albumin conjugate, pharmacokinetics, animal-human comparisons, RIA compared with TLC and GC □ Radioimmunoassay—triprolidine in animals and humans, comparisons with GC and TLC

Triprolidine hydrochloride {(*E*)-2-[3-(1-pyrrolidinyl)-1-*p*-tolylpropenyl]pyridine monohydrochloride monohydrate} has been shown to have potent antihistaminic activity in animals (1–3) and to be clinically efficacious in humans (4–8). However, no detailed reports have appeared on the disposition of this drug, although [^{14}C]triprolidine was shown to be metabolized extensively *in vitro* by the guinea pig liver (9).

Circulating concentrations of triprolidine in human plasma following administration of oral therapeutic doses are very low and quite variable (10), necessitating the use of highly sensitive analytical techniques for their determination. Although TLC (11) and GC (12) procedures have been described for triprolidine, no data on the disposition of the drug were derived from these studies. A sensitive, quantitative TLC method for triprolidine was recently described by DeAngelis and coworkers (10), and the method was used to study some aspects of the disposition of this drug in rats and humans.

In this paper we present details of a specific radioimmunoassay (RIA) procedure for triprolidine which is capable of detecting 0.1 ng/mL of drug in plasma. This assay employs a gamma-emitting ^{125}I-radioligand, and thus is convenient for the analysis of large-scale triprolidine disposition studies. In the course of validating this method for human plasma analysis, the absolute oral bioavailability of triprolidine in the dog was determined by quantitative TLC, and some pharmacokinetic comparisons were made between rats, dogs, rabbits, and humans.

EXPERIMENTAL SECTION

The assay buffer used was 0.05 M Na_2HPO_4/NaH_2PO_4–0.15 M NaCl–0.01 M EDTA·Na_2–0.1% gelatin, pH 7.0. For separation of antibody-bound from free radiolabel, a dextran-coated charcoal suspension was prepared by dissolving 0.5 g of dextran[1] in 200 mL of ice-cold assay buffer, and adding 2 g of RIA-grade charcoal[2] to this solution. This suspension was stirred for at least 30 min at 0°C before use.

Hapten Synthesis—*2-Bromo-6-(4-toluoyl)pyridine* (*I*)—Butyllithium (50 mL, 1.65 M in hexane) was added under nitrogen to a stirred suspension of 2,6-dibromopyridine (19.5 g) in dry ether (200 mL) at −50°C. After 0.75 h a solution of 4-tolunitrile (10 g) in ether (50 mL) was added; stirring was continued at −50°C for 3 h. The mixture was allowed to warm to −30°C and

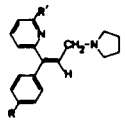
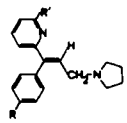
Table I—Structures and Cross-reactivities of Triprolidine and Related Compounds



IV and X



V-IX, XI and XII

Compound	R	R′	IC_{50}, ng/mL	Cross-reactivity, %[a]
IV	CH_3	$CH{=}CHCO_2H$	162.0	0.3
V	CH_3	$CH{=}CHCO_2H$	0.7	83.0
VI	CH_3	H	0.6	100.0
VII	CH_2OH	H	34.0	1.9
VIII	CO_2H	H	>1000.0	<0.05
IX	CF_3	H	1.12	49.1
X	CF_3	H	26.0	2.1
XI	CH_3		—	—
XII	CH_3		—	—

[a] Cross-reactivity of compound = (IC_{50} of triprolidine)/(IC_{50} of compound) × 100.

treated with HCl (200 mL, 2 M). The precipitated solid was collected, washed with water, and recrystallized from aqueous ethanol. The ketone formed colorless needles (12.2 g), mp 97–98°C. IR (KBr disk): 1660 cm^{-1} (aromatic ketone); ^{1}H-NMR ($CDCl_3$): δ 8.1–7.2 (m, 7, ArH) and 2.4 ppm (s, 3, Ar-CH_3).

Anal.—Calc. for $C_{23}H_{10}BrNO$: C, 56.52; H, 3.65; N, 5.07; Br, 29.0. Found: C, 56.48; H, 3.67; N, 4.93; Br, 28.53.

2-(6-Bromo-2-pyridyl)-2-(4-tolyl)-1,3-dioxolan (II)—A mixture of the above ketone (31 g), toluene (150 mL), ethylene glycol (10 mL), and *p*-toluenesulfonic acid (4 g) was heated at reflux for 6 h using a Dean–Stark trap. After cooling, the toluene solution was washed with excess ice-cold sodium bicarbonate solution, dried, and evaporated to 50 mL. Addition of petroleum ether to the warm solution induced crystallization of the dioxolan. From cyclohexane this formed colorless prisms (24.3 g), mp 110–112°C. ^{1}H-NMR ($CDCl_3$): δ 7.8–7.0 (m, 7, ArH), 4.1 (s, 4, $-CH_2-O-$), and 2.35 ppm (s, 3, Ar-CH_3).

Anal.—Calc. for $C_{15}H_{14}BrNO_2$: C, 56.25; H, 4.45; N, 4.4. Found: C, 56.48; H, 4.26; N, 4.29.

Ethyl (E)-3-[6-[(4-methylphenyl)carbonyl]-2-pyridinyl]propenoate (III)—A solution of II (3.5 g) in ether (100 mL) was cooled to −40°C and treated under nitrogen with butyllithium (10 mL, 1.64 M in hexane). After stirring at −50°C for 2 h, dimethylformamide (2 mL) was added. Two hours later the mixture was warmed to −30°C and treated with HCl (20 mL, 2 M). The organic phase was separated, washed with sodium bicarbonate solution, dried, and evaporated under reduced pressure. The residual aldehyde (2.5 g) was dissolved in 1,2-dimethoxyethane (10 mL) and added to a solution of the phosphonate carbanion produced from triethyl phosphonoacetate (2 g) and sodium hydride (0.22 g) in the same solvent. The mixture was stirred for 2 h, diluted with ether (25 mL), and treated with HCl (5 mL, 2 M). The organic phase was separated, washed with water, dried, and evaporated. The resulting oil was dissolved in ethanol (20 mL) containing concentrated HCl (3 mL) and water (3 mL). After heating on a steam bath for 10 min, the solution was diluted with ice water, rendered alkaline with sodium bicarbonate solution, and extracted with ether. After evaporation the residue was crystallized from cyclohexane as colorless platelets (1 g), mp 108–111°C. ^{1}H-NMR ($CDCl_3$): δ 7.65 (d, 1, J = 16 Hz, olefinic protons) and 6.85 ppm (d, 1, J = 16 Hz), implying *E* configuration.

Anal.—Calc. for $C_{18}H_{17}NO_3$: C, 73.2; H, 5.8; N, 4.75. Found: C, 72.7; H, 5.7; N, 4.59.

(E)-6-[(E)-3-(1-pyrrolinyl)-1-p-tolylpropenyl]-2-pyridineacrylic acid (V)—Butyllithium (10 mL, 1.64 M in hexane) was added under nitrogen to a stirred suspension of triphenyl-2-pyrrolidinoethylphosphonium bromide (13) (7.2 g) in dry toluene (75 mL). After 0.5 h, III (4.8 g) in toluene (50 mL) was added. The suspension, initially orange, became deep purple, then slowly faded to yellow during 2 h heating at 75°C. The cooled solution was diluted with ether (150 mL) and treated with HCl (50 mL, 2 M). The aqueous phase was separated, washed with ether, and basified with potassium carbonate (ice). Basic products were extracted into ether and immediately converted to oxalates by addition of oxalic acid (2.5 g) in ethanol (10 mL). The crude salts (5.1 g) melted at 148–155°C; it was shown by NMR that the new double bond had formed in the ratio 2:1, *Z*:*E*. The mixture of oxalates (3.7 g) was decomposed with sodium bicarbonate solution–ether. A solution of the bases in ethanol (100 mL) containing sodium hydroxide (20 mL, 1 M) was heated on the steam

bath under reduced pressure for 5 min, neutralized with sulfuric acid (20 mL, 0.5 M), and finally evaporated to dryness. The solid residue was extracted with hot isopropyl alcohol (3 × 50 mL), and the combined filtrates were evaporated to dryness. The pinkish solid residue (2.5 g) was dissolved in hot ethyl acetate. Crystals (1.5 g), mp 160–162°C, were deposited on cooling; recrystallization from ethyl acetate gave the *E,Z*-isomer IV, mp 173–174°C (0.8 g). ^{1}H-NMR ($CDCl_3$) isolated olefinic proton at δ 6.35 ppm (t, 1). Concentration of the mother liquors afforded a second crop of crystals, mp 215–220°C (0.65 g), raised to 220–222°C (dec.) by recrystallization from isopropyl alcohol (0.55 g). ^{1}H-NMR ($CDCl_3$) isolated olefinic proton at δ 7.58 (t, 1), confirming that this was the *E,E*-isomer V.

Anal.—Calc. for $C_{22}H_{24}N_2O_2$: C, 75.86; H, 6.95; N, 8.05. Found: C, 75.57; H, 7.10; N, 8.03.

Conjugation of Acid V with Bovine Serum Albumin—Compound V (30 mg, 0.086 mM) was dissolved in ethanol (3 mL), and water (12 mL) was added. Bovine serum albumin (40 mg, 0.0057 mM) was added, the pH of the solution was adjusted to 5.5, and 1-ethyl-3-(3-dimethylaminoethyl)-carbodiimide hydrochloride[3] (25 mg, 0.161 mM) was added. This final solution was stirred overnight at room temperature, then was subjected to ultrafiltration[4] with water as eluant. After UV absorbance in the dialysate had returned to baseline levels, the solution of protein conjugate in the cell was lyophilized to give the drug–bovine serum albumin conjugate as a fluffy white solid (34 mg).

(E,E)-N-[2-(4-hydroxy-3-^{125}I-phenyl)ethyl]-3-[6-[1-(4-methylphenyl)-3-(1-pyrrolidinyl)-1-propenyl]-2-pyridinyl]propenamide (XII)—Compound V (30 mg, 0.086 mM) was dissolved in dimethylformamide (3 mL), and to this solution triethylamine (20 μL, 0.129 mM) was added. The solution was cooled in an ice bath, isobutyl chloroformate (15 μL, 0.108 mM) was added, and the reaction mixture was stirred at 0°C for 30 min. Tyramine (13 mg, 0.095 mM) in dimethylformamide (1 mL) was added, and the pH was adjusted to 8 with 1 M NaOH. The mixture was stirred overnight at 4°C; the addition of tyramine changed the initial pink/purple color to brown/orange. Solvents were removed under reduced pressure, and the residue was purified by preparative TLC on silica gel plates[5] developed in $CHCl_3$–CH_3OH–NH_4OH (70:30:1). The UV-absorbing band at R_f 0.73, which gave a slowly developing blue color when sprayed with ferric chloride–potassium ferricyanide, yielded the amide XI as an oil (13.6 mg) on elution with 10% CH_3OH–$CHCl_3$.

Amide XI was iodinated in the phenolic moiety by the method of Hunter and Greenwood (14). Compound XI (2 μg) in ethanol (10 μL) was mixed with 0.5 M Na_2HPO_4–NaH_2PO_4, pH 7.4 (25 μL). To this solution was added carrier-free [^{125}I]NaI[6] (1 mCi in 10 μL of NaOH solution) followed by chloramine-T hydrate (10 μg in 10 μL of 0.05 M phosphate buffer). The mixture was stirred for 30 s at room temperature, then sodium metabisulfite (25 μg in 25 μL of 0.05 M phosphate buffer) was added to stop the reaction. Preparative TLC of the reaction mixture on silica gel[5], as above, gave one major radioactive band at R_f 0.77 when radioscanned[7]. The iodinated compound was eluted from the silica with ethanol (13 mL), and the resulting solution was stored at −20°C until required. The approximate yield of iodinated amide XII was 420 μCi.

Immunization Procedure—Male New Zealand White rabbits received a primary immunization of 1 mg of bovine serum albumin-drug conjugate in 1 mL of 0.9% NaCl emulsified with 1 mL of Freund's complete adjuvant[8]. This dose was administered as two intramuscular (vastus lateralis) and eight subcutaneous (along the sides of the dorsal column) injections of 0.2 mL each. At intervals of 2, 4, and 6 weeks following the primary immunization, and at monthly intervals thereafter, booster immunizations of 0.5 mg of immunogen in 0.5 mL of saline, emulsified with 0.5 mL of Freund's complete adjuvant, were administered at multiple subcutaneous sites. Following the second and all subsequent booster immunizations, blood samples were collected from the central ear artery, and serum was collected and stored at −20°C until checked for the presence of antibodies. The antiserum used for the work described in this paper was obtained after 3 months of immunization.

Radioimmunoassay Procedures—All assay points were determined in duplicate; the results were then averaged. All assays were established in 12 × 75-mm polystyrene tubes[9].

Antiserum Titer Determinations—Various dilutions of rabbit antiserum in assay buffer (0.7 mL) were incubated with ^{125}I-triprolidine (50,000 cpm when freshly prepared, in 0.2 mL of assay buffer) and additional assay buffer (0.1 mL) in polystyrene tubes (12 × 75 mm) at 0°C for 2 h. Tubes containing only ^{125}I-triprolidine (0.2 mL) and buffer (0.8 mL) served as total count and nonspecific binding (background tubes). After 2 h, a dextran-coated charcoal suspension (0.5 mL) was added to all assay tubes, except total count tubes, and the contents were vortex-mixed and incubated at 0°C for 5 min. All charcoal-treated tubes were centrifuged at 4°C (≥1000×*g* for 10 min); the supernatants, containing the antibody-bound ^{125}I-triprolidine were decanted into clean polystyrene tubes, and the radioactivity was quantitated in a gamma[10] counter. Radioactivity bound by each antiserum dilution was expressed as percentage of total counts added to each assay tube. The antiserum titer was defined as that dilution which bound 40% of added radioligand.

Radioimmunoassay of Plasma Samples—Plasma samples from the various species were assayed directly, *i.e.*, without any prior extraction from the plasma. This procedure was similar to that given above, except that the assay incubation mixtures consisted of ^{125}I-triprolidine (0.2 mL) antiserum at the appropriate dilution (0.7 mL), and triprolidine standard solutions (0.1 mL) in blank plasma covering the range 0.078–10.0 ng/mL (7.8–1000 pg actual mass per tube). In addition to total count and nonspecific binding tubes, tubes containing antiserum (0.7 mL), ^{125}I-triprolidine (0.2 mL), and assay buffer (0.1 mL) served as maximum binding (B_0) tubes. Incubation and work-up procedures were as above. After quantitation of radioactivity, standard curves were expressed as percent B/B_0 against standard concentration on linear-log

scales, where B is the antibody-bound radioactivity in the presence of a given standard concentration.

Cross-reactivity Studies—These studies were carried out as for the RIA except that in addition to the triprolidine standard curve, curves were established with the triprolidine metabolites and related compounds (IV–XI) shown in Fig. 2, and with some structurally unrelated compounds which might be administered concomitantly as medications (pseudoephedrine, guaifenesin, codeine, dextrorphan, aspirin, and acetaminophen). Percentage cross-reactivities were expressed as:

$$(IC_{50} - \text{Compound})/(IC_{50} - \text{triprolidine}) \times 100$$

where IC_{50} is the concentration required to inhibit binding of radioligand to antiserum by 50% (15).

Quantitative Thin-Layer Chromatographic Analysis of Triprolidine—This analytical method was used as published (10) with some modifications. Briefly, the drug was extracted into benzene, the organic layer was separated by centrifugation, and a portion was concentrated by evaporation. The residue was dissolved in chloroform–methanol (85:15, 80 μL) and the entire volume was spotted on a silica gel plate. The plate was developed in chloroform–methanol–ammonium hydroxide (91:8:1) to a height of 11 cm. After spraying with 2 M ammonium bisulfate, the induced fluorescence of the drug was quantitated at an excitation wavelength of 300 nm (cut-off filter 400 nm). The recovery of the drug from plasma across a 1–8-ng/mL concentration range was 95%.

Human Disposition Studies—Three healthy volunteers (2 male, 1 female; mean weight, 68.0 kg) who were not receiving any drug therapy, fasted overnight (12 h) and, at 8 a.m., the next morning, ingested a tablet containing 2.5 mg of triprolidine hydrochloride[11]. No food was consumed until 2 h after drug administration. Plasma was harvested and stored as above. After 1 week, each dog received the same dose of drug by the alternate route of administration, and blood samples were collected in the same manner.
stored at −20°C until analyzed for triprolidine by RIA or TLC.

Animal Disposition Studies—*Dogs*—Two male beagles were fasted overnight. The next morning, both dogs received 1-mg/kg doses of triprolidine hydrochloride, one as an oral dose (gelatin capsule) and the other as intravenous injection (saphenous vein) in isotonic saline (2 mL). Blood samples were collected into EDTA-containing evacuated tubes[12] prior to drug administration and at 0.08, 0.17, 0.33, 0.5, 0.66, 1, 1.5, 2, 4, 6, 8, 12, and 24 h after drug administration. Plasma was harvested and stored as above. After 1 week, each dog received the same dose of drug by the alternate route of administration, and blood samples were collected in the same manner.

Rabbits—Three male New Zealand White rabbits were fasted overnight before intravenous administration of triprolidine hydrochloride (1 mg/kg) in isotonic saline (2 mL) into the marginal ear vein. Blood samples were collected from the contralateral marginal ear veins prior to and at 0.03, 0.17, 0.33, 0.67, 1, 1.5, 2, 4, 6, 7.5, and 12 h after drug administration. Blood samples were processed as described above for dogs.

Bioavailability, %		4.1		3.7

Pharmacokinetic Analysis—The mean plasma concentration–time data from the present human and rabbit experiments and a previous rat study (10), and the individual data sets from the dog experiments were analyzed pharmacokinetically by the computer program NONLIN (16), which iteratively minimizes the sum of the squared deviations between observed and computed plasma concentrations at the time points following drug administration. The volume of distribution, Vd_β, was calculated from the intravenous data using the equation $Vd_\beta = \text{Dose}/\text{AUC} \times \beta$, where AUC is the area under the plasma concentration–time curve from time zero to the last plasma sampling time, and β is the rate constant describing the terminal exponential phase of drug elimination from the plasma. Absolute bioavailability was determined from the ratio of the AUC values following oral and intravenous drug administrations.

RESULTS AND DISCUSSION

Synthesis of Hapten and Radioligand—Drug molecules are normally not immunogenic *per se*, and require prior coupling to a macromolecular carrier in order to elicit antibody production in animals (17, 18). A hapten derivative of triprolidine, suitable for coupling to protein, was prepared as shown in Scheme I. Starting from 2,6-dibromopyridine (I), the toluoyl derivative (II) was readily prepared and protected as the dioxolan (III), while the remaining bromine atom was replaced in a three-step procedure leading to the ethyl acrylate derivative (III). A Wittig reaction on the ketone moiety, followed by hydrolysis gave the acryloyl analogue of triprolidine (V, *E,E*-isomer) along with a larger amount of the *E,Z*-isomer (IV). These isomers were readily separated and purified by fractional crystallization. The triprolidine analogue (V) was successfully conjugated to bovine serum albumin by carbodiimide-mediated peptide bond formation, and the resulting drug–protein conjugate, after purification by ultrafiltration, was used for rabbit immunization experiments.

A convenient, gamma-labeled radioligand was prepared by coupling of tyramine to the acryloyl-triprolidine derivative (V) by the mixed anhydride method, followed by iodination of the phenolic moiety of the resulting amide XI with [^{125}I]NaI by the chloramine-T method of Hunter and Greenwood (14). This compound (XII, ^{125}I-triprolidine) was well-recognized by the antiserum, with >80% of 50,000 cpm of freshly prepared radioligand being bound by excess antiserum.

Antiserum Production—All three rabbits immunized with the bovine serum albumin–triprolidine conjugate produced antisera capable of binding ^{125}I-triprolidine after 2–4 months of the immunization program. The titer of these sera was sensitive to the presence of heterologous animal serum added to the incubation mixture. Thus, serum 830/2, which was employed for all of the work reported in this paper, exhibited apparent titers (40% total ^{125}I-triprolidine bound) of 1:140,000, 1:70,000, and 1:50,000 in the presence of human, dog, and rat (Long-Evans and Sprague-Dawley) plasma, respectively. The possibilities that these differences may be due to species variations in plasma proteins or to the presence of endogenous substances which are recognized by the triprolidine antiserum, have not been explored.

Assay Sensitivity, Accuracy, and Precision—Figure 1 is a typical triprolidine RIA standard curve for the assay in human plasma. The sensitivity of this system, defined as the concentration of triprolidine required to inhibit binding of radiotracer to antiserum by 10%, is ~0.1 ng/mL (0.01 ng actual weight). Clearly, this sensitivity could be increased by manipulation of the weight of radioligand and titer of antiserum used in the assay. Multiple analyses (on

different days) were conducted using a series of control triprolidine samples, prepared by addition of the hydrochloride salt to pooled blank human plasma to give various free base concentrations. The concentrations added were 0.2 (n = 25), 2.0 (n = 26), and 20.0 (n = 24) ng/mL; mean concentrations ($\pm SD$) measured were 0.21 (±0.05), 2.15 (±0.23), and 20.35 (±1.81), respectively. The highest control (20 ng/mL) was diluted 1:10 with blank plasma before analysis. These values therefore reflect interassay accuracy and precision data from averaged pairs of data points. The close agreement of the mean measured triprolidine concentrations with those actually added indicates the accuracy of the method. Standard deviations on the 2- and 20-ng/mL control samples indicate roughly 10% CV, while this value rises above 20% for the 0.2-ng/mL sample. Thus, at concentrations clearly above the sensitivity limit of the procedure, the assay method has good precision.

Assay Specificity—The specificity of the antiserum was examined by studying the relative abilities of triprolidine and a series of its metabolites and some related compounds to displace ^{125}I-triprolidine from the antiserum (Table I). The hapten derivative (V), which was coupled to bovine serum albumin to provide the immunogen, is almost as effective as triprolidine in displacing the radiolabel, but the *cis* isomer (IV) is almost 28-fold less effective. Although the *cis* isomer of triprolidine itself was not available for study, the ability of the antiserum to distinguish stereoisomers about the central double bond of the triprolidine parent structure was confirmed by examination of the cross-reactivities of the trifluoromethyl analogues (IX and X). The direct trifluoromethyl analogue of triprolidine (IX) cross-reacted extensively with the antiserum (49%), which indicates that the trifluoromethyl substituent is quite similar, antigenically, to the methyl substituent in triprolidine. However, the *cis*-trifluoromethyl isomer (X) cross-reacted ~25-fold less (2%), again confirming the recognition of stereochemistry around the central double bond. Several other stereospecific drug antisera have been developed recently (19-21), emphasizing that the specific properties of antisera extend beyond recognition of gross stereoelectronic changes to that of relatively fine differences in stereochemistry.

The aromatic acid (VIII), which has been identified as a major metabolite of triprolidine in animals and humans (9), exhibited only 15% inhibition of binding at 1000 ng/mL, indicating very low cross-reactivity (≪0.5%). The structural change in the benzylic alcohol (VII), also a metabolite of triprolidine, was also well-recognized, leading to a relatively low cross-reactivity value of 1.9% relative to triprolidine. A number of compounds which were not structurally related to triprolidine, but which may be coadministered as medications with the drug, were also examined. Codeine, pseudoephedrine, aspirin, acetaminophen chlorpheniramine, guaifenesin, and dextrorphan all showed little inhibition of binding (2–8%) at a concentration of 10 μg/mL. Surprisingly, chlorpheniramine did have weak (2.5%), but measurable, cross-reactivity in the triprolidine radioimmunoassay.

Assay Validation—The RIA procedure for triprolidine in human plasma was validated by comparative analysis of a group of human plasma samples by RIA and by a previously published quantitative TLC method (10). The samples were collected from volunteers at various times after the ingestion of a single dose (2.5 mg) of triprolidine hydrochloride (Fig. 2). The regression equation obtained was, RIA = 1.076 × TLC − 0.071. An excellent correlation (r = 0.985) and good agreement (slope = 1.076) was found for these two analytical methods, confirming the validity of the RIA procedure for triprolidine analysis in human plasma.

To illustrate the utility of the assay procedure, several experiments involving the oral administration of triprolidine hydrochloride to dogs, rats, guinea pigs, rabbits, and humans were established. In the case of dogs and rats, direct analysis of triprolidine by RIA without extraction was unsuccessful due to the failure of plasma samples to dilute in a manner parallel to the triprolidine assay standard curve. Markedly increased apparent triprolidine concentrations were obtained on each dilution, perhaps as a result of cross-reaction from an unknown metabolite that may have a displacement curve nonparallel to that of triprolidine. These samples could be analyzed readily by RIA after a preliminary benzene extraction of triprolidine from the plasma (10). Plasma samples from guinea pigs, rabbits, and humans could be analyzed without prior extraction at dilutions which placed them clearly in the linear portion of the RIA standard curve.

The disposition of triprolidine in three male New Zealand White rabbits, following intravenous injection of 1 mg/kg of triprolidine hydrochloride, was determined by the present RIA procedure (Fig. 3). The plasma concentration–time data, as analyzed by the NONLIN computer program (16), fitted well to a two-compartment open model of drug disposition. The rapid disposition phase was characterized by a rate constant, α = 12.3 h^{-1} ($t_{1/2,\alpha}$ = 0.06 h), while the terminal elimination phase was described by the rate constant, β = 0.41 h^{-1} ($t_{1/2,\beta}$ = 1.68 h). Tissue distribution in the rabbit appeared to be extensive, as indicated by the relatively large volume of distribution (Vd_β = 4.66 L/kg). The $t_{1/2,\beta}$ value for triprolidine in the rabbit (1.68 h) is comparable to the $t_{1/2}$ in humans (10).

Table III—Species Comparison of Kinetic Parameters

Parameter	Rabbit[a]	Human[b]	Dog[a]	Rat[a,c]
α, h^{-1}	12.3	—	1.3	6.0
β, h^{-1}	0.41	0.31	0.45	0.79
$t_{1/2,\alpha}$, h	0.06	—	0.40	0.12
$t_{1/2,\beta}$, h	1.68	2.27	1.5	0.88
Vd_β, L/kg[c]	4.7	2.6	9.3	9.6
AUC, ng·h/mL	462.0	39	259	134

[a] Intravenous 1-mg/kg injections of triprolidine hydrochloride. [b] Total oral dose of 2.5 mg of triprolidine hydrochloride; Vd_β term is actually Vd_β/F. [c] Parameters derived from data in Ref. 10.

The disposition of triprolidine in the plasma of three healthy subjects (two males and one female) following ingestion of 2.5 mg of triprolidine hydrochloride in a proprietary tablet preparation was examined, using RIA for analysis of plasma drug concentrations. The mean plasma concentration–time data are plotted in Fig. 4. In these three subjects, peak triprolidine concentrations ranged from 3.1 to 9.4 ng/mL at 1–2 h after drug administration. Triprolidine could still be detected in the plasma by RIA 24 h after drug ingestion, but levels at that time were close to the sensitivity limit of the method. The concentration–time data gave a good fit to a one-compartment open model of drug disposition, with first-order absorption. The apparent elimination half-life of 2.3 h in these subjects was similar to previously reported values for triprolidine in humans (10). The value for Vd_β/F is large (2.6 L/kg), also implying extensive tissue distribution or drug metabolism, although knowledge of the value of F (fraction of dose bioavailable) is necessary before the true volume of distribution can be calculated.

Although triprolidine could not be determined in dog plasma by the direct RIA procedure, TLC analysis provided data on the disposition of triprolidine in the dog for comparison with other species. Plasma concentrations of triprolidine in two beagles following separate oral and intravenous administrations of 1-mg/kg doses are presented in Table II. Observed peak plasma levels following oral administration (4.8 and 6.6 ng/mL) were 12–26-fold lower than concentrations at the same time after intravenous drug administration. The trapezoidal rule (22) was used to determine the area under the plasma concentration–time curves (AUC), and the absolute bioavailability of the oral dose was expressed as the percentage ratio of AUC values following oral and intravenous drug administrations (23). The bioavailability of triprolidine in these dogs was very low (3.7 and 4.1%), suggesting extensive first-pass metabolism of the drug in the liver and/or gut after oral administration. However, the data available on triprolidine, both from the present study and in general, do not exclude the possibility that this drug is poorly absorbed by the dog after oral administration, which could also result in low oral bioavailability. The intravenous data fitted well to a two-compartment open model of drug disposition and the kinetic parameters emanating from this analysis are presented in Table III. The mean $t_{1/2,\beta}$ and Vd_β values of 1.5 h and 9.2 L/kg, respectively, are comparable with similarly derived parameters in the rabbit in this study and the rat (10) in a previous study (Table III).

In this paper we have described a new RIA procedure for triprolidine, which is sufficiently sensitive and specific for use in the analysis of the drug in human plasma samples up to 24 h after ingestion of therapeutic oral doses. The method has also been used to provide pharmacokinetic data for triprolidine in humans and rabbits for comparison with similar data in dogs and rats. This procedure is currently being used in studies of the pharmacokinetics of triprolidine in humans after oral administration of immediate- and sustained-release drug formulations.

Novel Approach to Zero-order Drug Delivery *Via* Immobilized Nonuniform Drug Distribution in Glassy Hydrogels

PING I. LEE

Received July 25, 1983, from the *Central Research, Ciba-Geigy Corporation, Ardsley, NY 10502.* Accepted for publication October 11, 1983. Present address: Menley & James Laboratories, Philadelphia, PA 19101.

Abstract □ A novel approach to zero-order drug delivery from glassy hydrogel matrices *via* an immobilized, sigmoidal, initial drug distribution has been developed. The method utilizes a controlled-extraction process on initially dry, drug-loaded hydrogels to generate an inflection-point-containing drug concentration profile followed by a vacuum freeze-drying step to rapidly remove the swelling solvent and immobilize *in situ* a nonuniform drug distribution. The drug release from such a system generally exhibits typical zero-order characteristics similar to that of a membrane-reservoir device. However, a saturated reservoir of active ingredient as in the membrane-reservoir device is not required because the constant release is achieved *via* an initially nonuniform concentration distribution instead of the constant activity in a reservoir. The applicability of the present concept and process has been demonstrated experimentally with the release of oxprenolol hydrochloride from hydrogel beads based on 2-hydroxyethyl methacrylate polymerized with a polymeric cross-linking agent.

Keyphrases □ Glassy hydrogels, oxprenolol hydrochloride—nonuniform drug distribution □ Oxprenolol hydrochloride—glassy hydrogels, nonuniform drug distribution □ Drug delivery systems—oxprenolol hydrochloride, glassy hydrogels

Diffusion-controlled polymeric delivery systems are finding increasing applications in the area of controlled release of pharmaceuticals (1–3). To achieve optimal therapeutic effects, especially for drugs with short physiological half-lives, it is often desirable to have a zero-order (or constant-rate) drug delivery (4). Unlike membrane-reservoir devices, monolithic systems where the drug is uniformly dissolved or dispersed in a polymer matrix generally do not exhibit zero-order release behavior. Instead, a release rate that continuously diminishes with time is observed (5, 6). This is a consequence of the increased diffusional distance and decreased area at the penetrating diffusion front. In addition to geometry factors (7), methods that approach zero-order release from monolithic matrices generally involve the introduction of either a constant rate of surface erosion much larger than the drug diffusion rate in the polymer matrix (8–10) or a constant rate of solvent front penetration (the so-called case II swelling) much smaller than the drug diffusion rate in the swollen region (11, 12). The applicability of these systems may be further limited by the need to maintain a constant surface area at the erosion or penetrating solvent front.

An important concept which has not been explored is the approach to zero-order drug release from a glassy polymer matrix having a specific nonuniform initial drug concentration distribution. Hydrogel polymers are unique for this application in that they are glassy in the dry state and capable of immobilizing any nonuniform drug distribution introduced prior to the dehydration step. In the presence of water, hydrogels can absorb a significant amount of water to form an elastic gel and, at the same time, release the dissolved drug by diffusion through the swollen region (13, 14).

This paper reports a method for immobilizing such a nonuniform drug concentration distribution in glassy hydrogel beads and the resulting zero-order drug release behavior. A

detailed kinetic study of such release systems will be published elsewhere[1].

EXPERIMENTAL SECTION

Spherical hydrogel beads containing purified 2-hydroxyethyl methacrylate[2] (70%) and a polymeric cross-linking agent (30%), which was derived from poly-*n*-butyleneoxide (mol. wt. 2000)[3] by end-capping with 3-isocyanatomethyl-3,5,5-trimethylcyclohexyl-isocyanate[4] followed by reaction with excess 2-hydroxyethyl methacrylate, were synthesized by free-radical suspension polymerization in a saturated salt solution using 0.1% *tert*-butyl peroxy-2-hexanoate[5] as the initiator (15). The fraction of beads with a mean dry diameter of 0.115 cm and a mean swollen diameter of 0.13 cm was used for the release study. These hydrogel beads exhibit a major glass transition temperature (T_g) of ~110°C (as determined by differential scanning calorimetry[6]), an equilibrium ethanol swelling of 49%, and an equilibrium water swelling of 25%.

Oxprenolol hydrochloride[7], a β-blocker with water solubility as high as 77% at room temperature, was used as the model drug. A drug loading of 34.4% was achieved by equilibrating the hydrogel beads in an excess amount (5:1 ratio) of a 50% oxprenolol hydrochloride solution prepared in ethanol–water (60:40). After filtration and a brief rinse, the swollen loaded beads were dried at 50°C in a vacuum oven. These dry, loaded beads were then divided into several portions and subjected to a controlled-extraction process in an excess volume of water under vigorous stirring at 23°C for 5, 15, 20, and 30 min, respectively. The extraction process was controlled so that the extraction time was shorter than the time required for the penetrating solvent fronts to meet at the center to ensure that there would always be an inner glassy core surrounded by a swollen, partially extracted region. Immediately after separation of the extracting solvent, the controlled-extracted beads were freeze-dried under reduced pressure (0.025 mm Hg) for 15 h to rapidly remove the swelling solvent and to immobilize the drug, which was distributed in a nonuniform sigmoidal manner, decreasing from the core to the surface.

The oxprenolol hydrochloride release (under perfect sink diffusion conditions at 37.5°C) was followed continuously on a spectrophotometer[8] at 272 nm using a flow-through cell. The storage stability tests were conducted in capped vials under room conditions.

RESULTS AND DISCUSSION

The release characteristics of matrix devices containing uniformly dissolved or dispersed drug are well known (10, 16–18). However, the effect of nonuniform initial drug distribution on the release behavior has not been reported in the literature. Figure 1 illustrates the characteristics of drug release from spherical matrices as a function of the initial drug distribution[1]. Based on solutions to the diffusion equation, these theoretical curves show that both the uniform and parabolic initial concentration distributions result in an initially high rate of release followed by a rapid decline; the latter distribution exhibits a reduced initial rate of release compared with the former. In contrast, a sigmoidal initial drug distribution is capable of introducing a characteristic inflection point and, therefore, considerable linearity into the cumulative release curve. The duration of the constant-rate release region in such systems generally depends on the slope at the inflection point in the concentration distribution. Although Fig. 1 describes the drug release from spherical matrices, similar results are expected for planar and cylindrical geometries.

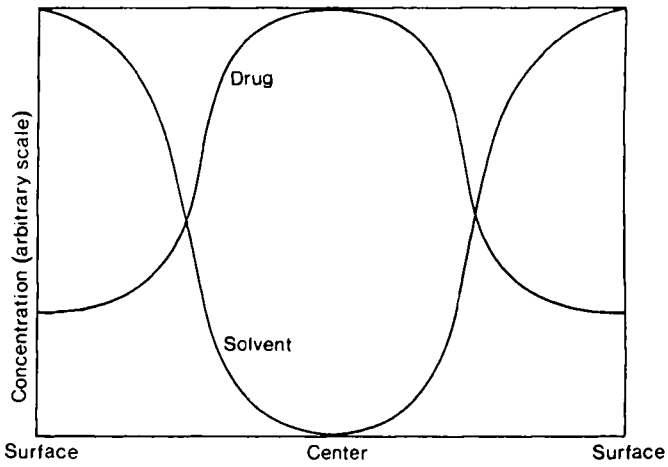

Figure 3—*Idealized solvent and drug distributions during solvent penetration in a drug-loaded glassy hydrogel matrix.*

The parabolic type of concentration distribution described above is characteristic of Fickian diffusion in rubbery polymers (19, 20), whereas the sigmoidal distribution is characteristic of glassy polymers partially penetrated by a swelling solvent undergoing non-Fickian diffusion. As a swelling solvent (in this case, water) penetrates a glassy hydrogel matrix having uniform drug loading, a clear discernible boundary separating an outer, rubbery, swollen region from an unpenetrated glassy core is usually observed (Fig. 2) (14). Such penetration and swelling generally do not follow Fickian diffusion. The existence of some molecular relaxation process in addition to diffusion is believed to be responsible for the observed non-Fickian behavior (12, 21). As a result, an inflection point is built into both the concentration profile of the penetrating solvent and the corresponding drug distribution, as shown in Fig. 3. This is similar to the solvent profiles reported for the partial penetration of organic swelling solvent in glassy polymers (22–24). The physical situation depicted in Fig. 3 is believed to reflect the solvent and drug distributions generated by the controlled-extraction process described in the *Experimental Section*. The subsequent vacuum freeze-drying step is intended to reduce the polymer segmental mobility by lowering the temperature and, at the same time, rapidly remove the swelling solvent to immobilize the drug *in situ* in a sigmoidal distribution in the hydrogel matrix.

As shown in Figs. 4A and B, scanning electron microscopy[9] X-ray microprobe chlorine scans for oxprenolol hydrochloride across the cross sections of the hydrogel beads confirm that the combination of controlled-extraction and freeze-drying steps has immobilized the drug *in situ* with a sigmoidal concentration profile in the 20-min extracted sample compared with the uniform concentration distribution in the unextracted control. The corresponding *in vitro* release of oxprenolol hydrochloride from the controlled-extracted beads is compared with that of the unextracted control in Fig. 5. It is evident that an inflection point and a zero-order release region of up to 60% of the total are introduced by the present process. With the increase in controlled-extraction time, the constant-rate release region extends, and the release half-life more than doubles. The constant-release region also shows a progressively decreasing slope with increased controlled-extraction time. In addition, release time-lags similar to that of membrane-reservoir devices are developed. Inevitably, a certain amount of drug will be lost during the controlled-extraction process. However, as shown in Fig. 6, where the oxprenolol hydrochloride loading is plotted as a function of controlled-extraction time in water, only ~10% of the drug is removed with an extraction time of 30 min.

In the absence of moisture, the sigmoidal drug concentration distribution generated by the present process can be preserved indefinitely in the glassy hydrogel matrix. The release of the entrapped drug should not occur until the hydrogel matrix is swollen at the time of usage. This is illustrated by a comparison of oxprenolol hydrochloride release rates from both the unextracted control and controlled-extracted beads at 0 and 59 d of storage as shown in

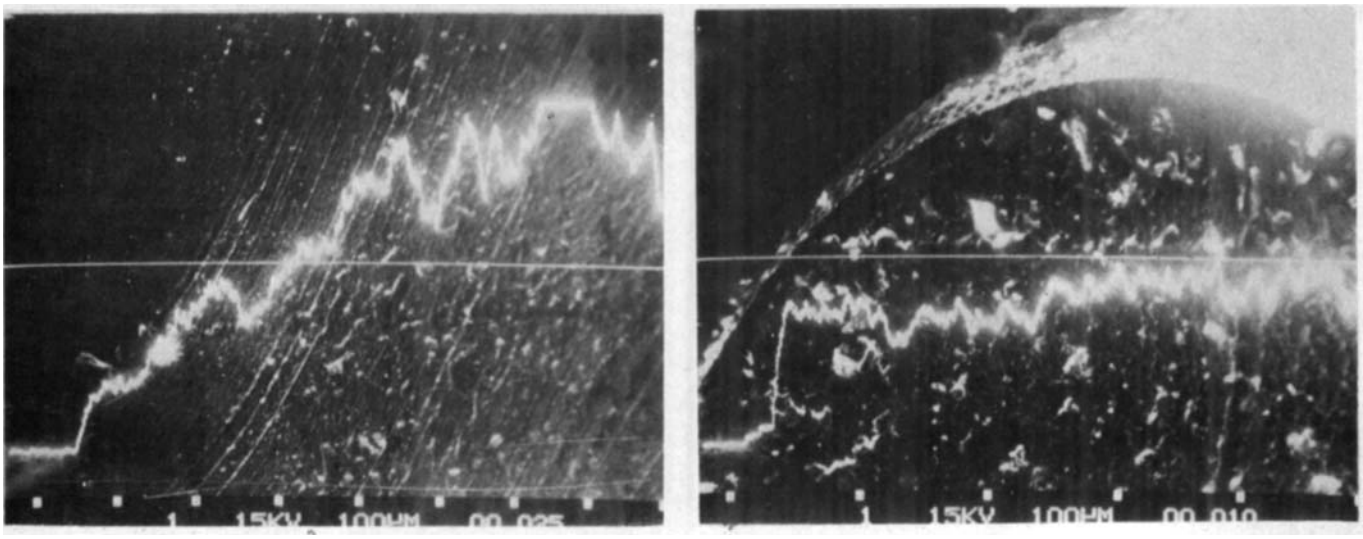

Figure 4—*Scanning electron microscope X-ray microprobe chlorine scans for oxprenolol hydrochloride on the cross section of hydrogel beads. Key: (A) controlled-extracted in water for 20 min; (B) unextracted control.*

Figs. 7A and B. In addition to the specific feature of prolonged zero-order release from controlled-extracted samples compared with the rapid decay of release rate in the unextracted control, there is very little change in the release rates after nearly 2 months of storage.

In summary, a novel appraoch to zero-order drug delivery from glassy hydrogel beads *via* an immobilized sigmoidal drug distribution is described. The combination of controlled-extraction and freeze-drying process is critical in the *in situ* immobilization of such a nonuniform concentration distribution.

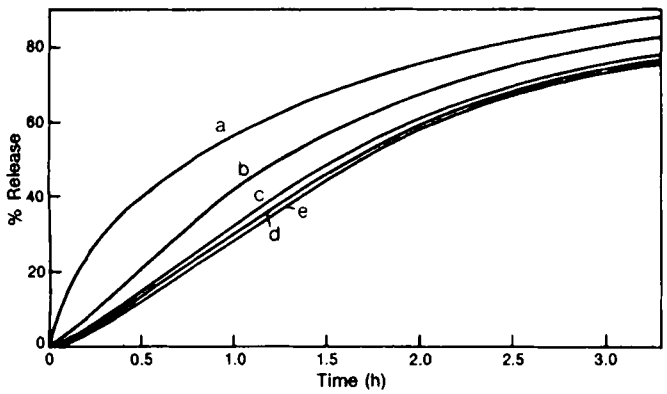

Figure 5—*Effect of controlled-extraction time in water on the* in vitro *release of oxprenolol hydrochloride. Key: (a) control; (b) 5 min; (c) 15 min; (d) 20 min; (e) 30 min.*

The evidence indicates that when the extraction process is carried out on drug-loaded beads in the fully swollen state instead of the dry glassy state, or when the drying is done at an elevated temperature instead of freeze-drying, no inflection point or constant-release region will be observed in the cumulative drug release profiles. Apparently, a parabolic type of drug concentration distribution, characteristic of Fickian diffusion in the rubbery state, does not lead to a zero-order release (Fig. 1). Other parameters such as the hydrogel composition and the extracting solvent also play important roles in determining the resulting release characteristics.

The concept and process described here have several distinct advantages

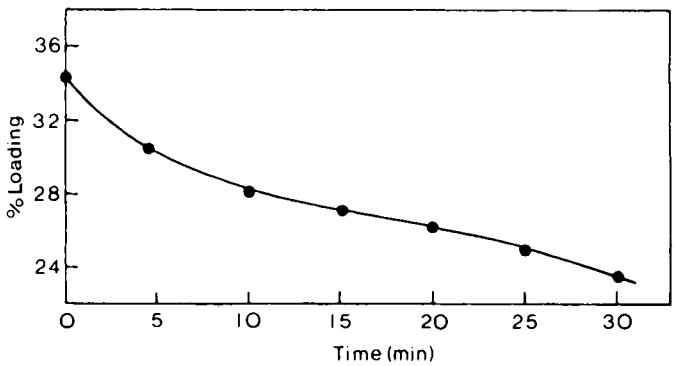

Figure 6—*Oxprenolol hydrochloride loading as a function of controlled-extraction time in water.*

Kinetics of Drug Action in Disease States III: Effect of Pregnancy on the Relationship Between Phenytoin Concentration and Antiseizure Activity in Rats

RUBY C. CHOU and GERHARD LEVY[x]

Received July 8, 1983, from the *Department of Pharmaceutics, School of Pharmacy, State University of New York at Buffalo, Amherst, NY 14260.* Accepted for publication November 16, 1983.

Abstract □ The purposes of this investigation were to determine the effect of pregnancy on the susceptibility of female rats to experimentally induced seizures and on the relationship between serum phenytoin concentration and antiseizure activity. Pregnant rats (on the 18th day of gestation) were more susceptible than nonpregnant female rats to seizures produced by maximal electroshock or by a body-weight-based dose of pentylenetetrazol. There was no apparent difference between pregnant (20th day of gestation) and nonpregnant rats in the relationship between seizure protection (percent of animals protected) and the serum concentration of total (free plus protein-bound) phenytoin. The relationship between concentration and effect was essentially the same 20 min after an injection of phenytoin and 2 h after the start of a constant-rate infusion preceded by a loading dose of the drug. Since the protein binding of phenytoin is appreciably decreased in late pregnancy, the serum concentration of free phenytoin required for seizure protection tended to be higher in pregnant than in nonpregnant rats. This may be due to the increased susceptibility of pregnant rats to seizure stimuli.

Keyphrases □ Phenytoin—antiseizure activity, effect of pregnancy, maximal electroshock seizure test □ Pregnancy—effect on antiseizure activity, phenytoin, maximal electroshock seizure test

Treatment of epileptic women with phenytoin often requires adjustment of drug dosage during pregnancy for adequate seizure control (1, 2). This appears to be due in part to pregnancy-associated alterations in the pharmacokinetics (3, 4) and possibly in the bioavailability (5) of the drug, and perhaps also to decreased compliance (6). However, the physiological changes associated with pregnancy, including water retention, electrolyte concentration and pH shifts, and altered hormonal concentrations, may provoke seizures in epileptic patients (7–9). It is possible, therefore, that the relationship between phenytoin concentration and antiseizure activity is altered during pregnancy. Such an effect would be in addition to the well-established change in the plasma protein binding of phenytoin in pregnancy (10), which makes it desirable that phenytoin plasma concentration monitoring during pregnancy be based on the concentrations of free rather than total drug.

The purpose of this investigation was to determine the effect of pregnancy on the relationship between serum phenytoin concentration and antiseizure activity in an animal model of experimentally induced seizures. The studies were designed to compare the response of nonmedicated pregnant and nonpregnant female rats to two types of seizure stimuli (electrical and chemical), to relate the antiseizure effect of phenytoin to the serum concentration of both total and free drug, and to compare the concentration–effect relationship after intravenous injection of phenytoin with the corresponding relationship at steady state during intravenous infusion of the drug. Information was also obtained concerning the effect of pregnancy on the distribution of phenytoin between plasma, brain, and cerebrospinal fluid (CSF).

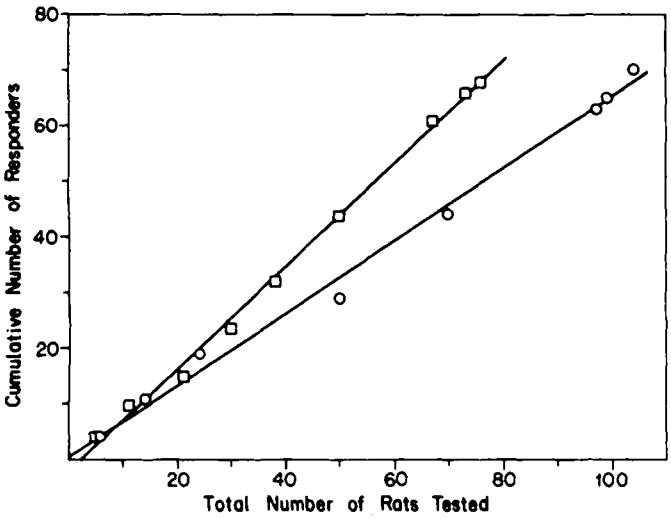

Figure 1—*Seizure response of pregnant (18th day of gestation) (□) and nonpregnant female (○) rats to a maximum electroshock (MES) stimulus. The cumulative number of animals in each group that responded to MES by tonic hind limb extension is plotted against the cumulative number of animals subjected to MES in the course of this investigation. The percentage of pregnant rats responding was 90%; 67% of the nonpregnant female rats responded. The slopes of the regression lines are significantly different,* $p < 0.001$.

EXPERIMENTAL SECTION

Methods—Inbred female Lewis rats, weighing 175–200 g on receipt, were used in this investigation. Some were mated (3) while others were designated as nonpregnant controls. On the 18th day of gestation, the pregnant animals and their concurrent controls were screened by subjecting them to maximal electroshock (MES), using an apparatus that was adjusted to deliver ~ 150 mA for 0.35 s *via* corneal electrodes (11). Only rats that responded to the stimulus by exhibiting the tonic hind limb extensor component of MES seizure were used in the subsequent experiment. The animals had access to food and water at all times except during the hour of testing to avoid possible alterations in their susceptibility to MES due to starvation or dehydration (11).

One day after the MES screening, the rats had a cannula implanted in the right jugular vein under light ether anesthesia (12). This procedure is known to not alter their seizure pattern (13). On the following day, *i.e.*, on the 20th day of gestation of the pregnant animals, the rats received an intravenous injection of phenytoin, 2–12.5 mg/kg, through the cannula (which was then flushed with saline solution). The drug was dissolved in 10% ethanol–normal saline in various concentrations and 1 mL/kg of the solution was injected over 1 min. The solutions were coded so that the experimenter did not know the

Table I—Effect of Pregnancy on the Tonic-Seizure Response of Rats to Pentylenetetrazol Injection [a]

Type of Rats	Body Weight, g	Number Responding/ Total Number
Nonpregnant female	201 ± 8	5/14
Pregnant 18th day of gestation		
Dosed per actual body weight	263 ± 16	8/9
Dosed per average weight of nonpregnant controls	261 ± 11	3/8

[a] Dose of pentylenetetrazol was 26 mg/kg iv.

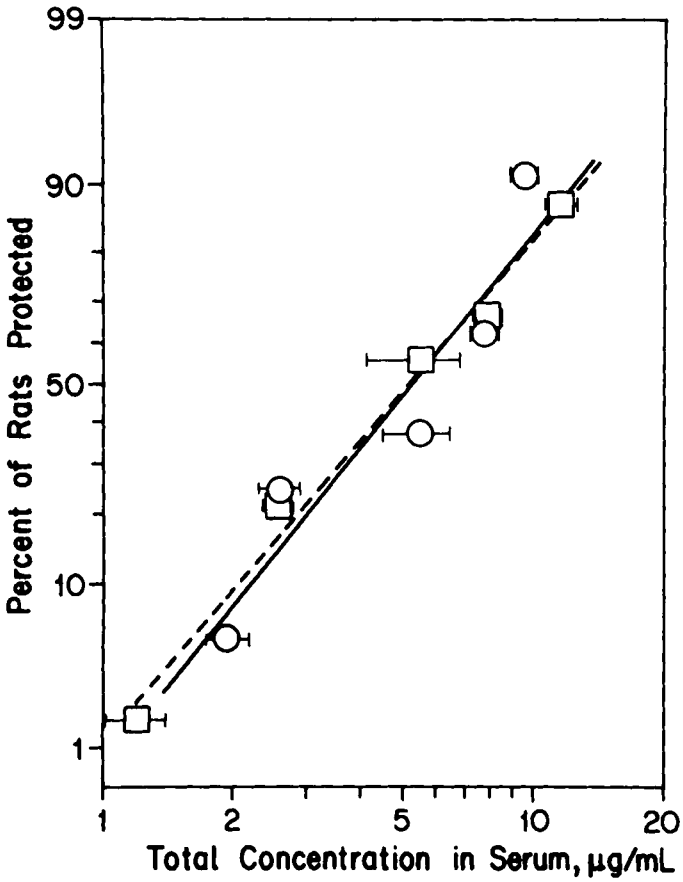

Figure 2—*Relationship between the percent of rats protected from MES-induced tonic seizures (both forelimb and hind limb extension) and serum concentration of phenytoin in pregnant rats at the 20th day of gestation (□) and nonpregnant female (○) rats. The determinations were made 20 min after a rapid intravenous injection of phenytoin, 2–12.5 mg/kg. The data points are based on results from 7–9 rats per point. The horizontal bars represent ± one* SD *of the concentration. The lowest square and the lowest and highest circles represent corrected values for 0 and 100% protection according to Litchfield and Wilcoxon (17). The regression lines and correlation coefficients ($r = 0.993$, $p < 0.001$ for the pregnant rats and $r = 0.940$, $p < 0.02$ for the nonpregnant rats) are based on the probit values for protection and on logarithmic values for serum concentration.*

dose administered. Twenty minutes after the injection, the rats were subjected to MES and the response was recorded. Complete protection was defined as the prevention of tonic seizure, *i.e.*, absence of both forelimb and hind limb extension (14, 15). A blood sample was then obtained through the cannula, and the serum was separated and assayed for phenytoin by HPLC (16).

In another part of the investigation, pregnant (20th day of gestation) and nonpregnant female rats received an intravenous injection of phenytoin solution, 0.340 mL/min for 1 min, followed immediately by a constant-rate infusion of 0.0136 mL/min for 2 h. The phenytoin concentrations of the solutions ranged from 0.874 to 2.46 mg/mL. At 2 h, the rats were subjected to MES and blood sampling.

Other pregnant (18th day of gestation) and nonpregnant female rats, with a jugular vein cannula implanted 1 d earlier, received a rapid injection of pentylenetetrazol, 26 mg/kg, as a 52-mg/mL aqueous solution. The syringe and cannula were then flushed immediately by withdrawal and reinjection of blood. Some of the pregnant rats received the dose based on their actual body weight while others received a dose based on the average body weight of the nonpregnant controls. Tonic seizures, when present, occurred within a few seconds after the injection and were recorded. The pharmacological activity data were analyzed according to Litchfield and Wilcoxon (17).

Also reported here is a summary of phenytoin distribution data derived from various experiments performed over ~1 year. Briefly, pregnant rats at the 20th day of gestation and nonpregnant female rats received a 14.7-mg/kg injection of phenytoin followed immediately by an infusion of 195 μg/min/kg for 2 h, through a jugular vein cannula. At the end of the infusion, samples of CSF and blood (using EDTA as the anticoagulant for separation of plasma) were obtained and the brain was removed. These fluids and one hemisphere of the

Table II—Effect of Pregnancy on the Median Effective Serum Concentrations of Total and Free Phenytoin for Protection Against Maximal Electroshock-Induced Tonic Seizures

Median Conc., μg/mL	Pregnant Female, Day 20 of Gestation	Nonpregnant Female
Total	5.20 3.58–7.55[a]	5.20 3.55–7.62[a]
Free[b]	1.03 0.710–1.49[a]	0.680 0.464–0.997[a]

[a] 95% Confidence limit. [b] Based on free fraction values obtained in studies on other rats (Table III).

brain were assayed for phenytoin by HPLC (16). The average CSF/plasma concentration ratios of phenytoin in pregnant and nonpregnant rats obtained in these studies were used to estimate the plasma concentrations of free phenytoin in the experiment in which the relationship between total phenytoin plasma concentration and antiseizure activity was determined. This had to be done because of the great difficulty in obtaining CSF from rats after MES.

RESULTS

The results of the screening study are summarized in Fig. 1. The data are plotted cumulatively and reflect the results obtained on successive groups of rats that were screened over approximately 6 months. Sixty-seven percent of the nonpregnant female rats and 90% of the pregnant rats exhibited tonic seizures (with hind limb extension) in response to MES, a significant difference in response rate ($p < 0.001$).

To determine if the apparent difference in the susceptibility of pregnant and nonpregnant rats to MES is limited to the electric stimulus only, other groups of nonmedicated animals were subjected to a chemical stimulus, *i.e.*, pentylenetetrazol injection. The seizure response rate of the pregnant rats was significantly higher than that of the nonpregnant controls [$p < 0.02$ when tested by a statistic comparing two success probabilities (18)] on injection

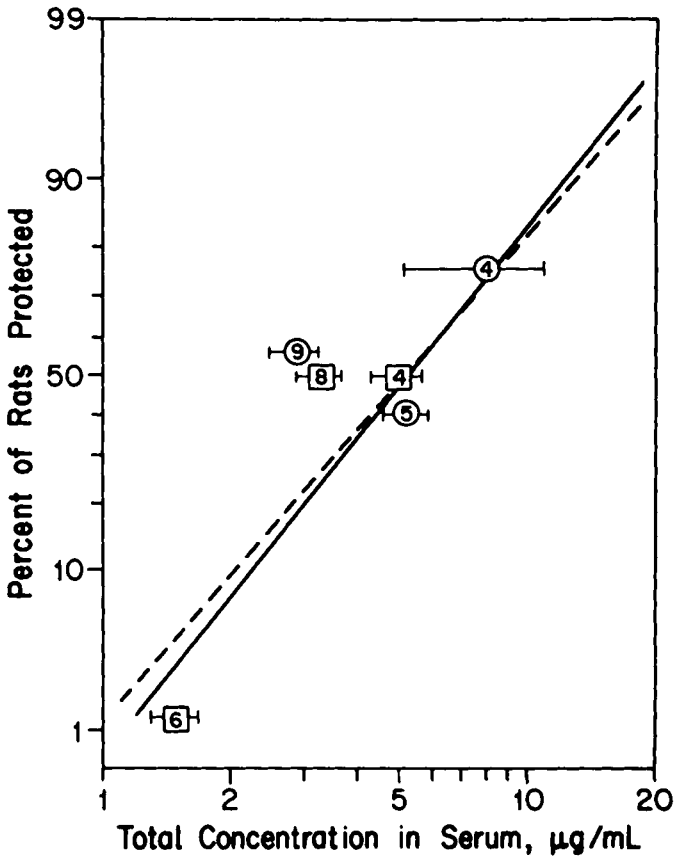

Figure 3—*A plot similar to Fig. 2, except that the results shown here were obtained after a 2-h intravenous infusion of phenytoin. The number of rats per groups are indicated by the number in the symbols. The regression lines are those obtained in the experiment shown in Fig. 2. The lowest square is a corrected value.*

Table III—Effect of Pregnancy on the Distribution of Phenytoin Between Plasma, Cerebrospinal Fluid, and Brain in Rats [a]

Variable	Pregnant Female, Day 20 of Gestation		Nonpregnant Female
Number of animals	22		19
Phenytoin conc., μg/mL or g			
Plasma	14.5 ± 2.4	N.S.	14.0 ± 3.7
CSF	2.78 ± 0.47	$p < 0.001$	1.78 ± 0.42
Brain	26.7 ± 7.3	$p < 0.005$	19.8 ± 5.0
Concentration ratio [b]			
CSF/Plasma	0.193 ± 0.027	$p < 0.001$	0.130 ± 0.019
Brain/Plasma	1.83 ± 0.36	$p < 0.001$	1.43 ± 0.19
Brain/CSF	9.51 ± 1.58	$p < 0.001$	11.1 ± 1.0

[a] Results (mean ± *SD*) obtained after intravenous injection of phenytoin, 14.7 mg/kg, followed by an intravenous infusion of 195 μg/min/kg for 2 h. [b] None of the ratios are significantly correlated with the plasma phenytoin concentration.

of both groups with the same relative (mg/kg) dose (Table I). On the other hand, pregnant rats injected with the convulsant in a dose based on the average weight of the nonpregnant controls exhibited essentially the same seizure response rate as the control animals.

The results of the experiments to determine the relationship between serum concentration of total phenytoin and seizure protection are shown in Fig. 2. The determinations were made 20 min after the intravenous injection of phenytoin. Essentially identical results were obtained with pregnant and nonpregnant rats (Table II).

The results of a more-limited series of experiments, performed under steady-state conditions (constant rate intravenous infusion of phenytoin), are summarized in Fig. 3. For both pregnant and nonpregnant rats the average concentration–response data at two of three phenytoin concentrations were essentially identical to those obtained when phenytoin was administered by rapid injection.

The steady-state distribution of phenytoin between brain and CSF was significantly altered during pregnancy (Table III). The decreased brain/CSF concentration ratio and the increased CSF/plasma concentration ratio of phenytoin in the pregnant rats are consistent with decreased binding of the drug in the brain and plasma, respectively.

The steady-state concentration ratio of phenytoin, CSF/plasma, is a measure of the free fraction of the drug in plasma under *in vivo* conditions (16). The average free fraction value of phenytoin, which is independent of concentration over a wide range (19), was substantially higher in pregnant than in nonpregnant rats (Table III). Using these free fraction values, the experimental concentration data summarized in Fig. 2 were converted to free phenytoin concentrations to determine the relationship between serum concentration of free phenytoin and seizure protection (Fig. 4). The thus estimated median effective serum concentration of free phenytoin was 1.03 μg/mL in the pregnant rats and only 0.680 μg/mL in the nonpregnant animals, while the median effective serum concentration of total (free plus protein-bound) drug was identical in both groups (Table II).

DISCUSSION

Pregnancy is obviously not a disease, but, like many diseases, it is associated with profound changes in physiological status. Thus, an investigation of the effect of pregnancy on the relationship between drug concentration and pharmacological activity is appropriate for inclusion in this series of reports concerning the kinetics of drug action in disease states.

Some women experience epileptic fits only during pregnancy. This condition, known as true gestational epilepsy (7), reflects an increased susceptibility of at least some individuals to the altered physiological conditions associated with pregnancy. Consistent with these observations, there is an increased incidence of electroencephalograms classified as slow or high-voltage fast in pregnant women, reflecting a type of cortical activity that is known to occur more frequently in conditions in which the incidence of convulsions is higher than in the general population (20).

In the present study, a greater percentage of pregnant than nonpregnant rats responded with seizures to an electroshock stimulus. To determine if this difference also occurs in rats after exposure to a chemical stimulus, other groups of animals were given a pentylenetetrazol injection. The design of such a study raises the problem of proper normalization of dosage (3, 21): should the pregnant animals receive the same absolute (mg) or relative (mg/kg) dose of the convulsant drug? Pharmacokinetic evidence suggests that pentylenetetrazol distributes in body water (22). However, animals have seizures within seconds after intravenous injection, *i.e.*, possibly before the distribution of pentylenetetrazol from blood to the total body water space is complete. Significantly, the *relative* volumes of both body water and blood remain essentially constant during pregnancy in rats (23, 24). These considerations suggest that the dose of pentylenetetrazol for pregnant rats should be based on their actual body weight. Under these conditions, the relative number of pregnant rats with tonic seizures after pentylenetetrazol injection was significantly higher than that of nonpregnant controls. No such difference was found when pregnant and nonpregnant rats received the same absolute dose of the convulsant. Thus, while the results of this experiment appear to be consistent with those of the electroshock study, *i.e.*, increased susceptibility to seizures during pregnancy, definitive studies with pentylenetetrazol require determination of effective concentrations of the convulsant in the brain, CSF, or plasma. Such studies are now in progress.

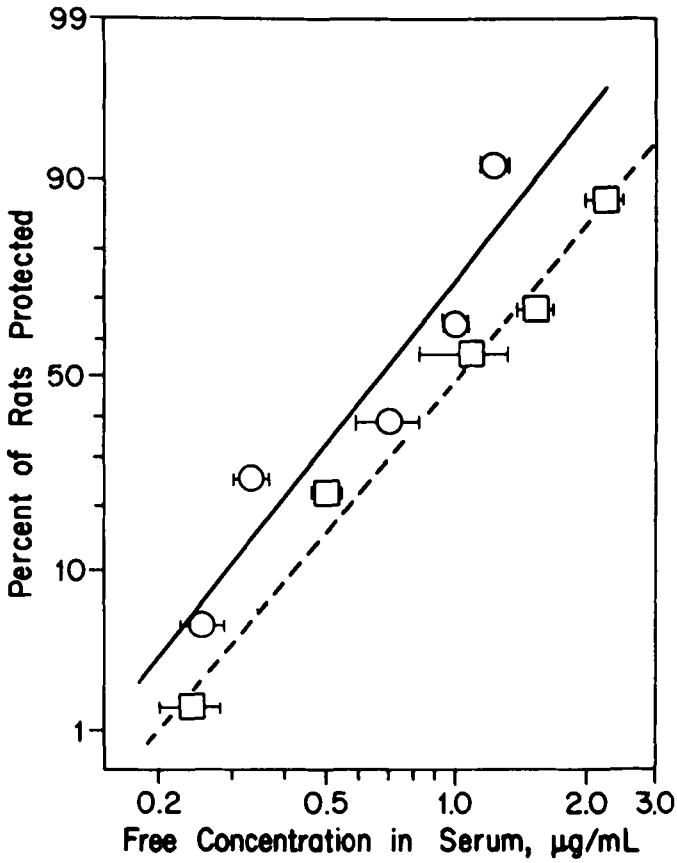

Figure 4—*A plot of the data in Fig. 2, except that serum phenytoin concentrations are corrected for protein binding (determined in other rats) to show the relationship between protection from MES-induced tonic seizures and the estimated serum concentration of free (unbound) phenytoin.*

The entry of phenytoin into the central nervous system (CNS) is rapid and may be blood-flow limited (8, 13, 25–27). Once in the CNS, the drug acts without any apparent delay (13). The major metabolites of phenytoin are pharmacologically inactive (28, 29). Under postdistribution conditions, phenytoin concentrations in plasma ultrafiltrate, brain ultrafiltrate, and CSF are essentially equal (25), and the anticonvulsant effect of the drug is, therefore better correlated with the plasma concentrations of free rather than total (free plus bound) phenytoin (30).

Pregnancy had no apparent effect on the relationship between the serum concentration of total phenytoin and antiseizure activity in rats subjected to maximal electroshock (Fig. 1). However, since the plasma or serum protein binding of phenytoin is significantly decreased during pregnancy in rats (3, 19), pregnant animals apparently require higher serum concentrations of free phenytoin than do nonpregnant controls for equivalent protection against MES-induced seizures.

The original design of this study included determination of phenytoin protein binding in the serum of every phenytoin-treated animal tested for protection against MES seizure. The protein binding determinations were made by equilibrium dialysis before it was found that the results thus obtained were of questionable value due to extensive *in vitro* lipolysis in plasma from pregnant rats (31, 32). Since it is difficult to obtain CSF from rats after application of MES, *in vivo* phenytoin free fraction values (*i.e.*, the ratio of phenytoin concentrations in CSF and plasma) were determined in separate groups of animals from the same source. It should be noted that the CSF-

plasma concentration ratios of phenytoin were obtained in a relatively large number of pregnant and nonpregnant rats (Table III), that the interindividual varition of these values is quite small, and that the free fraction value of phenytoin is independent of concentration over a wide range (19). As is evident in Fig. 4 and Table II, the serum concentrations of free phenytoin required for seizure protection tended to be higher in pregnant than in nonpregnant rats. While a statistical analysis of these hybrid data is not considered appropriate, we state for the record that the median effective concentrations of free drug in the serum of pregnant and nonpregnant animals were not statistically significantly different.

The phenytoin concentration–antiseizure effect relationship was also determined, in a more limited study, in rats that were infused with phenytoin to steady state. The data thus obtained are generally quite similar to those obtained 20 min after a rapid injection of phenytoin (Fig. 4), consistent with the rapid entry of phenytoin into the CNS and with the lack of pharmacological activity of phenytoin metabolites.

As already shown by other investigators (8, 25, 33, 34), it was found in this investigation that the total concentrations of phenytoin are higher in the brain than in the plasma (Table III). This appears to be due to extensive protein binding of the drug in the brain rather than to partitioning into brain lipids (35). The results of the present investigation are also consistent with previous findings of an increased brain–blood phenytoin concentration ratio during pregnancy (34). The reason for this change in drug distribution becomes apparent on examining the concentration ratios relative to CSF determined in this investigation. Since the concentration of proteins in normal CSF is very low, phenytoin in CSF exists almost totally in the unbound form. The increased CSF–plasma phenytoin concentration ratio during pregnancy reflects the decreased plasma protein binding of the drug. By the same reasoning, the decreased brain–CSF phenytoin concentration ratio during pregnancy indicates decreased protein binding of phenytoin in the brain. It appears that the decreased plasma protein binding of the drug is due to lower albumin concentrations and the presence of circulating endogenous binding inhibitors during pregnancy (19, 32); endogenous inhibitors may be responsible also for the decreased binding of phenytoin in the brain.

In an earlier study on Sprague–Dawley rats treated chronically with phenytoin, it was found that pregnant animals had increased serum concentrations of total phenytoin and exhibited increased protection against MES-induced convulsions (36). The present investigation has shown that the relationship between *total* phenytoin serum concentration and seizure protection is essentially the same in pregnant (20th day of gestation) and nonpregnant inbred Lewis rats. Since the protein binding of phenytoin in plasma or serum is appreciably decreased during pregnancy, this suggests that pregnant rats require higher serum concentrations of free phenytoin (the pharmacologically active form of the drug) than do nonpregnant animals for the same degree of seizure protection. This apparent difference may be related to the observed increased susceptibility of unmedicated rats to an experimental seizure stimulus during late pregnancy.

Drug Permeation Through Human Skin II: Permeability of Ionizable Compounds

JAMES SWARBRICK *x, GEOFFREY LEE *, JEFFREY BROM *, and NIGEL P. GENSMANTEL ‡

Received March 2, 1983, from the *School of Pharmacy, University of North Carolina, Chapel Hill, NC 27514 and ‡Fisons plc, Pharmaceutical Division, Loughborough, LE11 OQY England. Accepted for publication October 13, 1983.

Abstract □ The aim of this study was to establish whether ionized as well as un-ionized forms of certain 4-oxo-4*H*-1-benzopyran-2-carboxylic acids (chromone-2-carboxylic acids) with pK_a values <2 permeated through excised human skin and, if so, to determine the permeability coefficients of the permeating species. The permeation properties of four carboxylic acids were studied as a function of concentration over the pH range 5–7 at 37°C with plexiglass diffusion cells. Plots of J/C^{A^-} (the total flux due to un-ionized and ionized species obtained under steady-state conditions per unit concentration of ionized drug in the donor compartment) against $C^{H_3O^+}$ resulted in straight-line relationships. The intercepts of these plots were shown to equal P^{A^-}, whereas the slopes multiplied by the K_a values of the compounds equalled P^{HA}, the permeability coefficients of the ionized and un-ionized species, respectively. With all four compounds, both species were found to permeate skin, although the permeability coefficients of the un-ionized species were ~10^4 greater than those for the ionized species. It was demonstrated that the relative contributions of the ionized and un-ionized species to the total flux, as well as the total flux, vary significantly, depending on the pH of the drug solution in the donor cell. This may provide a means of controlling the flux of these and similar compounds through human skin.

Keyphrases □ Permeation—permeability of ionizable compounds through human skin, 4-oxo-4*H*-1-benzopyran-2-carboxylic acids □ 4-Oxo-4*H*-1-benzopyran-2-carboxylic acids—ionizable compounds, permeability through human skin □ Absorption—percutaneous, permeability of ionizable compounds through human skin

Many compounds evaluated for their ability to undergo percutaneous absorption following application to the skin are weak to moderately strong electrolytes. Depending on the pK_a of the compound and the pH of the vehicle, such compounds exist as an equilibrium mixture of ionized and un-ionized species in the immediate vicinity of the skin. To control properly the rate at which such electrolytes permeate human skin, it is necessary to determine the permeability coefficients of both forms of the drug. However, much of the theoretical background to percutaneous absorption has been developed through studies of nonelectrolytic permeating species (1, 2), and there is little information available regarding the effect of pH and pK_a on the permeation of ionizable drugs through skin (3, 4).

According to the simple pH-partition hypothesis, only the un-ionized forms of drugs are able to pass through lipoidal membranes in significant amounts (5). If correct, then membrane permeability should be related to the amount of un-ionized drug present, as well as being strongly pH dependent. However, in studies on isolated intestinal membranes (6), it has been indicated that ionized as well as un-ionized sulfonamides can pass through such a barrier. By using rat gastrointestinal segments *in vivo*, the rate constants for absorption of the ionized forms of sulfaethidole and barbital were found to be only three to five times less than those for the un-ionized material (7). With excised human skin, the permeabilities of the ionized forms of ephedrine and scopolamine were calculated to be ~1/20th of those for their un-ionized forms (3). The permeation of ionized drug molecules through skin thus is possible and cannot be assumed to be negligible, especially at pH values at which large numbers of ionized molecules are present. Such conditions would exist with compounds with low pK_a values present on the surface of normal skin.

Human skin is composed of three distinct layers—the stratum corneum, the epidermis, and the underlying dermis. The passage of molecules across the skin and into the capillaries present in the dermis occurs by passive diffusion. The resistance to diffusion is high in the stratum corneum; in contrast, the epidermis and dermis are relatively permeable (8). The steady-state flux (J) (in mol·cm^{-2}·h^{-1}) is given by (2):

$$J = P \cdot C = \frac{C \cdot K^{SC/V} D^{SC}}{\delta} \qquad \text{(Eq. 1)}$$

where P is the permeability coefficient, and C is the concentration of the permeating species in the vehicle. The terms $K^{SC/V}$ and D^{SC} refer, respectively, to the stratum corneum–vehicle partition coefficient and diffusion coefficient of the permeating species within the stratum corneum, which has a thickness of δ.

Assuming that both ionized (A^-) and unionized (HA) species contribute to the total steady-state flux of a permeating electrolyte (here considered to be a monoprotic acid), then:

$$J = J^{HA} + J^{A^-} = (P^{HA} \cdot C^{HA}) + (P^{A^-} \cdot C^{A^-}) \qquad \text{(Eq. 2)}$$

Since the relative concentrations of ionized and un-ionized species for such an acid are expressed as:

$$K_a = \frac{C^{H_3O^+} \cdot C^{A^-}}{C^{HA}} \qquad \text{(Eq. 3)}$$

then Eqs. 2 and 3 can be combined to give:

$$\frac{J}{C^{A^-}} = \left(\frac{P^{HA}}{K_a}\right) C^{H_3O^+} + P^{A^-} \qquad \text{(Eq. 4)}$$

Having determined the total steady-state flux as a function of chromone acid concentration and pH, a plot of J/C^{A^-} *versus* $C^{H_3O^+}$ should be a straight line with a slope of P^{HA}/K_a and an intercept of P^{A^-}. Equation 4 therefore allows estimation of the permeability coefficients of both un-ionized and ionized species. If the latter is zero, then the intercept will also be zero. Such an approach does not appear to have been used before in the determination of percutaneous absorption.

In the present study, the permeation properties of four related 4-oxo-4*H*-1-benzopyran-2-carboxylic acids (chromone-2-carboxylic acids) were investigated over a range of pH

values and concentrations. Equation 4 was then used to determine the permeability coefficients of the un-ionized and ionized species and to evaluate the effect of pH on the total steady-state flux observed and the relative contribution to this flux by the two species.

EXPERIMENTAL SECTION

Skin Samples—As previously reported (9), samples of whole skin were removed from the inner thighs of cadavers within 48 h postmortem. The stratum corneum plus attached epidermis (SCE) was removed from the dermis as an intact sheet of tissue. These SCE samples were dried overnight in a desiccator at 25% relative humidity and then stored at 1 ± 0.5°C. Samples were rehydrated before use in the permeation studies. Because of the large number of studies conducted (>100), it was necessary to use skin samples from at least 10 different cadavers during the total series of experiments.

Materials—Buffer capsules[1] were used to prepare buffers at pH 5, 6, and 7. The pH 7.4 buffer and the solvents used in the HPLC assay of the chromone-2-carboxylic acids have been reported previously (9). A triglyceride of fractionated coconut oil fatty acids[2] (principally caprylic and capric), was used as received.

Permeation Determinations—Plexiglass diffusion cells were used to measure the permeation of the chromone-2-carboxylic acids across samples of SCE at 37 ± 0.5°C. Their design has been described previously (9). Solutions of each chromone acid were prepared in aqueous buffer at pH 5, 6, and 7. At least three different concentrations of chromone acid were used to cover the range of solubilities at a particular pH up to saturation. These solutions were placed in the donor compartments of the cells, whereas pH 7.4 buffer was placed in the stirred receptor compartments. Samples of known volume ranging from 25 to 100 μL were removed from the receptor compartments at known time intervals of ~2 h and immediately replaced with an equal volume of pH 7.4 buffer. The diluting effect of this replacement was taken into account when the total amount of chromone acid that had permeated the SCE at any one time was calculated. The removed samples were analyzed by HPLC (see below), and the permeation study was continued until it became clear that steady-state conditions were achieved (generally, 48–60 h). Values of the steady-state total flux of carboxylic acid were calculated and expressed as moles per square centimeter of skin per hour.

Analysis—Samples were analyzed by HPLC[3] immediately after they were removed from the receptor compartment. The following retention times were observed: compound I, 4.3 min (7:3 MeOH–H_2O, 0.5% NH_4OAc); compound II, 2.9 min (7:3 MeOH–H_2O, 0.5% NH_4OAc); compound III, 5.2 min (1:1 MeOH–H_2O, 0.5% NH_4OAc); compound IV, 4.5 min (1:1 MeOH–H_2O, 0.5% NH_4OAc). The solvent flow rate was 2.0 mL/min, and detection was by UV absorbance at 254 nm. Under these conditions, baseline separation was achieved between the single chromone acid peak and that due to unknown components leached from the skin. All four chromone acids were shown to be stable under the experimental conditions used and for at least the duration of a permeation run. Standard solutions were injected at each time interval when samples were withdrawn and assayed. The coefficients of variation ranged from 3.2 to 5.6% for the four compounds studied. In all cases, the limit of detection was 1–2 ng of chromone acid following the injections of a 100-μL sample.

Solubility Determination—The aqueous solubilities of the chromone-2-carboxylic acids at 37°C were measured by adding excess compound to pH 5.0 buffer. The pH was readjusted to 5.0 with 0.1 M sodium hydroxide solution when necessary. After equilibration overnight, the mixtures were filtered and assayed by HPLC.

Partition Coefficients—Known weights of the four chromone-2-carboxylic acids were equilibrated between equal volumes of mutually saturated triglyceride[2] and the appropriate buffer solution at 37°C. The systems were gently shaken at frequent intervals over a period of 48 h, at which time samples of each phase were assayed by UV spectrophotometry. The apparent partition (distribution) coefficient D was calculated as the ratio of the total amount of drug in each of the two phases and subsequently converted into the true (*i.e.*, un-ionized) partition coefficient K by:

$$D = K(1 - \alpha) \qquad \text{(Eq. 5)}$$

where $(1 - \alpha)$ is the fraction of un-ionized drug and $\alpha = 1/[1 + \text{antilog}(pK_a - pH)]$.

Table II—Summary of Experimental Results

Compound	S_5, mol·L^{-1} × 10^3	log $K^{M/W}$	$K^{M/W}$·S_5, mol L^{-1}	P^{HA}, cm·h^{-1}	P^{A^-}, cm·h^{-1} × 10^5	D, cm^2·s^{-1} × 10^{10}
I	2.09	4.39	51.3	1.63 ± 0.25[a]	20.2 ± 12.5[a]	0.18
II	12.6	3.35	28.2	0.66 ± 0.08	4.85 ± 3.73	0.82
III	89.2	2.22	14.8	0.09 ± 0.03	2.51 ± 0.93	1.51
IV	187	1.78	11.3	0.15 ± 0.09	0.51 ± 1.63	6.91

[a] 95% Confidence limits.

Ionization Constants—Two methods were used to determine the ionization constants. In the first, a conductometric method (10), all measurements were made at 25°C with a conductivity meter[4]. In the second, a partition–distribution method (11), a biphasic solvent system of dichloroethane–hexane–water was chosen to minimize ion-pair extraction. Large partition coefficients (K) were determined by the interchange technique (12). Distribution coefficients (D) were obtained at various pH values, and the ionization constant was calculated by using a rearranged form of Eq. 5, namely:

$$\log\left(\frac{K}{D} - 1\right) = \text{pH} - \text{p}K_a \qquad \text{(Eq. 6)}$$

RESULTS AND DISCUSSION

The pK_a values of the four chromone-2-carboxylic acids determined in aqueous solution are: 1.93 ± 0.06 (not as previously reported in Ref. 9), 1.87 ± 0.06, 1.75 ± 0.05, and 1.44 ± 0.05 for I, II, III, and IV, respectively. The values for III and IV were obtained by the partition as well as the conductance methods and were consistent with each other. Only the partition method was used with I and II, as the solubility of the undissociated forms were too low to allow use of the conductance method.

Plots of the number of moles of chromone-2-carboxylic acid permeated per square centimeter of SCE *versus* time showed an initial lag phase, followed by a linear steady-state phase 24 to 48 h after initiation of the permeation run. The steady-state total flux of the permeating species (J; in mol/cm^2/h) was calculated from the slope of the linear portion of each plot, and a value of J/C^{A^-} was calculated for each individual determination. The mean, SD, range, and numbers of individual determinations are shown in Table I for the four compounds studied at each of the three pH values. Considering that over the course of the series of experiments it was necessary to use skin from at least 10 different cadavers, the SD values observed are acceptable. Regression analysis of the individual values of J/C^{A^-} *versus* $C^{H_3O^+}$ for each compound was used to compute the relationship expressed in Eq. 4. These results, together with the respective 95% confidence intervals, are also shown in Table I. In Fig. 1, the mean values of J/C^{A^-} listed in Table I plotted against $C^{H_3O^+}$ for the four compounds are shown. The vertical bars represent the SD values.

Utilization of the appropriate pK_a value yields the values of P^{HA} and P^{A^-} listed in Table II. The data show positive, but small, intercepts, indicating that the chromone-2-carboxylate ions have finite permeabilities, although those for IV are not significantly different from zero. In all instances, the permeability of the un-ionized form is ~10^4 times greater than the permeability of the ionized form. In Table II are also presented the solubilities of the compounds in pH 5.0 buffer (S_5) and the triglyceride[2]–water partition coefficients ($K^{M/W}$), calculated as described above.

The triglyceride[2] was chosen as the oil phase in the partition system because preliminary studies (13) over a range of pH values have shown this system to conform closely to the expected theoretical relationship between log D and pH, thereby allowing calculation of log K correctly from observed values of D. In contrast, partition data for I between SCE and water and stratum corneum and water as a function of pH showed a significant deviation from ideality (13). Accordingly, $K^{M/W}$ was used in the present study rather than $K^{SCE/W}$ or $K^{SC/W}$, as this parameter provides a more accurate index of the relative partitioning abilities of the four compounds studied.

By assuming a constant diffusion coefficient and stratum corneum thick-

[4] Model B642; Wayne Kerr, Chicago, Il.

ness, it is predicted by Eqs. 1 and 2 that the steady-state total flux is proportional to the product of the partition coefficient of the drug between the stratum corneum and the vehicle and its solubility in the vehicle. Although realizing that $K^{M/W}$ was used in the present study rather than $K^{SC/W}$, such a trend nevertheless appears evident since as $K^{M/W} \cdot S_5$ decreases, so does P^{HA} and P^{A^-} (Fig. 2). This suggests the use of this parameter as a relative indicator of permeability when examining a series of analogues for their ability to penetrate human skin, without recourse to actual permeation studies. The data imply that $K^{M/W} \cdot S_5$ must exceed 10–11 mol $\cdot$ L^{-1} before permeation of the chromone-2-carboxylic acids can be detected.

The values of P^{HA} and P^{A^-} obtained from these experiments can be used to determine how the relative permeation rates of the un-ionized and ionized species change with pH and how this affects the total steady-state flux, *i.e.*, $J^{HA} + J^{A^-}$. This is illustrated for I in Fig. 3, where it should be noted that the flux axis is given in log units. As the pH is increased above the pK_a of 1.93, the concentration of the un-ionized species falls. This leads to a continuous reduction in flux due to the un-ionized species, J^{HA}, since the product $P^{HA} \cdot C^{HA}$ is also falling. At the same time, the concentration of the ionized species rises with increasing pH and then remains constant at a pH value 2 or more units above the pK_a. The net effect is a continuous decline in the total flux as the pH of the solution is increased; in the case of I, this increase is to pH 7. Above this pH, the permeation of chromone ions constitutes the major portion of the total flux, although it is important to remember that the magnitude of the total flux falls dramatically as the pH is raised above the pK_a. Thus, for monoprotic acids in which un-ionized and ionized species have widely separated permeability coefficients (*e.g.*, the chromone-2-carboxylic acids in which the difference between P^{HA} and P^{A^-} is $\sim 10^4$), the pH should be held to as low a value as possible when seeking to maximize the total flux through the skin. The optimal value is at least 1 pH unit below the pK_a, assuming satisfactory tolerance by the skin to such a pH. Minimal flux in the example described here occurs at a pH that is ~5 units or more above the pK_a.

Diffusion coefficients (D) for the four compounds are calculated from Eq. 1 by using the values for $K^{M/W}$ given in Table II and a measured stratum corneum thickness of 10 μm. Since P^{HA} is much greater than P^{A^-}, P was taken to be equal to P^{HA}. The values presented in Table II lie within the range normally found for compounds of this size when they are diffused through the stratum corneum (2).

In summary, the results of this study indicate that chromone-2-carboxylic acids permeate human skin both as un-ionized and ionized species, although the former are $\sim 10^4$ times more permeable. Because of the effect of pH on the relative concentrations of un-ionized and ionized species, it would appear to be possible to control the total flux of these compounds by varying the pH of the drug-containing vehicle applied to the skin.

Adsorption of Phosphate by Aluminum Hydroxycarbonate

JUE-CHEN LIU *§, JOSEPH R. FELDKAMP ‡, JOE L. WHITE ‡, and STANLEY L. HEM *x

Received July 7, 1983, from the **Departments of Industrial and Physical Pharmacy and* ‡*Agronomy, Purdue University, West Lafayette, IN 47907.* Accepted for publication, October 27, 1983. §Present address: College of Pharmacy, Rutgers University, Piscataway, NJ 08854.

Abstract □ Phosphate is specifically adsorbed by aluminum hydroxycarbonate by anion ligand exchange. IR analysis indicated that phosphate exchanged with specifically adsorbed carbonate. Adsorption is favored by low pH and is inversely related to particle size. Adsorption of phosphate decreases the rate of acid neutralization of aluminum hydroxycarbonate. The results are applied to the treatment of hyperphosphatemia and hypophosphatemia.

Keyphrases □ Adsorption—phosphate by aluminum hydroxycarbonate □ Aluminum hydroxycarbonate— adsorption of phosphate

The adsorption of phosphate species by aluminum hydroxide is important, as aluminum hydroxide-containing antacids have been implicated in hypophosphatemia. In contrast, aluminum hydroxide is used as a phosphorus-binding agent in hyperphosphatemia. The interaction of phosphate species with crystalline forms of aluminum hydroxide has been extensively studied due to the wide occurrence of aluminum hydroxide in the soil and the extensive use of phosphorus-containing fertilizers. However, little is known about the interaction of phosphate species with amorphous aluminum hydroxycarbonate, the acid-reactive form of aluminum hydroxide containing specifically adsorbed carbonate which is used in antacids. The purpose of this study was to determine the mechanism of adsorption of phosphate species by aluminum hydroxycarbonate, with emphasis on possible adsorption of phosphate on surface carbonate sites.

BACKGROUND

The binding of phosphorus by aluminum hydroxide in the gastrointestinal tract during antacid therapy was first noted 40 years ago (1, 2). Since that time, it has been confirmed in numerous studies that aluminum hydroxide may reduce the intestinal absorption of phosphate (3–13). Clinical symptoms of phosphorus depletion syndrome parallel serum phosphorus levels and are most likely to be observed in patients who combine aluminum hydroxide antacid therapy with a low dietary phosphorus intake (14, 15). This observation is especially pertinent to critically ill patients who receive only parenteral nutrition and who also require antacid therapy to prevent upper GI bleeding (16).

ness, it is predicted by Eqs. 1 and 2 that the steady-state total flux is proportional to the product of the partition coefficient of the drug between the stratum corneum and the vehicle and its solubility in the vehicle. Although realizing that $K^{M/W}$ was used in the present study rather than $K^{SC/W}$, such a trend nevertheless appears evident since as $K^{M/W} \cdot S_5$ decreases, so does P^{HA} and P^{A^-} (Fig. 2). This suggests the use of this parameter as a relative indicator of permeability when examining a series of analogues for their ability to penetrate human skin, without recourse to actual permeation studies. The data imply that $K^{M/W} \cdot S_5$ must exceed 10–11 mol $\cdot$ L^{-1} before permeation of the chromone-2-carboxylic acids can be detected.

The values of P^{HA} and P^{A^-} obtained from these experiments can be used to determine how the relative permeation rates of the un-ionized and ionized species change with pH and how this affects the total steady-state flux, *i.e.*, $J^{HA} + J^{A^-}$. This is illustrated for I in Fig. 3, where it should be noted that the flux axis is given in log units. As the pH is increased above the pK_a of 1.93, the concentration of the un-ionized species falls. This leads to a continuous reduction in flux due to the un-ionized species, J^{HA}, since the product $P^{HA} \cdot C^{HA}$ is also falling. At the same time, the concentration of the ionized species rises with increasing pH and then remains constant at a pH value 2 or more units above the pK_a. The net effect is a continuous decline in the total flux as the pH of the solution is increased; in the case of I, this increase is to pH 7. Above this pH, the permeation of chromone ions constitutes the major portion of the total flux, although it is important to remember that the magnitude of the total flux falls dramatically as the pH is raised above the pK_a. Thus, for monoprotic acids in which un-ionized and ionized species have widely separated permeability coefficients (*e.g.*, the chromone-2-carboxylic acids in which the difference between P^{HA} and P^{A^-} is $\sim 10^4$), the pH should be held to as low a value as possible when seeking to maximize the total flux through the skin. The optimal value is at least 1 pH unit below the pK_a, assuming satisfactory tolerance by the skin to such a pH. Minimal flux in the example described here occurs at a pH that is ~5 units or more above the pK_a.

Diffusion coefficients (D) for the four compounds are calculated from Eq. 1 by using the values for $K^{M/W}$ given in Table II and a measured stratum corneum thickness of 10 μm. Since P^{HA} is much greater than P^{A^-}, P was taken to be equal to P^{HA}. The values presented in Table II lie within the range normally found for compounds of this size when they are diffused through the stratum corneum (2).

In summary, the results of this study indicate that chromone-2-carboxylic acids permeate human skin both as un-ionized and ionized species, although the former are $\sim 10^4$ times more permeable. Because of the effect of pH on the relative concentrations of un-ionized and ionized species, it would appear to be possible to control the total flux of these compounds by varying the pH of the drug-containing vehicle applied to the skin.

Adsorption of Phosphate by Aluminum Hydroxycarbonate

JUE-CHEN LIU *§, JOSEPH R. FELDKAMP ‡, JOE L. WHITE ‡, and STANLEY L. HEM *x

Received July 7, 1983, from the **Departments of Industrial and Physical Pharmacy and* ‡*Agronomy, Purdue University, West Lafayette, IN 47907.* Accepted for publication, October 27, 1983. §Present address: College of Pharmacy, Rutgers University, Piscataway, NJ 08854.

Abstract □ Phosphate is specifically adsorbed by aluminum hydroxycarbonate by anion ligand exchange. IR analysis indicated that phosphate exchanged with specifically adsorbed carbonate. Adsorption is favored by low pH and is inversely related to particle size. Adsorption of phosphate decreases the rate of acid neutralization of aluminum hydroxycarbonate. The results are applied to the treatment of hyperphosphatemia and hypophosphatemia.

Keyphrases □ Adsorption—phosphate by aluminum hydroxycarbonate □ Aluminum hydroxycarbonate— adsorption of phosphate

The adsorption of phosphate species by aluminum hydroxide is important, as aluminum hydroxide-containing antacids have been implicated in hypophosphatemia. In contrast, aluminum hydroxide is used as a phosphorus-binding agent in hyperphosphatemia. The interaction of phosphate species with crystalline forms of aluminum hydroxide has been extensively studied due to the wide occurrence of aluminum hydroxide in the soil and the extensive use of phosphorus-containing fertilizers. However, little is known about the interaction of phosphate species with amorphous aluminum hydroxycarbonate, the acid-reactive form of aluminum hydroxide containing specifically adsorbed carbonate which is used in antacids. The purpose of this study was to determine the mechanism of adsorption of phosphate species by aluminum hydroxycarbonate, with emphasis on possible adsorption of phosphate on surface carbonate sites.

BACKGROUND

The binding of phosphorus by aluminum hydroxide in the gastrointestinal tract during antacid therapy was first noted 40 years ago (1, 2). Since that time, it has been confirmed in numerous studies that aluminum hydroxide may reduce the intestinal absorption of phosphate (3–13). Clinical symptoms of phosphorus depletion syndrome parallel serum phosphorus levels and are most likely to be observed in patients who combine aluminum hydroxide antacid therapy with a low dietary phosphorus intake (14, 15). This observation is especially pertinent to critically ill patients who receive only parenteral nutrition and who also require antacid therapy to prevent upper GI bleeding (16).

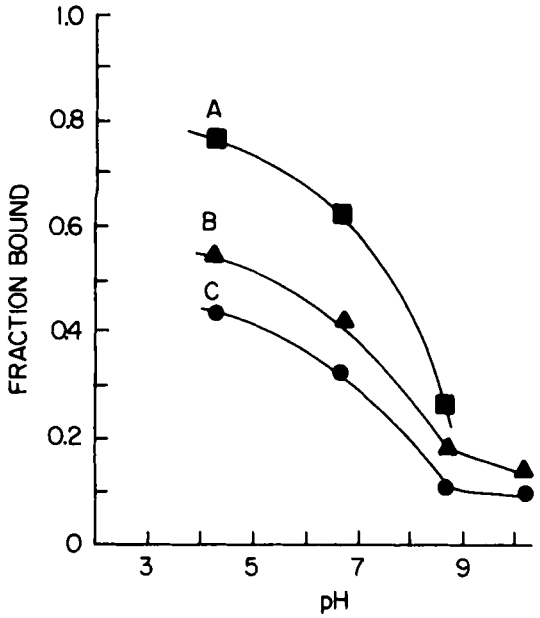

Figure 1—*Effect of pH on the fraction of phosphorus bound by AHCG 1 (A), aluminum hydroxide gel (B), and AHCG 2 (C).*

In two recent studies, slightly different conclusions were reached regarding the effect of aluminum hydroxide on serum phosphorus levels and phosphorus excretion, perhaps due to differences in dosage and duration of therapy. In the first study, seven daily doses containing 525 mg of equivalent aluminum oxide (15.4 mEq) per dose were administered for 28 d to 12 healthy subjects (15). No statistically significant change in serum phosphorus levels occurred, but a statistically significant decrease in phosphorus excretion led to values below the normal phosphorus excretion range. No clinical symptoms were observed in any subject. Because of the change in phosphate excretion, the subjects were described as exhibiting incomplete phosphorus depletion. In a second study, 15 healthy subjects were administered four daily doses containing 450 mg of equivalent aluminum oxide (13.2 mEq) per dose for 12 d (17). Serum phosphorus levels did not change significantly, and no clinical symptoms were observed, although a statistically significant decrease in phosphorus excretion was noted. However, in contrast to the first study, the phosphorus excretion values remained within the normal physiological limits. Therefore, it was concluded that aluminum hydroxide was tolerated by the subjects.

Hyperphosphatemia is most commonly encountered during renal failure. Therapy usually involves reduction in the uptake and absorption of exogenous phosphorus through a low phosphorus diet and the use of phosphorus-binding agents (18–23). Presently, aluminum hydroxycarbonate gel is the chief agent used to treat hyperphosphatemia.

Phosphate species are specifically adsorbed by hydrous metal oxides through anionic ligand exchange, displacing surface hydroxyl or water groups (24).

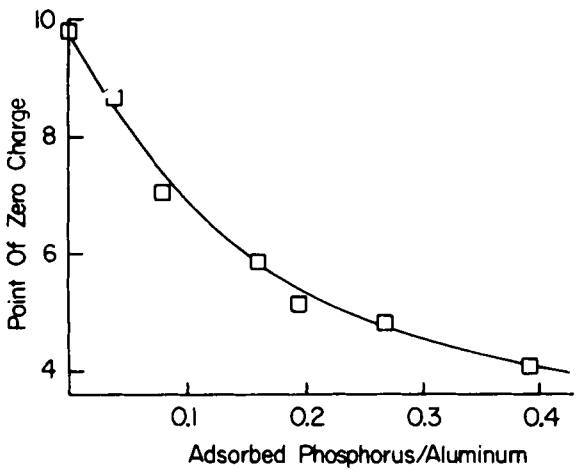

Figure 2—*Effect of phosphate adsorption on PZC of aluminum hydroxide gel.*

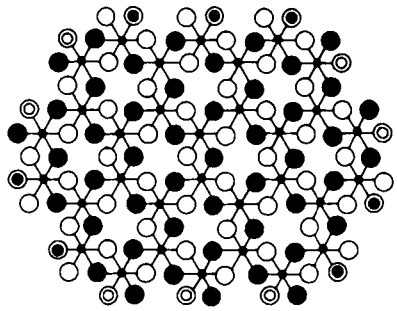

Figure 3—*Schematic of the unit layer of aluminum hydroxide showing the surface hydroxyl and aquo groups. Key: (⊛) upper OH; (○) upper OH_2; (●) lower OH; (⊛) lower OH_2.*

The affinity of anions for aluminum hydroxide at moderate pH conditions follows the order phosphate > arsenate > sulfate > chloride (25). The adsorption of phosphate shifts the point of zero charge (PZC) to lower values and thus alters the surface characteristics (24, 26). This must occur by entering the inner Helmholtz layer, *i.e.*, the first coordination sphere of the aluminum ions on the aluminum hydroxide surface, through the displacement of coordinated hydroxyl and aquo ions by a ligand exchange reaction.

The extent of phosphate adsorption depends on pH, time, concentration, surface area, temperature, and the nature of the adsorbent (26–28).

EXPERIMENTAL SECTION

Materials—Two aluminum hydroxycarbonate gels were obtained commercially and were identified as AHCG 1[1] and AHCG 2[2]. An aluminum hydroxide gel which was free of carbonate was precipitated by adding sufficient 3 M KOH to 2 L of 1 M $AlCl_3$ to reach pH 9.5. Immediately after washing with three volumes of distilled water, 68 g of sorbitol was dissolved in distilled water and added to the aluminum hydroxide gel. The final volume was then adjusted to 4 L by the addition of distilled water. Sorbitol was added to reduce the rate of polymerization (29) and thereby maintain the maximum surface area.

Analytical Procedures—The equivalent aluminum oxide content was determined by chelatometric titration (30). The carbonate content was determined by gasometric displacement (31). The PZC was determined by a potentiometric titration procedure (32). The rate of acid neutralization was determined by automated pH-stat titration[3] at pH 3 and 25°C (33). The amount of phosphorus in solution was determined by the heteropoly blue method (34). The mean hydrodynamic radius was determined by fiber optic Doppler anemometry[4] (35).

The fraction of phosphate species adsorbed at different pH conditions was determined by first adjusting portions of the aluminum hydroxycarbonate or aluminum hydroxide gel containing 15.5 mM of aluminum and 10 mM of KCl to the desired pH with a pH-stat titrator[3]. After the pH adjustment, 25 mL of 1 M NaH_2PO_4 was added, and the volume was adjusted to 100 mL with distilled water. The pH was maintained at the desired level for 1 h at 25°C with constant stirring with the pH-stat titrator[3]. The sample was centrifuged at 15,000 rpm (27,000×*g*) for 30 min, and the supernatant was analyzed for phosphorus. The quantity of phosphate adsorbed was determined by difference.

IR spectra[5] were obtained by air drying the sample and preparing a com-

pressed disk (1 mg of sample/300 mg of KBr). A sample of AHCG 2 containing 25 mM of equivalent aluminum oxide was diluted to 100 mL with distilled water and adjusted to pH 6.6. Five milliliters of 0.25 M NaH_2PO_4 was added. The sample was shaken at 25°C. Portions were removed and air dried after 1 and 72 h.

The exchange of phosphate species for specifically adsorbed carbonate in aluminum hydroxycarbonate was determined by adding 26.9 mM NaH_2PO_4 to a sample of AHCG 2 containing 15.5 mM equivalent aluminum oxide at pH 6.6 and 25°C. The pH was maintained with a pH-stat titrator[3]. Samples were taken after 30, 60, 120, or 240 min of reaction time and analyzed for total carbonate content and phosphorus in solution.

RESULTS AND DISCUSSION

Phosphate is adsorbed by both aluminum hydroxide and aluminum hydroxycarbonate (Fig. 1). The three adsorbents differed substantially in the amount of phosphate adsorbed. However, this difference does not appear to be related to the presence of carbonate surface groups, in addition to hydroxyl and aquo surface groups, as the fraction of phosphate bound by the sample of aluminum hydroxide (Fig. 1B) was intermediate between the two aluminum hydroxycarbonate gels (Fig. 1A and C). Particle size analysis showed that phosphate adsorption was directly related to surface area, as the mean hydrodynamic radii of aluminum hydroxycarbonate gel 1 (AHCG 1), aluminum hydroxide, and aluminum hydroxycarbonate gel 2 (AHCG 2) were 0.21, 0.28, and 0.51 μm, respectively.

The results shown in Fig. 1 also indicate that phosphate adsorption is dependent on pH, with all three adsorbents exhibiting a similar pH profile. However, the PZC varies from 9.8 for aluminum hydroxide to 7.6 and 6.5 for aluminum hydroxycarbonate 1 and 2, respectively. Thus, phosphate adsorption cannot be explained simply by electrostatic attraction, as the pH profile is not related to the PZC of the adsorbents. The fact that phosphate adsorption is independent of the PZC, *i.e.*, adsorption decreased at pH ~7 for all three adsorbents, indicates that phosphate is specifically adsorbed at the inner Helmholtz layer by a ligand-exchange reaction (24) which is independent of surface potential.

The nature of the surface and the ionic form of the adsorbate are influenced by pH. At low pH conditions, the surface is positive and aquo groups are the predominant sites on the surface. As the pH increases, the surface potential decreases and more hydroxyl sites occur on the surface as the hydroxide concentration in solution increases. Therefore, the phosphate species must compete with hydroxide ions for the hydroxyl sites on the increasingly negative surface. Thus, the high adsorption of phosphate species at low pH can be attributed to the high positive charge of the surface and the weaker competition of hydroxide ions. This behavior is in agreement with the results of a previous study by Huang (27), who concluded that surface acidity and the acid–base behavior of the adsorbed anions are the most important factors controlling the adsorption density.

The conclusion that phosphate is specifically adsorbed by aluminum hydroxide and aluminum hydroxycarbonate is further supported by the depression of the PZC of aluminum hydroxide following phosphate adsorption (Fig. 2). The PZC decreased from 9.8 to 4.1 as the adsorbed phosphate-to-aluminum molar ratio increased from 0 to 0.39. The decrease in PZC can be attributed to the negative charge introduced by the specifically adsorbed phosphate (27).

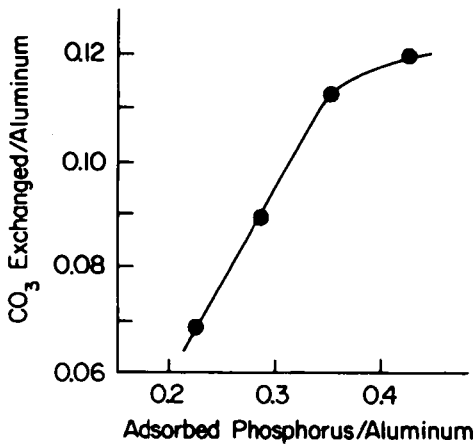

Figure 6—*Exchange of phosphate species for specifically adsorbed carbonate in AHCG 2 at pH 6.6 and 25°C.*

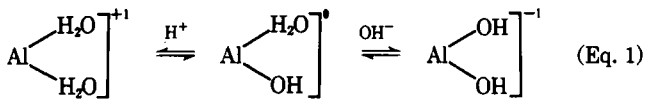
The potential exchangeable sites for aluminum hydroxide are illustrated in Fig. 3. The molecular structure is composed of two fundamental units: two planes of closely packed hydroxyl ions with aluminum sandwiched between them as fused, six-membered rings of octahedrally coordinated aluminum atoms joined by double hydroxide bridges (36). At the surface, the terminal aluminum atoms are coordinated with hydroxyl and aquo groups. The proportion of hydroxyl and aquo surface groups is controlled by the pH–PZC relationship (37) by[6]:



(Eq. 1)

Rajan *et al.* (38) have shown that aquo groups are the predominant adsorption site at low pH conditions and that exchange with surface hydroxyl groups predominates above pH 6.7.

Aluminum hydroxycarbonate has the same basic structure as aluminum hydroxide, except that carbonate groups are present at the surface in addition

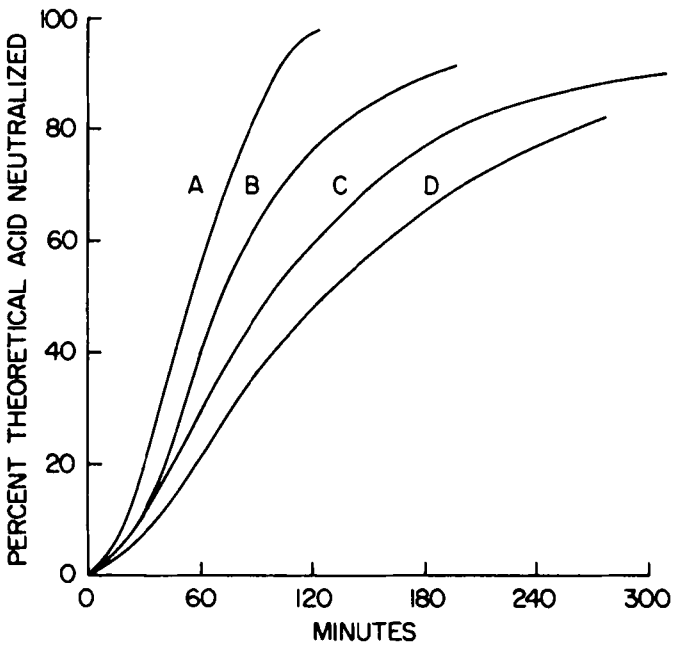


Figure 7—*Effect of phosphate adsorption on the rate of acid neutralization of AHCG 2 at various adsorbed phosphate-to-aluminum molar ratios. Key: (A) 0; (B) 0.016; (C) 0.032; (D) 0.066.*

[6] For clarity, only the bonds associated with the surface sites are shown, even though aluminum is in sixfold coordination in each structure.

to hydroxyl and aquo groups (39) (Fig. 4). The possibility of exchange of phosphate for surface carbonate sites was studied by IR spectroscopy (Fig. 5). The IR spectrum of aluminum hydroxycarbonate exhibits absorption bands between 1400 and 1500 cm^{-1} which have been assigned to specifically adsorbed carbonate (40). After interacting with phosphate for 1 h, the carbonate bands were diminished, and a band at 1080 cm^{-1}, corresponding to P—O stretching (41), was evident. The P—O stretching band increased in intensity with adsorption time while a concomitant decrease in the intensity of the carbonate band occurred. The exchange of phosphate species for carbonate was confirmed by the loss of carbonate which accompanied adsorption of phosphate by AHCG 2 at pH 6.6 (Fig. 6). At low phosphate levels, the ratio of phosphate adsorbed to carbonate exchanged was ~3, indicating that phosphate adsorption by aluminum hydroxycarbonate gel involves exchange with surface carbonate sites as well as hydroxyl and aquo sites.

The effect of phosphate adsorption on the rate of acid neutralization of aluminum hydroxycarbonate was investigated by pH-stat titration at pH 3 and 25°C (Fig. 7). The rate of acid neutralization decreased in response to adsorption of even small amounts of phosphate. For example, the time to neutralize 50% of the sample increased from 57 min, in the absence of phosphate, to 75 min when the adsorbed phosphate-to-aluminum molar ratio was only 0.016. The mechanism for this effect is believed to be related to the difference in solubility between $AlPO_4$, known mineralogically as berlinite, and amorphous aluminum hydroxide. The acid neutralization reactions of $AlPO_4$ and $Al(OH)_3$ are shown by:

$$AlPO_4 + 3H^+ \overset{K_1}{\rightleftharpoons} Al^{3+} + H_3PO_4 \qquad \text{(Eq. 2)}$$

$$Al(OH)_3 + 3H^+ \overset{K_2}{\rightleftharpoons} Al^{3+} + 3H_2O \qquad \text{(Eq. 3)}$$

The logarithims of the equilibrium constants for Eqs. 2 and 3 are 0.5 and 9.66, respectivcly (42). Thus, the Al—O—PO_3 bond is much more resistant to proton attack than the Al—O—H bond.

Adsorption of phosphate species occurs as readily by aluminum hydroxycarbonate as by aluminum hydroxide because phosphate can exchange with specifically adsorbed carbonate. Adsorption is favored by low pH and small particle size. In patients with hypophosphatemia, the depletion of phosphorus will be the greatest for those aluminum hydroxycarbonate gels with the smallest particle size, *i.e.*, those exhibiting the best antacid properties. Thus, an adequate dietary intake of phosphorus is essential of antacid therapy is required. Alternate steps, such as the use of aluminum phosphate gel as an antacid, are not satisfactory because of the poor antacid properties of aluminum phosphate. On the other hand, an aluminum hydroxide gel with the maximum surface area appears to be desirable to treat hyperphosphatemia. The aluminum hydroxide gel used in this study, which was stabilized by adding sorbitol immediately after precipitation (Fig. 1B), would be a good candidate, as it requires 270 min to neutralize 10% of its theoretical acid-neutralizing capacity at pH 3 and 25°C. Thus, this aluminum hydroxide gel will not undergo appreciable acid dissolution during the gastric residence time and will be present throughout the GI tract as a relatively high-surface-area colloidal solid capable of adsorbing phosphate species.

Pharmacokinetic Study on the Mechanism of Tissue Distribution of Doxorubicin: Interorgan and Interspecies Variation of Tissue-to-Plasma Partition Coefficients in Rats, Rabbits, and Guinea Pigs

TETSUYA TERASAKI, TATSUJI IGA ˣ, YUICHI SUGIYAMA, and MANABU HANANO

Received May 18, 1982, from the *Faculty of Pharmaceutical Sciences, University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113, Japan.* Accepted for publication September 9, 1983.

Abstract □ The mechanism of interorgan and interspecies variations in the tissue distribution of doxorubicin was studied in rats, rabbits, and guinea pigs. The permeation properties of doxorubicin were investigated by using isolated rat erythrocytes as a model membrane. A significant dependency of the uptake rate constant on medium pH was observed, suggesting that only un-ionized doxorubicin is diffusible through the plasma membrane. The values of plasma unbound fraction (f_p) of doxorubicin were 0.344 for rats, 0.415 for rabbits, and 0.529 for guinea pigs. The tissue DNA concentrations of rats were larger than those of rabbits and smaller than those of guinea pigs in corresponding organs or tissues. An *in vitro* organ model that described the distribution behavior of doxorubicin in the whole body was constructed, and an equation was derived to estimate the tissue-to-plasma partition coefficients, (K_p) from *in vitro* experiments. The *in vitro* K_p values showed comparatively good agreement with the *in vivo* K_p values for the various organs or tissues in all three species. Doxorubicin is exclusively bound to the nuclei in the cells. The variation of the K_p values in different organs depended on the amount of nuclei per gram of tissue. The primary determinant of the interspecies variation in the K_p values was the difference in tissue DNA concentrations among rats, rabbits, and guinea pigs, and a secondary determinant was the difference in f_p values.

Keyphrases □ Doxorubicin—pharmacokinetics, mechanism of tissue distribution, tissue-to-plasma partition coefficient □ Pharmacokinetics—doxorubicin, mechanism of distribution, tissue-to-plasma partition coefficients □ Partition coefficients—tissue to plasma, mechanism of distribution of doxorubicin

The tissue distribution of doxorubicin has been studied in several animal species (1–5). The characteristic feature of the tissue distribution of doxorubicin is that the tissue-to-plasma partition coefficient (K_p), a commonly used physiological pharmacokinetic parameter, is extraordinarily large and shows clear differences among tissues. Although it has been demonstrated that doxorubicin and its derivatives interact with DNA, chromatin, and nuclei (6–8), the mechanism of tissue distribution of doxorubicin has not been quantitatively elucidated.

In general, the physiological distribution of most drugs is governed by two factors: (*a*) their reversible binding equilibrium with proteins and/or other constituents in blood and tissues and (*b*) the concentration difference of unbound drug, which depends on the membrane permeability (9). Therefore, much has been done on the changes in plasma protein binding as a possible determining factor of interspecies, individual, or disease-state differences in drug distribution (10–12). However, it has not yet been possible to explain organ and interspecies differences in drug distribution in terms of the K_p values for any drug, despite various studies of drug interactions with intracellular organelles, e.g., nuclei, mitochondria, and microsomes.

In previous studies (13, 14), a comparatively good correlation was found between the K_p value of doxorubicin and the tissue DNA concentration, *i.e.*, the amount of nuclei per gram of tissue in rats and rabbits, and there was no significant difference in the characteristics of doxorubicin binding to the nuclei isolated from the rat liver and kidney tissues. The purpose of this study was to elucidate the mechanism of organ and interspecies variation in the tissue distribution of doxorubicin by means of measurements of tissue DNA concentrations and *in vitro* binding studies with plasma and nuclei.

THEORETICAL SECTION

Organ Model—A diagrammatic representation of an anatomical compartment in an organism is presented in Fig. 1. In estimating the K_p value of doxorubicin in the compartment from the results of *in vitro* experiments, the following assumptions were made:

1. The nucleus is the dominant organelle in tissue binding.
2. The variations in tissue distribution depend on the amount of nuclei per gram of tissue, *i.e.*, tissue DNA concentration, and the differences in nuclear binding parameters among tissues and species are negligible.
3. Only the un-ionized form which is free from plasma and nuclear binding can diffuse through the plasma membrane.

It has been reported on the basis of fluorescence microscopy in hamsters (15) that anthracycline antibiotics are localized in the cell nucleus. Furthermore, >85% of doxorubicin was also localized in the 600×*g* subcellular fraction of each tissue after intravenous administration of 10 mg/kg in rats[1]. In a previous study (13), a good correlation was found between *in vivo* K_p value and the tissue DNA concentration. Therefore, it was suggested that the dominant factor in organ differences in the tissue distribution is the amount of nuclei per gram of tissue. Moreover, there was no difference in tissue nuclear binding characteristics of doxorubicin between the liver and kidney (14). Although it was reported that a resistant type of tumor cell has a carrier-mediated influx system and active efflux mechanisms (16, 17), there is little information regarding the permeation of doxorubicin through the plasma membrane into the normal cell. Therefore, the membrane permeability to doxorubicin was examined by using isolated rat erythrocytes as a model membrane in the present study.

Lung	$2.35 \times 10^{-2} \pm 0.04 \times 10^{-2}$	$2.00 \times 10^{-2} \pm 0.08 \times 10^{-2}$	$3.25 \times 10^{-2} \pm 0.09 \times 10^{-2}$
Spleen	$5.41 \times 10^{-2} \pm 0.38 \times 10^{-2}$	$5.13 \times 10^{-2} \pm 0.27 \times 10^{-2}$	$5.99 \times 10^{-2} \pm 0.13 \times 10^{-2}$

[a] Mean ± *SE* of each experiment; $n = 3$–7. Calculated with calf thymus DNA (mol. wt. 330.9 per unit nucleotide as sodium salt) as the standard. [b] Obtained from a previous report (13).

From the aforementioned assumptions regarding the distribution of doxorubicin in the organs, an equation can be derived to estimate the K_p value as follows. K_p is defined as the ratio of the tissue concentration to the concentration in the leaving venous plasma, *i.e.*:

$$K_p = \frac{C_f^T + C_b^T}{C_f^P + C_b^P} \quad \text{(Eq. 1)}$$

where C^T and C^P are the drug concentrations in the tissue and venous plasma, respectively, and the subscripts f and b denote the unbound and bound drug species, respectively. Appropriate rearrangement of Eq. 1 gives:

$$K_p = \frac{C_f^T}{C_f^P} \times \frac{C_f^P}{C_f^P + C_b^P} \times \left(1 + \frac{C_b^T}{C_f^T}\right) \quad \text{(Eq. 2)}$$

It has been reported by several investigators that the intracellular pH is slightly lower than that in the extracellular fluid and the blood plasma (18). Since doxorubicin is a basic drug which is more highly ionized at lower than higher pH values, the antibiotic diffuses out less rapidly than it enters, and the concentration of unbound doxorubicin may be somewhat higher inside than outside the tissue cells. Therefore, the ratio of the unbound drug in the tissue to that in plasma can be expressed by:

$$\frac{C_f^T}{C_f^P} = \frac{1 + 10^{pK_a - pH_i}}{1 + 10^{pK_a - pH_e}} \quad \text{(Eq. 3)}$$

The concentration ratio of unbound to bound doxorubicin in the tissue can be described by a Langmuir-type equation:

$$\frac{C_b^T}{C_f^T} = \frac{nK_aC_N}{1 + K_aC_f^T} \quad \text{(Eq. 4)}$$

where n and K_a are the number of binding sites and the affinity constant to nuclei, respectively, and C_N is the tissue DNA concentration. If the relation $K_aC_f^T \ll 1$ holds, Eq. 5 is obtained:

$$\frac{C_b^T}{C_f^T} = nK_aC_N \quad \text{(Eq. 5)}$$

Substituting Eqs. 3 and 5 into Eq. 2 gives:

$$K_p = \frac{1 + 10^{pK_a - pH_i}}{1 + 10^{pK_a - pH_e}} \cdot f_p \cdot (1 + nK_aC_N) \quad \text{(Eq. 6)}$$

where f_p is the unbound fraction in plasma, and pH_i and pH_e are the intra- and extracellular pH values, respectively. The value used for f_p (0.344) was determined in the present study, whereas those for n and K_a were obtained from previously reported data (14) and are 6.70×10^{-2} and 4.85×10^5 M^{-1}, respectively. The values used for C_N were also obtained from previously reported data (13) and are listed in Table I. The values for pK_a, pH_e, and pH_i were obtained from the literature, and are 8.15 (8), 7.4 (18), and 7.0 (18), respectively.

Table II—Physiological Constants for Doxorubicin Tissue Distribution Modeling and the Apparent Tissue-to-Plasma Concentration Ratios at the Terminal Phase after Bolus Intravenous-Injections to Guinea Pigs[a]

Tissue	Volume, mL[b]	Blood flow, mL/min[c]	$K_{p,app}$[d]
Arterial blood	7.6	35.3	—
Adipose tissue	11.6	0.5	64 ± 6
Muscle	145.0	10.2	178 ± 24
Liver	11.6	13.5	273 ± 12
Gut	9.0	9.2	351 ± 60
Heart	0.9	2.7	585 ± 50
Stomach	2.4	3.0	436 ± 43
Kidney	2.1	8.4	595 ± 41
Lung	2.7	35.3	656 ± 91
Spleen	0.3	0.8	1964 ± 311

[a] Body weight, 290 ± 4 g ($n = 4$). [b] Determined experimentally from the wet tissue weight by assuming a density of 1.0 for each tissue except for muscle and arterial blood volume. The muscle volume was assumed to be one-half the body weight, as in rats (22), and the arterial blood volume was calculated from the body weight by previously reported methods (23). [c] Obtained from previously reported data (24, 25). [d] Mean ± *SE* of four guinea pigs.

EXPERIMENTAL SECTION

Materials—Doxorubicin hydrochloride[2] was used. The antibiotic was kept in the dark in a desiccator at 4°C. Solutions of doxorubicin (2×10^{-6}–5×10^{-4} M in 405 mM sucrose) were freshly prepared before use. All other reagents were commercial products of analytical grade.

Animals—Male Wistar rats[3] (weight, 250–270 g), male albino rabbits[4] (weight, 2.6–2.8 kg), and male Hartley guinea pigs[3] (weight, 280–300 g) were used.

Blood-to-Plasma Concentration Ratio—The blood-to-plasma concentration ratio (R_B) was determined as described previously (13).

***In Vivo* Apparent Tissue-to-Plasma Concentration Ratio ($K_{p,app}$) in Guinea Pigs**—Doxorubicin was dissolved in saline and administered to guinea pigs *via* a jugular vein at a dose of 10 mg/kg 2 h after the operation. Food and water were given *ad libitum*. At 6, 12, 24, and 48 h after administration, blood samples were collected *via* a jugular artery, and then the guinea pig was killed by exsanguination. Each tissue was immediately excised, rinsed with saline, and stored at −40°C until use. Doxorubicin contents in plasma and tissues were determined by a TLC scanning method as described previously (13).

Hepatic and Renal Clearances in Guinea Pigs—The urinary excretion of doxorubicin was determined from the total amount excreted through the urinary bladder until 48 h after injection of 10 mg/kg iv. The apparent renal blood clearance ($CL_{B,app}^{KD}$) and the apparent hepatic blood clearance ($CL_{B,app}^{LV}$) were determined, and then the organ intrinsic clearance (CL_{int}) was calculated by:

$$f_p \cdot CL_{int} = \frac{CL_{B,app} \cdot Q_B \cdot R_B}{Q_B - CL_{B,app}} \quad \text{(Eq. 7)}$$

where Q_B is the organ blood flow rate.

***In Vivo* K_p Value**—The K_p value for guinea pigs was calculated from $K_{p,app}$ by a previously described method (13).

Plasma Binding Experiment—The rat plasma was first dialyzed for 16 h at 4°C with a semipermeable membrane[5] against pH 7.4 isotonic buffer (30 mM Tris, 131 mM NaCl, 5.2 mM KCl, 0.9 mM $MgSO_4$, and 1.0 mM $CaCl_2$). The plasma unbound fraction was determined by equilibrium dialysis at 37°C for 15 h against the same buffer as used for predialysis in semimicro cells[6]. No denaturation of proteins after dialysis was observed by polarization analysis (19) with 1-anilino-8-naphthalenesulfonate, as reported previously (20). The degradation of doxorubicin during the equilibrium dialysis and the adsorption of doxorubicin on the dialysis membrane (~30% of the initial content) were corrected for in the calculation of the binding parameters. The concentrations of doxorubicin in both plasma and buffer were determined by a fluorospectrometric TLC scanning method (13).

Tissue DNA Concentration—The tissue DNA concentration of guinea pigs was determined by a previously described method (13). The molecular weight of the DNA used was 330.9 (per unit of nucleotide as the sodium salt).

Preparation of Rat Erythrocytes—After injection of heparin at a dose of 0.1 mL/100 g of body weight (100 U), whole blood was collected *via* a jugular

Table III—Pharmacokinetic Parameters of Doxorubicin in Guinea Pigs [a]

Parameter[b]	Value[c]
Dose, μg	$2.88 \times 10^3 \pm 0.001 \times 10^3$
AUC_p, $\mu g \cdot min/mL$	$2.24 \times 10^2 \pm 0.55 \times 10^2$
$CL^{tot}_{B,app}$, mL/min	5.35 ± 0.73
X_u, μg	$6.52 \times 10^2 \pm 0.35 \times 10^2$
$CL^{KD}_{B,app}$, mL/min	1.22 ± 0.19
$CL^{LV}_{B,app}$, mL/min	4.13 ± 0.57
$f_p CL^{KD}_{int}$, mL/min	3.42 ± 0.37
$f_p CL^{LV}_{int}$, mL/min	$1.43 \times 10 \pm 0.10 \times 10$
β, min^{-1}	$2.94 \times 10^{-4} \pm 1.61 \times 10^{-4}$

[a] Body weight, 290 ± 4 g (n = 4), except for X_u and $CL^{KD}_{B,app}$ (300 g; n = 2). [b] AUC_p, area under the plasma concentration *versus* time curve; $CL^{tot}_{B,app}$, apparent total blood clearance; $CL^{KD}_{B,app}$, apparent renal blood clearance; $CL^{KD}_{B,app}$, apparent hepatic blood clearance; X_u, amount excreted in urine; f_p, plasma unbound fraction; CL_{int}, renal intrinsic clearance; CL^{LV}_{int}, hepatic intrinsic clearance; β, slope of the plasma concentration—time curve at the terminal phase. [c] Mean ± *SE* of four guinea pigs.

artery at 30 min. Erythrocytes were prepared essentially by the procedure of Horie *et al.* (21), except that buffer (pH 7.4) containing 131 mM NaCl, 5.2 mM KCl, 0.9 mM $MgSO_4$, 0.12 mM $CaCl_2$, 3 mM dibasic sodium phosphate, and 10 mM Tris was used in the preparation.

Uptake Experiment—To determine the initial velocity of uptake of doxorubicin, 1.5 mL of the erythrocyte suspension (10% v/v) was incubated in medium containing 20 mM Tris, 131 mM NaCl, 5.2 mM KCl, 0.9 mM $MgSO_4$, 1.12 mM $CaCl_2$, 3 mM dibasic sodium phosphate, and 5 mM glucose. After preincubation for 3 min with shaking (2 Hz) at 37°C, 0.01 mL of an isotonic solution containing various amounts of doxorubicin (1.81–2.59 μg) was added. Triplicate samples of 1.0 mL of the medium were removed and layered on 200 μL of silicone oil with a density of 1.05[7] in a 2.0-mL polyethylene tube[8]. The samples were then centrifuged for 30 s in a tabletop microcentrifuge[8]. The supernatant was discarded, the oil surface was washed with 0.6 mL of distilled water, 0.6 mL of distilled water was again added, and the erythrocytes were completely hemolyzed with vigorous mixing. Then 0.6 mL of 50 mM Tris-HCl buffer (pH 7.4) was added, and the polyethylene tube was centrifuged for 30 s in a tabletop microcentrifuge[8]. To determine the amount of doxorubicin taken into the erythrocytes, doxorubicin in the supernatant was determined by fluorospectrometric TLC scanning method (13).

RESULTS

Distribution to Erythrocytes, Plasma Protein Binding, and Tissue DNA Concentration—No concentration dependency in doxorubicin distribution into erythrocytes in guinea pigs was observed over the tested plasma concentration range of doxorubicin (0.00947–1.549 μg/mL), which corresponded to the *in vivo* plasma concentration range after injection of 10 mg/kg iv. The value of the blood-to-plasma concentration ratio (R_B) was 2.40 ± 0.09 (n = 12).

Furthermore, no concentration dependency of plasma protein binding of doxorubicin was observed over the *in vivo* plasma concentration range of doxorubicin (0.0131–1.884 μg/mL for rats, 0.0108–1.992 μg/mL for rabbits, and 0.00733–2.183 μg/mL for guinea pigs). The values of plasma unbound fraction were 0.344 ± 0.014 (n = 15) for rats, 0.415 ± 0.019 (n = 11) for rabbits, and 0.529 ± 0.021 (n = 12) for guinea pigs. The tissue DNA concentrations in various tissues of guinea pigs are listed in Table I, along with those of rats and rabbits [determined previously (13)].

***In vivo* K_p Value**—The physiological parameters for guinea pigs and the $K_{p,app}$ at the terminal phase after bolus intravenous injection of doxorubicin are summarized in Table II. The pharmacokinetic parameters determined in guinea pigs are listed in Table III. By using the values listed in Tables II and III, the *in vivo* K_p values of doxorubicin of guinea pigs were calculated and are summarized inTable IV, along with those of rats [determined previously (13)] and rabbits [estimated from the literature values (3)].

Membrane Permeability—The uptake of doxorubicin into isolated erythrocytes was measured at pH 7.05, 7.42, 7.85, and 8.07. The plots of cell-to-medium ratio (C/M ratio) *versus* time were linear for 80 s at all pH values studied. When extrapolated, these lines passed through the origin, which suggested that there was no adsorption of doxorubicin on the cell surface. The slope of each line, which represents the uptake rate constant, k (min^{-1}), was plotted against the pH value of the medium (Fig. 2). The good correspondence

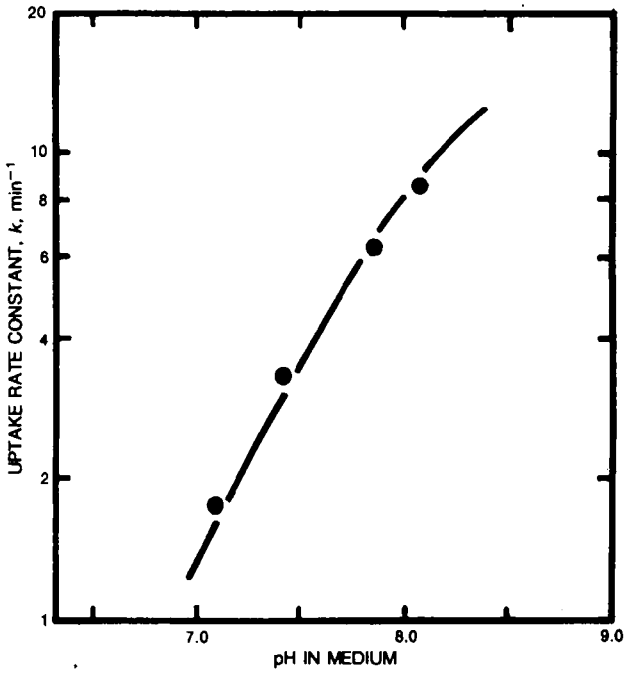

Figure 2—*Log* k-*pH profile for the uptake of doxorubicin into rat erythrocytes. The theoretical curve was calculated by a nonlinear iterative least-squares method (26) with a digital computer by* $k_{pH} = k_0(1/1 + 10^{pK_a - pH})$, *where* k_{pH} *and* k_0 *are the apparent uptake rate constant and the uptake rate constant of undissociated species, respectively;* $k_0 = 2.065 \times 10\ min^{-1}$; $pK_a = 8.15$. *Key: (●) observed values; (—) calculated curve.*

between the calculated and observed values suggests that only un-ionized doxorubicin can permeate through the cell membrane.

Estimation of the K_p value from *In Vitro* Experiments—*In vitro* K_p values for rats, rabbits, and guinea pigs were calculated by Eq. 6 and are listed in Table IV with the *in vivo* K_p values. The *in vivo* and *in vitro* K_p values for rats, rabbits, and guinea pigs are compared in Fig. 3.

DISCUSSION

In this study, the mechanism of *in vivo* tissue distribution of doxorubicin was examined in rats, rabbits, and guinea pigs. The goal of the study was to elucidate the characteristic tissue distribution mechanism to account for interorgan and interspecies variation in drug levels and to determine whether the K_p values obtained from *in vitro* studies coincide with those obtained from *in vivo* studies. The *in vivo* K_p values were characteristically large, and there were fairly large differences among tissues and animal species (Table IV). The K_p values of doxorubicin were also determined from the *in vitro* organ model (Fig. 1), on the basis of the three assumptions described in the *Theoretical Section*, for comparison with *in vivo* values to check the validity of the model. As far as we are aware, the mechanism of tissue distribution of a drug has never been elucidated in detail.

Since there was insufficient information on the plasma membrane permeability of doxorubicin in normal cells, we examined this permeability in isolated intact cells. In a preliminary study, the uptake of doxorubicin into isolated rat hepatocytes, prepared by the method of Berry and Friend (27) as modified by Bauer *et al.* (28), was examined, but the uptake rate of doxorubicin could not be exactly determined due to the rapid metabolism at the incubation temperature of 37°C. Therefore, rat erythrocytes, which can be easily prepared, were utilized as a model membrane. Since it appeared that only the un-ionized molecule could permeate through plasma membranes (Fig. 2), assumption 3 (see *Theoretical Section*) may be applicable to the tissue distribution of doxorubicin. The number of binding sites and the affinity constant for isolated nuclei, which were used for the calculation of the *in vitro* K_p values, were determined previously in quasi-physiological buffer (pH 7.0) containing 135 mM sucrose, 20 mM Tris, 50 mM NaCl, 100 mM KCl, 1 mM $MgSO_4$, and 1 mM $CaCl_2$ at 37°C, and values of $n = 6.70 \times 10^{-2}$ and $K_a = 4.85 \times 10^5\ M^{-1}$ were obtained for rat liver nuclei (14). Since the conditions used for measuring doxorubicin binding were considered to be close to physiological on the basis of both morphological examination of isolated nuclei and the concentrations of the intracellular metal ions (29, 30), the parameters of nuclear binding determined in the *in vitro* studies might be comparable with those determined for the *in vivo* tissue distribution of doxorubicin.

Table IV—*In Vivo* and *In Vitro* K_p Values in Three Species[a]

Tissue	Rat		Rabbit		Guinea Pig	
	In Vivo[b]	*In Vitro*	*In Vivo*[c]	*In Vitro*	*In Vivo*	*In Vitro*
Adipose tissue	33 ± 4.4	36 ± 1.7	19 ± 3.5	16 ± 1.0	54 ± 4.3	70 ± 3.4
Muscle	54 ± 4.2	24 ± 1.9	27 ± 3.9	9 ± 0.6	135 ± 14	34 ± 1.2
Liver	243 ± 39	166 ± 6.4	56 ± 10.3	119 ± 6.2	365 ± 16	335 ± 12
Gut	161 ± 23	528 ± 18	50 ± 7.5	551 ± 20	336 ± 55	1019 ± 43
Heart	230 ± 17	119 ± 5.4	57 ± 5.0	71 ± 2.4	571 ± 48	237 ± 8.4
Stomach	258 ± 29	286 ± 9.6	—	242 ± 9.1	417 ± 40	718 ± 22
Kidney	349 ± 27	322 ± 13	494 ± 43	399 ± 17	684 ± 47	679 ± 22
Lung	354 ± 54	605 ± 19	155 ± 24	623 ± 22	656 ± 91	1289 ± 40
Spleen	404 ± 72	1391 ± 56	746 ± 82	1596 ± 58	1795 ± 259	2374 ± 73

[a] Mean ± *SE* of each experiment. [b] Data obtained from a previous report (13). [c] Values of $K_{p,app}$, except for the spleen, were obtained from previously published data (3), K_p values were then calculated by assuming that R_B was equal to the R_B of the rat, determined previously (13). The value of $K_{p,app}$ for spleens was estimated from the observed values (at 8, 24, and 48 h) in Fig. 6 of Ref. 3, and then the K_p was calculated.

Since. Eq. 6 holds under the condition $K_a C_f^T \ll 1$, its applicability was examined as follows. The plasma concentrations of doxorubicin at the terminal phase after intravenous administration were $<2 \times 10^{-7}$, 8.2×10^{-8}, 1.3×10^{-7}, and 1.2×10^{-7} M for rats, rabbits, guinea pigs, and humans, respectively. Based on the assumption of pH partition, the value of C_f^T was estimated by:

$$C_f^T = \frac{1 + 10^{pK_a - pH_i}}{1 + 10^{pK_a - pH_e}} \cdot f_p C_p \qquad \text{(Eq. 8)}$$

Values for pK_a (8.15), pH_i (7.0), pH_e (7.4), K_a (4.85×10^5 M^{-1}), and f_p (0.344 for rats, 0.415 for rabbits, 0.529 for guinea pigs, and 0.5 for humans) were substituted into the equation; the f_p value for humans was obtained from the study of Chan *et al.* (4). The values of $K_a C_f^T$ were 7.8×10^{-2}, 4.0×10^{-2}, 6.1×10^{-2}, and 5.7×10^{-2} for rats, rabbits, guinea pigs, and humans, respectively. Therefore, Eq. 6 should be applicable to these four species.

To account for interorgan variations of tissue distribution of doxorubicin, four possibilities can be considered: (*a*) organ or tissue difference in the amount of nuclei per organ or tissue wet weight (C_N), (*b*) organ or tissue difference in binding parameters to nuclei (n and K_a), (*c*) larger binding capacity of doxorubicin to other organ or tissue constituents than to nuclei, and (*d*) a specific membrane transport mechanism. In view of the results that doxorubicin was exclusively localized in the cell nucleus (15) and that there was little difference of tissue nuclear binding parameters between liver and kidney (14), but a good correlation between the *in vivo* K_p values and the tissue DNA concentrations was observed (13), the first possibility might primarily account for the differences in doxorubicin distribution among tissues, although the evidence is insufficient to rule out some contribution of the other mechanisms, if they operate. On the assumption that there is no difference in nuclear drug-binding parameters of various tissues among rats, rabbits, and guinea pigs the *in vitro* K_p values were estimated. In Figs. 3A–C, the *in vitro* and *in vivo* K_p values for rats, rabbits, and guinea pigs listed in Table IV, respectively, are compared; comparatively good agreements can be seen. These results suggest that Eq. 6 is applicable to describe the tissue distribution of doxorubicin in rabbits and guinea pigs as well as in rats. Although slight discrepancies are apparent, the *in vitro* K_p values show a relatively good correlation with *in vivo* K_p values. The reason for the discrepancies are probably (*a*) a shift of the intracellular pH from 7.0, (*b*) operation of a specific transport system, (*c*) involvement of other tissue constituents which affect the intracellular binding, and (*d*) slight differences in the nuclear binding parameters among tissues.

Furthermore, the following factors may be involved in the interspecies variations in K_p values: (*a*) differences in tissue DNA concentrations (C_N), (*b*) differences in plasma unbound fraction (f_p), (*c*) differences in nuclear binding parameters (n and K_a), and (*d*) differences in the rate of specific transport. The tissue DNA concentrations of rabbits were smaller than those of rats in all tissues studied, except the kidney and spleen, and those of guinea pigs were larger than those of rats in most tissues except the muscle (Table I). These differences in tissue DNA concentration among rats, rabbits, and guinea pigs are similar to those among the *in vivo* K_p values for these animal species (Table IV). Thus, it was suggested that differences in tissue DNA concentration are an important factor in the interspecies variation in K_p values. Based on the results of plasma protein binding, the difference in f_p values between rats ($f_p = 0.344$) and guinea pigs ($f_p = 0.529$) may be one of the important factors in the variation of *in vivo* K_p values between rats and guinea pigs. However, the difference in f_p values between rabbits ($f_p = 0.415$) and rats ($f_p = 0.344$) may not be a determinant of the variation in K_p values between these two animal species, since the f_p value of rabbits was larger than that of rats, whereas the *in vivo* K_p values of rabbits were smaller than those of rats in most tissues (Table IV). Consequently, it was concluded that the primary determinant of the interspecies variation in K_p values among rats, rabbits, and guinea pigs is the interspecies differences in tissue DNA concentration and that the difference in f_p values is a secondary determinant.

Plasma binding, tissue binding, and membrane permeability have been considered to be factors that affect the tissue distribution of drugs (10), but little quantitative evidence has been obtained up to the present regarding interorgan and/or interspecies variation in the tissue distribution of drugs. To obtain the *in vitro* K_p value, it is important to estimate accurately the *in vitro* tissue binding under physiological conditions. A usual method is to use tissue homogenates, but this leads to several experimental problems such as disruption and degeneration of drug-binding components, requirement for binding cofactors, and drug metabolism. Moreover, the actual drug-binding component often cannot be distinguished from other intracellular constituents. A useful method for physiological estimation of the tissue binding would be to determine the drug binding by using isolated organelles or macromolecules known to be the primary drug binder in the tissues, as shown in the present study with doxorubicin in rats.

In conclusion, the mechanism of the organ or tissue distribution of doxorubicin in rats, rabbits, and guinea pigs may be summarized as follows. Doxorubicin is strongly and exclusively bound to the nuclei in the cells. The variations in the organ or tissue distribution of doxorubicin are due to dif-

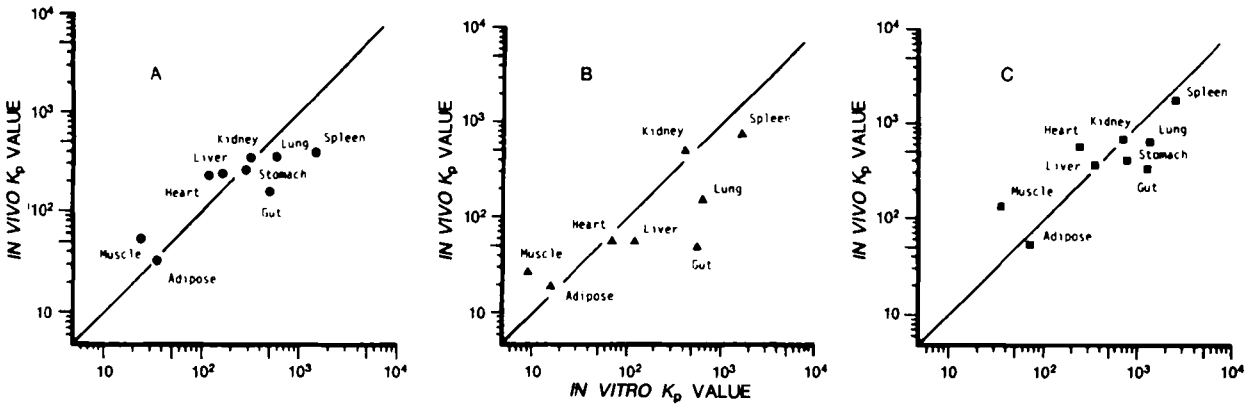

Figure 3—*Comparison between* in vivo *and* in vitro *tissue-to-plasma partition coefficients (K_p values) in rats (A), rabbits (B), and guinea pigs (C). Solid lines represent a 1:1 relationship.*

ferences in the amount of nuclei per gram of organ or tissue. The unbound concentration of doxorubicin in the cytosol must be ~2.3 times higher than that in plasma according to the pH partition hypothesis.

Preparation and Biodistribution of ^{99m}Tc-Labeled Tyramine Iminodiacetic Acid

FAROUK M. ALI *, RAUF SARPER, EUGENE J. MALVEAUX, and BAHJAT A. FARAJ ˣ

Received February 8, 1983, from the *Department of Radiology, Division of Nuclear Medicine, Emory University School of Medicine, Atlanta, GA 30322.* Accepted for publication August 22, 1983. *Present address: King Abdulaziz University, College of Medicine and Allied Sciences, Jeddah, Saudi Arabia.

Abstract □ The synthesis and biodistribution properties of ^{99m}Tc-labeled *N*-substituted tyramine, [*N*-(4-hydroxyphenethyl)iminodiacetic acid] are described. Tissue distribution studies in rats were indicative of high hepatic and kidney extraction, accompanied by rapid plasma and urinary clearance and minimal biliary excretion. These findings were substantiated by organ image analysis. The preliminary data indicate that this labeled material may represent a new class of radiopharmaceuticals for the evaluation of hepatic and renal functions.

Keyphrases □ Biodistribution—^{99m}Tc-labeled tyramine iminodiacetic acid, preparation □ Tyramine iminodiacetic acid—biodistribution and preparation □ Radiopharmaceuticals—preparation and biodistribution of ^{99m}Tc-labeled tyramine iminodiacetic acid

Tyramine (I), a noncatecholic phenethylamine found in a variety of plants and animal tissues (1), is produced by decarboxylation of its parent amino acid tyrosine (2). Normally, the physiological effects of tyramine are minimal because >90% of the tyramine is rendered metabolically inactive by mitochondrial monoamine oxidase during its first passage through the liver after absorption (3, 4). The rapid rate of elimination and its inability to cross the blood–brain barrier (5) protect the body from the adverse peripheral and neurotoxic effects of tyramine.

Abnormal metabolism of tyramine has been implicated in a variety of clinical disorders. Abnormal urinary excretion of the amine occurs in patients suffering from Parkinson's disease (6), schizophrenia, induced hypertensive crisis (7), cystic fibrosis (8), epilepsy (9), hypertyrosinemia (10), depression, and migration (11). We have recently demonstrated that the tyramine concentration is abnormally elevated in the plasma and urine of patients with cirrhosis (12, 13), hepatitis (14), and Reye's syndrome (15), as well as in experimental animals with hepatic insufficiency or portacaval shunt (16).

In view of its clinical importance, we have taken the initiative to develop a radiopharmaceutical from tyramine. In this report, we describe the synthesis, biological distribution, and image characteristics of ^{99m}Tc-labeled *N*-(4-hydroxyphen-

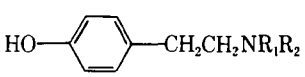
ethyl)iminodiacetic acid (II) an iminodiacetic acid-containing radiopharmaceutical which is structurally related to tyramine.

EXPERIMENTAL SECTION

Chemistry—*N*-(4-Hydroxyphenethyl)iminodiacetic acid (II) was prepared by a modified procedure of Callery *et al.* (17). A solution of tyramine[1] (1.37 g, 10 mmol) in 95% ethanol (100 mL) was added dropwise to a stirred solution of chloroacetic acid (1.9 g, 20 mmol) in 95% ethanol (50 mL). During the addition, the mixture was maintained at pH >7 with 5 M NaOH. The resulting mixture was heated under reflux for 48 h, was allowed to cool, and the resulting white precipitate was removed by filtration. This material was



I: $R_1 = R_2 = H$
II: $R_1 = R_2 = -CH_2CO_2H$

washed with 95% ethanol, recrystallized (80% ethanol) and dried under reduced pressure at 50°C, to give 1.0 g (40% yield). The resulting salt was dissolved in water, acidified to pH 3 by the dropwise addition of 6 M HCl, and the resulting precipitate was collected and recrystallized from methanol–water to yield white crystals, mp 284–287°C; IR (Nujol) 3200–2800, 1650, 900, 800, and 700 cm^{-1}; ^{1}H-NMR (D_2O): δ 2.5–3.2 (m, 4, CH_2CH_2), 3.4 (s, 4, CH_2COO), and 6.5–7.0 ppm (m, ArH). TLC on silica gel GF revealed one spot with R_f values of 0 in solvent system A (*tert*-amyl alcohol–benzene–40% methylamine; 24:8:12) and 0.4 in solvent system B (1-butanol–acetic acid–water; 25:4:10). Tyramine had R_f values of 0.75 and 0.65 in solvent systems A and B, respectively.

Anal.—Calc. for $C_{12}H_{15}NO_5$: C, 56.91; H, 5.93; N, 5.33. Found: C, 57.50; H, 6.18; N, 5.65.

Labeling with Technetium-99m—The iminodiacetic acid derivative of tyramine was labeled by stannous chloride reduction of sodium [^{99m}Tc]pertechnetate eluate from a molybdenum-99–technetium-99m generator in aqueous solution.

A solution of the derivative (5 mg, 0.043 mmol) in 1 mL of distilled water (pH 5–6) was prepared in an evacuated glass tube. To this was added 0.2 mL (0.25 mg, 0.0011 mmol) of a solution of stannous chloride prepared by the procedure of Mock (18). The mixture was vortex-mixed for 30 s. Labeling with technetium-99m was accomplished over a period of 5 min by the addition of the pertechnetate (5 mCi).

Radiochemical Purity—The radiochemical purity of ^{99m}Tc-labeled material was examined by silica gel (glass fiber support) and cellulose (plastic sheet support) ascending TLC, with normal saline, 1-butanol–acetic acid–water (4:1:7), and acetonitrile–water (3:1) as solvents. The radiochromatograms of imaging agent were compared with those obtained for both pertechnetate anion and for technetium-99m–tin colloid, which was prepared by the method used for the preparation of the ^{99m}Tc-labeled iminodiacetic acid. Gel permeation chromatography was used to assess the stability of the chemical bond between technetium-99m and tyramine diacetic acid. Prepacked (1 × 10-cm) disposable columns containing Sephadex G-25 medium[2] (10-mL volume) were used. The imaging agent (1 μCi) in 0.2 mL of normal saline was applied to the column and eluted with 50 mL of normal saline. Fractions (1 mL each) were collected and counted. The elution pattern of the ^{99m}Tc-labeled iminodiacetic acid was compared with that of pertechnetate and the technetium-99m–tin colloid.

Biodistribution Studies—The biodistribution studies were carried out in male Sprague–Dawley rats (200–300 g) that were fasted overnight. The rats were anesthetized with sodium pentobarbital (25 mg/kg). A catheter[3] (i.d., 0.58 mm; o.d., 0.965 mm) was inserted into the jugular vein for the administration of imaging agent; another one was placed in the carotid artery for blood sampling. A third catheter was inserted into the common bile duct, retrograde to the liver, for collection of bile. The mixture of the radiopharmaceutical preparation was administered intravenously (0.5 mCi/kg) as a bolus injection. Heparinized blood samples (1 mL) were drawn at predetermined intervals. The rats were then sacrificed serially at intervals to 180 min after injection. At the time of death, the wet weights of the liver, kidney, heart, intestine, brain, spleen, stomach, lung, and muscle were determined. The tissue samples were homogenized[4] in a 4:1 water–organ mixture, and 0.5-mL aliquots were counted. The radioactivity in plasma, bile, and tissue samples was expressed as a percentage of the injected dose per gram of sample. The urine (0.1 mL, 1:100 dilution) from the urinary bladder was also counted.

Image Analysis—Ten rats were evaluated. The imaging system consisted of a mobile camera[5] interfaced with a computer[6]. The study began with an anesthetized rat placed supine on a table under the detector of a portable gamma scintillation camera. The detector was positioned so that the field of view included the liver, lung bases, kidneys, and bladder. The imaging agent (0.5 mCi/mg) was injected intravenously into the jugular vein. Data acquisition by the computer started simultaneously with the injection. Serial images of the whole rat were taken and recorded at predetermined intervals over a period of 3 h.

RESULTS

Radiochemical Analysis—Chemical purity of the tyramine diacetic acid was established by elemental, spectral, and chromatographic analyses. The radiochemical purity and labeling yield of the imaging agent were determined by radiochromatographic analysis. The iminodiacetic acid was labeled with technetium-99m in yields >95% as assessed by silica gel and cellulose TLC

Table I—Average [a] Percent Injected Radioactivity in Tissues and Plasma of Rats after Intravenous Administration of ^{99m}Tc-Labeled Tyramine Diacetic Acid

Tissue	Radioactivity, % of Dose/g of Tissue					
	5 min	10 min	30 min	60 min	120 min	180 min
Liver	5.2	3.2	2.3	1.4	1.0	0.75
Kidney	8.5	5.21	3.0	2.2	1.8	1.0
Brain	0.3	0.01	0.008	0.007	0.007	0.0051
Heart	0.20	0.16	0.13	0.072	0.072	0.060
Intestine	0.30	0.15	0.11	0.067	0.067	0.0051
Plasma	4.1	1.7	0.85	0.65	0.47	0.28

[a] The range was <10% of each value; $n = 6$ rats per group.

in three solvent systems. On silica gel, the ^{99m}Tc-labeled material exhibited an R_f value of 1.0 in each of the solvents [0.9% NaCl, 1-butanol–acetic acid–water (4:1:1), and acetonitrile–water (3:1)], whereas pertechnetate and technetium-99m–tin colloid gave R_f values of 1 and 0, respectively, in these systems. On cellulose, the labeled iminodiacetic acid migrated with R_f values of 0, 0.8, and 0; the colloid remained at the origin and pertechnetate migrated with R_f values of 1.0, 0.4, and 1.0 in these solvent systems. In all cases, ^{99m}Tc-labeled tyramine diacetic acid yielded a well-defined chromatographic spot. The results of Sephadex G-25 chromatographic analysis revealed that >95% of the labeled material was eluted from the column as compared with 1% of labeled colloid. This was an indication that the iminodiacetic acid is a strong chelating agent. Increased dilution and prolonged standing at room temperature had minimal effect on the radiochemical purity of labeled material, providing further evidence of the stability of this ^{99m}Tc-labeled radiopharmaceutical.

***In Vivo* Studies in Rats**—*Tissue Distribution, Plasma, Urine, and Bile Analyses*—The data in Table I represent the activity in various tissues at 5, 10, 30, 60, 120, and 180 min after the intravenous injection of the imaging agent. Data are expressed as the percentage of administered dose per gram of tissue (wet weight). The tissue distribution data indicate a selective accumulation of the ^{99m}Tc-labeled material by the liver and kidney. There was an ~100-fold increase in the concentration of this agent in the liver and kidney as compared with the brain, intestine, and heart at 5 min postinjection. This was followed by a rapid clearance, since 50% of the activity was eliminated from the liver and kidney by 30 min.

The main elimination pathway of radioactivity after administration of the imaging agent was *via* the kidney. At 180 min, ~50–60% of the radioactive dose was accounted for in the urine. Less than 5% of the dose appeared in the bile at 180 min. Radiochromatographic analysis indicated that most of the activity in plasma, urine, and bile was in the form of the injected ^{99m}Tc-labeled material.

Image Analysis—Imaging studies substantiated the tissue distribution data. In Fig. 1 are shown whole rat body scans obtained at 2, 5, and 10 min after intravenous injection of 0.5 mCi/kg of ^{99m}Tc-labeled tyramine diacetic acid. The scans indicate high and selective uptake followed by a rapid wash-out of the radiopharmaceutical from the liver and kidney with concomitant accumulation of the radioactivity in the urinary bladder.

DISCUSSION

In the present study it has been demonstrated that substitution of the terminal amino group of tyramine with the chelating moiety iminodiacetic acid produced a tyramine derivative which was capable of complexing with technetium-99m in quantitative yield. By utilizing silica gel or cellulose TLC in several solvent systems, the labeled material exhibited a single distinct sharp peak and the absence of a radioactive band associated with pertechnetate or technetium-99m–tin colloid. The stability of the chelate in this radiopharmaceutical was indicated when increased dilution, prolonged storage (up to 4 h), and incubation at 37°C for 1 h had a minimal effect on its radiochemical composition.

Biodistribution studies in rats indicated avid extraction of the labeled material by the liver and kidney with minimal accumulation in the brain, heart, and intestine after intravenous administration. The plasma elimination pattern of ^{99m}Tc-labeled tyramine diacetic acid is indicative of the plasma clearance of endogenous and exogenous amines with high first-pass hepatic extraction (19, 20). The main elimination pathway of radioactivity after administration of the imaging agent was *via* the kidneys, which is similar to that of tyramine (3, 21). Biliary excretion was minimal since <5% of the injected dose appeared in the bile at 3 h postinjection.

Furthermore, evidence supporting the fact that extensive dissociation *in vivo* of ^{99m}Tc-labeled material to colloidal technetium or pertechnetate did not occur was obtained when radiochromatographic analysis of plasma, bile, and urine contents produced a chromatogram identical to that of the imaging agent before injection. This suggests that the ^{99m}Tc-labeled iminodiacetic acid chelate remains intact *in vivo* and is eliminated in an unchanged form.

These preliminary results indicate that ^{99m}Tc-labeled tyramine diacetic acid may represent a new class of radiopharmaceuticals for the evaluation of hepatorenal function independent of the hepatobiliary system.

Abstract □ The effects of polyacrylic acid aqueous gel on the absorption of rectally administered [Asu^{1,7}]-eel calcitonin, a calcitonin analogue, were investigated in rats. The [Asu^{1,7}]-eel calcitonin (1 U/kg) was given into the rectal loop in gel bases at various pH (5.5–8.5) and polyacrylic acid concentrations (0.01–1.0% w/v). The maximum hypocalcemic effect was obtained in ~30 min after administration of the analogue in a 0.1% w/v polyacrylic acid gel base at pH 5.5. The plasma calcium level decreased by ~18% from the initial level. Rectal administration in vehicles such as polyethylene glycol 1000, triglyceride fatty acid mixture base, or saline solution had little or no hypocalcemic effect at a dose of 5 U/kg. The results indicated that a polyacrylic acid aqueous gel base significantly improved the absorption of this analogue. Furthermore, rectal administration in a polyacrylic acid gel base (0.1% w/v; pH 5.5) required a dose 35 times greater than an intravenously administered dose to achieve an equivalent hypocalcemic effect.

Keyphrases □ Calcitonin—enhanced rectal absorption using polyacrylic acid aqueous gel base, rats, bioavailability □ Rectal absorption—Calcitonin, polyacrylic acid aqueous gel base, bioavailability, rats

Calcitonin, a hypocalcemic peptide hormone, has been isolated from the thyroid of mammals and ultimobranchials and has been used for the treatment of Paget's disease as well as certain types of osteoporosis (1). Peptides, such as calcitonin, can be given effectively only by injection because, when taken orally, they are digested by the proteolytic enzymes in the GI tract and metabolized by the liver. This is a problem for patients who are unable to have injections or are in need of long-term therapy.

Rectal administration would be favorable as a dosage route for several classes of drugs because the "first-pass elimination" of high clearance drugs may be partly avoided (2, 3). However, when comparing rectal and oral administration of absorbable drugs, the former dosage requires two or three times the drug concentration of the latter dosage because the absorption surface area of the rectum is smaller than that of the duodenum (1/10,000 the surface arera of small intestine). The bioavailability of poorly absorbable drugs such as calcitonin, a relatively high molecular weight compound, needs to be enhanced by pharmaceutical modification for rectal administration. The aqueous gel bases of polyacrylic acid, which are a group of carboxyvinyl polymers cross-linked with allyl sucrose, have been shown previously to significantly improve the absorption of insulin from the rectum (4, 5) and vagina (6). The present study was designed to evaluate the feasibility of rectally administering a calcitonin analogue using a polyacrylic acid aqueous gel base as an absorption promoter.

EXPERIMENTAL SECTION

Materials—[Asu^{1,7}]-eel calcitonin[1] a synthetic analogue of eel calcitonin in which the disulfide bridge between the first and seventh amino acids in the eel-calcitonin molecule is replaced by a $-CH_2CH_2-$ bridge (7) was used in this study. A polyacrylic acid aqueous gel base[2] of molecular weight 1,250,000 was used as obtained from the manufacturers. All reagents were of analytical or reagent grade.

Preparations—Polyacrylic acid aqueous gel base was prepared by presoaking in distilled water for 15 h at room temperature and adding 10% NaOH solution to adjust each pH and each concentration, as previously described (4). The concentrations of polyacrylic acid in the gel bases were 0.01, 0.05, 0.1, and 1.0% w/v. The pH values selected for the study were 5.5, 6.5, 7.5, and 8.5. [Asu^{1,7}]-eel calcitonin was dissolved in each gel base. If the mixing process trapped air in the gel preparation, the air was removed by centrifugation for 10 min at 3000 rpm. The viscosity of the gel preparation was measured with

a cone and plate viscometer[3] at 37°C, and its osmolarity determined by a freezing-point osmometer[4]. The gel preparations were stored in the dark at 6°C.

Rectal Absorption—Young Wistar strain male rats (4 weeks old) weighing 80–100 g were selected as the experimental animals. The animals were fasted for 20 h prior to the experiments, but water was given freely. During the experiment, the rats were anesthetized with pentobarbital (50 mg/kg). The gel preparations were warmed to 30°C and quantities of 0.25 mL/100 g body weight were injected into the rectal loop (2.5 cm above the anus), which was isolated by ligation with thread. In comparative studies, the analogue was also formulated and administered rectally to separate groups of rats as a saline solution, in a triglyceride fatty acid mixture base[5], and in polyethylene glycol 1000. A fourth group of rats was given the material intramuscularly. Blood samples (0.3 mL) were obtained with a heparinized syringe from the femoral vein 10 min before and at 30 min and 1, 2, and 3 h postdose. The plasma was separated by centrifugation at 3000 rpm. The plasma calcium levels were determined by the *o*-cresolphthalein complexone method as described by Morin (8). The plasma concentration of calcitonin was measured by an enzyme immunoassay described earlier (9).

Protein and Calcium Release from the Rectal Mucosa—Release of protein and calcium from the rectal mucosa caused by the polyacrylic acid gel was determined by the *in situ* recirculation technique. Wistar strain male rats, weighing 260–300 g, were fasted for 20 h prior to the experiments. During the experiments, the animals were anesthetized with pentobarbital (60 mg/kg). The perfusate (20 mL) was recirculated at the rate of 2 mL/min at 37°C for 1 h in the colon and rectum (5 cm above the anus). The amount of protein was determined by Lowry's method (10) and that of calcium by atomic absorption spectroscopy.

RESULTS

Rheological Characteristics of Polyacrylic Acid Aqueous Gel—Polyacrylic acid aqueous gel behaves like a non-Newtonian liquid, and the viscosity is unchanged over a wide range of pH 4.5–12. The apparent viscosities of gel bases at concentrations of 0.01, 0.05, 0.1, and 1.0% w/v were observed to be 24, 177, 285, and 1515 cps, respectively. The values were obtained with a cone and plate viscometer at 37°C and a shear rate of 38.4 s^{-1}. As may be readily seen, the viscosity of the gel base increased with the increase in the concentration of polyacrylic acid. The viscosity of the gel preparation did not change when the calcitonin analogue was dissolved in the gel base.

Rectal Administration of [Asu^{1,7}]-eel Calcitonin—The effects of the pH of gel bases (0.1% w/v) on absorption following the rectal administration at the dose of 1 U/kg in young rats are shown in Fig. 1. The absorption increased with the lowering of the pH of the gel preparation. The hypocalcemic effects were in the following order of strength: pH 5.5 > pH 6.5 > pH 7.5 > pH 8.5 of the gel bases. The peaks of hypocalcemic effects were obtained at 30 min after administration, except with the pH 8.5 gel base. The plasma calcium values, which decreased by ~18% from their original levels, recovered after 1 h.

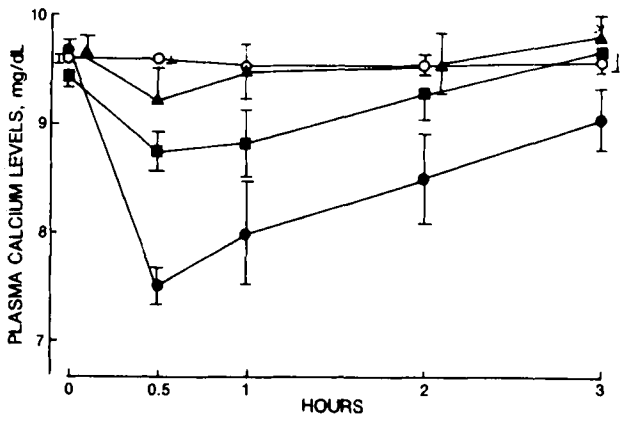

Figure 4—*Changes in plasma calcium levels following rectal administration of [Asu^{1,7}]-eel calcitonin in various bases in rats. The dose of [Asu^{1,7}]-eel calcitonin is 5 U/kg. Each point represents a mean ± SEM of five animals. Key: (○) saline solution; (▲) triglyceride fatty acid mixture base; (■) polyethylene glycol 1000; (●) 0.1% w/v polyacrylic acid gel (pH 5.5).*

The effects of the various concentrations of polyacrylic acid in the gel base (pH 5.5) on calcium levels after the rectal administration in the gel base to young rats are shown in Fig. 2. The time course of the hypocalcemic effects showed varying patterns with different concentrations of the gel after rectal administration. With the 0.1% w/v gel base, the plasma calcium level decreased rapidly for 30 min, at which time the maximum of the hypocalcemic effect was obtained. With the 0.05% w/v gel base, the plasma calcium level decreased slowly and the maximum hypocalcemic effect was found at 1 h. The 0.01% w/v and 1.0% w/v gel bases produced little hypocalcemic action; thus, the maximum hypocalcemic effect was obtained with the gel base at pH 5.5 and 0.1% w/v.
